Because the i-AlPdMn phase was the first one to be obtained with a very good structural quality and as a large single-grain quasicrystal, this is the icosahedral phase for which the most detailed analysis has been achieved. Starting from the crude spherical model and having identified some basic atomic clusters in a periodic approximant, A Yamamoto proposed a model based on a complex atomic surface construction. Starting from a decorated 3D Penrose tiling, the 6D model is built up: this leads to atomic surfaces with a complex shape. Each atomic surface is, in fact, made of small subdomains, each of the subdomains corresponding to a specific local environment. For each subdomain, it is then possible to refine not only a chemical composition, but also a small shift in the real space, which is equivalent to "relaxing" the local configuration. Both parameters are important in the success of the refinement. The quality of the

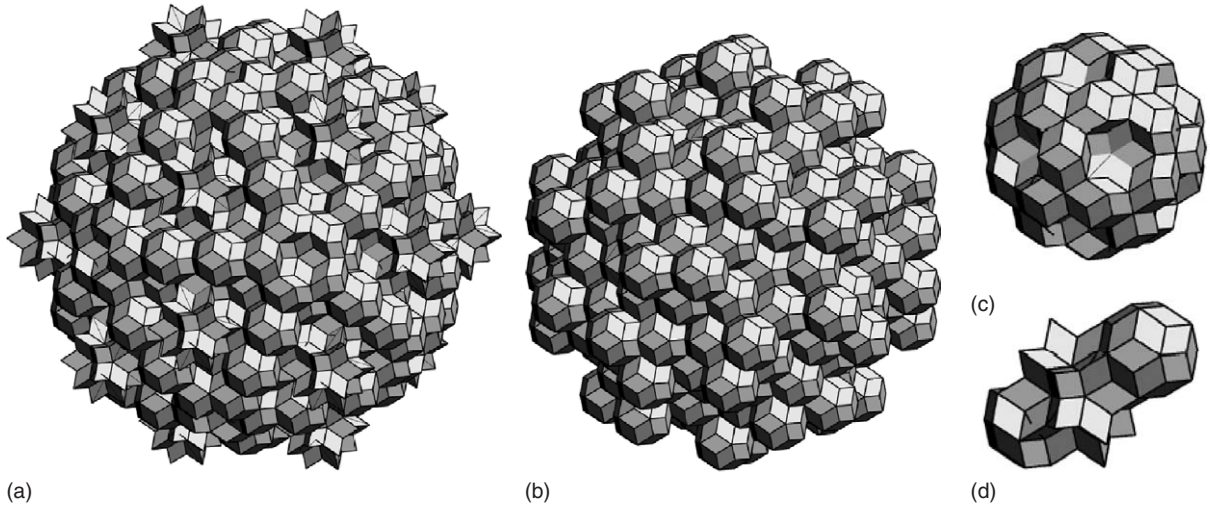

Figure 7 External shape of the atomic surfaces in the i-AlPdMn phase as proposed by A Yamamoto in his model. The average size is similar to the one of the spherical model. (a), (b), and (c) correspond to the n1, n2, and bc1 atomic surfaces of **Figure 6**, respectively. (d) The atomic surface is a supplementary one located on the mid-edge. Each atomic surface is composed of small volumes. (Courtesy of A Yamamoto, NIMS, Tsukuba, Japan.)

refinement is given by the R-factor, which is a measure of the difference between observed and calculated intensity and is found to be of the order 10% or less.

Figure 7 shows the external shape of the four atomic surfaces, which are much more complex than the spheres used in the simpler model! Note that there is a supplementary atomic surface located on a mid-edge position in the 6D cube. The smaller subdivisions are visible. This model compares well with neutron and X-ray data, in particular, for weak reflections. The agreement is, in this case, much better than for the spherical model, and demonstrates that the resulting structure is a good representation of the quasicrystal.

Once the 6D model is constructed, it is possible to deduce some fundamental properties of the resulting 3D structure. In particular, from the 6D model it is possible to determine which atomic clusters are present, and what their distribution is. The icosahedral AlPdMn phase contains two different atomic clusters, each one at least with two different chemical "decoration," which lead to at least four different clusters altogether. Two of these clusters are displayed in **Figure 8**: they correspond to the so-called pseudo-Mackay icosahedron, whose external shell is shown here. One cluster contains mainly Al and Mn atoms, whereas the other one contains mainly Al and Pd atoms. This shows that there is a strong chemical ordering in the i-AlPdMn phase. A more detailed examination shows, however, that there are some sites which are chemically disordered (at least within the experimental error), and that the structure can probably not be described uniquely with only a few

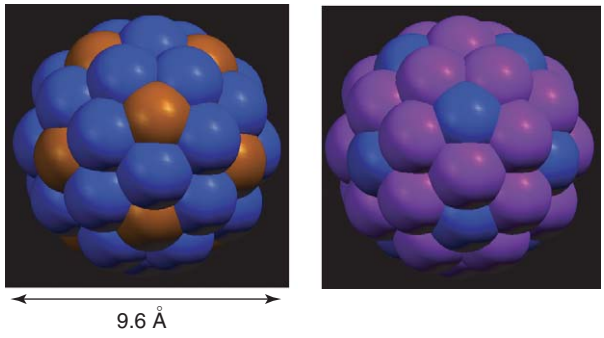

Figure 8 External shell of one of the two icosahedral clusters found in the i-AlPdMn phase. The two average chemical decorations are shown. Left, the cluster contains mainly Al and Mn atoms; right, the cluster contains mainly Pd and Al atoms.

clusters. Nevertheless, this description is useful in understanding the physical properties of quasicrystals. The arrangement of clusters in the 3D structure is perfectly deterministic, though not periodic. In particular, there is a hierarchy of cluster arrangements, with "clusters" of clusters. Another interesting property is the general one which states that if a cluster of radius R exists, then there will be at least one identical cluster in a sphere of radius $2R$. Both of these properties are responsible for the peculiar nature of wavefunctions in quasicrystals.

Another interesting approach of the description of the 3D structure is in terms of dense planes. Of course, the quasicrystal is not periodic and there are, in principle, no periodic planes. However, if we compute the projection of the structure down a high-symmetry axis, there are well visible planes

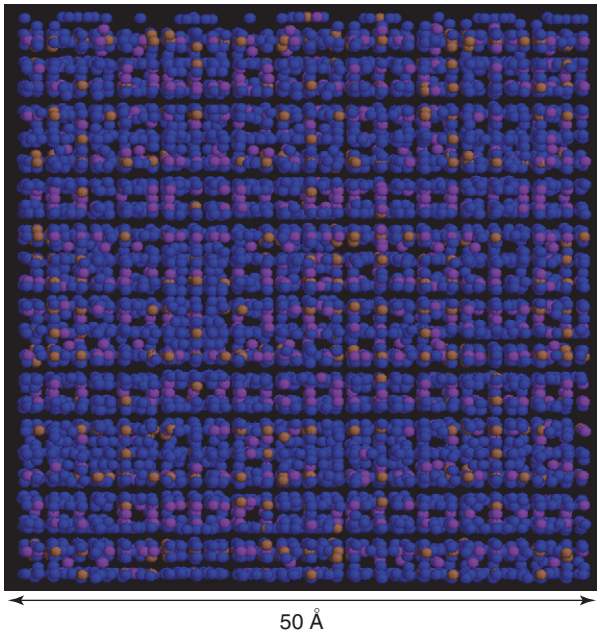

Figure 9 Side view of 50×50 Å cube of the 3D structure generated with the model of **Figure 7**. The vertical direction is parallel to a fivefold axis. Planes are visible and are grouped in small and thick layers. Blue, brown, and pink are for Al, Mn, and Pd atoms, respectively. (Courtesy of A Yamamoto, NIMS, Tsukuba, Japan.)

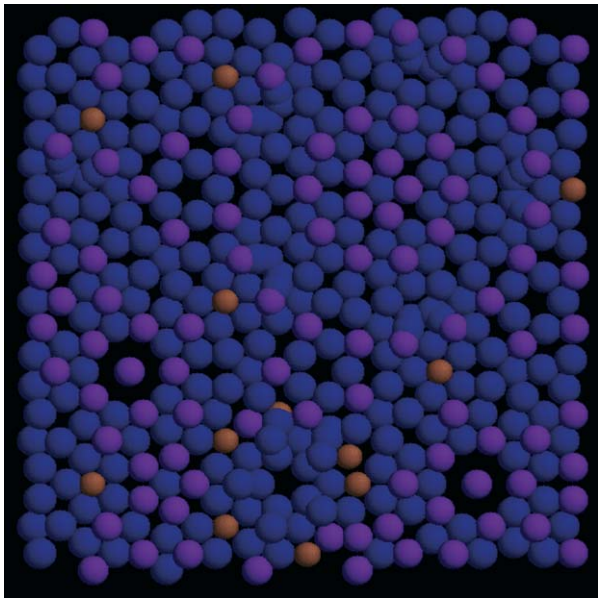

Figure 10 Examples of a fivefold atomic plane in the i-AlPdMn phase as generated by the 6D model of **Figure 7**. Same colors as **Figure 9**. (Courtesy of A Yamamoto, NIMS, Tsukuba, Japan.)

which are quasiperiodically stacked. This is exemplified in **Figure 9** which shows a lateral view of a 50×50 Å of a piece of quasicrystal generated from the 6D model. The different colors are for the different atoms, and the vertical axis is parallel to a fivefold axis. The structure in terms of dense atomic planes is clearly visible: there is a Fibonacci sequence of layers with two different thicknesses. There are some "gaps" in between the layers, which correspond to a physical separation of the planes of the order 1.2 Å. In this description, a strong chemical ordering is also visible, with the Pd atoms being concentrated in specific atomic planes. A characteristic plane is displayed in **Figure 10**. Tenfold and fivefold rings are visible, and correspond to the trace of the clusters.

Such a description in terms of dense atomic planes allows the understanding of some of the properties of quasicrystals. For instance, dense planes are certainly the stable ones and should show up as large facets in macroscopical grains: indeed this is what is observed, since the shape of i-AlPdMn single grains is frequently a dodecahedron, similar to **Figure 1**, with large facets perpendicular to a fivefold axis. Along the same lines of thought, it is possible to have some predictions on the favorable dislocation slip planes, which should be again the fivefold planes. Finally, recent studies on the surface of quasicrystals have evidenced terraces and steps, with a distribution of step heights in agreement with the result of the structure determination.

Decagonal Phase

The decagonal phase is a periodic stacking of quasiperiodic planes. If viewed along the tenfold symmetry axis, interpretation of high-resolution transmission electron microscopy images is possible. Indeed, a large number of models have been proposed from analysis of images. One should keep in mind, however, that the observed images are projections of the structure. In the "simple" decagonal phases, where the periodicity is of the order 4 Å, there are only two different atomic layers and the interpretation is relatively easy. This is not the case, however, for other decagonal phases.

The direct interpretation of images is appealing, since one can directly see the structure, although atomic resolution is difficult to achieve. The first step is to find the underlying quasiperiodic lattice, in the form of a tiling (Penrose tiling or equivalent). Note that it is not obvious, *a priori*, that a quasicrystal can be described by a decorated tiling. Various types of tilings have been used in the d-AlNiCo, most of them being a variant of the Penrose tiling which is made of two tiles. The second step is to find a decoration for the proposed tiling. This is achieved most of the time by super-imposing the tiling on the images. Since atoms are not visible, atom positions are inferred from the known approximant phases. An image is then simulated, and compared to the experimental image.

One interesting modeling has been proposed with the so-called quasi-unit cell approach. Instead of using two tiles, a single atomic cluster configuration is used to map the structure: specific overlap rules are used to generate a complete covering. **Figure 11** shows the electron diffraction pattern together with the corresponding high-resolution images of the d-AlNiCo phase. The single cluster covering is superimposed on the figure, and the decoration is shown in the enlarged part. Agreement between the simulated image and the experimental one is satisfactory. The same procedure, as the one described for the i-AlPdMn phase, has also been used. In this case, the atomic surfaces are 2D objects. Refinement of the occupation parameters and of the parallel shift is carried out in a similar way. The resulting structure is close to the one obtained by HREM images analysis, although a description in terms of a single cluster is probably too crude an approximation.

In conclusion, the atomic structure of the quasicrystal is now rather well understood. The high-dimensional approach is a very powerful tool for analyzing diffraction data and a detailed analysis is now possible. The resulting structure can be analyzed in terms of clusters or dense atomic planes. Whether the structure can be described as a decorated Penrose tiling is still an open question. However, the understanding of the atomic structure is sufficient now for the purpose of simulation or for physical properties calculations.

Quasicrystals, Electronic Structure of

U Grimm, The Open University, Milton Keynes, UK
M Schreiber, Technische Universität Chemnitz, Chemnitz, Germany

Introduction

Quasicrystals are aperiodically ordered solids. Their unusual transport properties, especially the low electric conductivity, are indications of the particular electronic structure of these materials. There are several approaches toward understanding the electronic structure of these systems. Whereas a complete understanding is still lacking, quasicrystals can heuristically be described as Hume–Rothery alloys, which qualitatively account for the experimentally observed properties. Other approaches that have been followed are based on the investigation of electrons in aperiodic potentials and on a hierarchical cluster picture of quasicrystals.

Aperiodically Ordered Solids

Quasicrystals were first discovered in a rapidly quenched AlMn alloy in the early 1980s. Today, many quasicrystalline compounds have been identified, mostly in aluminum or zinc–magnesium-based ternary alloys, some of which can be grown to form nicely faceted single crystals of macroscopic size.

The fingerprint of a quasicrystal is a diffraction which consists of Bragg peaks, like in a periodic crystal, but which shows a symmetry which is not compatible with lattice periodicity in three-dimensional space. So far, the noncrystallographic symmetries that have been observed in experiments are icosahedral symmetry, featuring axes of two-, three-, and fivefold rotational symmetry, and three classes of dodecagonal, decagonal, and octagonal quasicrystals with a single axis of twelve-, ten-, or eightfold rotational symmetry, respectively, which are periodic along the distinguished axis. In contrast to the icosahedral quasicrystals, such phases show anisotropic physical properties.

The apparent paradox of a Bragg-like diffraction with crystallographically forbidden symmetry can be resolved by interpreting quasicrystals as aperiodically ordered solids. The definition of a crystal has been adapted to include quasicrystals, alongside incommensurate structures, as aperiodic crystals. Their structure is usually described in terms of quasiperiodic tilings (or coverings) of space, which play the role of the lattice in conventional crystals. Quasiperiodic tilings can, for instance, be derived as projections of sections through higher-dimensional periodic lattices, which can accommodate the symmetries that are observed in quasicrystals. Structure models consist of decorating the basic building blocks of these tilings with atoms, very much like the unit-cell picture of a conventional periodic crystal. For icosahedral quasicrystals, this yields a six-dimensional description of the structure, for the quasicrystalline phases with one periodic axis the analogous description of a quasiperiodic plane requires at least four space dimensions, and the positions of the Bragg peaks can be indexed accordingly. Direct evidence for the structure is furthermore obtained by high-resolution electron microscopy and atomic force microscopy. While there exist sophisticated structure models for various quasicrystals, many important quetions remain unanswered, for instance concerning inherent disorder in the structure such as stochastic occupancy of atomic sites, or how the quasicrystalline structure actually grows.

Due to the aperiodic structure of these materials, important concepts used in conventional crystals, such as the notion of a Brillouin zone, do not strictly apply for quasicrystals. However, in many cases there are, albeit often less precisely defined, analogs of these concepts, such as the pseudo-Brillouin or Jones zone. This zone is constructed from the main structural peaks, it is nearly isotropic in quasicrystals and, in contrast to the case for amorphous alloys, is a sharply defined polyhedron.

Quasicrystal Surfaces

Many of the experimental techniques, such as photoemission experiments, used to probe electronic properties of quasicrystals are surface sensitive, because the escape depth for elastic electrons is of the order of a few nanometers. Therefore, it is important to know something about the surface structure in order to interpret the experimental results of such measurements.

There has been a long discussion about quasicrystal surfaces, with results depending on the preparation of the surface. However, due to recent progress in experimental techniques, both concerning the preparation of quasicrystalline samples and the image resolution of electron microscopy, it now appears to have been established that quasicrystal surfaces, prepared by sputtering in ultrahigh vacuum and suitable annealing, are themselves quasicrystalline and can be understood as a termination of the bulk structure.

Recent evidence for this is presented in **Figure 1**, which shows a high-resolution scanning tunneling microscopy image of a flat terrace of the fivefold surface of an icosahedral quasicrystal. This technique measures corrugations in the electronic density at the surface arising from the positions of the surface atoms. As shown in **Figure 1**, the pattern obtained for the particular terrace is in good correspondence with a patch of a perfect quasiperiodic Penrose tiling. The matching of the surface structure for this terrace and other terraces with a bulk model of the icosahedral quasicrystal corroborates that the surfaces in this case are consistent terminations of the bulk structure, so there should be no artifacts in experimental measurements due to surface reconstructions.

Transport Properties

The particular, nearly isotropic, order in quasicrystals, which in a sense is intermediate between that of conventional periodic crystals and amorphous systems, is reflected in unusual electronic properties. Quasicrystals, despite being composed of elements which in their pure form are good conductors, show very low electric conductivity which decreases with temperature and also with the structural perfection of the quasicrystal. So their behavior is not at all metallic; it is rather reminiscent of a system at a metal–insulator transition, with no energy gap but zero conductivity at zero temperature. An example is the icosahedral phase in the Al–Pd–Re system, which shows extremely high resistivity at low temperatures, up to $10^6\,\mu\Omega\,\mathrm{cm}$, with a very strong temperature dependence – the resistivity at a temperature of 0.3 K being about 100 times as large as that at 300 K.

Also other transport properties show interesting phenomena, such as large thermoelectric powers and Hall coefficients that depend crucially on the composition and may even undergo sign changes as the temperature is changed. Though these transport properties partly resemble those of amorphous phases and crystalline complex metal alloy phases of similar composition, the anomalies appear to be particularly pronounced in quasicrystals, in the sense that the residual conductivity is lowest and the thermopower largest for the "optimal" quasicrystal composition, to an extent that such properties, alongside diffraction, are often used to measure the structural perfection of quasicrystals.

An example of an *in situ* measurement on a thin film is presented in **Figure 2**. It shows that, while the temperature dependence of the conductivity is similar in the amorphous and icosahedral phase, the transition to the quasicrystal is accompanied by a strong decrease in conductivity and increase in thermopower, and the low-temperature conductivity in the quasicrystal is nearly zero after several hours of heat treatment.

Experimental values of the conductivity $\sigma_{4\,\mathrm{K}}$ at a temperature of 4 K are in the range of a few tens to a few hundreds $(\Omega\,\mathrm{cm})^{-1}$. The increase in conductivity with temperature is well described by a relationship of the form $\sigma_{4\,\mathrm{K}} = A(\sigma_{300\,\mathrm{K}} - \sigma_{\mathrm{M}})$, which shows that

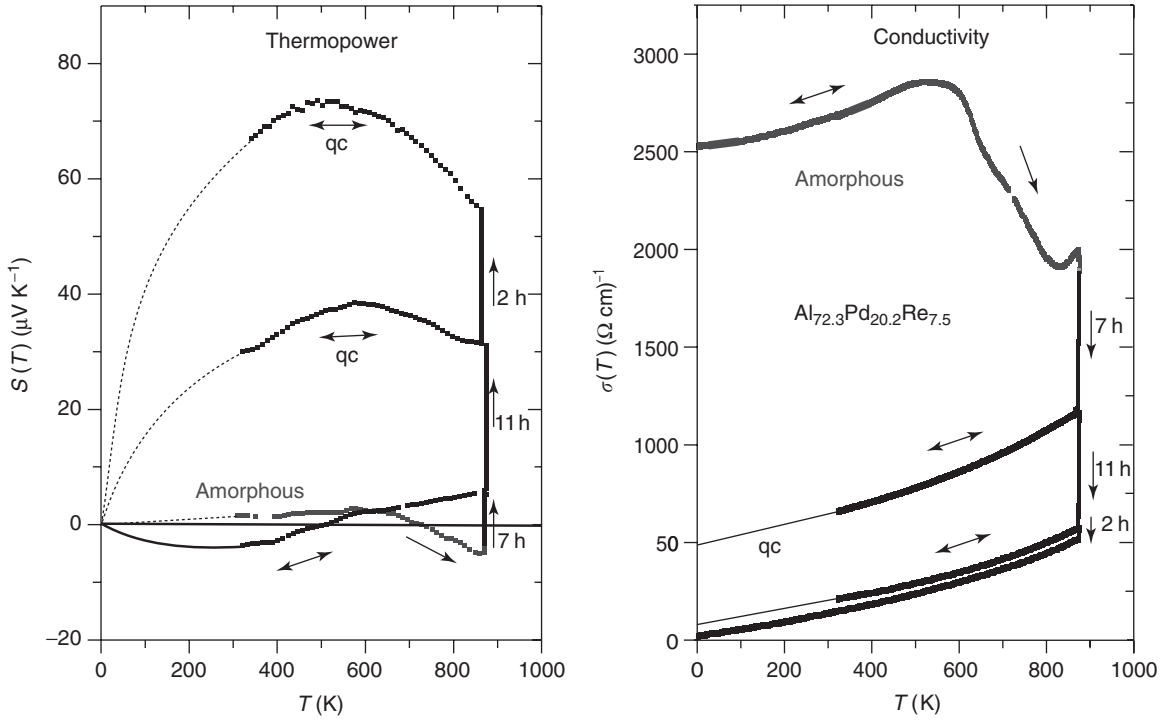

Figure 2 *In situ* measurements of the thermopower (left) and conductivity (right) of an initially amorphous AlPdRe thin film during heat treatment and formation of the quasicrystalline (qc) phase. Arrows indicate reversible and irreversible branches. (Reprinted with permission from Haberkern R (2002) Electronic transport properties of quasicrystalline thin films. In: Suck J-B, Schreiber M, and Häussler P (eds.) *Quasicrystals – An Introduction to Structure, Physical Properties, and Applications,* pp. 364–378. Berlin: Springer; © Springer.)

the low-temperature conductivity could vanish even for a finite conductivity at temperature 300 K. Experimentally, σ_M turns out to be $\sim 150(\Omega\,\mathrm{cm})^{-1}$ for high-quality icosahedral quasicrystals. Given that the actual values for $\sigma_{300\,K}$ are in the range of 200–500 $(\Omega\,\mathrm{cm})^{-1}$, this indicates that these materials are not far from a metal–insulator transition.

For the Hall effect, the temperature dependence can be reasonably well reproduced by a description of the Fermi sphere with electron and hole pockets. In a simple two-band model of free electrons, a change in composition can affect the balance between electrons and holes, and thus account for changes in the sign of the Hall coefficient. Within this picture, the Hall coefficient provides information about the matching between the Fermi surface and the pseudo-Brillouin zone. Similar comments apply to the strong variations and sign changes observed in the temperature dependence of the thermopower, which appear to be correlated to changes in the Hall coefficients and hence might also reflect the sign of majority carriers in the alloy.

Magnetic Properties

One might expect quasicrystals to show interesting magnetic properties. The reason is that most aluminum-based quasicrystals contain a fair amount of transition metals, and there is a class of magnesium–zinc-based quasicrystals containing rare-earth atoms, which provide strong localized magnetic moments. However, no long-range magnetic order has been observed in quasicrystals to date.

In aluminum-based quasicrystals, it appears that only a low fraction of the transition metal atoms in the quasicrystal actually have magnetic moments. One often finds rather small paramagnetic susceptibilities; structurally perfect quasicrystals tend to show diamagnetic behavior, and there appears to be a correlation between diamagnetism and high resistance in the samples. The situation is somewhat different in quasicrystals containing rare-earth elements. Though there have been early reports on an antiferromagnetic ordering in these quasicrystals, these results have not been confirmed and have probably been caused by the presence of conventional crystalline phases in the samples. However, spin-glass freezing transitions have been observed at relatively low temperatures.

Electronic Density of States

To date, the transport properties and the electronic structure of quasicrystals have not been completely

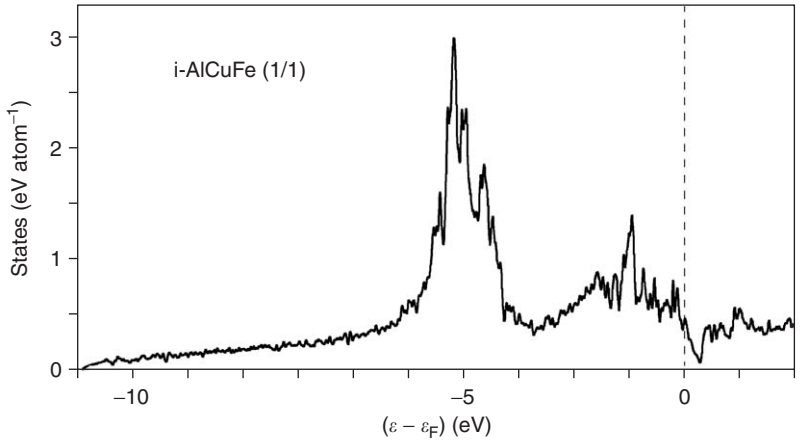

Figure 3 *Ab initio* electronic density of states for the 1/1 cubic approximant of the icosahedral AlCuFe quasicrystal, as obtained by the atomic-sphere approximation to the linear muffin-tin orbital method (ASA-LMTO). The Fermi energy ε_F is indicated by a dashed line. (Courtesy of H Solbrig (Chemnitz).)

understood. Experimental results for aluminum-based quasicrystals such as AlPdMn, which is unique in that it has both icosahedral and decagonal phases, clearly indicate that hybridization between the aluminum *sp* states and the transition-metal *d* electrons plays an important role, which is sensitive to details of the local atomic environments.

There is a rather general heuristic picture that interprets quasicrystals as Hume–Rothery solids. The idea behind this is that there exists a strong interaction between the structure and the electrons, and that quasicrystals occur precisely when the number of electrons available to the system is such that the Fermi surface in momentum space closely matches the pseudo-Brillouin zone. The matching gives rise to a resonant scattering between the conduction electrons and the static structure, leading to a deep pseudogap in the electronic density of states and a stronger tendency toward localization at the Fermi level. Thus, it offers an explanation why the effects are more pronounced in quasicrystals.

This heuristic argument, in combination with the hybridization effects mentioned above, can account for the qualitative behavior of transport properties and their dependency on the composition of the alloy, and has also been supported by experimental and theoretical investigations. It also provides an explanation for the stability of quasicrystals and their existence at certain compositions, because the pseudogap formation reduces the energy of the occupied states close to the Fermi energy, and thus lowers the total energy.

An example of an *ab initio* calculation of the electronic density of states for a periodic approximant of an icosahedral quasicrystal, that is, a cubic system with very similar short-range ordering as the quasicrystal, is presented in **Figure 3**. It clearly shows a pronounced pseudogap feature close to the Fermi energy.

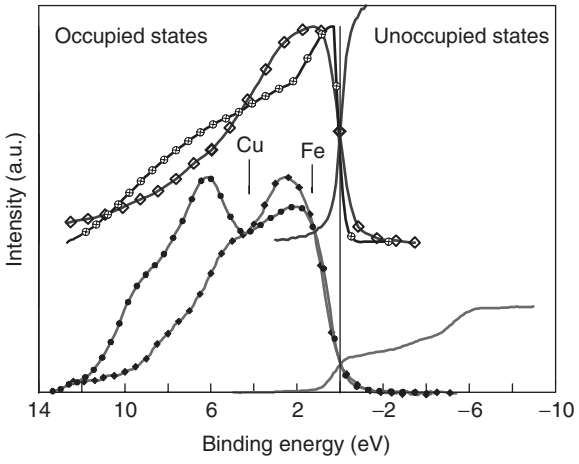

Figure 4 Occupied Al 3*p* and Al 3*s*, *d* (left side of the figure) and unoccupied Al *p* (right side of the figure) spectral distributions in f.c.c. Al (upper set of curves) and icosahedral AlCuFe (lower set of curves). Changes in the shapes of the spectral curves from f.c.c. Al to the icosahedral compound emphasize that the quasicrystal is no longer a free-electron system. The vertical bars show the maxima of the Cu 3*d* and Fe 3*d* distributions in the quasicrystal, respectively. (Courtesy of E Belin-Ferré (Paris).)

Experimentally, the electronic density of states has been investigated by X-ray emission (XES) and absorption (XAS) spectroscopy. **Figure 4** shows an example of experimentally obtained results for the aluminum partial density of states in pure faced-centered cubic (f.c.c.) aluminum and in icosahedral AlCuFe quasicrystals. Clearly, the aluminum valence band is shifted toward higher binding energies, an effect caused by the strong *sp–d* hybridization in the alloy. In addition, the observed conduction band is

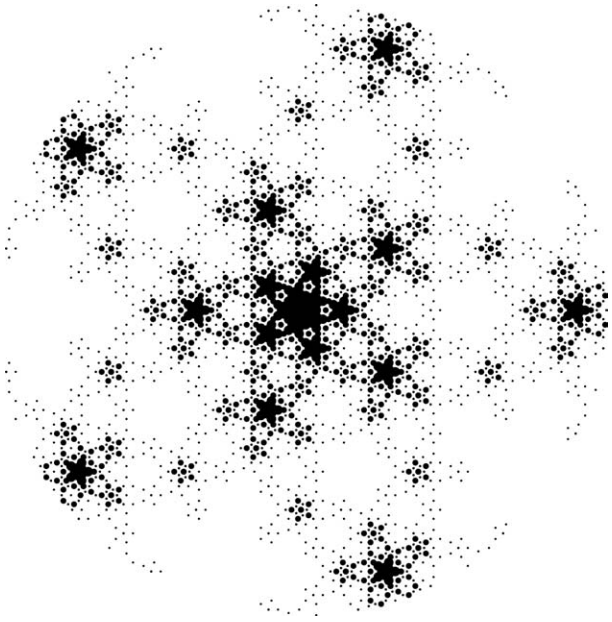

Figure 6 Sketch of the probability distribution for a multifractal wave function of a simple tight-binding model Hamiltonian on the Penrose tiling. (Reprinted with permission from Repetowicz P, Grimm U, and Schreiber M (1998) Exact eigenstates of tight-binding Hamiltonians on the Penrose tiling. *Physical Review* B 58: 13482–13490; © American Physical Society.)

much flatter in the quasicrystalline alloy than in pure aluminum. Together, this leads to a depletion of available states at the Fermi energy, as seen in **Figure 4**, and thus an experimental verification of a pronounced pseudogap at the Fermi energy, in accordance with the majority of experimental results.

However, as shown in **Figure 5**, recent angle-resolved photoemission experiments on decagonal AlCoNi revealed free-electron-like behavior of the *sp* and *d* bands, with *d* bands crossing the Fermi energy. This indicates that, even though the density of electronic states may still be very low at the Fermi energy, there might be quasi-free electronic states that can contribute to electronic transport.

While these results point to a well-defined sharp Fermi surface, previous experimental attempts to investigate the Fermi surface using the de Haas–van Alphen effect have not been very successful. There has been one published report on de Haas–van Alphen oscillations in quasicrystals, but these results have so far remained unreproduced. In other investigations, quantum oscillations have not been found. However, this does not rule out their existence, but the effects may be small due to a rather short mean free path of the electrons.

The Nature of the Electronic States

From a theoretical point of view, the particular aperiodic order present in quasicrystals must affect the nature of electronic states in such systems. On the one hand, in a conventional, periodic crystal, there are extended Bloch states, and conduction electrons can move freely through an idealized perfect crystal. This allows for electronic transport, so the system is a conductor, as long as the Fermi energy lies within a band of electronic states and not in a gap. In a three-dimensional system, this property is not destroyed by weak disorder. In a strongly disordered system, on the other hand, one expects the electrons to be localized at energetically favorable positions, and the system behaves as an insulator.

In quasicrystals, apart from the periodic direction in dodecagonal, decagonal, and octagonal phases, there are no extended Bloch waves due to the aperiodicity. There exists a competition between the aperiodicity, which tends to localize the electron, and the repetitivity of the structure (the same structural motifs appearing over and over again), which tends to have a delocalizing effect because electrons can tunnel between identical local environments. The result is that in simple model Hamiltonians one usually observes electronic states that are neither extended over the entire system nor exponentially localized, but so-called "critical" states that show a multifractal probability distribution. **Figure 6** shows an example of such a probability distribution which was obtained for a model of an electron moving on the Penrose tiling, which is a planar aperiodic tiling of decagonal symmetry.

For large classes of one-dimensional quasiperiodic systems, it can be shown in a mathematically rigorous way that the corresponding energy spectra have

the unusual property that they contain neither a continuous part nor a point part, but are purely singular continuous. Roughly, this means that the density of states is a fractal structure, such as a Cantor set, and the integrated density of states is a "devil's staircase." These rather strange spectral properties of discrete aperiodic Schrödinger operators provide another hint at the origin behind the particular behavior of quasicrystals.

However, the recent angle-resolved photoemission results mentioned above indicate the presence of quasi-free electronic states. The data, however, cannot rule out that these eigenstates are critical which might explain the weakness of the band-like emission observed in the quasicrystal when compared to that for periodic crystalline materials.

The Role of Clusters

Finally, there has been an attempt to explain the electronic properties by using a cluster-based picture of quasicrystals. This acknowledges the doubtlessly very important role of local clusters of atoms in quasicrystals. According to this approach, the quasicrystal structure is described in terms of a hierarchical sequence of clusters of atoms making up larger superclusters of clusters and so on. This hierarchical structure leads to a density of states that has spiky, self-similar features.

Whereas clusters are definitely important features of the local structure of quasicrystals, the assumption of a hierarchical cluster structure appears somewhat artificial, however, and leads to strange consequences, such as the presence of holes in the structure. Therefore, the validity of this approach appears limited, though it does predict an asymmetry of the density of states at the Fermi energy, which is in accordance with the experimental results.

Summary

The electronic structure of quasicrystals continues to be an active and controversially discussed topic of current research. While we now have a reasonable qualitative picture of some important aspects, the electronic structure is still not completely understood. Any progress is intimately linked to a better understanding of the structure formation and growth of quasicrystals, and of the theory of electronic transport in aperiodically ordered solids.

However, current experiments lead to an improved knowledge of the actual structure and the amount and type of inherent disorder, and it is conceivable that a more coherent picture of the electronic structure of these fascinating materials will emerge in the near future.

Radioactive Tracers

P Brisset, CEA-DRT-LIST-DETECS-SSTM, Gif sur Yvette, France
J Thereska, International Atomic Energy Agency, Vienna, Austria

Introduction

Radioactive tracers were first used in industry and environment in the 1950s. Since then, there has been a continuous expansion in their usage so that, today teams around the world are actively promoting and developing both theory and practice of radiotracer methods as a unique tool to study various types of flows generally inside opaque "chemical" reactors measuring directly *in situ* mass transfer parameters inside the reactor. As industrial application fields, chemical engineering, petrol engineering, steel industry, cement industry, water treatment plants, and all types of reactors, processes, and flows existing in such industries can be quoted.

The success of radioisotope applications is due primarily to the ability, conferred by the unique properties of radioactive materials, to collect data which cannot be obtained by other investigative techniques. Though radiotracers are continually under pressure from alternative techniques, nevertheless, they continue to make an increasingly important contribution to the better management of natural resources, industrial efficiency, and environmental conservation.

The economic and technical benefits are considerably high and already proofed and recognized by end-users; benefit-to-cost ratios between 10 : 1 and 4000 : 1 may be achieved. The cost effectiveness of radioisotope applications should be widely promulgated to encourage industrialists to take full advantage of the technology.

Radiotracer methodology generally comprises four interrelated aspects, namely, experimental design, data acquisition, data treatment, and processing and data interpretation. Radiotracer technology deals with tools to prepare adequate radiotracers, to inject them in a proper way, to measure the radioactivity in the field or through sampling in the laboratory, as well as to obtain reliable experimental data, to treat them with specific software and to extract maximum of results about the process in investigation.

This article presents the industrial applications of radioactive tracers. The medical and environmental applications are considered as out of the scope but the general principles here described are applicable.

Residence Time Distribution

The method advocated by Danckwerts in 1953 consists of writing the material balances at the entrance and exit of the studied system in order to find a characteristic relationship between the corresponding concentrations.

The principle of the tracer experiment consists in a common impulse–response method: injection of a tracer at the inlet of a system and recording the concentration–time curve at the outlet. The function obtained $C(t)$ is presented in **Figure 1**.

In case the tracer inlet pulse is not a Dirac pulse, the concentration–time curve should be recorded at the inlet as well (**Figure 2**).

The residence time distribution (RTD) function, also called exit age distribution function $E(t)$, is represented mathematically by the equation

$$E(t) = \frac{C(t)}{\int_0^\infty C(t)\,\mathrm{d}t} \quad \text{or} \quad \int_0^\infty E(t)\,\mathrm{d}t = 1$$

where $C(t)$ is the tracer concentration versus time at the outlet of the system.

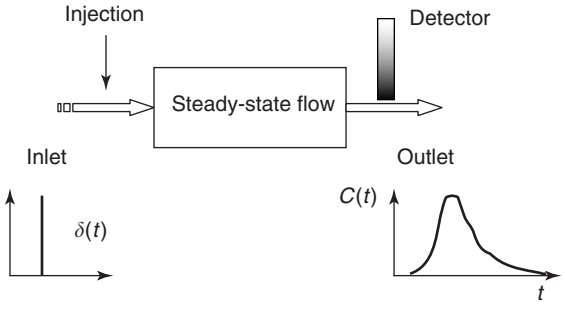

Figure 1 System impulse–response: one detector at the outlet is enough.

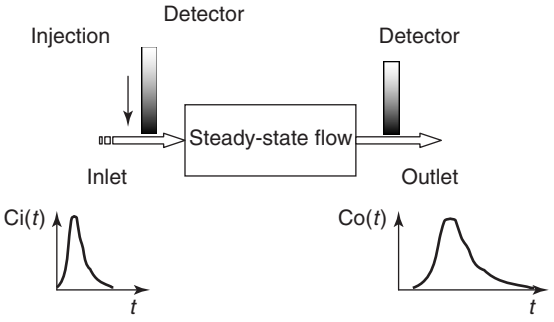

Figure 2 System response to a non-Dirac injection: two detectors at the inlet and at the outlet.

The experimental RTD, $E(t)$, is calculated from the count rate distribution at the outlet of the system $l(t)$.

There are some physical parameters which can be obtained directly by experimental RTD: $E_{\exp}(t)$ is measured as a series of numerical values. This experimental RTD is used for diagnosis of some reactor troubleshooting, for example, parallel flows, dead space, bypass, or holding-up. The direct calculation of the experimental mean residence time, the mean velocity, or tracer balance is quite useful for determination of some process parameters. More data about the hydrodynamics (flow pattern, mixing) of the system can be extracted through the modeling of the RTD curve.

Moment's Method for Simple Parameter Calculation

The moment's method is the simplest method of estimating the distribution parameters. The probability distribution with m parameters $pf(x, p_1, p_2, \ldots, p_m)$ is considered where x is a random variable. Having the empirical probability distribution, one can evaluate the estimator of the parameters by estimating the first m moments:

$$\mu_n = \int_0^\infty x^n f(x)\,\mathrm{d}x$$

The mean residence time (moment of first order (MRT)) is directly related to the flow rate Q and the effective flow volume of the system V by the relation

$$\bar{t} = \frac{V}{Q}$$

The standard deviation (SD) characterizes the mixing rate in the system (full width at half maximum (FWHM = 2SD). The higher the mixing rate, the greater the value of SD. SD equals zero in the case of lack of mixing (plug flow). For a perfect mixing system, $E(t)$ is an exponential function.

RTD Modeling

Experimental RTD is the basic information for further treatment. Throughout its modeling, the optimal parameters for process simulation and control could be determined. Modeling is realized generally by mathematical equations involving empirical or fundamental parameters, such as axial dispersion coefficients or arrangement of ideal mixers.

Evaluation of the dynamic parameters of continuous flows in vessels by optimizing the experimental RTD with the theoretical model (or RTD) is almost a common approach in field experiments (parametric approach or gray box principle). The fitting coefficient is found by using the least-squares method. Always knowing some features of the reactor performance, parametric modeling can be used to find the dynamic parameters.

Two classes of classical well-known models are mostly used: N (of equal size) fully mixed tanks in series and axial dispersion model with Peclet number Pe as a parameter of axial dispersion. In practice, however, the above ideal conditions are rarely achieved and the situation is usually somewhere between the two.

The axial dispersion model is used when the material that passes through a vessel moves along the longitudinal direction by advection as it tends to mix in the transverse section. The differential equation representing the unidirectional dispersion model is

$$\frac{\partial C(x,t)}{\partial t} = D\frac{\partial^2 C(x,t)}{\partial x^2} - u\frac{\partial C(x,t)}{\partial x}$$

where $C(x,t)$ is the concentration at a distance x at time t, D is the axial dispersion coefficient, and u is the mean velocity of advective transport.

For an instantaneous and planar injection at $t = 0$ and $x = 0$, the solution is

$$C(x,t) = \frac{M}{A\sqrt{4\pi Dt}}\,\mathrm{e}^{-(x-ut)^2/4Dt}$$

where M is the mass of a tracer injected into the cross section at the inlet.

The model parameter normally used as an index of mixing is the nondimensional Peclet number, $Pe = ux/D$ (Pe = infinite for plug flow whereas $Pe = 0$ for completely mixed flow).

Ideal stirred tanks connected in series model are frequently used to describe the systems where it is assumed that an injected tracer is immediately (in comparison to the flow rate) mixed with the entire volume of the system as a result of either mechanical mixing or some circulation (**Figure 3**).

In such a case, the concentration of the tracer at the inlet and the outlet is equal. Then the

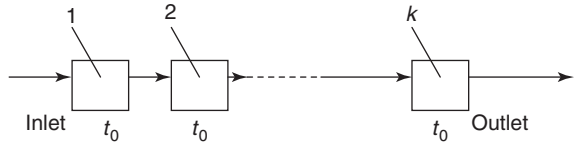

Figure 3 Scheme of ideal stirred mixing tanks in series model.

time–concentration function for the outlet is

$$\frac{dC_0(t)}{dt} = \frac{1}{\bar{t}}[C_0(t) - C_i(t)]$$

As the $C_i(t)$ function is usually a Dirac pulse $\delta(t)$, normalized $C_0(t)$ represents the RTD which in the time domain is equivalent to

$$E(t) = \frac{1}{\bar{t}} \exp\left(-\frac{1}{\bar{t}}\right)$$

It is common, in practice, to present the system as an arrangement of perfect mixers connected in series. For such a model, $E(t)$ is

$$E(t) = \frac{1}{(k-1)!}\frac{1}{t_0}\left(\frac{t}{t_0}\right)^{k-1} \exp\left(-\frac{t}{\bar{t}}\right)$$

where t_0 is the MRT for a single mixer, k is the number of mixers. The total MRT is then $\bar{t} = kt_0$.

In order to compare $E(t)$ curves for different flow conditions and mixing efficiency, normalization to dimensionless time θ is performed: $\theta = t/\bar{t}$. Then the equation takes the form

$$E(t) = \frac{k^k}{(k-1)!}\theta^{k-1} \exp(-k\theta)$$

where k is infinite for plug flow and is equal to 1 for completely mixed flow.

For continuous process vessels with high dispersion, the best model is the cascade of mixers-in-series. When dispersion is low, either the axial dispersion or the cascade of mixers follows the material transfer well. In the latter case, both models are equivalent (Villermaux): $Pe = 2^*(N-1)$.

The cascade of mixers in series model describes quite well all the simple flows with partial dispersion. Moreover, the cascade of mixers-in-series model offers the possibility to build up more complicated models, combining the mixer units in various arrangements as well as adding into them several cells or zones with different flow regimes, that is, plug flow, stagnant zone, dead volume, bypass, recirculation, etc.

Radioisotopes Used as Radiotracers

Theoretically, it can be said that all the radio nuclides existing in the Mendeleyev classification can be used as tracers. Practically, one is limited to γ emitters able to be industrially produced in nuclear reactors.

Radioisotope generators are also very important in tracer work. Such generators use the filiation chain phenomenon. That means the radioactive father decays through particle emission (e.g., β) thus producing a son which is also radioactive of shorter half-life. The father is chemically fixed in a chromatographic column. An appropriate fluid percolating in the column recovers the son (elution). The result of this operation is a radioactive solution containing the son only. There are two easily available generators for remote tracer experiments: ^{99}Mo–^{99m}Tc and ^{113}Sn–^{113m}In. The tracer is obtained in an aqueous form by the elution of the generator. An appropriate chemical treatment will give the possibility of using the radio nuclide to label solid particles (by adsorption) or liquid phase (aqueous or organic).

Some other generators also exist, such as ^{137}Cs–^{137m}Ba for an aqueous phase or ^{81}Rb–^{81m}Kr for a gas phase (**Table 1**).

Factors Affecting RTD Measurement

The formulation of RTD and its utilization for system analysis are well established. Accurate RTD formulation can be affected by tracer mixing length and detector response.

Tracer Mixing Length

Good mixing of tracer into the flowing system is a precondition for formulating the RTD.

The mixing length in-duct flows is defined as the distance beyond which the tracer concentration in the cross section is almost constant. An accurate way to determine the mixing length is the use of a computational fluid dynamics (CFD) code to model both the bulk flow and tracer injection.

There are a few theoretical formulas to calculate mixing length for various velocity and turbulent diffusion coefficient profiles as a function of injection configuration (central injection and annular injection). These formulas are known to underestimate, by a wide margin, the experimentally observed mixing lengths, probably because the simulation of the injection is too simplistic. Values for good mixing length determined experimentally in a straight pipe of circular cross section with central injection are about twice as large as theoretical values. The main reason for this discrepancy is the difference between actual and postulated flow conditions. These formulas should therefore be used with some caution.

In general, good tracer mixing requires as many as 200 pipe diameters to achieve. It is often not possible

Table 1 The most commonly used radiotracers in industry

Isotope	*Half-life*	*Gamma energy* MeV (%)	*Chemical form*	*Tracing of phase*
Bromine 82	36 h	0.55 (70) 1.32 (27)	Ammonium bromide *p*-dibromo-benzene	Aqueous Organic
Lanthanum 140	40 h	1.16 (95) 0.92 (10) 0.82 (27) 2.54 (27)	Chloride or oxide	Solid adsorbed or particles
Gold 198	2.7 d	0.41 (99)	Chloride or glass	Solid adsorbed or particles
Mercury 203	46.6 d	0.28 (86)	Mercury metal	Mercury
Iodine 131	8 d	0.36 (80) 0.64 (9)	KCl or NaCl Iodobenzen	Aqueous organic
Technetium 99m	6 h	0.14 (90)	Sodium technetate	Aqueous organic or solid
Krypton 79	35 h	0.51 (15)	Krypton	Gas
Argon 41	1.8 h	1.29 (99)	Argon	Gas
Indium 113m	1.6 h	0.39 (65)	Chloride complexed	Solid adsorbed aqueous organic

to inject the tracer at such a distance upstream to the measurement section. Every singularity in the pipe promotes turbulence that tends to decrease good mixing length. It is therefore useful to be able to reduce the length by using appropriate devices.

A substantial reduction of mixing length can be obtained by injecting the tracer through multiple orifices uniformly distributed on the pipe wall or (if possible) inside the pipe.

Injecting the tracer currently at a velocity much larger than the bulk flow velocity induces high mixing at the end of the jet. Reduction in good mixing length depends on the number and momentum of the jet, and of its angle with respect to the main flow direction. Little quantitative data are available on these effects. However, a simple jet arrangement can bring a 30% reduction with respect to a single central injection point.

Incorporating obstacles within the pipe, in the vicinity of tracer injection, produces turbulence that enhances mixing and reduces good mixing length. As an example, injecting the tracer through three triangular plates at an angle of 40° with respect to the main flow direction reduces the mixing length by one-third with respect to a central single injection point.

If a tracer is injected upstream a pump or a turbine, the mixing length is considerably reduced. Available information indicates that centrifugal pumps reduce the mixing length by $\sim$100 pipe diameters.

Detector Response

An important point dealing with RTD formulation is "what is really seen by a detector," since a wall radiation detector does not perform local measurement but collects a certain amount of information within a solid angle called the volume of sensitivity. Since the radiotracers commonly used are γ emitters, the photons they emit undergo multiple random interactions, that is, with the fluid itself, walls, screens, and collimator, until they reach the detection probe crystal scintillator and photomultiplier.

The importance of these interactions is a function of the energy of the emitted photons and the nature (density and chemical composition) of the fluid and materials. The link between the tracer concentration and detector signals is therefore not direct, the problem lying mainly in the correct representation of interactions.

A relatively simple method to calculate the detection volume is the Monte Carlo method. The basic principle is to choose randomly the initial position, energy, direction, and free path of a photon. Its new position is then calculated. If the photon has not left the system, it is going to interact with the surrounding matter. The major types of interactions to be considered are photoelectric effect, Raleigh effect, Compton effect, and pair creation. The probability of these processes is a function of the energy of the incident photon. The type of interaction is randomly chosen and the procedure is repeated until the photon

either leaves the system or is absorbed by any material of the simulated system. When a sufficiently large number of photons have been treated in this way, it is possible to build statistics in terms of energies of detected photons and numbers, which in turn can be translated into count numbers. Thus, the Monte Carlo simulation provides the detector response.

Radiation Safety

Radiotracer technology is one of the many beneficial applications of ionizing radiation that is used around the world. To ensure that people are protected from the harmful effects of radiation, such applications must comply with the international basic safety standards (BSS) or equivalent national regulations.

Any work with radioactive materials will normally require authorization from the relevant national regulatory authority. The authorized person or organization will have the prime responsibility to ensure that the radioactive materials are used safely and in compliance with the relevant regulations and standards.

Integration of RTD Tracing with CFD Simulation for Industrial Process Visualization and Optimization

The RTD method has been continuously developed and used. The treatment of RTD curves for extracting important parameters of industrial processes has achieved a good standard. Efficient RTD software was validated for modeling of various chemical engineering reactors, but the RTD method still remains a global approach. An RTD systemic analysis requires the choice of a model, which is often semi-empirical and rather idealized (combination of perfect mixers, dead volumes, etc.). There are some situations in which the RTD approach cannot be applied, that is, nonlinear systems.

The industry is looking for more predictive techniques. The CFD method is a fine and predictive analysis, which provides nice spatial pictures of the insight of a process, such as flow patterns and velocity map. A CFD simulation could be easily extrapolated to other flow conditions once validated. Owing to lack of physical experimental data, the CFD calculation provides qualitative results only, especially in systems with strong interaction of hydrodynamics with physicochemical reactions. This is the reason why CFD models have to be verified and validated by experimental tracer RTD results.

The RTD–CFD interaction is on both sides. The CFD can also be used to complement the information obtained from the RTD systemic approach. CFD provides data that can quantify the RTD systemic model, which means the CFD model can "degenerate" into a more quantitative RTD systemic analysis, providing more comprehensive results for chemical engineers. In fact, these two approaches, experimental and numerical, are complementary to each other. The RTD systemic approach detects and characterizes the main features of the flow (mixing and recirculation) while CFD enables one to locate them. The trend is to combine the RTD experimental and CFD numerical approaches in an integrated CFD–RTD method, which provides reliable quantitative results for industrial complex processes.

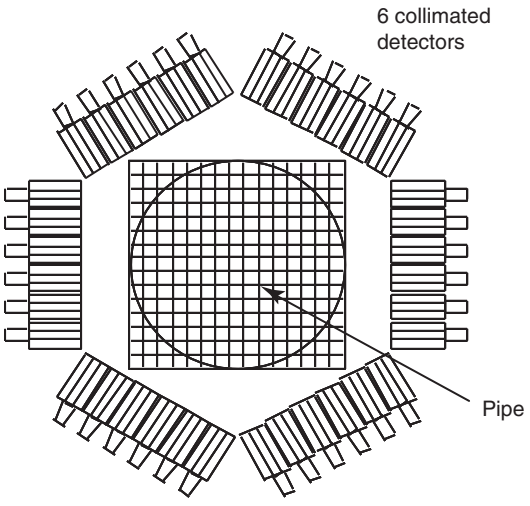

Figure 4 SPECT principle (Legoupil).

Figure 5 Example of a SPECT reconstruction of a tracer in a pipe.

Radiotracer Imaging Techniques for Industrial Process Visualization

New development is expected in introducing new radiotracers (two-dimensional (2D) and 3D imaging techniques) for localization and visualization of flow patterns in multiphase systems.

Emission tomography is the last step in research and development in radiotracer methodology. The real time imaging techniques for flow pattern visualization inside vessels are important for investigating multiphase flow systems. Industrial process gamma tomography is quite similar to nuclear medicine imaging.

Among the various techniques, single photon emission computed tomography (SPECT) shows good results on an industrial scale (**Figure 4**).

Emission tomography provides 2D maps of the count rates which, when properly interpreted, yield the radiotracer instantaneous concentration field as shown in **Figure 5**.

Radioactivity

W Greiner and D N Poenaru, J. W. Goethe Universität, Frankfurt, Germany

Introduction

All substances are made of atoms with electrons orbiting around the nucleus consisting of two kinds of nucleons: protons (p's) and neutrons (n's). Inside the nucleus, p's and n's are held together by a strong interaction overcoming the electrostatic repulsion between the positively charged p's. The first information about the atomic nucleus was obtained at the beginning of the twentieth century by studying radioactivity, and the investigations at the origin of all developments led to nuclear physics, particle physics, radiochemistry as well as many applications in medicine, biology, and industry. Radioactivity, a spontaneous disintegration of nuclei, is a natural phenomenon taking place since the very beginning of the universe. Over 60 radionuclides can be found in nature. Henri Becquerel discovered, in 1896, an invisible radiation emitted by uranium. Two other emitters, polonium and radium, were added after two years by Marie and Pierre Curie, who coined the name radioactivity. By using radium, it was possible to devise the first medical application of radioactivity. Artificial radioactivity was discovered by Irène and F Joliot-Curie in the 1930s. They obtained a new radioactive element ^{30}P by bombarding a stable nucleus ^{27}Al with α-particles. Many radionuclides for biomedical studies were produced after the invention of the cyclotron by E Lawrence in 1930.

A chemical transformation of the emitter into a different element (the daughter) takes place during this process, as shown for the first time by E Rutherford and F Soddy in 1902. An exception is the γ-decay, in which an upper excited energy level is de-excited toward a lower one of the same nucleus. The detection of radiations is based on their interactions with matter, leading mainly to ionizations.

For a long period of time, only three kinds of nuclear decay modes (α, β, and γ) were known. They illustrate three of the fundamental interactions in nature: strong, weak, and electromagnetic. Spontaneous fission became popular soon after its discovery in 1940 by K Petrzhak and G Flerov owing to both military and peaceful applications of the neutron-induced fission discovered in 1939 by O Hahn, Lise Meitner, and F Strassmann, employing the large amount of energy released during the process. Seven Nobel prizes for physics and chemistry were received (in 1903, 1908, 1911, 1921, 1935, 1939, and 1944) by almost all scientists mentioned above. At present, many other kinds of radioactivities are known, for example,

heavy ion radioactivities, proton decays, various beta-delayed decay modes (p, 2p, 3p, n, 2n, 3n, 4n, d, t, α, f), fission isomers, particle-accompanied fission. The height of the potential barrier, mainly of Coulomb nature, for emission of the charged particles is much higher than the observed kinetic energy of the emitted particles. The spontaneous decay can only be explained by quantum mechanical tunneling.

There are many applications of radioactivity. Nuclei are identified by measuring their characteristic radioactive transitions, for example, the energy spectrum of α-particles or the rotational γ-spectra, etc. Radionuclide tracers are used to study reaction mechanisms and transport processes in chemistry, biochemistry, and agriculture. Dating with ^{14}C and other nuclides became a routine in archeology and geology. Since 1921, radioelements have been employed to study the metabolism of plants. The radionuclides contributed essentially to the spectacular progress of biomedicine and genetics. The positron emission tomography (PET) is presently one of the best imaging devices in life sciences. Therapeutic radionuclides are routinely used. Other applications are: sterilization of medical instruments, industrial γ-ray radiography, smoke detectors, electric batteries for satellites (based on radioactive ^{239}Pu, ^{60}Co, or ^{90}Sr sources), improving the properties of materials or producing new materials, etc.

Binding Energy

The nuclear masses in atomic units are very close to the mass number $A = Z + N$, where Z is the number of protons and N the number of neutrons. This is the reason why usually the mass excess (or the mass defect) Δ is used:

$$\Delta(A, Z) = [M(A, Z) - A]c^2$$

where c is the speed of light. In the following, it is assumed that masses are expressed in units of energy, hence the factor c^2 is dropped. The binding energy accounts for the stability of a nucleus:

$$B(A, Z) = ZM_{\mathrm{p}} + NM_{\mathrm{n}} - M(A, Z)$$

where M_{p} and M_{n} are, respectively, the proton and neutron masses in units of energy.

The energy needed to remove a nucleon,

$$S_{\mathrm{n}}(A, Z) = M(A-1, Z) + M_{\mathrm{n}} - M(A, Z)$$

or

$$S_{\mathrm{p}}(A, Z) = M(A-1, Z-1) + M_{\mathrm{p}} - M(A, Z)$$

is called separation energy. The neutron drip line is defined by $S_{\mathrm{n}} = 0$. A negative value, $S_{\mathrm{p}} < 0$, characterizes a proton radioactive nucleus.

Decay Law

In many decay modes, a parent nucleus ^{A}Z, with mass and atomic numbers A and Z, in its ground state, is split into a daughter (heavy fragment) $^{A_1}Z_1$ and an emitted (light fragment) $^{A_2}Z_2$:

$$^{A}Z \rightarrow {}^{A_1}Z_1 + {}^{A_2}Z_2$$

with conservation of the hadronic numbers, $A = A_1 + A_2, \quad Z = Z_1 + Z_2$. This binary decay process is energetically allowed if the released energy (or the Q-value)

$$Q = M - M_1 - M_2$$

is a positive quantity. The mass excess is transformed into energy according to the Einstein formula $E = mc^2$. In the absence of any energy loss for fragment deformation and excitation, as in cold-fission phenomena or in α-decay, the total kinetic energy (TKE) is equal to the Q-value and is divided between the particles in inverse proportion with their masses, as required by the conservation of linear momentum, hence for the small fragment,

$$E_{k2} = QA_1/A$$

which can be experimentally determined.

Another important measurable quantity is the partial half-life, T, of the parent nucleus against this decay mode. The nucleus is metastable or, in other words, it exhibits a radioactivity by spontaneous emission of the particle $^{A_2}Z_2$, if both the Q-value and the potential barrier height are positive quantities: $Q > 0, E_{\mathrm{b}} > 0$. Only temporarily, the two fragments are held together by the nuclear forces. There is a finite probability, P, per unit time for penetration through the barrier by quantum-mechanical tunneling effect, as it was shown in 1928 by Gamow and independently by Condon and Gurney in the case of α-decay. The activity $\mathscr{A}$ (number of disintegrations per second) of a radioactive source is measured in the SI system in terms of becquerel; 1 Bq corresponds to the decay of one atom per second. The traditional unit is 1 curie (Ci) $= 3.7 \times 10^{10}$ decays per second. The probability of decay may be expressed in terms of its half-life, T, the time in which only half of the initial quantity remains. By assuming a disintegration rate independent of the past history of the individual decaying nuclei, the variation of the number $\mathscr{N}(t)$ of radioactive nuclei at a time t during the time dt must be proportional to $\mathscr{N}(t)$ and to dt : d$\mathscr{N} = -\lambda \mathscr{N}dt$. After integration, one obtains the exponential decay law:

$$\mathscr{N}(t) = \mathscr{N}(0)\, \exp(-t/\tau)$$

where the time constant $\tau = 1/\lambda$ defines the lifetime of the parent nucleus and λ is the disintegration constant.

The half-life, T, is defined by $\mathcal{N}(t) = \mathcal{N}(0)/2$, hence $T = \tau \ln 2 = 0.683147/\lambda$.

The quasiclassical Wentzel–Kramers–Brillouin (WKB) approximation allows one to calculate the penetrability in a one-dimensional case as

$$P = [1 + \exp(K)]^{-1}$$
$$K = \frac{2}{\hbar}\int_{q1}^{q2} \{2B_q(q)[E(q) - Q]\}^{1/2}\, \mathrm{d}q$$

where K is the action integral, $E(q)$ is the potential barrier, q_1, q_2 defined by $E(q_1) = E(q_2) = Q$ are the classical turning points, and B_q is the nuclear inertia.

In the presence of two decay modes of the same nucleus with half-lives T_1 and T_2, the total half-life is $T = T_1 \cdot T_2/(T_1 + T_2)$. The experimentally accessible range of nuclear lifetimes covers more than 45 orders of magnitude. Specific methods of measurements have been designed for different subdomains.

Decay Modes

Many nuclei are unstable against emission of: (1) protons or heavier charged particles, (2) electrons or positrons, or/and (3) photons. The first type (p- and α-decay, heavy ion radioactivities, spontaneous fission) involves the breakup of a nucleus into two fragments. When protons pass through matter, they have a low penetrating power or a short range because they ionize atoms strongly. A sheet of paper is enough to stop them. In the second type, one kind of nucleon transforms into the other via the weak interaction. With a mass smaller by three orders of magnitude than that of the nucleons and the charge of one unit, β-particles have a medium penetrating power; they are stopped by a sheet of aluminum. A photon is emitted when a state of a given nucleus passes from a higher to a lower excitation or to the ground state. The γ-rays do not directly ionize the atoms; they have a high penetrating power. A thick sheet of metal such as lead is necessary to attenuate them significantly.

Alpha Decay

An α-particle is the doubly magic ^{4}He nucleus. Nuclei with closed shells (or magic numbers $N, Z = 2, 8, 20, 28, 50, 82, 126$) are relatively stable. One of the strongest α-decay is that of ^{212}Po, leading to two double-magic nuclei ^{208}Pb and ^{4}He:

$$^{212}_{84}\mathrm{Po}_{128} \rightarrow {}^{4}_{2}\mathrm{He}_2 + {}^{208}_{82}\mathrm{Pb}_{126}$$

During this process, an energy $Q_\alpha = 8.954$ MeV is released in a form of kinetic energy of the α-particle

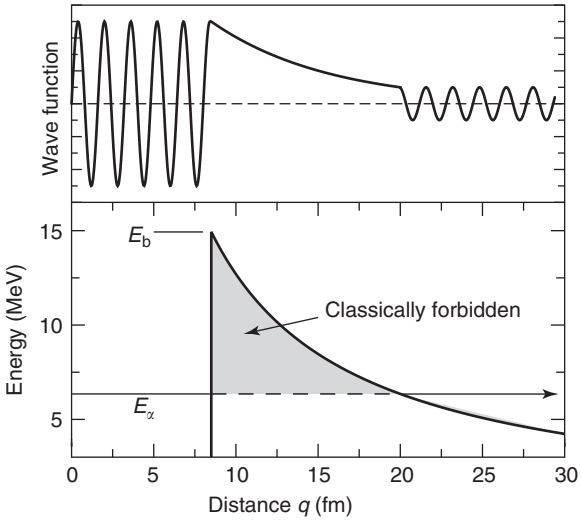

Figure 1 Quantum tunneling penetration of the potential barrier by an α-particle.

$E_\alpha = (208/212)Q_\alpha = 8.785$ MeV and a small (169 keV) recoil energy of the daughter. Both this kinetic energy and the half-life $T_{1/2} = 0.298$ μs are measurable quantities. In order to display not only the mass number, $A = 208$, and the chemical symbol, Pu, but also the number of protons, $Z = 82$, and neutrons, $N = 126$, it is written as $^{208}_{82}\mathrm{Pb}_{126}$.

According to classical physics, a particle of energy E_α less than the height E_b of a barrier could not penetrate; the region inside the barrier is classically forbidden (see **Figure 1** at the bottom). The particle is supposed to be preformed at the nuclear surface. The wave function associated with a free particle must be continuous at the barrier and will show an exponential decay inside the barrier. It must also be continuous on the far side of the barrier, so there is a finite probability that the particle will tunnel through the barrier.

There are more than 400 known α-emitters, mostly proton-rich nuclei, as shown in **Figure 2**. The neutron-rich fission fragments of ^{252}Cf shown in the same figure do not decay by α-emission because they have a negative Q_α.

Beta Decay

A beta-particle can be either an electron, e^-, emitted when a neutron is transformed into a proton, or a positron, e^+, when a proton is transformed into a neutron. A neutrino (ν) or antineutrino ($\overline{\nu}$) is simultaneously emitted. In the electron-capture (EC) process, an orbital electron is captured by the nucleus and in the atom, this de-excitation produces an X-ray. As for β^+-decay, the daughter has a lower atomic number, $Z - 1$. EC always coexists in competition

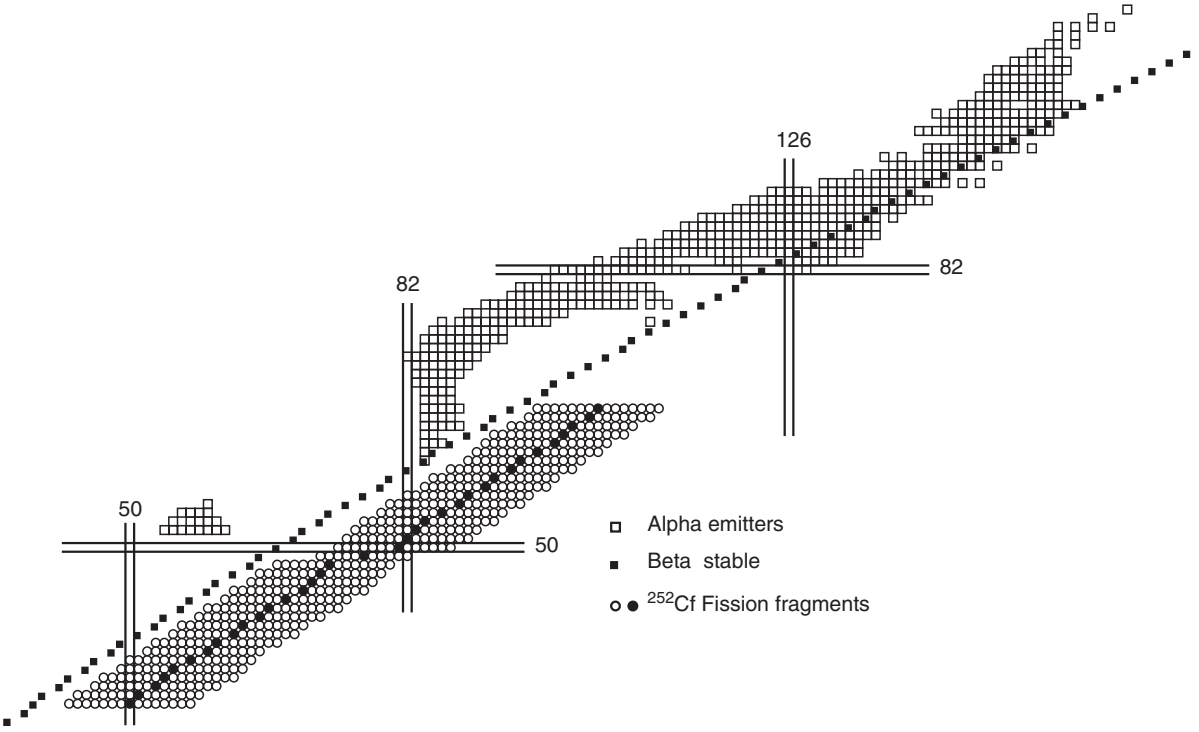

Figure 2 Nuclear chart of α-emitters and the fission fragments of ^{252}Cf. Fission fragments are neutron-rich nuclei; because of $Q_\alpha < 0$, they are stable against α-decay. (Reproduced with permission from Poenaru DN, Greiner W, Hamilton JH, and Ramayya AV (2001) *Journal of Physics G: Nuclear and Particle Physics* 27: L19–L28; © IOP Publishing Limited.)

with positron emission; that is why the resulting half-life β^+/EC is given.

For the three kinds of β-decay – β^-, β^+, and EC – one has

$$^AZ \rightarrow {}^A(Z+1) + e^- + \overline{\nu}_e$$
$$^AZ \rightarrow {}^A(Z-1) + e^+ + \nu_e$$
$$^AZ + e^- \rightarrow {}^A(Z-1) + \nu_e$$

As an example, the neutron-rich nucleus ^{212}Bi is a β^- and α-emitter with $Q_{\beta^-} = 2.254$ MeV, $T_{\beta^-} = 94.52$ min (branching ratio 64%) and $Q_\alpha = 6.207$ MeV($E_\alpha = 6.090$ MeV) $T_\alpha = 168.5$ min (branching ratio 36%), leading to a total half-life of 60.55 min.

The nucleus ^{151}Eu decays by electron conversion with $Q_{EC} = 2.261$ MeV and a half-life of $T_{EC} = 35.8$ y. Other examples are given in **Figure 3**, where a chain of α and β^- decays of one of the three natural radioactive families, ^{235}U, are shown together with two rare decay modes of ^{14}C and ^{24}Ne. The other two natural families start with α-decay of ^{232}Th and ^{238}U.

The very broad energy spectrum of electrons emitted in the β-decay, explained by E Fermi in 1934, is typical for the kinematics of three bodies in the final state. In this way, a need for existence of another particle was seen by W Pauli who introduced the neutrino. It is not easy to detect neutrinos because they interact very weakly with matter. The main sources of low-energy neutrinos are: β^- activity of fission fragments in high-power nuclear reactors, solar thermonuclear fusion processes (p–p chain and CNO cycle), stellar collapse leading to neutron stars in supernova explosions, and the capture of atomic electrons in strong sources of ^{51}Cr or other isotopes.

There are two-step processes, beta-delayed particle emissions discovered by V Karnaukhov in 1962, in which, after the population of an excited state by the β-decay of a precursor, a neutral (n, 2n, 3n, 4n) or a charged particle (p, 2p, 3p, d, t, α, light fission fragment, etc.) is rapidly emitted. In the vicinity of the drip line, the Q_β-values are rather high; when the corresponding daughters possess low separation energies for hadrons or clusters of nucleons, a beta-delayed particle emission takes place, usually from an excited state. In this way, the particle emission is much faster; the half-life is determined by the preceding β-decay of the precursor.

Gamma Decay

An excited nuclear state decays to a lower one or to the ground state of the same nucleus by emission of electromagnetic radiations, such as X-rays and light,

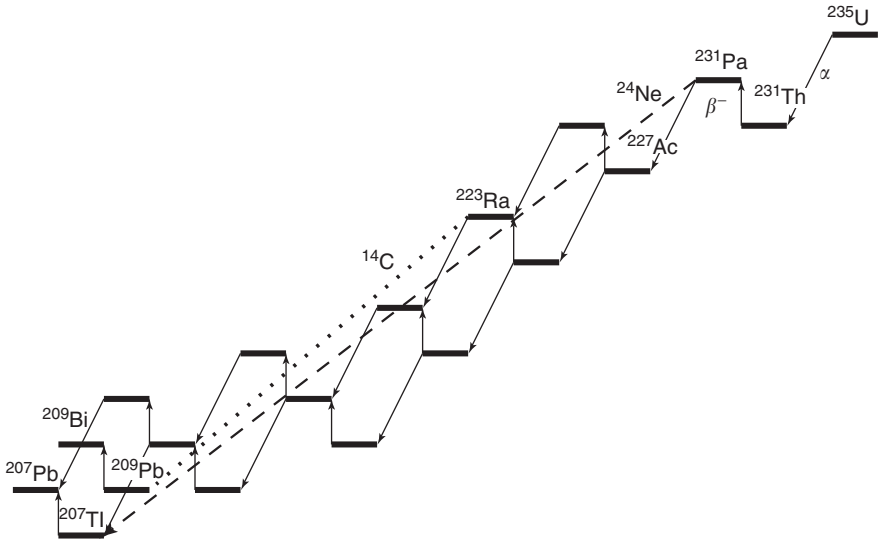

Figure 3 One of the three natural radioactive families. Starting with ^{235}U, there are several sequences of α and β^- disintegrations ending up with a stable nucleus ^{207}Pb. From ^{231}Pa to the same ^{207}Pb, one needs only one ^{24}Ne radioactivity (dashed line) followed by one β^- decay. Alternatively, from ^{223}Ra one can reach the stable nucleus ^{209}Bi with one ^{14}C decay (dotted line) followed by one β^- decay.

but with shorter wavelengths. The energy of the emitted photon is equal to the difference of the two levels. The half-lives are usually very short, under 1 ns, except for the decay of isomeric states which have a large spin and low excitation energy, hence the emission of γ-rays is strongly hindered. They decay mainly by electron conversion with half-lives in the range 10^{-10} s to 5000 yr. In an electron conversion process, the excited state decays by transferring its energy to an orbital electron which becomes free. Unlike in beta-decay, there is no change of Z or N. The isomeric or metastable states are indicated with a superscript m, as in ^{166m}Ho which decays by β^- emission ($T = 1200$ yr).

Important characteristics of a gamma transition are: the energy, the character (electric, E, or magnetic, M), and the multipolarity (dipole, $L = 1$, quadrupole, $L = 2$, etc). The order of magnitude of transition probabilities can be estimated by using the Weisskopf formula obtained in the assumption of a single nucleonic motion. For the decay constant of electric quadrupole and magnetic dipole transitions, one has: $\lambda(E2) = 7.3 \times 10^7\ A^{4/3}E^5$, $\lambda(M1) = 5.6 \times 10^{13}E^3$, where λ is obtained in s^{-1}, if E is given in MeV. When the measured $E2$ transition is much stronger than that given by the Weisskopf estimate, one may conclude that many nucleons are involved; in other words, the decaying nuclear level has a collective character.

In a level scheme, as that of $^{10}_5B_5$ in **Figure 4**, the energy levels are represented as horizontal lines, the heavy one for the ground state (gs), and transitions

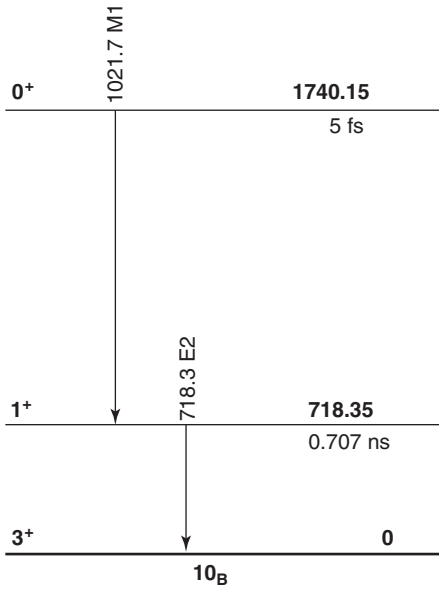

Figure 4 The energy level scheme and γ-transitions of ^{10}B.

by vertical arrows. Level energies expressed in keV are written in bold type near the right end of a level above the line. The half-life of each level is given under the line. The spin and parity are located near the left end. The energy and the multipolarity of each transition is written vertically on top of the corresponding arrow. The upper excited level at 1740.15 keV with a half-life of 5 fs and a spin and parity 0^+ decays 100% to the lower excited level at 718.35 keV (half-life 0.707 ns) with a spin and parity 1^+ by emitting M1 γ-rays with the energy

1740.15 – 718.35 = 1021.7 keV. In its turn, this level is 100% de-excited to the ground state 3^+ by an $E2$ transition of 718.3 keV.

The β^-decay of the 0^+ nucleus ^{10}Be with $Q_{\beta^-} = 555.9$ keV and a half-life of 1.51×10^6 y feeds the gs of ^{10}B. Its excited states can be fed by EC of 0^+ ^{10}C with $Q_{EC} = 3647.81$ keV and a half-life of 19.25 s in a proportion of 98.53% for the lower level and 1.47% for the upper one. The level schemes of heavy nuclei are very complex, with a lot of levels and γ-transitions.

Spontaneous Fission

Intermediate mass nuclei (fission fragments) are emitted during spontaneous fission. Fission fragments are usually deformed and excited, hence the process continues with neutron evaporation as well as β and γ decays. A neutron multiplicity of the order of 2 to 3 neutrons per fission act in fissile materials is very important for making possible the self-sustained chain reaction to produce energy in nuclear power plants. The nuclear fission is the most complex decay process, in which more than 500 different nuclides are produced. Fission characteristics not only provide basic information on this large amplitude collective motion, but they are also important for certain applications, such as nuclear power plants, safeguards, and nuclear incineration. The TKE of fission fragments increases with the fissility parameter from ~160 MeV for ^{232}Th to 270 MeV for the heaviest elements. The half-lives against spontaneous fission of even–even transuranium nuclei decrease with increasing Z from $\sim 10^{15}$ yr for U($Z = 92$) to ~1 ms for Hs ($Z = 108$). The frequently used source of ^{252}Cf decays by spontaneous fission with a partial half-life of $T_f = 85.5$ yr (branching ratio 3%) and α-decay $T_\alpha = 2.73$ yr (branching ratio 97%), leading to a total half-life of 2.64 yr.

In the usual mechanism of fission, a significant part (~25–35 MeV) of the released energy Q is used to deform and excite the fragments, which subsequently cool down by neutron and γ-ray emissions; hence the total kinetic energy of the fragments, TKE, is always smaller than Q. Since 1981, a new mechanism has been experimentally observed by C Signarbieux *et al*. – cold fission characterized by a very high TKE, practically exhausting the Q-value, and a compact scission configuration. Experimental data have been collected in two regions of nuclei: (1) thermal neutron-induced fission on some targets, such as ^{233,235}U, ^{238}Np, ^{239,241}Pu, ^{245}Cm, and the spontaneous fission of ^{252}Cf, and (2) the bimodal spontaneous mass-symmetrical fission of ^{258}Fm, ^{259,260}Md, ^{258,262}No, and ^{260}104 discovered by K Hulet *et al*. in 1986. The yield of the cold fission mechanism is comparable to that of the usual fission events in the latter region, but it is much lower (~5–6 orders of magnitude) in the former. An example of a cold fission process of ^{234}U is given in **Figure 5** in comparison with α-decay (the strongest decay mode of this nucleus) and two heavy-particle radioactivities (^{24}Ne and ^{28}Mg).

The particle-accompanied fission (or ternary fission) was observed both in neutron-induced and spontaneous fission. It was discovered in 1946 by L Alvarez and independently by T San-Tsiang *et al*. Several such processes, in which the charged particle is a proton, deuteron, triton, $^{3-6,8}$He, $^{6-11}$Li, $^{7-14}$Be, $^{10-17}$B, $^{13-18}$C, $^{15-20}$N, $^{15-22}$O, and other heavier isotopes of F, Ne, Na, Mg, Al, Si, P, S, Cl, Ar, and even Ca, have been detected. Some of them are shown in **Figure 6**.

Fissioning isomers are the first superdeformed states experimentally determined. A spontaneous fission activity of ^{242}Am with ~14 ms half-life was discovered in 1961 by S Polikanov *et al*. during the irradiation of U and Pu targets with ^{16}O and ^{22}Ne ions. Many other isomers, with half-lives in the range 5 ps to 14 ms, have been found in the region of heavy elements with $92 \leqslant Z \leqslant 97, 141 \leqslant N \leqslant 151$. The phenomenon was explained on the basis of the Strutinsky's double-humped fission barrier according to which these states are shape-isomers, characterized by a very large prolate distortion (major-to-minor semi-axis ratio ~2:1).

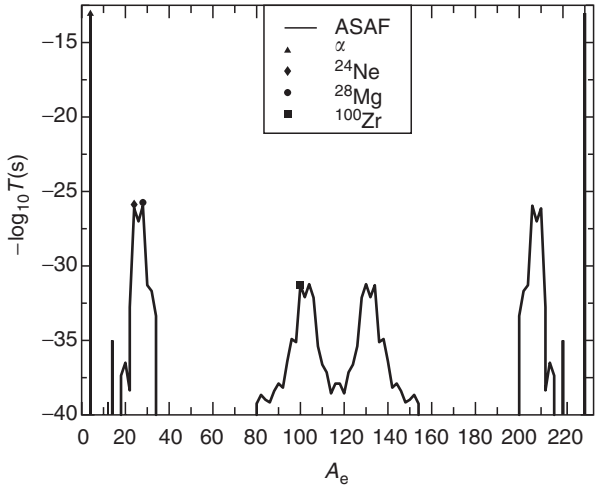

Figure 5 Lifetime spectra calculated with ASAF model for three groups of decay modes of ^{234}U: α-decay; heavy ion radioactivities (^{24}Ne and ^{28}Mg) and cold fission with light fragment ^{100}Zr. Except for CF for which T was not determined, the experimental points are in good agreement with calculations. Proton Radioactivity

The radioactive emission of one and two protons has been theoretically predicted by V Goldansky since 1960. S Hofmann *et al.* discovered, in 1980, the spontaneous proton emission from the ground state of ^{151}Lu with a half-life of 85 ms and a kinetic energy of 1233 keV. The relatively large angular momentum involved by making a transition from ^{151}Lu with a spin and parity $11/2^-$ to the ground state 0^+ of ^{150}Yb contributes substantially to the potential barrier by this centrifugal component. There are almost 30 proton emitters beyond the proton drip line with odd atomic numbers between 51 and 83. Examples are: ^{105}Sb, ^{109}I, ^{112,113}Cs, ^{117}La, ^{131}Eu, ^{141}Ho, ^{145,146,147}Tm, ^{150,151}Lu, ^{156}Ta, ^{160,161}Re, ^{164,165,166,167}Ir, ^{170,171}Au, ^{177}Tl, and ^{185}Bi.

The odd–even staggering of the proton separation energy S_p, responsible for the nonregular structure of the drip line, leads to situations where $S_p > 0$ for a given nucleus, while $S_{2p} < 0$. Possible candidates for two-proton radioactivity are: ^{17}Ne, ^{19}Mg, ^{39}Ti, ^{42}Cr, ^{49}Ni, ^{59}Ge, ^{152}Hf, ^{153}Ta, ^{154}W, and ^{155}Re. In 2002, there were two successful experiments at GANIL and GSI reporting the 2p radioactivity of ^{45}Fe with an energy of 1.14 MeV and a half-life of 4.7 ms.

Heavy Ion Radioactivity

Heavy ion radioactivities were predicted in 1980 by A Sandulescu, D Poenaru, and W Greiner, four years before the first experimental evidence reported by H J Rose and G A Jones. Some of the cluster emitters are members of the natural radioactive families (see **Figure 3**, where part of the disintegration chain of ^{235}U is shown). The main region of emitters experimentally observed is above $Z = 86$ with daughters around ^{208}Pb: ^{221}Fr, $^{221–224,226}$Ra, ^{225}Ac, ^{228,230}Th, ^{231}Pa, $^{230,232–236}$U, ^{236,238}Pu, and ^{242}Cm. There is a strong competition with α-decay. The largest branching ratio with respect to α-decay, $b = T_\alpha/T$, is $\sim 10^{-9.2}$.

From many decay modes with half-lives and branching ratios relative to α-decay predicted with the analytical superasymmetric fission (ASAF) model, the following have been experimentally confirmed: ^{14}C, ^{20}O, ^{23}F, $^{24–26}$Ne, ^{28,30}Mg, ^{32,34}Si. The experimental data are in good agreement with predicted values (see the examples given in **Figure 7**). A strong shell effect can be seen: as a rule, the shortest value of the half-life (maximum of $1/T$) is obtained when the daughter nucleus has a magic number of neutrons ($N_d = 126$) and/or protons ($Z_d = 82$).

The fine structure in ^{14}C radioactivity of ^{223}Ra, for the first time discussed by M Greiner and W Scheid in 1986, was discovered in 1989 by E Hourani, M Hussonnois *et al.* at IPN Orsay. Surprisingly, they observed that a transition of the daughter to the first excited state was stronger than that to the ground state.

The measurable decay constant $\lambda = vSP$ is a product of three model-dependent terms of which the frequency of assaults on the barrier per second, v, may be considered constant. The preformation probability, S, can be calculated quasiclassically as the internal barrier penetrability in a fission model. With good approximation, one can obtain one universal curve for any kind of cluster decay mode with a mass number A_e, including α-decay:

$$\log T = -\log P - 22.169 + 0.598(A_e - 1)$$

where the penetrability, P, is calculated easily for the given split. In a logarithmic scale, the equation $\log T = f(\log P)$ represents a single straight line which can be conveniently used to estimate the half-life.

Nuclear Stability

The area of experimentally identified nuclei until 2003, covering 2228 species, extends well beyond the central region of about 300 beta-stable nuclides (shown as black squares in **Figure 8**), both on the proton and neutron-rich sides. A semi-empirical approximation for the line of β-stability, $N - Z = 0.4A^2/(200 + A)$, allows one to estimate which mass number, A, or neutron number, N, corresponds to a given proton number, Z, for a β-stable nucleus. It is

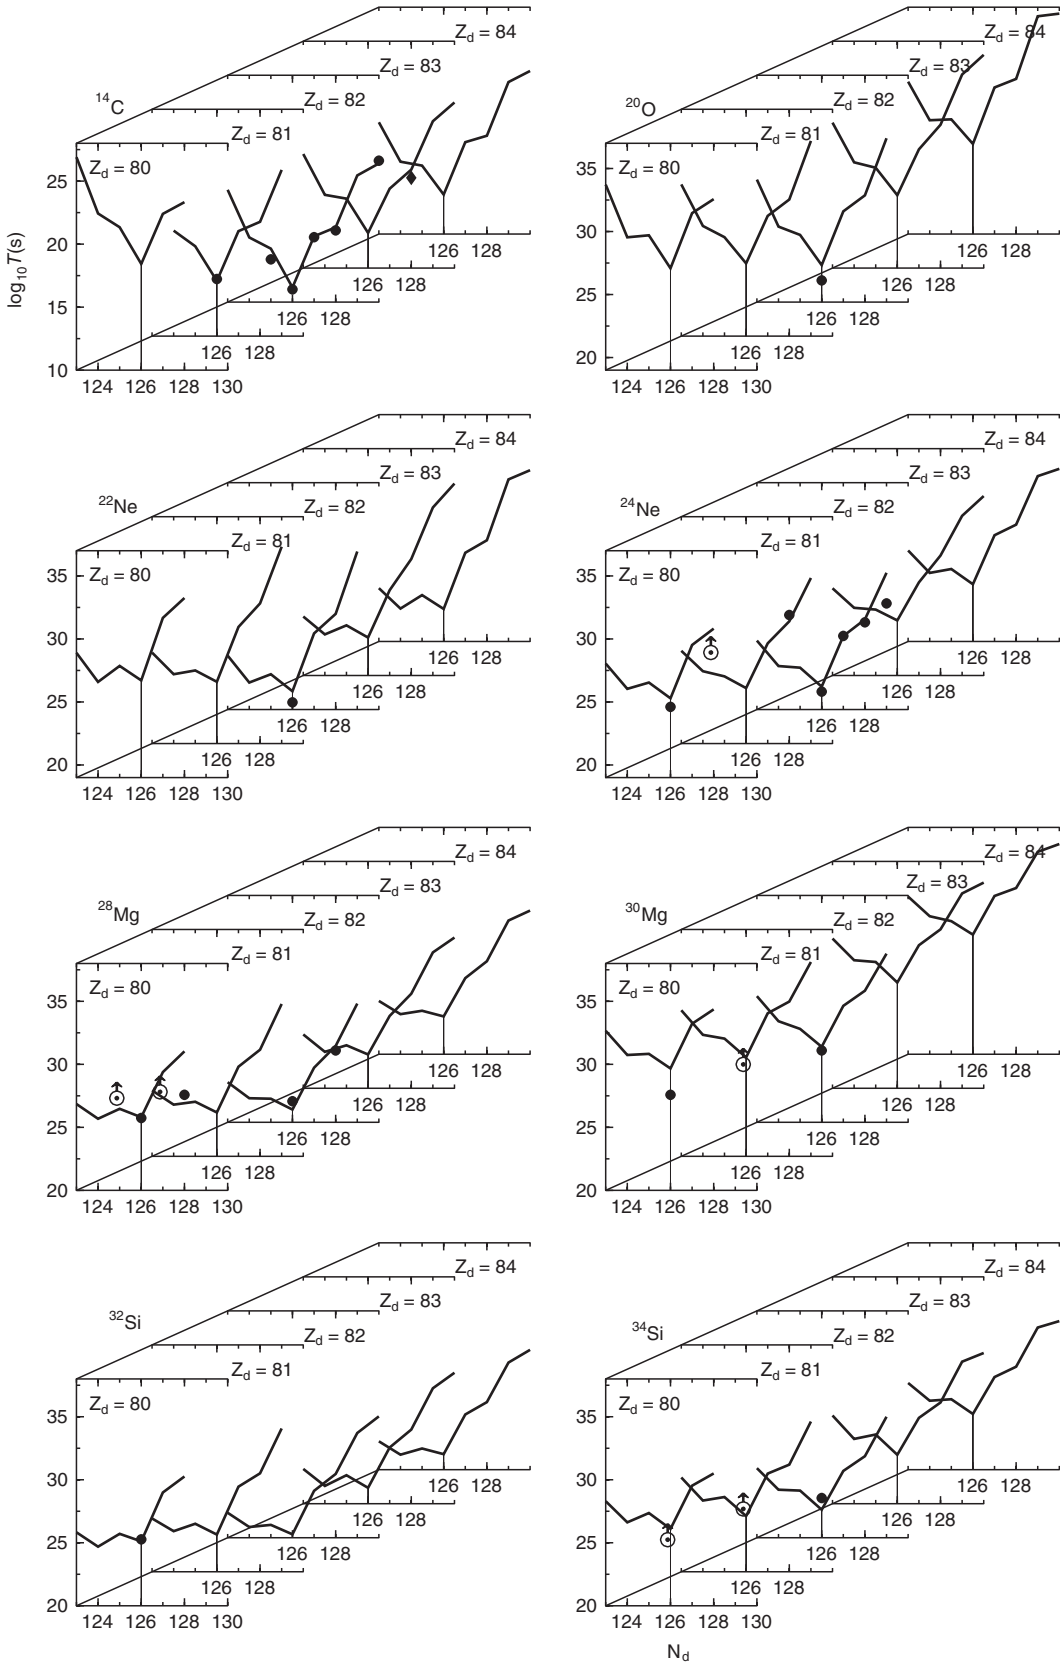

Figure 7 Predicted half-lives within the ASAF model (lines) and measurements (points) for eight kinds of cluster decay modes vs. proton (Z_d) and neutron (N_d) number of the daughter nucleus. The shell effects are clearly seen as minima of lifetime for magic numbers of the daughter, $Z_d = 82$, $N_d = 126$.

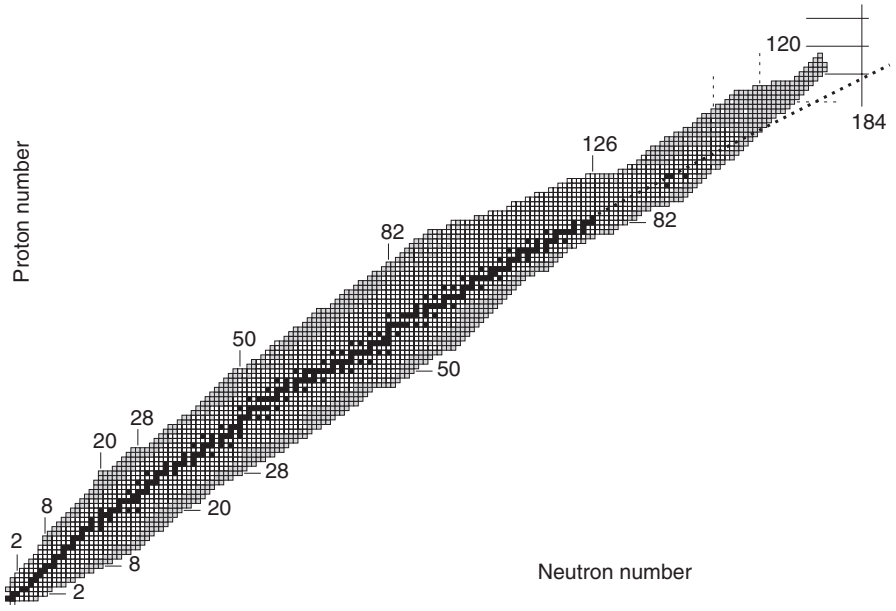

Figure 8 Nuclear chart. The nuclides found in nature are represented by black squares. The closed shell ("magic") numbers of neutrons and protons are displayed. There are ~2228 nuclides with measured masses, and for some 951 others (dashed squares on the figure), the masses were obtained by extrapolation. (From Audi G, Wapstra AH, and Bersillon O (2003) *Nuclear Physics A* 729: 337–676.)

displayed as a dotted line for $Z > 82$ in **Figure 8**. Like the noble gases He, Ne, Ar, Kr, Xe, and Rn, which have an increased stability due to their closed-shell electron configuration (for 2, 10, 18, 36, 54, and 86 electrons) nuclei with the magic number of protons or neutrons, 2, 8, 20, 28, 50, 82, shown in **Figure 8**, are particularly stable as a consequence of quantum-mechanical laws.

Many nuclides found in nature or produced artificially by nuclear reactions decay by spontaneous emission of certain particles or electromagnetic radiation. The daughter nucleus can in its turn be unstable, and the phenomenon continues until a stable configuration is reached.

The limits of nuclear stability are determined either by hadron-decay modes, or (for heavy nuclei) by α-decay or spontaneous fission. The most important limits are the proton and neutron drip lines, where the proton or the neutron has roughly zero binding energy. A large proton excess is not possible owing to the Coulomb repulsion; for light nuclei, the proton drip line is very close to $N = Z$. By combining the Coulomb and centrifugal (angular momentum) barriers, the lifetime of proton emission from an unbound state can be long enough to be experimentally detected in a proton-decay experiment. In this way, the proton drip line can be overstepped: one accedes to a nucleus situated outside the drip line. A series of proton-rich In and Sn isotopes (including the doubly magic ^{100}Sn) were produced. The heaviest known proton emitter is $^{185}_{83}\mathrm{Bi}_{102}$. The neutron drip line has been reached only for the lightest nuclides up to $^{49}_{16}\mathrm{S}_{33}$.

The existence of extremely heavy nuclei is prevented by the spontaneous fission process. When the number of protons becomes very high, the Coulomb repulsion is no longer counter-balanced by the strong interaction, and the phenomenological liquid drop model (LDM) fission barrier height may approach zero. By adding a shell correction term to the LDM energy of a superheavy nucleus, a potential barrier shows up. This shell-stabilizing property, characteristic of the superheavy nuclei, is already present in the heaviest elements known to date with $Z = 107 - 118$ (see **Figure 9**). An example of a potential energy surface of the superheavy nucleus with $Z = 120$ and $A = 304$ is given in **Figure 10**.

Owing to shell effects, the fission barriers of these nuclei are so high that they decay mainly by α-emission instead of spontaneous fission. The magic numbers in the superheavy region are still not known. The candidates are $Z = 114, 120, 126$ and $N = 184$.

Radiation Exposure

Human beings and different materials are permanently exposed to radiations coming from primordial (since the origin of the Earth), cosmogenic (formed as a result of cosmic-ray interactions), or human-produced elements. More than 2/3 of the radiation dose corresponds to natural radioactivity and about 1/4 to

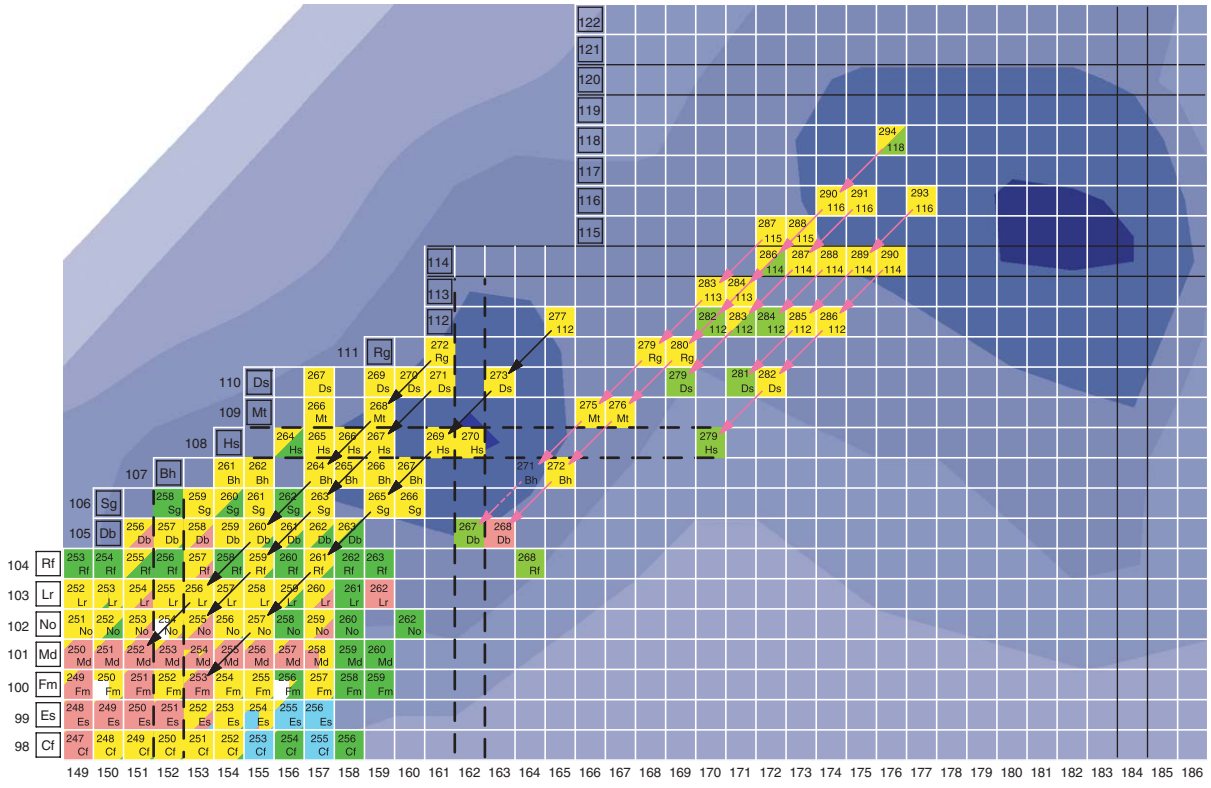

Figure 9 Part of the nuclear chart displaying the superheavy nuclei produced at GSI Darmstadt and JINR Dubna. The background shows two minima (dark blue) of shell correction energies where the most stable nuclides are expected to be found, around $Z = 114$, $N = 184$ for spherical nuclei and $Z = 108, N = 162$ for the deformed ones. (From Hofmann S and Darmstadt GSI (2004).)

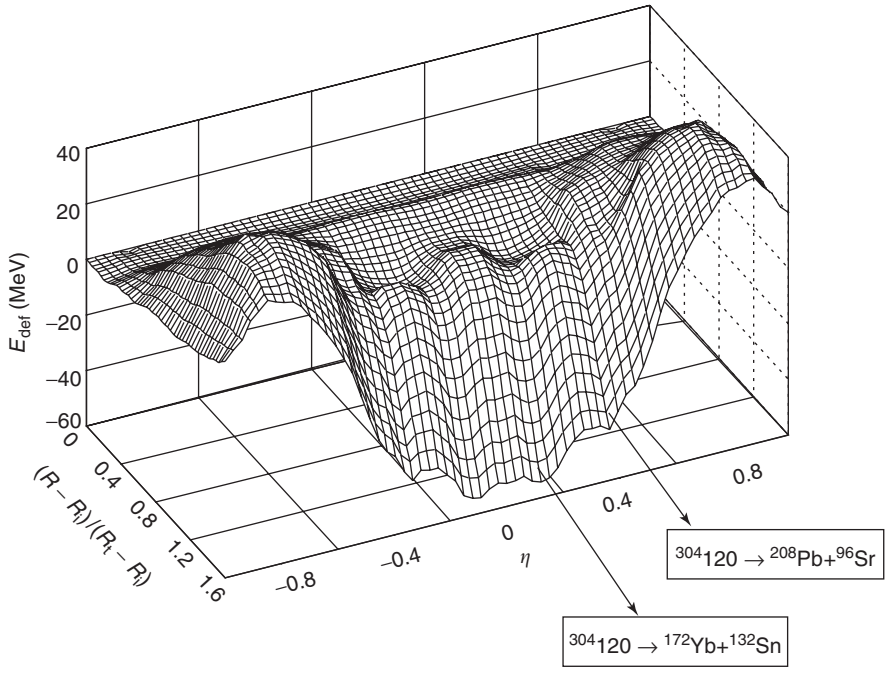

Figure 10 Potential energy surface of the superheavy nucleus $^{304}120$ vs. fragment separation and mass asymmetry $\eta = (A_1 - A_2)/(A_1 + A_2)$. The survival of this nucleus is based on the existence of a finite value of potential barrier. Two main valleys corresponding to the split with one doubly magic fragment ^{132}Sn and ^{208}Pb can be seen. (Reproduced with permission from Gherghescu RA, Poenaru DN, and Greiner W (1998) *Journal of Physics G* 24: 1149; © IOP Publishing Limited.)

medical irradiations (mainly X-rays). When passing through air, ionizations are produced. The exposure is the total electric charge on the ions produced in a given mass of air and is measured traditionally in roentgen (R). The SI unit is coulomb per kilogram: $1\,\mathrm{R} = 2.58 \times 10^{-4}\,\mathrm{C\,kg^{-1}}$.

The quantity expressing the energy absorbed in a mass unit by ionization in different materials is called the absorbed dose, D. The traditional unit 1 rad corresponds to the absorption of 100 ergs per gram of material. The SI unit is the gray (Gy) equal to the absorption of $1\,\mathrm{J\,kg^{-1}}$, hence $1\,\mathrm{Gy} = 100\,\mathrm{rad}$. Under 250 mGy, no sizeable biologic or medical effect has been observed. On the other extreme, the lethal dose is $\sim$5000 mGy.

For human beings, it is important to take into account the biological effects of different radiations. Ionizing radiation causes physical damage to cells and DNA. A quality factor (QF) is calculated for a given type and energy of radiation according to the energy deposited per unit path length. For X-rays, β and γ, which deposit little energy per unit length, $\mathrm{QF} = 1$, and for α-particles QF may reach a value as high as 20. The dose equivalent $\mathrm{DE} = D \cdot \mathrm{QF}$ is measured traditionally in rem and the SI unit is called sievert (Sv), $1\,\mathrm{Sv} = 100\,\mathrm{rem}$.

The International Commission on Radiation Protection recommended a limiting annual whole-body absorbed dose of 5 mSv per year for the general public and 50 mSv per year for professionals working with radiations. The mean value of the natural radiation dose received in France is $\sim$3.5 mSv per person in a year: $\sim$0.4 mSv from cosmic radiations coming from space, 0.4 mSv from the earth (uranium, thorium, potassium), 1.6 mSv from the elements absorbed by breathing (particularly the gas radon) and eating (potassium), and 1.1 mSv from artificial exposure of medical origin (mainly X-rays). The industrial activity represents $\sim$0.1 mSv, of which only 0.02 mSv comes from nuclear energy.

Z	atomic number
Δ	mass defect (MeV)
λ	decay constant ($\mathrm{s^{-1}}$)
τ	lifetime (s)

Recovery, Recrystallization, and Grain Growth

N Hansen, Risø National Laboratory, Roskilde, Denmark
R A Vandermeer, Columbus, OH, USA

Introduction

Metallic materials harden when deformed and soften, if afterward annealed. This behavior has been known to man since the beginning of our civilization, and it is today exploited in the industrial fabrication of metals and alloys by thermomechanical processing. Hundreds of millions of tons of metallic materials are produced annually.

Examples of such processing are aluminum beverage cans, steel sheets and plates for cars and ships, and light metals such as aluminum and titanium for aeroplanes and satellites.

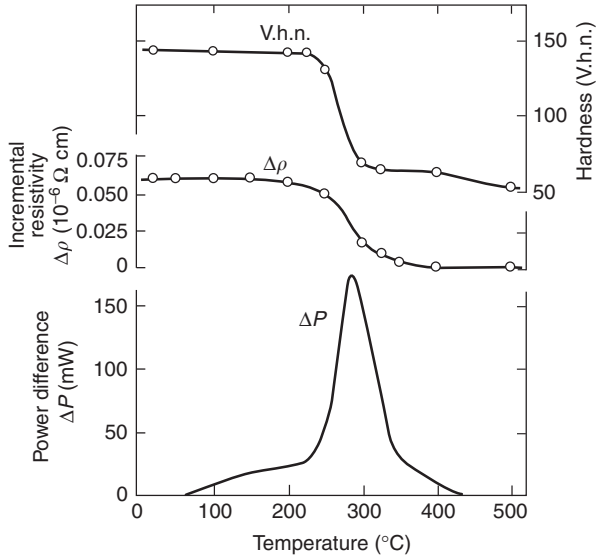

Figure 1 Change in hardness, electrical resistivity, and stored energy (represented by a power differential) during heating of deformed pure copper. (Reproduced from Clareborough HM, Hargreaves ME, and West GW (1955) *Proceeding of the Royal Society London* 232 A, 252.)

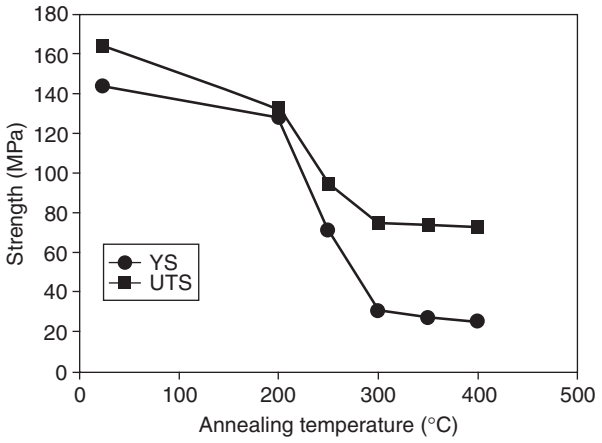

Figure 2 Yield stress (YS) and ultimate tensile strength (UTS) at room temperature after heating of a sheet of cold rolled aluminum.

During a thermomechanical treatment, the metal is exposed to a plastic deforming force, which hardens it and to an elevated temperature, which leads to softening either during deformation or after. A thermomechanical process can therefore, for example, be hot rolling or cold rolling followed by annealing, that is, a heat treatment at elevated temperatures. A simultaneous exposure to force and temperature typically gives rise to the processes of dynamic recovery and dynamic recrystallization. In the case where the heat treatment is applied after deformation, these processes are recovery, recrystallization, and grain growth, which are considered in what follows.

Recovery, recrystallization, and grain growth refer to thermally activated microstructural or even submicrostructural processes, which directly affect the properties of the metal (**Figure 1**). This is because substantial and important relationships exist between the structure of metallic materials and their properties. Therefore, to understand and model such properties, the microstructural changes taking place during recovery, recrystallization, and grain growth must first be described and quantified. For this purpose, microstructural parameters are determined linking processing and properties. This article focuses on mechanical properties, but physical and chemical properties also are influenced by the microstructure.

The mechanical properties of a metal describe its resistance to flow, when subjected to a load. Mechanical properties of a metal are therefore legion. They can be general parameters such as the yield and flow stress, or they can be more specific, for example, related to the metal's formability where the work hardening rate, elongation, etc., may be important. Furthermore, the properties depend on the deformation mode, which may be mono tonic or cyclic. Therefore, with an application in view, many different structure–property relationships must be evaluated. This article will concentrate on strength properties such as the yield stress, the flow stress, and the hardness (**Figure 2**). This is because these properties have been most frequently used in previous studies, they are easy to measure, and physically based models have been formulated for their dependency on a variety of microstructural parameters. Further properties, which directly reflect the strength of the metal, are of general interest from the point of view of applications as there always has been an incentive to develop strong metals, which can carry larger loads by smaller cross sections.

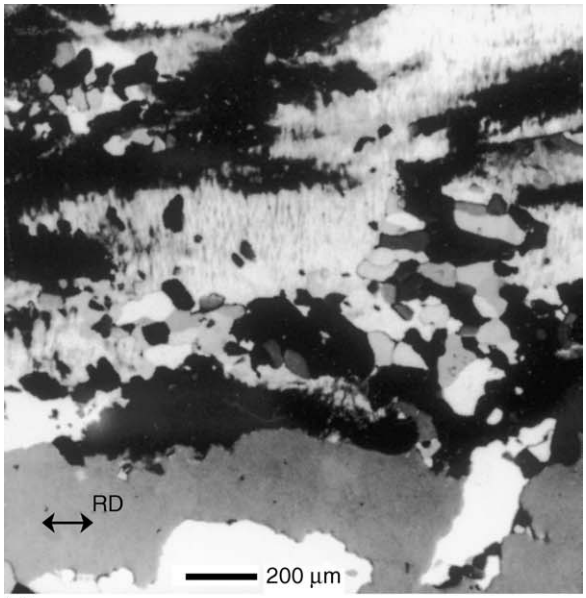
Recovery, Recrystallization, and Grain Growth (Phenomena)

Recovery refers to the structural changes associated with the annihilation of deformation-induced defects, and/or their rearrangement into lower-energy configurations giving rise to substantive changes in properties without changing the basic orientation or crystallographic texture of the material. Recovery is often characterized and described in terms of the recovery of specific properties, chief among them the hardness, flow stress, stored energy, and electrical resistivity. But, since the advent of the electron microscope, changes in microstructural features such as the dislocation density and subgrain and dislocation

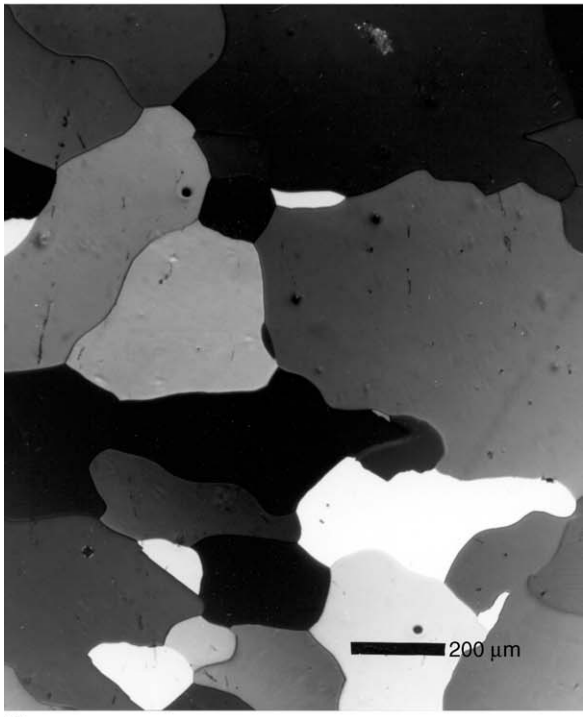
cell sizes have also been detailed along with the property changes. Usually recovery mechanisms alone, which occur primarily at the lower annealing temperatures, cannot restore the material to its pre-deformation state. The term recovery is sometimes also used to describe the phenomena associated with annealing out of quenched-in point defects such as vacancies, and the annealing out of irradiation-produced defects such as interstitials and voids.

In competition with the various recovery mechanisms acting to anneal out the deformation-induced defects is the microstructural phenomenon called primary recrystallization or simply recrystallization, which manifests itself at intermediate annealing temperatures. Recrystallization is understood to entail the evolutionary change whereby a population of new, strain-free grains emerge from the deformed volumes in a step referred to as nucleation, that is, they become identifiable at a length scale of a few micrometers, followed by the increase in size or growth of these nuclei/grains until the deformed volumes are consumed and the new grains all impinge upon one another (**Figure 3**). The hallmark of a growing grain is that its grain boundary, a portion of which is required to be of the high-angle type sweeps through the deformed volumes by a boundary migration mechanism. In so doing, the deformation-induced defects in the swept-out path are eliminated. When one new grain meets another, the segments of their grain boundaries that impinge, that is, come together to form a new grain boundary, cease to migrate. Recrystallization can create new crystallographic orientations in local regions and often a different texture is developed in the material as a result of recrystallization.

When recrystallization is complete, the material is polycrystalline but with the deformation-induced defects eliminated. In this state the substance is composed of many contiguous crystals, that is, grains, defined by an interconnected grain boundary network consisting of nodes (grain corners), branches (grain edges), and faces (grain boundaries), and having a thickness of atomic dimensions. In a thermodynamic sense, this interface array imparts an excess energy to the material, which would not be present in a single crystal. The material perceives the excess energy through the topological grain boundary network as an interfacial tension in the Gibbsian sense. Equilibration of the interfacial tensions throughout and the requirement to maintain perfect space filling causes the grain boundary faces to be curved, and so gives rise to pressure differences between grains. Given sufficient thermal activation and atomic mobility, these pressure differences cause grain boundaries to migrate toward their centers of curvature, thereby reducing the amount of grain boundary area in the material and systematically eliminating some of the grains. Concomitantly the remaining grains, on average, enlarge. This



(a)



(b)

Figure 3 (a) Partly recrystallized structure in deformed and annealed aluminum. Regions with remaining deformed (recovered) matrix material have a stripy appearance and contain new grains of different size. (b) Fully recrystallized state showing a polycrystalline structure. (Reproduced from Juul Jensen D (1997) *Orientation Aspects of Growth during Recrystallization*, Risø-R-978 (EN). Roskilde, Denmark: Risø National Laboratory.)

evolutionary process is known as grain growth and usually occurs at higher annealing temperatures. When the growth process is characterized microstructurally by a progressive increase in average size of the grains and the grain size distribution behaves in a statistically self-similar manner, that is, consecutive configurations of the system are geometrically similar in a statistical sense, the process is referred to as normal or steady state grain growth. A few special grains may also grow rapidly to sizes much larger than the average, and consume the smaller stagnant grains in a process termed abnormal grain growth. Thus, the driving force for grain growth is derived from the grain boundary energy unlike that for recovery and recrystallization, which arises from the deformation-induced defects.

Microstructural Parameters

The microstructural parameters determining the mechanical property change during annealing from fine scale dislocation structures to coarse scale grain structures, that is, microstructures must be characterized over length scales from the nanometer/submicrometer range to the micrometer/millimeter range. A thorough microstructural characterization must therefore be based on the application of a number of microscopical techniques such as optical microscopy (OM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). By these techniques, a qualitative and quantitative description of the morphological changes taking place during annealing is obtained. Combined with techniques for analyzing the local and macroscopic crystallography, that is, orientations (texture), structural parameters can be quantified.

The changes in microstructural and crystallographic parameters taking place during annealing of a deformed metallic material relate directly to the structure in the deformed state. This structure depends on a number of materials and process parameters. However, microstructural characterization and modeling of a variety of metals and alloys deformed by different thermomechanical processes have shown a universal structural evolution. Dislocations are generated during deformation and they accumulate in dislocation boundaries, which subdivide the original grains on a finer and finer scale as the degree of deformation (the plastic strain) is increased. This universal structural evolution has its origin in common principles and processes that apply to the formation and storage of dislocations during plastic deformation (**Figure 4**).

The universal structural evolution during plastic deformation is defined by a number of microstructural

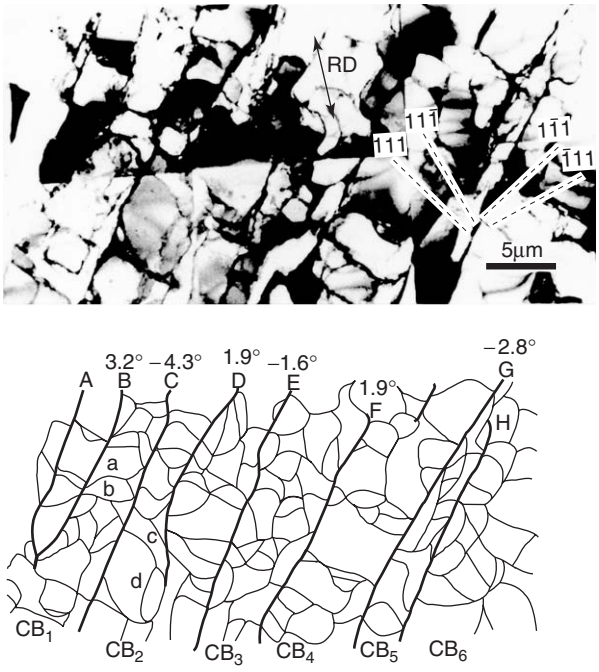


Figure 4 Transmission electron microscopy image and sketch of microstructure in aluminum, cold rolled to 10% reduction in thickness. The structure is subdivided by extended dislocation boundaries (marked A, B, C, etc.) and short cell boundaries (marked a, b, c, etc.). (Liu Q and Hansen N (1995) Geometrically necessary boundaries and incidental dislocation boundaries formed during cold deformation. *Scripta Metallurgica et Materialia* 32: 1289–1295.)

parameters, which in various ways have been related to the mechanical properties of materials in the deformed state and after recovery. Recovery leads to a coarsening of the deformed structure, that is, the recovered structure is to an extent similar to the deformed structure. However, after nucleation and growth have initiated recrystallization, the microstructure changes into a composite structure, where large nuclei are embedded in a deformed matrix. After completion of recrystallization, this composite structure is replaced by a grain structure (**Figure 3b**) characterized by the average grain size and the grain size distribution. During grain growth the structural evolution is self-similar, that is, the probability distributions of grain size collapse into one function, when scaled with the average grain size for each distribution.

Mechanical Properties and Microstructural Parameters

A large research effort has been devoted to the formulation and validation of relationships between the mechanical properties and a number of different microstructural parameters.

In the deformed state, the most general relationship expresses the dependency of the flow stress (σ_f) on the total dislocation density ρ_t:

$$\sigma_f - \sigma_0 = M_1 \alpha b G \sqrt{\rho_t} \quad [1]$$

where σ_0 is a friction stress, M_1 is the so-called Taylor factor, α is a number of the order of 0.2–0.3, b is the Burgers vector, and G is the shear modulus. Apart from a variation in α, eqn [1] is in general fairly insensitive to changes in the dislocation structure, purity, strain rate, and temperature.

In the recrystallized state, the yield stress σ_y can be related to the grain size D by the Hall–Petch equation:

$$\sigma_y - \sigma_0 = kD^{-0.5} \quad [2]$$

where k is a constant, and σ_0 is the yield stress of an undeformed single crystal orientated for multiple slip or approximately the yield stress of a very coarse untextured polycrystal. An equation similar to eqn [2], however not as universal, relates the flow stress at a particular strain $\sigma(\varepsilon)$ to the grain size:

$$\sigma(\varepsilon) - \sigma_0(\varepsilon) = k(\varepsilon)D^{-0.5} \quad [3]$$

where $\sigma_0(\varepsilon)$ and $k(\varepsilon)$ are constants at a given strain (**Figure 5**).

A characteristic structural feature in many deformed, recovered, and partly recrystallized metals is dislocation cells or subgrains. These features can be defined as follows: (1) A cell is a roughly equiaxed volume element within which the dislocation density is well below the average density and which is rotated relative to similar adjacent volume elements, from which it is separated by more or less well-formed rotational dislocation boundaries. (2) A subgrain is a dislocation cell, where the relative rotations between the lattice on either side of the boundary has become so large that the neighboring cell can no longer operate with the same combination of simultaneously operating glide systems. For cell- and subgrain-forming metals, numerous experiments have shown that an empirical relationship exists between the flow stress σ_f and the average cell or subgrain diameter d:

$$\sigma_f - \sigma_0 = k_2 G b d^{-n} \quad [4]$$

where k_2 is a constant. In contrast to the Hall–Petch equation the exponent is not a constant, but is normally found to be in the range 0.5–1.0 with values in the upper end of this interval characteristic of dislocation cell structures, and a value in the lower end characteristic of subgrain structures. The exponent is, therefore, an indirect measure of the boundary strength. For a cell structure, where the cell boundaries are of low angle and $n \simeq 1$, it follows from eqns [1] and [4] that the dislocation density must be related to the cell size. This relationship has been expressed in an equation for a mixed tilt/twist boundary:

$$\rho_t = \rho_0 + \frac{1.5\theta}{b} S_v \quad [5]$$

where ρ_0 is the dislocation density in the material between the dislocation boundaries, θ is the angle of misorientation across the boundaries, and S_v is the area of dislocation boundaries per unit volume of material being inversely proportional to the boundary spacing. For equiaxed cells, S_v is typically equal to $3/d$.

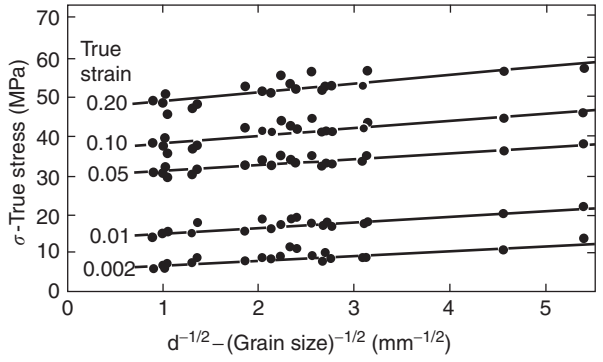

Figure 5 The dependence of yield stress and flow stress on the grain size of polycrystalline copper. (Hansen N and Ralph B (1982) The strain and grain-size dependence of the flow-stress of copper. *Acta Metallurgica* 30: 411–417.)

Structure and Mechanical Properties

The structural parameters of the deformed state relate to the presence of the original grain boundaries and the density of dislocations introduced by the deformation. On the assumption that the strength contributions of grain boundaries and dislocations can be added linearly, the flow stress can be expressed by eqn [2] when introducing the dislocation strengthening expressed by combining eqns [1] and [5]. The flow stress can then be written as

$$\sigma(\varepsilon) = \sigma_0(\varepsilon) + M_1 \alpha G \sqrt{\rho_0 + 1.5 b S_v \theta} + k(\varepsilon) D^{-0.5} \quad [6]$$

In studies of the flow stress behavior of cold rolled aluminum, nickel, and iron, good agreement between theory and experiment has been found (**Figure 6**).

In the recovered state, the microstructure may be quite similar to that of the deformed state but the structure has coarsened leading to reduction in S_v. The value of θ may also change, however, to a much lesser extent. Finally, the dislocation density between the boundaries (ρ_0) decreases as dislocations are annihilated or are integrated into the cell/subgrain

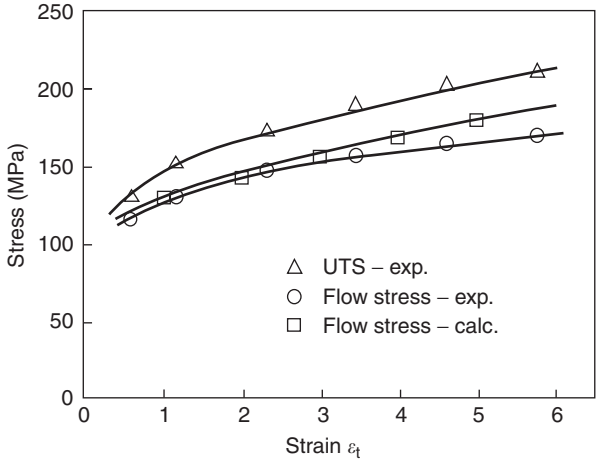

Figure 6 Comparison of experimental and calculated strength properties (ultimate tensile strength and flow stress at 0.2% offset) of aluminum cold rolled up to a strain of 5.5, which corresponds to a 99.6% reduction in thickness. (Liu Q, Huang X, Lloyd DJ, and Hansen N (2002) Microstructure and strength of commercial purity aluminum (AA 1200) cold-rolled to large strains. *Acta Materialia* 50: 3789–3802.)

boundaries. As a result the flow stress decreases with a rate, which depends on the rate of annealing processes, for example, vacancy and dislocation annihilation and migration of subboundaries, and high-angle boundaries.

In the recrystallization stage, the structure is a composite of soft recrystallized grains in a much harder matrix (**Figure 7**); the flow stress can be expressed by the equation

$$\sigma_f - \sigma_0 = V_r\sigma_r + (1 - V_r)\sigma_m \qquad [7]$$

where V_r is the volume fraction of recrystallized material, and σ_r and σ_m are the flow stresses of undeformed (recrystallized) and recovered structures, respectively. The recovered structure is strengthened mainly by cells/subgrains, that is, σ_m can be expressed by eqn [4]. During recrystallization, σ_m decreases due to coarsening of the cell/subgrain structure, and as V_r increases, the flow stress decreases rapidly.

In the recrystallized state and after normal grain growth (steady state) the mechanical properties (e.g., yield stress, flow stress, and hardness) can be expressed by a Hall–Petch type relationship, expressing proportionality between the property and the reciprocal square root of the grain size (**Figure 5**).

Kinetics

The change in mechanical properties and in the strength-determining structural parameters may be related directly to the time and temperature of annealing and expressed in rate equations.

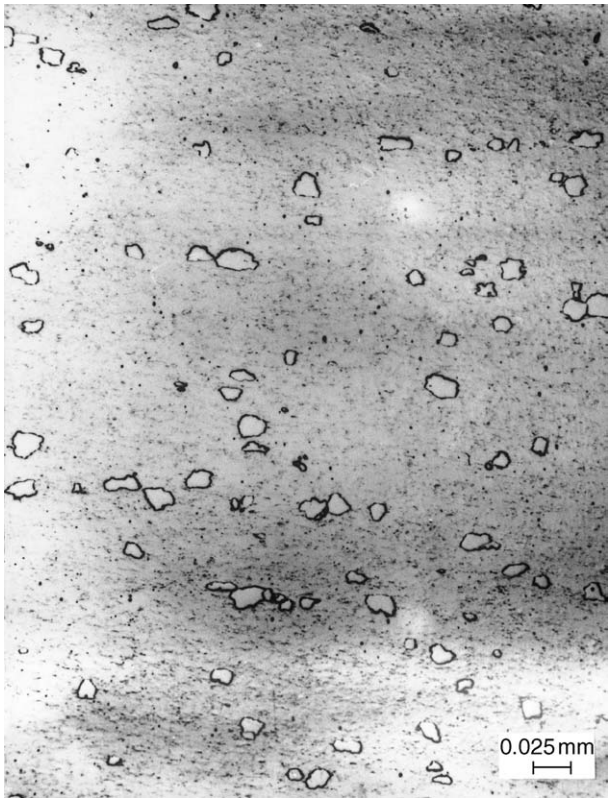

Figure 7 Early stage of recrystallization in deformed crystals of iron. (Vandermeer RA and Rath BB (1989) Modeling recrystallization kinetics in a deformed iron single crystal. *Metallurgical Transaction A* 20A: 391–401.)

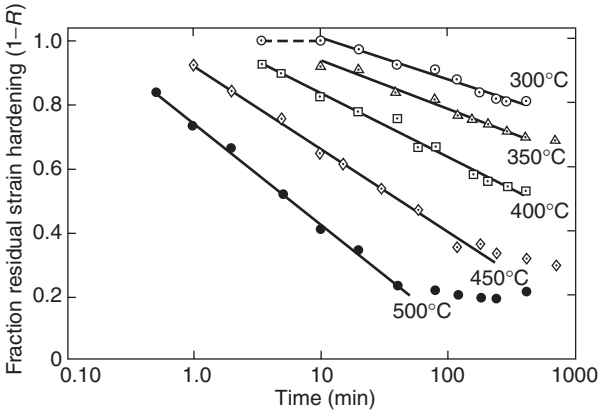

Figure 8 Recovery kinetics of flow stress of polycrystalline iron following 5% prestrain (1-*R*) represents the fraction of residual hardening, i.e., (1-*R*) is one in the deformed state and zero after recrystallization. (Michalak JT and Paxton HW (1961) Some recovery characteristics of zone melted iron. *Transactions of the Metallurgical Society of AIME* 221: 850–857.)

During recovery, the change in the mechanical properties during isothermal recovery is highest initially and decreases with time as recovery proceeds (**Figure 8**). There is no universal rate equation, which can describe all the changes during annealing;

however, one rate equation has been found to give a good empirical description:

$$\frac{dP}{dt} = -(P - P_r)K_0 \exp - \left(\frac{Q_0 - \beta(P - P_r)}{RT}\right) \quad [8]$$

where P is the instantaneous value of the property, for example, the flow stress or the hardness, P_r is the remnant value of the property which is unrecoverable after very long annealing times, T is the absolute temperature, t is the annealing time, R is the gas constant, and K_0, Q_0, and β are constants characterizing the recovery behavior. Except at large or small times, this rate equation for recovery may be integrated to yield a property change that depends approximately on the logarithm of the annealing time. Because recovery is something of a generic term used to represent various and sundry property changes, usually no single atomic mechanism can be invoked to characterize it. Thus, other rate equations may be required to adequately describe some experiments.

The change in mechanical properties with time and temperature may also be analyzed, based on rate equations describing the changes in strength-determining structural parameters, for example, the dislocation density, the cell/subgrain size, and the grain size. Common to these changes is that, they are controlled by a driving pressure (the stored energy). For a deformed structure, this driving pressure P ($N\,m^{-2}$) is proportional to the dislocation density multiplied by the energy per unit length of dislocation line or approximately

$$P = 0.5\rho_t G b^2 \quad [9]$$

where ρ_t is the total dislocation density stored in boundaries and between the boundaries. For a structure subdivided into cells/subgrains of grains, the driving pressure can be related to the total boundary energy per unit volume when

$$P \cong S_v \gamma_b \quad [10]$$

where S_v is the boundary area per unit volume and γ_b is the boundary energy per unit area. For cell/subgrain boundaries γ_b increases with the angle of misorientation across the boundary, whereas for high-angle grain boundaries ($>15^\circ$), γ_b is the grain boundary energy ($J\,m^{-2}$) taken to be a constant for all boundaries.

The rate equations for the structural parameters, describing the change in dislocation density as a function of temperature and time during recovery, involve a number of processes, which have been modeled separately. However, no universal relations have been proposed. In contrast, it is generally accepted that for boundary migration there is a simple linear relationship between velocity V and the driving pressure P:

$$V = MP \quad [11]$$

where M is the boundary mobility, which is a parameter characterizing the boundary migration mechanism. The temperature dependence of M can be expressed by an Arrhenius equation:

$$M = M_0 \exp[-Q/RT] \quad [12]$$

where M_0 is a pre-exponential "constant," and Q is the activation energy for the rate determining process (e.g., an atom transfer process). Equation [12] can be derived from either an absolute reaction rate mechanistic premise or on an irreversible thermodynamic principle.

The change in mechanical properties during recrystallization is expressed in eqn [7], where a key parameter is V_r, the volume fraction of recrystallized material. Phenomenologically, recrystallization may be envisioned as a nucleation and growth "transformation" and treated so, kinetically. Unlike recovery, the isothermal rate of recrystallization exhibits "sigmoidal" kinetics starting out low, increasing to a maximum value, and then decreasing again with time. Isothermal recrystallization kinetics are usually described experimentally in terms of the Avrami equation:

$$V_r = 1 - \exp(-Bt^k) \quad [13]$$

where V_r is the volume fraction recrystallized, t is the annealing time, and B and k are parameters that depend on the characteristics of recrystallization such as the nucleation rate, growth rate, the shape of the recrystallized grains, and the nature of the new grain impingement patterns. Ideally B and k may be constants, but often one or the other (usually the k) is not. Deviations from the ideal may be caused by competition between the recovery and recrystallization mechanisms for the stored energy of cold deformation, by the heterogeneous nature of the deformed microstructure, by changes in the growth rate mechanism, by complex impingement patterns, or combinations of these phenomena.

Finally, considering normal grain growth as an example, the driving pressure is $\gamma_b S_v$ and S_v is $2/D$, where D is the grain size measured along random lines. The boundary migration rate is therefore

$$\frac{dD}{dt} = \frac{2M\gamma}{D} \quad \text{or} \quad (D^2 - D_0^2) \cong Kt \quad [14]$$

where D_0 is the length scale of the grain size at time equal to zero (fully recrystallized grain size), and K is a temperature-dependent rate parameter. However, failure of experiment to conform to parabolic kinetics

is the rule rather than the exception and may be attributed to a number of material related factors: (1) the scaled grain size distribution has not achieved statistical self similarity, and grain growth is in a transient period, (2) pinning forces causing growth stagnation are present, for example, second phase precipitates, surface grooving of grain boundaries, and intrinsic drag forces due to soluble impurities, and (3) the onset of abnormal grain growth.

Based on eqns [2] and [14], the changes in yield stress with annealing time can be expressed as $\sigma \simeq t^{-0.25}$, or $\sigma^4 \approx 1/t$. In a similar way, the flow stress of a subgrain structure may be related to the annealing time, however, with the further complication that both the mobility of the subgrain boundaries and the driving pressure depend on the angle across the subgrain boundaries.

Ultrafine Structures

In most annealing studies, the initial deformed microstructure has been formed by deformation to low and medium strains. However, recently there has been a growing interest to explore the behavior of metals deformed to high and ultrahigh strains, for example, more than 90% reduction in thickness by rolling. The reason is that the microstructure refines with increasing strain and as a microstructural refinement induces an increase in strength, it is the intention to produce very strong metals by only applying plastic deformation, for example, to replace traditional alloying. A large strain leads to an increase in the dislocation density but also to the formation of deformation induced high-angle boundaries, which are indistinguishable from the original grain boundaries in the deformed structure (**Figure 9**). For these structures, subdivided by a mixture of dislocation boundaries and high-angle boundaries, the flow stress can be expressed by an equation of the same form as the Hall–Petch relation:

$$\sigma_f - \sigma_0 = k_2 D_b^{-0.5} \qquad [15]$$

where k_2 is a constant and D_b is the average boundary spacing. However, the constancy of k_2 assumes that the boundaries are identical as in a polycrystalline metal, whereas for structures, which are a mixture of dislocation boundaries and high-angle boundaries, k_2 is not a constant. Instead of eqn [15], eqn [6] may be used, where S_v and θ are the surface area and angle, respectively of low-angle boundaries, and D is the random spacing between high-angle boundaries.

The presence of a very fine microstructure and a large concentration of high-angle boundaries in a deformed structure significantly affects its annealing

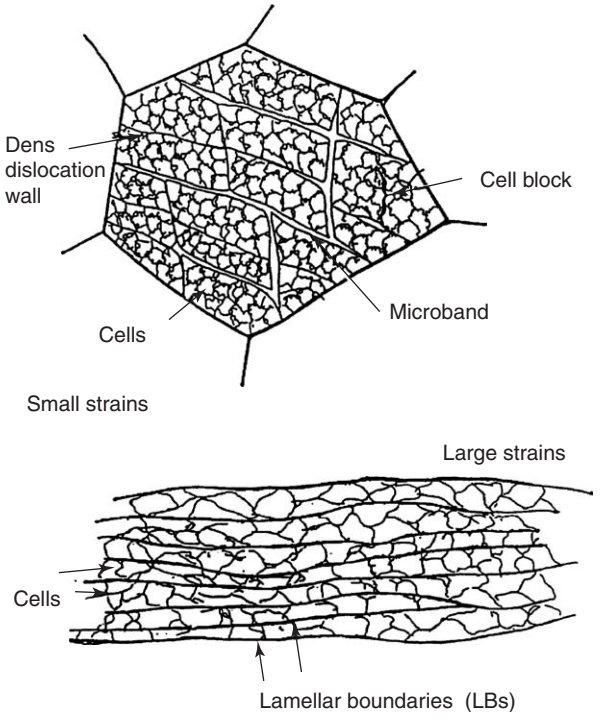

Figure 9 Schematic drawing of deformation microstructures and grain subdivision illustrating the structural refinement with increasing plastic strain. The structure is in both cases subdivided by extended boundaries and short interconnecting boundaries. The average spacing between the boundaries can at very large strain decrease below 100 nm. (Reproduced from Hughes DA and Hansen N (1997) High-angle boundaries formed by grain subdivision mechanisms. *Acta Materialia* 45: 3871–3886, with permission from Elsevier.)

behavior. Both the driving pressure and the boundary mobility are increased. Therefore, the migration rate of boundaries is increased in accordance with eqn [11]. As a result, both the rate of recovery and of recrystallization will be enhanced. The concentration of high-angle boundaries may also reach a level, where small subgrains or nuclei will be so abundant that their growth will stop early due to impingement, that is, a very fine grain structure may result. A route has thereby been established to produce metallic materials with a grain size of the order of a few micrometers or less. Such materials will have a very high strength as experiments show that strength–structure relationships as eqns [2] and [3] also are applicable at such small grain sizes.

Conclusion and Outlook

The change in mechanical properties during recovery, recrystallization, and grain growth has been and still is an important research area driven by scientific curiosity and industrial demand. The research and development at present concentrates on exploration

of mechanisms and formulation of models for the structural evolution. In parallel, advanced and new experimental methods are under development for fast and precise structural characterization in 2D and 3D over length scales from the macroscopic range to the atomic dimension. This research and development also expands the experimental and theoretical basis for the development of property structure models for the evolution of mechanical properties during annealing of deformed metals.

Recursive Methods for Electronic States

R Haydock, University of Oregon, Eugene, OR, USA

Recursive Approaches

A wide variety of recursive methods are used to calculate electronic properties of systems to which band-structure methods do not apply due to lack of periodicity, for example surfaces or other defects and disordered systems. These methods range from Gram–Schmidt orthogonalization, to the method of moments, modified moments, orthogonal polynomial expansions such as Chebyshev expansions, the Lanczos method, including the conjugate gradient method, and the recursion method (also related to the Mori projection method). In their simplest applications, recursive methods determine densities of states from path counting, for example, a tight-binding *s*-band on a square lattice. The common ingredients of recursive methods are: they start with some initial state of physical significance and apply the Hamiltonian repeatedly to it generating a sequence of states, which span the time evolution of the initial state; and they use the normalizations and overlaps between states in the sequence to construct expansions, such as continued fraction expansions of electronic Green functions, from which physical properties are calculated. Some of the advantages of recursive approaches are efficient computing because they are usually formulated in position space making Hamiltonians sparse, and the well-developed mathematical theory of moments. One of the main challenges for these methods is obtaining reliable information about singularities in the densities of states for macroscopic systems.

Path Counting

Calculation of the density of states for a tight-binding *s*-band on a square lattice, shown in **Figure 1**, illustrates the basic ideas of recursive methods. The density of states $n(E)$ is defined as the volume-normalized trace, $\mathrm{tr}\{\delta(E-\boldsymbol{H})\} = \sum \delta(E-E_n)/V$, where $\boldsymbol{H}$ is the Hamiltonian operator, E is the

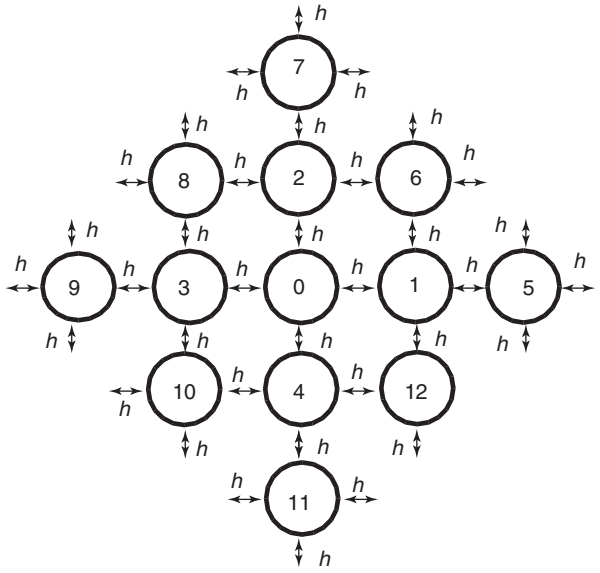

Figure 1 A tight-binding *s*-band on a square lattice with hopping matrix elements *h* between nearest-neighbor orbitals.

energy, δ is the Dirac delta distribution, and the sum is over the eigenvalues $\{E_n\}$ of $\boldsymbol{H}$ normalized by the volume V. The nth power moment μ_n of $n(E)$ is $\mathrm{tr}\{E^n\delta(E-\boldsymbol{H})\}$, or $\mathrm{tr}\{\boldsymbol{H}^n\}$, and since the orbitals on all sites are equivalent, this is $\langle 0|\boldsymbol{H}^n|0\rangle$, where the unit volume is taken to be the area of the unit cell and $|0\rangle$ is the orbital at the origin.

Evaluation of the moments can be reduced to path counting by inserting a resolution of the identity, the sum $\Sigma|\alpha\rangle\langle\alpha|$ over a complete, orthonormal set of orbitals $\{|\alpha\rangle\}$, between each factor of $\boldsymbol{H}$ in $\langle 0|\boldsymbol{H}^n|0\rangle$ to give

$$\mu_n = \sum \langle 0|\boldsymbol{H}|\alpha_1\rangle\langle\alpha_1|\boldsymbol{H}|\alpha_2\rangle\langle\alpha_2|\boldsymbol{H} \cdots \boldsymbol{H}|\alpha_{n-1}\rangle\langle\alpha_{n-1}|\boldsymbol{H}|0\rangle \quad [1]$$

where the sum is over all the orbitals $|\alpha_1\rangle$, $|\alpha_2\rangle, \ldots, |\alpha_{n-1}\rangle$. Each term in this sum is the product of matrix elements along a path of n hops starting and finishing at $|0\rangle$. In the method of moments, paths are enumerated giving 1, 0, $4h^2$, 0, and $36h^4$, for moments μ_0 through μ_4, respectively, where the nearest-neighbor hopping elements of $\boldsymbol{H}$ are h and the diagonal elements are zero. The problem of moments is to construct a positive density of states from these moments.

The classical solution to the moment problem is a continued fraction $b_0^2/E - a_0 - b_1^2/E - a_1 - b_2^2/E - a_2 - \cdots - b_n^2/E - a_n - \cdots$, where the slash "/" means division by everything to the right, and the parameters $\{a_n, b_n\}$ *are* constructed so that as E approaches the real axis from below, the imaginary part of the continued fraction is an approximate density of states, which reproduces a number of moments equal to the number of parameters in the continued fraction. While moments are useful for analysis, they are difficult numerically because they must be computed with exponentially increasing accuracy to maintain a given accuracy in the resulting density of states.

The solution to this numerical instability is to calculate the continued fraction parameters directly by constructing an orthonormal basis u_0, $u_1, u_2, \ldots u_n, \ldots$, in which the Hamiltonian is a tridiagonal matrix, equivalent to the three-term recurrence

$$\boldsymbol{H}u_n = a_n u_n + b_{n+1}u_{n+1} + b_n u_{n-1} \quad [2]$$

For the above example and referring to **Figure 1**: u_0 is $|0\rangle$, u_1 is $(|1\rangle + |2\rangle + |3\rangle + |4\rangle)/2$, and u_2 is $(|5\rangle + 2|6\rangle + |7\rangle + 2|8\rangle + |9\rangle + 2|10\rangle + |11\rangle + 2|12\rangle)/\sqrt{20}$. This gives the parameter values $a_0 = a_1 = 0$, $b_0 = 1$, $b_1 = 2h$, and $b_2 = \sqrt{5}h$.

The Projected Density of States

The electronic structure of disordered and defective electronic systems is difficult to calculate because such systems have a macroscopic number of inequivalent orbitals, and the interactions between these orbitals exceed their energy differences, and macroscopic quasi-degeneracy. Band-structure methods cannot be used because the unit cells are macroscopic, and perturbation methods cannot be used because of the small differences in the energies of the orbitals. The main effect of quasi-degeneracy is that individual states are unstable in the sense that the interactions between two such states, which are close in energy, can mix them arbitrarily.

Densities of states are more stable than those of individual states, because the only states which get strongly mixed are close in energy. However, approximate total densities of states for finite systems only converge slowly to their macroscopic limits as the ratio of surface area to volume. The density of states, which converges fastest with increasing size, is the projected density of states

$$n_0(E) = \langle 0|\delta(E-\boldsymbol{H})|0\rangle \quad [3]$$

where $\boldsymbol{H}$, is the Hamiltonian and $|0\rangle$ is the spatially localized orbital on which the states are being projected. Physically $n_0(E)$ is the probability distribution for finding an electron with energy E in the orbital $|0\rangle$. In analogy with the blackbody properties of electromagnetic spectra, $n_0(E)$ converges in the mean (integrals over smooth functions) with increasing system size, and the error at E decreases exponentially with the number of wavelengths of the state at E between $|0\rangle$ and the boundary.

Recursive Tridiagonalization

The projected density of states $n_0(E)$ is simply the Fourier transform of the time evolution (taking time in units of inverse energy) of the orbital $|0\rangle$ projected back onto $|0\rangle$, $\langle 0|\exp\{-\mathrm{i}t\boldsymbol{H}\}|0\rangle$, which can be expanded in the power moments to give $\sum(-\mathrm{i}t)^n\mu_n/n!$. This series shows that if the moments of a physical system grow faster with n than $n!$, the evolution of $|0\rangle$ is singular at $t=0$. This also shows that truncation of the series at some power of t makes the high moments zero producing an $n_0(E)$, which is nonzero only at $E=0$.

Recursive approaches are based on truncating the moment expansion in state space, rather than powers of t. The nth truncated state space or Krylov subspace is spanned by $|0\rangle$ and the first n powers of $\boldsymbol{H}$ acting on $|0\rangle$: the power states, $|0\rangle, \boldsymbol{H}|0\rangle, \boldsymbol{H}^2|0\rangle, \ldots, \boldsymbol{H}^n|0\rangle$. Recursive methods differ in the choice of vectors used to span the Krylov subspaces and the parameters generated. In the method of moments, the spanning states are just the above power states, and the parameters are the overlaps between them; these overlaps are the power moments, and there are only $2n+1$ of them because $\boldsymbol{H}$ is Hermitian making overlaps equal between pairs of states whose powers of $\boldsymbol{H}$ add up to the same total. In modified moment methods, the above power states are replaced by polynomial states, the results of polynomials in $\boldsymbol{H}$ acting on $|0\rangle$.

The Lanczos and recursion methods are special cases of modified moments in which Gram–Schmidt orthogonalizatio n is applied to the power states, tridiagonalizing $\boldsymbol{H}$ recursively, in the basis of orthonormal polynomial states $\{p_n(\boldsymbol{H})0\rangle\}$. These polynomials are also orthonormal with respect to integration over the projected density of states $\delta_{n,m} = \int p_n(E)p_m\ (E)n_0(E)\ \mathrm{d}E$, as can be seen by substituting $\langle 0|\delta(E-\boldsymbol{H})|0\rangle$ for $n_0(E)$ and replacing E by $\boldsymbol{H}$ in the polynomials. Since $\boldsymbol{H}$ is Hermitian in the inner product between states, the only nonzero terms produced by Gram–Schmidt orthogonalization are the three terms in eqn [2], corresponding to a tridiagonal representation of $\boldsymbol{H}$ in which the diagonal matrix elements are the $\{a_n\}$ and the off-diagonal matrix elements are the $\{b_n\}$.

Analytic systems of orthogonal polynomials are known for many model projected densities of states $n_0(E)$. As a result, combinations of $|0\rangle$ and $\boldsymbol{H}$ which have such $n_0(E)$ can be tridiagonalized analytically by substituting $\boldsymbol{H}$ for E in the polynomials and applying them to $|0\rangle$; or they can be tridiagonalized perturbatively if $n_0(E)$ differs only slightly from one of the analytic models. When $n_0(E)$ does not have analytic polynomials, $\boldsymbol{H}$ can be tridiagonalized numerically using eqn [2] to construct u_{n+1} from u_n and u_{n-1}, with a_n determined by orthogonality and b_{n+1} determined by the normalization. The first step of most diagonalization methods is tridiagonalization, and recursive tridiagonalization is very efficient when $\boldsymbol{H}$ is short-ranged, because the zero-valued matrix elements of $\boldsymbol{H}$ are not changed by the transformation. For systems in D spatial dimensions, the number of arithmetic operations required to construct $u_0, \ldots, u_n$ and the associated parameters only increases as n^D. This scaling is independent of the size of the system because the projected density of states is a local rather than global quantity.

It is important to note that the recursively generated states, whether power states, polynomial states, or the tridiagonal basis of orthonormal states, are generally not a complete set of states. The recursive states span only the evolution of the starting state $|0\rangle$; so if there is a symmetry or any other property of the system such as disorder, which prevents the evolution of $|0\rangle$ from exploring all the states of the system, then the recursive basis is not complete. Because the recursive states span only the evolution of a single state, they may be interpreted as an abstract, one-dimensional subsystem of the original physical system, a semibounded chain model illustrated in **Figure 2**. This abstract system evolves along the sequence $\{u_n\}$ with matrix elements $\{a_n\}$ and $\{b_n\}$. It is one-dimensional, semibounded, and hence nondegenerate, because the starting state $|0\rangle$ contains at most one state from each degenerate subspace of the states of the original system.

Another important property of recursively generated states is that they can be linearly dependent. A simple example is the sequence of power states when $|0\rangle$ is an eigenstate or a mixture of just a few eigenstates. The basis $\{u_n\}$ is orthonormal if $\boldsymbol{H}$ is exactly Hermitian and if the orthonormalization in eqn [2] is carried out exactly, but neither is the case when the recursion is numerical. As in all recursive processes, errors grow exponentially with n in u_n, a_n, and b_n; however, it has been shown that the errors introduced into the projected densities of states or related projected quantities calculated from the $\{u_n\}$, $\{a_n\}$, and $\{b_n\}$ do not accumulate and are comparable to the error in a single recursion eqn [2].

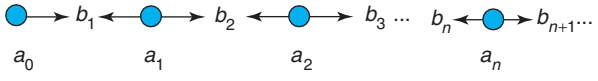

Figure 2 A chain model with site energies $\{a_n\}$ and nearest-neighbor hopping matrix element $\{b_n\}$.

Macroscopic Systems

The main applications of recursive methods are to macroscopic systems, which can only be partly tridiagonalized numerically. The challenge in these cases is to extract the maximum information about a macroscopic system from a small tridiagonal matrix. There are many parts to this problem ranging from whether it is better to approximate the original system by a finite cluster, and including methods for approximating the projected density of states and quantities calculated from it.

Cluster Size and Shape

The electronic Hamiltonian $\boldsymbol{H}$ is usually represented in terms of localized orbitals so that each orbital has nonzero matrix elements with only a few neighboring orbitals. A numerical calculation is generally limited by the total number of these orbitals which can be included, and there is often a trade-off between the number of orbitals included and the size of the tridiagonal matrix, which can be produced.

Viewing the tridiagonal matrix as a chain model (**Figure 2**), the blackbody property of $n_0(E)$ explains that the deeper errors occur in the chain, the exponentially smaller their effect on $n_0(E)$. From this it seems best to use the largest possible power cluster, the cluster of orbitals which completely contains as many power states as possible, because this gives the largest tridiagonal matrix containing only rounding errors. This simple conclusion has to be modified by consideration of subsequent approximations in the calculation. If the resulting tridiagonal matrix is going to be extended with approximate matrix elements, then an abrupt change from the numerical matrix elements to approximate matrix elements can produce unstable results. Consequently, in many calculations the changeover from numerical to approximate matrix elements is smoothed by using clusters with highly disordered boundaries, very different from the typically flat boundaries of power clusters.

Projected Densities of States

The central problem in applications to macroscopic systems is that of approximating the projected density of states, particularly its singularities. This is difficult because at singularities the blackbody property of $n_0(E)$ breaks down, the wavelengths of eigenstates go to infinity, and the spectrum becomes very sensitive to distant parts of the system. The simplest approach to this problem is through the continued fraction

$$R(z) = b_0^2/z - a_0 - b_1^2/z - a_1 - b_2^2/z - a_2 - \cdots - b_n^2/z - a_n - \cdots \quad [4]$$

which is of Jacobi form because the $\{a_n\}$ and $\{b_n\}$ are all real, and hence has singularities which are nonnegative imaginary and only occur on the real z-axis. The projected density of states $n_0(E)$ is then just $\mathrm{Im}\{R(E - \mathrm{i}\varepsilon)\}/\pi$ in the limit as ε goes to zero from the positive side.

The three main approaches to approximate the projected density of states for macroscopic systems are bounding, averaging, and continuing. While $n_0(E)$ itself cannot be bounded because it only converges in the mean, there are rigorous bounds on integrals $F = \int n_0(E) f(E)\, \mathrm{d}E$ for smooth $f(E)$ as well as for some singular $f(E)$. This is important because physical quantities can be expressed as integrals over $n_0(E)$: for example, the occupation of $|0\rangle$ is the integral of $n_0(E)$ over the Fermi function, defined by $f(E)$ is 1 for $E < E_\mathrm{F}$ and 0 for $E > E_\mathrm{F}$. The bounds on integrated quantities such as the occupation can then be used to estimate $n_0(E)$, in this example by the derivative of the occupation with respect to E_F for $E_\mathrm{F} = E$. This method has the advantage that it does not introduce spurious structure into $n_0(E)$, but the disadvantage is that it does not reproduce the exact moments when $n_0(E)$ is integrated.

The simplest form of averaging is to approximate $n_0(E)$ by $\mathrm{Im}\{R(E - \mathrm{i}\varepsilon)\}/\pi$, where ε is positive so that singularities within about ε of E are averaged into the approximation for $n_0(E)$. This is equivalent to replacing δ-distributions on the real E-axis with functions broadened by 2ε. A more sophisticated form of averaging is to maximize the entropy functional $-\int n_0(E) \ln[n_0(E)]\, \mathrm{d}E$, where ln is the natural logarithm and subject to the constraint that $n_0(E)$ has the correct moments. This produces an approximate density of states of the form $\exp\{-\mathrm{P}(E)\}$, where $\mathrm{P}(E)$ is a polynomial in E of the same degree as that of the highest moment used as a constraint.

Another way of looking at the problem is that the part of $R(E)$ in eqn [4] is known and the rest is estimated. In certain cases the singularities of $n_0(E)$ are known, e.g., band edges. It is the singularity of $n_0(E)$, which determine the behavior of $\{a_n\}$ and $\{b_n\}$ for large n; so, this known asymptotic behavior can be used to continue the numerical part of $R(E)$. Results are greatly improved by smoothing the transition from the numerical part to the asymptotic part of the continued fraction.

In many cases only a small part of the tridiagonalization of $\boldsymbol{H}$ is known numerically and it would be best to locate singularities and other structure in $n_0(E)$. This problem could be considered in terms of a chain model **Figure 2** for which the parameters only up to b_N are known. For this model, $n_0(E)$ is simply the squared amplitude of the state on site zero at energy E, for which all the parameters of the model

need not be known; just the boundary condition at site N on the chain is required. Experience in trying different boundary conditions shows that wrong boundary conditions introduce spurious reflections, which in turn produce spurious structure in $n_0(E)$. Consistent with this, a good choice of boundary condition seems to be the one which produces the least reflection, the perfectly absorbing boundary at site N.

The perfectly absorbing boundary can be defined as the one which does not reflect a wave traveling to the right along the chain. In order to implement this definition, the current $J_n = -b_n \, \mathrm{Im}\{\psi_n^* \psi_{n-1}\}$ carried by a complex wave from site $n-1$ to site n needs to be calculated. For waves ψ, which are eigenstates of the Hamiltonian for the chain, this current is conserved and $J_n = J$, independent of n, a property also known as the Christoffel–Darboux identity. The probability p_n of finding the system on the nth site is $\psi_n^* \psi_n$, and the probability P_N of finding it on one of the first N sites is the sum of p_n from $n=0$ to N, which is related to the Christoffel function. The wave which travels to the right with the least reflection is the one which minimizes P_N for a fixed, positive J. **Figure 3** shows approximate $n_0(E)$ for the tight-binding s-band on a square lattice that **Figure 1** calculated this way for chains of different lengths.

Binding Energies

The definition of the binding energy of an atom to a solid is the difference between the total energy of the solid without the atom and with it, the difference between two large numbers, each of which depends on the electronic structure of the whole system. However, binding the atom only changes the electronic structure of the solid locally, so there is a local way to calculate it. The simplest example is the binding energy of a single orbital $|0\rangle$ to the other orbitals in a system, the change in the total energy of the system due to removing the matrix elements of the Hamiltonian between $|0\rangle$ and the other orbitals. Binding energies of more complicated systems can be expressed as the sum of the binding energies as individual orbitals are decoupled from the system, one by one.

The key to the local calculation of binding energies is the observation that in the simplest case, decoupling $|0\rangle$ from the rest of the system only changes the energies of states which evolve from $|0\rangle$, the states spanned by the chain model in **Figure 2**. At zero temperature the states below the Fermi level E_F are doubly occupied by electrons of opposite spin, and those above E_F are unoccupied, so the binding energy is twice the sum of the shifts in the energies of the occupied states when $|0\rangle$ is decoupled from them. Since $\langle 0|\delta(z-\boldsymbol{H})|0\rangle$ can be represented as the limit of $\mathrm{Im}\{\langle 0|(z-\boldsymbol{H})^{-1}|0\rangle\}/\pi$ as z becomes real, $R(z)$ is $\langle 0|(z-\boldsymbol{H})^{-1}|0\rangle$, and in terms of determinants this inverse element is $\det|z-\boldsymbol{H}'|/\det|z-\boldsymbol{H}|$, where $\boldsymbol{H}'$ is $\boldsymbol{H}$ with the row and column for $|0\rangle$ each deleted. From this it can be shown that the binding energy U is

$$U = \mathrm{Im}\left\{\int_F \ln R(z)\, dz\right\}/\pi \qquad [5]$$

where the integral is around the Fermi contour which encloses the energies of the occupied states, and ln $R(z)$ is the natural logarithm of the continued fraction, single-valued because the Fermi contour avoids zeros and infinities of $R(z)$.

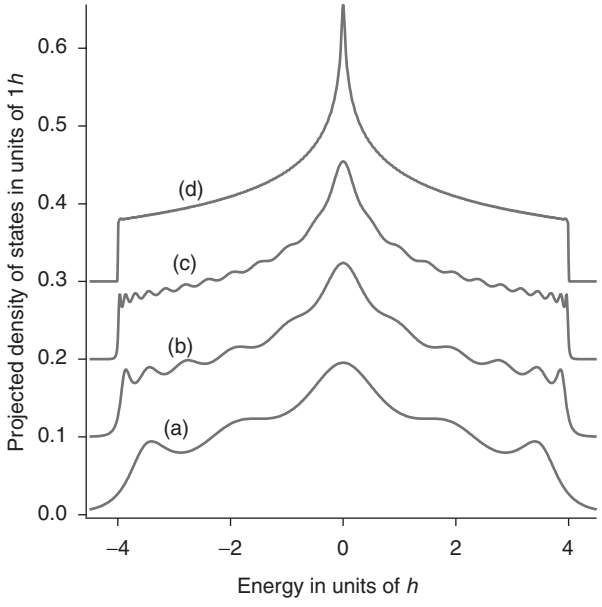

Figure 3 Projected density of states for the tight-binding s-band on a square lattice calculated using (a) 5, (b) 11, (c) 23, and (d) 199 pairs of tridiagonal matrix elements.

Red Blood Cells, Physical Properties of

A Bifone, GSK Medicines Research Centre, Verona, Italy

Introduction

Erythrocytes (also known as red blood cells) are highly specialized cells whose primary function is to transport oxygen from the lungs to the tissues, an essential process to sustain human life. The physical properties of red blood cells (RBCs) appear to have been optimized via evolutionary processes. Their biconcave shape increases the cell surface area, facilitating gas exchange with the extracellular environment. The high physical flexibility of RBCs allows them to squeeze through tiny capillaries. Most importantly, red blood cells are packed with hemoglobin, an iron-containing protein that reversibly binds oxygen. Under physiological conditions, the vast majority of oxygen molecules in the RBCs are bound to hemoglobin. The large concentration of hemoglobin in the RBC cytoplasm, close to crystallization, increases the apparent solubility of oxygen in the intracellular medium, thus improving the efficiency of oxygen delivery to the target tissue. Moreover, hemoglobin affinity for oxygen is modulated by microenvironmental factors such as oxygen and carbon dioxide concentrations, pH, that regulate oxygen delivery to meet the local oxygen demand.

Hemoglobin consists of four polypeptidic units, each containing a heme group with an iron ion in the center (**Figure 1**). When oxygen binds to the heme group in one of the four subunits, the protein undergoes conformational changes that affect the ability of the other subunits to bind oxygen. These changes in quaternary structure are responsible for the characteristic sigmoidal oxygen saturation curve of hemoglobin (i.e., the curve that describes the saturation of the oxygen-binding sites as a function of the partial pressure of oxygen in solution), a behavior referred to in terms of positive cooperativity.

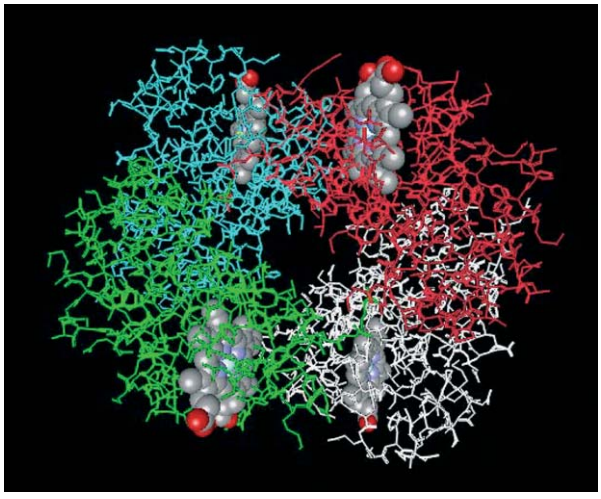

Figure 1 Stick-model of hemoglobin in the fully deoxygenated form. The four subunits are shown in different colors. The atoms of the heme groups are represented as space-filling spheres.

In the deoxygenated form, the iron atom is in a Fe(II) oxidation state, with a total electron spin $S = 2$, and the Fe–heme complex is paramagnetic. Upon oxygen binding, the electronic spin state goes from $S = 2$ to $S = 0$, and the paramagnetic contribution to the protein susceptibility vanishes. As a consequence of the very high concentration of hemoglobin in the cytoplasm, the magnetic susceptibility of the entire RBC is strongly dependent on blood oxygenation.

In this article, the magnetic properties of erythrocytes are reviewed. Besides an interest in the fundamental physical properties of biological materials, several motivations have stimulated experimental and theoretical studies on this subject. A better

understanding of magnetism in living cells is important to assess safety issues related to the exposure of the human body to strong static magnetic fields, like those used for medical diagnostics, or in passenger transport systems based on magnetic levitation. Moreover, the magnetic properties of RBCs have recently found an important application in the study of human brain function. The effects of the blood oxygenation level on RBCs' magnetic susceptibility can be detected noninvasively in living organisms with nuclear magnetic resonance (NMR) methods. This endogenous contrast mechanism is exploited in "functional magnetic resonance imaging" (fMRI), the most powerful technique to date, to map the temporal and spatial patterns of brain activity in conscious human subjects.

The next section describes the magnetic properties of RBCs, their dependence on blood oxygenation levels, and the effects of oxygenation on the field distribution in a suspension of RBCs immersed in a static magnetic field. In the subsequent section, the mechanisms whereby these magnetic field gradients affect NMR signals are discussed. In the last section, the application of this effect to brain function imaging is presented briefly.

RBCs in Static Magnetic Fields

RBCs in a strong static magnetic field tend to orient themselves with the disk plane along the field, a result of the anisotropy of the cell's diamagnetic response. Almost 100% orientation is observed in blood samples exposed to a static field of 4 T. Interestingly, neither the direction nor the degree of orientation depends on the oxygenation state of hemoglobin. This is not surprising though, as the torque that orients the cell is solely determined by the anisotropic component of the susceptibility tensor. Hemoglobin has a small anisotropic susceptibility even in the deoxygenated form. Consequently, the magnetic field-related energy is lower than thermal energy, and monomolecular hemoglobin is not oriented at field strengths up to several tesla. Moreover, the vast majority of hemoglobin molecules are in solution, and free to reorient without transferring torque to the cell body. Thus, hemoglobin does not influence the cell orientation, which can be attributed primarily to the anisotropic susceptibility of membrane components (phospholipids and membrane proteins). Interestingly, sickle RBCs behave quite differently, and orient themselves perpendicular to the magnetic field. In sickle cells most of the hemoglobin is polymerized, and forms bundles of filaments that are integrated with the cell membrane, causing the characteristic cell deformation. In this pathological situation, the anisotropic susceptibility of polymerized hemoglobin is much larger, and determines the orientation of the cell.

The isotropic susceptibility of RBCs is dominated by the contribution of hemoglobin, and is affected by changes in the oxidation state of the iron ion upon oxygen binding. For deoxygenated and oxygenated RBCs, susceptibilities $\chi_{\mathrm{rbc}}^{\mathrm{deoxy}} = -6.7 \times 10^{-6}$ and $\chi_{\mathrm{rbc}}^{\mathrm{oxy}} = -9.2 \times 10^{-6}$ have been measured, respectively. The negative sign of the magnetic susceptibility implies that the cell is diamagnetic even when hemoglobin is in its deoxygenated state. Indeed, the total magnetic susceptibility is the weighted sum of the susceptibilities of all the constituents of the cell. While the iron atom is paramagnetic in its deoxygenated form, the diamagnetic contributions from globins, water, membrane, etc. are still dominant. It is predicted that RBCs would have a paramagnetic susceptibility if all hemoglobin were in the met-state, where the iron ion is oxidized to its Fe(III) form, with a total electron spin $S = 5/2$. However, this situation is not physiologically relevant, since the concentration of met-hemoglobin in blood is normally very low. Met-hemoglobin is potentially harmful for the organism, since it has lost its ability to bind oxygen, and active biological mechanisms are in place to convert the small amount of met-hemoglobin that spontaneously forms in blood to its normal Fe(II) state.

The magnetic susceptibility of the plasma, the fluid in which RBCs are suspended, is $\chi_{\mathrm{plasma}} = -9.06 \times 10^{-6}$. Oxygen molecules are paramagnetic, and changes in oxygen tension affect plasma susceptibility slightly. However, this variation is small compared with the large changes of magnetic susceptibility of the cells, and can be neglected to a first approximation.

Even though both RBCs and plasma are diamagnetic, there is an oxygenation-dependent mismatch between their susceptibilities that causes an inhomogeneous field distribution in the cell suspension. If RBCs had a spheroidal or an ellipsoidal shape, and were sufficiently far apart from each other, the magnetic field would be uniform inside the cell, and nonuniform outside. However, RBCs have a complex, bi-concave shape (**Figure 2**), which results in an inhomogeneous distribution of magnetic field in both regions. The field distribution can be calculated by integrating the Maxwell equations over the surface of discontinuity of magnetic susceptibility. As a particular case, the solution for a spherical surface can be calculated analytically, and corresponds to a uniform field distribution. For more complex shapes, like that of an RBC, the Laplace equation has to be solved numerically. The model shown in **Figure 2** captures the essential features of the geometry of an

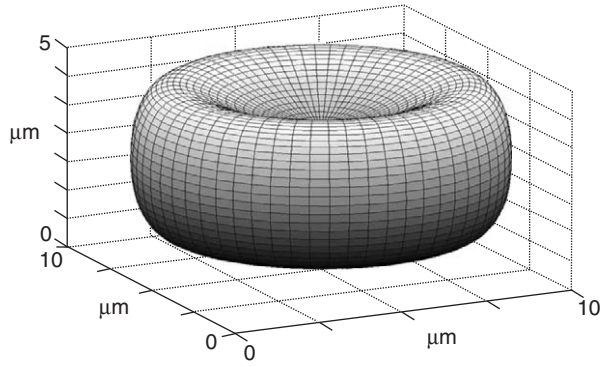

Figure 2 A physicist's model of an RBC.

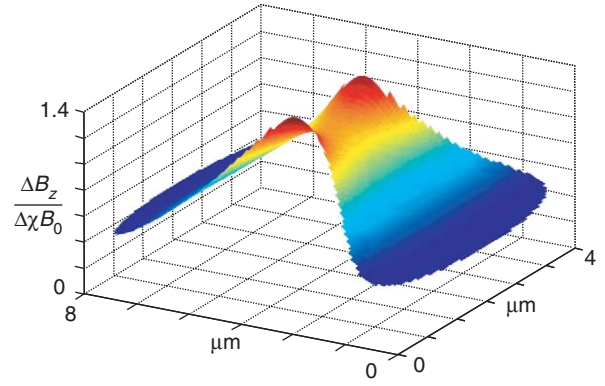

Figure 3 Distribution of the z component of the magnetic field in the plane perpendicular to the disk of an RBC. The applied magnetic field is along the plane of the cell.

RBC, and is described by the simple equations:

$$x = \sin\vartheta\cos\varphi$$
$$y = \sin\vartheta\sin\varphi$$
$$x = \cos\vartheta(0.2 + \sin^2\vartheta)$$

The field distribution inside this model-cell with its plane of symmetry parallel to the external magnetic field is shown in **Figure 3**. In a deoxygenated RBC, the internal field gradients in a static field of 1.5 T are $\sim 250\,\mathrm{mT\,m^{-1}}$. Similarly, large magnetic field gradients are present around the cell. The strength of the gradients increases with the mismatch in susceptibility between the cell and the surrounding medium, that is, with lower levels of blood oxygenation.

Effects of Oxygen Saturation Levels on Nuclear Magnetic Resonance Signals

The NMR frequency of nuclei with a nonzero spin is proportional to the nuclear gyromagnetic ratio, and to the strength of the local field experienced by the nucleus. Thus, changes in field distribution in and around RBCs affect several NMR parameters, including resonance frequency, and NMR relaxation times. These two parameters will be discussed separately in the next few paragraphs. The discussion will be focused on hydrogen nuclei, the most commonly studied nuclear species in biomedical NMR and MRI. The largest part of the hydrogen NMR signals from living organisms comes from unbound water that is present in high molar concentration in many tissues, including blood. High concentration, large gyromagnetic ratio, and high isotopic abundance greatly increase the sensitivity of NMR detection of hydrogen, thus making it possible to obtain high-resolution MR images of living organisms.

The local microscopic field experienced by a nucleus in a homogeneous medium of given susceptibility χ immersed in an externally applied field $\boldsymbol{B}_0$ is

$$\boldsymbol{B}_\mathrm{L} - \boldsymbol{B}_0 = (D_\mathrm{s} - \tfrac{2}{3})(\chi - \chi_0)\boldsymbol{B}_0$$

where D is a demagnetizing factor dependent on sample geometry, and 2/3 is the geometric factor of a sphere drawn around the nucleus. This construct is normally referred to as the "sphere of Lorentz," a notional spherical vacuum cavity surrounding the nucleus that accounts for the fact that, at an atomic scale, the medium cannot be represented as a continuum. It is interesting to note that for a spherical sample $D_\mathrm{s} = 2/3$ and the resonance frequency is independent of the changes of χ. For an RBC, the geometry is far from spherical, and a shift in resonance frequency is to be expected for water molecules in a suspension of RBCs when the cell susceptibility changes. Indeed, a difference of 0.33 ppm in the resonance frequency of the hydrogen nuclei in oxygenated, and deoxygenated human blood has been measured by Thulburn and co-workers in experiments conducted *in vitro* at high magnetic fields. In order to calculate the susceptibility effects on the NMR signals in a complex medium like blood, one needs to refine the theoretical framework.

In a homogeneous material, the actual size of the sphere of Lorentz does not explicitly appear in the calculation. However, blood is highly heterogeneous, with hemoglobin compartmentalized in discrete units (the RBCs) embedded in plasma. A quantitative calculation of the shift of the NMR line of protons in blood requires a slightly more complex construct, to account for the different characteristic length scales of the contributions to the local field arising from distant RBCs and from hemoglobin. A sphere of Lorentz around the nucleus of sufficient size to comprise a large number of erythrocytes is first drawn, so that the contributions to the local field from distant sources around the sphere vary smoothly. The field experienced by the nucleus in the center

of the sphere is

$$\boldsymbol{B}_{\mathrm{L}} = \boldsymbol{B}_0 + (D_{\mathrm{s}} - \tfrac{2}{3})\chi_{\mathrm{blood}}\boldsymbol{B}_0 + \boldsymbol{B}_{\mathrm{i}}$$

where $\boldsymbol{B}_{\mathrm{i}}$ denotes the contributions to the local field from sources inside the sphere, and χ_{blood} is the susceptibility of blood (the sphere is large on a cellular scale, and the external medium appears as a continuum). χ_{blood} depends on the relative volume occupied by RBC V_{rbc} (i.e., the hematocrit):

$$\chi_{\mathrm{blood}} = V_{\mathrm{rbc}} \times \chi_{\mathrm{rbc}} + (V_{\mathrm{rbc}} - 1)\chi_{\mathrm{pl}}$$

In order to evaluate $\boldsymbol{B}_{\mathrm{i}}$, a second sphere of Lorentz, smaller than a cell, but large on a molecular scale is drawn. If this sphere is entirely comprised within the intracellular space:

$$\boldsymbol{B}_{\mathrm{i}} = (D_{\mathrm{rbc}} - \tfrac{2}{3})(\chi_{\mathrm{rbc}} - \chi_{\mathrm{pl}})\boldsymbol{B}_0$$

For the complex shape of an RBC, the geometric factor D_{rbc} has to be evaluated numerically with procedures similar to those used to calculate the field distribution of **Figure 3**, and depends on the orientation of the cell with respect to the external magnetic field. At the high fields used by Thulburn and co-workers, the RBCs are fully oriented in the configuration of minimum energy, and $D_{\mathrm{rbc}} = 0.75$.

Using this construct, the fractional changes in local field experienced by nuclei can be calculated for the plasma and RBC compartments:

$$\Delta B_{\mathrm{pl}}/B_0 = (D_{\mathrm{s}} - \tfrac{2}{3})V_{\mathrm{rbc}}\Delta\chi_{\mathrm{rbc}}$$

$$\Delta B_{\mathrm{rbc}}/B_0 = (D_{\mathrm{s}} - \tfrac{2}{3})V_{\mathrm{rbc}}\Delta\chi_{\mathrm{rbc}} + (D_{\mathrm{rbc}} - \tfrac{2}{3})\Delta\chi_{\mathrm{rbc}}$$

Water molecules diffuse rapidly within and outside the cell, and dynamically average the entire field distribution on the typical NMR timescale. In this fast exchange regime, the NMR signal consists of a narrow resonance, whose center frequency reflects the average field experienced by the nucleus. The resonance shift for the hydrogen nuclei of a water molecule in blood is therefore proportional to the average of the local-field changes in the intra- and extracellular environments, weighted by the relative sizes of the water compartments (0.3 and 0.7, for RBC and plasma, respectively).

For a change in intracellular magnetic susceptibility of $\Delta\chi_{\mathrm{rbc}} = 2.5 \times 10^{-6}$, corresponding to the difference between oxygenated and deoxygenated RBCs, and for a cylindrical blood sample of 40% hematocrit, these calculations predict a shift of the hydrogen resonance of 0.3 ppm, in close agreement with the shift measured by Thulburn and co-workers under similar conditions. The theoretical estimate reported above shows that this shift can be attributed almost entirely to changes in blood magnetic susceptibility, rather than to direct interactions of water molecules with the paramagnetic centers.

A shift in resonance frequency is not the only, nor the strongest effect of the oxygenation-dependent magnetic properties of blood on NMR parameters. The rapid diffusion of water molecules in the field gradients inside and outside the cells, and in the vicinity of small capillaries, contributes to the irreversible loss of phase-coherence of the nuclear spin-system. The characteristic time of this process is termed spin–spin relaxation time, or T_2. For larger blood vessels, the mismatch in susceptibility between blood and the surrounding tissue results in magnetic field gradients on a larger length scale than that sampled by diffusing water molecules. The partially reversible dephasing of spins induced by these more spatially extended gradients is governed by a time constant referred to as T_2^*.

Both relaxation mechanisms are more efficient in the presence of stronger gradients, and T_2 and T_2^* are shorter in deoxygenated blood. It is important to note that changes in blood oxygenation do not only affect the NMR relaxation times of nuclear spins in blood, but also in the surrounding tissue. The vascular network is highly structured, with the smallest capillaries measuring only a few microns in diameter, and separated by a few tens of μm. Therefore, a change in blood oxygenation affects the relaxation times of a large number of spins in both intra- and extravascular compartments, and NMR relaxation times are more sensitive than the relatively small shift in resonance frequency to changes in blood oxygenation levels. MR images can be sensitized to T_2 and T_2^* by using appropriate sequences of radiofrequency pulses, thus using RBC as an endogenous source of contrast. The application of these methods to map the patterns of brain activity is discussed in the next section.

The Blood Oxygenation Level Dependent Effect, and its Application to Mapping Brain Activity

It has been known for a long time that neural activation is accompanied by changes in brain microcirculation. In 1896, Roy and Sherrington reported local increases in blood flow associated with changes in brain activity. Following this pioneering work, many studies have shown that an increase in neuronal electrical activity elicits a complex response, including changes in regional cerebral blood flow, blood volume, and metabolic rate. The net result of this complex response is a time-dependent change in blood oxygenation.

In correspondence to a local increase in brain activity, for instance in response to somatosensory

stimuli or motor tasks, the T_2 and T_2^* in the image voxel comprising the activated area become longer, causing an increase in NMR signal intensity. This phenomenon is known as the "positive" blood oxygenation level dependent (BOLD) effect. In a typical experiment, a time-series of brain MR-images is acquired, and the time-course of signal intensity is analyzed for each pixel to identify the activated brain areas. By way of example, **Figure 4** shows the pattern of brain activity in a healthy subject exposed to an oscillating check-board visual stimulus. More complex paradigms, including cognitive or emotional tasks, can be designed to investigate higher brain functions.

It has been seen in the previous section that longer T_2 and T_2^* correspond to higher levels of blood oxygenation (i.e., to weaker magnetic field gradients in the surroundings of RBCs and blood vessels). Therefore, the positive BOLD effect indicates that the increase in oxygen supply exceeds the increase in oxygen demand by the activated tissue, and more oxygen is left in the bloodstream. Consequently, the level of oxygenation in the venous part of the capillary bed is higher (the arterial blood is already close to saturation, and is not affected). Whether this implies an uncoupling of the hemodynamic and the metabolic responses to changes in brain electrical activity, or simply reflects less efficient oxygen extraction at higher flow rates is still the subject of investigation.

Several research groups have reported a transient decrease in signal intensity immediately following the onset of activation, and before the larger and longer-lasting signal overshoot. This "dip" in the signal intensity time-course is sometimes called the "negative" BOLD effect, and indicates a transient decrease in blood oxygenation. The negative BOLD signal is normally attributed to a transient mismatch between the rapid increase in oxygen consumption following the onset of activity, and the slower hemodynamic response, resulting in a temporary decrease in blood and tissue oxygenation. While the negative BOLD effect is in principle more specific to changes in neuronal activity, and is more spatially localized, its amplitude is smaller than the positive BOLD effect, and the majority of fMRI studies make use of the positive contrast.

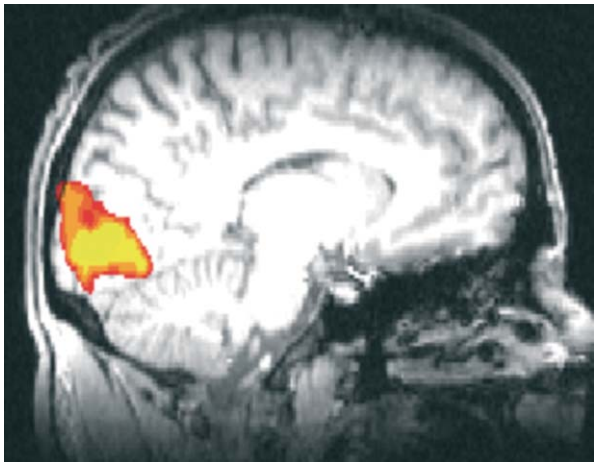

Figure 4 Functional MR image showing the pattern of brain activity elicited by a visual stimulus. (Courtesy of Dr. Peter Chiarelli of the Oxford Centre for Functional Magnetic Resonance Imaging of the Brain.)

Despite more than a century of investigation, the physiological mechanisms underlying the hemodynamic response to changes in brain activity are not completely understood. In particular, the apparent lack of coupling between changes in oxygen consumption and increase in blood flow, ultimately responsible for the BOLD effect, is the subject of much debate in the scientific community. Nevertheless, a decade of fMRI studies has demonstrated the power of this method, which has contributed enormously to our understanding of brain function in healthy subjects and in patients.

Conclusion

RBCs are highly unusual compared to other cells, in so far as their magnetic susceptibility can change over a wide range of values, depending on oxygenation levels. The molecular mechanism of this phenomenon can be attributed to changes in electron-spin state of the heme groups in hemoglobin, the main constituent of RBCs. The unusual magnetic properties of RBC result in a nonuniform field distribution in blood, and in the vicinity of blood vessels, that can be calculated within the framework of classical magnetostatics. These relatively strong magnetic field gradients affect the NMR signals in living tissues and *in vitro* preparations containing RBCs. The calculation of the effects of the field distribution on nuclear spins must take into account the different length scales of the magnetic field gradients, ranging from the cellular scale to the macroscopic scale. Experiments and theoretical calculations show that changes in the oxygenation level for RBCs affect several NMR parameters, including the transverse relaxation times T_2 and T_2^*. Thus, NMR can be QJ;applied to measure local variations in blood oxygenation arising from changes in brain activity. This effect, known as the BOLD effect, is exploited in functional MRI, a powerful method to investigate human brain function. In principle, exogenous paramagnetic or super-paramagnetic contrast agents could also be used to manipulate blood susceptibility, and to measure hemodynamic changes in the brain.

However, the peculiar magnetic properties of red blood cells provide an endogenous source of contrast, thus allowing for totally noninvasive functional studies in human subjects.

Introduction

In 1905, a young German physicist, Albert Einstein, published in "Annalen der Physik" an article titled "Zur Elektrodynamik Bewegter Körper" (On the electrodynamics of moving bodies), which marked the birth of "relativity," a revolutionary view of space, time, and motion, and one of the highest achievements of the human mind. The special theory of relativity (the subject of the 1905 paper) was followed ten years later by the general theory of relativity.

Broadly speaking, relativity explores the relationship between the descriptions of physical phenomena carried out by different observers. Special relativity considers only inertial observers; general relativity removes this limitation and accounts also for accelerated and freely falling observers. The crucial difference between the two theories resides in the geometry of space–time: while the space–time of special relativity (the Minkowski space) is flat, the space–time of general relativity is a curved manifold (curvature is indeed the manifestation of gravity).

Special relativity introduces new kinematic and dynamical laws. The Newtonian theory survives as an approximation, valid in the low-velocity limit, that is when the velocities of particles are much smaller than the velocity of light. Maxwell's electromagnetic theory, on the other hand, does not need to be modified, as it is inherently consistent with relativity.

This article is mainly devoted to the special theory of relativity. The general theory, which deals with gravitational phenomena and is less relevant for microphysics and mesophysics, is briefly discussed in the last section.

The Origins of Relativity

In Einstein's own words, the main motivation of special relativity was to eliminate some "asymmetries" in the electrodynamics of moving bodies. These asymmetries emerge when one combines Maxwell's electromagnetism with Newtonian mechanics. The latter is consistent with Galilean relativity, that is with the invariance of mechanical laws under the transformation

$$x' = x - vt \qquad [1]$$

between two inertial frames with constant relative velocity v (an inertial frame is, by definition, a frame in which free particles have constant speed). A fundamental assumption of Newtonian mechanics is

that time is absolute: quoting the "Principia," it "flows equably without relation to anything external." Thus, the Galilean transformation [1] is accompanied by

$$t' = t \qquad [2]$$

From [1] and [2], one obtains the velocity addition formula

$$\boldsymbol{u}' = \boldsymbol{u} - \boldsymbol{v} \qquad [3]$$

Now, consider the Maxwell equations. They contain a constant parameter c, which represents the speed of the electromagnetic waves in vacuum (i.e., the speed of light). If velocities (including c) change according to [3], one concludes that Maxwell equations are valid only in a privileged reference frame, traditionally identified with the ether. To Einstein, the existence of the ether and the frame-dependence of electromagnetic equations were unacceptable features of classical physics. He realized that, in order to avoid these problems, it was necessary to give up eqn [2] and introduce a new operational definition of time, based on a fundamental assumption about the velocity of signals: the absolute constancy of c.

The Postulates of Special Relativity

Galileo Galilei (in his "Dialogue concerning the two chief systems of the world") was the first who noticed that the two frames in uniform relative motion are physically indistinguishable. Einstein raised this empirical observation to the status of a universally valid principle, applicable to all physical phenomena (not only to mechanics). According to the "principle of relativity," the laws of physics have the same form in any inertial frame. In other terms, the inertial frames are physically equivalent and no experiment can discriminate them. The second pillar of special relativity, as already mentioned, is the "postulate of the constancy of the velocity of light": the velocity of light in vacuum, c, has the same value in any inertial frame, independent of the motion of the source. These two postulates lead to transformation laws between inertial frames, which are quite different from the Galilean transformation [1] and mix time and space variables.

Lorentz Transformations

Consider two inertial frames $\mathscr{K}(x, y, z, t)$ and $\mathscr{K}'(x', y', z', t')$, and it is supposed that their origins O and O' coincide at $t' = t = 0$. The transformation laws between $\mathscr{K}$ and $\mathscr{K}'$ must be linear, so that a uniform motion in $\mathscr{K}$ transforms into a uniform motion in $\mathscr{K}'$. If a spherical light wave is emitted at $t = t' = 0$ from $O \equiv O'$, the equation of its front is

$$x^2 + y^2 + z^2 - c^2t^2 = 0 \qquad [4]$$

in $\mathscr{K}$, and

$$x'^2 + y'^2 + z'^2 - c^2t'^2 = 0 \qquad [5]$$

in $\mathscr{K}'$ (recall that the velocity of light is the same). Thus,

$$x'^2 + y'^2 + z'^2 - c^2t'^2 = \lambda(x^2 + y^2 + z^2 - c^2t^2) \qquad [6]$$

and, due to the symmetry of $\mathscr{K}$ and $\mathscr{K}'$ as postulated by the principle of relativity, λ must be equal to unity:

$$x'^2 + y'^2 + z'^2 - c^2t'^2 = x^2 + y^2 + z^2 - c^2t^2 \qquad [7]$$

From this invariance condition, one can derive the coefficients of the transformation, relating $\mathscr{K}$ to $\mathscr{K}'$ (the "Lorentz transformation" (LT)). For the configuration of **Figure 1** ($\mathscr{K}'$ and $\mathscr{K}$ are assumed to have parallel axes, and $\mathscr{K}'$ is supposed to move relative to $\mathscr{K}$ with velocity v along the positive x direction), the transformation laws are

$$\begin{aligned} x' &= \gamma(x - vt) \\ y' &= y \\ z' &= z \\ t' &= \gamma(t - vx/c^2) \end{aligned} \qquad [8]$$

where γ is the Lorentz factor

$$\gamma = \frac{1}{\sqrt{1 - (v^2/c^2)}} \qquad [9]$$

It is to be noted that, for $v \to c$, the γ factor goes to ∞ and hence the LTs become meaningless. Therefore, c is a limiting speed. In the formal limit $c \to \infty$, that is for velocities much smaller than c (the Newtonian limit), eqns [8] reduces to the Galilean transformations [1] and [2].

Let $\boldsymbol{u} = \mathrm{d}\boldsymbol{x}/\mathrm{d}t$ be the velocity of a particle in $\mathscr{K}$ and $\boldsymbol{u}' = \mathrm{d}\boldsymbol{x}'/\mathrm{d}t$ its velocity in $\mathscr{K}'$. Differentiating

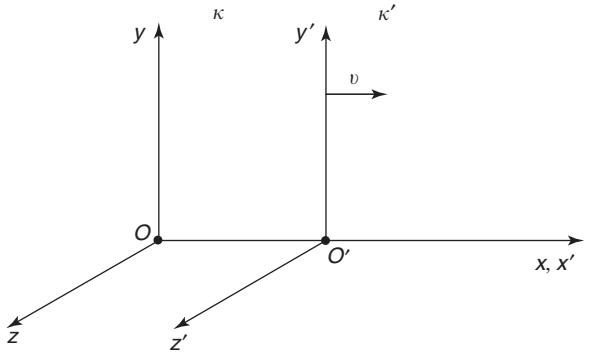

Figure 1 Two inertial frames in uniform relative motion along the x-axis.

eqn [3], one obtains the relativistic transformation of velocities:

$$u'_x = \frac{u_x - v}{1 - (u_x v/c^2)}, \qquad u'_y = \frac{u_y}{\gamma(v)[1 - (u_x v/c^2)]}$$
$$u'_z = \frac{u_z}{\gamma(v)[1 - (u_x v/c^2)]} \quad [10]$$

In particular, if $u_x = c$, the first of these relations gives $u'_x = c$, consistently with the postulate of the constancy of the velocity of light.

An LT between frames with parallel axes is called a "boost." Thus, [8] is a boost along x. A boost along an arbitrary direction is given by

$$\boldsymbol{x}' = \boldsymbol{x} + [(\gamma - 1)\boldsymbol{v} \cdot \boldsymbol{x}/v^2 - \gamma t]\boldsymbol{v}$$
$$t' = \gamma(t - \boldsymbol{v} \cdot \boldsymbol{x}/c^2) \quad [11]$$

The most general (homogeneous) LT combines a boost with a rotation of the axes.

Measurements of Time Intervals and Lengths

An immediate consequence of LTs is the relativity of simultaneity: two events A and B which are simultaneous in an inertial frame $\mathscr{K}$, $t_A = t_B = t$, are not simultaneous in another frame $\mathscr{K}'$. According to [8], their time interval in $\mathscr{K}'$ is, in fact,

$$\Delta t' \equiv t'_B - t'_A = \gamma \frac{v}{c^2}(x_A - x_B)$$

It is supposed that two events occur at the same point in a given inertial frame $\mathscr{K}'$. Let $\Delta\tau$ be their time interval measured by a clock at rest in $\mathscr{K}'$ (τ is called the "proper time"). The time interval Δt in another inertial frame $\mathscr{K}$ moving with velocity v relative to $\mathscr{K}'$ is given by

$$\Delta t = \frac{\Delta\tau}{\sqrt{1 - (v^2/c^2)}} \quad [12]$$

and is larger than $\Delta\tau$. This phenomenon is known as "time dilatation." It is worth noting that, whereas in $\mathscr{K}'$ the two events occur at the same point, in $\mathscr{K}$ they occur in two different points, and one needs two clocks to measure their time interval Δt.

Another important relativistic effect is the "length (or Lorentz–Fitzgerald) contraction". Consider a rod at rest in a certain frame $\mathscr{K}'$, and let L_0 be its length in $\mathscr{K}'$ (i.e., its proper length). An observer in another inertial frame $\mathscr{K}$ moving with velocity v relative to $\mathscr{K}'$ measures a length L which is smaller than L_0:

$$L = \sqrt{1 - (v^2/c^2)} \quad L_0 < L_0 \quad [13]$$

This phenomenon can be understood by observing that the measurements of the ends of the rod, which are simultaneous in one of the two frames, are not simultaneous in the other. Since the transverse coordinates do not change under a boost, the transformation law of volumes is the same as [13]: $V = \sqrt{1 - (v^2/c^2)}V_0$.

Doppler Effect

Consider a light source $\mathscr{S}$ and an observer $\mathscr{O}$ in relative motion. The frequency of light measured by the observer is different from the proper frequency of light (i.e., the frequency measured in the source rest–frame). This phenomenon is known as the "Doppler effect." Special relativity introduces some important corrections to the nonrelativistic predictions. Given a plane wave $e^{i(2\pi\nu t - \boldsymbol{k}\cdot\boldsymbol{x})}$, its phase $\phi \equiv 2\pi\nu t - \boldsymbol{k} \cdot \boldsymbol{x}$ counts the number of wave crests passing by a fixed point in a time interval t, and therefore is an invariant quantity:

$$2\pi\nu' t' - \boldsymbol{k}' \cdot \boldsymbol{x}' = 2\pi\nu t - \boldsymbol{k} \cdot \boldsymbol{x} \quad [14]$$

Using the LT of coordinates and the dispersion relations $\nu = ck/2\pi$ and $\nu' = ck'/2\pi$, one finds

$$\nu' = \nu \frac{\sqrt{1 - (v^2/c^2)}}{1 + (v/c)\cos\vartheta'} \quad [15]$$

where ν' is the frequency measured by the observer (supposed to be at rest in $\mathscr{K}'$), ν is the proper frequency (the frequency in the source rest-frame $\mathscr{K}$), and ϑ' is the angle between the direction of light and the x-axis (which is assumed to be the direction of the relative motion of $\mathscr{S}$ and $\mathscr{O}$). For $\vartheta' = 0$, one has the "longitudinal Doppler effect":

$$\nu' = \nu \sqrt{\frac{1 - (v/c)}{1 + (v/c)}} \quad [16]$$

If the observer $\mathscr{O}$ recedes from the source ($v > 0$), then ν' is smaller than ν; if $\mathscr{O}$ approaches the source ($v < 0$), then ν' is larger then ν. Equation [16] differs from the nonrelativistic result

$$\nu' = \frac{\nu}{1 + (v/c)} \quad [17]$$

by terms of second order in v/c. When the light propagates perpendicularly to the direction of the relative motion of $\mathscr{S}$ and $\mathscr{O}$ ($\vartheta' = \pi/2$), one obtains from [15],

$$\nu' = \nu \sqrt{1 - (v^2/c^2)} \quad [18]$$

This is the formula for the "transverse Doppler effect", which is genuinely a relativistic effect, with no

Newtonian counterpart. The first measurement of the Doppler effect to order v^2/c^2 was performed by Ives and Stilwell in 1938.

Relativistic Dynamics

The relativistic dynamics of a particle of mass m under the action of a force $\boldsymbol{F}$ is governed by the "Minkowski equation"

$$\frac{\mathrm{d}}{\mathrm{d}t}(m\gamma\boldsymbol{v}) = \boldsymbol{F} \qquad [19]$$

which has been experimentally verified for the first time by Bucherer in 1909. Equation [19] reduces to Newton's second law of motion in the low-velocity limit ($v \ll c,\ \gamma \to 1$) whose left-hand side denotes the derivative of the relativistic momentum $\boldsymbol{p}$,

$$\boldsymbol{p} = m\gamma\boldsymbol{v} = \frac{m\boldsymbol{v}}{\sqrt{1-(v^2/c^2)}} \qquad [20]$$

This expression of $\boldsymbol{p}$ guarantees that the conservation of momentum, $\sum_i \boldsymbol{p}_i = \text{constant}$, is preserved by LTs. If the kinetic energy T is defined as the work needed to accelerate a particle, initially at rest, to a velocity v, that is,

$$\mathrm{d}T = \boldsymbol{F}\cdot\boldsymbol{v}\mathrm{d}t \qquad [21]$$

using [19], one obtains

$$T = \frac{mc^2}{\sqrt{1-(v^2/c^2)}} - mc^2 \qquad [22]$$

where the first term,

$$E = \frac{mc^2}{\sqrt{1-(v^2/c^2)}} \qquad [23]$$

is the total energy, and the second term,

$$E_0 = mc^2 \qquad [24]$$

is the energy possessed by the particle at rest. By combining [20] and [23], one gets

$$\boldsymbol{v} = \frac{c^2\boldsymbol{p}}{E} \qquad [25]$$

and the momentum–energy relation

$$E^2 = p^2c^2 + m^2c^4 \qquad [26]$$

which is relativistically invariant. In a classical framework, only the positive-energy solution of [26] makes sense,

$$E = \sqrt{p^2c^2 + m^2c^4} \qquad [27]$$

since no continuous process can generate a transition from positive-energy states (with $E \geqslant mc^2$) to negative-energy states (with $E \leqslant -mc^2$). In quantum physics, the situation is different because discontinuous changes are possible. A problem of stability then arises. In order to circumvent this difficulty, in 1930, Dirac suggested that the negative-energy levels (the so-called "Dirac sea") are completely occupied. A hole in the Dirac sea would correspond to an oppositely charged particle with positive energy (an antiparticle). In the modern quantum field theory, one does not need to introduce negative-energy states: particles and antiparticles are described by the same physical object, a quantum field.

An important peculiarity of relativistic mechanics is that it allows the existence of massless particles. If $m = 0$ in [26], one obtains the energy–momentum relation

$$E = pc \qquad [28]$$

which shows that the energy of a massless particle is proportional to its momentum. Inserting [28] into [24], one finds $v = c$: in any frame, massless particles travel at the speed of light (it is to be noticed that for $v \to c$, eqns [20] and [23] diverge, unless $m \to 0$). An important example of massless particles is given by the photons, which are the quanta of electromagnetic radiation. Combining [28] with the Planck–Einstein formula relating the photon energy E to its frequency ν,

$$E = h\nu \quad (h = \text{Planck constant}) \qquad [29]$$

one obtains for the photon momentum, the expression $p = h\nu/c$.

Mass–Energy Equivalence

The rest-energy formula $E_0 = mc^2$ is of enormous importance. It implies that mass and energy are, so to speak, "equivalent": mass can be converted into energy, and vice versa. Since E_0 is a constant, it is thought to be simply readsorbed in a redefinition of the zero-level of energy. This is not true, since mass is not conserved; therefore, the rest-energy has observable consequences. The law of energy conservation is

$$\sum_i E_i = \sum_f E_f \qquad [30]$$

where $i(f)$ labels the initial (final) state of a physical process. Splitting E into the kinetic energy T and the rest-energy mc^2, one has

$$\sum_i T_i + \sum_i m_ic^2 = \sum_f T_f + \sum_f m_fc^2 \qquad [31]$$

Except for elastic scattering, the kinetic and mass contributions are not separately conserved: one converts into the other. The effect is too small to be

appreciated in the ordinary experience (and in chemistry), but is quite relevant in nuclear and subnuclear physics. For instance, in the fission of a nucleus of ^{238}U induced by a neutron (n),

$$n + {}^{238}\mathrm{U} \rightarrow {}^{143}\mathrm{Ba} + {}^{93}\mathrm{Kr} + 3n$$

the fractional mass loss is $\Delta m/m \sim 0.8 \times 10^{-3}$ and the energy produced is $\Delta E = (\Delta M)c^2 = 2.7 \times 10^{-11}\,\mathrm{J} = 170\,\mathrm{MeV}$. An example of a process characterized by a total conversion of mass into energy is electron–positron annihilation in two photons: $\mathrm{e}^- + \mathrm{e}^+ \rightarrow 2\gamma$.

Relativistic Motion of Charged Particles

The equation of motion of a particle of charge e in an electromagnetic field is (in the Gauss system of units)

$$\frac{\mathrm{d}}{\mathrm{d}t}(m\gamma \boldsymbol{v}) = e\boldsymbol{E} + \frac{e}{c}\,\boldsymbol{v} \times \boldsymbol{B} \qquad [32]$$

where $\boldsymbol{E}$ is the electric field and $\boldsymbol{B}$ the magnetic field. Two noteworthy cases are considered here.

Constant Electric Field

The electric field $\boldsymbol{E}$ is considered here to be directed along the x axis. With $v_x = v_y = v_z = 0$ at $t = 0$, the motion is rectilinear, and assuming $x(0) = 0$, one obtains

$$x(t) = \frac{1}{\alpha}\left(\sqrt{1 + \alpha^2(ct)^2} - 1\right), \quad (\alpha \equiv e|\boldsymbol{E}|/mc^2) \qquad [33]$$

Graphically, $x(t)$ is a hyperbola. For this reason, the one-dimensional motion of a particle acted on by a constant force is called "hyperbolic motion." If $\alpha \ll 1$, eqn [33] reduces to the nonrelativistic result $x(t) = 1/2\alpha(ct)^2$ (a parabola).

Constant Magnetic Field

If the magnetic field is directed along z-axis, the motion of the particle along this axis is uniform, whereas in the xy plane, one has

$$x(t) = \frac{v_\perp}{\Omega}\sin(\Omega t - \alpha) + x_0 \qquad [34]$$

$$y(t) = \frac{v_\perp}{\Omega}\cos(\Omega t - \alpha) + y_0 \qquad [35]$$

where $v_\perp$ is the initial transverse velocity and

$$\Omega = \frac{e|\boldsymbol{B}|}{m\gamma c} \qquad [36]$$

is the "cyclotron frequency." The particle follows a helical path centered at (x_0, y_0) and of radius $R = m\gamma v_\perp c/e|\boldsymbol{B}|$. The relativistic expressions of Ω and R differ from the nonrelativistic ones by the presence of the γ factor.

Minkowski Space

"Henceforth, space by itself, and time by itself, are doomed to fade away into mere shadows, and only a kind of union of the two will preserve an independent reality." These words, pronounced by Hermann Minkowski in 1908 at the Assembly of German Natural Scientists, are a perfect synthesis of the implications of relativity on the physical concepts of space and time. In the Newtonian view of physical processes, the evolution of a system is pictured as a succession of "snapshots" of $\boldsymbol{R}^3$ (the three-dimensional Euclidean space), labeled by time, which is an absolute parameter. In relativity, on the contrary, time is a frame-dependent coordinate, on the same ground as the three spatial coordinates. The primary elements of the relativistic description of physical world are the events, which are specified by four space–time coordinates, $x^\mu = (x^0, x^1, x^2, x^3) = (ct, x, y, z)$ (hereafter Greek indices take values 0,1,2, and 3, whereas Latin indices take values 1,2, and 3). From a mathematical point of view, events are points of a four-dimensional Riemannian manifold, the Minkowski space $\mathscr{M}$. Given two infinitesimally close events x^μ and $x^\mu + \mathrm{d}x^\mu$, the interval (or separation) $\mathrm{d}s$ between them is defined as

$$\mathrm{d}s^2 = c^2\mathrm{d}t^2 - \mathrm{d}x^2 - \mathrm{d}y^2 - \mathrm{d}z^2 = g_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu \qquad [37]$$

where Einstein's summation convention is adopted (repeated indices are summed), and $g_{\mu\nu}$, the "metric tensor," has the form

$$g_{\mu\nu} = \begin{pmatrix} +1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \qquad [38]$$

The quadratic differential form [37] is called the metric of $\mathscr{M}$. It is related to the proper-time interval $\mathrm{d}\tau$ by $\mathrm{d}s = c\,\mathrm{d}\tau$.

A general definition of LTs is given here. A homogenous LT is a linear transformation

$$x'^\mu = \Lambda^\mu_\nu x^\nu \qquad [39]$$

which preserves the metric $\mathrm{d}s^2$. The condition $\mathrm{d}s'^2 = \mathrm{d}s^2$ implies that the 4×4 real matrix Λ^μ_ν must satisfy

$$g_{\mu\nu}\Lambda^\mu_\rho\Lambda^\nu_\sigma = g_{\rho\sigma} \qquad [40]$$

or, in matrix form,

$$\Lambda^T g \Lambda = g \qquad [41]$$

The most general transformation preserving $\mathrm{d}s^2$ is the inhomogeneous LT (or "Poincaré transformation")

$$x'^\mu = \Lambda^\mu_\nu x^\nu + a^\mu \qquad [42]$$

which includes a space–time translation (a^μ is a set of four real quantities).

The Lorentz matrices Λ^μ_ν have two important properties: (1) their determinant is ± 1 and (2) their Λ^0_0 element is either $\geqslant +1$ or $\leqslant -1$. LTs with $\det \Lambda = +1$ ($\det \Lambda = -1$) are called proper (improper). LTs with $\Lambda^0_0 \geqslant +1$ ($\Lambda^0_0 \leqslant -1$) are called "orthochronous" ("antichronous"). Proper orthochronous LTs are called special, or restricted LTs. Improper and/or antichronous LTs incorporate space and time inversions. Boosts (i.e., LTs relating two inertial frames with parallel axes) and rotations are examples of restricted LTs. For instance, the Lorentz matrix B_x of a boost along the x-direction is

$$B_x(\beta) = \begin{pmatrix} \gamma & -\beta\gamma & 0 & 0 \\ -\beta\gamma & \gamma & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \qquad [43]$$

where $\beta \equiv v/c$ is the so-called "rapidity" of the boost. Any restricted LT can be decomposed in the product of a boost B and a rotation R:

$$\Lambda = B(\boldsymbol{\beta})R(\boldsymbol{\theta}) \quad \text{or} \quad \Lambda = R(\boldsymbol{\theta}')B(\boldsymbol{\beta}') \qquad [44]$$

where $\boldsymbol{\beta}$, $\boldsymbol{\beta}'$ and $\boldsymbol{\theta}$, $\boldsymbol{\theta}'$ are uniquely fixed, but in general $\boldsymbol{\beta} \neq \boldsymbol{\beta}'$ and $\boldsymbol{\theta} \neq \boldsymbol{\theta}'$.

Four-Vectors and Four-Tensors

The most elegant way to implement the principle of relativity is to write the laws of physics in a manifestly covariant form. To understand this, some elementary notions of tensor calculus are to be introduced. A "contravariant four-vector" is a set of four quantities $A^\mu = (A^0, A^1, A^2, A^3)$, which transform, under an LT $x'^\mu = \Lambda^\mu_\nu$, as

$$A'^\mu = \Lambda^\mu_\nu A^\nu \qquad [45]$$

Multiplying A^μ by the metric tensor $g_{\mu\nu}$, one obtains the covariant four-vector A_ν,

$$A_\nu = g_{\mu\nu}A^\mu \qquad [46]$$

which transforms as

$$A_\mu = \Lambda^\nu_\mu A_\nu \qquad [47]$$

where $\Lambda^\nu_\mu \equiv (\Lambda^{-1})^\nu_\mu$. The scalar product of two four-vectors A^μ and B^μ is $A \cdot B \equiv A_\mu B^\mu$. A^μ and B^μ are orthogonal, if $A_\mu B^\mu = 0$. The (squared) norm of a four-vector A^μ is $A^2 \equiv A \cdot A \equiv A_\mu A^\mu$. If $A^2 > 0$, the four-vector A^μ is said to be "timelike"; if $A^2 < 0$, it is said to be "spacelike"; if $A^2 = 0$, it is said to be "lightlike."

A "four-tensor" of rank n is a set of 4^n quantities $T^{\mu_1 \ldots \mu_p}_{\nu_1 \ldots \nu_q}$ (with $p + q = n$) which transform under an LT as

$$T'^{\mu_1 \ldots \mu_p}_{\nu_1 \ldots \nu_q} = \Lambda^{\mu_1}_{\alpha_1} \ldots \Lambda^{\mu_p}_{\alpha_p} \Lambda^{\beta_1}_{\nu_1} \ldots \Lambda^{\beta_q}_{\nu_q} T^{\alpha_1 \ldots \alpha_p}_{\beta_1 \ldots \beta_q} \qquad [48]$$

where $T^{\mu_1 \ldots \mu_p}_{\nu_1 \ldots \nu_q}$ is contravariant in the indices $\mu_1 \ldots \mu_p$ and covariant in $\nu_1 \ldots \nu_q$. Note that four-vectors are four-tensors of rank 1. A four-tensor of rank 0 is a (Lorentz) scalar, that is a quantity which does not change under LTs. Contraction of all indices of a tensor quantity results in a scalar. For instance, $T^{\mu\nu}A_\mu B_\nu$ is a scalar.

The metric tensor $g_{\mu\nu} = g^{\mu\nu}$ raises or lowers the indices. For example,

$$A^\mu = g^{\mu\nu}A_\nu, \qquad A_\mu = g_{\mu\nu}A^\nu, \qquad T^\mu_\nu = g_{\nu\rho}T^{\mu\rho} \qquad [49]$$

The raising or lowering of the 1,2,3 indices yields a change of sign; the raising or lowering of the 0 index leaves the component unchanged:

$$A^0 = A_0, \quad A^1 = -A_1, \quad A^2 = -A_2, \quad A^3 = -A_3 \qquad [50]$$

According to the principle of relativity, physical laws must be invariant in form under LTs. This means that they must be of the type

$$R^{\mu_1 \ldots \mu_p}_{\nu_1 \ldots \nu_q} = T^{\mu_1 \ldots \mu_p}_{\nu_1 \ldots \nu_q} \qquad [51]$$

By definition, the tensor quantities appearing on the two sides transform in the same way under an LT: thus, if [51] holds in a given inertial frame, it holds in any inertial frame. A tensor law such as [51] is said to be "manifestly covariant."

In the following, the Levi–Civita completely antisymmetric symbol $\varepsilon^{\mu\nu\rho\sigma}$ is used, defined as

$$\varepsilon^{\mu\nu\rho\sigma} = \begin{cases} +1 & \text{for even permutations of} \\ & \quad \mu = 0,\ \nu = 1,\ \rho = 2,\ \sigma = 3 \\ -1 & \text{for odd permutations of} \\ & \quad \mu = 0,\ \nu = 1,\ \rho = 2,\ \sigma = 3 \\ 0 & \text{otherwise} \end{cases} \qquad [52]$$

Lorentz Group and Poincaré Group

The homogeneous LTs form a group, the "Lorentz group" $\mathscr{L}$. The set of restricted LTs is a subgroup of $\mathscr{L}$, called the "restricted Lorentz group" (denoted by $\mathscr{L}^\uparrow_+$), and isomorphic to SO(3,1), the group of four-dimensional pseudo-orthogonal matrices with unit determinant. The main mathematical properties of $\mathscr{L}^\uparrow_+$ are: (1) $\mathscr{L}^\uparrow_+$ is a six-parameter semisimple Lie group; (2) it is noncompact; and (3) it is doubly connected (its universal covering being SL(2, C), the

group of two-dimensional complex matrices with unit determinant). A generic representation of $\mathscr{L}_+^\uparrow$ is an invertible linear operator of the form

$$\mathscr{D}(\Lambda) = \exp\left(\frac{\mathrm{i}}{2}\,\omega_{\mu\nu}J^{\mu\nu}\right) \qquad [53]$$

where $\omega_{\mu\nu} = -\omega_{\nu\mu}$ are six real parameters, and $J^{\mu\nu}$ are the generators of the restricted Lorentz group, satisfying the commutation rule

$$[J^{\mu\nu}, J^{\rho\sigma}] = -\mathrm{i}(g^{\mu\sigma}J^{\nu\rho} + g^{\nu\rho}J^{\mu\sigma} - g^{\mu\rho}J^{\nu\sigma} - g^{\nu\sigma}J^{\mu\rho}) \qquad [54]$$

which defines the Lie algebra of $\mathscr{L}_+^\uparrow$. The meaning of the generators of $\mathscr{L}_+^\uparrow$ is better understood if one introduces the vector operators

$$\boldsymbol{J} = (J^{23}, J^{31}, J^{12}), \quad \boldsymbol{G} = (J^{01}, J^{02}, J^{03}) \qquad [55]$$

in terms of which the commutator [54] becomes

$$[J^i, J^j] = \mathrm{i}\,\varepsilon^{ijk}J^k \qquad [56]$$

$$[G^i, G^j] = -\mathrm{i}\,\varepsilon^{ijk}J^k \qquad [57]$$

$$[J^i, G^j] = \mathrm{i}\,\varepsilon^{ijk}G^k \qquad [58]$$

An LT is then represented by

$$\mathscr{D}(\boldsymbol{\theta}, \boldsymbol{\eta}) = \exp\{\mathrm{i}(\boldsymbol{\theta}\cdot\boldsymbol{J} - \boldsymbol{\eta}\cdot\boldsymbol{G})\} \qquad [59]$$

where $\boldsymbol{J}$ is the generator of rotations (i.e., the "angular momentum" operator), and $\boldsymbol{G}$ is the generator of boosts (the so-called "center-of-mass motion" operator). Considering the linear combinations

$$N^i \equiv \tfrac{1}{2}(J^i + \mathrm{i}G^i), \quad M^i \equiv \tfrac{1}{2}(J^i - \mathrm{i}G^i) \qquad [60]$$

The Lie algebra ([56]–[58]) translates into:

$$[N^i, N^j] = \mathrm{i}\,\varepsilon^{ijk}N_k \qquad [61]$$

$$[M^i, M^j] = \mathrm{i}\,\varepsilon^{ijk}M_k \qquad [62]$$

$$[N^i, M^j] = 0 \qquad [63]$$

These are two independent SU(2) Lie algebras (in mathematical terms, this means that the algebra of $\mathscr{L}_+^\uparrow$ is the same as that of $\mathrm{SU}(2)\otimes\mathrm{SU}(2)$).

Physical variables (position, momentum, angular momentum, etc.) and fields (electromagnetic field, gravitational field, Dirac field, etc.) transform as the finite-dimensional representations of $\mathscr{L}_+^\uparrow$ (which are not unitary, since $\mathscr{L}_+^\uparrow$ is a noncompact group). These representations are labeled by the eigenvalues of the Casimir operators N^2 and M^2 of the $\mathrm{SU}(2)\otimes\mathrm{SU}(2)$ algebra, which are $n(n+1)$ and $m(m+1)$, respectively, with n and m integers or half-integers. The representation associated with the eigenvalues n, m has dimension $(2n+1)(2m+1)$ and is denoted by (n,m). The most important finite-dimensional representations of $\mathscr{L}_+^\uparrow$ are:

1. The scalar representation (0,0), in which all LTs reduce to the identity.
2. The vector representation (1/2,1/2), in which the LTs are represented by the matrices Λ_ν^μ, and the generators are $(J^{\rho\sigma})_\nu^\mu = -\mathrm{i}(g^{\rho\mu}g_\nu^\sigma - g^{\sigma\mu}g_\nu^\rho)$.
3. The two (inequivalent) spinor representations (0,1/2) and (1/2,0), in which LTs are represented by two-dimensional SL(2, C) matrices and the generators are given by:

$$(0,\tfrac{1}{2}):\ \boldsymbol{J} = \frac{\boldsymbol{\sigma}}{2}, \quad \boldsymbol{G} = \mathrm{i}\,\frac{\boldsymbol{\sigma}}{2}; \quad (\tfrac{1}{2},0):\ \boldsymbol{J} = \frac{\boldsymbol{\sigma}}{2}, \quad \boldsymbol{G} = -\mathrm{i}\,\frac{\boldsymbol{\sigma}}{2} \qquad [64]$$

   where σ^i are the Pauli matrices. The fields transforming in this representation are the two-component "Weyl spinors."
4. The four-dimensional reducible $(1/2,0)\oplus(0,1/2)$ representation, whose generators are

$$\boldsymbol{J} = \begin{pmatrix} \frac{1}{2}\boldsymbol{\sigma} & 0 \\ 0 & \frac{1}{2}\boldsymbol{\sigma} \end{pmatrix}, \quad \boldsymbol{G} = \begin{pmatrix} -\frac{\mathrm{i}}{2}\boldsymbol{\sigma} & 0 \\ 0 & \frac{\mathrm{i}}{2}\boldsymbol{\sigma} \end{pmatrix} \qquad [65]$$

The fields transforming in this representation are the four-component "Dirac spinors."

The Poincaré transformations (i.e., [42] form the Poincaré group $\mathscr{P}$, which is a 10-parameter noncompact Lie group. The generators of $\mathscr{P}$ are $J^{\mu\nu}$ and the momentum operators P^μ, which generate space–time translations. The Lie algebra of $\mathscr{P}$ is defined by [54] and

$$[P^\mu, J^{\rho\sigma}] = \mathrm{i}(g^{\mu\rho}P^\sigma - g^{\mu\sigma}P^\rho) \qquad [66]$$

$$[P^\mu, P^\nu] = 0 \qquad [67]$$

The Pauli–Lubanski operator is introduced as

$$W^\mu = \tfrac{1}{2}\,\varepsilon^{\mu\nu\rho\sigma}J_{\nu\rho}P_\sigma \qquad [68]$$

The unitary irreducible representations of $\mathscr{P}$ (which are infinite-dimensional, since $\mathscr{P}$ is noncompact) are labeled by the eigenvalues of $P^2 = P^\mu P_\mu$ and $W^2 = W^\mu W_\mu$, which are the two Casimir operators of $\mathscr{P}$. The physical states of particles transform according to these representations. In particular, for massive particles one has $P^2 = M^2$ and $W^2 = -M^2 s(s+1)$, where M is the mass and $s = 0, 1/2, 1, 3/2, \ldots$, is the spin of the particle; for "massless particles," one has $P^2 = W^2 = 0$ and $W^\mu = \lambda P^\mu$, where $\lambda = \pm s$ is the helicity of the particle.

Covariant Formulation of Dynamics

The trajectory of a particle in the Minkowski space is represented by a world-line $x^\mu(\tau)$, where τ is the proper time (recall that $d\tau = ds/c$). Since τ is an invariant parameter, the derivative of x^μ with respect to τ is a four-vector, the four-velocity

$$u^\mu = \frac{dx^\mu}{d\tau} = (\gamma(v)c, \quad \gamma(v)\boldsymbol{v}) \qquad [69]$$

The norm of u^μ is

$$u^\mu u_\mu = c^2 \qquad [70]$$

Multiplying u^μ by m, one obtains the four-momentum p^μ:

$$p^\mu = mu^\mu = (m\gamma(v)c, \ m\gamma(v)\boldsymbol{v}) = \left(\frac{E}{c}, \boldsymbol{p}\right) \qquad [71]$$

It is seen that the time component of p^μ is the energy of the particle (apart from a factor $1/c$), whereas the spatial components form the three-momentum $\boldsymbol{p}$. From [70], it follows that the norm of the four-momentum is

$$p^\mu p_\mu = m^2c^2 \qquad [72]$$

This relation (called "mass-shell relation") is equivalent to [26].

The covariant equation of motion of a free particle,

$$m\frac{du^\mu}{d\tau} = 0 \qquad [73]$$

is obtained by applying Hamilton's variational principle to the action

$$S_0 = -mc^2 \int d\tau \qquad [74]$$

It is to be noted that S_0 is proportional to the proper time of the particle. Expressing (noncovariantly) S_0 as $\int dt\, L_0$ and using $d\tau = dt\sqrt{1-(v^2/c^2)}$, the free–particle Lagrangian L_0 is

$$L_0 = -mc^2\sqrt{1-(v^2/c^2)} \qquad [75]$$

The canonical momentum $\boldsymbol{p} = \partial L_0/\partial \boldsymbol{v}$ and the Hamiltonian $H = \boldsymbol{p}\cdot\boldsymbol{v} - L_0$ coincide with [20] and [27] respectively.

For an interacting particle, the covariant form of the Minkowski equation is

$$m\frac{du^\mu}{d\tau} = \mathscr{F}^\mu \qquad [76]$$

The four-vector on the right-hand side is the four-force, which is related to the ordinary three-force $\boldsymbol{F}$ by

$$\mathscr{F}^\mu = \left(\frac{\gamma}{c}\boldsymbol{F}\cdot\boldsymbol{v}, \gamma\boldsymbol{F}\right) \qquad [77]$$

Since $\mathscr{F}^\mu$ is orthogonal to u^μ,

$$\mathscr{F}^\mu u_\mu = 0 \qquad [78]$$

the four-force must necessarily depend on the velocity of the particle (it is seen that the electromagnetic force acting on a particle is linear in u^μ).

The distributions of energy and momentum of a continuous system (field, fluid, etc.) are contained in the "energy–momentum tensor" $T^{\mu\nu}$, whose components have the following meaning: T^{00} is the energy density; T^{0j}/c is the momentum density; cT^{i0} is the energy flux density in the i direction; T^{ij} (called stress tensor) is the momentum flux density in the i direction. Consider, for instance, a perfect (i.e., completely nonviscous) fluid. In a frame $\mathscr{K}'$ where a given point P of the fluid is instantaneously at rest, the energy–momentum tensor of the fluid has the diagonal form

$$T'^{\mu\nu} = \begin{pmatrix} p & 0 & 0 & 0 \\ 0 & p & 0 & 0 \\ 0 & 0 & p & 0 \\ 0 & 0 & 0 & c^2\rho_m \end{pmatrix} \qquad [79]$$

where p is the pressure and ρ_m is the proper mass density at P. By a Lorentz transformation, one obtains the expression of $T^{\mu\nu}$ in an arbitrary frame:

$$T^{\mu\nu} = \left(\rho_m + \frac{p}{c^2}\right)u^\mu u^\nu - g^{\mu\nu}p \qquad [80]$$

where u^μ is the four-velocity of the fluid at P. In the case of an incoherent fluid, one has $p = 0$ (no stress), and hence $T^{\mu\nu} = \rho_m u^\mu \mu^\nu$.

Relativistic Scattering

A scattering process is schematically represented by

$$1 + 2 \to 3 + 4 + \cdots + N \qquad [81]$$

where 1 and 2 are the incoming particles and $3, 4, \ldots, N$ are the outgoing particles. One normally assumes that the initial and final states are asymptotic states, which means that, before and after the scattering, the particles are free and satisfy the mass-shell relations

$$p_a^2 = m_a^2 \quad (a = 1, 2, \ldots, N) \qquad [82]$$

The energy–momentum (i.e., four-momentum) conservation law reads

$$p_1 + p_2 = p_3 + p_4 + \cdots + p_N \qquad [83]$$

Due to [82] and [83] and to the arbitrariness in the choice of the reference frame, the number of independent kinematic variables describing the N-body process [81] is $3N - 10$.

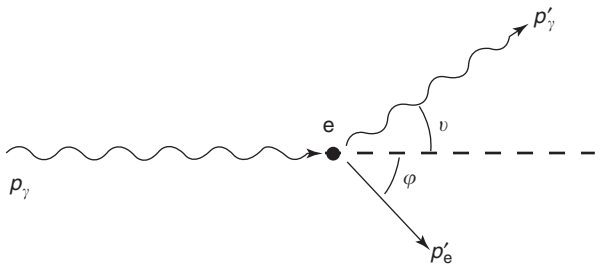

Figure 2 Compton scattering.

Elastic scattering is a two-body process of the type $1+2\rightarrow 1'+2'$, with the same initial and final particles. In this case, the total mass and the total kinetic energy of the particles are separately conserved. An important example of a relativistic elastic process is "Compton scattering," wherein a photon collides elastically with an electron (**Figure 2**):

$$\gamma + e^- \rightarrow \gamma + e^- \qquad [84]$$

In the electron rest-frame, the four-momenta are (apices denote final-state variables)

$$p_\gamma = \left(\frac{E_\gamma}{c}, \boldsymbol{p}_\gamma\right), \qquad p_e = (m_e c, \boldsymbol{0});$$
$$p'_\gamma = \left(\frac{E'_\gamma}{c}, \boldsymbol{p}'_\gamma\right), \qquad p'_e = \left(\frac{E'_e}{c}, \boldsymbol{p}'_e\right) \qquad [85]$$

with

$$E_\gamma = h\nu, \quad |\boldsymbol{p}_\gamma| = \frac{h\nu}{c}; \quad E'_\gamma = h\nu', \quad |\boldsymbol{p}'_\gamma| = \frac{h\nu'}{c} \qquad [86]$$

If four-momentum conservation is applied, one obtains

$$\nu' = \frac{\nu}{1+\varepsilon(1-\cos\vartheta)} \quad (\varepsilon \equiv h\nu/m_e c^2) \qquad [87]$$

where ϑ is the photon scattering angle. In terms of wavelengths, eqn [87] becomes

$$\lambda' - \lambda = \lambda_C(1-\cos\vartheta) \qquad [88]$$

where $\lambda_C = h/m_e c^2$ is the Compton wavelength of the electron (its numerical value is 0.024×10^{-10} m).

Consider now an inelastic production process, such as [81]. This reaction is kinematically allowed only if the initial energy is greater than a threshold value, determined by the condition

$$W^2 \equiv (p_1+p_2)^2 \geqslant (m_3+m_4+\cdots+m_N)^2 \qquad [89]$$

where W is the so-called "invariant mass" of the system. For instance, in the rest-frame of particle 2 (the laboratory frame), the energy of particle 1 must be

$$E_1 \geqslant \frac{(m_3+m_4+\cdots+m_N)^2 - (m_1^2+m_2^2)}{2m_2} \qquad [90]$$

Covariant Formulation of Electrodynamics

The most elegant way to show that electromagnetism is relativistically invariant is to put Maxwell's equations in a covariant form. The four-potential

$$A^\mu = (\varphi, \boldsymbol{A}) \qquad [91]$$

is introduced, which contains the scalar potential φ and the vector potential $\boldsymbol{A}$. The electric field $\boldsymbol{E}$ and the magnetic field $\boldsymbol{B}$ are incorporated into the "field strength tensor" $F^{\mu\nu}$, an antisymmetric tensor of rank 2 defined as

$$F^{\mu\nu} = \partial^\mu A^\nu - \partial^\nu A^\mu \qquad [92]$$

This expression must be equivalent to

$$\boldsymbol{E} = -\boldsymbol{\nabla}\varphi - \frac{1}{c}\frac{\partial \boldsymbol{A}}{\partial t} \qquad [93]$$

$$\boldsymbol{B} = \boldsymbol{\nabla}\times\boldsymbol{A} \qquad [94]$$

so that the components of $F^{\mu\nu}$ are

$$F^{\mu\nu} = \begin{pmatrix} 0 & -E_x & -E_y & -E_z \\ E_x & 0 & -B_z & B_y \\ E_y & B_z & 0 & -B_x \\ E_z & -B_y & B_x & 0 \end{pmatrix} \qquad [95]$$

In terms of $F^{\mu\nu}$, the inhomogeneous Maxwell equations

$$\boldsymbol{\nabla}\cdot\boldsymbol{E} = 4\pi\rho, \quad \boldsymbol{\nabla}\times\boldsymbol{B} - \frac{1}{c}\frac{\partial \boldsymbol{E}}{\partial t} = \frac{4\pi}{c}\boldsymbol{j} \qquad [96]$$

read

$$\partial_\mu F^{\mu\nu} = \frac{4\pi}{c} j^\nu \qquad [97]$$

where $\partial_\mu \equiv ((1/c)\partial/\partial t, \boldsymbol{\nabla})$ and the four-density j^μ is

$$j^\mu = (c\rho, \boldsymbol{j}) \qquad [98]$$

The operator ∂_ν is now applied to eqn [97]. Due to the antisymmetry of $F^{\mu\nu}$, one has $\partial_\nu\partial_\mu F^{\mu\nu} = 0$, and, therefore,

$$\partial_\nu j^\nu = 0 \qquad [99]$$

which is equivalent to the equation of continuity of electric charge,

$$\frac{\partial\rho}{\partial t} + \boldsymbol{\nabla}\cdot\boldsymbol{j} = 0 \qquad [100]$$

Inserting [92] into [97], and adopting the Lorentz gauge, $\partial_\mu A^\mu$, one obtains

$$\Box A^\nu = \frac{4\pi}{c} j^\nu \qquad [101]$$

where $\Box \equiv \partial_\mu\partial^\mu$ is the d'Alembertian. The simplest covariant expression of the homogeneous Maxwell

equations,

$$\nabla \cdot \boldsymbol{B} = 0, \qquad \nabla \times \boldsymbol{E} + \frac{1}{c}\frac{\partial \boldsymbol{B}}{\partial t} = 0 \quad [102]$$

is obtained by introducing the "dual field strength" $\tilde{F}^{\mu\nu}$,

$$\tilde{F}^{\mu\nu} = \frac{1}{2}\,\varepsilon^{\mu\nu\rho\sigma}\,F_{\rho\sigma} = \begin{pmatrix} 0 & -B_x & -B_y & -B_z \\ B_x & 0 & E_z & -E_y \\ B_y & -E_z & 0 & E_x \\ B_z & E_y & -E_x & 0 \end{pmatrix} \quad [103]$$

in terms of which eqn [102] becomes

$$\partial_\mu \tilde{F}^{\mu\nu} = 0 \quad [104]$$

The (symmetrized) energy–momentum tensor of the electromagnetic field is

$$T^{\mu\nu} = -\frac{1}{4\pi}\,F^{\mu\rho}F^{\nu}_{\rho} + \frac{1}{16\pi}\,F^{\rho\sigma}F_{\rho\sigma}g^{\mu\nu} \quad [105]$$

It contains the energy density $\omega \equiv T^{00}$ and the momentum density $\pi^i \equiv T^{0i}/c$, which are given explicitly by

$$\omega = \frac{1}{8\pi}(\boldsymbol{E}^2 + \boldsymbol{B}^2), \quad \boldsymbol{\pi} = \frac{1}{4\pi c}\,\boldsymbol{E} \times \boldsymbol{B} \quad [106]$$

With $F^{\mu\nu}$ and $\tilde{F}^{\mu\nu}$, the two invariants are constructed as

$$F^{\mu\nu}F_{\mu\nu} = -2(\boldsymbol{E}^2 - \boldsymbol{B}^2), \qquad \tilde{F}^{\mu\nu}F_{\mu\nu} = -4\boldsymbol{E}\cdot\boldsymbol{B} \quad [107]$$

and it is seen that, if the fields $\boldsymbol{E}$ and $\boldsymbol{B}$ are equal in magnitude and/or orthogonal in a given inertial frame, they are equal in magnitude and/or orthogonal in any inertial frame. The LTs of $\boldsymbol{E}$ and $\boldsymbol{B}$ for a boost along a generic direction are ($\boldsymbol{\beta} = \boldsymbol{v}/c$)

$$\boldsymbol{E}' = \gamma(\boldsymbol{E} + \boldsymbol{\beta} \times \boldsymbol{B}) - \frac{\gamma - 1}{\beta^2}(\boldsymbol{E}\cdot\boldsymbol{\beta})\boldsymbol{\beta} \quad [108]$$

$$\boldsymbol{B}' = \gamma(\boldsymbol{B} - \beta \times \boldsymbol{E}) - \frac{\gamma - 1}{\beta^2}(\boldsymbol{B}\cdot\boldsymbol{\beta})\boldsymbol{\beta} \quad [109]$$

A charged particle interacting with the electromagnetic field is now considered. The equation of motion of the particle is

$$m\,\frac{\mathrm{d}u^\mu}{\mathrm{d}\tau} = \frac{e}{c}\,F^{\mu\nu}u_\nu \quad [110]$$

and corresponds to [32]. The action leading to [110] is

$$S = -mc^2\int \mathrm{d}\tau - \frac{e}{c}\int A_\mu(z)\,\mathrm{d}z^\mu \quad [111]$$

From this, the noncovariant Lagrangian is extracted as

$$L = -mc^2\sqrt{1 - \frac{v^2}{c^2}} - e\varphi + \frac{e}{c}\,\boldsymbol{v}\cdot\boldsymbol{A} \quad [112]$$

The canonical momentum $\boldsymbol{P}$ differs from the kinetic momentum $\boldsymbol{p} = m\gamma\boldsymbol{v}$ by a term proportional to $\boldsymbol{A}$:

$$\boldsymbol{P} = \frac{\partial L}{\partial \boldsymbol{v}} = m\gamma\boldsymbol{v} + \frac{e}{c}\,\boldsymbol{A} = \boldsymbol{p} + \frac{e}{c}\,\boldsymbol{A} \quad [113]$$

The Hamiltonian associated to [112] is

$$H = \left[\left(\boldsymbol{P} - \frac{e}{c}\,\boldsymbol{A}\right)^2 c^2 + m^2c^4\right]^{1/2} + e\varphi \quad [114]$$

The relativistic treatment of a system of interacting charged particles is complicated by the fact that each particle has its own proper time. It is possible, however, to write an approximate Lagrangian, valid to second order in v/c (a, b are particle indices):

$$L = \sum_a\left(\frac{1}{2}\,m_a\boldsymbol{v}_a^2 + \frac{1}{8c^2}\,m_a\boldsymbol{v}_a^4\right) - \frac{1}{2}\sum_a\sum_{b\neq a}\frac{e_ae_b}{r_{ab}} + \frac{1}{4c^2}\sum_a\sum_{b\neq a}\frac{e_ae_b}{r_{ab}}\left[\boldsymbol{v}_a\cdot\boldsymbol{v}_b + \frac{(\boldsymbol{v}_a\cdot\boldsymbol{r}_{ab})(\boldsymbol{v}_b\cdot\boldsymbol{r}_{ab})}{r_{ab}^2}\right] \quad [115]$$

This Lagrangian was derived in 1920 by C G Darwin and leads, in quantum mechanics, to the Breit equation.

The electromagnetic potentials generated by a point charge in motion are obtained by solving eqn [101] with the four-density j^μ given by

$$j^\mu(x) = ec\int_{-\infty}^{+\infty}\mathrm{d}\tau\,u^\mu(\tau)\delta^4(x - z(\tau)) \quad [116]$$

where $z^\mu(\tau)$ is the world-line of the particle. Assuming there are no incident fields, one obtains the so-called "Liénard–Wiechert potentials":

$$\varphi(\boldsymbol{x}, t) = \left[\frac{e}{R - \boldsymbol{R}\cdot\boldsymbol{v}/c}\right]_{\mathrm{ret}}$$
$$\boldsymbol{A}(\boldsymbol{x}, t) = \left[\frac{e(\boldsymbol{v}/c)}{R - \boldsymbol{R}\cdot\boldsymbol{v}/c}\right]_{\mathrm{ret}} \quad [117]$$

where

$$\boldsymbol{R}(t) = \boldsymbol{x} - \boldsymbol{z}(t) \quad [118]$$

is the position of the observation point relative to the charge (located in $\boldsymbol{z}$), and the subscript "ret" means that all quantities in the brackets are evaluated at the retarded time, defined by

$$t_{\mathrm{ret}} = t - \frac{R(t_{\mathrm{ret}})}{c} \quad [119]$$

The fields corresponding to the potentials [117] are ($\boldsymbol{\beta} \equiv \boldsymbol{v}/c, \boldsymbol{n} \equiv \boldsymbol{R}/R$)

$$\boldsymbol{E}(\boldsymbol{x},t) = e\left\{\frac{(1-\beta^2)(\boldsymbol{n}-\boldsymbol{\beta})}{R^2(1-\boldsymbol{\beta}\cdot\boldsymbol{n})^3}\right\}_{\text{ret}} + \frac{e}{c}\left\{\frac{\boldsymbol{n}\times[(\boldsymbol{n}-\boldsymbol{\beta})\times\dot{\boldsymbol{\beta}}]}{R(1-\boldsymbol{\beta}\cdot\boldsymbol{n})^3}\right\}_{\text{ret}} \quad [120]$$

$$\boldsymbol{B}(\boldsymbol{x},t) = [\boldsymbol{n}\times\boldsymbol{E}(\boldsymbol{x},t)]_{\text{ret}} \quad [121]$$

At large distances from the source, the dominant contributions come from the first term of [120] and the corresponding term in [121], which behave as $1/R$ and are the acceleration-dependent radiation fields.

Spin Dynamics

The spin $\boldsymbol{s}$ of a massive particle is incorporated into a four-vector S^μ orthogonal to the four-velocity, given by

$$S^\mu = \left(\gamma\boldsymbol{\beta}\cdot\boldsymbol{s}, \boldsymbol{s} + \frac{\gamma^2}{\gamma+1}(\boldsymbol{\beta}\cdot\boldsymbol{s})\boldsymbol{\beta}\right) \quad [122]$$

In the particle rest-frame $\mathscr{K}'$, the spin four-vector [122] reduces to $(0,\boldsymbol{s})$, and the equation of motion of $\boldsymbol{s}$ in presence of a magnetic field is

$$\frac{\mathrm{d}\boldsymbol{s}}{\mathrm{d}t'} = \frac{eg}{2mc}\,\boldsymbol{s}\times\boldsymbol{B}' \quad [123]$$

where g is the "gyromagnetic ratio." The covariant generalization of [123] in an arbitrary inertial frame $\mathscr{K}$ is the so-called "Bargmann–Michel–Telegdi equation":

$$\frac{\mathrm{d}S^\mu}{\mathrm{d}\tau} = \frac{e}{mc}\left[\frac{g}{2}F^{\mu\nu}S_\nu + \left(\frac{g}{2}-1\right)S_\rho F^{\rho\sigma}u_\sigma u^\mu\right] \quad [124]$$

From this, one can extract the corresponding equation for the spin vector $\boldsymbol{s}$, which reads

$$\frac{\mathrm{d}\boldsymbol{s}}{\mathrm{d}t} = \frac{eg}{2mc}\,\boldsymbol{s}\times\left[(\boldsymbol{B}-\boldsymbol{\beta}\times\boldsymbol{E}) - \frac{\gamma-1}{\gamma\beta^2}\,\boldsymbol{\beta}(\boldsymbol{\beta}\cdot\boldsymbol{B})\right] + \boldsymbol{\omega}_{\text{T}}\times\boldsymbol{s} \quad [125]$$

with

$$\boldsymbol{\omega}_{\text{T}} = -\frac{\gamma-1}{\beta^2}\,\boldsymbol{\beta}\times\frac{\mathrm{d}\boldsymbol{\beta}}{\mathrm{d}t} \quad [126]$$

The term containing $\boldsymbol{\omega}_{\text{T}}$ represents the "Thomas precession" of spin. Recalling the transformation law [109] of $\boldsymbol{B}$, it is seen that eqn [125] is related to the equation of motion [123] of $\boldsymbol{s}$ in the particle rest-frame $\mathscr{K}'$ (which is a noninertial frame) by

$$\left(\frac{\mathrm{d}\boldsymbol{s}}{\mathrm{d}t}\right)_{\mathscr{K}} = \left(\frac{\mathrm{d}\boldsymbol{s}}{\mathrm{d}t}\right)_{\mathscr{K}'} + \boldsymbol{\omega}_{\text{T}}\times\boldsymbol{s} \quad [127]$$

General Relativity

Special relativity does not describe gravitational phenomena. Newton's law of gravity is, in fact, incompatible with the principle of relativity and all the attempted covariant generalizations of this law have led to various inconsistencies and/or to wrong predictions. A coherent and empirically successful theory of gravity is provided by general relativity (Einstein, 1916), which extends the co-variance of physical laws to arbitrary coordinate transformations ("principle of general covariance"). One of the starting points of general relativity is the "equivalence principle," namely the fact that the inertial mass is equal to the gravitational mass. As noticed by Einstein, this equality (which has no explanation in Newtonian physics) allows one to cancel, or simulate, gravity by an inertial force (i.e., by a transformation to an accelerated frame), provided the space–time region where this is done is so small that nonhomogeneities of the gravitational field can be neglected. In Einstein's theory, the equivalence principle takes the form of a postulate which states that for any space–time event, it is always possible to choose a coordinate system such that in a sufficiently small neighborhood of the event at hand, physical laws are written in the same way as in inertial systems. Unlike the Minkowski space $\mathscr{M}$, the space–time of general relativity is a curved Riemannian manifold. Its metric tensor $g_{\mu\nu}(x)$ depends on the coordinates and cannot be reduced to the Minkowskian metric tensor [38]. From a physical point of view, $g_{\mu\nu}(x)$ represents the gravitational field. To be precise, in the weak-field limit, one has

$$g_{00} = 1 + \frac{2\Phi}{c^2} \quad [128]$$

where Φ is the Newtonian gravitational potential ($\Phi = -GM/r$ for a spherical mass M). Thus, general relativity establishes a fundamental link between geometry and physics: gravity manifests itself as the curvature of space–time. This curvature is given by a tensor of rank 4, the "Riemann tensor" $R_{\mu\nu\rho\sigma}$, which contains first and second derivatives of $g_{\mu\nu}(x)$. The dynamics of the gravitational field is governed by the Einstein equation

$$R_{\mu\nu} - \frac{1}{2}\,g_{\mu\nu}R = \frac{8\pi G}{c^4}\,T_{\mu\nu} \quad [129]$$

where $R_{\nu\sigma} = g^{\mu\rho}R_{\mu\nu\rho\sigma}$ is the "Ricci tensor," $R = g^{\nu\sigma}R_{\nu\sigma}$ is the "curvature scalar," and $T^{\mu\nu}$ is the symmetrized energy–momentum tensor. An important point to be noticed is that gravity is generated not only by matter, but by any distribution of energy and momentum. In particular, since the gravitational field carries energy and momentum, it acts as a source of itself (this is signaled by the fact that the Einstein

equation is a nonlinear equation). Qualitatively, eqn [129] shows that the curvature is proportional to the mass density $\rho_m \sim T_{00}/c^2$,

$$\text{curvature} \sim \frac{G\rho_m}{c^2} \qquad [130]$$

Here, the constant coefficient is $G/c^2 = 7.4 \times 10^{-30}$ kg m^{-1}. The low value of this quantity indicates that only very high densities of energy and mass produce an appreciable curvature of space–time. When $G\rho/c^2 \ll 1$, the space–time is approximately flat and special relativity applies.

Rhodopsin and the First Step in Vision

R R Birge, University of Connecticut, Storrs, CT, USA

Introduction

Rhodopsin is a membrane-bound photoreceptor protein that is responsible for dim light vision in humans and animals with image resolving eyes. This protein is a member of a special class of membrane bound proteins known as G-protein coupled receptors (GPCRs), but it is the only GPCR for which an atomic level structure has been obtained. The primary event of rhodopsin involves the photochemical conversion of a bound chromophore, 11-*cis* retinal, to the all-*trans* form. Evolution has optimized both the thermodynamics and kinetics of this process to be highly efficient, and the photochemistry is complete in roughly 200 fs while storing 134 kJ mol^{-1} of energy. The process is facilitated by the interaction of a lowest energy, strongly allowed excited state, which absorbs the photon, and a nearby forbidden state, which interacts with the lower state to produce a barrierless excited state potential energy surface. In this article, one can examine the photophysical properties of rhodopsin and the cone pigments that are responsible for color vision. The discussion not only emphasizes the photophysical aspects of rhodopsin photochemistry, but also includes an overview of the biochemistry of vision and the potential relevance of rhodopsin structure and function to other GPCR proteins. Where possible, one can refer to review articles rather than the primary literature in order to obtain relevant background information and perspective.

G-Protein Coupled Receptors

Life would not be possible without communication between the cells and the external environment. This critical capability allows cells to monitor the status of the organs and tissues and to respond to environmental threats and opportunities. Intercellular and interspecies communication is mediated by a group of membrane-bound proteins known as G-protein coupled receptors (GPCRs). Each GPCR monitors a specific compound or group of compounds and becomes activated when the target ligand (agonist) occupies the active site. The activated GPCR signals the presence of the ligand through interaction with a separate protein known as a G-protein. G-proteins are so named because they bind guanine nucleotides GDP and GTP, and the G-protein that is utilized by rhodopsin is called transducin. When rhodopsin becomes activated by light, the GDP on transducin is replaced with GTP which activates the signaling cascade responsible for the nerve impulse. The G-protein based activation process provides reliable signaling and, in the case of the vision, significant amplification. There are at least 700 GPCRs encoded in the human genome. Despite significant biological importance, the structure and function of most GPCRs are poorly understood and a high-resolution crystal structure of only one GPCR, that is, the visual

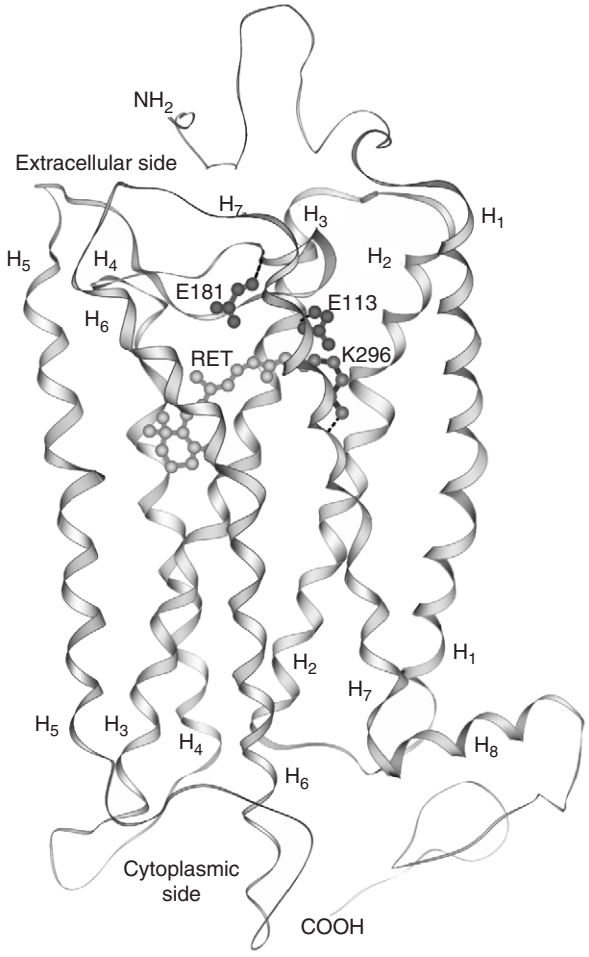

Figure 1 A ribbon picture of rhodopsin based on the crystal structure. The transmembrane helices are labeled H1–H7. A short helical segment that lies on the cytoplasmic surface of the membrane is marked H8. The 11-*cis* retinal chromophore (RET) is attached to the protein via a protonated Schiff base linkage to lysine 296 (K296). The two nearby glutamic acid residues E113 and E181 are also shown. (Adapted from Palczewski K, Kumasaka T, Hori T, Behnke CA, *et al.* (2000) Crystal structure of rhodopsin: a G protein-coupled receptor. *Science* 289 (5480): 739–745; and Okada, Ernst O, Palczewski K, and Hofmann K (2001) Activation of rhodopsin: new insights from structural and biochemical studies. *Trends in Biochemical Science* 26: 318–324.)

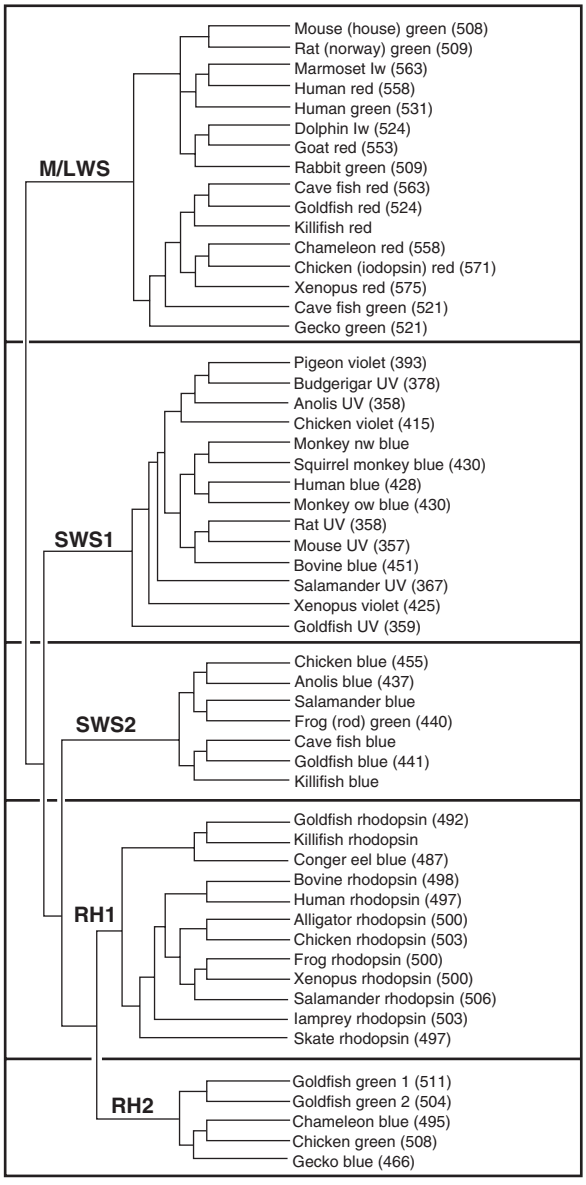

Figure 2 A dendogram showing selected vertebrate visual opsins grouped as suggested by Shozo Yokoyama. The rhodopsin pigments are responsible for scotopic (low-light) vision and are in group RH1. The cone pigments responsible for photopic (high flux, color) vision are found in the other groups. The absorption maxima, known, are listed in nanometers in parentheses. (Adapted from Ebrey T and Koutalos Y (2001) Vertebrate photoreceptors. *Progress in Retinal and Eye Research* 20: 49–94.)

pigment rhodopsin, has been reported. The three-dimensional structure of rhodopsin protein is shown in **Figure 1**.

The Visual Pigments

The rhodopsins ($\lambda_{max} \approx 500$ nm) are members of the visual pigment family, which are divided into groups based on similarities in primary structure (the sequence of amino acids in the protein) and wavelength of absorption (see **Figure 2**). The rhodopsins are found in group RH1 and are responsible for scotopic (low light level) vision. The cone pigments are found in RH2, SWS1, SWS2 or M/LWS groups and are responsible for photopic (high light level) color vision. All of these visual pigments are seven transmembrane alpha helical proteins that bind 11-*cis* retinal and initiate the light transduction signaling pathway in retinal photoreceptors. While other GPCRs interact with their ligands noncovalently, the visual pigments consist of 11-*cis* retinal covalently attached to the

apoprotein through a Schiff base linkage to a conserved lysine residue in the seventh transmembrane helix (H7, see **Figure 1**). Following absorption of light, the retinal chromophore isomerizes to the all-*trans* conformation and triggers a series of conformational changes that lead to the formation of the active state, R$*$ or meta II. All-*trans* retinal is eventually released from the vertebrate protein and visual pigments, can be regenerated from 11-*cis* retinal spontaneously. Although some consider a photon of light to represent the agonist, a more logical choice is all-*trans* retinal, which is photochemically generated from the 11-*cis* retinal cofactor. Thus, the visual pigments have a covalently attached agonist but one that starts out in an inactive form. The fact that the agonist is covalently attached allows studies of the activation process at a level not possible with the vast majority of the other GPCRs, where the mode and location of interaction of the agonist remains obscure.

The Primary Event of Vision

The primary photochemical event that follows the absorption of light by rhodopsin is localized within the light-absorbing chromophore, the 11-*cis* retinal. This chromophore is attached to the protein via a protonated Schiff base linkage as shown in **Figure 3**. Upon the absorption of light, the 11-*cis* chromophore isomerizes rapidly to form an 11-*trans* photoproduct that is schematically shown in **Figure 3**. Although experimental studies show that this chromophore is 11-*trans*, it is possible that rotations about single bonds have taken place to accommodate the change in geometry. The remarkable feature of the primary event is that it is complete in 200 fs. Detailed vibronic analyses indicate that the process is vibrationally coherent, which indicates that there is a direct path that the 11-*cis* excited state species will follow in carrying out the isomerization to the 11-*trans* ground-state photoproduct. This observation, coupled with the observation that photoisomerization also occurs with high efficiency at 4 K, indicates that the photochemistry takes place along a barrierless excited state surface. A simplified diagram presenting some of the important aspects of the photoisomerization surface is shown in **Figure 4**. In addition to having a fast photochemical conversion, rhodopsin must store enough energy in the primary event to drive the subsequent thermal reactions that activate the protein. The primary event stores $\sim 134\,\mathrm{kJ\,mol^{-1}}$, which is $\sim 57\%$ of the energy available from light absorption. The quantum efficiency of the primary event is 0.65 which means that 65% of the photons absorbed yield activated protein. Thus, the net efficiency of the protein in carrying out its photoreceptor function is 36%. The efficiency is all the more remarkable when one considers that the probability that a rhodopsin molecule will spontaneously activate to produce a false signal is extremely small, $\sim 10^{-11}$ false (thermal) events per rhodopsin molecule per second. There is no human-made device that approaches this level of speed, efficiency, and reliability. The question arises, however, why nature would optimize the visual pigment to have a primary event that is so fast. The neural signal is separated from the original photon absorption by tens of milliseconds, and one might conclude from this observation that there would be no evolutionary rationale for selection of a coherent, femtosecond isomerization process. The answer to this conundrum is simple. Natural selection optimized the kinetics of the primary event so that the significant energy storage required could be accommodated while simultaneously eliminating possible side reactions. It is noted that the primary photochemical event of bacteriorhodopsin, which stores roughly one-third as much energy in the primary event, is approximately three times slower despite having a nearly identical quantum efficiency. The interesting question is why both light-transducing proteins have converged on nearly identical quantum efficiencies, an interesting and important mechanistic observation that is not yet understood.

What remains to be examined here is the mechanistic origin of the barrierless excited state potential energy surface. As background, it is noted that the protonated Schiff base chromophore of 11-*cis* retinal does not undergo comparable photochemistry in solution. Although the quantum efficiency is only slightly lower in solution, the photoisomerization takes nanoseconds, not femtoseconds, which is many orders of magnitude slower. Clearly the protein binding site has a significant impact on the excited state potential surface.

The mechanism relies on the electronic properties of polyenes. In the late 1970s, a new excited singlet state was experimentally identified by Bryan Kohler and his graduate student, Bruce Hudson, who were both at Harvard at that time. The state is the lowest-lying excited singlet state in long-chain linear polyenes and has the same symmetry as the ground state, which under the C_{2h} point group is ^1A_g. One-photon selection rules prohibit $^1A_g^* \leftarrow {}^1A_g$ transitions (the asterisk indicates an excited state), and hence the $^1A_g^*$ state is spectroscopically forbidden which explains why nearly 50 years of polyene spectroscopy had failed to observe it. Of note is the fact that this forbidden state is responsible for the fluorescence from long-chain polyenes, and that in all-*trans* retinal, this

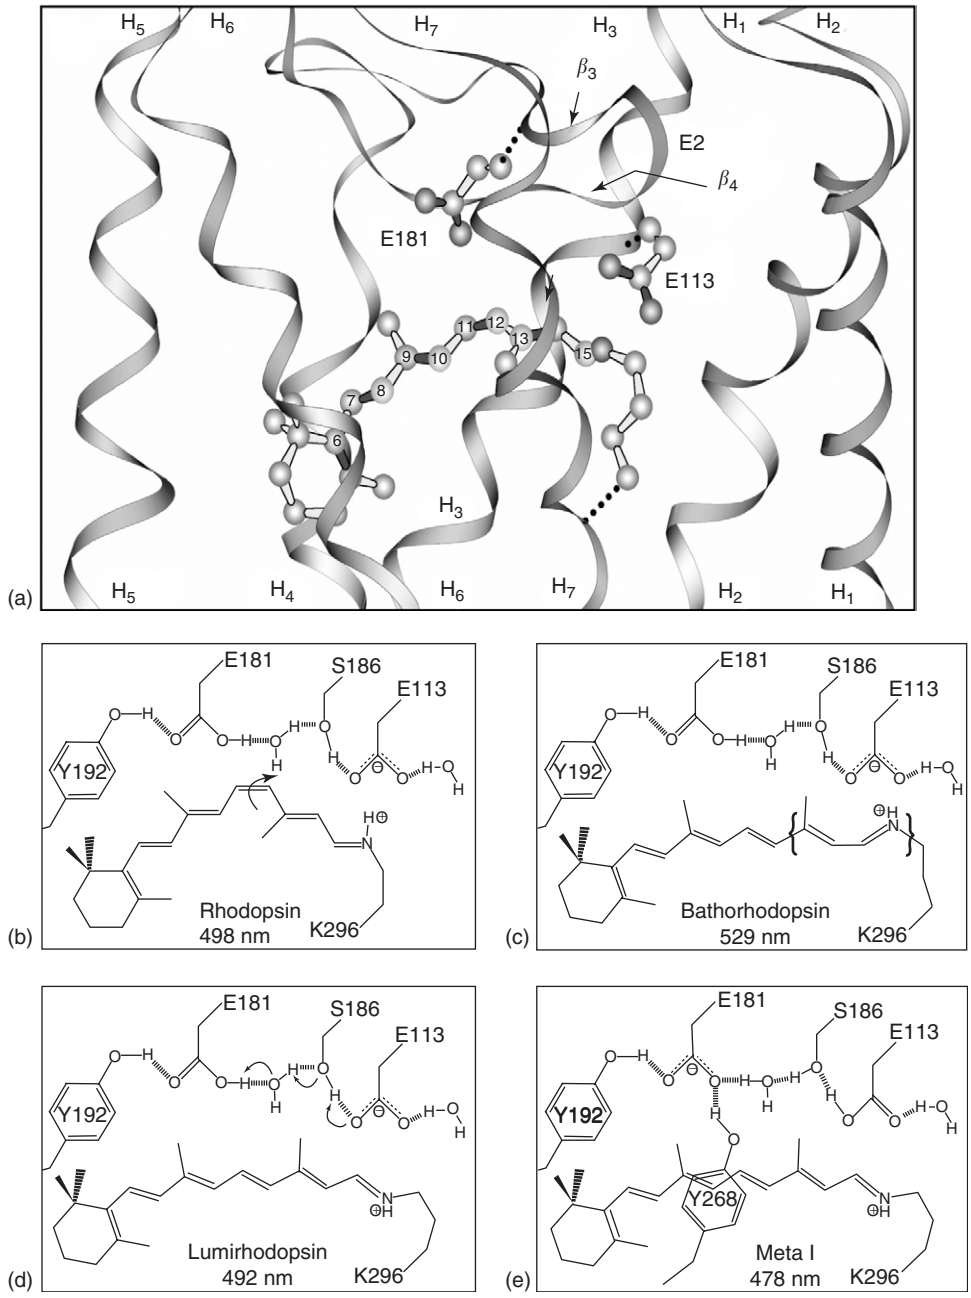

Figure 3 The second extracellular loop, E2, extends into the chromophore binding site in the form of two beta sheets (β3 and β4) as shown in (a) (coordinates from Palczewoski K, Kumasaka T, Hori T, Behnke CA, *et al.* (2000) Crystal structure of rhodospin: a protein-coupled receptor. *Science* 289(5480): 739–745). Glutamic acid residues 113 and 181 are also shown in (a), and the protonation states of these two residues as a function of photobleaching intermediate is schematically shown in panels b–e (assignments from Yan ECY, Kasmi MA, Ganim Z, Hou JM, Pan D, *et al.* (2003) Retinal counterion switch in the photoactivation of the G protein-coupled receptor rhodopsin. *Proceedings of National Academy of Sciences* USA 100: 9262–9267). The arrows in panels b and d indicate the key conformational or chemical changes associated with transformation of rhodopsin (to bathorhodopsin) and lumirhodopsin (to meta I). The chromophore geometry in bathorhodopsin remains controversial, and the brackets are intended to reflect both distortion and conformational uncertainty. The relative location of the residues is approximate and does not reflect possible movement during the thermal relaxations.

state lies below the strongly allowed $^1B_u^*$ state responsible for the strong absorption band characteristic of the visual chromophores. Experimental and theoretical studies indicate that the $^1A_g^*$ state is characterized by significant bond order reversal, which lowers the barrier to dihedral distortion around the (ground state) double bonds in the excited state. Two-photon studies indicate that in protonated Schiff

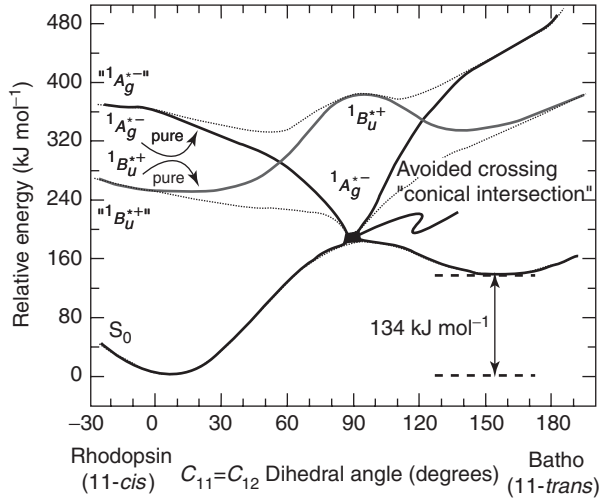

Figure 4 A schematic drawing of the adiabatic ground and excited singlet-state potential surfaces for isomerization of the chromophore in rhodopsin. Interaction between the lowest-excited $^1B_u^*$-like state and the second excited $^1A_g^*$-like state is responsible for generating a barrierless excited state potential surface for isomerization. At the orthogonal point near 90°, the excited singlet-state surface crosses the ground state surface and produces what is called a conical intersection which facilitates rapid and coherent transfer into the ground state.

bases and in the protein bound chromophore, the $^1A_g^*$ state lies above the allowed $^1B_u^*$ state. This level inversion is responsible for the barrierless excited state potential surface because as the amount of torsional distortion increases, the amount of repulsion between the two states increases. This repulsion causes the lowest-lying excited state to have lower energy as torsion increases and is responsible, at least in part, for the barrierless surface. The situation is shown graphically in **Figure 4**. It is parenthetically noted that, the level ordering shown in **Figure 4** also applies to the unprotonated Schiff base chromophores in the UV cone pigments. Protonation, conformation, and external charges are each capable of inducing level order inversion in the visual chromophores.

The protein matrix enhances the photoisomerization process by placing the primary negatively charged glutamic acid counterion, E113, near the Schiff base group. In the ground state, this group stabilizes the positive charge which is primarily localized in the imine region. The absorption of light creates a hyperpolarized charge shift that transfers electron density down the polyene chain toward the imine linkage as shown in **Figure 5**. The primary counterion, E113, is now a source of destabilization due to electrostatic repulsion between the chromophore excited state charge distribution and the nearby glutamic acid residue. This repulsion alters the excited state potential surface to have a larger initial slope toward product formation and enhances the kinetics of photoisomerization.

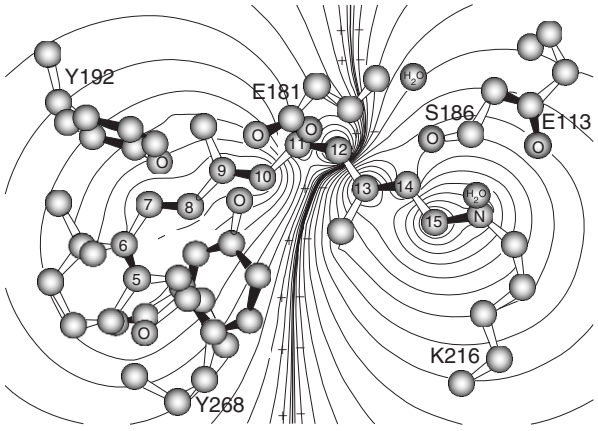

Figure 5 Electrostatic contours associated with excitation of the protein-bound 11-*cis* retinal protonated Schiff base chromophore in rhodopsin. The chromophore undergoes a significant charge shift upon excitation that transfers electron density toward the imine linkage (C14–C15 = N), and produces electrostatic repulsion between the chromophore and the primary counterion E113. The polyene atoms of the chromophore are numbered, and the nitrogen and oxygen atoms are labeled (oxygen atoms on water are labeled H_2O).

The Photobleaching Process

The primary event initiates a series of thermal reactions that ultimately produce meta II, the active form of rhodopsin. The early intermediates of this process are called bathorhodopsin (the primary photoproduct), lumirhodopsin, and metarhodopsin I (meta I). Recent site-directed mutagenesis and spectroscopic studies indicate that there is a counterion shift during the lumi to meta I transition, as shown in **Figure 3**. This counterion shift is also found in the UV cone pigment of the mouse (MUV), which is important because the chromophore is unprotonated in the MUV-rho and MUV-batho states. The MUV chromophore is ultimately protonated in the lumi intermediate via donation of a proton from the nearby (neutral) E113 residue. The remaining portion of the photobleaching sequence essentially duplicates that found in rhodopsin. This observation provides support for the importance of the counterion switch to the activation of visual pigments in general. Otherwise, why would such a convoluted sequence of events evolve if it were not a key contributor to function? From another perspective, the counterion switch mechanism makes it possible for ultraviolet vision, which uses an unprotonated chromophore to achieve short wavelength absorption. The counterion switch mechanism provides a comprehensive activation strategy that will work for both protonated and unprotonated chromophores.

Ruthenates

B Raveau, Laboratoire de Cristallographie, ISMRA, Caen, France

Introduction

The properties of ruthenium oxides are mainly governed by the ability of Ru to adopt, preferentially, the tetravalent state and the octahedral coordination. For this reason, in the system Ru–O, RuO_2 is the only stable oxide. The latter exhibits the rutile structure with a large axial ratio $c/a > 2/3$, so that the π^* orbitals in this system are half-filled. As a consequence, RuO_2 exhibits a metallic conductivity ($\rho \approx 10^{-5}$ Ω cm at room temperature) and its magnetic susceptibility is small, nearly temperature independent, characteristic of Pauli paramagnetism.

The rather low reactivity of RuO_2 with other oxides suggests that the number of ruthenates that have been synthesized to date is rather limited. They are of two types, Ru(IV) and Ru(V) ruthenates. The first ones tend to exhibit a metal-like behavior, whereas the second ones are generally insulators or semiconductors. In a general way, the magnetic properties of these materials are governed by the low-spin configuration of the d^4 Ru(IV) and d^3 Ru(V) species. The ruthenates can be classified, according to their structure, in five categories: perovskites, Ruddlesden and Popper (RP), hexagonal perovskites, pyrochlores, and 1D Ln_3RuO_7. It must also be emphasized that ruthenium can substitute for various transition metal species of oxides modifying their physical properties in a spectacular way.

Ruthenate Perovskites

The ruthenates $CaRuO_3$ and $SrRuO_3$ and their solid solution constitute the basis of our knowledge for the understanding of magnetism in ruthenium oxides. Both of them have an orthorhombically distorted perovskite structure (Pnma with $a \sim c \sim a_c$ and $c \sim 2a_c$), but $SrRuO_3$ is much less distorted and often described as pseudocubic. Their transport properties also exhibit a similarity: they both exhibit a metal-like behavior, so that they are often described as bad metals (**Figure 1**), with comparable resistivities at room temperature. The latter properties have been explained very early by Goodenough by the strong covalent coupling between the Ru-4*d* and O-2*p* orbitals, leading to a narrow band model. Nevertheless, the magnetic properties of these oxides are very different: $SrRuO_3$ is ferromagnetic with a T_c of 165 K, whereas $CaRuO_3$ has been described for a long time as a paramagnetic metal involving antiferromagnetic interactions and is now believed by several authors to be nearly ferromagnetic, as supported by NMR observations. The different behavior of $SrRuO_3$ compared to $CaRuO_3$ is also observed on its $\rho(T)$ curve (**Figure 1**), which shows a Fischer–Langer type anomaly at T_c. The highly correlated nature of the 4*d*-electron band in these perovskites is

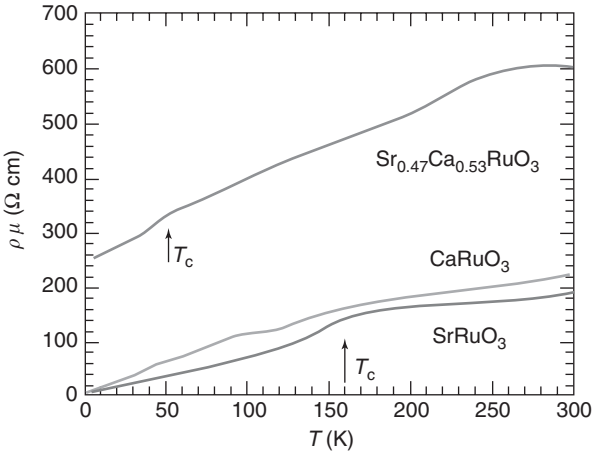

Figure 1 Resistivity vs. temperature for $Sr_{1-x}Ca_xMnO_3$ perovskites ($x = 0$, 0.53, 1). (Reprinted with permission from Cao G, McCall S, Shepard M, Crow JE, and Guertin RP (1997) Thermal, magnetic, and transport properties of single-crystal $Sr_{1-x}Ca_xRuO_3$ ($0 \lesssim x \lesssim 1.0$). *Physical Review B* 56: 321–329; © American Physical Society.)

also confirmed by the recent studies of their solid solution $Sr_{1-x}Ca_xRuO_3$. The peculiar magnetic behavior of $CaRuO_3$, and the fact that it sits on the verge of a ferromagnetic instability is also supported by recent studies, which show that the substitution of Ti(IV) for Ru(IV) in this phase induces ferromagnetism for low Ti level (2%).

Besides, the Ru(IV) perovskites, a series of Ru-based perovskites with the generic formulation A_2LnRuO_6, have been reported for A = Ca, Sr, or Ba and Ln = La, Nd, Y, Ho, Lu, or Er. In all these oxides, ruthenium is pentavalent in contrast to $CaRuO_3$ and $SrRuO_3$. The crystal symmetry of these phases is often monoclinic ($P2_1/n$ $a \sim b \sim a_c\sqrt{2}$, $c \sim 2a_c$ $\beta \sim 90.2$) and more rarely cubic (Fm3m $a \sim 2a_c$).

All these oxides exhibit a 1 : 1 ordering between Ru(V) and Ln(III) or Ca(II) on the octahedral sites. Thus, in this structural type (**Figure 2**), one RuO_6 octahedron alternates with one LnO_6 or CaO_6 octahedron along the three crystallographic directions. In all these compounds, the Ru(V) lattice is antiferromagnetic at low temperature with T_N values ranging from 26 to 40 K. Most of them exhibit an A-type antiferromagnetic structure at low temperature (**Figure 3a**), except Ba_2LaRuO_6 which belongs to the third type (**Figure 3b**). Moreover, the lanthanide cations may be involved in the long-range antiferromagnetic order depending on their nature, as illustrated, for example, for Sr_2ErRuO_6 (**Figure 3c**) which consists of two interpenetrating A-type antiferromagnetic sublattices on Ru^{5+} and Er^{3+} sites, respectively. Though no transport measurements have been carried out, no metallic conduction should be expected for these materials at least at low temperature, due to the isolated character of the RuO_6 octahedra. Nevertheless, high-temperature magnetic susceptibility measurements, carried out on Ba_2YRuO_6, Ba_2LuRuO_6, and Sr_2LuRuO_6 suggest that Ru^{5+} *d*-electrons should be itinerant rather than localized. Such a feature may result from a direct overlap of the neighboring Ru-*t2g* orbitals. Double perovskites involving a disorder of ruthenium and of a transition element M over the same octahedral sites have been synthesized for M = Ni, Co, Fe, Cu. This is indeed the case for the compounds Sr_2MRuO_6 (M = Fe, Co), $BaLaMRuO_6$ (M = Ni, Co), and $SrLaCoRuO_6$, all of which exhibit a monoclinic symmetry, either I2/*c* or I2/*m* or $P2_1/n$, with $a \sim b \sim a_c\sqrt{2}$, $c \sim 2a_c$, and $\beta \sim 90.1^\circ$, except $BaLaNiRuO_6$ which is triclinic. These oxides exhibit a complex magnetic behavior, due to the fact that two alioelectronic cations are distributed at random over the sites of a nonfrustrated lattice. It often results in a spin-glass behavior as shown from the magnetic susceptibility curves of $BaLaCoRuO_6$ (**Figure 4a**) and of Sr_2FeRuO_6 (**Figure 4b**) which exhibit a cusp around 50 and 40 K, respectively. This behavior is significantly different from that of the double perovskites, $BaLaZnRuO_6$ and $BaLaMgRuO_6$, which exhibit an

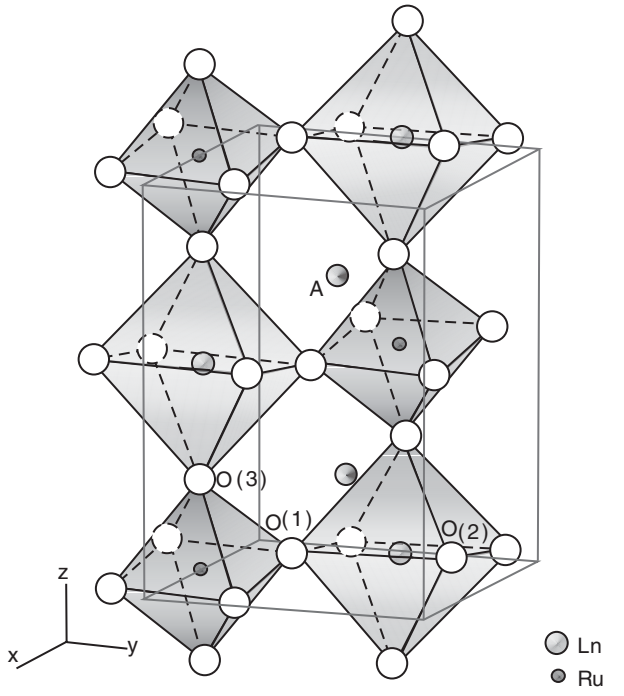

Figure 2 Crystal structure of the ordered perovskites A_2LnRuO_6. (After Battle PD, Jones CW, and Studer F (1991) *Journal of Solid State Chemistry* 90: 302–312.)

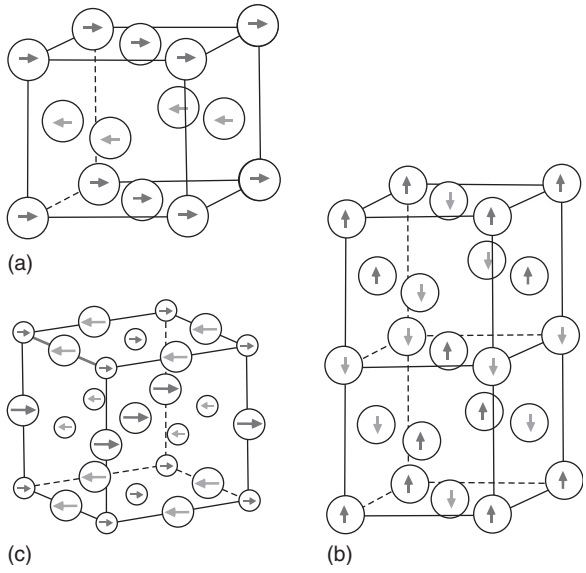

Figure 3 Antiferromagnetic structures of: (a) A-type A_2LnRuO_6 (Ln = Pr−Ln), (b) third-type Ba_2LaRuO_6, and (c) of Sr_2ErRuO_6 with two sublattices, Ru^{5+} (small circles) and Er^{3+} (large circles). (After Battle PD, Jones CW, and Studer F (1991) *Journal of Solid State Chemistry* 90: 302–312.)

A-type antiferromagnetic ordering at low temperature. This difference may be explained by the fact that the Ru^{5+} and Zn^{2+} (or Mg^{2+}) species, which are distorted according to a 1 : 1 ordering, do not interact magnetically, due to the d^{10} (Zn^{2+}) or d^0 (Mg^{2+}) configurations.

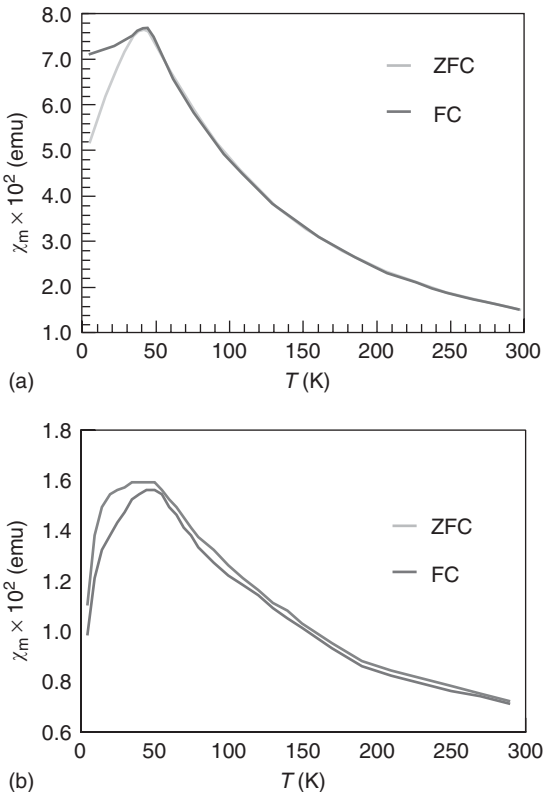

Figure 4 Magnetic susceptibility vs. temperature of (a) BaLaCoRuO$_6$ and (b) Sr_2FeRuO_6. (b) (After Battle PD, Jones CW, and Studer F (1991) *Journal of Solid State Chemistry* 90: 302–312.)

Ruddlesden and Popper Ruthenates

Ca_2RuO_4 and Sr_2RuO_4 represent the first member of the RP series $A_{n+1}Ru_nO_{3n+1}$ (A = Ca, Sr), that is, their structure (**Figure 5a**) consists of single perovskite layers "$SrRuO_3$" or "$CaRuO_3$" intergrown with single rock-salt layers "SrO" or "CaO." These quasi-two-dimensional ruthenates exhibit very different physical properties due to the different distortions of their structure. Ca_2MnO_4 exhibits a metal–insulator (MI) transition at $T_{MI} = 357$ K (**Figure 6a**). This Mott insulator is antiferromagnetic below $T_N = 110$ K. In contrast, Sr_2RuO_4 is a superconductor below $T_c = 1.5$ K and is paramagnetic above this temperature with a tendency toward ferromagnetism. The study of the system $Ca_{2-x}Sr_xMnO_3$ shows that the system changes successively with decreasing x, from $x = 2$ where it is a nonmagnetic Fermi liquid, to a ferromagnetic metal for $x = 0.5$, to an antiferromagnetically correlated metal for $0.2 < x < 0.5$, and to an antiferromagnetic insulator for $x < 0.2$. Neutron powder diffraction studies clearly demonstrate that the magnetic state changes are associated to structural transitions as shown from the phase diagram in **Figure 7**. Based on structural distortions, a magnetic phase diagram can be calculated which demonstrates that the rotation and the tilting of the RuO_6 octahedra are responsible for the ferro- and antiferromagnetism respectively, whereas the flattening of the RuO_6 octahedra controls the stability of these magnetic states. The substitution of La^{3+} for

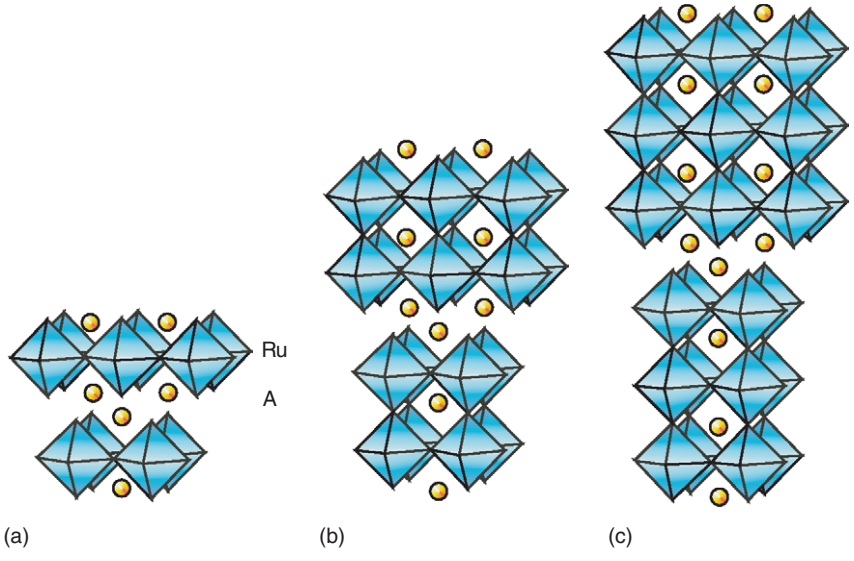

Figure 5 Structure of the RP ruthenates $A_{n+1}Ru_nO_{3n+1}$: (a) $n = 1A_2RuO_4$, (b) $n = 2A_3Ru_2O_7$, and (c) $n = 3A_3Ru_4O_{10}$.

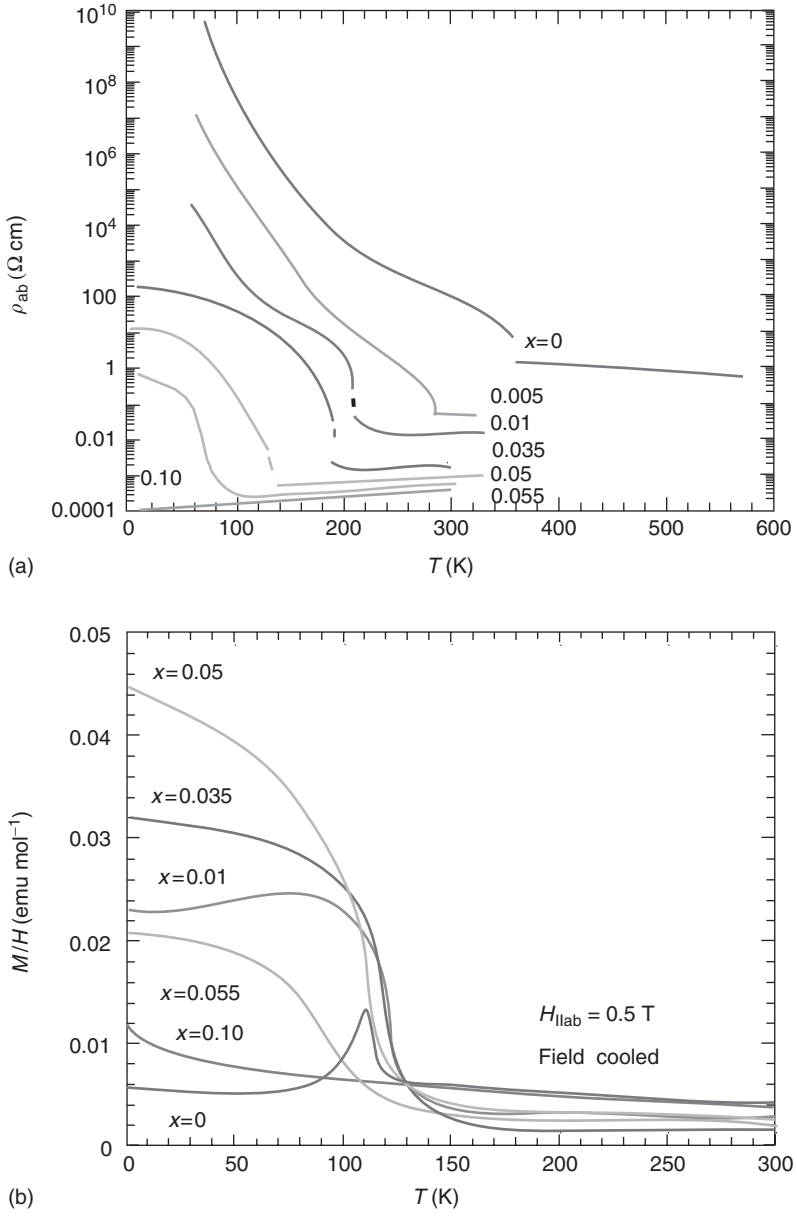

Figure 6 (a) Evolution of the resistivity and (b) of the magnetization vs. temperature for the oxides $Ca_{2-x}La_xMnO_4$. (Reprinted with permission from Cao G, McCall S, Shepard M, Crow JE, and Guertin RP (1997) Thermal, magnetic, and transport properties of single-crystal $Sr_{1-x}Ca_xRuO_3$ ($0 \lesssim x \lesssim 1.0$). *Physical Review B* 56: 321–329; © American Physical Society.)

Ca^{2+} in Ca_2RuO_4 shows that the doping with very small amounts of lanthanum lowers the MI transition dramatically down to 100 K and simultaneously the resistivity at low temperature can be decreased by several orders of magnitude (**Figure 6a**). Concomitantly, ferromagnetism is induced in the material (**Figure 6b**). The Curie temperature can reach up to 100 K, and remains lower than T_{MI}, suggesting that the metal–insulator transition is not driven by the magnetic instability. These results emphasize the competition of ferromagnetism and antiferromagnetism in these ruthenates.

The $n = 2$ members of the RP series, $Ca_3Ru_2O_7$ and $Sr_3Ru_2O_7$ consist of double perovskite layers "$A_2Ru_2O_6$" intergrown with single rock-salt "SrO" layers (**Figure 5b**). $Ca_3Ru_2O_7$ exhibits, like Ca_2RuO_4, a metal-to-insulator transition as T decreases, with $T_{MI} = 48$ K. Its magnetic phase diagram (**Figure 8**) shows that it is an antiferromagnetic Mott insulator below 48 K, and becomes a metallic ferromagnet between $T_{MI} = 48$ K and $T_N = 56$ K. Above T_N, this phase becomes paramagnetic and remains metallic. Remarkably, the phase becomes metallic as the magnetic field is increased beyond 6 T, suggesting that the

system becomes ferromagnetic (FMM). Note that the confluence of the limits at $T = 48$ K and $H = 4.1$ T lead to a multicritical point. Similar to $Ca_{2-x}La_{x}RuO_4$, the doping of $Ca_3Ru_2O_7$ at Ca sites changes the magnetism and transport of this oxide rapidly. The resistivity is decreased as x increases up to 0.04 in $Ca_{3-x}La_xRu_2O_7$ (**Figure 9**): finally, a fully metallic state is obtained for $x = 0.05$. In contrast to $Ca_{2-x}La_xRuO_4$, no ferromagnetism is induced by doping, that is, the antiferromagnetic metallic state characteristic of $Ca_3Ru_2O_7$ persists. However, remarkably, the application of a magnetic field, even modest, induces substantial ferromagnetism. The $M(H)$ curves (**Figure 10**) show that M_{sat} decreases rapidly as x increases and disappears for $x = 0.04$. They demonstrate that the metamagnetic transition is associated with the insulator-to-metal transition. Thus, La-doped or not, $Ca_3Ru_2O_7$ exhibits a negative magnetoresistance which can reach as high as 88%, depending on the temperature and magnetic field.

In contrast to $Ca_3Ru_2O_7$, $Sr_3Ru_2O_7$ is an itinerant ferromagnet at low temperature. Single crystals of this compound are grown. The zero field cooled (ZFC) and field cooled (FC) $M(T)$ curves (**Figure 11**) of this oxide registered at low field show a large magnetic anisotropy below $T_c = 104$ K, the easy axis being near [0 0 1]. It also evidences a broad maximum below T_c at $H \perp (0\,0\,1)$ (inset **Figure 11**) suggesting the presence of noncollinear spin structure in the ferromagnetic matrix. The $M(H)$ curves registered at $H \perp (0\,0\,1)$ for low temperature ranges show that the spin system undergoes a transition to a parallel spin configuration for a critical value of the magnetic field smaller than 3 T. This reorientation transition disappears at about 66 K in agreement with additional transition observed at $T^* = 66$ K on the $M(T)$ curve (**Figure 11**). All these observations are explained by a possible canting of the spins away from the [0 0 1] directions for $T < T^*$. The resistivity also exhibits a very large anisotropy as shown from the $\rho(T)$ curves (**Figure 12**). ρ_c/ρ_{ab} is indeed close to 3 at room temperature in accordance with the bidimensional character of the structure which favors the delocalization of the carriers within the basal plane of the RuO_6 octahedra. Note that besides the anomalies at T^* and T_c on the $\rho(T)$ curve, there exists a third anomaly $\sim$250 K whose origin is unknown. Like $SrRuO_3$, this oxide exhibits negative magnetoresistance, as shown from the $MR(T)$ curve (**Figure 13**)

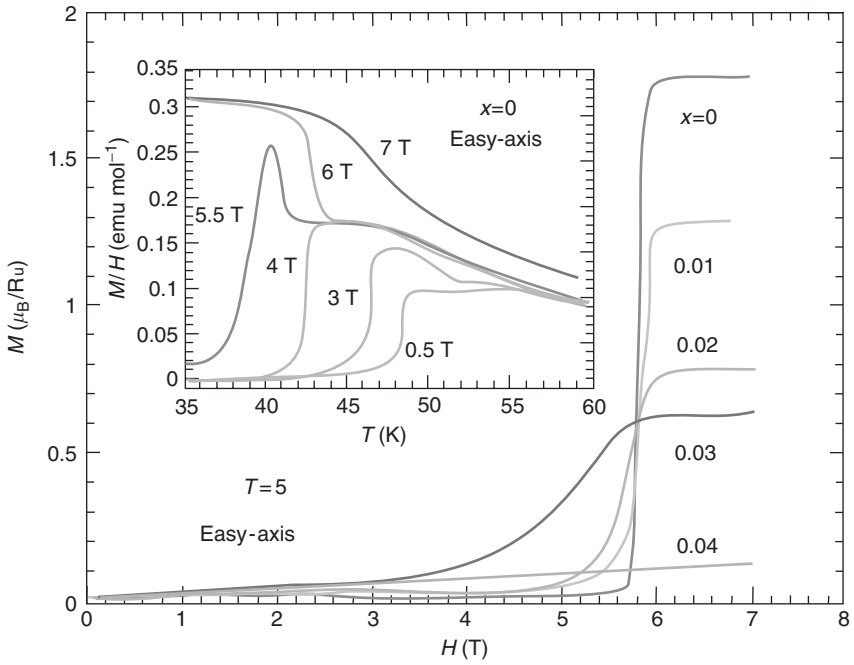

Figure 10 Magnetization vs. field at 5 K for $(Ca_{1-x}La_x)_3Ru_2O_7$. (Reprinted with permission from Cao G, McCall S, Shepard M, Crow JE, and Guertin RP (1997) Thermal, magnetic, and transport properties of single-crystal $Sr_{1-x}Ca_xRuO_3$ $(0 \lesssim x \lesssim 1.0)$. *Physical Review B* 56: 321–329; © American Physical Society.)

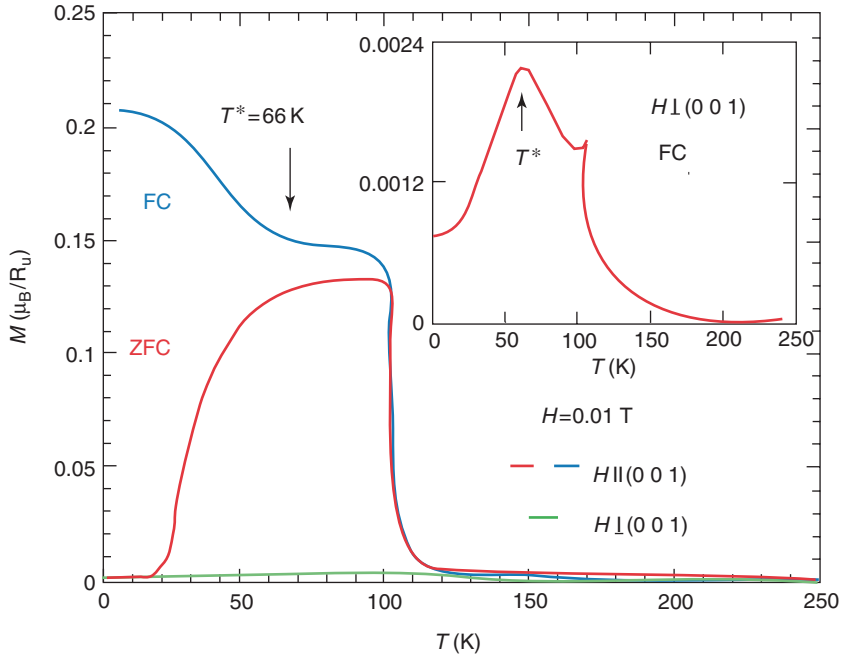

Figure 11 Magnetization vs. temperature at $H = 0.01$ T for $Sr_3Ru_2O_7$; red and blue lines: M vs. T with H II(0 0 1) measured in a zero field cooled (ZFC) and field cooled (FC) sequence; green line: M vs. T with $H\perp(0\,0\,1)$ after FC. Inset: M vs. T for FC at $H\perp(0\,0\,1)$. with $MR = (\rho(0\mathrm{T}) - \rho(10\mathrm{T}))/\rho(0\mathrm{T})$. One indeed observes a peak of magnetoresistance of $\sim$15% below T^*, suggesting that the effect originates mainly from the spin reorientation under the magnetic field. In contrast, the effect of T_c is small compared to $SrRuO_3$ which exhibits a maximum MR of $\sim$10% at T_c.

The third member of the RP series, $Sr_4Ru_3O_{10}$ consists of triple octahedral layers "Ru_3O_9" intergrown

with single rock salt "SrO" layers. The single-crystal study of this compound shows that like $Sr_3Ru_2O_7$, this oxide is ferromagnetic, with a T_c of 148 K, intermediate between that of $SrRuO_3$ and $Sr_3Ru_2O_7$. The $M(T)$ curves (**Figure 14a**) show that, in contrast to $Sr_3Ru_2O_7$, the easy axis lies in the *ab*-plane. Also differently from the latter phase, there is no clear evidence for spin reorientation at low temperature. The saturation value of the magnetization, of 1.75 μ_β, is in agreement with the low spin configuration generally observed for Ru(IV) d^4. The $\rho(T)$ curve (**Figure 14b**) of this phase is similar to that observed for $SrRuO_3$ with a Fisher–Langer anomaly at $T_c =$ 148 K. Like for $SrRuO_3$, one observes a small magnetoresistance, maximum at T_c ($\sim$6% under 10 T) due to the disappearance of the Fisher–Langer anomaly under a magnetic field.

Comparing the magnetic properties of the different members of the RP series, and taking into consideration the properties of the perovskite $(n = \infty)$, it clearly appears that in the Sr-RP series, ferromagnetic strength and consequently T_c increases as n increases, that is, as the dimensionality of the structure increases. In the same way, in the Ca-RP series, it is remarkable that the tendency to ferromagnetism, that is, T_N decreases as n increases, that is, as the dimensionality of the structure increases.

Hexagonal Ruthenates and Relatives

For large A-site cations, as, for instance, in $BaRuO_3$, the perovskite structure is no more stable and transforms into a "hexagonal perovskite" by sharing partly the faces of the RuO_6 octahedra. In this way, three forms of $BaRuO_3$ are actually known, called 9L, 6L,

and 4L due to the number of layers L characterizing the periodicity.

Two forms 9L and 4L, have been studied as single crystals. Their structures (**Figure 15**) consist of two-face sharing octahedra and three-face sharing octahedra for the 4L and 9L, respectively. These units are then connected along c through the apices of their octahedra like in the perovskite structure. It results in two sorts of overlapping of the d orbitals of Ru(IV): direct Ru–Ru *d*-interactions for the face-sharing octahedra and superexchange Ru–O–Ru–*p* interactions forming 180° angles for the corner-shared octahedra. Both oxides exhibit an almost temperature-independent magnetic susceptibility so that no local moment is detected on ruthenium, and can be interpreted as Pauli paramagnetism of conduction electrons. $BaRuO_3$ 4L exhibits indeed a metal-like behavior in the range 300–4 K, in both in-plane and out-of-plane directions (**Figure 16**). In contrast, $BaRuO_3$ 9L exhibits a very unusual behavior: the conductivity is first metal-like from 300 to ~100 K, but then an upturn of the resistivity is observed below 100 K (**Figure 16**). Moreover, the resistivity of these materials is sensitive to annealing under different temperatures.

The ruthenates $Ba_3MRu_2O_9$, with M = Fe, Co, Ni, Cu, In, all exhibit a 6H structure built up of units of two-face shared octahedra occupied by Ru, interconnected by single MO_6 octahedra (**Figure 15c**). In these phases, ruthenium is either pentavalent or mixed valent Ru(IV)–Ru(V). In contrast to $BaRuO_3$, all these oxides are semiconductors, due to the isolation of the Ru dimers by the M atoms. Magnetic susceptibility measurements show that the M-3*d* species have local moments below 400 K and that compounds with M = Co, Ni, Cu exhibit a magnetic transition near 100 K. The magnetic structure of these oxides varies with the nature of the M element. The oxides $Ba_3MRu_3O_9$ with M = Mg, Ca, Cd, Sr also exhibit the same 6H structure with a similar ordering of the ruthenium ions in the face-shared bioctahedra and of the M cations in the isolated corner-shared octahedra. These oxides are also semiconductors as expected for pure Ru(V) phases. The magnetic susceptibility behavior suggests that the *d*-electrons of Ru(V) are delocalized between the two sites of the bioctahedra in agreement with the Heisenberg–Dirac–Van Vleck model.

Pyrochlore Ruthenates

Ruthenates with the pyrochlore structure (**Figure 17**), built up of corner-sharing octahedra were extensively studied, mainly for their transport properties, which are closely related to their oxygen nonstoichiometry. For instance, $Bi_2Ru_2O_7$ and $Pb_2Ru_2O_{6.5}$ were found to exhibit a metal-like behavior, with resistivity of $\sim 10^{-3}\,\Omega$ cm at room temperature and a Pauli paramagnetism. Based on XPS, UPS, and EELS

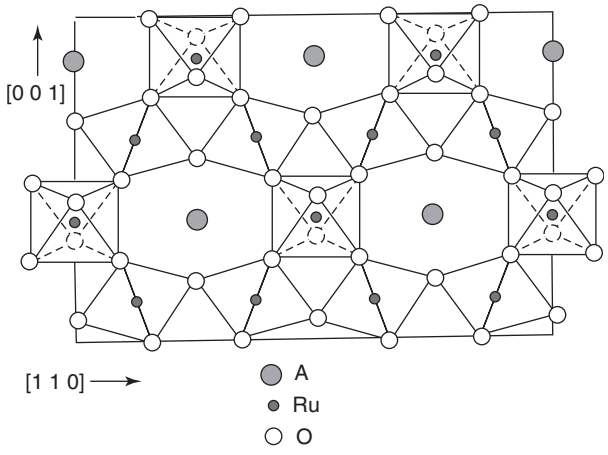

Figure 17 Pyrochlore structure of $A_2RU_2O_{7-\delta}$ ruthenates.

studies, it was shown that the *6p* states of Bi and Pb which are close to the Fermi level can participate in the conductivity by mixing with Ru-4*d*-orbitals via the 2*p*-oxygen-orbitals. In contrast, rare-earth ruthenates $Ln_2Ru_2O_7$ Ln = Pr−Lu, Y were found to be semiconductors with low activation energies. The difference in conductivity between $Ln_2Ru_2O_7$ and $Bi_2Ru_2O_7$ has been attributed to the bending of Ru–O–Ru band which is larger for $Ln_2Ru_2O_7$ (Ru–O–Ru angle $\approx 128^\circ$) than for $Bi_2Ru_2O_7$ (Ru–O–Ru angle $\approx 138^\circ$). This viewpoint is supported by the study of the solid solution $La_{2-x}Cd_xRu_2O_7$, which also exhibits metallic conductivity, for Ru–O–Ru band angles similar to $Bi_2Ru_2O_7$, but is characterized by large paramagnetic susceptibilities. Similarly, the studies of the solid solutions $Bi_{2-x}Ln_xRu_2O_7$ and $Pb_{2-x}Ln_xRu_2O_7$ with Ln = Y, Pr–Lu, clearly show that the metal–insulator crossover observed for these oxides at temperatures ranging from 40 to 80 K, is correlated to the bending of the Ru–O–Ru band and to the distortion of the RuO_6 octahedra. Finally, the pyrochlore $Tl_{2-x}Ru_2O_{7-\delta}$, which was synthesized under high pressure, is a good example of the great influence of cationic and oxygen non-stoichiometry upon the transport properties of this structural family, prepared under high pressure. In reducing conditions, these phases exhibit a metallic behavior (**Figure 18a**) whereas in neutral atmosphere (**Figure 18b**) or under high oxygen pressure (**Figure 18c**), they show a metal-to-insulator transition at about 40 and 120 K respectively. The latter transitions are correlated to structural changes versus temperature. The magnetic properties of these oxides are so far not completely elucidated showing spin-glass-like behavior and magnetic anomalies at different temperatures (40 and 120 K), depending on

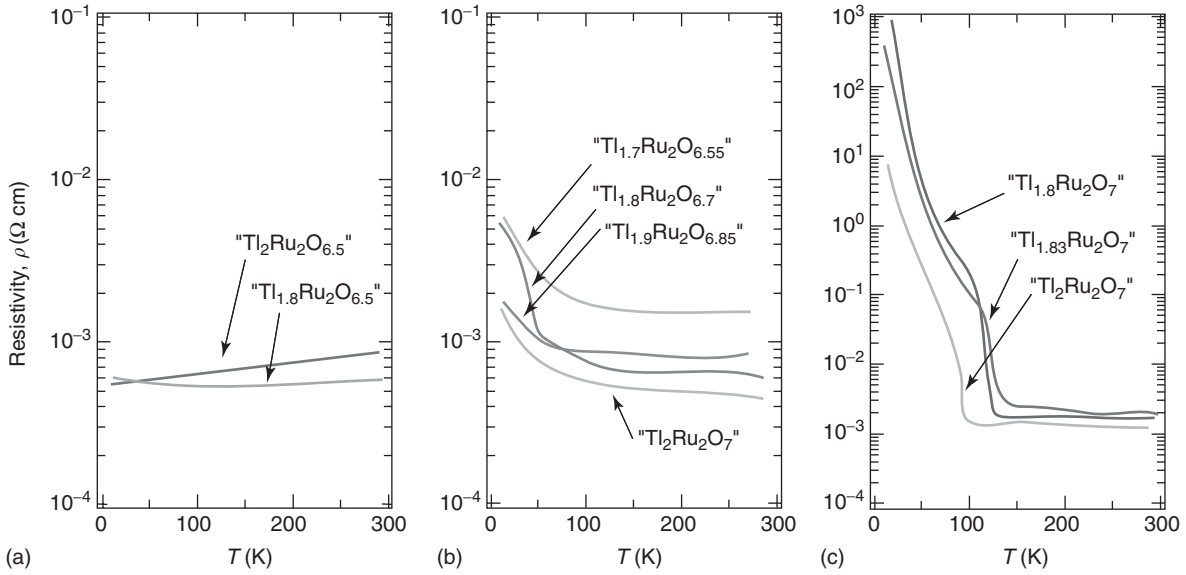

Figure 18 Temperature dependence of resistivity for thallium pyrochlores with various nominal compositions prepared under pressure (a) in reducing conditions (b) in neutral atmosphere, and (c) under high oxygen pressure. (After Takeda T, Nagata M, Kobayashi H, Kanno R, Kawamoto Y, *et al.* (1998) *Journal of Solid State Chemistry* 140: 182–193.)

the conditions of synthesis, that is, of the chemical composition of the so-studied pyrochlore.

The Quasi-One-Dimensional Ruthenates Ln_3RuO_7

The lanthanide ruthenates Ln_3RuO_7 (Ln = La−Sm) exhibit, from the viewpoint of Ru arrangement, a 1D-type structure built up of chains of corner-sharing RuO_6 octahedra. The magnetic and transport properties of La_3RuO_7 reflect its 1D geometry. One indeed observes that this phase is a semiconductor even along the chain, though the Ru–O–Ru angles of 145° are very similar to those observed for 3D pyrochlore ruthenates. The magnetic data show that this Ru(V) oxide exhibits a Curie–Weiss behavior above 50 K and an antiferromagnetic order below this temperature. In fact, a short-range antiferromagnetic order is observed in the range 20–50 K which becomes long range below 20 K.

Ruthenium as a Substituting Element in Oxides

The ability of ruthenium to adopt an octahedral coordination makes it possible to be substituted for transition elements in many oxides. As a consequence, its electronic configuration either as d^4 Ru(IV) or as d^3 Ru(V), and the broad extension of its d orbitals, suggests that such an element is susceptible to induce new physical properties in already known materials.

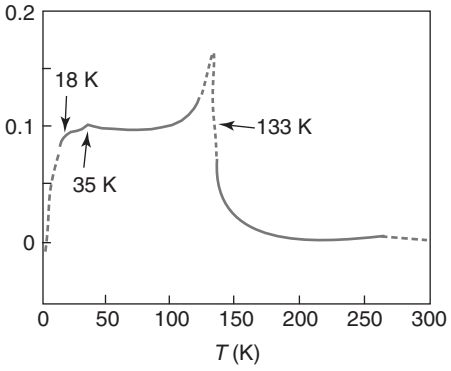

Figure 19 AC susceptibility measurements of $RuSr_2Cu_2O_8$, showing that superconductivity exists up to 35 K, with $T_c = 18$ K and $T_c = 133$ K. (Reprinted figure with permission from Chmaissem O, Jorgensen JD, Shaked H, Dollar P, and Tallon JL (2000) *Physical Review B* 61: 6401–6407; © American Physical Society.)

Two examples of this promising role of Ru to induce exciting properties are described.

The first example deals with the introduction of Ru in the 1212 structure of cuprates. It has been discovered that the 1212 ruthenocuprate $RuSr_2GdCu_2O_8$ is both a superconductor with a T_c = 15–40 K, and a ferromagnet with a $T_c = 133-136$ K (**Figure 19**). The coexistence of superconductivity and ferromagnetism below 15–40 K appears most surprising, since, according to Ginzburg investigations, such a feature should not be possible at a microscopic scale. The particular layered structure of this compound (**Figure 20**), which consists of superconducting pyramidal copper layers stacked with octahedral ruthenium layers, is certainly the key to

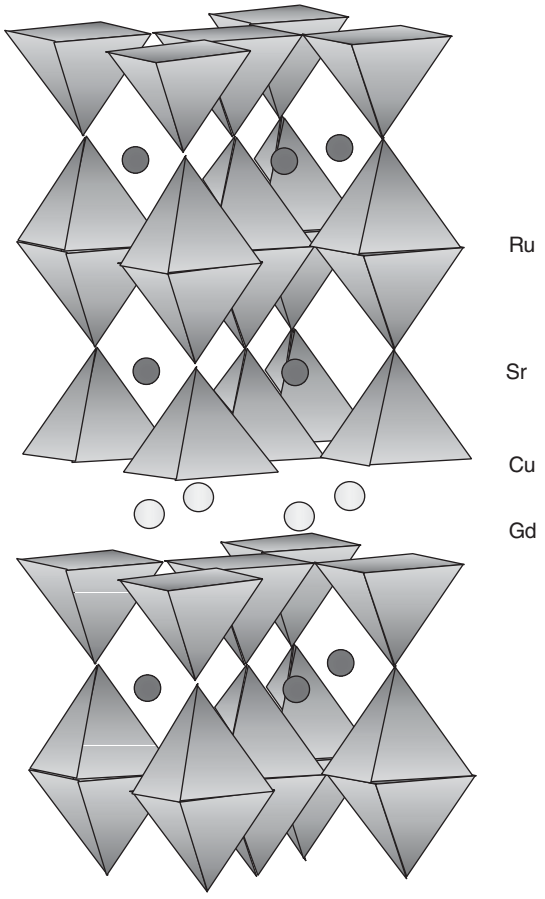

Figure 20 The 1212 structure of $RuSr_2GdCu_2O_8$ built up of layers of RuO_6 octahedra stacked with layers of CuO_5 pyramids.

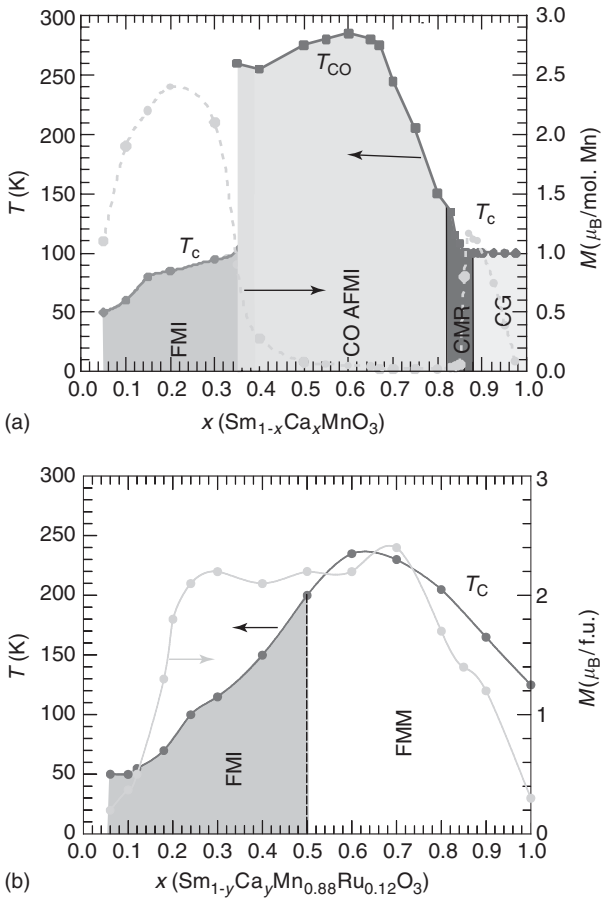

Figure 21 Magnetic phase diagrams of the manganites $Sm_{1-x}Ca_xMnO_3$ (a) and $Sm_{1-x}Ca_xMn_{0.88}Ru_{0.12}MnO_3$ (b).

the understanding of this behavior, since this structural separation should decrease the interactions between ferromagnetism and superconductivity dramatically. In any case, this extraordinary behavior suggests that numerous investigations are still in progress to help understand the physics of these materials.

The second example deals with the doping of perovskite manganites with ruthenium at the Mn site. It was shown that the partial substitution of ruthenium for manganese in charge-ordered manganites such as $Sm_{0.5}Ca_{0.5}MnO_3$, which are insulator ferromagnets, induces ferromagnetism and a metal–insulator transition, and consequently, colossal magnetoresistance (CMR) effects. Thus, very high T_c up to 220 K can be reached by Mn-site doping, changing completely the magnetic-phase diagram of the manganites. This is illustrated for $Sm_{1-x}Ca_xMnO_3$ (**Figure 21a**) doped with 12% Ru (**Figure 21b**). It can be seen that the T_c of the ferromagnetic insulating region is increased by Ru substitution, but, more importantly, that the broad charge-ordered antiferromagnetic domain (**Figure 21a**) is suppressed and replaced by a ferromagnetic metallic region with a T_c up to 200 K. This great ability of Ru to induce ferromagnetism and metal-like behavior can be explained by both, its ability to couple ferromagnetically with manganese neighbors, and the large extension of its *d*-orbitals allowing conduction paths to be enhanced.

Scanning Near-Field Optical Microscopy

A Cricenti, ISM-CNR, Rome, Italy

Introduction

Historical Background

At the beginning of the twentieth century, a method was proposed to overcome the resolution limits of classical optical microscopy. The idea was based on raster-scanning an aperture much smaller than the wavelength in close proximity to the sample. Furthermore, in order to obtain a subwavelength resolution, such a scan should be performed at very small distances from the sample. This proposal was demonstrated to be very far ahead of its time, but due to the necessity of performing the scan at less than 10 nm from the sample, it could not be verified experimentally. The first proof of this idea came in the microwave region half a century later. Subsequently, after the invention of the scanning tunneling microscope (STM) in 1982, it became possible to rely on the introduction of experimental techniques able to maintain a strongly localized tip at distances <10 nm from the surface, whereas the tip–sample distance control was realized by monitoring a well-determined physical parameter in the interaction region (in the case of the STM, this parameter is the tunneling current between tip and surface). In 1984 scanning near-field optical microscopy (SNOM) was reinvented on the basis of the proposed method and opened the doors to a new kind of spectroscopy.

Basic Principle of SNOM

SNOM is based on the detection of the evanescent waves that are directly connected to the subwavelength features of the object: such waves do not propagate and are confined in the near-field region, decaying on distances of the order of fractions of the wavelength λ. They are revealed and transformed into propagating waves, in air or inside an optical fiber, by a nanodetector (tapered optical fiber) located few nanometers from the surface. In this way, it is possible to overcome the $\lambda/2$ limit imposed by diffraction and to obtain information on sample details absolutely not accessible to conventional microscopy. In order to try to understand this phenomenon, some very simple arguments in the theory of the electromagnetic field are first summarized.

Far Field and Near Field

What is the electromagnetic field generated by an electrical dipole placed at a given point O with the moment-vector parallel to the z-axis?

The electromagnetic field generated by an electrical dipole in a point $P(r, \theta, \phi)$ (see **Figure 1**), placed at a distance r from the origin O, and with the condition that the dipole axis $d \ll r$, can be calculated by using the Maxwell equations, starting from the potential vector A_z and the scalar potential $V(\boldsymbol{r}, t)$, assuming an oscillating retarded function of time $p = p_0 \sin \omega(t - r/c)$ for the emitted light with p' and p'' as its first and second derivative, respectively, and $p_0 =$ constant:

$$A_z = \frac{\mu_0}{4\pi}\frac{p'}{r}$$

$$V(\boldsymbol{r}, t) = \frac{1}{4\pi\varepsilon_0}\left(\frac{p'}{rc} + \frac{p}{r^2}\right)\frac{z}{r}$$

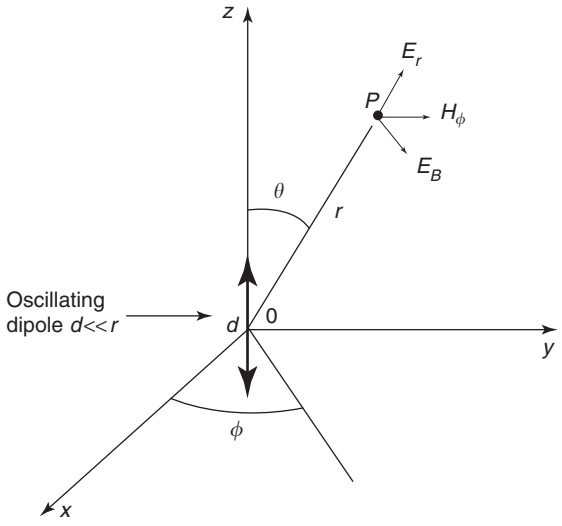

Figure 1 Diagram of the electromagnetic field generated by a dipole oscillating along z-axis.

Using spherical coordinates,

$$A_r = \frac{\mu_0}{4\pi}\frac{p'}{r}\cos\theta, \quad A_\theta = \frac{-\mu_0}{4\pi}\frac{p'}{r}\sin\theta, \quad A_\phi = 0$$

$$V = \frac{1}{4\pi\varepsilon_0}\left(\frac{p'}{rc} + \frac{p}{r^2}\right)\cos\theta$$

With

$$\boldsymbol{B} = \text{rot}\,\boldsymbol{A}$$

$$B_r = 0, \quad B_\theta = 0, \quad B_\phi = \frac{\mu_0}{4\pi}\left(\frac{\sin\theta}{r}\right)\left(\frac{p''}{c} + \frac{p'}{r}\right)$$

$$\boldsymbol{E} = -(\text{grad}\,V + \boldsymbol{A})$$

$$E_r = \frac{1}{4\pi\varepsilon_0}\left(\frac{2\cos\theta}{r}\right)\left(\frac{p'}{cr} + \frac{p}{r^2}\right)$$

$$E_\theta = \frac{1}{4\pi\varepsilon_0}\left(\frac{\sin\theta}{r}\right)\left(\frac{p''}{c^2} + \frac{p'}{cr} + \frac{p}{r^2}\right), \quad E_\phi = 0$$

Note that the electric field is perpendicular to the magnetic field and that there are terms depending on $1/r$, $1/r^2$, and $1/r^3$; different components have a different meaning. The energy associated with the electromagnetic field traveling in a certain direction with velocity c is due only to the terms containing $1/r$. In fact, for $r \gg \lambda$, i.e., for large distances,

$$B_r = 0, \quad B_\theta = 0, \quad B_\phi = \frac{\mu_0}{4\pi}\left(\frac{p''}{rc}\right)\sin\theta$$

$$E_r = 0, \quad E_\theta = \frac{1}{4\pi\varepsilon_0}\left(\frac{p''}{rc^2}\right)\sin\theta, \quad E_\phi = 0$$

The Poynting vector and its flux are given by

$$\boldsymbol{S} = \boldsymbol{E} \times \boldsymbol{H} = \frac{\mu_0}{16\pi\varepsilon_0 c^3}\left(\frac{p''}{r}\right)^2 \sin^2\theta$$

$$F(\boldsymbol{S}) = \int Sr^2 \sin\theta\, \mathrm{d}\theta = \text{constant}$$

The flux does not depend on the radius of the sphere. There is no decrease or accumulation of energy when the wave is passing and the wave has an independent identity. If the condition of near-field, $r \ll \lambda$, is satisfied, the terms $1/r^2$ and $1/r^3$ present in the electromagnetic field must also be taken into account. In the calculation of the Poynting vector, new terms with higher-order dependence in r (r^{-3}, r^{-4}, and r^{-5}) are present and correspond to nonradiating field components. By time average, one obtains

$$S' = S \quad \text{and} \quad F(S) = F(S')$$

The terms $1/r^2$ and $1/r^3$ do not contribute to the traveling wave: they describe the near field that is important only for $r \ll \lambda$.

Experimental Setup

SNOM Configurations

There are many configurations in which SNOM can work, both in reflection and in transmission. Some of the most used ones are:

1. *Transmission collection mode*. The tip collects the light transmitted by the sample illuminated by a conventional source;
2. *Transmission illumination mode*. The tip plays the role of a nanosource and the light transmitted is collected by a conventional detector;
3. *External reflection collection mode*. The sample is illuminated by a laser beam and the tip collects the light scattered locally and drives it into the detector;
4. *Internal reflection collection mode*. The illumination beam is totally reflected inside a piece of glass and the tip collects the resulting evanescent waves lying on the sample surface;
5. *External illumination collection mode*. It is a combination of (1) and (2);
6. *Internal reflection illumination mode*. It is the inversion of (4) so that the light is detected beyond the critical angle (where the conditions of total reflection are realized); and
7. *Internal reflection perturbation mode*. A completely opaque tip perturbs the evanescent field on the object surface generated as in (4).

Photocurrent measurements can also be performed by directly illuminating the sample by the optical fiber. In this case the back contact of the specimen is directly fed into an *I–V* converter preamplifier with a fixed gain to reveal the electron current induced by the incoming photons.

Besides these configurations, the SNOM can work in two different modes of operation: *constant-height mode* (the tip raster-scans the surface at fixed height), and *constant-distance mode* (the tip raster-scans the surface maintaining the same gap from the sample).

For any of the SNOM arrangements, in order to monitor the tip position, a shear-force control mechanism is operating: in this configuration the tapered tip is forced to oscillate laterally (see **Figure 2**) by a piezoceramic at its resonance frequency. When the fiber is approaching the surface, the vibration amplitude begins to decrease progressively with distance due to the tip–sample interaction. By monitoring the

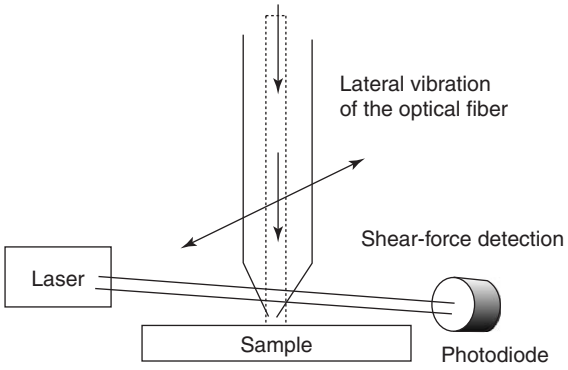

Figure 2 External reflection collection mode and shear-force control.

shear-force signal it is possible to maintain the tip at nanometric distance from the sample and to obtain a topographic image of the sample area over which the scan is realized. The electronic apparatus allows one to collect one or more optical images simultaneously, so that information concerning the local sample optical properties, the dielectric constant, etc., are obtained with a resolution well below $\lambda/2$.

The possibility to change the wavelength λ of the external laser beam allows the observation of the presence of topographic, chemical, or electronic defects in the optical image with a lateral resolution limited by the size of the fiber-tip aperture (~ 50 nm), and a vertical resolution that depends both on the light penetration depth and on the matrix element that governs the interaction between the light and the sample. Considering a penetration depth proportional to λ, we can suppose that the observed defect in the optical image is at a distance less than λ from the sample surface. This kind of investigation turns out to be very important in characterization of defects in layers below transparent films not accessible to a topographic analysis and in the observation of toxic compounds inside biological samples.

Instrument Description

As already stated, in order to bypass the diffraction limit, it is necessary to have a subwavelength aperture of the tapered fiber and small structures in the sample so that features smaller than $\lambda/2$ can be observable in the optical image. How do we create a subwavelength aperture at an optical fiber? SNOM probes for visible and near-infrared light can be fabricated starting from single-mode silica fibers (range of transmission, 450–2000 nm), whereas infrared SNOM (range of transmission, 2000–10 000 nm) probes can be made from single-mode chalcogenide (arsenic sulphide) fibers (**Figure 3**).

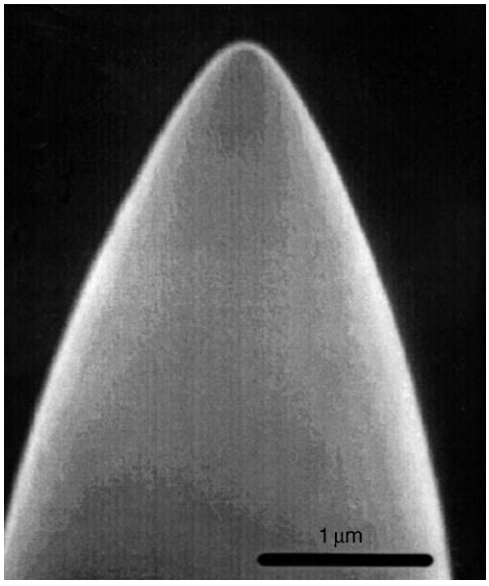

Figure 3 Scanning electron micrograph of a chalcogenide fiber SNOM tip.

One end of the fiber is interfaced to the detector while the other end is reduced to a small aperture using a standard micropipette puller or chemically etched using a protective layer etching system. The tips so obtained are then coated with a metal, aluminum, or gold, using a thermal evaporation deposition system at a pressure of 10^{-6} mbar. In order to leave an aperture, the tips are put at an angle of 25–30° above the evaporation point source and rotated to achieve a fairly uniform coating with an approximate coating thickness of 100–125 nm. With this procedure, tips with an aperture ranging between 20 and 100 nm are easily obtained.

The main components of an SNOM unit are a sample movement and a detection system combined in a way that, apart from the requirements of reliability and mechanical stability, would allow analyzing a sample with all available geometries for input/output of photons, in order to get as much information as possible on the sample. This instrument is shown in **Figure 4** and in the picture in **Figure 5** and is essentially shaped like a two-piece cylinder, the lower part containing the sample holder with its movements and the upper part hosting the fiber and the detection system. The two halves are held together by means of a screwlock that is used both to fit samples of several millimeters height and for a rough approach between fiber and sample.

The fiber tip fits tightly into a small tube, attached to a piezoceramic, used to vibrate the fiber for a few nanometers, thus allowing a shear-force signal, and mechanically attached to the top half of the cylinder. The lower half of the cylinder contains the sample

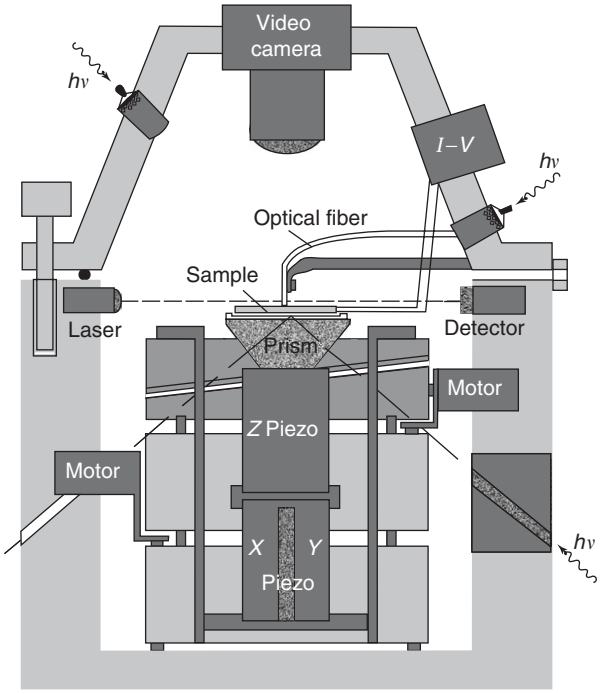

Figure 4 Schematic diagram of the mechanical part of the SNOM head (upper cylinder) and the sample holder (lower cylinder).

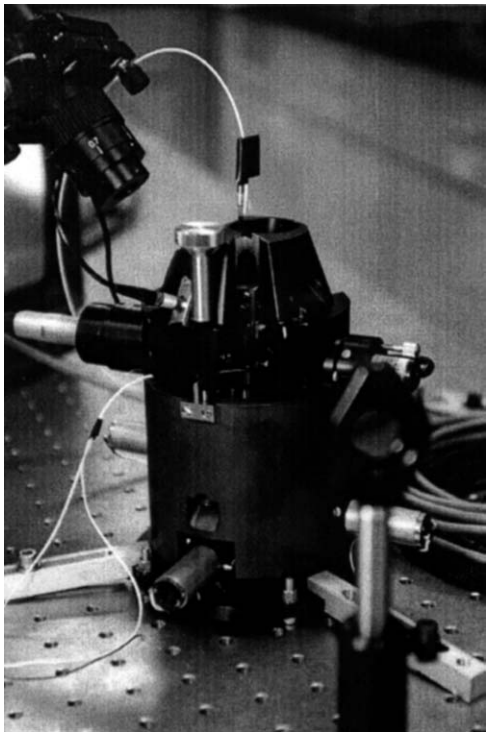

Figure 5 Diagram of the SNOM described in **Figure 4**.

holder, a piezoelectric scanner and *x*–*y*–*z* motor-controlled translators. The piezoscanner consists of two piezoceramic hollow cylinders glued together, with the upper one used for *z*-motion and a magnetic piece for holding samples attached to a magnetic support. The front and back contacts of the sample holder are used to feed a signal into an *I*–*V* converter in order to measure the electron current induced by the incident photons on the sample. The lower piezo is divided into four perpendicular sectors for *x*–*y* motion with an available *z*-motion of $\sim 8.0\,\mu m$ and an *x*–*y* scanning motion of $\sim 40.0\,\mu m$ for each axis. The piezoscanner is fixed onto a motorized *x*–*y*–*z* translator that can be moved several millimeters along the three axes. A video camera is usually mounted onto the top cylinder in order to control the rough approach between tip and sample and to position different regions of the sample below the probe.

The instrument allows measuring the local reflectivity when the sample is illuminated by an external source either directly or through the fiber: in both cases the optical fiber picks up the light reflected by the surface. Several detectors, positioned at the other end of the optical fiber, can be used to detect light depending on the photon wavelength. The detected signal is revealed by a lock-in amplifier whose analog output is converted by an analog-to-digital converter (ADC) module and read by the computer through a digital I/O card. The fiber can also detect the evanescent wave when the sample is illuminated in the back.

Figure 6 shows the layout of an SNOM experiment. The shear force is detected through a 670 nm single-mode diode laser that is focused onto the external body of the oscillating fiber and the resulting shadow is revealed by a two-sector position-sensitive detector and fed into the electronic feedback loop to keep a constant shear-force signal between fiber and sample while scanning the sample. Shear-force images are taken with a signal that is 70% of the initial amplitude value of free oscillation. A feedback circuit operates in such a way that as the sample approaches the fiber and a change in the shear-force amplitude is detected, the feedback circuit becomes active and the stepping is stopped: this method avoids fiber crashing onto the specimen.

A major requirement of any SNOM apparatus is a suitable photon source which must be both intense and tunable. Tunability is required to cover the relevant absorption bands that are present on the sample. Intensity is a critical point because of the inefficient light transmission of the narrow fiber tip. Laser modules and free electron laser (FEL) sources are ideal for this problem because of their unique combination of extreme intensity and broad tunability.

Experimental Results

Some results on representative samples will now be presented to give an overview of possible applications in materials science and biology and the great potential of the SNOM technique when used in a spectroscopy mode with an appropriate tunable source.

Diamond on Silicon

The first results concern a polycrystalline diamond film prepared by vapor-phase deposition on a silicon substrate. In principle, these should be hydrogen-free specimens after annealing to remove residual hydrogen and water. This point was tested by looking with Fourier transform infrared spectroscopy (FTIR) for absorption near 3.5 μm, due to the C–H vibrational stretch mode. In fact, the observed presence of such a band in the FTIR spectrum indicates that some hydrogen is left in the sample after annealing.

Figure 7 shows a $10 \times 10\,\mu m$ shear-force image together with the corrugation along the AA′ line. Small features on the individual diamond grains are quite well resolved: from reproducible structures in several consecutively acquired images, the best lateral resolution of the probe is estimated to be between 50 and 80 nm. Since irregularities in the probe are expected to be a large detriment to lateral resolution on rough specimens, these topographical images indicate that the probe tip itself is smoothly rounded.

Figure 8 shows a $10 \times 10\,\mu m$ reflectivity image of the same zone as in **Figure 7**, with the FEL operating at 3.5 μm, together with the corrugation along the

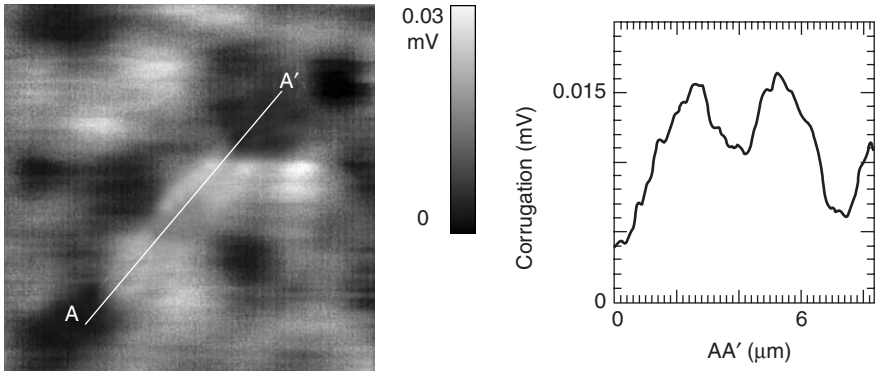

Figure 8 Reflectivity image, taken simultaneously with the topography of **Figure 7**, of diamond grains on a silicon substrate taken with a photon wavelength of 3.5 μm, together with the corrugation along the AA′ line.

AA′ line. The correlation between optical data and certain features in the topographical image can be seen clearly. When the FEL is tuned outside the C–H absorption band (to 3.2 or 3.7 μm), the topographical image is reproduced, whereas the optical image becomes featureless, indicating that the dark regions in the optical image of **Figure 8** correspond to regions where the absorption was stronger, or where there was residual hydrogen in the film. Although the relative intensity noise in the FEL (which could not be normalized out in the apparatus used for this experiment) is evident in **Figure 8**, several small features and edges are still resolved. From these, the optical lateral resolution was estimated to be 100 nm, well below the classical limit of $\lambda/2$.

Boron-Doped Silicon

B^+ ion implantation in silicon is the most useful *p*-type doping process and it is crucial to determine as-implanted and postanneal impurity distributions with the highest possible accuracy. Since implantation of energetic ions into silicon induces a large amount of crystal damage in the semiconductor consisting of high concentrations of interstitials and vacancies much higher than the implant dose, rapid thermal annealing is used to restore lattice order and to achieve dopant activation. Any annealing step is a highly nonequilibrium process and involves the formation/dissolution of extended defects, metastable phases and precipitates. As a result, both point defects and dopant atoms experience a high mobility characterized by anomalous diffusion, namely, transient enhanced diffusion. Dopant atoms may also form inactive immobile clusters and may deactivate much below their solid solubility. Since the solid solubility of B in Si is limited to 2×10^{20} atoms per cm^3, for increasingly high implant doses there is an increasing tendency for impurity atoms to cluster within the Si lattice after annealing.

In this case, a combination of internal photoemission (IPE) and SNOM has been used to investigate the electronic properties of silicon after boron implantation and annealing. Three different wavelengths have been used (633 nm (not shown), 1330 nm, and 1550 nm (not shown)) to locally illuminate the sample. Shear-force, reflectivity, and photocurrent images were collected simultaneously and compared in order to discriminate between true structures and artifacts. For the acquisition of R images the tapered optical fiber locally illuminates the sample and collects the light normally reflected at the surface by means of a fiber coupler while the photocurrent signal is measured by an *I–V* converter preamplifier with a gain of $10^8\,V\,A^{-1}$.

Depending on the level of boron concentration, the photocurrent shows intensity variations within two orders of magnitude. Boron clusters behave as metal clusters embedded into the silicon matrix and introduce gap states, which give rise to the observed photocurrent. The images reported here are for an Si(1 0 0) sample with the mean boron concentration values, in the first micron of depth, of $\sim 5 \times 10^{19}\,cm^{-3}$.

Figure 9 shows a 10×10 μm image of the shear-force (a), photocurrent (b), and reflectivity (c) taken with a photon wavelength of 1330 nm, that is below the indirect bandgap of silicon: as visible, there is no correspondence between the shear-force and photocurrent images acquired on the same silicon sample scanned area. As evidenced by the white traces (AA′) in both the images, there is a reflectivity enhancement with no correspondence in the shear-force image and that might be due to a subsurface defect. The shear-force and reflectivity images show surface-related structures not related to boron and give rise to local minima in the photocurrent image due, probably, to scattering of the impinging light. The photocurrent image shows the presence of a buried boron cluster, which has no correspondence in the

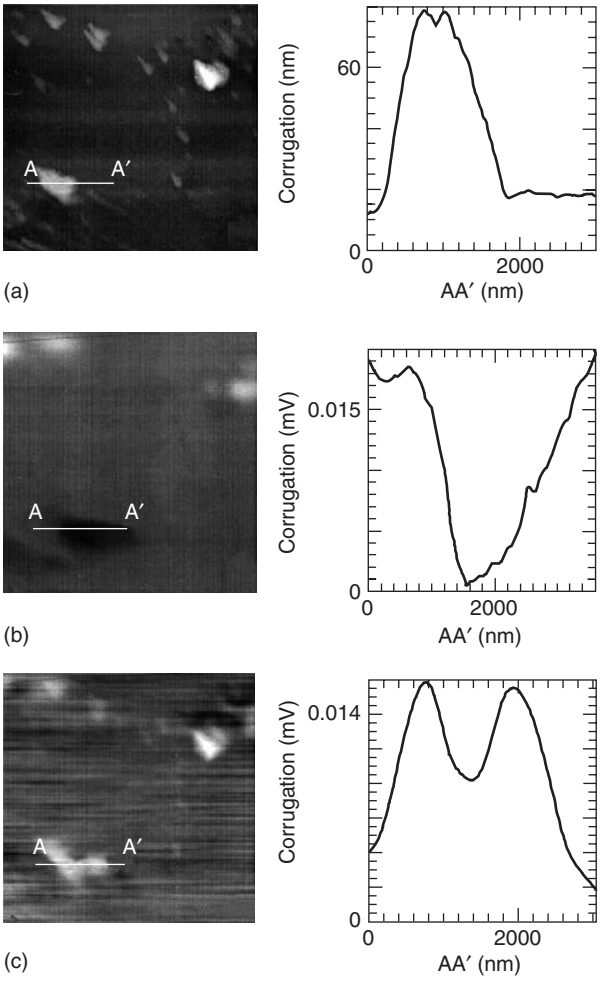

Figure 9 A $10 \times 10\,\mu m$ image of the shear-force (a), photocurrent (b), and reflectivity (c) taken with a photon wavelength of 1330 nm, for a Si(1 0 0) sample with the mean boron concentration values, in the first micron of depth, of $\sim 5 \times 10^{19}\,cm^{-3}$.

shear-force and reflectivity images and is characterized by lateral dimensions of several hundred nanometers. A resolution less than 100 nm (i.e., $\sim\lambda/13$) is observable in both the reflectivity and the photocurrent images that have been collected in many different areas of the sample. However, it has to be mentioned that these results are certainly affected by the convolution of the tip aperture with the penetration depth, $\alpha = \lambda/4\pi k$, of the light and by the subsequent diffusion of the excited carriers from the excitation volume, which should deteriorate the ultimate resolution.

Biological Growth Medium

An important first step in the SNOM evaluation of biological structures is the IR characterization of the biological growth medium. The growth medium is composed of several products, primarily sulfur and nitrogen oxide compounds, whose vibrational stretch mode absorption bands occur in the infrared $\sim 7\,\mu m$. The SNOM images presented here were taken by tuning the FEL to $\lambda = 6.95\,\mu m$, that is, at such absorption band, and at $6.6\,\mu m$, which is outside the absorption band, in order to estimate the noise-background contributions. Also in this case, the tunability is required to cover the relevant absorption bands, and intensity is a critical point because of the inefficient light transmission of the narrow fiber tip. FEL sources are ideal for this problem because of their unique combination of extreme intensity and broad tunability. The FEL photons are sent to the sample surface and detected after reflection by the narrow-point optical fiber tip mounted on the SNOM module.

Figure 10 shows two $20 \times 20\,\mu m$ SNOM reflection images obtained with $\lambda = 6.95\,\mu m$ photons (image (c)) and with the adjacent wavelength, $\lambda = 6.6\,\mu m$ (image (a)). In the reflection images, darker areas correspond to stronger absorption. The contrast between the featureless image off-absorption and the microstructures of the on-absorption image is striking. Are these microstructures really related to the growth medium constituents or are they just artifacts? To answer this question, it is important to compare the corresponding shear-force (topological) image of (b). First, the same topological image is observed at the two different wavelengths (image (b)). The topological images show the presence of several biological growth medium grains with width and height of a few micrometers. Furthermore, for artifacts, one would expect a similar optical image when collecting data at $6.6\,\mu m$ (image (c)) and $6.95\,\mu m$ (image (a)): absolutely no one-to-one correlation is observed between the two SNOM images, ruling out artifacts. This proves, in fact, that the dark regions in the on-absorption SNOM image of (c) correspond to regions with strong growth medium component concentrations related absorption.

It is quite instructive to analyze the lateral resolution of the topographic and spectroscopic-SNOM images obtained in this work. For the topographic images, line scans yield a lateral resolution of 50–80 nm, demonstrating the high quality of the fiber tips. On the other hand, similar line scans for the spectroscopic SNOM images (see the slope in the profile AA′) demonstrate a lateral resolution of 200 nm, which is well below the classical-microscopy limit ($\lambda/2$).

Fluorescence SNOM on Biological Cells

Another particularly exciting application of SNOM is in the observation of fluorophore agents inside a

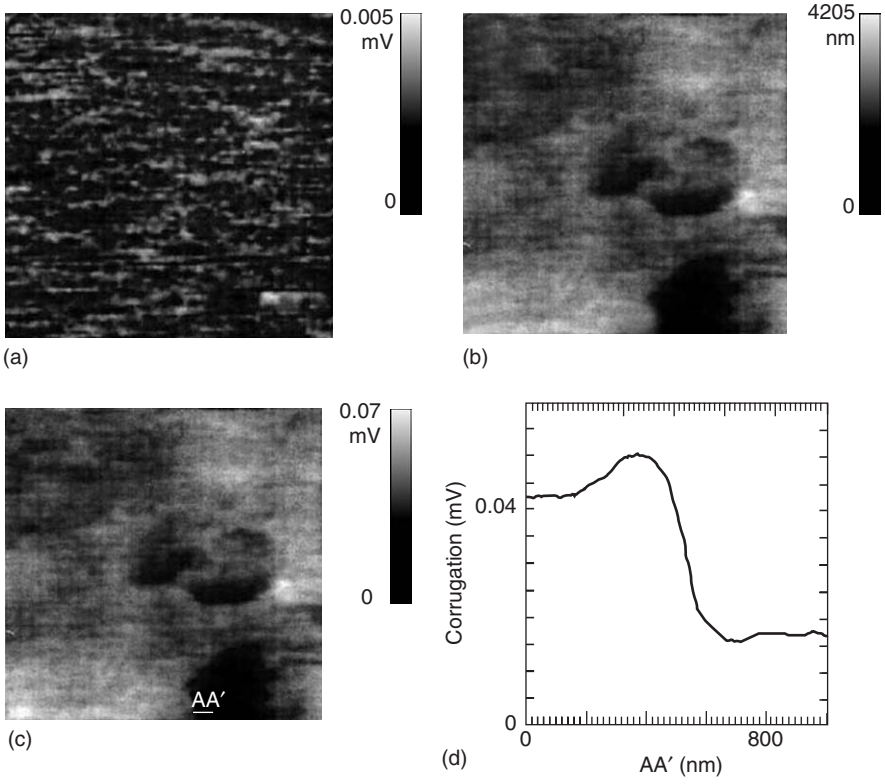

Figure 10 Left: $20 \times 20\,\mu m$ SNOM reflection images obtained with $\lambda = 6.95\,\mu m$ photons (c), corresponding to the vibrational stretch mode absorption bands of sulfur and nitrogen oxide compounds, and with an adjacent wavelength outside the absorption band, $\lambda = 6.6\,\mu m$ (a). Darker areas correspond to stronger absorption. Right: corresponding shear-force (topographic) image (b), brighter areas correspond to higher topography values, and a corrugation (d) taken along the AA′ line on the reflectivity image taken with $\lambda = 6.95\,\mu m$ in (c).

biological cell. The effect of a 50 Hz electromagnetic field (EMF) on morphological and biochemical properties of human keratinocytes (HaCaT) is being shown here. Control and exposed cells were immunolabeled with a fluorescent antibody to test the cells for the presence of $\beta 4$ integrin, a molecule marker for cell adhesion and differentiation. In this case the tapered metal-coated optical fiber is illuminating the sample through its small aperture, acting as a subwavelength light source, exciting the fluorophore locally, at a wavelength of 488 nm. Thus, only a small volume of the sample is optically illuminated, minimizing the fluorophore bleaching and the biological damage normally occurring in the optical fluorescence microscopy. The fluorescence signal is detected at 514 nm after blocking the excitation wavelength.

Figure 11a is a $20 \times 20\,\mu m$ topographic image of exposed cells showing that, after exposure to an electromagnetic field, cells become much closer to each other. The corresponding SNOM fluorescence image is reported in **Figure 11b**, showing strong fluorescence signal at all cell structures, demonstrating the presence in the cell membrane of the adhesion molecule $\beta 4$ integrin (a protein implicated in cell–cell adhesion, binding cytoplasmic domain of cadherin, and in signal transduction). It is worth observing that, at the border of the cells, fluorescence is accumulating in filamentous structures that can be defined as gap junctions between cells. On the contrary, no fluorescence was observed in control cells.

Perspectives

SNOM is becoming more and more important in current research in materials science and biology. The examples shown here indicate that one is far away from the limits in resolution of the technique, and the use of tunable infrared FEL radiation together with near-field optical collection opens the way to realize a nondestructive tool able to measure unknown properties of solid samples as well as of biological samples. The tunability of the source as well as the variation in the angle of incidence will allow a three-dimensional reconstruction of the shape and position of features and local inhomogeneities deeply located in the sample with the "finger-print region" between 2 and 10 μm of particular interest in view of its

spectroscopic selectivity. Particularly interesting are the efforts to reliably develop the technique to realize photochemical processing on the nanometer scale, the characterization of cellular and subcellular structures, and also the *in vivo* monitoring of external agent uptake. New setups are currently very promising in the so-called SNOM "apertureless" approach that combines the high resolution obtained in STM with optical spectroscopy, and once the method is reliably established, it will overcome any limitations imposed by the limited transmission of the optical fiber.

Introduction

The scanning probe microscope (SPM) is an extremely versatile instrument that has steadily evolved from its invention in the early 1980s. SPMs are now routinely available in many research labs throughout the world and are widely acknowledged for ushering in the study of matter at the nanoscale range.

The underlying principles of an SPM are quite simple but yet completely different in many significant ways from traditional microscopes. Essentially, the SPM works by positioning a sharp tip (often called a proximal probe) $\sim$1 nm above a substrate. The highly local information provided by the microscope is achieved by a combination of the sharpness of the tip, as well as the small separation between the tip and substrate. The critical feature of any SPM is the ability to maintain a constant tip–substrate distance (with a precision approaching a few picometers), while the tip is rastered across the substrate in a highly controlled way. To achieve this precision, a signal must be acquired that is very sensitive to the tip–substrate separation. The exact physical origin of this signal then determines the property of the substrate that is mapped by the SPM. A key discovery during the development of the SPM was the realization that with a sufficiently sharp tip, a quantitative three-dimensional image of surfaces can be obtained, often with atomic resolution.

The worldwide interest in scanning probe instruments was ignited by the research accomplishments of G Binnig and H Rohrer, at the IBM Zurich Research labs in Switzerland. These two individuals shared the Nobel prize in physics in 1986 for their seminal work in scanning probe microscopy. A reading of the published literature reveals relevant prior art that resembles the implementation of SPMs in the early 1980s. As examples, work on surface profilers (using optical deflection techniques similar to those used in current scanning force microscopes) can be found in the published work of G Shmalz in 1929. In 1972, R Young, J Ward, and F Scire developed an instrument (called a topografiner) designed to measure the surface microtopography of a substrate. This latter work used a controllable metal–vacuum–metal separation to maintain a fixed tip–substrate distance, in some sense foreshadowing by some 10 years the tunnel gap approach developed independently by Binnig and Rohrer.

In what follows, the general principles underlying all SPMs are discussed first. Then the two widely used families of SPMs are discussed – the scanning tunneling microscope (STM) for studying the surface topography of "electronically conducting" substrates and the scanning force microscope (SFM), also known as the atomic force microscope (AFM), developed to investigate the surface topography of "electronically insulating" substrates. The proliferation and development of seminal SPM technology has produced a wide variety of dual-probe implementations of SPMs (often called SxMs; where x stands for some physical variable of interest), which have led to simultaneous measurements with high lateral and vertical resolution, not only of surface topography but also of other local properties of substrates.

Generic SPM Components

Virtually all SPMs share a number of common features that are schematically illustrated in **Figure 1**. This figure shows a sharp tip placed in proximity to a substrate. A vibrationless coarse approach mechanism (not illustrated) is required to initially position the tip close to the substrate without damage. After this approach, the substrate is scanned (rastered) in a controlled way under the tip by a computer program which oversees the operation of the instrument. A specially designed signal transducer forms a central part of the microscope as it measures (with high gain) a particular physical property related to the tip–substrate interaction, producing a measurable voltage that can be monitored by the computer.

The key feature of the microscope is a feedback loop, which acts to keep the output of the signal transducer constant during the scanning procedure. This is usually accomplished with a controller, based on the general principle of a proportional–integral–differential (PID) controller. By recording the z-motion of the substrate necessary to keep the signal transducer output constant, a point by point "image" of the substrate's surface can be generated. The image consists of $N \times N$ ordered values of (x, y, z) coordinates where N is usually of the order of a few hundred points. A one-dimensional ordered array of N points is usually referred to as one scan. An SPM image is therefore made up of N individual scans. Typically, the microscope can complete from $\sim$1 to $\sim$10 scans in one second; the speed is largely

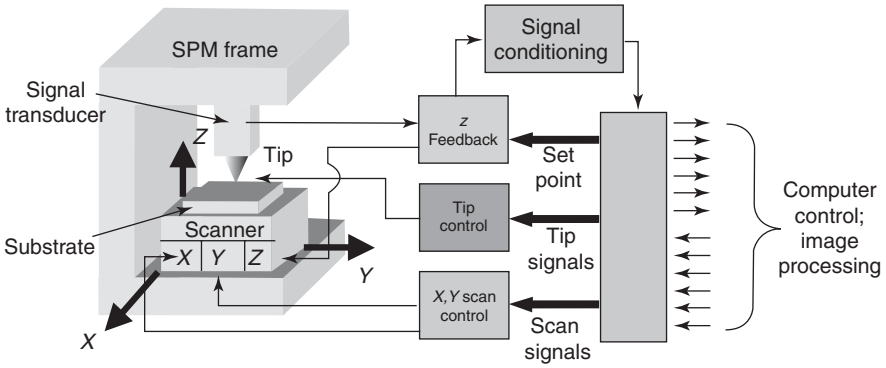

Figure 1 A schematic of a generic SPM in which a sharp tip interacts with a substrate. The design of the signal transducer allows different local properties of the substrate to be probed. The relative tip–substrate separation is controlled via a *Z*-feedback mechanism, producing an image of the substrate as it is rastered in a controlled way beneath the tip.

determined by the substrate roughness and the time constant of the feedback loop, which in turn, is related to the internal mechanical resonances of the SPM frame. Once the digital image is acquired, it can be displayed in a wide variety of two- or three-dimensional formats and further analyzed using a wide variety of sophisticated processing software.

Because of the close proximity between the tip and substrate (typically ~ 1 nm), the SPM head must be carefully isolated from uncontrolled wall and floor vibrations. Adequate vibration isolation is an absolute must and is often achieved by the use of a spring system designed to isolate the SPM from surrounding environmental vibrations. Immunity to vibration is also achieved by designing the SPM frame to be small, compact, and rigid thereby ensuring that the instrument's resonant vibrational frequencies lie in the kHz range, far removed from building vibrations which tend to occur in the 1–20 Hz regime. Very often, acoustic shielding surrounds the microscope to prevent the interaction of unwanted sound waves (audible noise) with the microscope. Care must be taken to minimize temperature gradients, since a small gradient between different pieces of the instrument can cause uncontrolled expansion or contraction of ~ 50–100 nm. If the substrate reacts spontaneously and uncontrollably with ambient environmental conditions, then further precautions must be taken to slow down or eliminate these uncontrolled surface modifications before a faithful image of the substrate's surface can be obtained. Very often, this requirement dictates either an ultrahigh vacuum environment or the submersion of the substrate under a protective liquid.

The controlled and vibrationless rastering of the substrate under the tip is critical to the operation of any SPM. This is often achieved through the use of piezoelectric ceramics which bend, contract, and expand in an appropriate manner by applying voltages

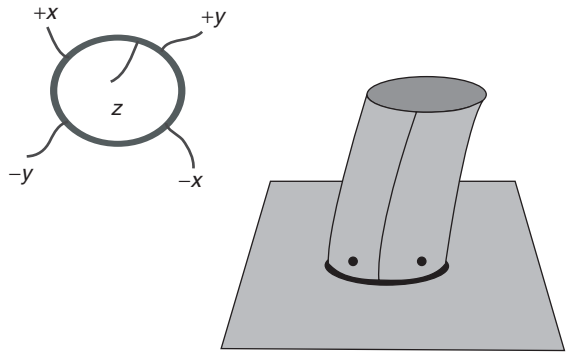

Figure 2 A schematic diagram of a segmented piezotube often used in SPMs to perform a controlled rastering in the *x*, *y*, and *z* directions.

in the 100–500 V range. Piezoelectric ceramics, that are fashioned in the shape of tubes, seem to be the current choice because of their high performance-to-cost ratio. Piezotubes (see **Figure 2**) are hollow piezoceramic cylinders (typically having a length $L \cong 2-4$ cm, an outside diameter $D \cong 0.5$ cm, and a wall thickness $w \cong 0.1$ cm), electroplated with thin metal films to form continuous inner and outer electrodes spanning the entire length of the tube. The inner electrode is continuous while the outer electrode is often segmented into four orthogonal quadrants or sectors to enable motion in an *xy* plane.

When a voltage is applied between the inner electrode and all four outer electrodes, the piezotube expands or contracts, depending on the polarity of the applied voltage. A bending motion closely resembling a pure lateral translation is achieved by applying a voltage between the inner electrode and one quadrant of the outer electrode. In order to achieve maximum translations, the applied voltage is often inverted and simultaneously applied to the opposing quadrant of the piezotube. In this way, orthogonal translations in an *x*–*y* plane can be achieved

by utilizing all four segmented sectors along the outer wall of the piezotube.

The displacements achieved by this action can be calculated from a knowledge of the d_{31} piezoelectric constant of the piezoceramic material comprising the piezotubes. Typical values of d_{31} (at room temperature) lie between -100 and $-300\times10^{-12}\,\mathrm{mV}^{-1}$. For an applied voltage V, the elongation (or contraction) of the piezotube along its axis is given by $\Delta z = L(V/w)d_{31}$. The displacement of the scanner in the x–y plane can be estimated from $\Delta x = \Delta y = (2\sqrt{2}/\pi D)\,(V/w)L^2 d_{31}$. In practice, intrinsic nonlinearities, hysteresis, aging, and creep all conspire to limit the performance of piezoceramics, which in practice often require constant calibration against established standards if high-fidelity metrology is a requirement.

The Scanning Tunneling Microscope

The STM was historically the first scanning probe microscope, and was introduced in 1982 by G Binnig and H Rohrer with the demonstration that a controllable vacuum tunneling gap could be achieved between a sharp metallic tip and a conducting substrate. The vertical resolution of the microscope is a few picometers while the lateral resolution is $\sim$0.1 nm. STM images typically span an area ranging from a few nanometers to few hundred nanometers.

To understand tunneling through a vacuum gap, it is useful to consider what happens when an electron wave with incident energy E encounters a barrier with a characteristic width d and a characteristic height V_o (**Figure 3a**). Such a barrier is present in the region of space formed by the physical gap between the tip and substrate, in which case $V_o = \varphi + \mu_t$ where φ is the work function of the tip and μ_t is the characteristic Fermi energy of the tip. The presence of this gap prevents the transit of a classical electron, but within the context of quantum mechanics, the electron has a finite probability of penetrating the barrier.

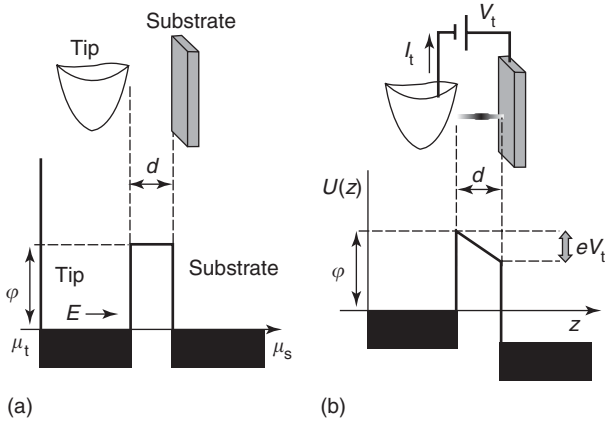

Figure 3 (a) A schematic of a potential barrier of width d between a metallic tip and metallic substrate. In equilibrium, the electrochemical potential of the tip (μ_t) and that of the substrate (μ_s) are aligned. The height of the potential barrier is $V_o = \varphi + \mu_t$, (b) The situation that develops when a bias (V_t) is applied between tip and substrate.

The basic physics required to understand how an STM operates, begins by considering electrons incident upon a barrier at an energy $E < V_o$. Such electrons can quantum mechanically tunnel through the barrier with a transmission probability T that can be obtained from a time-independent solution to the Schrödinger equation. For a square barrier, the transmission probability is given by

$$T = \frac{4E(V_o - E)}{4E(V_o - E) + V_o^2 \sinh^2(\kappa d)} \qquad [1]$$

valid when $E < V_o$, where

$$\kappa \equiv \frac{2\pi}{h}\sqrt{2m(V_o - E)}$$

m is the electron mass, and h is Planck's constant. When $\kappa d \gg 1$, an approximation appropriate for STM experiments, eqn [1] reduces to the well-known result that

$$T \approx \frac{16E(V_o - E)}{V_o^2} e^{-2\kappa d} \qquad [2]$$

If $E \cong \mu_t$, as is the case for low applied bias, then $V_o - E \cong \varphi$. Since φ is $\sim$5 eV (typical values of the work function in metals and semiconductors), the coefficient 2κ in eqn [2] is $\sim 23\,\mathrm{nm}^{-1}$.

To pass an electrical current I_t between the tip and substrate, a bias voltage V_t must be applied between the tip and the substrate (**Figure 3b**). This bias voltage distorts the shape of the square barrier, which is also rounded and lowered in height by many-body electron correlation effects not illustrated here. The electric current between tip and substrate is proportional to the transmission probability displayed in eqn [2]. After integrating over the appropriate range of energies, the tunnel current I_t is given by an expression of the general form

$$I_t \approx f(V_t, \varphi) e^{-2\kappa d} \qquad [3]$$

where $f(V_t, \varphi)$ is a function that depends on the applied voltage and the exact details of the barrier under consideration. For applied voltage differences of 1 V, typical tunnel currents encountered in STM experiments lie between 0.01 and 1 nA.

The strong exponential dependence of I_t with distance d is the important conclusion drawn from this calculation. Rough estimates using eqn [2] indicate that a change in the barrier width d by 0.1 nm causes a change in I_t by roughly a factor of 10. This large amplification implies that small tip motions can be easily detected, measured, and hence controlled.

The exquisite sensitivity of I_t to tip–substrate separation can be used as the signal transducer referred to in **Figure 1** to control the vertical tip position above a substrate. Two modes of imaging can be contemplated: (1) constant-height imaging in which the tip is moved at a fixed height above the substrate and where variations in the tunnel current due to height variations are recorded and (2) constant-current imaging in which the tip position is continually adjusted by the z-feedback loop to produce a constant tunnel current. These two modes of imaging in STM are illustrated in **Figures 4a** and **4b**, respectively.

The constant-height mode (**Figure 4a**) is of limited use, since it is only appropriate for substrates that are essentially flat at the atomic length scale. Furthermore, since variations in the tunnel current measured in the constant-height mode depend exponentially on the distance, they cannot be directly interpreted as height profiles. The three-dimensional imaging process in STM is most easily understood by considering the constant-current imaging mode (**Figure 4b**). The STM image is formed by recording the relative motion of the substrate to maintain a constant tunnel current as the tip is swept across a preselected area of the substrate. To achieve this, a high-gain current amplifier (typical gain is $\sim 10^8$ to $\sim 10^9\,\mathrm{VA}^{-1}$) is required.

Sharp tips are necessary to produce images with high lateral resolution. Common ways of producing STM tips from metal wires (such as W or Pt) with diameters of $\sim 1 \times 10^{-4}$ m rely on electrochemical etching or physical cutting. The reliable formation of sharp tips may seem like a daunting venture, but ultimately every tip formed must end with one or possibly a few atoms which ever so slightly protrude from the apex, forming a small mini-tip at the tip's apex. The presence of such mini-tips, along with the strong exponential drop-off of current with distance, provides a reasonable way to understand why the total tunnel current between tip and substrate may be dominated by an atomically small protrusion from an otherwise large tip.

More complete theories of STM clearly have shown that the tunnel current can be related to the wave function overlap between electron states in the tip with electron states in the substrate. This implies that the images obtained from an STM not only contain surface topographic information, but also information about the variation of the local density of electronic states. This complication provides a caveat against the direct translation of relative tip–substrate separation into surface topographic features. With this caution in mind, a few representative STM images from a variety of different surfaces are given in **Figure 5**. STM images are notable for the amazing detail they reveal about the atomic periodicity and surface morphology of clean, electronically conducting substrates.

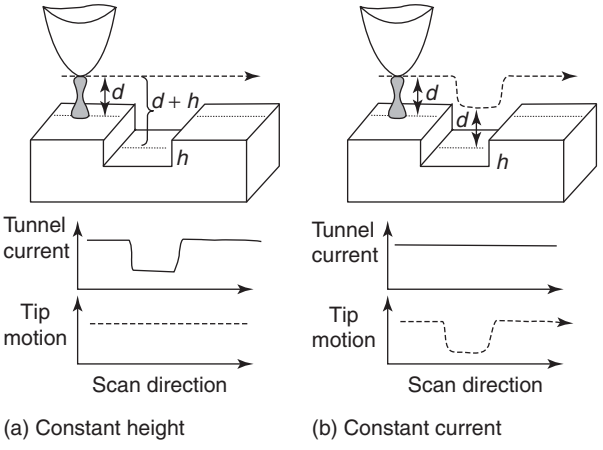

Figure 4 A schematic illustrating two modes of imaging employed in STMs. (a) The tip–substrate separation is held constant and the variations in tunnel current are measured; (b) the tunnel current is held constant by a feedback loop and the relative tip–substrate separation is varied to maintain a constant tunnel current.

The Scanning Force Microscope

While STMs provide a quantitative map of surface topography with atomic resolution, they suffer from a fundamental limitation that the substrate studied must be sufficiently conducting to support a tunnel current. In order to overcome this difficulty, an AFM was first demonstrated in 1986 by Binnig, Quate, and Gerber. The operation of this microscope relied on the surface forces acting on a sharp tip in close proximity to a nonconducting surface. For sufficiently small tip–substrate separations, these interaction forces can range from tens of pN (10^{-12} N) to tens of μN (10^{-6} N), with typical values of a few nN (10^{-9} N). An understanding of these interaction forces is central to understanding how an AFM (also called an SFM) functions. Most importantly, these forces are not predicated on the fact that either the tip or substrate is electrically conducting. Because of the long-range nature of the interaction forces, the vertical resolution of an SFM is typically a few

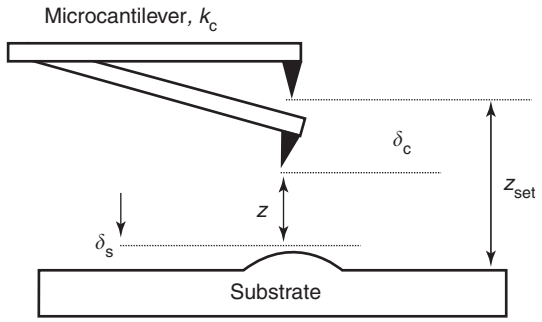

Figure 6 A schematic illustrating the sequence of events when a tip on a microcantilever is brought into close proximity to a substrate. Initially, the tip is located a distance z_{set} from the substrate. Attractive interaction forces between the tip and substrate bend the tip toward the substrate until a deflection δ_c of the cantilever brings the system into equilibrium. If the interaction forces are sufficiently strong, the substrate may also experience a distortion δ_s, which may be appreciable if the substrate is soft. The final tip–substrate separation is indicated by the parameter *z*.

picometers (comparable to an STM) while the lateral resolution is $\sim$10–20 nm, somewhat larger than for STMs. SFM images typically span an area ranging from $\sim$100 nm to around tens of micrometers.

In practice, the operation of an SFM relies on a sharp tip which is usually supported on the end of a microcantilever whose minute deflections can be carefully monitored. As shown in **Figure 6**, a microcantilever with spring constant k_c, when positioned at a distance z_{set} from a substrate, will deflect toward the substrate by an amount δ_c due to interaction forces that exist between the tip and substrate. In addition, it is possible that the surface will distort by an amount δ_s due to the action of the same forces. In general, it is difficult to determine the exact tip–substrate separation z due to a lack of knowledge about the distortion δ_s as well as the inability to accurately determine the initial tip–substrate separation z_{set}. For sufficiently small deflections, the cantilever motion can be well approximated in terms of Hook's law, which predicts a restoring force F given by $F = -k_c\delta_c$.

Table 1 provides some dimensions and relevant properties of typical microcantilevers that are commercially available. An uncertainty in cantilever thickness causes a considerable spread in the resulting spring constants. Sharp tips, with effective radius R (typically, R is between 5 and 30 nm), are routinely formed onto these cantilevers using lithographic techniques developed by the semiconductor industry. The widespread availability of microcantilevers means that interaction forces $\sim$1 nN between the tip and the substrate can be monitored and that cantilever deflections $\sim$1 nm or less can be readily detected.

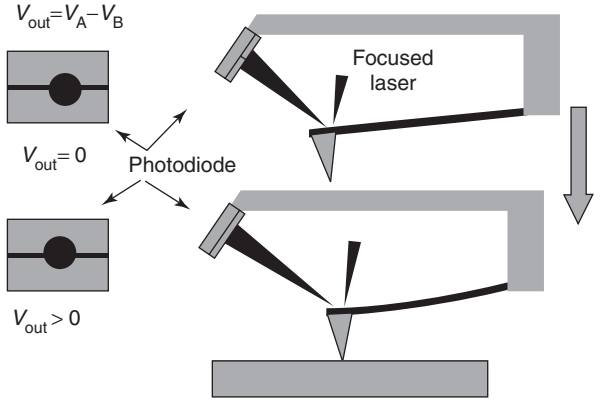

Figure 7 A common method employed to measure the deflection of a cantilever is a beam bounce technique in which a diode laser beam is reflected from a microcantilever onto a segmented photodiode. By monitoring the voltage from each segment of the photodiode, the relative motion of the reflected laser spot can be monitored and information about sub-nanometer motion of the cantilever can be inferred.

To measure cantilever motion while scanning, a high-gain transducer of cantilever deflection (the signal transducer referred to in **Figure 1**) plus a feedback mechanism is required. A variety of techniques – capacitance, optical interferometry, piezoelectric microcantilevers, and optical beam deflection – have been successfully implemented to accurately detect cantilever deflection. Each technique seems to have its own advantages. Currently, the technique most often implemented is an optical deflection scheme shown schematically in **Figure 7**.

Using this approach, a focused laser beam is deflected from a microcantilever and the reflected light is directed onto a segmented photodiode. Fine positioning of the reflected spot allows for a null condition characterized when the voltages from the appropriate photodiode segments are made to sum to zero by an external operational amplifier (not shown). A small cantilever deflection disrupts this null condition, giving rise to a voltage proportional to beam deflection. The origin of the high amplification for this particular system follows from simple geometrical considerations. For a cantilever displacement Δz, the reflected laser spot moves a distance $\Delta s = \Delta z(d/l)$, where d is the distance of the cantilever from the photodiode and l is the cantilever's length. Typically, the ratio of d/l for a microcantilever can easily be a factor of 100–500.

When discussing the nature of the interaction force between tip and substrate, it is often convenient to approximate the tip as a sphere with radius R. This sphere then interacts with the substrate via a number of possible forces, which can cause the cantilever to deflect as shown in **Figure 6**.

The exact details of the relevant interaction forces, as well as their variations on z, depend to a large extent on the composition of the tip and substrate. For the ideal case of a clean, electrically neutral tip positioned above an electrically neutral, clean substrate in ultrahigh vacuum, the interaction forces might be well-approximated by a superposition of a short-range, hard-wall repulsion (effective when the tip–substrate separation is less than ~ 0.3 nm) plus a longer range surface interaction due to the van der Waals (vdW) force acting between dipoles induced on the individual atoms comprising the tip and substrate. The z-dependence of this vdW force is related to the detailed shape of the substrate and tip. If the substrate/tip are studied under ambient conditions, hydration forces due to adsorbed water, as well as long-range electrostatic forces due to uncontrollable charging of the tip or substrate, may well dominate.

Without a detailed knowledge of the system under study, it is difficult to accurately specify a force versus distance relationship. In general, such a curve would have the approximate shape shown in **Figure 8**. This figure qualitatively illustrates (1) the attractive regime ($F<0$) in which the interaction forces cause the tip (and microcantilever) to bend toward the substrate and (2) the repulsive regime ($F>0$) that causes the microcantilever to bend away from the substrate when the tip comes into contact with it.

A qualitative appreciation of the important features of this force curve is critical to understanding how an SFM obtains an image of a substrate. By rastering the substrate beneath the tip, all the while maintaining a constant force between the tip and the

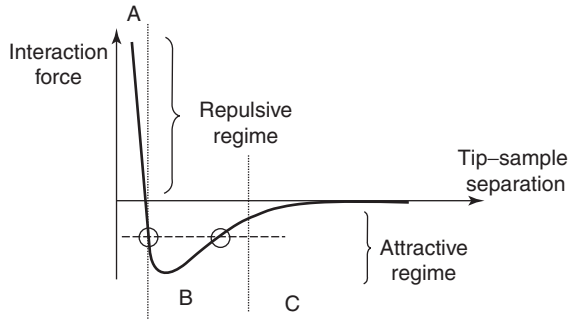

Figure 8 A schematic illustrating how the interaction force between tip and substrate varies as a function of separation. Three regions (A, B, C) are indicated. Different modes of imaging are achieved when the tip is positioned in each region.

substrate, an image closely resembling the surface topography of the substrate's surface can be obtained. There are a variety of methods that have been developed to achieve this task. The exact method employed depends on the distance between the tip and substrate.

If the tip is in region A in **Figure 8**, then imaging is performed in a "contact mode"; the tip exerts a force directly on the sample as it is scanned across it. In contact mode imaging, the direct up and down motion of the cantilever is measured while scanning. This motion can be used to produce a three-dimensional image of the substrate in much the same way as a conventional profilometer, except that now the applied force lies in the nN range and the radius of the stylus is in the 5–30 nm range. This mode of operation can be damaging, especially for soft substrates and stiff microcantilevers since significant lateral forces develop during the scanning process.

If the tip is in region C of **Figure 8**, the interaction forces are sufficiently weak so that very small deflections of the cantilever result. Since the substrate–tip separation is large, imaging in this region is often referred to as the "noncontact mode." Under these circumstances, indirect detection schemes are usually employed. As an example in noncontact mode imaging, the tip is often driven sinusoidally at a frequency near its mechanical resonance. Small position-dependent shifts in the resonance frequency occur when the substrate is rastered beneath the tip. These frequency shifts can then be used as a sensitive measure of tip–substrate separation, thereby providing the transducer signal for the feedback controller. Because of the noncontact feature of this mode, it is preferred when studying soft substrates.

If the tip is placed in region B of **Figure 8**, the interaction forces become comparable to the restoring force of the microcantilever, implying that static tip displacements, although measurable, cannot be reliably measured because of resulting instabilities. In simple terms, the instabilities arise because of the double-valued nature of the interaction force as illustrated by the horizontal dotted line in **Figure 8** which indicates that for the same value of the interaction force, there are two possible tip–sample separations. These instabilities are often referred to as jump-to-contact because the tip spontaneously snaps into contact with the substrate no matter how carefully the procedure is employed. To scan in region B, the tip must assume a time-dependent behavior which is carefully controlled by the SFM computer. During the tip's motion, it is possible that the tip might periodically come into contact with the substrate, giving rise to what is known as "intermittent-contact" or "tapping mode" imaging.

The boundaries between the different regions in **Figure 8** are not necessarily well defined, so a precise distinction between the different imaging regimes is difficult to provide. When operating an SFM in either region B or C, the SFM is often referred to as a dynamic force microscope (DFM) and the imaging process is often referred to as dynamic mode imaging.

To better appreciate the information contained in an SFM image obtained in regions B and C of **Figure 8**, it is useful to discuss in more detail the appropriate imaging modes. If the tip hovers at some distance above the substrate, then a sinusoidal modulation of the cantilever's position is usually required to monitor the interaction forces. This is often accomplished by mounting the cantilever assembly directly onto a small piezoelectric slab, which is driven at a preset angular frequency ω. During the oscillatory motion of the cantilever, the tip feels two forces: a restoring force due to the cantilever and an interaction force due to the forces acting between the tip and substrate.

Under these circumstances, the tip motion can be visualized by considering the two spring systems shown in **Figure 9**. One spring, with spring constant k_c, accounts for the restoring force of the cantilever, while the other spring, with effective spring constant k_{inter}, accounts for the interaction forces. Effectively, the tip is acted on by a single spring with effective spring constant $k_{eff} = k_c - k_{inter}$. If the interaction force curve is accurately known (rarely the case), k_{inter} could be estimated according to $k_{inter} = dF_{inter}/dz$, where it is understood that the derivative must be evaluated at the equilibrium separation between the cantilever and substrate.

When the tip is far from the sample, $k_{inter} \cong 0$ and the equation of motion of a tip with mass m can be analyzed using the equations for a damped oscillator (with damping coefficient β), driven by a sinusoidal

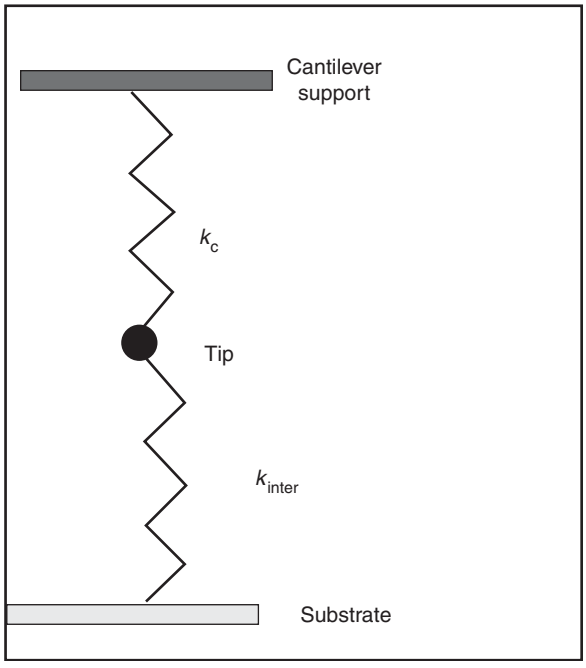

Figure 9 A simple way to understand the different forces acting on a tip when it is positioned in close proximity to a substrate. The tip is acted upon by two springs, one due to the restoring force of the cantilever, the other due to the interaction force between tip and substrate.

force $F_o \cos(\omega t)$:

$$m\ddot{z} + \beta\dot{z} + k_c z = F_o \cos(\omega t) \qquad [4]$$

The steady-state tip motion $z(t) = \mathrm{Re}(z_o e^{-i\alpha} e^{i\omega t})$ is specified by

$$z_o = \frac{F_o}{\sqrt{m^2(\omega_o^2 - \omega^2)^2 + \beta^2\omega^2}} \qquad \tan\alpha = \frac{\omega\beta}{m(\omega_o^2 - \omega^2)} \qquad [5]$$

where the resonance frequency $\omega_o = 2\pi f_o \equiv \sqrt{k_c/m}$. Clearly, the amplitude of the oscillating cantilever is maximu'm when the driving frequency equals the resonance frequency (i.e., when $\omega = \omega_o$).

As the tip moves closer to the substrate, the interaction force F_{inter} shown schematically in **Figure 8** comes into play and the equation of motion becomes

$$m\ddot{z} + \beta\dot{z} + k_c z = F_o \cos(\omega t) + F_{inter} \qquad [6]$$

The details of the tip motion now depend on F_{inter}.

A general analysis of this problem usually starts by expanding F_{inter} in a Taylor series about the equilibrium tip–substrate separation. This analysis shows that the resonance frequency (which can be accurately measured) becomes a function of the tip–substrate separation. The effective resonant frequency ω_e is given approximately by

$$\omega_e \cong \omega_o \left(1 - \left.\frac{dF_{inter}}{dz}\right|_{z=z_{eq}}\right)^{1/2} \qquad [7]$$

As a consequence, the amplitude of the cantilever's oscillation, driven at a frequency ω slightly off-resonance, will vary with position as the substrate is rastered beneath the oscillating microcantilever. The amplitude change resulting from variations in ω_e can be measured using a conventional phase-sensitive detection of the signal from the microcantilever/photodiode assembly. The substrate–tip separation can be continuously adjusted by a feedback loop to maintain either a constant resonance frequency or a constant amplitude of oscillation. By measuring the required motion of the substrate in the z-direction required to achieve this condition, it is possible to render an "image" of the surface of the substrate. Such an SFM image reflects relative changes in the tip–substrate separation required to maintain a constant resonant frequency, or equivalently a constant amplitude of the tip's oscillation.

As the equilibrium separation between the cantilever and substrate decreases and the tip passes from region C to region B, the intermittent mode of operation comes into play. The situation becomes considerably more complicated. The interaction forces are now comparable to the restoring forces of the cantilever. If $k_c = k_{inter}$ at some z_{set}, instabilities will result. If the amplitude of the tip oscillation drives the tip from region B to region A, the tip will intermittently "tap" the surface. This could produce a substrate damage, especially if the cantilever has a high spring constant. Also, nonlinearities and instabilities in the tip motion can produce a chaotic rather than a periodic motion of the cantilever. Considerable operator skill and insight is often required to produce artifact-free images under these conditions.

Another way of implementing intermittent contact mode imaging is to use an alternative approach often referred to as the "jumping mode." In this procedure, the cantilever does not undergo sinusoidal motion but instead follows a motion determined by the software controlling the SFM. In practice, the software is programmed to retract the tip, position it at the beginning of a selected scan range, and then drive the substrate toward the tip under feedback control until the cantilever bending reaches a preset loading force. At this point, the z-displacement of the substrate required to meet this condition is measured and the tip is withdrawn, moved to a nearby adjacent location above the substrate where the process is again repeated. After completing a scan, the relative

z-motion of the substrate at each point in the scan is plotted for further analysis. The advantage of this technique is that the force applied to the substrate can be carefully monitored during the imaging process. Furthermore, the lateral force imparted to the substrate while scanning is eliminated. The disadvantage is that the scan proceeds at a somewhat slower rate than when the cantilever is sinusoidally driven. **Figure 10** provides a schematic diagram of these different imaging modes.

Table 2 summarizes the above discussion by listing a few very general guidelines for cantilever selection during each mode of SFM operation.

By way of summary, in SFM, no matter which mode of imaging is employed, the motion of the z-piezo is used to form an image to keep a required signal constant. In contact mode imaging, the static deflection of the cantilever is used. In noncontact mode imaging, the amplitude of the cantilever oscillation is employed. The SFM is characterized by a lateral resolution of $\sim$10–20 nm, somewhat higher than that for STM since the tip radius R plays a central role. Atomically resolved images in SFM have been demonstrated, but usually this requires an SFM operating under ultrahigh vacuum conditions. The vertical resolution (typically better than 0.1 nm) rivals that of STM, while a force sensitivity of the order of 1 pN can be achieved.

A few typical SFM images taken in noncontact mode are given in **Figure 11**.

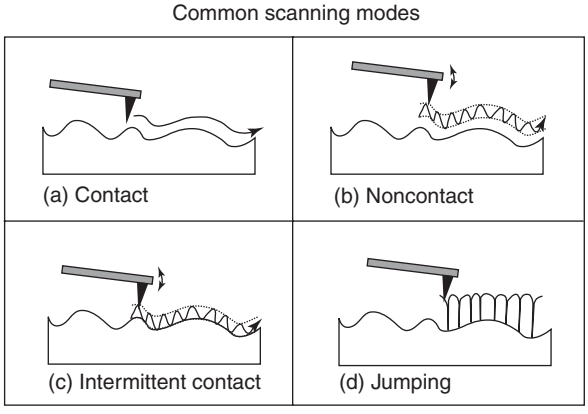

Figure 10 A schematic illustrating the different scanning modes commonly employed in SFM. (a) The contact mode of imaging where the tip is in constant contact with the substrate; (b) the noncontact mode of imaging, where the tip oscillates sinusoidally while maintaining a fixed difference between tip and substrate; (c) the intermittent contact mode where the tip "taps" the substrate during the scanning process (Note that the frequency of tip oscillation in (b) and (c) is much greater than the scanning frequency of the microscope.); (d) the jumping mode where the tip is moved into contact with the substrate, then lifted and moved to another location before contact with the substrate is re-established.

The SxM Family of Microscopes

The basic techniques described above have been extended in a number of very clever ways, producing a large family of SPMs, often referred to as SxMs, each designed to detect the local variation in some quantity of interest. This extension of SPM is often referred to as dual-probe microscopy because the tip not only measures topography but also some other physical parameter of interest with high lateral resolution. A few examples include an electrostatic force microscope (EFM or scanning Kelvin probe), a magnetic force microscope (MFM), a photon scanning tunneling microscope (PSTM), a scanning electrochemical microscope (SECM), a scanning near-field optical microscope (SNOM), a scanning capacitance microscope (SCM), scanning tunneling spectroscopy (STS), and a frictional force microscope (FFM).

Summary

The rapid evolution of SPMs since their first demonstration in the early 1980s has truly been remarkable. Largely because they are versatile and relatively inexpensive, SPMs have ushered in a worldwide interest in nanotechnology. With precise engineering, SPMs are capable of very high resolution (subatomic scale) metrology. Also, it is now clear that SPM tips can be used as tools capable of nanometer manipulation and fabrication. Active research in nanolithography is underway to controllably use the

SFM tip to locally modify a substrate in a very precise way at the nanometer length scale. SPM operation has been extended to scanning under liquids, allowing a window into the biological world. Linear parallel arrays of cantilevers have been designed and fabricated to work in a massively parallel fashion, and efforts to independently control individual cantilevers in the array have also been reported. Current indicators are that technology underlying these proximal probe microscopes will continue to improve, and the SPM class of instruments will continue to become ever more commonplace as a tool of choice to probe the properties of nanoscale objects.

Introduction

"Compton scattering" refers to a collision between a photon and a charged particle, often an electron, in which the photon loses a substantial fraction of its energy. The use of words "photon" and "collision" suggests a corpuscular nature of light, that is, that light may be viewed as a stream of particles with well-defined energies and momenta. The first indications that light can lose a part of its energy when scattered in this manner appeared at the beginning of the twentieth century. Convincing evidence was provided by the pioneering experiments in the 1920s by Arthur Compton after whom the effect has been named.

This was not the first time the suggestion had been made that light may behave as a particle. The photoelectric effect, in which a material irradiated by light can be seen to emit electrons, was earlier explained by Einstein by postulating that light of frequency v consists of particles called light quanta (and later photons), each with energy hv, where h is Planck's constant. For a given material, the photoemitted electrons possess energies, which depend on the frequency (or equivalently the wavelength, $\lambda = c/v$, where c is the speed of light), but not on the intensity of the incident light. Above a certain wavelength no electron emission is possible, as is observed to be the case, because a photon does not carry enough energy to overcome the binding energy of the electron to the material. Compton scattering, which views the photon–electron scattering to behave rather like billiard balls colliding with other billiard balls, thus reinforces Einstein's explanation of the photoelectric effect.

An outline of this chapter is as follows. The following section gives an overview of the theory of Compton scattering. The equations for energy and momentum transfer and the cross section for the Compton scattering process are given. Various forms of Compton scattering are discussed: (1) Compton scattering from the charge distribution of electrons in a material; (2) magnetic Compton scattering; and (3) $(\gamma, e\gamma)$ scattering, in which additional information is obtained by measuring the properties of the recoil electron in addition to those of the scattered photon. The third section addresses issues of instrumentation. In keeping with current trends, the emphasis is on experiments using synchrotron radiation facilities around the world, which provide bright sources of X-rays. The forth section touches upon the effect of multiple scattering of a Compton scattered photon

within the sample, which complicates the interpretation of data. The fifth section turns to methods of analyzing Compton scattering data. In those cases where an adequate data set is available, one can in principle obtain the three-dimensional momentum density of the many-body electronic ground state of the material. Much insight has been gained into the electronic structure and bonding properties in wide classes of materials via comparisons of measured Compton scattering data with corresponding *ab initio* computations. The last section concludes with a presentation of a few illustrative examples of such comparisons.

Theory

Consider first a collision between a photon and a stationary electron in free space. The incident photon has momentum $\boldsymbol{k}_0$ and energy $E_0 = |\boldsymbol{k}_0|c$. As a result of the collision, the electron recoils with momentum $\boldsymbol{p}_1$ and relativistic energy $\varepsilon_1 = [(p_1c)^2 + m^2c^4]^{1/2}$, while the momentum and energy of the scattered photon are $\boldsymbol{k}_1$ and $E_1 = |\boldsymbol{k}_1|c$, respectively. Energy and momentum conservation laws then yield

$$\varepsilon_1 + E_1 = E_0 + mc^2 \qquad [1]$$

$$\boldsymbol{p}_1 + \boldsymbol{k}_1 = \boldsymbol{k}_0 \qquad [2]$$

Equation [2] shows that the momentum gained by the recoiling electron, $\boldsymbol{p}_1 = \boldsymbol{k}_0 - \boldsymbol{k}_1 \equiv \hbar\boldsymbol{q}$, is the same as the momentum lost by the photon, which, after division by $\hbar$, is called the scattering vector $\boldsymbol{q}$ (**Figure 1**). Eliminating the electron momentum $\boldsymbol{p}_1$ from eqns [1] and [2] gives

$$E_0 - E_1 = \frac{E_0E_1}{mc^2}(1 - \cos\phi) \qquad [3]$$

Recalling the relation $\lambda = hc/E$ for photons, this can be written as

$$\lambda_1 - \lambda_0 = \frac{h}{mc}(1 - \cos\phi) \qquad [4]$$

The quantity $h/mc \sim 0.00\,243$ nm, called the Compton wavelength of the electron, is the natural unit of length in quantum electrodynamics. The shift in wavelength is seen from eqn [4] to be independent of the energy of the incident photon. Therefore, this shift can be more easily detected by using high-energy radiation since the percentage change in wavelength is then larger. Equation [3] can also be rewritten as

$$E_1 = \frac{E_0}{1 + (E_0/mc^2)(1 - \cos\phi)} \qquad [5]$$

This equation shows that for X- or γ-rays of energy E_0 comparable to $mc^2 \sim 511$ keV, the energy loss at large scattering angles ϕ is a substantial fraction of the initial energy E_0.

It is important to note that the energy conservation (eqn [1]) neglects changes in the potential energy of the system, that is, the potential energy of the electron is assumed to be the same before and after the collision. In scattering from atoms, molecules, and solids, this approximation is valid only if the energy transferred in the scattering process is much larger than relevant binding energies involved. Moreover, for high energy transfers, the scattering process is a fast one in that the duration of the interaction is too short for the system to rearrange itself. This is called the "impulse approximation," and it is at the heart of much of the interpretation of the Compton scattering spectra from materials. In the deeply inelastic regime, where the "impulse approximation" is valid, Compton scattering provides a direct probe of the many-body ground state of the electronic system.

In the more realistic case of a moving electron with initial momentum $\boldsymbol{p}_0$ and energy $\varepsilon_0 = [(p_0c)^2 + m^2c^4]^{1/2}$, the energy and momentum conservation conditions are

$$\varepsilon_1 + E_1 = \varepsilon_0 + E_0 \qquad [6]$$

$$\boldsymbol{p}_1 + \boldsymbol{k}_1 = \boldsymbol{p}_0 + \boldsymbol{k}_0 \qquad [7]$$

The scattering vector (**Figure 2**) once again is $\hbar\boldsymbol{q} \equiv \boldsymbol{k}_0 - \boldsymbol{k}_1 = \boldsymbol{p}_1 - \boldsymbol{p}_0$. Here, ε_0 and ε_1 cannot be eliminated

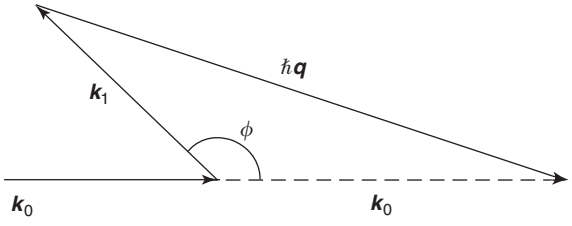

Figure 1 Momentum conservation diagram for Compton scattering of an incident photon of momentum $\boldsymbol{k}_0$ from a free electron at rest. $\boldsymbol{k}_1$ is the momentum of the scattered photon, q the scattering vector, and ϕ the scattering angle.

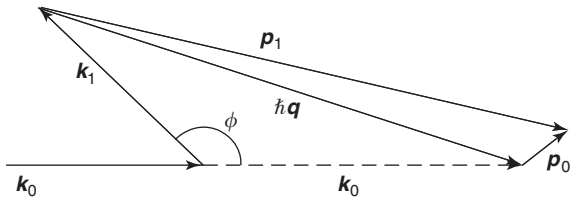

Figure 2 Momentum conservation diagram for Compton scattering of an incident photon of momentum $\boldsymbol{k}_0$ from an electron with momentum $\boldsymbol{p}_0$. Upon recoiling, the electron has a momentum $\boldsymbol{p}_1$. The initial momentum $\boldsymbol{p}_0$ is typically much smaller than $\boldsymbol{p}_1$.

simultaneously from eqns [6] and [7] to obtain an equation involving just the photon kinematics. However, elimination of $\boldsymbol{p}_1$ leads to the expression

$$(E_0 - E_1)(\varepsilon_0 + \varepsilon_1) = (\hbar^2 q^2 + 2\hbar \boldsymbol{p}_0 \cdot \boldsymbol{q})c^2 \qquad [8]$$

Substituting $\varepsilon_0 = \varepsilon_1 = mc^2$ in eqn [8], one obtains the useful nonrelativistic relation

$$E_0 - E_1 = \frac{\hbar^2 q^2}{2m} + \frac{\hbar \boldsymbol{p}_0 \cdot \boldsymbol{q}}{m} \qquad [9]$$

The term $\hbar^2 q^2/2m$ is called the Compton shift, while the term $\hbar \boldsymbol{p}_0 \cdot \boldsymbol{q}/m$ has the character of a Doppler shift in that this term is proportional to the velocity component of the electron along the direction of $\boldsymbol{q}$. It is customary to choose p_z as the component of the initial electron momentum along the scattering vector so that $p_z = \boldsymbol{p}_0 \cdot \boldsymbol{q}/q$. If $p_z = 0$, then eqn [9] becomes

$$E_0 - E_C = \frac{\hbar^2 q^2}{2m} \qquad [10]$$

where E_C is the energy corresponding to the top of the Compton profile.

In the relativistic case eqn [8] immediately yields

$$p_z = \frac{(E_0 - E_1)(\varepsilon_0 + \varepsilon_1) - \hbar^2 q^2 c^2}{2\hbar q c^2} \qquad [11]$$

The scattering vector squared is

$$\begin{aligned} \hbar^2 q^2 &= k_0^2 + k_1^2 - 2k_0 k_1 \cos\phi \\ &= (E_0^2 + E_1^2 - 2E_0 E_1 \cos\phi)/c^2 \end{aligned} \qquad [12]$$

Substituting [12] into [11], one obtains

$$p_z = \frac{(E_0 - E_1)\varepsilon_0 - E_0 E_1 (1 - \cos\phi)}{c\sqrt{E_0^2 + E_1^2 - 2E_0 E_1 \cos\phi}} \qquad [13]$$

The width of the Compton profile is very narrow compared with E_C so that $E_C \approx E_1$, and one can use the leading order nonrelativistic approximation $\varepsilon_0 = mc^2$ to obtain the following equation:

$$\frac{p_z}{mc} \approx \frac{E_0 - E_1 - (E_0 E_1/mc^2)(1 - \cos\phi)}{\sqrt{E_0^2 + E_1^2 - 2E_0 E_1 \cos\phi}} \qquad [14]$$

This expression allows one to convert the energy scale of the Compton profile to a momentum scale. Conventionally, a minus sign is added to the left-hand side of [13] and [14], so that positive values of p_z correspond to the high-energy side of the profile. Notice also that the energy and momentum of the electron do not occur on the right-hand side of eqn [14]. In a typical Compton scattering experiment the kinematics of the recoil electron is not measured, so that the data are in effect integrated over the p_x- and p_y-components and p_z is the only electron momentum component measured.

The double differential scattering cross section for spin-dependent Compton scattering from a material containing a collection of moving electrons is

$$\begin{aligned} \frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\ \mathrm{d}E_1} = (e^2/mc^2)^2 (m/2\hbar q)(E_1/E_0) \\ \times \{f J(p_z) + (\cos\phi - 1) P_c \hat{\boldsymbol{\sigma}} \\ \cdot [(\boldsymbol{k}_0 \cos\phi + \boldsymbol{k}_1)/mc] J_{mag}(p_z)\} \end{aligned} \qquad [15]$$

where

$$\begin{aligned} f = 1 + \cos^2\phi + [(E_0 - E_1)/mc^2](1 - \cos\phi) \\ + P_l \sin^2\phi \end{aligned} \qquad [16]$$

and P_c and P_l denote the Stokes parameters which give the degree of circular and linear polarization, respectively, of the incident beam, $\hat{\boldsymbol{\sigma}}$ is a unit vector along the direction of magnetization, and e^2/mc^2 is the classical electron radius r_0. Equation [15] is valid at low energies, but at high energies the factor $m/2\hbar q$ should be replaced by the more accurate expression

$$m/2\hbar q[1 + E_0/mc^2(1 - \cos\phi)]$$

Due to the presence of the factor $(\boldsymbol{k}_0 \cos\phi + \boldsymbol{k}_1)/mc$, the magnetic part of the cross section increases with the photon energy.

The first term in the cross section of eqn [15] is proportional to the so-called Compton scattering profile $J(p_z)$ due to charge scattering, which is defined as the projection of the total ground-state momentum density $\rho(\boldsymbol{p}) = \rho^{\uparrow}(\boldsymbol{p}) + \rho^{\downarrow}(\boldsymbol{p})$ onto the scattering vector $\boldsymbol{q}$ which was chosen as the z-axis, or, in other words,

$$J(p_z) = \int\int [\rho^{\uparrow}(\boldsymbol{p}) + \rho^{\downarrow}(\boldsymbol{p})]\ \mathrm{d}p_x\ \mathrm{d}p_y \qquad [17]$$

Here, $\rho^{\uparrow(\downarrow)}(\boldsymbol{p})$ denotes the momentum density of electrons with spin up (down) in a magnetic material. In a nonmagnetic material, of course $\rho^{\uparrow}(\boldsymbol{p}) = \rho^{\downarrow}(\boldsymbol{p})$. The momentum density, which is the probability distribution of electrons in momentum space, is given as

$$\rho(\boldsymbol{p}) = \sum_i n_i |\chi_i(\boldsymbol{p})|^2 \qquad [18]$$

where

$$\chi_i(\boldsymbol{p}) = (2\pi\hbar)^{-3/2} \int \psi_i(\boldsymbol{r}) \mathrm{e}^{-\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{r}/\hbar}\, \mathrm{d}\boldsymbol{r} \qquad [19]$$

is the Fourier transform of the wave function $\psi_i(\boldsymbol{r})$ and the summation runs over all (spin-dependent) states i. A property of the Fourier transform is that $\psi_i(\boldsymbol{r})$ and $\chi_i(\boldsymbol{p})$ weight inverse regions of configuration space: the valence electrons, which tend to lie farther away from the nuclei contribute to $\chi_i(\boldsymbol{p})$ at low momenta, whereas the tightly bound core electrons contribute at higher momenta. Also, since $\chi_i(\boldsymbol{p})$ is the Fourier transform of $\psi_i(\boldsymbol{r})$, it contains the same fundamental information as $\psi_i(\boldsymbol{r})$. Thus, the momentum density describes the electronic system as well as the more familiar charge density. The occupation number n_i gives the number of electrons populating the ith state. In the absence of correlations between the electrons, $n_i = 1$ for an occupied state and $n_i = 0$ when the state is empty. Integrating the Compton profile $J(p_z)$ over p_z is equivalent to integrating the momentum density $\rho(\boldsymbol{p})$ over the entire $\boldsymbol{p}$-space, which from the properties of the Fourier transform is the same as the integral of the real-space charge density. But the integral of the charge density (appropriately normalized) obviously is the number of electrons Z per formula unit. This observation makes it possible to normalize the Compton profile on an absolute scale. However, it is emphasized that the simple relationship [17] between the Compton profile and the electron momentum density (EMD) only exists by the grace of the impulse approximation.

The second term in formula [15], which can be measured due to the circular polarization P_c of the incident radiation, contains the magnetic Compton scattering profile:

$$J_{\mathrm{mag}}(p_z) = \int\int [\rho^{\uparrow}(\boldsymbol{p}) - \rho^{\downarrow}(\boldsymbol{p})]\, \mathrm{d}p_x\, \mathrm{d}p_y \qquad [20]$$

which, like the $J(p_z)$ of eqn [17], is a projection along p_z, except that $J_{\mathrm{mag}}(p_z)$ involves the difference (rather than the sum) of the up- and down-spin momentum densities. $J_{\mathrm{mag}}(p_z)$ is thus related to the ground-state momentum distribution of the electrons with unpaired spin. The magnetic term in the cross section [15] is typically smaller than the charge scattering term proportional to $J(p_z)$ by a few orders of magnitude. This is due firstly to the factor of $(\boldsymbol{k}_0 \cos\phi + \boldsymbol{k}_1)/mc \approx E/mc^2$, since the photon energy is usually only a fraction of mc^2, and secondly because the integral of the magnetic Compton profile $\int J_{\mathrm{mag}}(p_z)\, \mathrm{d}p_z$ equals the number of electrons with unpaired spin, which is much less than the total number of electrons Z. The magnetic effect, however, increases with photon energy. It is to be noted that, in contrast to the scattering of polarized neutrons, magnetic Compton scattering only involves the electron spin, and does not depend on the orbital moment.

It is helpful to consider the momentum density of the noninteracting free-electron gas at 0 K. In this case, electrons occupy all available energy levels up to the Fermi energy E_F. Since $E = p^2/2m$, the occupied states fill a sphere in momentum space, the Fermi sphere, of radius $p_F = \sqrt{2mE_F}$, which is called the Fermi momentum. Thus, $n_i = 1$ and $n_i = 0$ inside and outside the Fermi sphere, respectively. It is then easily shown from eqn [17] that the Compton profile is given by the area of the slice of the Fermi sphere at $p = p_z$ (**Figure 3**):

$$\begin{aligned} J(p_z) &= 2\pi(p_F^2 - p_z^2) \quad p_z \leqslant p_F \\ J(p_z) &= 0 \qquad\qquad\quad p_z > p_F \end{aligned} \qquad [21]$$

which has the shape of an inverted parabola. The factor of 2 in $J(p_z)$ here accounts for the spin degeneracy of free-electron states. Equation [21] describes the basic shape of $J(p_z)$ associated with the loosely bound conduction electrons in metals. The contribution of the more tightly bound core electrons varies smoothly and extends to much higher momenta, so that the total Compton profile possesses the shape of an inverted parabola sitting on top of the broader core contribution (**Figure 3**). The positions of the two kinks in $J(p_z)$ at $p_z = \pm p_F$ mark the Fermi momentum p_F. In a measured Compton profile these kinks

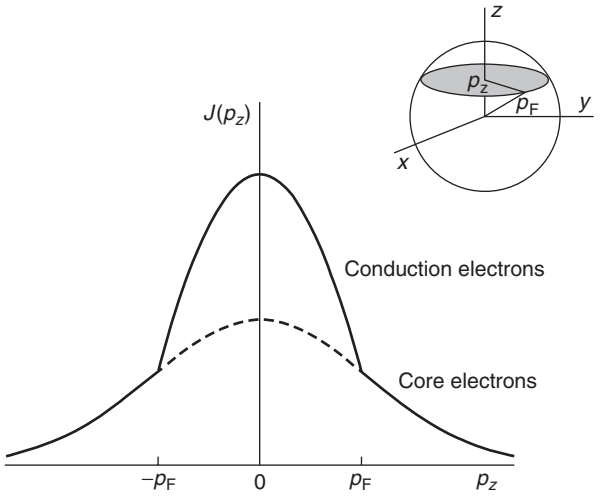

Figure 3 Schematic Compton profile $J(p_z)$ for a hypothetical metal with two core electrons and one free conduction electron per atom. The parabolic contribution of the free electron is given by the area of the slice (for different p_z values) through the Fermi sphere of radius p_F as shown in the inset.

will only appear as rapid changes in slope around the Fermi momentum due to the effect of finite experimental resolution. The width of the rapidly varying portion of the Compton profile is a direct result of the spreading of the electrons throughout the Fermi sphere due to Pauli's exclusion principle and the associated Fermi–Dirac statistics of electrons, which forbids more than one electron (of a given spin) to occupy any energy level.

In a real electron gas, electrons interact through Coulomb forces, so that electronic motions become correlated in the sense that an individual electron no longer moves independently of the positions of other electrons. The Coulomb interaction kicks some electrons out of the Fermi sphere, even at zero temperature, and in the process free-electron (noninteracting) states above the Fermi momentum become partially occupied at the expense of states inside the Fermi sphere. The occupation numbers thus become <1 below E_F and nonzero above E_F, and the momentum distribution becomes more spread out. This effect of electron correlations can be identified in experimental Compton scattering profiles.

In a crystal, electrons experience a periodic potential due to the presence of the underlying lattice. The energy spectrum of the crystal can be shown to consist of groups of levels or bands, where eigenstates within each band are characterized by the wave vector $\boldsymbol{k}$, which is restricted to lie within the first Brillouin zone. The crystal wave function $\phi_i(\boldsymbol{k})$ for the ith band for wave vector $\boldsymbol{k}$ contains momentum contributions not only at $\boldsymbol{p} = \hbar\boldsymbol{k}$, but also at momenta $\boldsymbol{p} = \hbar(\boldsymbol{k} + \boldsymbol{K})$, where $\boldsymbol{K}$ is any one of the group of reciprocal lattice vectors associated with the real-space crystal lattice (there should be no confusion with the photon momenta $\boldsymbol{k}_0$ and $\boldsymbol{k}_1$ introduced earlier). The periodic potential thus has the effect of broadening the valence electron momentum distribution somewhat like the effect of electron correlations. Moreover, the Fermi surface breaks in the momentum density of the crystal will generally occur not only at the momenta $\boldsymbol{p}_F$, but also at all the Umklapp images of the Fermi surface at momenta $\boldsymbol{p}_F + \hbar\boldsymbol{K}$ with appropriate weights.

The twofold integration of $\rho(\boldsymbol{p})$ in eqn [17] reflects the fact that in a standard Compton experiment, only the characteristics of the incoming and outgoing photons are measured and those of the recoiling electrons are ignored. It is obviously attractive to devise a way of measuring the three-dimensional momentum density $\rho(\boldsymbol{p})$. This is possible if the kinematics of the recoil electron is measured in coincidence with that of the Compton scattered photon. This is referred to as a $(\gamma, e\gamma)$ experiment since here one measures the cross section for the process in which a γ-ray photon scatters into a photon and an electron. **Figure 4** clarifies the various momenta involved. The recoil electron is emitted at an angle α (this angle does not necessarily lie in the plane defined by $\boldsymbol{k}_0$, $\boldsymbol{k}_1$, and $\hbar\boldsymbol{q}$) with respect to the primary beam direction. The angle α_0 for an electron initially at rest is given by

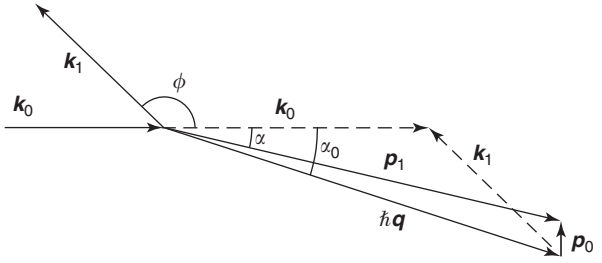

Figure 4 Momentum conservation diagram for $(\gamma, e\gamma)$ scattering, where various momenta have been defined previously in **Figures 1** and **2**. α_0 refers to the limiting case where the electron is initially at rest.

$$\cot \alpha_0 = (1 + E_0/mc^2) \tan(\phi/2) \qquad [22]$$

The components p_x and p_y of the initial electron momentum $\boldsymbol{p}_0$ cause the recoil electron to end up in solid angles closely around the direction α_0, where it can be detected with the aid of a position-sensitive detector. As before, p_z can be determined from the Doppler broadening formula [13]. Alternatively, one may measure the energy of the recoil electron by a time-of-flight method in coincidence with that of the photon. It should be emphasized that if the coincidence condition is not imposed, the energy distribution of the scattered photons as well as that of the recoil electrons is each proportional to the Compton profile. Only by observing the photon and the electron in coincidence does one obtain $\rho(\boldsymbol{p})$. Since electrons interact strongly with matter, $(\gamma, e\gamma)$ experiments require very thin samples in order to minimize the scattering of the recoil electrons.

A technique closely related to $(\gamma, e\gamma)$ scattering is $(e, 2e)$ scattering in which an incoming electron generates two outgoing electrons, the scattered and the recoiling one, and the kinematics of the two outgoing electrons is measured in coincidence. Electron scattering is even more of a problem in such an experiment. Finally, inverse Compton scattering in which a photon takes up energy by collision with an energetic electron plays a role in astrophysics.

Instrumentation

In its simplest form, a Compton scattering experiment involves a source of X- or γ-rays of a

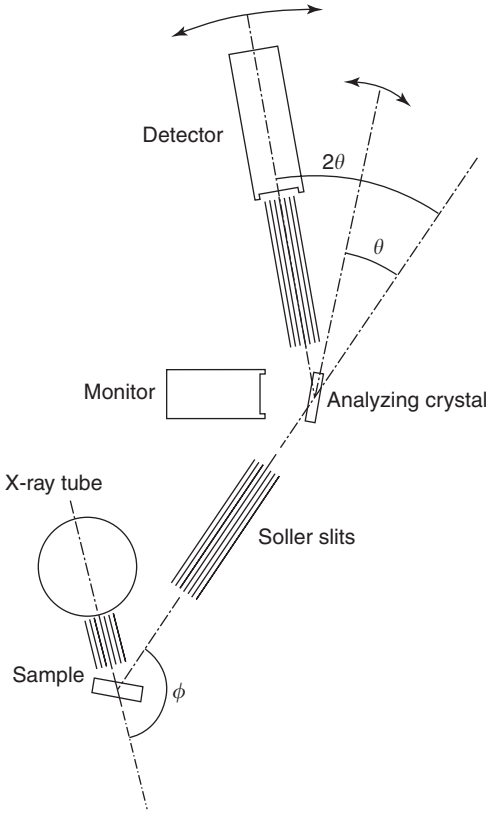

Figure 5 Schematic setup of an X-ray Compton scattering experiment.

well-defined energy (or at least with a strong monochromatic component in its energy spectrum), a sample, an energy analyzer, and a detector to register the scattered radiation (**Figure 5**). Along its path the radiation is narrowly collimated by systems of parallel Soller slits in order to achieve an accurate definition of the various angles and thus of the energy of the scattered radiation. The scattered photons are energy-analyzed by Bragg reflection from an analyzing crystal (usually LiF or Si) and detected with the aid of a scintillation detector. In such a setup, the Compton profile is obtained via a step-by-step energy scan, and the experiment therefore suffers from long data collection times and possible instabilities due to temperature variations, electronic drift, and other effects. Improvement is achieved by replacing the analyzer–detector combination with a high-resolution high-purity or lithium-drifted germanium solid-state detector, which registers the entire spectrum simultaneously, at the expense, however, of resolution.

When an X-ray tube is used, the energy of the incoming radiation is limited to several tens of keV (Mo or Ag anode) or at most to ~ 60 keV for the Kα1 line of a tungsten anode. The flux from X-ray tubes is often too low to allow the use of a primary monochromator, and the scattered spectrum therefore consists of contributions from the Kα1 and Kα2 lines, in addition to other parts of the spectrum, which complicates the interpretation of the measured profiles. Over the years, the count rates have improved with the development of more powerful X-ray tubes, sometimes with rotating anodes, and the use of large samples in combination with bent analyzing crystals, which focus the broad scattered beam onto the detector, thereby allowing radiation with a larger divergence angle to be used. Momentum resolutions for this type of setup vary between 0.15 and 0.5 a.u. full-width-at-half-maximum (1 a.u. of momentum equals 1.9929×10^{-24} kg m s^{-1}), depending on the details of the instrumental design.

The relatively low energy of the radiation provided by X-ray tubes limits Compton experiments to materials with low Z values, since at these energies Compton scattering increases as Z while the competing photoelectric absorption increases as Z^5. Also, at low photon energies, the impulse approximation, which requires the energy transferred in the scattering process to be large compared to the binding energies involved, ceases to be valid for high Z atoms. Higher-energy radiation is needed to circumvent these limitations. γ-ray sources using radioactive isotopes offer the advantage of providing radiation of a high, single energy, and often possess a long half-life $t_{1/2}$. Examples include ^{241}Am (60 keV, $t_{1/2} =$ 425 years), ^{198}Au (412 keV, 2.7 days), and ^{137}Cs (667 keV, 30 years). In combination with a solid-state detector, these sources allow the simultaneous detection of the entire Compton scattered spectrum in an apparatus without moving parts. Shielding is a serious problem at these high energies and limits the maximum scattering angle that can be used. An annular shape of the source with the scattered beam passing through the center of the ring can offer a solution. Scattering in the source itself should be kept low since it produces a tail at the low-energy side of the Compton line, which must be corrected for in data handling procedures. For this purpose, a source material with a high specific activity should be used. The best momentum resolution of ~ 0.40 a.u. that can be achieved with γ-ray sources is substantially worse than that of a high-resolution X-ray setup using an analyzing crystal. This is an important consideration in some investigations since a high momentum resolution of ~ 0.1 a.u. or better is generally needed for observing Fermi surface signatures in the Compton spectra.

The most versatile source of X-rays is synchrotron radiation, which is produced by the acceleration of charged particles, most commonly electrons, going around a circular orbit. The synchrotron radiation beam has a small angular divergence, and is emitted

in the forward direction by the orbiting particles, rather like the searchlight beam in a lighthouse. Photons emitted in the orbital plane are linearly polarized, while those emitted above and below this plane are circularly polarized. The energy range over which an intense flux of linearly or circularly polarized photons is produced can be extended by increasing the acceleration of the orbiting particles over a small portion of their trajectory. This can be achieved with the aid of a suitably designed insertion device, an "undulator" or "wiggler," which introduces a small wiggle in the particle orbit. In a symmetric wiggler the two directions of circular polarization cancel, so the insertion device should contain a certain degree of asymmetry. Since the energy spectrum of synchrotron radiation is "white," a monochromator must be used to "cut" a monochromatic slice from this spectrum. Perfect Si or Ge single crystals with a rocking curve of a width comparable to the beam divergence are often used as monochromators. These have to be cooled to maintain stability in the presence of an intense heat load of several 100 W to a few kW to which they are exposed. The scattered beam is analyzed using a curved analyzing crystal and focused onto a detector. The high intensity of radiation may in some cases cause overloading of the detector electronics. **Figure 6** shows the Compton setup in use at ESRF in Grenoble, France.

Typical synchrotron fluxes at the sources used for Compton scattering vary between 10^{10} and a few times 10^{13} photons s^{-1}, while initial photon energies range from 10 keV to >250 keV. Such fluxes are sufficiently high for carrying out a number of different types of experiments. For example, using unpolarized or linearly polarized light, conventional Compton profiles for electronic structure studies

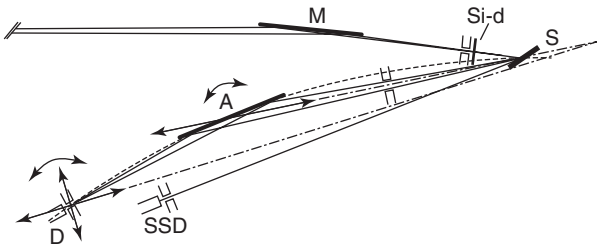

Figure 6 Drawing of the scanning spectrometer at ESRF, Grenoble, France. The beam reflected by the monochromator (M) is collimated by the entrance slit, and the beam scattered by the sample (S) is collimated by the aperture slit. The sample, analyzer crystal (A), and the detector slit lie on the dashed circle. The detector (D) is an NaI scintillation counter. A Si-diode (Si-d) and a Ge detector (SSD) are used for monitoring. The arrows indicate translations and rotations of the analyzer and detector. The monochromator part of the figure is scaled down by a factor of 10. (Courtesy of V Honkimaki.)

may be measured with a resolution of 0.10–0.15 a.u. or better. If the initial radiation is circularly polarized, the presence of the spin-dependent term in the scattering cross section [15] enables one to measure the magnetic momentum density of electrons with unpaired spin in ferromagnetic or ferrimagnetic media (since Compton scattering is an incoherent process, no magnetic effect is observed in antiferromagnetics). Since the synchrotron beam decays exponentially in time, the magnetization of the sample or the circular polarization (helicity) of the photons should be reversed every 10 s or so in the pattern $(+--+)$. A high circular polarization is achieved at the expense of a high flux. In view of the smallness of the magnetic effect and the importance of good statistics, resolution has therefore to be traded against intensity and much of the currently existing magnetic Compton scattering work is limited to a resolution of ~ 0.4 a.u. or worse.

Finally, the way is open to $(\gamma, e\gamma)$ spectroscopy. As discussed in the second section, by measuring the recoiling electron in coincidence with the scattered photon it is possible to determine the three-dimensional momentum density $\rho(\boldsymbol{p})$ of the electrons in a material. $(\gamma, e\gamma)$ measurements are only feasible with an intense flux of high-energy (100–150 keV) photons. Measurements of $\rho(\boldsymbol{p})$ on very thin (17–25 nm thick) graphite samples have been performed in this way with a momentum resolution of 0.60 (0.85) a.u. in the $p_z(p_x)$-direction. A better resolution has been obtained with a time-of-flight spectrometer. In cases where the extremely low cross section of the process makes it necessary to integrate over the energy distributions of the recoil electron as well as the scattered photon, one is left with information only on the perpendicular components p_x and p_y of the initial electron momentum. The quantity measured is then a once-integrated, two-dimensional distribution of the EMD similar to a two-dimensional angular correlation distribution of photons from positrons annihilating in a solid.

Multiple Scattering

Multiple scattering refers to events in which the Compton scattered photon is further scattered one or more times within the sample before it escapes to the detector. The presence of multiple scattering events in the measured Compton profile complicates the analysis of the data. Generally, the multiple scattering contribution tends to broaden the profile somewhat, but its detailed energy dependence on sample geometry and thickness is complex. The effect can be reduced by choosing a thin sample, but that also results in a reduction in the intensity of the primary

Compton scattering events of interest. Attempts to measure a Compton profile for various thicknesses followed by extrapolation to zero thickness suffer from the nonlinear dependence of multiple scattering on sample thickness. The most reliable results are obtained using an iterative Monte Carlo approach to simulate the effect of multiple scattering under the specific experimental conditions.

Data Analysis

Although all electrons contribute equally to the Compton profile, one is usually interested in the properties of the smaller group of valence electrons, which are mainly responsible for bonding as they undergo substantial changes when the material is formed by bringing the atoms together. The tightly bound core electrons are relatively unaffected and their contribution to the Compton profile is isotropic. One way to highlight the contribution of valence electrons in analyzing Compton data is to consider differences $\Delta J(p_z)$ between the Compton profiles measured along various pairs of directions of the scattering vector from an oriented monocrystalline specimen, for example, $\Delta J(p_z) \equiv [J_{100}(p_z) - J_{110}(p_z)]$, for the directional difference between the [1 0 0] and [1 1 0] profiles. The advantage is that the contributions from core electrons, background, and correlation effects (to the extent these are isotropic) cancel in $\Delta J(p_z)$ and the anisotropies related to the valence electrons become clearer.

As seen in the second section, the Compton profile in a crystal generally contains kinks (with appropriate weights) at the Fermi momentum $\boldsymbol{p}_F$ as well as at the images of the Fermi surface at higher momenta induced by the periodic crystalline potential. These kinks originate from breaks in the underlying three-dimensional momentum density $\rho(\boldsymbol{p})$. They can be made more clearly visible by considering the first or even the second derivative of the Compton spectrum.

Relation [17], which defines the Compton profile $J(p_z)$ as a two-dimensional integral of the momentum density $\rho(\boldsymbol{p})$, may alternatively be viewed as an integral equation for determining the three-dimensional function $\rho(\boldsymbol{p})$. The problem can then be formulated as one of "inverting" relation [17] or "reconstructing" $\rho(\boldsymbol{p})$ from a given set $J_\beta(p_z)$ of profiles corresponding to different orientations (scattering vectors) β of a monocrystalline sample. For this purpose, two approaches are commonly used. One is to expand $\rho(\boldsymbol{p})$ into a series of appropriately chosen directional harmonics. These can be the spherical harmonics, but often the crystal lattice possesses an inherent point symmetry, in which case harmonics of a higher symmetry (called lattice harmonics) are advantageous to use since one needs a smaller number of such harmonics. The expansion coefficients in this series can be expressed as Hankel or Bessel transforms of linear combinations of the set of profiles $J_\beta(p_z)$. This method is particularly useful if the momentum density $\rho(\boldsymbol{p})$ and the Fermi surface are not too far from being spherical. Methods of the second category disregard the point symmetry and solve the problem by Fourier transform techniques. The reconstruction itself can be performed in either the $\boldsymbol{p}$- or the $\boldsymbol{r}$-space. In the latter case one considers the reciprocal form factor $B(\boldsymbol{r})$ by taking the Fourier transform of $\rho(\boldsymbol{p})$:

$$B(\boldsymbol{r}) = \int \rho(\boldsymbol{p}) \exp(\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{r}/\hbar)\, \mathrm{d}\boldsymbol{p} \qquad [23]$$

from which it is easily shown that

$$B(z) = \int_{-\infty}^{\infty} J(p_z) \exp(\mathrm{i}p_z z/\hbar)\, \mathrm{d}p_z \qquad [24]$$

Thus, the one-dimensional Fourier transform of a Compton profile with the scattering vector along a given direction β equals $B_\beta(\boldsymbol{r})$ along a ray in that same direction in $\boldsymbol{r}$-space through the origin. $B_\beta(\boldsymbol{r})$ can thus be obtained along different rays in $\boldsymbol{r}$-space from the set of Compton profiles $J_\beta(p_z)$. It is then a simple matter to find the three-dimensional function $B(\boldsymbol{r})$ via interpolation, followed by an inverse Fourier transformation of $B(\boldsymbol{r})$,

$$\rho(\boldsymbol{p}) = (2\pi\hbar)^{-3} \int B(\boldsymbol{r}) \exp(-\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{r}/\hbar)\, \mathrm{d}\boldsymbol{r} \qquad [25]$$

to find the momentum density $\rho(\boldsymbol{p})$.

A useful theorem (the "Lock-Crisp-West" (LCW) theorem) connects the momentum density $\rho(\boldsymbol{p})$ with the occupation density $n(\boldsymbol{k})$, which represents the number of filled electron states at wave vector $\boldsymbol{k}$:

$$n(\boldsymbol{k}) = \sum_{\boldsymbol{K}} \rho(\hbar\boldsymbol{k} + \hbar\boldsymbol{K}) \qquad [26]$$

where the summation is over the reciprocal lattice vectors $\boldsymbol{K}$. The occupation density $n(\boldsymbol{k})$ is a periodic function of $\boldsymbol{k}$, that is, $n(\boldsymbol{k}) = n(\boldsymbol{k} + \boldsymbol{G})$ for any reciprocal vector $\boldsymbol{G}$. The theorem states that the occupation density at wave vector $\boldsymbol{k}$ is obtained by folding the momentum density at all corresponding points $\boldsymbol{p} = \hbar(\boldsymbol{k} + \boldsymbol{K})$ in the higher Brillouin zones back into the first zone.

Comparison with Theory

The methods discussed in the preceding section have all been used extensively in analyzing Compton data. Insight into wide classes of materials has been gained via comparisons between experimental Compton spectra and corresponding first-principles electronic structure computations. In this connection, many reliable techniques based on the local (spin) density approximation of density-functional theory have been developed for treating crystalline systems during the last few decades such as the (linearized) augmented plane wave (LAPW) method, the linearized muffin-tin orbital (LMTO) method, and the Korringa–Kohn–Rostoker (KKR) method. The KKR method is based on the use of multiple scattering theory and possesses the advantage that it can be generalized straightforwardly to treat the electronic structure and momentum densities in substitutionally disordered (random solid solution) phases of alloys

within the KKR–CPA scheme. A few illustrative examples of comparison between theory and experiment are presented now. These results will also serve to highlight some of the general features of the Compton spectra that have been discussed throughout this chapter.

Figure 7 shows the Compton profiles for lithium (Li). The measured and computed Compton profiles for the scattering vector lying along three high-symmetry directions are shown in **Figure 7a**. All profiles have been normalized so that the area under each of the profiles equals the number of electrons (three) in Li. The first derivatives of the profiles in **Figure 7b** show that unbroadened theory curves (long dashes) contain breaks at Fermi radii (a_1–a_3) and one set of associated images at $p_F + \hbar K$ (b_1–b_3). The resolution broadening of 0.12 a.u. (full-width-at-half-maximum) washes out the breaks b_1–b_3 as seen from the solid lines. The first derivative for the free-electron profile of eqn [21], shown for reference only along the [1 1 1]-direction by the dot-dashed line, makes it clear that the momentum density in even a relatively simple system such as Li is modified significantly from the free-electron behavior due to solid-state effects. In addition, note how differences in the results for the three directions, that is, the anisotropy of the profile, are more evident in **Figure 7b** compared to **Figure 7a**. The actual Fermi surface radii a_1–a_3 are more easily determined from the second derivatives of **Figure 7c** and are denoted in the theory curves by arrows. The Fermi surface of lithium is a distorted sphere, somewhat elongated along the $\langle 1\,1\,0 \rangle$ directions. The agreement between theory and experiment is good overall, although the theoretical distribution and particularly the Fermi surface breaks are broader in the experiment. This discrepancy reflects the residual electron correlation effects that are not treated accurately in the conventional band theory picture underlying the computations of **Figure 7**.

Figure 8 considers directional anisotropies with the example of an alloy. The results here are for a solid solution of $Ni_{75}Cu_{25}$. The maximum value of the anisotropy $\Delta J(p_z)$ is typically one to two orders of magnitude smaller than the Compton peak intensity. The experimental data in **Figure 8** were taken using a γ-ray source with a momentum resolution of 0.4 a.u. (FWHM), under which all Fermi surface signatures in the data are essentially washed out. Despite some differences in detail, the undulations in $\Delta J(p_z)$ are similar in theory and experiment. The presence of oscillations in $\Delta J(p_z)$ extending to rather high momenta is indicative of interactions in the solid state.

Figure 9 takes up an example where a reconstruction technique has been applied to obtain the Fermi

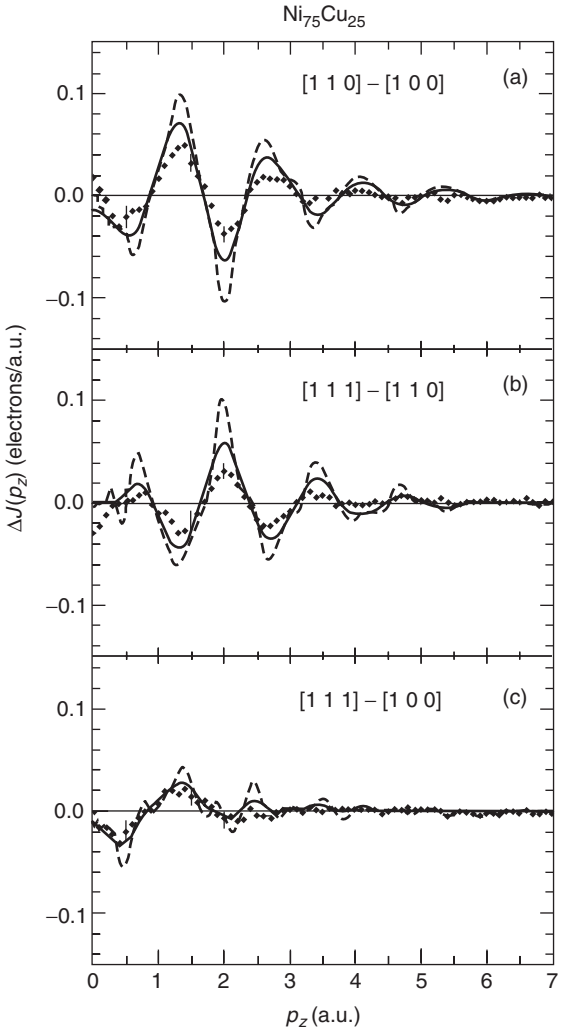

Figure 8 Directional difference profiles for the disordered alloy $Ni_{75}Cu_{25}$. The experimental (♦) results are compared with theoretical profiles with (——) and without (- - -) the experimental resolution of 0.4 a.u. surface of the alloy Al–3at.%Li. Here nine Compton profiles with scattering vectors in the (1 1 0) plane were measured and Fourier-transformed to obtain a projection of the momentum density $\rho(\boldsymbol{p})$ onto the (1 1 0) plane. Using the LCW folding procedure of [26] over a selected set of $\boldsymbol{K}$'s then yields the projected image of the Fermi surface shown in **Figure 9**. The presence of the Fermi surface outside the indicated geometrical boundaries of the first Brillouin zone is clearly seen. The theoretical maps in the figure have been obtained from nine corresponding computed profiles following procedures which were identical to those used to treat the experimental data.

Figure 10 presents the magnetic momentum density of the electrons with unpaired spin in iron. In this

study Compton profiles were measured for 14 orientations of an iron single crystal. By reversing the magnetization, two profiles were obtained for each of the 14 orientations; their differences yielded 14 magnetic Compton profiles. The Fourier transforms of these 14 profiles were used to map the reciprocal magnetic form factor $B_{mag}(\boldsymbol{r})$ along the lines of eqn [24]. The inverse transform of [23] was then performed to obtain the magnetic momentum density $\rho_{mag}(\boldsymbol{p})$ of **Figure 10a,** which is seen to display a large negative momentum density at low momenta. **Figure 10b** depicts the corresponding theoretical results and shows a similar general behavior of the computed momentum density.

Finally, a recent example of a complex material is given in **Figure 11**. The magnetic Compton profile from the double layer manganite $La_{1.2}Sr_{1.8}Mn_2O_7$ for the scattering vector along the [1 1 0] direction is shown. The measurements were carried out at a temperature of 5 K under an external magnetic field of 7 T along [1 1 0]. The theoretical profile computed within the standard band theory picture is seen after resolution broadening (thick line) to be in good accord with experiments. Studies such as those shown in **Figure 11** indicate the potential of magnetic Compton scattering as an emerging spectroscopic tool for investigating properties of magnetic electrons in complex materials.

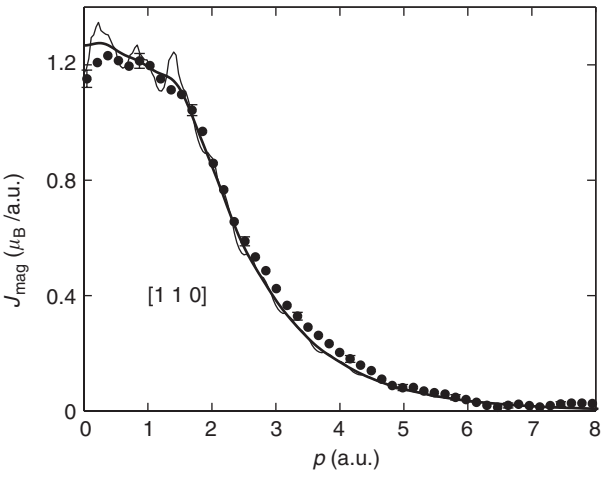

Figure 11 Experimental (•) and theoretical magnetic Compton profile along [1 1 0] in the double layer manganite $La_{1.2}Sr_{1.8}Mn_2O_7$. Measurements were carried out at 5 K under a magnetic field of 7 T. The theoretical profile is shown with (——) and without (—) resolution broadening of 0.4 a.u. All profiles are normalized such that the area gives the measured magnetic moment of 3.4 μ_B/Mn atom. Introduction

X-rays were discovered in 1895 by the German scientist W C Röntgen, who immediately realized the enormous field of applications resulting from their deep penetration in solid substances. This was dramatically demonstrated by the early photographs of human bones and small metallic objects, such as the wedding ring of Mrs. W C Röntgen. It took several years, however, before their physical nature could be really understood. Since their trajectories were not modified by a magnetic field, the only possible

alternative choice was some form of electromagnetic (e.m.) radiation. The problem was that none of the typical features of e.m. radiation – such as reflection by mirrors, refraction, polarization, and diffraction from a grating – could be reproduced. Refraction, for example, was not considered to take place because no change of angle was observed when a collimated beam of X-rays was observed to penetrate a slab of a solid substance. It was later understood that X-rays are indeed e.m. waves, of extremely short wavelength, ~ 0.1–0.2 nm. Using an oversimplified theory for the index of refraction, based on a model in which atoms are treated as harmonic oscillators, with resonant frequencies much smaller than the X-ray frequency, it is easy to show that the index of refraction is less than 1, and can be written as $n = 1 - \delta$, with $\delta \sim 10^{-5}$. Now it becomes clear why X-rays cannot be reflected by mirrors. In effect, they are reflected, provided the angle of incidence is very small, less than a critical value $\theta_c = \sqrt{2\delta} \sim 10$–$30$ arcmin. The small value of δ also explains why refraction was not observed. It was just too small to be observed with standard techniques borrowed from optics in the visible range. When the precision of the observations was improved, it could be observed and measured. If X-rays are e.m. radiation, one would expect to see polarization effects. These were indeed observed by the English scientist Ch G Barkla, who showed that X-rays scattered at 90° by a carbon block are polarized, which is what one would expect from a transverse e.m. radiation. The decisive event which proved the wave nature of X-rays unambiguously was the discovery in 1912, by the German scientist M von Laue, that X-rays are diffracted by a crystal. In this experiment, a zinc sulfide crystal was used, in which the interatomic distances are ~ 0.2–0.3 nm, supposedly of the same order of magnitude as the X-rays. It became clear that all slits normally used in optical experiments were several thousand times greater than the X-ray wavelength, and therefore no visible diffraction effects could be produced by slits. Diffraction of X-rays by crystals is a milestone in the development of condensed matter physics. In fact, von Laue's experiment not only clarified the wave nature of X-rays, but also gave the key for determining crystal structures, the internal arrangements of atoms in a periodic medium. A new chapter in the development of solid-state physics was started by the English scientist W L Bragg, who showed, in collaboration with his father W H Bragg, how the cell parameters of a crystal could be determined by comparing the intensities of the various diffracted beams in Laue's experiment. They also found, more importantly, that the atomic positions within each crystal cell could be determined. W L Bragg can certainly be considered the founder of modern crystallography.

The big question is: how can a crystal behave the same way as a ruled grating? Laue's equations are derived under the assumption that each atom acts as a source of spherical waves, which are capable of producing mutual interference. These equations show that the interference is generally negative (destructive), except for certain special directions in space. The analysis is considerably simplified if Bragg's viewpoint is adopted. Bragg's scheme is based on the notion of "atomic plane," plane surfaces populated by atoms. Each atomic plane is considered to behave like a weakly reflecting mirror. When the distance d between parallel atomic planes, the angle of incidence θ, and the wavelength λ are related so that the beams reflected by each plane are all in phase, a strong reflection is produced (**Figure 1**). Since there are many possible choices of atomic planes in a point lattice, many diffracted beams are produced in several different directions (**Figure 2**). For example, in a cubic point lattice the most populated atomic planes are defined by the faces of the cube. But one can also visualize atomic planes containing the body diagonals of the cube. Different atomic planes are identified by means of sets of three integer numbers, called "Miller indices." They are the reciprocals of the intercepts that a given atomic plane, closest to the origin, cuts through the three axes used to define the point lattice of the crystal. So, for example, the faces of the cube in **Figure 3** are the {1 0 0} planes, the planes through the body diagonals are the {1 1 0} planes, etc.

In the Laue method, the incident X-ray beam is "polychromatic." In this way, every set of atomic planes $\{h\,k\,l\}$ will utilize appropriate X-ray energy, present in the incident beam, to produce a spot on the film. So, in principle, every spot of the diffraction pattern corresponds to a given set of Miller indices. The Laue technique, the oldest experimental

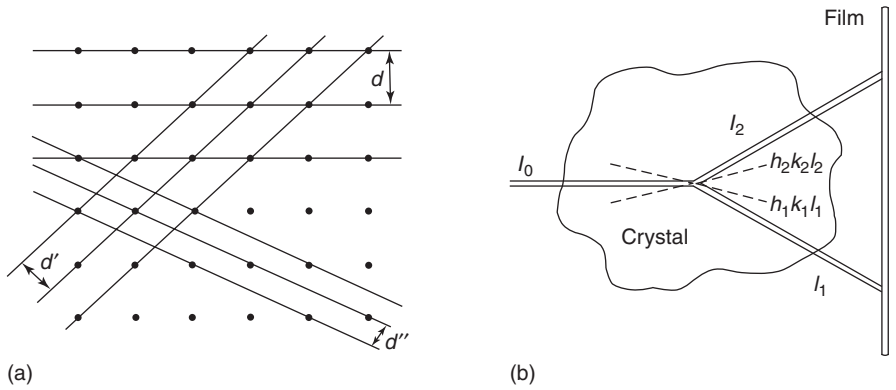

Figure 2 (a) Three sets of parallel Bragg planes with different grating spacings. (b) Principle of the Laue method. The incident beam is polychromatic. Two sets of lattice planes h_1 k_1 l_1 and h_2 k_2 l_2 reflect two monochromatic beams I_1 and I_2, with different wavelengths, according to Bragg's law.

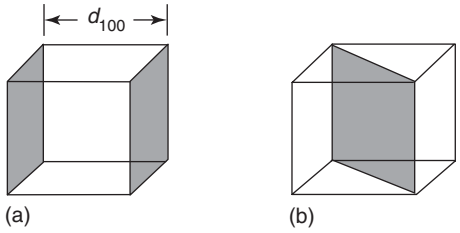

Figure 3 Lattice planes corresponding to the (a) {1 0 0} and (b) {1 1 0} Miller indices in a simple cubic lattice.

technique for X-ray diffraction, is still used for finding the orientation of single crystals. It has been resurrected as a research experimental tool for the crystal structure determination of proteins and other biological crystals. It is used at synchrotron sites, in a time-resolved mode, to study time-dependent phenomena, with resolution times $\sim 10^{-9}$ s or less.

Temperature Effects

It is already discussed in the previous section that a three-dimensional ordered array of pointlike scattering centers can produce positive interference along certain directions in space, giving rise to diffracted beams. The assumption was that these scattering centers are fixed. In reality, it is known that atoms in a solid are not stationary; they vibrate around their equilibrium positions. These thermal vibrations are the origin of thermal energy. Two identical bodies at different temperatures correspond to two identical atomic arrays with different amplitudes of thermal vibrations. If the atoms are at rest, exactly located at their lattice positions, no X-rays are scattered outside of the Bragg beams. Thermal vibrations produce attenuation of the Bragg beams, and diffuse scattering outside of the Bragg beams. Thermal vibrations are present at all temperatures, even at absolute zero. It is a phenomenon called "zero-point energy," an effect predicted by the quantum theory and amply verified by experiment. Typical frequencies of thermal vibrations are in the range of 10^{12}–10^{13} Hz. Thermal amplitudes are normally a large fraction of the interatomic distances. They can be easily $\sim 10\%$ of the distance between atoms. The time a photon takes to go through a crystal and be channeled into one of the diffracted beams is comparable with the period of thermal vibrations. So, the crystal appears to be totally disordered to an incoming photon. This fact was well recognized by the early pioneers of X-ray physics, to the point that it was believed that X-ray diffraction could not be possible as a consequence of thermal disorder. Fortunately, Laue decided to try anyway, and the experiment was a great success.

It was later understood that the process of X-ray scattering from a vibrating atom is equivalent, apart from inelastic effects, to scattering from an electronic "cloud," which represents the time average of the electronic charge. So, a thin two-dimensional sheet of atoms acquires a certain "thickness," as a result of thermal vibrations. Clearly, interfering effects over the electronic clouds decrease the scattering amplitude by a factor e^{-M} called "Debye–Waller factor." It should be emphasized that thermal disorder is not equivalent to the kind of structural randomness present in a glass or a liquid. The diffraction spots are sharp and well-defined; only they become weaker as temperature is increased. What counts is the time average of the charge density, which still preserves the same kind of long-range order present in a nonvibrating crystal.

The Debye theory gives for a monoatomic crystal

$$M = \left(\frac{\sin\theta}{\lambda}\right)^2 \frac{6h^2T}{M\kappa_B\Theta^2}\left(\varphi(x) + \frac{x}{4}\right) \qquad [1]$$

where θ is half of the scattering angle, λ the X-ray wavelength, h is the Planck constant, M the atomic mass, T the absolute temperature, κ_B the Boltzmann constant, Θ the Debye temperature, and $\varphi(x)$ is the Debye function

$$\varphi(x) = \frac{1}{x}\int_0^x \frac{y\,dy}{e^y - 1} \quad \text{with } x = \frac{\Theta}{T} \qquad [2]$$

Note that eqn [1] shows that M is never zero, not even at $T = 0$.

One important point which has been clarified only recently (say, after 1960) is that the diffraction spots of a vibrating crystal are due to purely elastic scattering events. The inelastic events produce scattering outside of the Bragg reflections. This is surprising because every scattering event involves a substantial transfer of energy from the X-ray photons to the scattering centers (the energy transfer can be positive or negative). For a large number of scattering events, the energy is transferred to the whole crystal, not just to a single atom. This important point is the physical origin of the Mössbauer effect. It turns out that the ratio of recoilless events is just given by e^{-M}, typically between 0.9 and 1.

Dynamical Diffraction

The amplitude of X-rays scattered by the unit cell in a crystal is given by

$$A(\boldsymbol{H}) = \sum_i f_i \exp(i\boldsymbol{r}_i \cdot \boldsymbol{H}) \qquad [3]$$

where f_i are the individual scattering form factors for individual atoms, $\boldsymbol{r}_i$ are the atomic sites, and $\boldsymbol{H}$ is the momentum exchanged in the scattering process. It is also called "scattering vector," and it has components h, k, l, the Miller indices of the diffracting planes. Equation [3] simply states that each atom becomes a source of radiation, with an appropriate phase factor. It is assumed in eqn [3] that each X-ray photon is scattered "only once," within each cell. This is the essence of the first Born approximation in the scattering theory. When many unit cells are considered, this assumption is not always verified. Typical crystal size dimensions are in the range of 10 μm or more. Each atom acts as an oscillator, capable of absorbing and emitting radiation. A balance between emission and absorption is established, which is consistent with the notion of multiple scattering. A condition of self-consistency is set up for all plane waves existing in the crystal. This was the doctoral thesis assigned in 1912 by A Sommerfeld to P P Ewald before the discovery of X-rays by W C Röntgen: to investigate what happens when electromagnetic radiation of short wavelength (0.1–0.5 nm) interacts with a crystal. For X-rays, the appropriate set of equations suitable for this problem are Maxwell equations; for electrons and neutrons – the Schrödinger equation. In either case, the crystal is described as a medium which is periodic in three dimensions. More specifically, the index of refraction is supposed to be periodic in three dimensions, and can therefore be Fourier analyzed. In principle, an infinite number of plane waves is considered, one for every reciprocal lattice node, and an infinite number of homogeneous linear equations is obtained for the amplitudes of the plane waves. In practice, a finite number n of plane waves is considered, where n is the number of sets of atomic planes for which Bragg's law is close to be satisfied. The number n is typically 2, which means that only one Bragg reflection is excited. It turns out that solutions can be found for two distinct values of the index of refraction (eigenvalues); in other words, the crystal becomes "birefringent" when Bragg's law is close to being satisfied for a particular set of atomic planes. An incident beam with wave vector $\boldsymbol{k}_o$ generates in the crystal two refracted beams with the same tangential components $\boldsymbol{\beta}_{o1}$, $\boldsymbol{\beta}_{o2}$, which in turn, by virtue of Bragg's law, generate two diffracted beams with wave vectors $\boldsymbol{\beta}_{H1}$, $\boldsymbol{\beta}_{H2}$, (H stands for h, k, l) . The two wave vectors $\boldsymbol{\beta}_{o1}$, $\boldsymbol{\beta}_{o2}$ only differ by a small amount along the normal to the surface. The same holds for $\boldsymbol{\beta}_{H1}$, $\boldsymbol{\beta}_{H2}$. It is expected that waves with almost identical wave vectors will generate beating effects. Such effects can only be seen in highly perfect crystals. These beating effects were predicted by M von Laue in the 1930s and named by him as "Pendellösung," but they could only be observed in the late 1950s, when the semiconductor industry was able to produce highly perfect crystals of germanium and silicon, which were needed for the production of transistors. It was also realized that the two eigenvalues for the index of refraction, corresponding to two different modes of propagation called "wave fields," acquire different absorption coefficients when Bragg's law is satisfied. One mode (can be called α) propagates through the crystal very easily, even when the average photoelectric absorption is very strong (the value in operation when Bragg's law is far from being satisfied). The α mode corresponds to a situation called 'anomalous transmission." The other mode (can be called β) corresponds to a very high absorption, higher than the average value. The physical reason for this difference in absorption coefficients is that at the Bragg condition a system of standing waves is set up in the crystal for both branches, α and β. The α branch has maxima between atomic planes; therefore, absorption is weak because there are no electrons

where the electric field has maxima. The β branch has maxima on the atomic planes; therefore, it is heavily absorbed. The standing waves maxima and minima can be shifted in a controlled fashion between the atomic planes. By looking at the X-ray fluorescence emitted by particular impurities (such as arsenic in silicon), it has been possible to confirm that the arsenic atoms lie on substitutional sites. The X-ray standing waves technique (XRSW) is also used quite often to characterize the structure of epitaxial layers deposited on a perfect crystal, such as silicon or germanium.

A perfect crystal is characterized by a high level of coherence between distant regions, which favors multiple scattering and consequently a marked reduction in scattered intensity. A strained region therefore diffracts more intensely. This is the basis of "X-ray topography," a technique in which the contrast of X-ray images is used to learn about the structural defects present in the crystal.

X-Ray Interferometry

Interference between coherent beams requires precise machining of the optical elements (lenses and mirrors) to an accuracy of the order of the wavelength of light or less. For visible light, this means an accuracy of $\sim 5000\,\text{Å}$, which is feasible. For X-rays a typical wavelength is 1 Å, which is comparable to the size of an atom. So, it would seem that X-ray interferometry is out of the question. In 1965 a report by Ulrich Bonse and Michael Hart appeared in print in which coherent interference effects were observed between spatially separated X-ray beams. Use was made of "Laue diffraction," namely, diffraction through crystal slabs, in transmission geometry, from lattice planes perpendicular to the surface. Typically, in Laue diffraction, two beams emerge from the backside of the slab, which are coherently related (**Figure 4**). By combining three silicon slabs in sequence, U Bonse and M Hart were able to observe interference fringes when a plastic wedge was inserted in one of the interfering beams. The thickness gradient was perpendicular to the plane of **Figure 5**. To guarantee a perfect alignment of the three slabs with atomic precision, they were carved out from a monolithic silicon block (**Figure 6**). A plastic wedge was introduced on one of the interfering beams in order to produce a variable phase shift, which gave rise to a number of interference fringes on the beams T and H emerging from the backside of the right slab in **Figure 5**. Since it is impossible to polish a surface to angstrom accuracy, one may wonder how X-ray interferometry can be observed in the angstrom region. The question to be asked, both for X-ray and optical interferometry, is

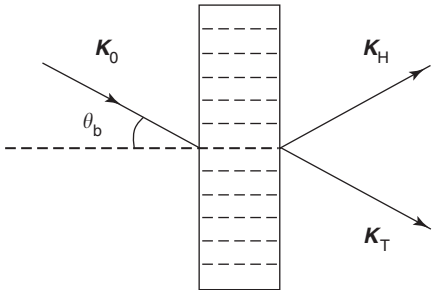

Figure 4 Geometry of Laue case diffraction. The diffracted beam propagates in a half-space which is the backside of the crystal, different from the one in which the incident beam is propagating.

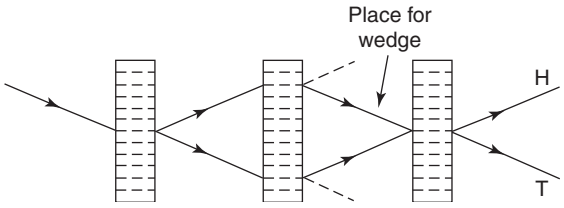

Figure 5 The three crystals are combined in one single unit. They are carved out from the same monolithic block. A plastic wedge is inserted along one of the interfering beams. The upper optical path is different from that of the lower beam. Interference fringes are expected to become visible.

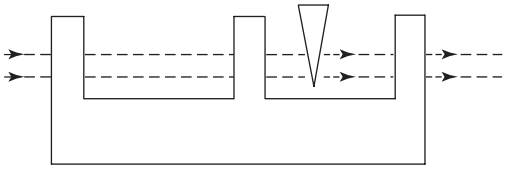

Figure 6 Side view of the Bonse–Hart interferometer. A plastic wedge is inserted to intercept one of the interfering beams. The optical path in the upper ray is smaller than that in the lower ray. Interference fringes are produced and made visible on a photographic film placed on the backside of the interferometer.

how much is the phase of a beam going to be affected by a step Δt. In the case of visible light, the dephasing effect amounts to $2\pi\ \Delta t/\lambda$, which is a big effect. In the case of X-rays, the situation is different, because X-rays are scattered by "atoms," not by the surface itself. The dephasing amounts to $2\pi\Delta t(n-1)/\lambda$, which is quite small, because $(n-1)$ is $\sim 10^{-5}$, in magnitude. So, for X-rays, relatively large values of Δt can be tolerated. To enable coherent photons to meet on the third slab on the right (**Figure 5**), the distances between the slabs should be "exactly" equal. How exactly? Within the longitudinal and transverse coherence lengths of the X-ray photons, typically in the range of 5–20 μm, which is not too hard to achieve in most cases.

A question may be asked about the requirement of monochromaticity for the incident X-ray beam. The trajectories of the X-ray photons are determined by the Bragg diffraction angles. Since the peak widths of the Bragg diffracted beams are quite narrow (seconds of arc), photons with even slightly different energies follow distinctly different paths. Since every photon can only interfere with itself, it is realized that $\Delta\lambda$ does not depend on the monochromator upstream, but only on the peak width $\Delta\theta$. So, monochromaticity is not an issue.

X-ray interferometers have been used by Deslattes and Henins in 1973 to calibrate X-ray wavelengths against optical standards. The same X-ray interferometers have been successfully used with thermal neutrons giving rise to a whole new field of "neutron interferometry." Many quantum effects have been observed for the first time by means of neutron interferometry and have been described in the book by Rauch and Werner. The list includes the following:

1. The observation of gravitationally induced quantum interference.
2. The observation of the phase shift of a neutron due to precession in a magnetic field.
3. The effect of the Earth's rotation on the quantum mechanical phase of the neutron, and many others.

Multiple Beam Diffraction

An X-ray diffraction experiment yields the magnitudes of the various Fourier components of the scattering object. The phases, however, are lost. This is a severe limitation in the ability to determine structures by means of diffraction experiments. This is the essence of the so-called "phase problem" in crystallography. One technique that provides experimental determination of phases is based on the principle of multiple Bragg scattering, a situation in which two or more Bragg reflections are excited at the same time. Suppose that a weak Bragg reflection $\boldsymbol{P}$ is excited, and that the crystal is rotated around $\boldsymbol{P}$ in such a way that the incident X-ray beam always forms the same angle with the lattice planes associated with the $\boldsymbol{P}$ reflection. A plot of the intensity of $\boldsymbol{P}$ versus the rotation angle ψ is called "azimuthal plot." When another reflection $\boldsymbol{H}$ is excited simultaneously for a particular value of ψ, a strong perturbation in the $\boldsymbol{P}$ intensity is observed, typically a sharp peak. A careful analysis of the azimuthal plot reveals that in most cases a pronounced asymmetry is present at the base of the peak. This is called "the asymmetry effect." It can be shown that the asymmetry effect is due to interference between Bragg beams, and that it carries phase information. Specifically, a three-beam experiment (which involves two Bragg reflections plus the incident beam) provides a value for the so-called "triplet invariant":

$$\delta = \varphi_{\boldsymbol{H}} + \varphi_{\boldsymbol{P}-\boldsymbol{H}} - \varphi_{\boldsymbol{P}}$$

This definition of δ makes it independent of the origin chosen for calculating structure factors. For a centrosymmetric structure, δ is restricted to two possible values, 0° or 180°. These ideas have been fruitfully applied to improve the understanding of the structure of quasicrystals. This is the name given to solid substances which are not periodic, yet they are capable of producing sharp diffraction peaks, similar to those produced by regular crystals. In structural analysis of new substances, the first question to be asked is whether the structure is centrosymmetric or not. It was generally assumed, without a strong justification, that most quasicrystals, with very few exceptions, are centrosymmetric. However, when there is no periodicity, it is difficult to understand what centrosymmetry really means. A number of three-beam diffraction experiments have been done to clarify this issue. **Figure 7** shows the azimuthal plot of Al–Pd–Mn quasicrystal, a very high-quality material, generally considered to be centrosymmetric. It is noted that the scattering vectors for quasicrystals are defined in a six-dimensional space, and therefore they have six components. It is a mathematical convenience which allows one to treat quasicrystals as periodic objects in a six-dimensional space. The asymmetry effect is clearly visible, and it is consistent

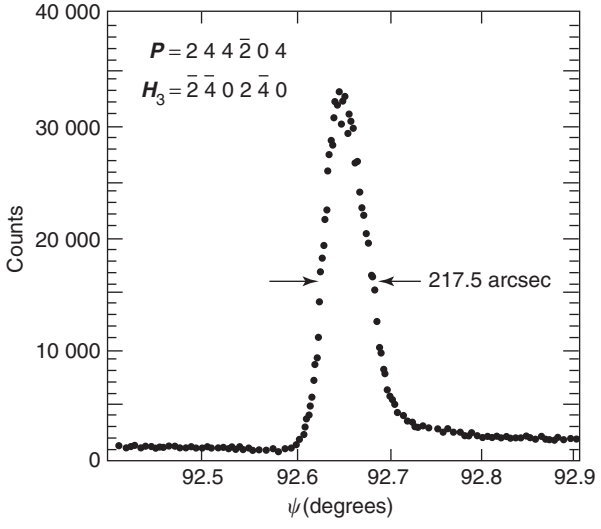

Figure 7 Azimuthal plot of the $(2\,4\,4\,\bar{2}\,0\,4)$ reflection, a three-beam case. The simultaneous reflection $\boldsymbol{H}_3$ is the $(\bar{2}\,\bar{4}\,0\,2\,\bar{4}\,0)$. The X-ray energy is 7000 eV.

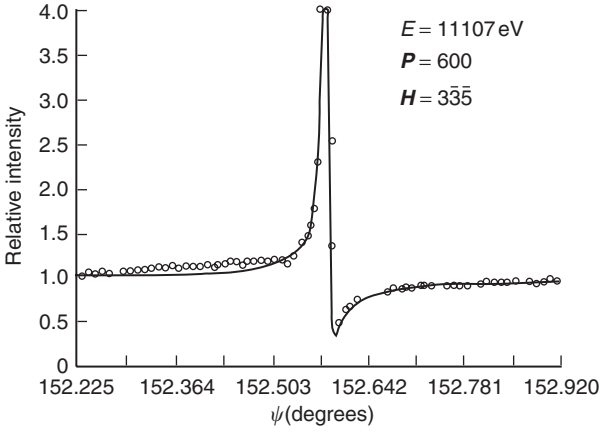

Figure 8 Azimuthal dependence of the 600 in germanium, near a peak due to three-beam diffraction (the $3\,\bar{3}\,\bar{5}$). Circles represent experimental data. Solid line is theory. The agreement is excellent.

with a triple invariant $\delta = 112.5^\circ$, a clear indication of lack of centrosymmetry. While the deviations from centrosymmetry are probably very small, it is found that multibeam diffraction tends to overemphasize even a small amount of centrosymmetry.

Another area in which three-beam diffraction is finding useful applications is that of resonant scattering. In germanium crystal, the 600 reflection is space-group forbidden. This means that the 600 cannot be turned on even for the most general charge density consistent with the symmetry properties of the Fd3*m* space group. This means that if an electron is put in a general position (x, y, z) within the unit cell, and then one electron is placed in all other 47 equivalent positions, as dictated by the symmetry properties of the space group, the 600 structure factor for these electrons is always zero. Surprisingly enough, the 600 can be turned on again if resonant scattering is used. It is found that the 600 exhibits a beautiful asymmetry effect around a three-beam situation, and that interesting phase effects can be observed, which should provide a much more detailed description of the valence charge density in Ge. **Figure 8** is an example of a three-beam experiment in Ge-600 at resonance. Again, the asymmetry effect is clearly visible, and phases can be reliably extracted from the azimuthal profiles.

Introduction

Brillouin light scattering (BLS), in its historical sense, is the inelastic scattering of light by acoustic phonons. It thus provides information on the elastic properties of the scattering medium and it has been used to study gases, liquids, crystals, polymers, glasses, semiconductors, nontransparent thin layers, and superlattices. BLS yields information similar to that obtained using ultrasonic techniques but it has certain advantages when dealing with small samples, reactive samples, or in cases where contact with a transducer poses experimental difficulties (e.g., high temperatures and pressures). The Fabry–Perot interferometer (FP) is, par excellence, the instrument of choice to achieve the 1–100 GHz resolution required in typical BLS experiments. Because of this, BLS has become synonymous for all experiments performed with an FP independent of whether the scattering is produced by acoustic phonons, by magnons, or by electronic states. Here BLS is used in this broader context.

This article provides a brief historical review and a condensed description of the origin of the effect. Also, some key experimental aspects are briefly described. The emphasis of this article is to illustrate, via specific examples, the range of problems that can

be investigated using BLS. This will include the determination of elastic constants with emphasis on its application under adverse experimental conditions (temperature, size, and pressure), as well as its application to magnetic systems and electronic levels.

Brief History of BLS

The term Brillouin light scattering (BLS) was derived from the theoretical prediction made by L Brillouin in 1914 of a possible inelastic interaction between light and sound. The description of light-scattering experiments was published in his PhD dissertation. A similar prediction was made independently in 1926 by L I Mandelstam. The first experiment was performed by E Gross in 1930. BLS spectroscopy developed rapidly in the early 1960s as lasers became available. The first light-scattering experiments in pure liquids were done by G B Benedek *et al*. in 1964. The technique remained almost an academic curiosity until the multipassed and later the tandem FP, both introduced by J Sandercock, enabled the weak Brillouin signals to be observed in the presence of the usually overwhelming intensity of the elastically scattered light. At that point, BLS became a powerful and versatile tool for material characterization. This article describes how it has made significant contributions to a wide range of problems in condensed matter physics.

Origin of BLS

Any excitation that produces a time-varying change in the polarizability of a medium (for a longitudinal sound wave this is related to the change in refractive index caused by the densification and rarefaction produced by the wave) interacts with electromagnetic radiation via the polarizability α. The polarization of the medium induced by the electromagnetic wave becomes

$$\boldsymbol{P}(\boldsymbol{r},t) = [\langle \alpha \rangle + \delta\alpha(\boldsymbol{r},t)]E_0 \mathrm{e}^{\mathrm{i}(\boldsymbol{k}_i \cdot \boldsymbol{r} - \omega_0 t)}$$

and it can be shown that this leads to the re-radiation of electromagnetic waves with frequencies $\omega_0 \pm \omega_{\mathrm{phon}}$. The origin of the polarizability changes ($\delta\alpha$) is different for different excitations: bulk phonons modulate the polarizability via elastooptic effects (strain-induced changes in the refractive index), surface phonons produce polarizability changes as the interface moves into and out of the vacuum (known as the ripple mechanism), and magnons interact via magnetooptic contributions.

Interference between the radiation emanating from throughout the sample leads to the condition that only excitations with wave vector $\boldsymbol{q}$ that satisfy

$$\boldsymbol{q} = \boldsymbol{k}' - \boldsymbol{k}$$

where $\boldsymbol{k}$ and $\boldsymbol{k}'$ are the wave vectors of the incident and scattered radiation, respectively, will produce scattered radiation. Since $\boldsymbol{k}$ and $\boldsymbol{k}'$ are determined by the directions of the incident and scattered radiation, it is clear from the above equation that in a given experiment only excitations with a fixed wave vector will be probed. This also makes it clear that the geometry chosen for the experiment is crucial for analyzing the resulting data.

Scattering Geometries and Frequency Analysis

There are a number of scattering geometries that are often used in Brillouin experiments; these are shown schematically in **Figure 1**. Not only does each scattering geometry select different q values but it is clear that geometries (a), (b), and (c) are only suitable for transparent materials while geometries (d) and (e) can be used even if the sample is not transparent. The (e) geometry is a variant of the back-scattering geometry (d). The magnitude of the wave vector probed in each geometry, calculated from the $\boldsymbol{q} = \boldsymbol{k}' - \boldsymbol{k}$ equation, is also indicated in **Figure 1**. In these expressions, $|\boldsymbol{k}| = 2\pi/\lambda$ (with λ the wavelength of the incident radiation, and the refractive index of the medium). In opaque materials, only the component of q parallel to the surface is conserved so that the $\boldsymbol{q} = \boldsymbol{k}' - \boldsymbol{k}$ equation yields only the value of $\boldsymbol{q}$ in the surface plane $\boldsymbol{q}_s$. Typically, the choice of scattering geometry depends on the nature of the sample and the constraints of the experiment being performed; for example, cryostat, magnet, and furnace. In the laboratory, the incident radiation depicted in **Figure 1** is usually delivered by a laser. Since the frequency shifts are small, it normally requires a laser operating in a single longitudinal cavity mode. The scattered radiation is typically collected by a high-quality lens (often a camera lens). Frequency analysis of the scattered light is accomplished using an FP interferometer. In all but a few cases, experiments rely on the high contrast provided by multipassed and/or tandem instruments. These very delicate instruments are technically complex. Excellent reviews on their operation and fabrication exist in the literature (see the "Further reading" section).

Examples

To highlight BLS, a selection of examples are discussed. First, the classical application is described: the

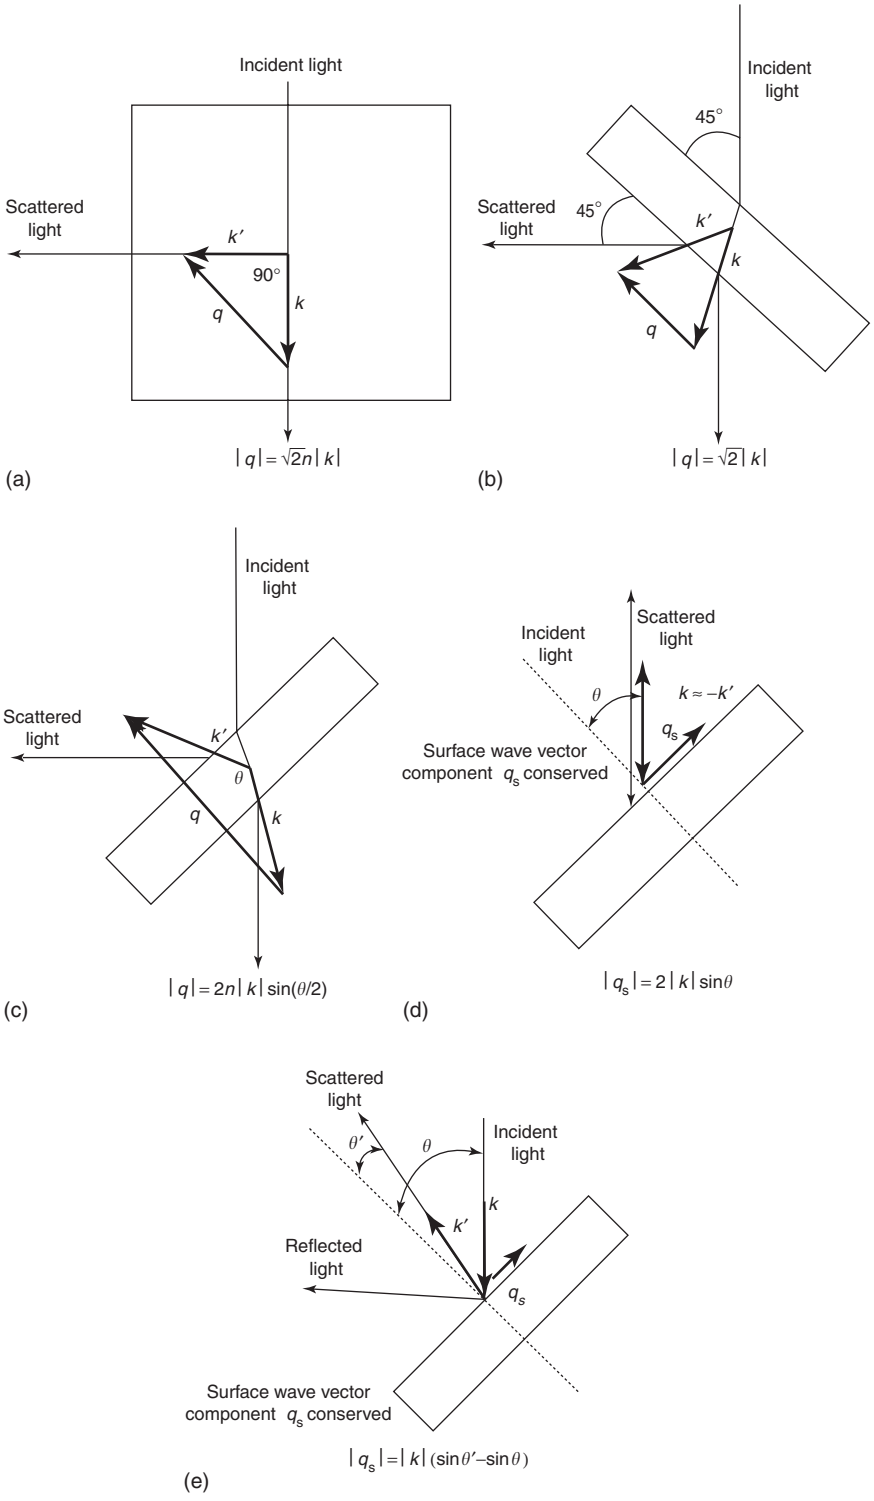

Figure 1 Scattering geometries: (a) a bulk-type analysis of excitations inside a transparent material using 90° geometry, (b) a thin transparent layer – this geometry is sensitive to excitations propagating in the plane of the sample, (c) a transparent layer with near-normal incidence – this geometry is sensitive to wave vectors perpendicular to a sample surface, (d) a back-scattering geometry in an opaque material which is sensitive to in-plane, surface wave vectors, and (e) a variant of geometry (d), where $\boldsymbol{k}'$ is not along the direction of the incident light, is also used for studying surface excitations. For geometries (a) and (c), the material refractive index n is required for data analysis.

determination of elastic constants in a bulk transparent material. In this subsection, references to examples are provided where the determination of c_{ij} has been done at high temperatures and high pressures. Then examples of BLS applied to liquids, glasses, opaque materials (surface wave BLS), magnetic materials (magnons), and electronic levels are given.

Determination of Elastic Constants of a Bulk Crystal

Figure 2 shows a Brillouin spectrum obtained from a diamond crystal in the backscattering geometry shown in **Figure 1c**. Since the diamond surface was (1 1 1) and since the phonons probed in the experiment propagate along the surface normal, the peaks observed in **Figure 2** correspond to phonons along the [1 1 1] direction. Along this direction the longitudinal sound velocity is $v_L = \sqrt{(c_{11} + 2c_{12} + 4c_{44})/3\rho}$ and the velocity of the (degenerate) transverse phonons is $v_T = \sqrt{(c_{11} - c_{12} + c_{44})/3\rho}$. The peaks in **Figure 2** have therefore been labeled as L and T, respectively.

Since diamond crystals are large enough to be cut and polished with any desired orientation, it is clear that from a combination of measurements in different scattering geometries and/or crystal orientations the whole set of elastic constants can be determined. In **Table 1**, the c_{ij} of diamond determined by both Brillouin scattering and by ultrasonic techniques are listed. The results of both techniques are in very good agreement but it is interesting to note that while the BLS measurements were performed on crystals of around 1/3 carat, the ultrasonic measurements used a 22-carat diamond.

In cases where large, transparent crystals are available, it is clear from **Table 1** that BLS has no particular advantage over ultrasonic techniques. However, when only small samples are available the BLS technique becomes the technique of choice. Single crystals of cubic boron nitride (BN), for example, cannot be grown as single crystals larger than $\approx 500\,\mu m$. In this case, BLS becomes the technique of choice and yields the c_{ij} also included in **Table 1**.

The preceding section outlines how BLS can be used to determine c_{ij}. At ambient conditions, c_{ij} can often be determined more accurately using ultrasonic techniques. In some cases, however, BLS becomes a much more versatile tool than ultrasonics. Such cases usually involve samples where transducer bonding is difficult, as was mentioned above, in small or thin samples, high-pressure and/or high-temperature experiments, or cases where chemical reactivity becomes severe. For example, the temperature dependence of the c_{11} and c_{44} elastic constants of $Ba_{1-x}La_xF_{2+x}$ over the range 300–1600 K was determined by P E Ngoepe and J D Comins who found a linear decrease that they attributed to anharmonicity. A case involving high pressures is represented by measurements of liquid and solid argon in a diamond anvil cell up to 70 GPa.

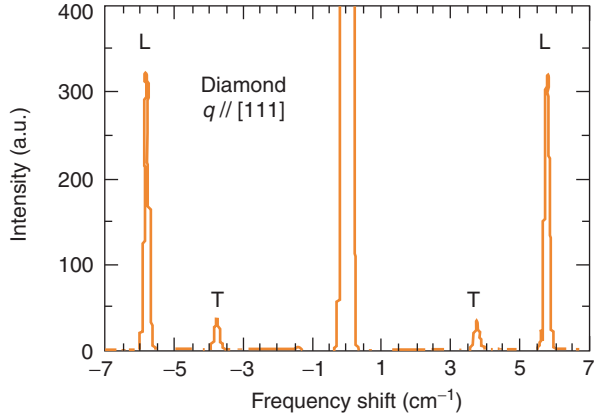

Figure 2 Brillouin spectrum from a diamond crystal in the geometry from **Figure 1c**. The longitudinal (L) and transverse (T) phonons propagate along the [1 1 1] direction.

Diamond, ultras	1079	124	578
Boron nitride, BLS	820	190	480

Measurements of Spectral Features in Liquids

BLS can also be used to determine the elastic response of liquids. In contrast to solids, however, where the unshifted peak is dominated by the effects of impurities and surface scattering, in pure liquids the central peak is due to entropy fluctuations. The intensity of the unshifted component is related to that of the shifted BLS peaks via the Landau–Placzek ratio, C_p/C_v–1, where C_p and C_v are the specific heats at constant pressure and volume, respectively. In pure liquids, therefore, BLS can be used to study the intensity and shape of the central peak. Frequency broadening of this peak can be caused by fluctuations in the orientation of anisotropically polarizable molecules or by diffusive processes governed by the equations of hydrodynamics. In liquids, it is also possible to investigate relaxation and damping effects via the phonon lifetime that translates into changes in the shape and line width of the phonon peaks. The same approach cannot usually be applied to most bulk crystals, because of a very low damping that results in line widths below the experimental resolution.

However, in temperature regions where structural phase transitions occur, damping processes influence Brillouin line widths enough so that the changes are detectable, for example, in molten and crystalline alkali halides, during order–disorder transitions in mixed crystals, or during ferroelastic phase transitions in some crystals.

Glasses

BLS has been extensively used to investigate the transition of liquid to solid in materials that do not crystallize: for example, silica, $Rb_{1-x}(NH_4)_x/H_2PO_4$ (10–300 K), $Rb_x(NH_4)_y/H_2PO_4$ (20–80 K), and $Ca(NO_3)/KNO_3$ (320–640 K). Across the transition region, the phonons in these materials become highly damped and the resulting line shapes can be interpreted in terms of the underlying mechanism of the glass transition. These types of investigations are also of practical importance, because these materials are often used in fiber optics technology and in optoelectronic devices.

Gases

BLS in gases detects local fluctuations that lead to frequency shifts in the 0.1–1 GHz range. These shifts can also be viewed as a Doppler shift from the motion of individual atoms. In this context, BLS has also been used to investigate how the phonon spectrum evolves as a gas is pressurized to become a fluid. This evolution reflects the hydrodynamic transformation as the thermal mean free path for atomic motion becomes comparable and then shorter than the wavelength at which the medium is being probed by the scattering of visible light. These experiments can also be interpreted in terms of the hydrodynamic equations of motion. Investigations of CO_2 up to 8 atm pressure, and Xe over the range 0.022–0.66 atm are two instances where this phenomenon has been investigated.

Surface Acoustic Modes in Thin Layers

Light scattering from acoustic excitations in opaque materials results from a purely surface-induced mechanism, viz. phonon-induced thermal ripples. In these cases, the scattering geometries (d) and (e) in **Figure 1** must be employed. In a semi-infinite medium, the strongest coupling is to Rayleigh waves (reminiscent of waves in the ocean) with some weaker features induced by bulk waves reflecting from the free surface. In thin films and layered structures, however, it is also possible to couple to modes that are localized within the layers or at the interfaces; these modes are generally referred to as Sezawa modes. If the medium is not completely opaque, it is possible to couple to the phonons via both the ripple and elastooptic mechanisms. In these cases, unusual interference effects are possible.

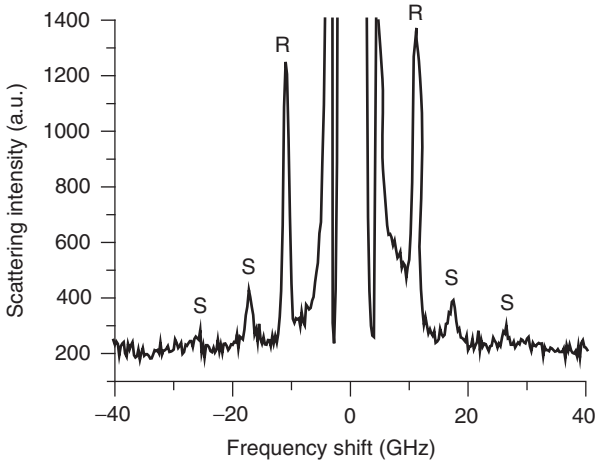

Figure 3 BLS from surface acoustic phonons in the Co/Cu superlattice. Descriptions: R – the Rayleigh surface mode, S – Sezawa or higher-order Rayleigh modes. The measurement was carried out for (*s*–*s*) polarizations of the incident and scattered light.

Figure 3 shows a BLS spectrum from a Co/Cu superlattice built from 60 bilayers of 1 nm Co/0.8 nm Cu in which the Rayleigh and Sezawa modes are observed. The experiment was carried out using a Sandercock-type tandem 3-pass interferometer. From these results, the effective elastic properties of the superlattice can be extracted.

In cases where the surface layers become much thinner than the wavelength of light, the medium again becomes equivalent to a homogeneous solid. In these cases, Brillouin scattering has been a very efficient and reliable tool for determining the effective elastic constants of the heterogeneous solid. For example, R Danner *et al.* in the Ni/V superlattice, for different layer thicknesses from the range of 1.85–63.3 nm, proved that this b.c.c./f.c.c. system reveals softening of elastic parameters. J A Bell and co-workers measured effective elastic constants in the Mo/Ta superlattice (c_{11}, c_{13}, c_{33}, c_{44}) with an elementary spatial bilayer thickness ranging from 0.7 to 20 nm.

Observation of Bulk and Surface Spin Waves in Metallic Superlattices

Brillouin scattering can also be used to investigate the magnetic properties of materials via their magnetic excitations – magnons. In this sense, the information it yields is similar to that obtained in ferromagnetic resonance (FMR) experiments. However, contrary to

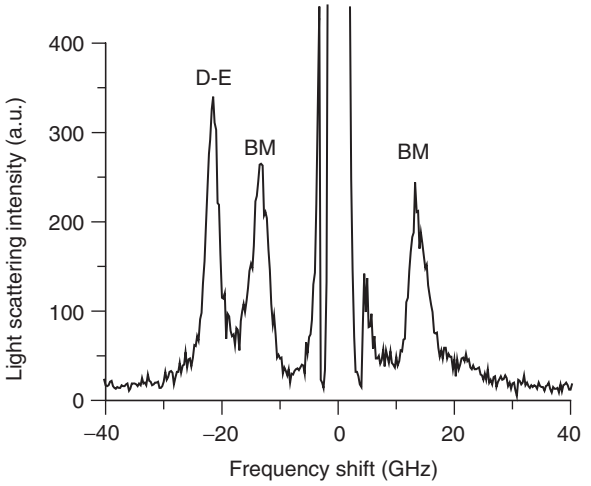

Figure 4 BLS from spin waves in a multilayered Co/Cu system. Descriptions: D-E, Damon–Eshbach surface mode, BM, (bulk magnon) collective excitations of a bulk-like nature resulting from coupling between spin waves through the nonmagnetic spacer layer. The measurement was carried out for (*s*–*p*) polarizations of the incident-scattered light.

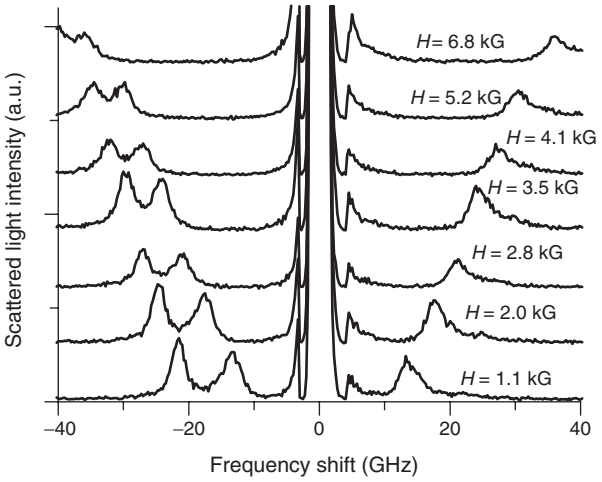

Figure 5 A set of Brillouin spectra measured for different magnetic field intensities in the Co/Cu superlattice. The peaks that appear only on the left side (Stokes signals) result from scattering from a unidirectional surface-like spin wave (D-E mode from **Figure 4**).

FMR that probes the infinite wavelength excitations, Brillouin scattering probes excitations with wavelengths comparable to the wavelength of light. As for phonons, magnons can be subdivided into surface-like and bulk-like excitations. Expressions relating the magnon frequencies to the magnetic properties of the material – magnetization, anisotropies, applied field, and gyromagnetic ratio – can be quite complex and often cannot be rendered in analytical form.

The Brillouin scattering technique has also been used to investigate the nature of magnetic excitations in nonconventional materials. In the case of the Co/Cu superlattice described in the previous paragraph, which is built from alternating magnetic and nonmagnetic materials, bulk-like collective excitations resulting from coupling between spin waves across the nonmagnetic spacer are detected (**Figure 4**). Additionally, a surface-like mode propagating on the surface of the sample was also found. The experiment was carried out with a tandem 3-pass spectrometer, with (*s*–*p*) polarization of the incident and scattered light, and a constant magnetic field lying in the sample plane. **Figure 5** provides results for different magnetic field intensities, from which the gyromagnetic ratio and saturation magnetization can be determined.

Scatterings from Electronics Levels

More recently, BLS has been used to probe the low-lying excitations of B impurity atoms in a diamond host . In this case, since the excitations are local and

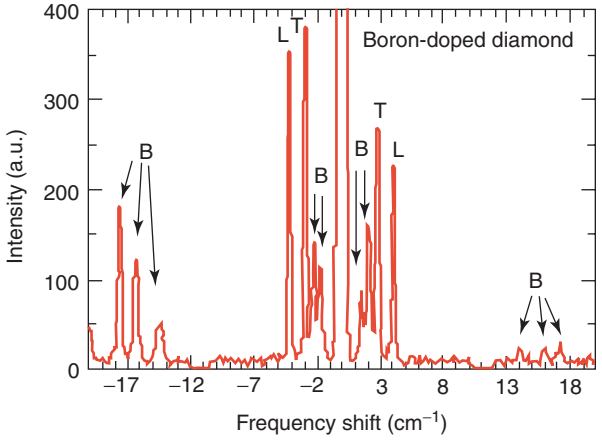

Figure 6 Brillouin scattering from B impurities in a diamond crystal as a host. Descriptions: (L) longitudinal phonons, (T) transverse phonons, and (B) electronic transitions between the hydrogen-like states surrounding the B atoms.

are not described by a wave vector, the results do not depend on the scattering geometry. **Figure 6** shows a spectrum recorded at low temperature and with an applied field of 4 T; apart from the expected longitudinal (L) and transverse (T) phonon peaks, the additional peaks labeled B can be traced to electronic transitions between the hydrogen-like states surrounding the B atoms. Under the effect of an applied field these modes split and from the measured splittings, the degeneracy and nature of the transitions is extracted. This, in turn, provides information on how B impurities in diamond lead to its semiconducting properties.

Scattering, Inelastic: Electron

M Erbudak, Laboratorium für Festkörperphysik, Zürich, Switzerland
D D Vvedensky, Imperial College, London, UK

Introduction

Inelastic electron-scattering phenomena are used to obtain information on the electronic properties and atomic structure of materials. An interaction event between an electron and a target material is called inelastic if the electron loses some or all of its energy; otherwise, the event is called elastic. Any energy loss by the electron is equal to the energy gained by the material and is characteristic of the type of scattering event. The measurement of an inelastic event determines the energy transferred and the rate at which this transfer occurs, which provides physical information about the elementary excitations of the material.

Inelastic interactions can be grouped according to different energy-transfer regimes that form the basis of the principal experimental techniques. Historically, inelastic electron scattering was developed prior to the availability of continuous-energy photon sources from dedicated storage rings. In fact, under certain circumstances, electronic excitations are equivalent to photon excitations in that they can be described within a common conceptual and theoretical framework.

An electron is an elementary particle with a mass m and, owing to its wave nature, has a wave number $\boldsymbol{k} = \boldsymbol{p}/\hbar$, where $\boldsymbol{p} = m\boldsymbol{v}$ is the momentum, $\boldsymbol{v}$ is its velocity, and $\hbar$ is Planck's constant. The kinetic energy is expressed classically by $E = (1/2)mv^2$, where $v = |\boldsymbol{v}|$. Electrons have a negative charge e and a nonclassical angular momentum (spin). These properties play a central role in the interactions between electrons and their environment and constitute the basis of a wide range of spectroscopic techniques. Owing to their unique properties, there are both advantages and disadvantages in using electrons as a probe in analytical applications. Spin-polarized or spin-averaged beams of electrons are readily created, electrons can be accelerated to any energy, and focused on a target at will. After they interact with

the target material, electrons can be analyzed according to their intensity, momentum, energy, and spin polarization. In the final state, there are, even in an idealized single-scattering event, two electrons which arbitrarily share the initial energy. These electrons are indistinguishable, which makes the interpretation of the results especially challenging.

The Cross Section for Inelastic Scattering

Electron–atom scattering is the cradle of today's quantum mechanical understanding of many solid-state interactions. Electron–solid interactions, however, not only present a wealth of phenomena to aid the development of modern physics, but have also made spectroscopies based on electronic excitations one of the major sources of information on atomic and electronic structure and on elemental composition of materials. In order to account for all electronic interactions, a first-principles theory should be developed, though a semiclassical approach often suffices.

The strength of the electronic interaction depends on the electron energy and the material, which endows the energy dependence of a type of event with dynamical information about the interaction. If the interaction is weak, the energy $\hbar\omega$ lost by the electron and the associated momentum transfer $\boldsymbol{q}$ involve the creation of a single excitation with an energy $\hbar\omega$ and momentum $\boldsymbol{q}$. In this case, the Born approximation is valid, so the initial (i) and final (f) states of the electron are given by plane waves:

$$\psi_{\mathrm{i}} = \mathrm{e}^{\mathrm{i}\boldsymbol{k}_{\mathrm{i}}\cdot\boldsymbol{r}} \quad \text{and} \quad \psi_{\mathrm{f}} = f(\boldsymbol{k}_{\mathrm{i}})\mathrm{e}^{\mathrm{i}\boldsymbol{k}_{\mathrm{f}}\cdot\boldsymbol{r}} \qquad [1]$$

where $f(k_{\mathrm{i}})$ is the scattering amplitude. The interaction between the electron and the environment is described by a Hamiltonian containing the energy of the unperturbed sample, the energy of the electron, and the Coulomb potential $V(\boldsymbol{r})$ between the sample and the electron. During the interaction, energy and momentum are conserved: $E_{\mathrm{i}} - E_{\mathrm{f}} = \hbar\omega$ and $\boldsymbol{k}_{\mathrm{f}} - \boldsymbol{k}_{\mathrm{i}} = \boldsymbol{q}$. Using Fermi's golden rule, the scattering cross section can be expressed as

$$\mathrm{d}\omega = \frac{2\pi}{\hbar}|M^{E_{\mathrm{i}},\boldsymbol{k}_{\mathrm{i}}}_{E_{\mathrm{f}},\boldsymbol{k}_{\mathrm{f}}}|^2\delta(E_{\mathrm{i}} - E_{\mathrm{f}})\mathrm{d}^3\boldsymbol{k} \qquad [2]$$

where the matrix element $M = \langle \phi_{\mathrm{f}}\psi_{\mathrm{f}}|V(\boldsymbol{r})|\psi_{\mathrm{i}}\phi_{\mathrm{i}}\rangle$, and ϕ_{i} and ϕ_{f} are the wave functions of the target before and after the scattering.

When an electron scatters from an atom, the interaction only with the other electrons can be inelastic because no energy is transferred to the nucleus via Coulomb scattering. The most general type of energy transfer in electronic excitations produces a transition from an occupied to an unoccupied state separated by an energy equal to the energy loss of the primary electron. The differential cross section of such a transition is obtained by integrating eqn [2] over ω:

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}E\,\mathrm{d}q} = 8\pi\left(\frac{e^2m^2}{\hbar^2}\right)^2\frac{1}{q^3k_{\mathrm{i}}^2}|\langle \phi_{\mathrm{f}}|\mathrm{e}^{-\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}}|\phi_{\mathrm{i}}\rangle|^2 \qquad [3]$$

where $q = |q|''$. The cross section $N(E) \propto \mathrm{d}\sigma/\mathrm{d}E$ is dominated by processes for which the momentum transfer is small. If $\boldsymbol{q}\cdot\boldsymbol{r} \ll 1$, one can write $\mathrm{e}^{-\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}} \approx 1 - \mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}$, and the dipole approximation used in optics becomes applicable to inelastic electron scattering:

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}E\,\mathrm{d}q} = 8\pi\left(\frac{e^2}{\hbar^2 v_i}\right)^2\frac{1}{q}|\langle \phi_{\mathrm{f}}|\boldsymbol{n}\cdot\boldsymbol{r}|\phi_{\mathrm{i}}\rangle|^2 \qquad [4]$$

where $v_{\mathrm{i}} = \hbar k_{\mathrm{i}}/m$, $\boldsymbol{q} = \boldsymbol{n}q$, and $\boldsymbol{n}$ is the unit vector along $\boldsymbol{q}$.

Interband Transitions

The validity of the dipole approximation means that the scattering cross section can be related to the dielectric properties of the target material. The dielectric response $\varepsilon(\boldsymbol{q},\omega) = \varepsilon_1(\boldsymbol{q},\omega) + \mathrm{i}\varepsilon_2(\boldsymbol{q},\omega)$ depends on the energy transfer $\hbar\omega$ and momentum transfer $\boldsymbol{q}$. Electrons interacting with the target produce a longitudinal perturbation over the long-range dipole fields. These fields attenuate the electron intensity through the absorptive part ε_2 of the dielectric constant. Since the field is screened by $1/\varepsilon$, the electron-loss function can be written as the sum of surface and bulk contributions:

$$\begin{aligned} N(E) &\propto -\operatorname{Im}\left[\frac{S}{1+\varepsilon(\omega,\boldsymbol{q})} + \frac{B}{\varepsilon(\omega,\boldsymbol{q})}\right] \\ &\equiv -\operatorname{Im}\left[\frac{1}{\tilde{\varepsilon}(\omega,\boldsymbol{q})}\right] \end{aligned} \qquad [5]$$

where S and B are weighting factors for the surface and the bulk, respectively. The cross section $N(E)$, therefore, contains fundamental information on the dielectric behavior of the bulk and the surface of the sample. A direct link between electron energy losses and the effective dielectric function $\tilde{\varepsilon}(\boldsymbol{q},\omega)$ is provided by the Kramers–Kronig relation,

$$\operatorname{Re}\left[\frac{1}{\tilde{\varepsilon}(\omega,\boldsymbol{q})}\right] = 1 - \frac{2}{\pi}\int_0^\infty \frac{\operatorname{Im}[-1/\tilde{\varepsilon}(\omega,\boldsymbol{q})]}{\omega'^2 - \omega^2}\omega'\,\mathrm{d}\omega' \qquad [6]$$

which gives

$$\tilde{\varepsilon}(\omega, \boldsymbol{q}) = \frac{\mathrm{Re}[1/\tilde{\varepsilon}(\omega, \boldsymbol{q})] - \mathrm{i}\,\mathrm{Im}[1/\tilde{\varepsilon}(\omega, \boldsymbol{q})]}{[1/\tilde{\varepsilon}(\omega, \boldsymbol{q})]^2} \qquad [7]$$

The practical advantage of energy-loss measurements over optics lies in the fact that they cover a larger energy range than experiments with photons, which facilitates a more complete evaluation of eqn [6]. The electron energy-loss function, in fact, depends on the joint density of states (DOS), defined as the convolution of the occupied initial states and the unoccupied final states that are separated by the energy loss and are coupled by the matrix element. The optical dielectric function contains the transverse properties of the solid, which may be different from the longitudinal properties accessible to electron-energy loss spectroscopy. The differences between the transverse and the longitudinal responses are negligible for a small momentum transfer $\boldsymbol{q}$ and become equal for $\boldsymbol{q} = 0$ (the random phase approximation). For higher values of $\boldsymbol{q}$, multipole transitions are well resolved in electron-induced transitions, but are strictly forbidden in optics.

Inelastic interactions are responsible for the intensity attenuation of electrons within a bulk material. The characteristic quantity for the penetration depth of the electrons is called the mean free path Λ, the value of which depends on the available excitations at a particular energy. For the range of energies $\sim$30–100 eV, Λ has values comparable to interatomic distances. Thus, the experiments contain information mainly on the surface properties (small B in eqn [5]). In optics, on the other hand, photons penetrate deep into the target material, so the information is dominated by the bulk DOS (small S in eqn [5]). Transitions that are characteristic of the surface (e.g., surface states, adsorbates) help to distinguish between bulk and surface excitations.

Plasmon Excitations

The cross section $N(E)$ in eqn [5] attains peak values for $\varepsilon_1 = 0$ or -1 and $\varepsilon_2 = 0$. This condition corresponds to charge-density fluctuations caused by the incident electrons. A longitudinal plasma wave along the crystal produces long-range Coulomb forces between positive and negative charges and excites collective oscillations. These are called plasmons in the case of a quasi-free electron gas. The plasmon energy is obtained from the Fourier modes of the electron density,

$$\rho(r) = \sum_{\boldsymbol{k}} \rho_{\boldsymbol{k}} \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} \qquad [8]$$

The $\rho_{\boldsymbol{k}}$ are amplitudes of harmonic density fluctuations obeying

$$\ddot{\rho}_{\boldsymbol{k}} + \omega_{\mathrm{p}}^2 \rho_{\boldsymbol{k}} = 0 \qquad [9]$$

in which ω_p is the Langmuir frequency

$$\omega_{\mathrm{p}} = \sqrt{\frac{n_e e^2}{\varepsilon_0 m}} \qquad [10]$$

n_e is the bulk charge density, ε_0 is the permittivity of free space, and the energy loss due to plasmon creation is $\hbar\omega_{\mathrm{p}}$. Plasmons are quantized excitations, so the energy loss is $n\hbar\omega_{\mathrm{p}}$, where n is an integer.

Plasmon energies can be used to extract changes in the electron density that accompany changes of the electronic properties or the volume of a solid. For example, the alloy Al–3 at.%Ag shows a transition from a high-temperature phase, where Al and Ag form a homogeneous solid solution, to a regime $\sim$400°C where Ag atoms precipitate as Ag_2Al clusters. The formation of these precipitates can be monitored by observing the plasmon energies of Al across the transition. With Ag atoms homogeneously distributed in the bulk, more volume is available to Al atoms, resulting in a lower effective electron density, thus shifting the plasmon energy to lower values. The spectra in **Figure 1** show that, at 480°C, the plasmon energy is reduced from 15.8 to 15.5 eV, signaling a 3.8% volume reduction. At temperatures below 440°C, Ag_2Al precipitates form that are largely decoupled from the aluminum matrix, thus leaving the volume and electron density unaltered from their values in pure Al. Thus, there is no change in the plasmon energy.

There are detailed investigations of the dependence of plasmon excitations on the momentum transfer. For increasing values of $\boldsymbol{q}$, the peak in the loss function moves to higher energies until the excitation decays into electron–hole pairs. In semiconductors, electron–hole pairs form a hydrogenic bound state called excitons which, for a material with an indirect bandgap, such as Si, have very long lifetimes because the recombination process requires the emission of a phonon to conserve momentum.

Surfaces have different charge distributions from those in the bulk. This moves the plasmon frequency to ω_{s}, where

$$\omega_{\mathrm{s}}^2(1 + \varepsilon) = \omega_{\mathrm{p}}^2 \qquad [11]$$

which, with $\varepsilon = 1$, yields

$$\omega_{\mathrm{s}} = \frac{1}{\sqrt{2}}\omega_{\mathrm{p}} \qquad [12]$$

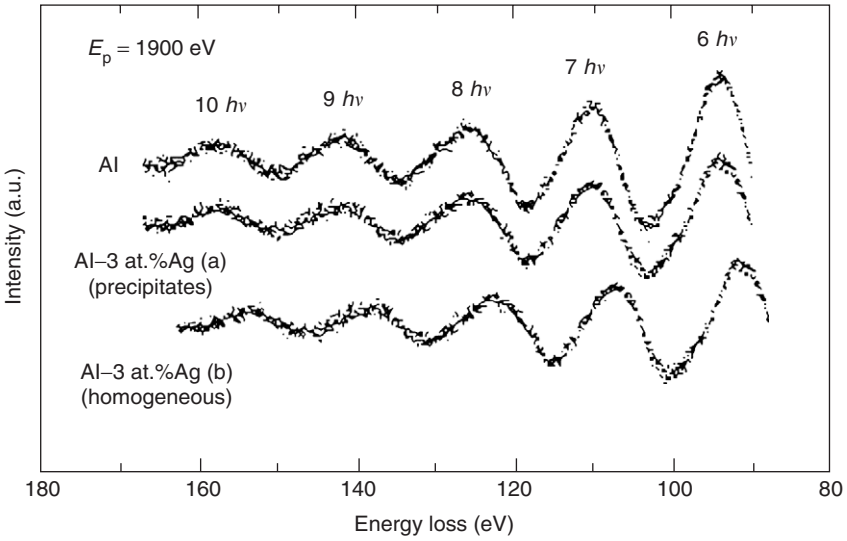

Figure 1 Energy losses in pure Al and Al–3 at.%Ag with (a) Ag_2Al precipitates, and (b) Ag atoms homogeneously distributed at 480°C. To accurately determine the plasmon energy, the measurements are extended up to the tenth plasmon loss. Figure 2 (a) Periodic textures on the metal surface that (b) lead to the formation of a photonic bandgap of surface plasmons. (Adapted from Barnes WL, Dereux A, and Ebbesen TW (2003) Surface plasmon subwavelength optics. *Nature* 424: 824–830.)

Surface plasmons are generated by the resonant interaction between the surface-charge oscillations and the electric field of the electrons. In electron energy-loss spectra, these plasmons reflect transitions associated with surface charges. In optics, they have potential uses in magnetooptic data storage. **Figure 2a** shows a corrugated metal surface with a period of a. If a corresponds to a surface-plasmon wavelength, there are two standing-wave solutions that have the same wavelength, but different energy, giving rise to a photonic bandgap (**Figure 2b**). At this point, surface plasmons cannot propagate, producing a significant increase in the electromagnetic field.

Vibrations at Surfaces

Electrons moving near the surface of a solid can excite localized and collective vibrations. The major experimental achievement in the measurement of these vibrations has been the development of near-monochromatic primary-electron beams and, additionally, the detection of reflected electrons with a resolution of the order of vibrational energies (a few meV). On Si(111), one of the most intensively studied surfaces, the local arrangement of atoms at and near the surface, including the stretching of Si–Si bonds, has been obtained from surface phonon

measurements and found to be consistent with the dimer-adatom-stacking-fault model.

Adsorbates are foreign atoms that are bound to sites with a particular point-group symmetry of the surface structure. If the dipole image charge of the adsorbate has a component normal to the surface, the adsorbate can be excited into vibrational states, while modes with their dipole moment parallel to the surface are screened by a factor $1/(\varepsilon+1)^2$. These selection rules are similar to those governing infrared transitions. One can determine the local symmetry by observing the number of vibrational modes. The local geometry is modeled by a rigid substrate against which the adsorbates vibrate. **Figure 3** shows some fundamental types of bonding arrangements. In (a), an adsorbate atom is placed at a top position. This site would produce a single low-energy vibrational mode. In (b), the same atom is shown in a bridge position. Energy loss would be observed at an even lower value than (a), corresponding to the normal vibrational component. If the chemical bonding were not symmetrical, then one would observe two peaks at similar energy losses. Generally, a lowering of the adsorption symmetry, such as uneven bonding, increases the number of vibrational modes. For molecular adsorbates (**Figures 3c** and **3d**), a high-energy loss would be due to the stretching mode of the atoms in the molecule, while a low-energy loss would be observed, due either to the vibration of each atom against the substrate, or the entire molecule. Hence, for molecular adsorption one always expects at least two modes. Observation of a single mode is, therefore, evidence for the dissociative adsorption of a molecule. Apart from the number of observed modes, the vibrational energy contains information about the chemical nature of the bond. An adsorption site on top of a substrate atom results in a higher force constant compared to an adsorbate at a bridge or hollow site, where the bond strength is shared by several surface atoms.

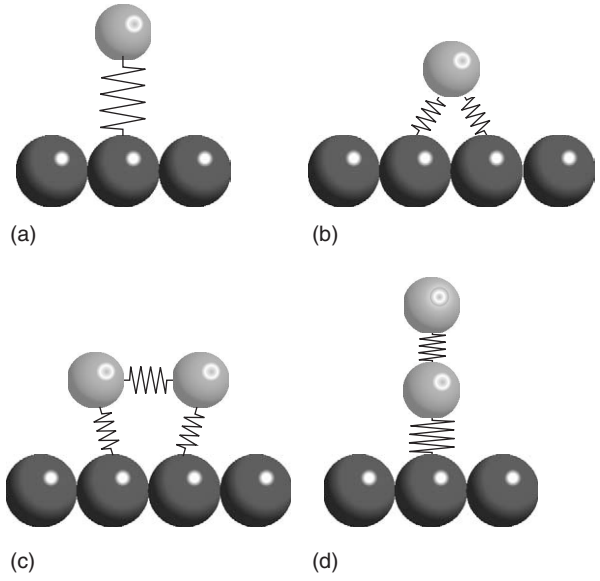

Figure 3 A schematic description of four typical adsorption states. The springs represent chemical bonds of different strengths.

Excitation of Core Electrons

A special case of interband transitions is the excitation of core electrons with a binding energy, E_B. The primary electron can transfer any amount of energy $E_L \leqslant E_i$ to the core electron. By measuring the energy loss of the primary electron, one knows the kinetic energy of the core electron after scattering, that is, how far above E_F the core electron has been excited. The excitation into states at E_F corresponds to zero kinetic energy, and hence, $E_L = E_B$. This is called the absorption edge. It is characteristic of a particular element and its chemical state, and can thereby be used as a tool for chemical analysis.

Nanotubes provide a topical illustration of such measurements. Their chemical and physical properties can be manipulated by incorporating atoms or molecules within the tubes. **Figure 4** shows a high-resolution electron micrograph of an isolated single-wall nanotube containing C_{82} fullerenes and a schematic representation of the structure. The image reveals single Gd atoms encapsulated in the fullerene cages. **Figure 5** displays a spatially resolved electron-energy-loss spectrum of C *K*-edge (1*s* initial state) and Gd *N*-edge (4*d* initial state) absorption edges. Thus, it is possible to detect and identify single Gd atoms encaged in a complex C environment. Core-electron binding energies may show a chemical shift depending on the chemical state of the element because,

(Adapted from Cai YQ, Vos M, Stoner P, Kheifets AS, MacCarthy IE, *et al.* (1995) Direct imaging of the valence electronic structure of solids by (*e*, 2*e*) spectroscopy. *Solid State Communications* 95: 25–29.)

through chemical binding, the electronic charge density is redistributed, thereby shifting the binding energy. The core-electron binding energy of Gd shows a downward shift compared to the neutral Gd metal, which suggests a charge transfer from the Gd to a C atom.

Core states have almost no overlap between neighboring atoms, leading to extremely narrow bandwidths. Therefore, the energy-loss spectrum at and above the absorption edge is indicative of the unoccupied DOS at the site of the excited atom with an orbital angular momentum determined by the symmetry of the final state. If the final states are far above E_F, the modulations in the spectra can be described within a single-scattering framework and used to extract structural information about the local environment of the excited atom. This is known as extended energy-loss fine structure (EELFS); the optical analog is extended X-ray-absorption fine structure (EXAFS). Closer to the absorption edge, the interpretation of the spectra requires a multiple-scattering treatment, as in near-edge X-ray-absorption fine-structure (NEXAFS) in optics.

e^-2e^- Scattering

A general, yet simple, case of electron–atom or electron–solid interactions is considered. The target has electrons of initial energy $E_i^{(2)}$ and momentum $\boldsymbol{k}_i^{(2)}$, while the primary-electron energy has $E_i^{(1)}$ and momentum $\boldsymbol{k}_i^{(1)}$. In the final state, there are two electrons: one with an energy $E_f^{(1)}$ and momentum $\boldsymbol{k}_f^{(1)}$, and the initially bound electron, now with energy $E_f^{(2)}$ and momentum $\boldsymbol{k}_f^{(2)}$. In the limit of large energy and momentum transfer, the $E_f^{(1)}$ and $E_f^{(2)}$ are well above the band structure regime, so the unoccupied DOS is parabolic and does not impose additional structure upon the measurement. This interaction regime is the basis of $(e^-, 2e^-)$ spectroscopy for solids. For atomic or molecular targets, $(e^-, 2e^-)$ spectroscopy provides information about the wave function density in momentum space by measuring the momentum distribution of the bound electron as a function of the momentum transfer. For crystalline targets, both the momentum density and the energy dispersion of valence electrons can be determined. Since the momentum of any ejected electron can be measured, the results are not confined to the first Brillouin zone.

In a binary collision between a high-energy electron and a band electron, the conservation of energy requires that $E_i^{(1)} = E_f^{(1)} + E_f^{(2)} + E_i^{(2)}$ and the conservation of momentum is given by $\boldsymbol{k}_i^{(1)} = \boldsymbol{k}_f^{(1)} + \boldsymbol{k}_f^{(2)} + \boldsymbol{k}_i^{(2)}$. There is, however, a continuous spectrum of single- and multiple-scattering events that leads to $E_f^{(1)} + E_f^{(2)}$. To single out the event for which both equations hold, the particles must be recorded in coincidence.

Figure 6a shows the geometry of primary electrons impinging upon a solid sample. A binary collision event is depicted in which a target electron acquires energy and is ejected from the back of the sample together with the primary electron. For simplicity, the scattering event is shown with coplanar initial and final wave vectors. In general, the 2π azimuthal distribution relative to the primary-electron incidence is measured to access the details of the initial

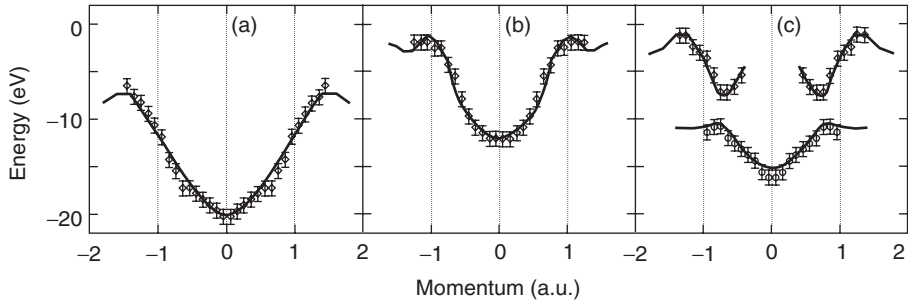

Figure 7 Measured (markers) and calculated (solid line) energy-band dispersions of (a) the amorphous C, (b) the amorphous Si, and (c) the polycrystalline SiC. (From Cai YQ, Vos M, Stoner P, Kheifets AS, MacCarthy IE, *et al.* (1995) Direct imaging of the valence electronic structure of solids by (*e*, 2*e*) spectroscopy. S*olid State Communications* 95: 25–29.)

state, as shown in **Figure 6b**. Energy conservation requires that the binary-collision event takes place as close to the surface as possible, so inelastic interactions after the indicated principal collision are not considered. Consequently, the spectroscopic results are characteristic of the near-surface region of the target material.

Figure 7 shows an energy-band dispersion in amorphous C and Si and polycrystalline SiC obtained in an $(e^-, 2e^-)$ experiment. The results compare favorably with the computational band structure spherically averaged over the cubic Brillouin zone. Thus, momentum densities determined in $(e^-, 2e^-)$ spectroscopy are associated with local order and energy-band dispersion exists in disordered and amorphous systems.

Introduction

A light scattering experiment is sketched in **Figure 1a**. Monochromatic light with frequency ω_I, polarization $\boldsymbol{e}_I$, and the external electric field $\boldsymbol{E}_I(\omega, \boldsymbol{r})$ is incident on the medium and induces a polarization $\boldsymbol{P}(\omega, \boldsymbol{r})$. The medium scatters light of spectral density $\rho(\boldsymbol{q}, \omega)$ with frequency ω_S and polarization $\boldsymbol{e}_S$. This dipole-like radiation scales in intensity $I \propto \omega_S^4$. The Raman or combination scattering effect was discovered in 1928 independently by C V Raman, G S Landsberg, and L I Mandel'shtam. Raman scattering (RS) is analyzed as a function of the frequency difference or Raman shift $\omega = \omega_I - \omega_S$ with respect to the incident light and registered using a sensitive detector. Only 10^{-7}–10^{-9} of the incident photons are scattered inelastically. If the Raman shift is negligible, $\omega_S \approx \omega_I$, the process is elastic and called Rayleigh scattering, while for $\omega_S < \omega_I$ or $\omega_S > \omega_I$, it is denoted as Stokes scattering or anti-Stokes scattering, respectively. The ratio of anti-Stokes to Stokes intensities is strongly temperature dependent:

$$I_{AS}/I_{ST}(\Delta\omega, T) = \left(\frac{\omega_I + \omega}{\omega_I - \omega}\right)^4 \exp\left(-\frac{\hbar\omega}{k_B T}\right) \quad [1]$$

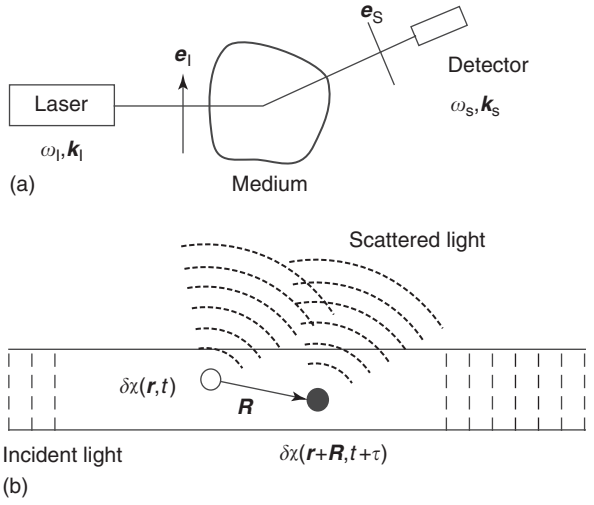

Figure 1 (a) Schematic description of light scattering geometry. (b) Interference of secondary waves from different points inside the incident beam.

The induced polarization $\boldsymbol{P}$ is related to the electronic susceptibility tensor $\chi(\omega)$, a material specific quantity, using the response relation $\boldsymbol{P}(\omega, \boldsymbol{r}) = \varepsilon_0 \chi(\omega) \boldsymbol{E}(\omega, \boldsymbol{r})$. In a homogeneous medium, χ is constant in space and time. Secondary waves from different points inside the incident beam cancel each other out according to the Huygens–Fresnel principle (see **Figure 1b**). The scattering process is therefore a result of spatial and temporal fluctuations of χ in the medium. The spectral density of light scattering is given by a correlation function of the fluctuations:

$$\rho(q, \omega) \sim \int \langle \delta\chi^*(q, t) \delta\chi(q, 0) \rangle e^{i\omega t} \, dt \quad [2]$$

with $\boldsymbol{q} = \boldsymbol{k}_I - \boldsymbol{k}_S$ and $\omega = \omega_I - \omega_S$, the change of wave vector and wave number according to their conservation in the scattering process. The fluctuation spectrum $\chi(\omega)$ in solids originates either from density fluctuations or from internal degrees of freedom, as phonons. The former leads to a weak scattering continuum that quickly decreases in intensity as a function of the Raman shift. The corresponding energy transfer from the electromagnetic field to low-energy electronic states has no well-defined eigenfrequency and this response is usually screened. The latter fluctuation contribution leads to peaks in $\rho(\omega)$ at frequencies corresponding to the energy of excitations.

Typical Raman shifts of phonons in solids range from 50 to 1000 cm^{-1}, while molecular vibrations may range up to 3500 cm^{-1}. The unit wave number (cm^{-1}) corresponds to the difference of the inverse of the corresponding wavelengths λ in centimeters and can be converted using 1 (cm^{-1}) $\approx$ 1.44 (K) $\approx$ 1/8 (meV) $\approx$ 33 (GHz) to other units used in solid-state spectroscopy.

Phonon wave vectors over a major part of the Brillouin zone are two to three orders of magnitude larger than the wave vectors of electromagnetic radiation in the visible range. Therefore, the kinematics of the scattering process restricts phonons scattering to small wave vectors close to the origin of the Brillouin zone. Acoustic modes with small wave vectors and corresponding to very small energies can only be detected in Brillouin scattering setups based on interferometers. The conservation of momentum may be lifted at surfaces, defects, in the case of multiparticle scattering, and if nonadiabatic scattering is involved. In metals, the very small penetration depth of light may lead to the observation of excitations with a broad range of momenta.

Classical Theory

RS originates from radiating dipole moments induced by an incident electric field. In a crystal, the electric field of a plane, monochromatic wave with angular frequency ω_I is given by $\boldsymbol{E}_I(\omega, \boldsymbol{r}) = \boldsymbol{E}_I \cos \omega_I t$. In general, the polarization of the crystal is a function of the instantaneous positions of the atoms in the lattice. Thus, the susceptibility can be expanded in terms of normal coordinates of the crystal:

$$\chi = \chi_0 + \sum_a \left(\frac{\partial \chi}{\partial Q_a}\right)_0 Q_a + \frac{1}{2} \sum_{a,a'} \left(\frac{\partial^2 \chi}{\partial Q_a \partial Q_{a'}}\right)_0 Q_a Q_{a'} + \cdots \quad [3]$$

The linear term in Q_a leads to first-order scattering, while the quadratic and higher terms are responsible for second- and higher–order effects. The laser power used in Raman experiments is small and the induced atomic displacements do not exceed 10^{-10} m. Therefore, higher-order derivatives that, for example, lead to hyper-RS at multiples of ω_I can be neglected. Since the lattice waves are described by $Q_a = Q_0 \cos \omega_p t$ for each normal coordinate, the induced polarization becomes

$$\boldsymbol{P} = \varepsilon_0 \left[\chi_0 + \sum_a \left(\frac{\partial \chi}{\partial Q_a}\right)_0 Q_0 \cos \omega_p t\right] \times \boldsymbol{E}_I \cos \omega_I t \quad [4]$$

where $\varepsilon_0 \chi_0 \boldsymbol{E}_I \cos \omega_I t$ corresponds to elastic scattering. The inelastic terms of the polarization can be transformed to

$$\begin{aligned} \boldsymbol{P}_i &= \boldsymbol{A} \cos \omega_p t \cos \omega_I t \\ &= \frac{\boldsymbol{A}}{2} [\cos(\omega_I + \omega_p)t + \cos(\omega_I - \omega_p)t] \\ &\text{with } \boldsymbol{A} = \varepsilon_0 \sum_a \left(\frac{\partial \chi}{\partial Q_a}\right)_0 Q_0 \boldsymbol{E}_I \end{aligned} \quad [5]$$

The frequency shift of $\omega_I + \omega_p$ and $\omega_I - \omega_p$ corresponds to anti-Stokes and Stokes scattering, respectively. The former (latter) process can be interpreted as the destruction (creation) of elementary excitations in the solid. The intensity of the inelastically scattered light is given by the amplitude factor $\boldsymbol{A}$ and especially by the derivative $\sum_a (\partial \chi / \partial Q_a)_0$. It follows that a phonon is Raman active only if the first derivative of the polarizability with respect to the phonon displacement is nonzero. This derivative depends on crystal symmetry and scattering configuration. The latter is given by the polarization of the incident and scattered light, $\boldsymbol{e}_I$ and $\boldsymbol{e}_S$, with respect to the crystal structure.

In crystals where the corresponding point group has an inversion center, a phonon mode can be either IR or Raman active. The Raman active modes are "gerade" with respect to an inversion. Furthermore, using the group theory, the number of Raman-active phonons and their selection rules (measurement geometry) can be derived. This scheme consists of determining the site symmetry of each atom in the unit cell of the investigated compound, finding the corresponding irreducible representations (phonons), and subtracting from the sum of these representations the acoustic-, silent-, and infrared-active modes. These steps and the needed tables are documented in literature. A calculation or estimation of the optical phonon frequencies can be performed using shell lattice models or a comparison with known compounds.

The modes are classified with respect to the dimensionality of their representations as 1D (A_{1g} or B_{1g}), 2D (E_{2g}), 3D (T_{1g} or F_{1g}). A and B distinguish a positive/negative value of χ with respect to rotation about the principal axis. The possible indices are g for gerade, u for ungerade with respect to the inversion center, and the numbers 2 and 3 are used to denote a symmetry with respect to other rotations or with respect to reflections, respectively. An irreducible representation of Raman-active modes may then look like the following:

$$\Gamma_{\text{Raman}} = A_{1g} + E_{1g} + 3B_{1g} \quad [6]$$

This means that, in total, five phonon modes would be expected. Experimentally, the phonon modes can be differentiated using the symmetry properties of their Raman tensor. For example, modes with A_{1g} observed with $(\boldsymbol{e}_I, \boldsymbol{e}_S)$ both parallel to one of the crystallographic directions, while, for example, B_{1g} are observed with $\boldsymbol{e}_I$ perpendicular to $\boldsymbol{e}_S$ and both polarizations turned by 45° within a crystallographic plane. These scattering geometries are abbreviated as $z(xx)\text{-}z$ and $z(x'y')\text{-}z$, with x, y, z parallel to the crystallographic axes and x' turned by 45° within the xy-plane. In this experiment the wave vectors $\boldsymbol{k}_I, \boldsymbol{k}_S$ are parallel to the z-axis. As an example, the matrix representations of a tetragonal group, D_{4h}, is used:

$$A_{1g}: \begin{pmatrix} a & 0 & 0 \\ 0 & a & 0 \\ 0 & 0 & b \end{pmatrix}; \quad B_{1g}: \begin{pmatrix} c & 0 & 0 \\ 0 & -c & 0 \\ 0 & 0 & 0 \end{pmatrix}; \quad \text{and} \quad E_g: \begin{pmatrix} 0 & 0 & d \\ 0 & 0 & e \\ d & e & 0 \end{pmatrix} \quad [7]$$

Application of Raman Scattering and Experimental Setup

Application of Raman Scattering

The most fruitful application of RS is certainly the investigation of phonons in semiconductors or insulators. The penetration depth of light in the visible range is large and the phonon scattering cross section is also normally high. **Figure 2** shows a measurement in Si with a phonon at $520\,\mathrm{cm}^{-1}$, and two-phonon scattering at $950\,\mathrm{cm}^{-1}$. Due to surface defects, a phonon density of states (DOS) is observed with a very small intensity for $\Delta\omega < 1000\ \mathrm{cm}^{-1}$.

RS may furthermore be used for the characterization of strain, interface properties, and the control of epitaxy and growth processes of thin films. Frequently, RS is applied to determine the chemical composition and doping profiles with a topographical resolution using scanning stages. This makes use of the fact that phonon modes of the respective materials sensitively depend on composition. The spacial resolution of such investigations is limited by the focus diameter, which is of the order of the light wavelength. An improvement can be gained if optical near-field techniques are used.

The strong dependence of light penetration depth on the frequency of the incident light can be used to determine depth profiles. Furthermore, the RS cross section can be enhanced using electronic resonances in the bulk (resonance scattering) or on the surface (surface-enhanced RS) of the medium. Sensitivity of single molecules can be achieved.

Experimental Setup

Setups for inelastic light scattering experiments can be optimized either for high-resolution and quasi-elastic light rejection (**Figure 3**), or for small sample and surface characterization with a microscope. They contain the following functional elements:

Monochromatic light source and beam tailoring Noble gases (helium/neon, argon, krypton) ion lasers or frequency-doubled laser diodes are used as a light source. Spurious contributions at frequency different from the desired one (plasma lines) are filtered by a prism double monochromator or a notch filter. The polarization and ellipticity of the laser beam are adjusted by transmitting through $\lambda/4$ and $\lambda/2$ wave plates. The beam is then focused on the sample. A typical light power level on the sample is 4–20 mW on a focus diameter of 50–100 μm or a smaller power, if a Raman microscope with a focus of 1–5 μm is used.

Sample and scattering configuration A backscattering configuration is frequently used as solids are usually opaque or semi-opaque. A small canting of the sample with respect to the incoming laser beam suppresses quasi-elastic light. RS allows one to change the sample environment or temperature easily using a cryostat, pressure cell, or glass fibers, as the Raman shift of the scattered light is small with respect to the used excitation frequency, $\Delta\omega/\omega_\mathrm{I} \approx 10^{-2}$. Therefore, only one set of window material (fused silica) is needed. The scattered light is collected with a lens, for example, a photographic camera lens, and filtered

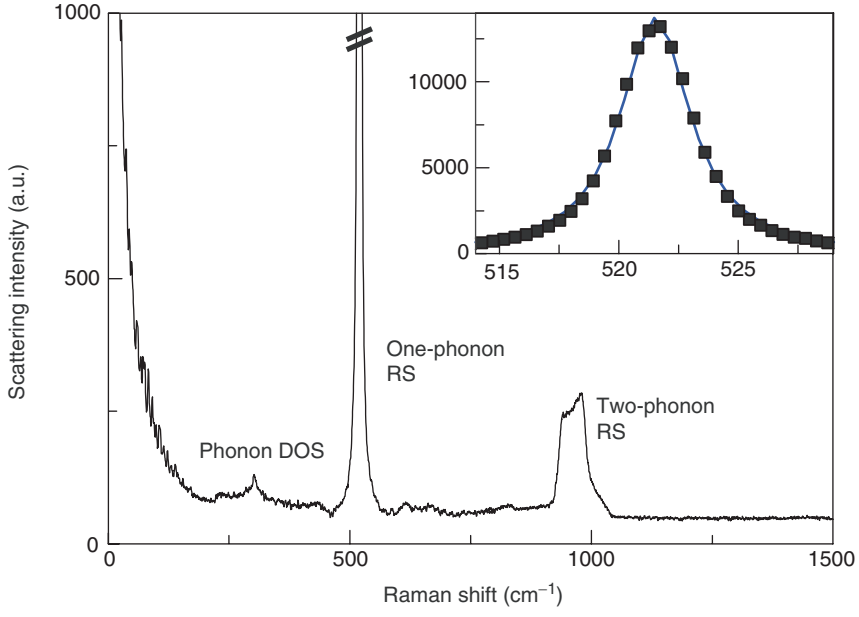

Figure 2 Raman scattering in silicon in (*xx*) polarization including one-phonon and two-phonon scattering. The inset shows a Gaussian fit (solid line) to the one-phonon scattering data (points).

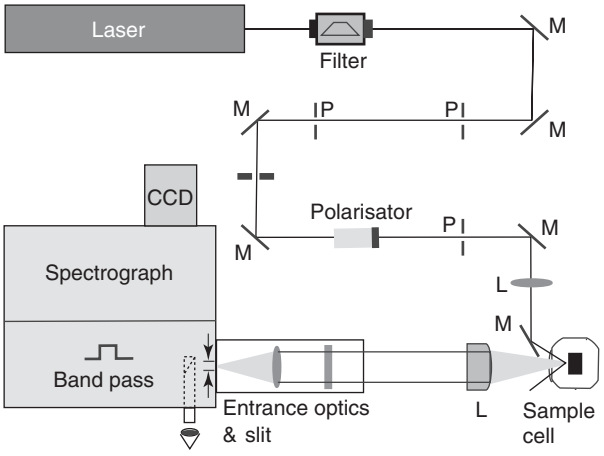

Figure 3 RS setup in quasi-backscattering geometry with a spectrometer, mirrors (M), pinholes (P), and lenses (L).

with respect to polarization. The light is then focused on the entrance slit of a monochromator. It is convenient to use an eyepiece or a camera with a view on the sample from behind the open entrance slit as an aid for the optical alignment. The definition of the focus can be improved using confocal entrance optics (spacial filtering).

Monochromator and detection Quasi-elastic light due to surface roughness or Raleigh scattering is suppressed by an interference filter or by a subtractive double monochromator used as a bandpass. The transmitted light is then dispersed on the detector with a single monochromator stage with blazed, holographic gratings used as dispersing elements. The detection of light is usually performed by a charge coupled device (CCD). This array detector allows the simultaneous detection of a broad frequency band with single-photon sensitivity. Sensors with quantum efficiencies of 80% are available. Typical accumulation times may range from 10 s to 5 min. Several of these measurements are averaged to further reduce noise and to eliminate spikes induced by cosmic muons in the detector.

Scattering Cross Section and Quantum Mechanics

The inelastic scattering process by a crystal involves incident photons of energy $\hbar\omega_I$ and momentum $\hbar\boldsymbol{k}_I$ leading to photons of energy $\hbar\omega_S$ and momentum $\hbar\boldsymbol{k}_S$. At the same time, an initial state of the crystal, i, with energy E_i transits into a final state, f, with energy E_f. The probability of scattering, P_{if}, can be formulated with the help of Fermi's golden rule of the second-order perturbation theory as

$$P_{if} = \frac{2\pi}{\hbar}\rho_{\mathrm{dos}}(\omega_S)|H(\boldsymbol{k}_I, i : \boldsymbol{k}_S, f)|^2 \times \delta(\hbar\omega_I + E_i - \hbar\omega_S - E_f) \quad [8]$$

where $\rho_{\mathrm{dos}}(\omega_S)$ is the DOS of photons, which is given by $\rho(\omega_S)\,\mathrm{d}\omega_S\,\mathrm{d}\Omega = (1/2\pi c)^3\omega_S^2\,\mathrm{d}\omega_S\,\mathrm{d}\Omega/\hbar$. Here, $\mathrm{d}\Omega$ is a solid angle. The main difficulty is to determine the Hamiltonian, $H(\boldsymbol{k}_I, i : \boldsymbol{k}_S, f)$, which describes the interaction between the electromagnetic radiation and the crystal. Taking into account that the wavelength of the incident/scattered light is much larger than the sizes of atoms, the effective Hamiltonian can be written in terms of the polarizations as

$$H(\boldsymbol{k}_I, i : \boldsymbol{k}_S, f) = \sum_{r,\alpha,\beta} E_I^{\alpha}\chi(r)^{\alpha\beta}E_S^{\beta} \quad [9]$$

Here, α and β denote Cartesian coordinates. The electric field is described in terms of the photon creation (annihilation) operator, $b^{\dagger}(k)$ $[b(k)]$:

$$\boldsymbol{E}_I = i\sqrt{2\pi\hbar\omega_I}E_I\boldsymbol{e}_I[b(\boldsymbol{k}_I) - b^{\dagger}(-\boldsymbol{k}_I)] \quad [10]$$

where $\boldsymbol{e}_I$ is the polarization vector of the photon. Using these results, one can obtain the total RS intensity

$$I_R \sim \omega_I\omega_S^3 \int \ll\chi(\boldsymbol{k}_I\boldsymbol{k}_S; t)\chi^{\dagger}(\boldsymbol{k}_I\boldsymbol{k}_S; 0)\gg \mathrm{e}^{\mathrm{i}\omega t}\,\mathrm{d}t \quad [11]$$

The brackets $\ll\cdots\gg$ denote a thermodynamic average, and $\omega = \omega_I - \omega_S$. Since $\omega_I \approx \omega_S$, the intensity has an approximate form of the dipole radiation as mentioned above. It is important to note that the RS involves a pair correlation functions of the fluctuating polarization. This microscopic derivation confirms the classical picture discussed in the section "Classical theory." Note that an explicit form of the susceptibility can be provided by the dipole matrix elements $\langle f|\boldsymbol{M}_\beta|i\rangle$ with the moments $\boldsymbol{M}_\alpha = e r_\alpha$ between the initial and final states with $\omega_{fi} = [E_f - E_i]/\hbar$:

$$\chi_{\alpha\beta}(\omega) = 2\sum_{i,f}\int \langle i|\boldsymbol{M}_\alpha|f\rangle\langle f|\boldsymbol{M}_\beta|i\rangle \times \left(\frac{1}{\omega_{fi} - \omega} + \frac{1}{\omega_{fi} + \omega}\right)\frac{\mathrm{d}^3k}{(2\pi)^3} \quad [12]$$

The factor 2 is due to the spin.

Phonon Scattering

The RS intensity of solids is usually dominated by phonon modes. In an adiabatic approximation, an optical phonon $v(= 1, \ldots, 3N_c)$, with N_c the number

of ions per unit cell, consists of atomic displacements with the eigenvector Q_v that can be treated as a very slow ionic displacement leading to a static potential within the unit cell $\delta U_v(r)$. This slow varying potential will (1) shift the energy of the initial state by $\delta E_{i,v} = \langle i|\delta U_v(r)|i\rangle$ and (2) change the band wave function as

$$\delta|i\rangle = \sum_{f\neq i} \frac{\langle i|\delta U_v(r)|i\rangle}{E_f - E_i}|f\rangle$$

Thus, the susceptibility tensor in [12] will be changed:

$$\delta\chi_v^{\alpha\beta} = \sum_{a=1}^{N_c} Q_{a,v} \frac{\partial\chi^{\alpha\beta}(\omega)}{\partial Q_a} \qquad [13]$$

This leads to the scattering intensity at the phonon frequency Ω_v:

$$\rho(\omega) = \frac{1}{\pi} I_R \frac{\gamma_v}{(\omega - \Omega_v)^2 + \gamma_v^2} \qquad [14]$$

where γ_v is the phonon line width and I_R is given by eqn [11]. By inserting [12] into [13], one sees that the integrated intensity of phonons is determined by two contributions. The first one is due to the dependence of the band energy on the ion configuration, $\partial\omega_{fi}/\partial Q_a$. The second one can be ascribed to the polarization of band wave functions and the change in the interionic distances $\partial\langle f|\mathbf{M}_\alpha|i\rangle/\partial Q_a$. Note here that phonon RS is not the result of a direct light–phonon interaction because of the large difference of the photon energy ($\hbar\omega_I \approx 1.5-2.5$ eV) and the phonon energy (<100 meV). Rather, one-phonon RS arises from the third-order time-dependent perturbation theory as depicted by a diagram in **Figure 4**.

The RS process includes three virtual electronic transitions, which can be understood as three steps:

1. The incident photon excites a virtual electron–hole pair state via the electron–radiation coupling.
2. The electron–phonon interaction causes a transition of the electron (Stokes process) or hole (anti-Stokes one) to a different state.
3. The transition to the electronic ground state occurs via a recombination of the electron–hole pair emitting the scattered photon.

The relevant Hamiltonian involving a phonon excitation may be written as

$$H_R = -\frac{e}{mc}\boldsymbol{p}\cdot\boldsymbol{A} + \sum_{ijk} g_{ij}(k)(b^\dagger + b)c_{ik}^\dagger c_{jk} \qquad [15]$$

where $g_{ij}(k)$ is the electron–phonon coupling between the band i and j, while $b^\dagger(b)$ and $c_{ik}^\dagger(c_{jk})$ are the phonon and electron creation (annihilation) operators, respectively. The first term in [15] is the electron–radiation interaction involving steps 1 and 3. It describes a scattering process via an intermediate state resulting in an interband transition. The second term in [15] is a contribution, which is linear in terms of the electron–phonon interaction. This term involves step 2 by coupling phonons to electrons states in two ways: (1) the phonon couples electron states with the same occupancy (both are empty or occupied) and (2) the phonon couples occupied and unoccupied states.

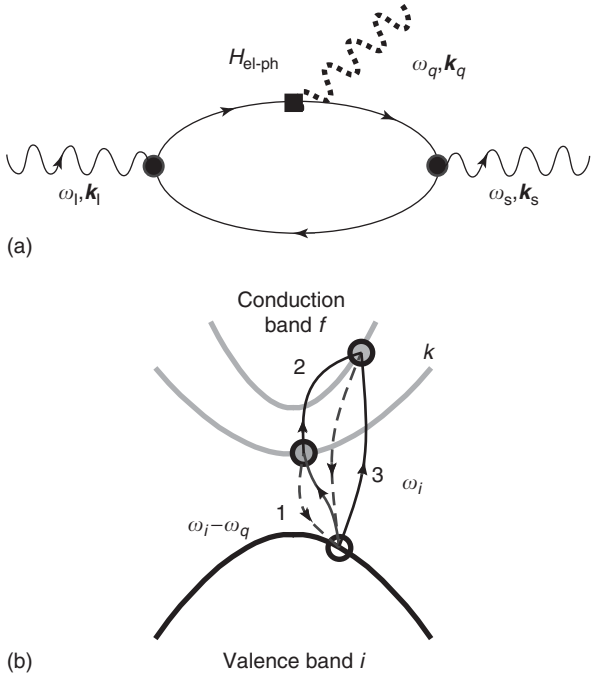

Figure 4 (a) Illustration of a first-order phonon scattering process. (b) Schematic electronic energy bands of a crystal showing the electronic transitions of the third-order light-scattering process for Stokes scattering. The pair state that is created in the first transition step transforms in the second step within the conduction band before recombining again during final transition step.

Often, higher-order phonon RS shows a substantial scattering cross section. This signal may deliver valuable information about the electronic states of semiconductors and insulators. **Figure 2** gives an example of such an observation in the semiconductor Si. The microscopic origin of the two-phonon process is considered by expanding the electron–phonon interaction up to the quadratic term:

$$\begin{aligned} H_{e-p} = &\sum_q g_1(q)(b_{-q}^\dagger + b_q)c_{k+q}^\dagger c_k \\ &+ \sum_q g_2(q)(b_{q1}^\dagger b_{q2}^\dagger + b_{q1}^\dagger b_{q2} \\ &+ b_{q1}b_{q2})c_{k+q}^\dagger c_k \end{aligned} \qquad [16]$$

Here, g_2 is the anharmonic interaction constant. The second term of the Hamiltonian [16] accounts for a simultaneous emission of two phonons due to the lattice anharmonicity. In contrast, the first term in the Hamiltonian [16] shows that two phonons are created separately in a pair of first-order electron–lattice interactions. This process contains an additional virtual electron state besides the emission of two phonons. This state can be in resonance when the energy of the incident light is suitably selected. In this case, the intensity of two-phonon scattering as a function of the incident light energy can determine interband energies.

When the two phonons are created, the energy and momentum conservation gives

$$\begin{aligned} \omega_{\sigma q} + \omega_{\sigma' q'} &= \omega_{\mathrm{I}} - \omega_{\mathrm{S}} \\ \boldsymbol{q} + \boldsymbol{q}' &= \boldsymbol{k}_{\mathrm{I}} - \boldsymbol{k}_{\mathrm{S}} \end{aligned} \qquad [17]$$

Here σ and σ' denote the branch of phonons. Thus, one can see that only the total momentum of a pair of emitted phonons $\boldsymbol{q} + \boldsymbol{q}' = 0$ should vanish. This is because phonon scattering is restricted to a regime near the Γ-point of the Brillouin zone. Then, the frequencies are the same at wave vectors $\boldsymbol{q}$ and $-\boldsymbol{q}$, and the energy conservation can be written as $\omega_{\sigma q} + \omega_{\sigma' q} = \omega_{\mathrm{I}} - \omega_{\mathrm{S}}$. To the first approximation, the second-order light-scattering spectrum of the phonons is provided by the combined DOS of pairs of phonons:

$$\rho_2(\omega) = \sum_{\sigma,\sigma'} \sum_{q} \delta(\omega - \omega_{\sigma q} - \omega_{\sigma' q}) \qquad [18]$$

In contrast to one-phonon scattering, this implies that higher-order scattering can provide indirect information about the whole Brillouin zone.

Until now, it has been assumed that electronic states of the ground and excited state do not change in the RS process by phonons. For solids and large molecules, this is largely true as **Figure 4b** depicts. For small molecules, however, the positions of vibrational functions are substantially shifted from the initial to the intermediate state. A sketch of such a situation is shown in the inset of **Figure 5**. As a result, the overlap between the vibrational wave functions of the two states is nonvanishing. This can lead to a multiphonon process near resonance via the so-called Frank–Condon mechanism. A representative example of multiphonon RS for the molecular system $(C_5H_{12}N)_2CuBr_2$ is given in **Figure 5**. Higher-order scattering appears exactly at the integer multiples of the one-phonon frequency. Furthermore, higher-phonon peaks are sharp. This behavior, arising from a local mechanism, should be contrasted with the observations in Si. For the latter, the main contribution to an n-phonon scattering comes from regions of the Brillouin zone where the phonon DOS is the largest. Moreover, on going to a higher order, the respective maxima shift to lower energy due to anharmonic phonon–phonon interactions. Note that the Frank–Condon mechanism is not restricted to small molecules. Even in solids and semiconductors, a local mechanism, such as self-trapped excitons, can lead to similar features of multiphonon scattering.

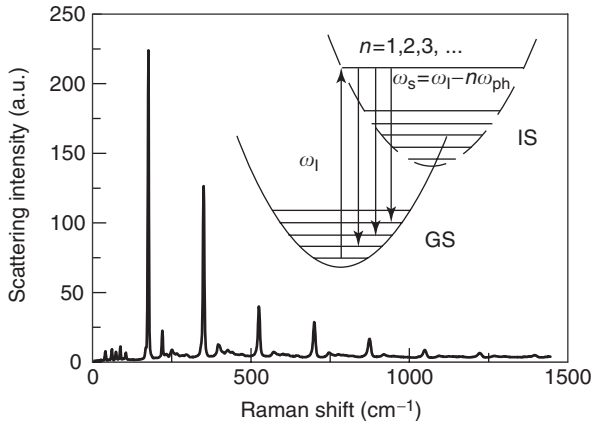

Figure 5 Multiphonon RS in the molecular system $(C_5H_{12}N)_2CuBr_4$ in (*xx*) polarization. The inset shows a configurational diagram including the electronic ground state (GS), intermediate state (IS), and phonon transitions $\omega_{\mathrm{S}} = \omega_{\mathrm{I}} - n\omega_{\mathrm{ph}}$ of different order.

Electronic Raman Scattering

Electronic systems can also contribute to the RS response. The scattering mechanism is related to fluctuations of effective charge density. If the incident energy of the photons is smaller than a bandgap, the effective charge density is expressed in terms of the curvature of the bands. This means that fluctuations of the effective mass tensor give a dominant contribution to electronic RS. Here, the effective charge density is not a conserved quantity in contrast to real charge. Thus, RS has no sum rule of spectral weights in contrast to IR absorption. In a clean metal, however, electronic RS is suppressed by screening. This is demonstrated taking the Lindhard expression in the limit of a small wave vector. For strongly correlated electron systems, the electronic Raman response contains valuable information about the lifetime or scattering rate of quasiparticles. Compounds with a metal–insulator transition show a strong spectral rearrangement of electronic RS with a characteristic frequency (the so-called isosbestic point) where RS is independent of temperature. This

behavior is common for Kondo systems, mixed-valence materials, and underdoped high-temperature superconductors. In superconductors with an anisotropic gap, this anisotropy can be determined using the polarization dependence of the electronic scattering and the respective depletion of spectral weights.

Magnetic Raman Scattering

For many materials, light scattering through magnetic excitations is relevant. Magnons induce a spatially periodic modulation of the susceptibility tensor. In this case, the modulation of $\chi^{\alpha\beta}(r)$ can be expressed in the Taylor series in terms of spin operators:

$$\chi^{\alpha\beta}(r) = \chi_0^{\alpha\beta}(r) + \sum_{\mu} K_{\mu}^{\alpha\beta}(r) S_r^{\mu} + \sum_{\mu,\nu} G_{\mu\nu}^{\alpha\beta}(r) S_r^{\mu} S_r^{\nu} + \sum_{\delta} \sum_{\mu,\nu} H_{\mu\nu}^{\alpha\beta}(r,\delta) S_r^{\mu} S_{r+\delta}^{\nu} + \cdots \quad [19]$$

Here, the coefficient tensors K, G, and H denote the strength of the coupling between light and the magnetic system. The constant term $\chi_0^{\alpha\beta}$ corresponds to an elastic scattering contribution. The linear term in S_r^{μ} can be written as a combination of the terms S_r^{+} and S_r^{-} which describe one-magnon creation and annihilation, respectively. The quadratic term in spin operators at a single ionic site r also gives rise to one-magnon scattering because this term can be rewritten in terms of a linear, transverse spin operator as $S_r^{+}S_r^{z}$, $S_r^{z}S_r^{+}$, $S_r^{-}S_r^{z}$, and $S_r^{z}S_r^{-}$. The quadratic spin term at different sites also has a contribution to the one-magnon scattering due to the terms proportional to $S_r^{+}S_{r+\delta}^{z}$, $S_r^{z}S_{r+\delta}^{+}$, $S_r^{-}S_{r+\delta}^{z}$, and $S_r^{z}S_{r+\delta}^{-}$.

This phenomenological description of one-magnon scattering can be derived from a microscopic mechanism of spin–orbit coupling. For simplicity, the ground state consisting of zero-orbital angular momentum and spin S, as displayed in **Figure 6a**, is considered. The effective magnetic field will split this state into $(2S+1)$ components. An excited orbital state with $L=1$ and the same S as the ground state is assumed. This will be split into three components corresponding to $J=S+1$, S, and $S-1$ by spin–orbit interaction $\lambda L \cdot S$, where λ is the spin–orbit coupling constant. Each excited state $|J, J^z\rangle$ is expressed as a linear combination of the unperturbed $|L^z, S^z\rangle$ states. Then, the transition from $S^z = S$ ground state to $S^z = S-1$ takes place by a successive electric dipole transition via the $L=1$ virtual intermediate state. In this way, the coupling constant K can be calculated in terms of the spin–orbit coupling λ.

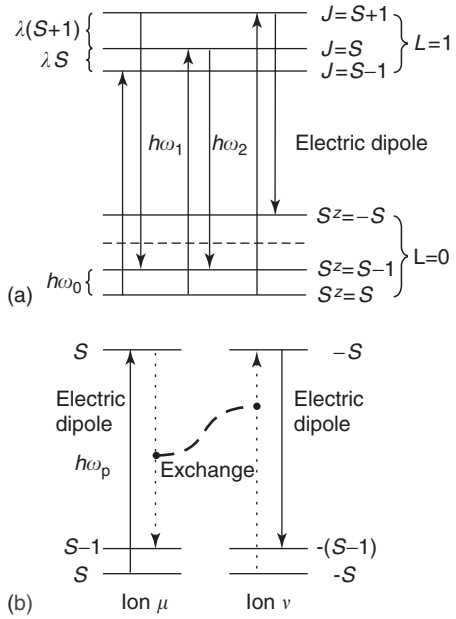

Figure 6 (a) One-magnon scattering and (b) two-magnon exchange scattering.

Two-magnon scattering arises from a fundamentally different process. Although it is a higher-order scattering process, it has generally a larger scattering cross section compared to one-magnon scattering. Two-magnon scattering is based on a double spin-flip caused by the matrix elements of the Coulomb interaction conserving the total z-component of spins. The so-called exchange scattering mechanism is illustrated in **Figure 6b**. The ground state of ion μ has an electron r_1 with $S^z = 1/2$ (denoted by $\uparrow$) in an orbital $|\mu\rangle$, while ion ν has an electron r_2 with $S^z = -1/2$ (denoted by $\downarrow$) in an orbital $|\nu\rangle$. The simultaneous change of the spin components of ions μ and ν occurs through the second order in the electric dipole interaction, and the first order in the exchange interaction between two electrons via Coulomb interaction. As a result, the effective spin Hamiltonian is given by

$$H_{2-\mathrm{mag}} \propto \sum_{ij} E_{\mathrm{S}}^{i} E_{\mathrm{I}}^{j} S_{\mu}^{-} S_{\nu}^{+} \quad [20]$$

Note that the two-magnon Hamiltonian has the same form as the Heisenberg Hamiltonian, as the same exchange mechanism involving the Coulomb interaction is relevant. Two-magnon scattering is effective for nearest-neighbor spins of an antiferromagnetic system, and even short-range correlations of exchange coupling can be detected. It allows one to determine exchange constants and magnon–magnon interactions. As an example, a two-magnon

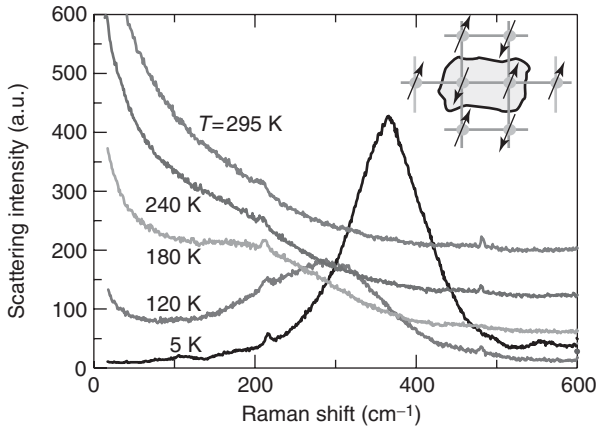

Figure 7 Two-magnon exchange scattering in ($x'y'$) polarization in $LaSrMnO_4$ with a maximum at $\Delta\omega = 360\ cm^{-1}$ as a function of temperature. The ordering temperature of the compound is $T_N = 126$ K. Curves are given an offset for clarity. The inset shows a sketch of the spins in a plane involved in an exchange scattering process.

scattering on the antiferromagnet $LaSrMnO_4$ with layers of Mn^{3+} and localized $S = 2$, as sketched in the inset of **Figure 7**, is shown. Each spin pair involved in a two-magnon process has six neighbors. A rough estimation of the energy of such a process would be $E_{2-\mathrm{mag}} = 6S \cdot J$. The broad maximum at $\Delta\omega = 360\ cm^{-1}$ shown in **Figure 7** is attributed to the two-magnon scattering. It leads to an exchange coupling constant $J = 43$ K, in good agreement with neutron scattering experiments. At elevated temperatures, the maximum is broadened but still visible for $T > T_N = 126$ K. With even higher temperatures, it is superimposed by a quasi-elastic tail of scattering that is induced by energy fluctuations.

Quasi-Elastic Scattering

In many magnetic systems, the energy of a magnetic system is not constant, but fluctuates about its mean value. This leads to quasi-elastic scattering as shown in the RS data on $LaSrMnO_4$ at $T = 295$ K. This tail of scattering around $\Delta\omega \approx 0$ on the Stokes and anti-Stokes side of the spectrum increases strongly with increasing temperature. The scattering intensity is described as a pair correlation function of the spin energy:

$$I(\omega) \propto \int_{-\infty}^{\infty} \ll E(k,t)E^*(-k,0) \gg \mathrm{e}^{-\mathrm{i}\omega t}\, \mathrm{d}t \quad [21]$$

where $E(k,t)$ is magnetic energy density given by the Fourier transform of $E(r) = -\langle \sum_{i>j} J_{ij} S_i \cdot S_j \delta(r - r_i) \rangle$ with the position of the ith spin r_i. Under hydrodynamic conditions and for high temperatures, the scattering intensity is simplified as a Lorentzian lineshape

$$I(\omega) \propto C_\mathrm{m} T^2 \frac{D_\mathrm{T} k^2}{\omega^2 + (D_\mathrm{T} q^2)^2} \quad [22]$$

This equation implies that the integrated intensity and the half-width at half maximum of the quasi-elastic scattering is determined by the magnetic specific heat C_m and thermal diffusion constant D_T, thus enabling one to determine thermodynamic quantities of the magnetic system by a spectroscopic experiment.

Scattering, Inelastic: X-Ray (Methods and Applications)

M Krisch and F Sette, European Synchrotron Radiation Facility, Grenoble, France

Introduction

Inelastic X-ray scattering (IXS) experiments, including both energy and direction (momentum) analysis of the scattered photons, provide an important spectroscopic tool in the study of dynamical properties of matter. The different methods can be roughly classified according to the size of the energy (and momentum) transfer. This is schematically illustrated in **Figure 1**. IXS from collective ion excitations aims at the study of phonons and phonon-like excitations. It is complementary to inelastic neutron scattering (INS), and has proven to be particularly powerful in cases where INS techniques cannot be applied. Electron dynamics and electronic excitations are studied in various regimes. Compton scattering (which will not be further discussed in detail, see contribution by A Bansil) allows one to determine the electron momentum distribution. IXS from valence and core electrons bears a very close resemblance to electron-energy-loss spectroscopy, X-ray absorption, and photoemission techniques, and gives access to single-particle or collective electron (plasmon) excitations.

Despite the fact that most of the IXS techniques were developed several decades ago, they gained their full maturity only after the outstanding properties of storage ring-based X-ray sources, in terms of source brilliance and energy tunability, became apparent. IXS experiments are performed over a very large spectral range – from the vacuum-ultraviolet over the soft X-ray range into the hard X-ray regime. Consequently, the associated instrumentation is very diversified, and is based on diffraction gratings for the low energy range, whereas perfect Bragg crystal optics are utilized in the X-ray range.

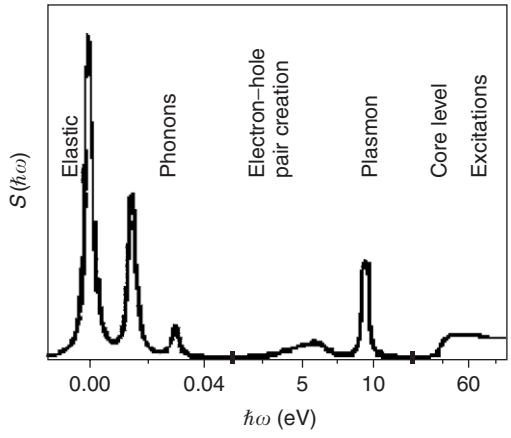

Figure 1 Schematic X-ray excitation spectrum $S(\hbar\omega)$ as a function of energy transfer.

Theoretical Aspects

The basic kinematics of the inelastic scattering process are depicted in **Figure 2**. The incident photon of energy $\hbar\omega_1$ and momentum $\hbar\boldsymbol{k}_1$ is scattered from the sample into a photon of energy $\hbar\omega_2$ and momentum $\hbar\boldsymbol{k}_2$. The process is therefore characterized by the energy transfer $E = \hbar\omega_1 - \hbar\omega_2$ and the momentum transfer $\hbar Q = \hbar\boldsymbol{k}_1 - \hbar\boldsymbol{k}_2$. Here, the polarization transfer is not considered. In cases where the energy transfer is much smaller than the incident photon energy, Q is solely controlled by the scattering angle Θ_s, and is given by the following expression:

$$Q = 2k_1 \sin(\Theta_s/2)$$

The Hamiltonian, describing the electron–photon interaction in the scattering process, is composed, in the weak relativistic limit, of four terms. Neglecting the much weaker magnetic couplings, only two terms have to be retained:

$$H_{\text{int}} = \sum_j \frac{e}{2mc^2} A_j^2 + \sum_j \frac{e}{mc} A_j p_j$$

where $r_0 = e^2/mc^2$ is the classical electron radius, $\boldsymbol{A}$ the vector potential of the electromagnetic field, and $\boldsymbol{p}$ the momentum operator of the scattering electrons. The sum extends over all the electrons in the system. Treating the scattering process in the lowest-order perturbation theory, representing the vector potential $\boldsymbol{A}$ in terms of photon creation and annihilation operators, and assuming that both the initial and the final photon states can be represented by plane waves, one obtains, for the double differential cross

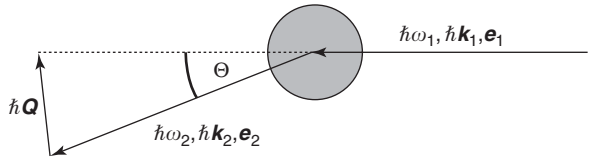

Figure 2 Kinematics of the scattering process.

section (DDCS),

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega_2} = r_0^2\left(\frac{\omega_2}{\omega_1}\right)\sum_F\left|\left\langle F|\sum_j \mathrm{e}^{\mathrm{i}(\boldsymbol{k}_2-\boldsymbol{k}_1)\boldsymbol{r}_j}|I\right\rangle(\boldsymbol{e}_1\cdot\boldsymbol{e}_2)\right.$$
$$-\frac{1}{m}\sum_N\left\{\frac{\left\langle F|\boldsymbol{e}_2\cdot\sum_j \boldsymbol{p}_j\mathrm{e}^{-\mathrm{i}\boldsymbol{k}_2\boldsymbol{r}_j}|N\right\rangle\left\langle N|\boldsymbol{e}_1\cdot\sum_j \boldsymbol{p}_j\mathrm{e}^{\mathrm{i}\boldsymbol{k}_1\boldsymbol{r}_j}|I\right\rangle}{E_N-E_I-\hbar\omega_1-0.5i\Gamma_N}\right.$$
$$\left.\left.+\frac{\left\langle F|\boldsymbol{e}_1\cdot\sum_j \boldsymbol{p}_j\mathrm{e}^{\mathrm{i}\boldsymbol{k}_1\boldsymbol{r}_j}|N\right\rangle\left\langle N|\boldsymbol{e}_2\cdot\sum_j \boldsymbol{p}_j\mathrm{e}^{-\mathrm{i}\boldsymbol{k}_2\boldsymbol{r}_j}|I\right\rangle}{E_N-E_I+\hbar\omega_2}\right\}\right|^2$$
$$\times\,\delta(E_\mathrm{F}-E_I-\hbar\omega)$$

where $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ are the polarization vector of the incident and the scattered photon, respectively, and Γ_N is the lifetime broadening of the intermediate state. The δ-function ensures energy conservation. The DDCS is proportional to the number of incident probe particles scattered within an energy range $\Delta E(\Delta\hbar w_2)$ and wave vector transfer variation ΔQ into a solid angle $\Delta\Omega$. If the interference terms are neglected, the cross section is composed of three contributions. The first term, derived from the A^2-term in first-order perturbation, describes nonresonant IXS. The second and the third term are derived from the $p\cdot A$-term in second-order perturbation. The second term describes an absorption process followed by an emission process, coupled via a resonant intermediate state $|N\rangle$, leading to an increase of the cross section, whenever the energy of the incident photon is close to an absorption edge of the element under study. The third term can be neglected in practical cases.

From the first term of the DDCS, which implicitly contains the correlation function of the electron density, one arrives at the correlation function of the atomic density, on the basis of the following considerations:

(1) *Validity of the adiabatic approximation*. This allows one to separate the system quantum state $|S\rangle$ into the product of an electronic part, $|S_\mathrm{e}\rangle$, which depends only parametrically on the nuclear coordinates, and a nuclear part, $|S_\mathrm{n}\rangle : |S\rangle = |S_\mathrm{e}\rangle|S_\mathrm{n}\rangle$. This approximation is particularly good for exchanged energies that are small with respect to the excitation energies of electrons in bound core states: this is indeed the case in basically any atomic species when considering phonon energies. In this approximation, one neglects the portion of the total electron density contributing to the delocalized bonding states in the valence band region.

(2) Limitation to the case for which the electronic part of the total wave function is not changed by the scattering process, and therefore the difference between the initial state $|I\rangle = |I_\mathrm{e}\rangle|I_\mathrm{n}\rangle$ and the final state $|F\rangle = |I_\mathrm{e}\rangle|F_\mathrm{n}\rangle$ is due only to excitations associated with the atomic density fluctuations.

IXS from Electronic Excitations

In the following, the various IXS processes which arise from electronic excitations (with the exception of Compton scattering) are discussed. These can be roughly divided into two main fields according to the corresponding piece of the DDCS: (1) nonresonant IXS and (2) resonant IXS. In contrast to spectroscopies utilizing electron detection, IXS experiments are bulk sensitive and, if performed in the hard X-ray regime, allow one to study systems under extreme conditions such as very high temperatures and pressures.

Nonresonant Inelastic X-Ray Scattering from Electrons

The cross section for nonresonant IXS is derived from the A^2-term of the interaction Hamiltonian, and constitutes the first term in the expression of the DDCS. The DDCS can be factorized into two parts, the first describes the coupling of the scattering probe to the system, and the second contains the properties of the system in the absence of the perturbing probe:

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}\omega_2} = r_0^2(\boldsymbol{e}_1\cdot\boldsymbol{e}_2)^2\left(\frac{\omega_2}{\omega_1}\right)S(\boldsymbol{Q},\omega)$$
$$= \left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_\mathrm{Th}S(\boldsymbol{Q},\omega)$$

where $(\mathrm{d}\sigma/\mathrm{d}\Omega)_\mathrm{Th}$ is the Thomson cross section. The dynamical structure factor contains the information about electronic excitations via the imaginary part of the dielectric response function $1/\varepsilon(\boldsymbol{Q},\omega)$:

$$S(\boldsymbol{Q},\omega) = \left(-\frac{\hbar Q^2}{4\pi^2e^2n}\right)\mathrm{Im}\left[\frac{1}{\varepsilon(\boldsymbol{Q},\omega)}\right]$$

where n is the electron density of the system. The dielectric response function in turn is directly related to the polarization function $\chi(\boldsymbol{Q},\omega)$:

$$\frac{1}{\varepsilon(\boldsymbol{Q},\omega)} = 1+\frac{4\pi e^2}{Q^2}\chi(\boldsymbol{Q},\omega)$$

where $\chi(\boldsymbol{Q},\omega)$ connects the Fourier-transformed induced charge $n_\mathrm{ind}(\boldsymbol{Q},\omega)$ with the Fourier transform of the external potential $\Phi_\mathrm{ext}(\boldsymbol{Q},\omega)$:

$$n_\mathrm{ind}(\boldsymbol{Q},\omega) = -e\chi(\boldsymbol{Q},\omega)\Phi_\mathrm{ext}(\boldsymbol{Q},\omega)$$

The basic ingredient of the polarization function is the so-called Lindhard polarization function, which describes the polarization of a homogeneous electron system by taking into account all single-particle excitation processes (particle–hole excitations) mediated by the momentum transfer, assuming that they are allowed by Pauli's principle, but neglecting the interaction of the particle and the hole with the surrounding electron fluid as well as any interaction between the particle and the hole left behind. A first step of approximating the Lindhard polarization function is the so-called random phase approximation (RPA) where, in addition to the external potential, the potential due to the induced polarization also acts on the system.

IXS from valence electrons **Figure 3** shows three characteristic $S(\boldsymbol{Q},\omega)$ spectra along with the real and imaginary parts of the dielectric function $\varepsilon(\boldsymbol{Q},\omega)$. The evolution of the spectra can be understood by inspection of $\varepsilon(\boldsymbol{Q},\omega)$ and $\mathrm{Im}[\varepsilon(\boldsymbol{Q},\omega)^{-1}]$ for three different regimes of the momentum transfer Q. Within the RPA formalism, a sharp structure in the $S(\boldsymbol{Q},\omega)$ appears at a frequency $\omega=\omega_\mathrm{p}$, the plasma frequency of the system, when $\mathrm{Re}[\varepsilon(\boldsymbol{Q},\omega)]$ has a zero passage and simultaneously $\mathrm{Im}[\varepsilon(\boldsymbol{Q},\omega)]$ is close to zero. This behavior persists up to the so-called critical momentum transfer Q_c, for which the zero passage of $\mathrm{Re}[\varepsilon(\boldsymbol{Q},\omega)]$ coincides with the high-energy cutoff of $\mathrm{Im}[\varepsilon(\boldsymbol{Q},\omega)]$. In the above regime of $Q<Q_\mathrm{c}$, the plasmon dispersion can be determined. For $Q>Q_\mathrm{c}$, the plasmons can decay into particle–hole excitations, and a much larger spectral range yields a significant contribution to the $S(\boldsymbol{Q},\omega)$. A comparison of the experimental spectra with relevant calculations gives an insight into electron correlation and band-structure effects. Moreover, IXS allows one to determine the bandgap of semiconductors or insulators, and – in the case of an indirect gap – its relative momentum. Furthermore, IXS spectra recorded in the particle–hole excitations regime provide information about the combined electron density of states. Finally, one gains access to the off-diagonal response of the dynamical structure factor by performing the IXS experiment in the presence of a standing-wave field, generated by the coherent superposition of an incident and diffracted wave vector when the sample is positioned in Bragg reflection conditions.

IXS from core electrons (X-ray Raman scattering) Here, the final state $|F\rangle$ of the electron system is characterized by a hole in a core level and an electron in a continuum state above the Fermi level. Within the RPA, the dynamical structure factor takes the following form:

$$S(\boldsymbol{Q},\omega)=\left(\frac{\hbar Q^2}{4\pi e^2 n}\right)\sum_{k',v'}|\langle \boldsymbol{k}'v|\exp(\mathrm{i}\boldsymbol{Q}\boldsymbol{r})|c\rangle|^2 \times\delta(\hbar\omega+E_\mathrm{c}-E(\boldsymbol{k}',v))$$

where $|c\rangle$ is a core state with energy E_c and $E(\boldsymbol{k}',v)$ is the energy of a one-electron Bloch state with reduced wave vector $\boldsymbol{k}'$ and band index v. The characteristics of the electronic transition are controlled by the transition operator. XRS from core electrons of low Z materials is analogous to soft X-ray absorption spectroscopy (XAS), as long as the momentum transfer Q is small compared with the radial extent of the wave function of the core electron, involved in the inelastic scattering process. While in XAS the incident photon energy has to be tuned to the absorption edge energy under consideration, in XRS this role is taken by the energy transfer, thus leaving a certain

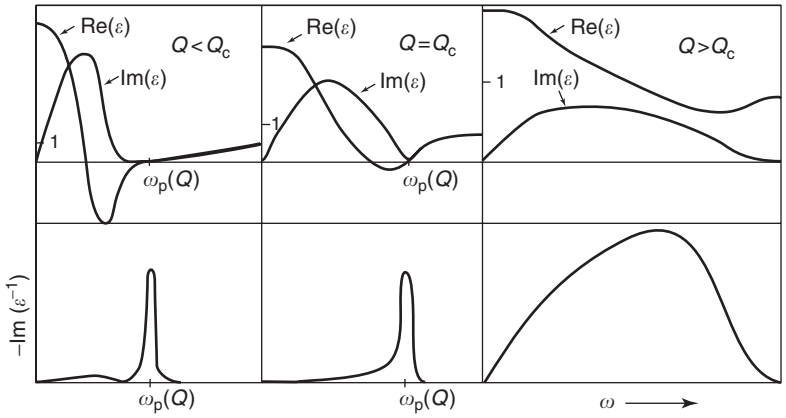

Figure 3 Upper panel: real and imaginary part of the RPA dielectric function $\varepsilon_{\mathrm{RPA}}(Q,\omega)$ for $Q<Q_\mathrm{c}$, $Q=Q_\mathrm{c}$, and $Q>Q_\mathrm{c}$. Lower panel: corresponding imaginary part of $-\varepsilon^{-1}_{\mathrm{RPA}}(Q,\omega)$. (Adapted from Schülke with permission.)

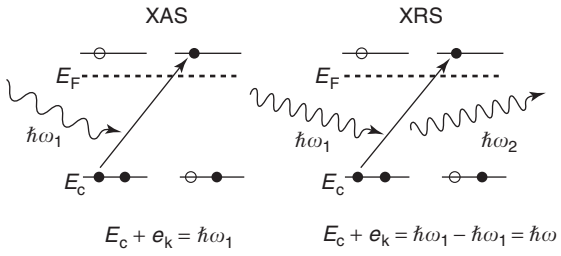

Figure 4 Schematic representation of the X-ray absorption (left) and X-ray Raman scattering (right) process. E_c denotes the binding energy of a core level, e_k the kinetic energy of the photoelectron, and E_F the Fermi energy.

freedom in the choice of the incident photon energy. This is schematically illustrated in **Figure 4**. XRS therefore allows one to perform soft X-ray absorption studies in the hard X-ray regime, with the advantage of probing truly bulk properties and study systems which are not compatible with an ultrahigh vacuum environment, necessary in the soft X-ray regime. Moreover, by varying the momentum transfer $\hbar Q$, the electric dipole selection rule, defining the final state symmetry which can be reached in an absorption process, is relaxed and the full multipolar expansion of the transition operator has to be taken into account: in particular, electric monopole transitions become possible.

Resonant IXS

The cross section for resonant inelastic X-ray scattering (RIXS) is derived from the $p \cdot A$-term in the interaction Hamiltonian, and constitutes the second term of the DDCS. It is a second-order optical process in which a core electron is excited by an incident X-ray photon of energy $\hbar\omega_1$ into empty states above the Fermi level. This excited state then decays, and the deep core hole is filled by an electron from a shallower core level or the valence band under emission of a photon of energy $\hbar\omega_2$ (see **Figure 5**). In the most common case, both the excitation and deexcitation step involve electric dipolar transitions. If the intermediate core excited states are closely located in energy, interference between the absorption and emission process is possible. Dynamics in the time domain can be assessed if the intermediate state undergoes a transition (emission or absorption of a phonon) in the time interval between the excitation and the emission step. The rate for this transition can then be directly compared to the core hole decay rate, and information about the time development in the range of the core hole lifetime can be obtained. Well above the absorption threshold, the IXS process can be regarded as a decoupled two-step process, and is commonly dubbed X-ray fluorescence. In general, a simple one-electron picture is not sufficient to account for all the observed phenomena. Especially for open shell systems, such as transition metals or rare earths, a many-body description has to be invoked. Despite these complexities RIXS is a very powerful spectroscopic tool, thanks to its high degree of selectivity. It is element and angular momentum selective (via its resonant intermediate state and the transition selection rules, respectively). Site selectivity with respect to identical atomic species in different chemical environments can be obtained by choosing an excitation energy so that a core electron is promoted to an unoccupied state which has a strong localization on that particular site. Detecting the scattered X-rays with angular selectivity adds further information: in solids band-structure information can be obtained, whereas for molecules the symmetry of molecular states can be studied. Furthermore, exploiting the unique polarization properties of synchrotron-based X-ray sources, linear and circular dichroism phenomena can be studied. As in the case of nonresonant IXS, the various applications can be roughly classified according to the transferred energy.

RIXS from valence electrons These experiments aim to detect low-lying electronic excitations such as interband, *d–d*, and charge-transfer excitations. To perform these experiments resonant with a characteristic absorption edge bears several advantages: (1) the resonant enhancement of the cross section of typically two orders of magnitude allows one to study essentially all compounds of interest while nonresonant IXS is practically limited to low Z materials; (2) the presence of (an) intermediate state(s) and eventual interference effects between them make the RIXS process highly selective in terms of angular momentum selection rules and geometrical considerations when the experiment is performed on single crystals. For example, the shape of resonantly excited valence fluorescence spectra from single crystals depends strongly on the energy of the incident photon and the momentum transfer Q (both direction and

size) which is a direct consequence of momentum conservation, stating that Q must be equal to the vector difference $\boldsymbol{k}_e - \boldsymbol{k}_h$ between the Bloch vectors of the excited electron and those of the hole left behind, modulo a reciprocal lattice vector $\boldsymbol{G}$. This Bloch k-selective RIXS allows, in principle, one to obtain band-structure information although attention has to be paid to the relaxation processes in the intermediate state.

RIXS from core electrons Since the final state of the RIXS process is characterized by a hole in a shallow core level (or the valence band), spectral features narrower than the intermediate state lifetime width can be observed. The ultimate resolution is limited by the final-state lifetime width. If these final state RIXS features are associated with different excitation channels (located at different energies in the intermediate state), they will resonate at different incident photon energies. RIXS, therefore, can reveal different excitation channels that are completely obscured in the corresponding X-ray absorption spectrum due to the large core hole lifetime width. This allows, for example, one to determine the energy position and the relative strength of weak quadrupolar $(2p \rightarrow 4f)$ transitions in rare-earth compounds.

Spin-selective RIXS The shape of X-ray fluorescence spectra of elements which contain an open electronic shell (e.g., transition metals or rare earths) shows characteristic shoulders or satellites which reflect the energies of the different electronic configurations of the excited atom. Besides the Coulomb interactions between the electrons occupying different orbital configurations, there are some interactions that have a magnetic origin, in particular in cases where the excited atom has valence electrons with unpaired spin giving rise to a magnetic moment. These exchange interactions between the magnetic electrons of the valence shell and the core electrons in the orbital where the photon emission process has left a core hole lead to features in the emission spectrum of dominant spin character. The energy separation is related to the strength of these interactions, which are largest when the hole is in an orbital with the same principal quantum number n of the magnetic electrons. In a simple picture, the X-ray emission is separated into high- and low-spin states whose energy separation is proportional to the exchange integral J and $(2S+1)$, where S is the total spin moment of the magnetic shell, and whose intensity ratio is given by $S/(S+1)$. Changes in the magnetic state (induced, for example, by pressure, temperature, or doping) can therefore be witnessed by changes in the X-ray emission lineshape. By its nature, this method does not need a long-range magnetic order, and it is sensitive to the local (atomic) magnetic spin moment of a specific valence orbital. As a consequence, however, the method cannot discriminate between ferro-, antiferro-, ferri-, and paramagnetism.

Dichroism effects in RIXS Resonant IXS and fluorescence spectral shapes are sensitive to both the polarization of incident and scattered photons. In ferromagnetically aligned samples, the emission spectra therefore display dichroic effects, in close analogy to X-ray absorption spectroscopy utilizing circular or linear polarized X-rays. RIXS from valence electrons, excited with circular polarized X-rays, provides information on the occupied spin density, whereas RIXS from core electrons allows one to reveal the magnetic character of the predominant features composing the emission line. The X-ray emission linear magnetic dichroism effect represents the angular dependence of the X-ray emission cross section with respect to the magnetization axis. For a given configuration, the sizes of these dichroic effects are proportional to the magnetic moment of the involved magnetic shell.

IXS from Phonons

The study of atomic dynamics in condensed matter at momentum transfers Q and energies E, characteristic of collective motions, is traditionally the domain of neutron spectroscopy. There are, however, situations where the use of photons has important advantages over neutrons. The most significant is that there are no kinematic limitations: for IXS, any energy transfer can be reached for a given momentum transfer, whereas for INS, due to the neutron mass and typical neutron energies, the small-Q range is not accessible. This is depicted in **Figure 6** for different scattering angles Θ_s. Another advantage of IXS arises from the fact that very small beam sizes, in the order of a few tens of micrometers or less, can presently be obtained at third generation synchrotron sources (in contrast to centimeter-sized neutron beam sizes).

In its most general form, the DDCS can be written as

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\omega_2\,\mathrm{d}\Omega} = r_0^2(\boldsymbol{e}_1\cdot\boldsymbol{e}_2)^2\frac{\omega_2}{\omega_1}\sum_{I_n,F_n}P_{I_n} \times\left|\left\langle F_n\left|\sum_j f_j(\boldsymbol{Q})\mathrm{e}^{\mathrm{i}\boldsymbol{Q}\boldsymbol{R}_j}\right|I_n\right\rangle\right|^2 \times\delta(\hbar\omega+\hbar\omega_2-\hbar\omega_1)$$

where $|I_n\rangle$ ($|F_n\rangle$) are the initial (final) nuclear states, P_{I_n} represents the thermal population of the initial

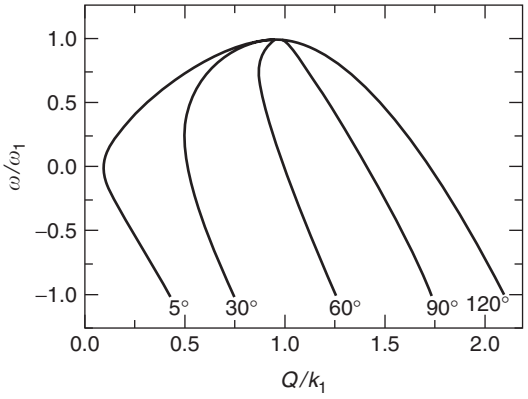

Figure 6 Accessible energy–momentum transfer regions for inelastic neutron scattering for different scattering angles Θ_s, reported normalized to the incident neutron energy $\hbar\omega_1$ and incident neutron momentum $\hbar k_1$.

states, and $f_j(\boldsymbol{Q})$ is the atomic form factor of the jth particle whose center-of-mass position is $\boldsymbol{R}_j$.

With respect to the INS cross section, the following aspects are noteworthy.

1. X-rays couple to the electrons of the system with a cross section proportional to the square of the classical electron radius, $r_0 = 2.82 \times 10^{-15}$ m, that is with a strength comparable to the neutron-nucleus scattering cross section b^2.
2. The IXS cross section is proportional to $f_j^2(\boldsymbol{Q})$. In the limit $Q \to 0$, the form factor is equal to the number of electrons in the scattering atom, Z; for increasing values of Q, the form factor decays with decay constants of the order of the inverse of the atomic wave function dimensions of the electrons in the atom.
3. For elements with $Z > 4$ and typical X-ray energies of 10–30 keV, photoelectric absorption is the main attenuation process. Far away from any absorption resonances, it is roughly proportional to Z^4, leading therefore to a reduction of the cross section for heavier elements.
4. The cross section for X-rays is highly coherent; therefore, only static or quasistatic structural and/or chemical disorder contributions have to be considered. Finally, it is noted that the instrument resolution function for IXS is independent of the energy and momentum transfer.

Phonons in Crystalline Materials

The capability of providing micrometer-sized X-ray beams opens up the possibility of studying systems available only in small quantities down to a few $10^{-6}\,\text{mm}^3$. These comprise novel or advanced materials such as superconductors for which sufficient crystalline quality and homogeneous doping can only be obtained for tiny crystals, by far too small to be studied by INS. Moreover, materials can be studied under very high pressures (>100 GPa) using diamond anvil cells thus allowing an important insight into the dynamics close to structural phase transitions and the pressure evolution of elastic properties.

IXS from phonons in single crystalline materials provides the same information as coherent INS, and all aspects of lattice dynamics in terms of symmetry considerations, phonon eigenvectors, and selection rules are identical. One exception, however, concerns the relative intensity of the phonons in a multi-species system (with j different atom species in the unit cell), which can be very different due to the different weight of the atomic form factor $f_j(\boldsymbol{Q})$ with respect to the neutron scattering length b_j.

For polycrystalline materials, only the modulus of Q is well defined, and in general the $S(\boldsymbol{Q}, \omega)$ spectrum will contain contributions from all the phonon branches. The density-of-states limit is reached, if a fine sampling of a sufficiently large Q-space is performed. On the other hand, if Q is confined within the first Brillouin zone, $Q = q$ (q is the momentum of the phonon), only phonon modes which have a longitudinal symmetry component are excited, allowing the determination of an orientation-averaged acoustic phonon dispersion.

High-Frequency Dynamics in Liquids and Glasses

The absence of kinematic limitations for IXS has allowed one to access a previously unexploited region in Q–ω space, the so-called mesoscopic region, in which the momentum transfer $\hbar Q$ approaches the inverse of the interparticle separation a. This Q-range is particularly important, because here the collective dynamics undergoes a transition from a hydrodynamic behavior to a microscopic single-particle one.

Numerous IXS studies in glasses have identified – despite qualitative differences – several common features in the high-frequency dynamics.

1. Propagating acoustic-like excitations exist up to a maximum Q-value Q_m($Q_m a \approx 1$–3), depending on the fragility of the system).
2. The excitations are well defined and display a linear dispersion $\hbar\omega(Q)$. An extrapolation toward the $Q \to 0$ limit yields the macroscopic sound velocity.
3. The width $\Gamma(Q)$ of the inelastic peaks follows a power law, $\Gamma = DQ^{\alpha}$ with $\alpha = 2$ within the current experimental accuracy.
4. The value of D does not depend significantly on temperature, indicating that this broadening in the

high-frequency region does not have a dynamic origin, but is instead due to static disorder.

For liquids, the dynamical structure factor is strongly affected, if the probed distances ($l = 2\pi/Q$) are comparable to those that characterize structural correlations among particles (over typical correlation lengths ξ), and times ($t = 1/\omega$) comparable to the lifetime τ of these correlations. In this case, one observes a positive sound dispersion $c(Q)$ from its low-frequency ($\omega = 2\pi\nu \ll 1/\tau$) adiabatic value c_0 to the high-frequency ($\omega \gg 1/\tau$) elastic value c_∞. A quantitative analysis of the $S(Q,\omega)$ can be performed within the framework of a generalized Langevin equation formalism using the memory function approach. This allows the reliable extraction of c_∞, relaxation times, and relaxation strengths.

Deep Inelastic X-Ray Scattering

Quantitative information on the atomic momentum distribution can be obtained at sufficiently large momentum transfers, where the core electrons of the system under study recoil almost freely with an effective mass equal to the atomic mass. These conditions are met, if the electron dynamics is instantaneous compared to the atomic one and if the atoms have an appropriate quantity of electronic charge on a length scale smaller than $1/Q$. Deep IXS provides a complementary technique to deep INS, and is particularly valuable for polyatomic or polyisotopic systems, for which the relative contrast between the different atomic/isotopic species in the sample is different for INS and IXS.

Introduction

Nuclear resonant scattering (NRS) is a set of experimental techniques that use synchrotron radiation (SR) and well-defined resonances in atomic nuclei. Dynamics of the neutrons and protons cause a spectrum of these resonances for every nucleus except hydrogen. A nucleus can be created in an excited state by radioactive decay of a parent nucleus, or it can be brought into an excited state by collision with energetic particles (electrons, protons, neutrons, etc.) or the absorption of a photon. The latter process, a resonant excitation, becomes important if the energy of the photon is very close to the energy difference between the nuclear ground state and a nuclear excited state (see **Figure 1**.) Studies using NRS require isotopes with large nuclear resonant cross sections and transition energies that can be produced with high intensity by SR sources. NRS methods use timing techniques, and the observation of NRS from isotopes with very short lifetimes is technically difficult. Therefore, energy widths of the excited state $\sim 10^{-8}$ eV are favorable. Large values potentially result in higher counting rates in scattering experiments but also lead to shorter natural lifetimes.

Spectroscopic techniques with nuclear resonances are based on either the use of radioactive sources or parent nuclei, for example, Mössbauer spectroscopy and time-perturbed angular correlation (TPAC), or the direct excitation with photons, for example, nuclear magnetic resonance (NMR) or the SR-based NRS described here. Nuclear resonant inelastic X-ray scattering (NRIXS) for the study of lattice dynamics and synchrotron Mössbauer spectroscopy (SMS) for the study of hyperfine interactions assumed practical importance during the past decade at highly brilliant SR facilities.

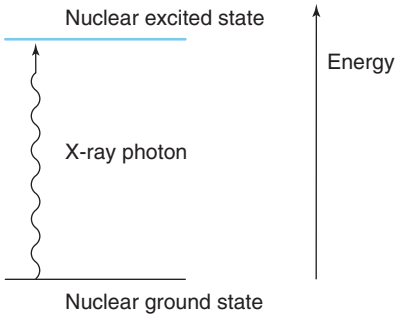

Figure 1 Resonant excitation of a nucleus. The energy width of the excited state is typically 12 orders of magnitude smaller than the energy of the photon. Nuclei show the most narrow resonances in the X-ray regime.

SMS includes scattering processes that occur without recoil, that is, without participation of lattice vibrations, and provides information about the electronic environment of the resonant nuclei analogous to conventional Mössbauer spectroscopy. The use of very collimated SR permits focusing to micrometer levels and easy manipulation of X-ray polarization. SMS has been applied very successfully to problems in high-pressure and biophysics research. In the study of magnetism, the strategic use of the isotopes ^{57}Fe (resonant) and ^{56}Fe (nonresonant) opened unique possibilities for analysis of thin films and nanostructures.

NRIXS is used for the study of lattice vibrations and provides one with a spectrum of the phonons experienced by the resonant isotope. Most importantly, one determines the phonon density of states (DOS) In contrast to other experimental techniques, NRIXS gives direct access to the partial and projected DOS of the resonant isotope only. This complete isotope selectivity is truly unique in the area of lattice dynamics research. For example, materials surrounding the sample that do not contain resonant nuclei do not produce a background, and this feature permitted high-pressure experiments in the Mbar regime that were impossible earlier. Many proteins contain only a few iron atoms at their biologically active sites; NRIXS studies using ^{57}Fe were conducted on several model compounds for such proteins, as well as on the proteins themselves. Among the thousands of atoms, NRIXS selects only the iron vibrations and thus permits detailed studies of protein dynamics related to these active sites. The same reasoning applies to studies of thin films and buried interfaces. Also, for nanoparticles and disordered alloys, the NRIXS method has been applied very successfullly. In those cases, as well as for amorphous materials, phonon dispersions are difficult or impossible to measure, but the DOS still gives valuable information.

Properties of Nuclear Resonances

X-ray scattering is generally treated solely with the electronic charge and spin. A justification is provided by classical electrodynamics in terms of the Thomson-scattering cross section, which is a factor of $(Zm/M)^2 \approx 10^{-7}$ smaller for the nucleus than for the electron shell. Here, m and M are the masses of electron

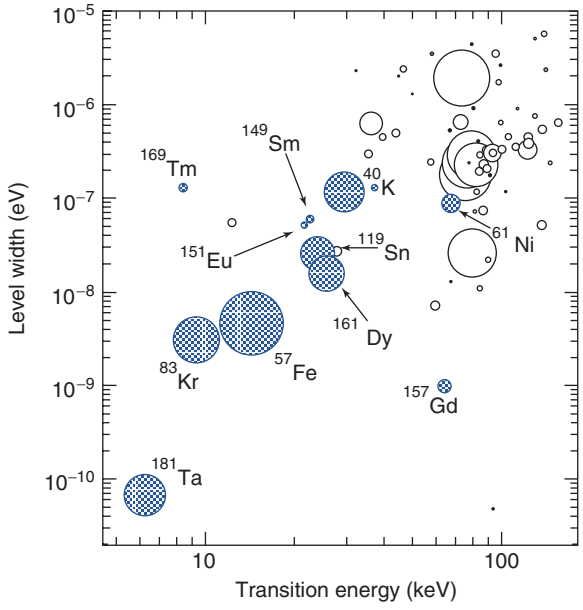

Figure 2 Level widths of nuclear resonances below 150 keV. The size of the symbols is proportional to the nuclear resonant cross section. Isotopes that have been used in NRS experiments are identified.

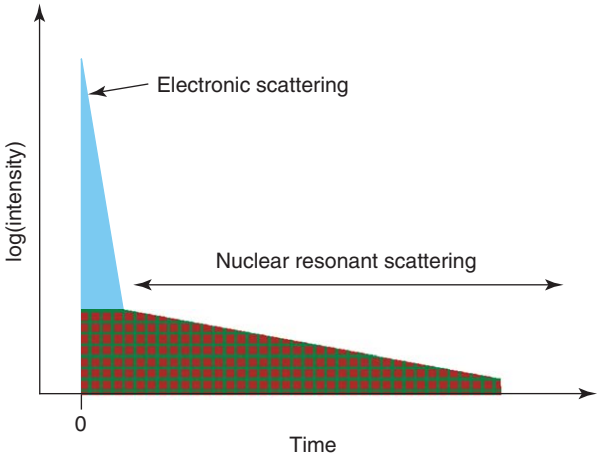

Figure 3 Scattered intensity vs. time. At zero time, an SR pulse excites a sample containing a nuclear resonant isotope. Electronic scattering is prompt whereas the response of the resonant nuclei is delayed. Time discrimination is the key to distinguishing nuclear and electronic scattering.

and nucleus respectively, and Z is the atomic number. Based on this, it seems appropriate to ignore the scattering contributions from the nucleus. However, the above argument fails if the timescale of internal nuclear dynamics matches the energy of the X-ray photon, that is, the nucleus experiences a resonant excitation. Then the nuclear resonant cross section is calculated as

$$\sigma_N = \frac{\lambda^2}{2\pi}\frac{1}{1+\alpha}\frac{2I'+1}{2I+1} \qquad [1]$$

where λ is the wavelength of the resonant X-rays, α is the internal conversion coefficient, and I,I' are the spins of nuclear, ground, and excited states. Values of α for relevant nuclear transitions range from 1 to 1000. The nuclear resonant cross section can become very large, for example, the 14.4 keV nuclear transition of ^{57}Fe gives (with $\lambda = 86$ pm $\alpha = 8.6$, $I = 1/2$, $I' = 3/2$) a value of $\sigma_N = 2.56$ Mbarn and a ration of $\sigma_N/\sigma_{pe} \approx 450$, where σ_{pe} is the photoelectric cross section. **Figure 2** displays nuclear resonant cross sections and nuclear-level widths for isotopes with resonances below 150 keV. Higher transition energies are less favorable because the intensity of SR sources decreases, and X-ray optics, as well as detectors, become less efficient. Even though the nuclear resonant cross section is very large, the extraordinarily narrow energy width of these resonances leads to a small energy-integrated cross section. For example, the best energy resolutions of X-ray optics are of the order $\delta E \approx 100\,\mu$eV, and a resonant enhancement over a neV scale would remain unresolved and unnoticed because $\sigma_N\Gamma \ll \sigma_{pe}\delta E$. Therefore, NRS experiments require special observation techniques.

A sample containing resonant nuclei responds to an SR pulse on a timescale defined by the lifetime of the nuclear state τ. The value of τ is inversely related to the nuclear-level width via $\tau\Gamma = \hbar$. Whereas values for τ are in the ns–μs range, the duration of an SR pulse is typically less than 100 ps. All electronic scattering of X-rays occurs typically on the timescale of femtoseconds, virtually instantaneous compared to nuclear resonant contributions. A "time-discrimination trick," which is illustrated in **Figure 3**, can cleanly separate nuclear resonant signals from other scattering contributions. The use of this time-discrimination trick makes NRS techniques possible.

Scattering Processes

A schematic of the excitation process of a nuclear resonance is shown in **Figure 1**. For a description of NRS, the de-excitation pathways must also be considered. The classification of elastic–inelastic and coherent–incoherent scattering processes is based on an analysis of the initial and final quantum state of the scatterer symbolized by

$$|\Phi_i\rangle|\gamma_i\rangle \rightarrow |\Phi_n\rangle \rightarrow |\Phi_f\rangle|\gamma_f\rangle \qquad [2]$$

States of the X-ray field and the scatterer are described by $|\gamma\rangle$ and $|\Phi\rangle$, respectively. The intermediate state exists without X-ray photons. An inelastic scattering process is characterized by different

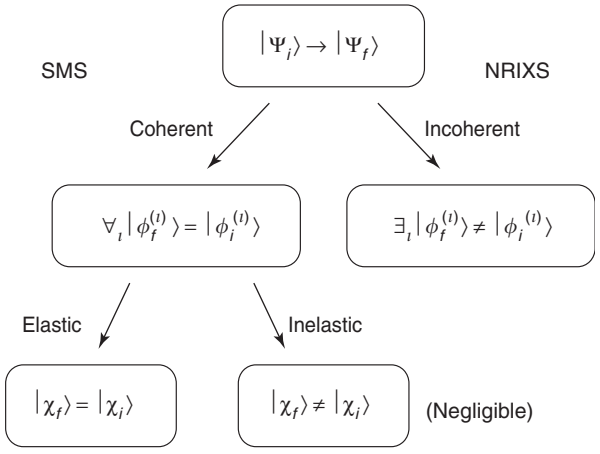

Figure 4 Classification scheme for scattering processes. Incoherent scattering implies energy transfer unless some core states are degenerate. Coherent inelastic NRS is of negligible strength.

energies of the initial and final photon states, which implies an energy transfer to the scatterer. A meaningful definition of coherent and incoherent scattering can only be given for a collection of atoms, for which

$$|\Phi_i\rangle = |\chi_i\rangle \prod_j |\phi_i^{(j)}\rangle \qquad [3]$$

Here, $|\phi^{(j)}\rangle$ symbolizes a core state, that is, the state of the nucleus and inner electron shell, of atom j. The collective state of itinerant electrons and lattice vibrations is written as $|\chi\rangle$.

A classification of scattering processes using this nomenclature is presented in **Figure 4**. Coherent processes leave all core states $|\phi^{(j)}\rangle$ unchanged. The scattering atom, in principle, cannot be identified, and the situation is analogous to a quantum mechanical multislit experiment. The change of the state of just one atom serves as an indicator, and the process will be incoherent. In particular, SMS is based on the coherent elastic process, whereas NRIXS originates from incoherent processes. Coherent inelastic scattering by resonant nuclei is of negligible strength. The almost purely incoherent character of inelastic NRS simplifies the interpretation of NRIXS data and presents a clear distinction to inelastic neutron scattering where incoherent and coherent processes often occur with similar strength.

Nuclear Resonant Inelastic X-Ray Scattering

The resonant absorption of an X-ray photon can lead to a simultaneous change of nuclear state and vibrational quantum state of the solid as illustrated in

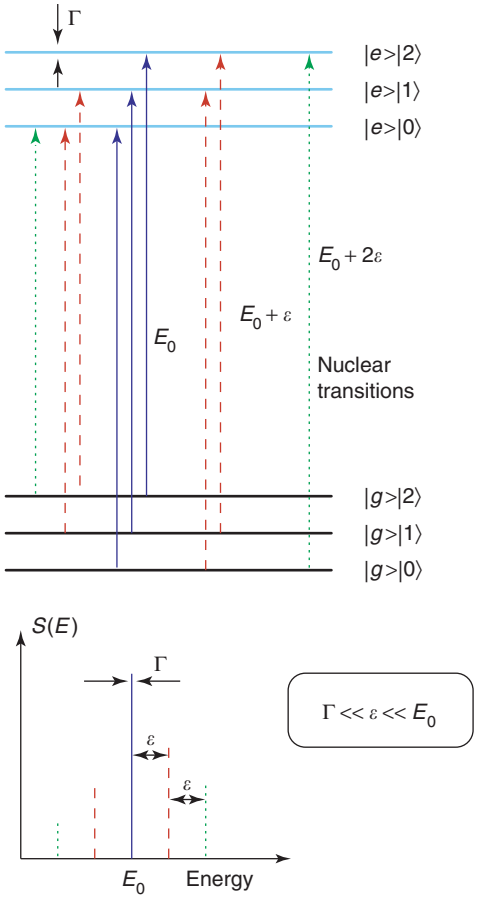

Figure 5 The influence of atomic vibrations on the nuclear level scheme. The nucleus is embedded in an Einstein solid with a specific phonon energy ε. This leads to sidebands in the excitation probability density $S(E)$ corresponding to phonon creation or annihilation.

Figure 5. Three energy scales determine the properties of this process: the transition energy of several keV; the phonon energies of the order of meV; the nuclear-level width of less than μeV. The energies are different by a many orders of magnitude, and energy eigenstates are very well described by a simple combination of nuclear states and phonon states, for example, $|g\rangle|1\rangle$ is a quantum state with the nucleus in the ground state and one phonon present. If one investigates the vibrating nucleus with monochromatic X-rays, one would observe transitions with nuclear transition energy E_0 described by $|g\rangle|n\rangle \rightarrow |e\rangle|n\rangle$ and m-phonon creation of the type $|g\rangle|n\rangle \rightarrow |e\rangle|n+m\rangle$ leading to upshifted transition energies $E_0 + m\varepsilon$, where ε is the energy of the phonon. Also, m-phonon annihilation of the type $|g\rangle|n\rangle \rightarrow |e\rangle|n-m\rangle$ with $n \geqslant m$ leads to downshifted transition energies $E_0 - m\varepsilon$. The absorption behavior is quantitatively described by the excitation probability density $S(E)$. The value of $S(E)\mathrm{d}E$ gives the probability that the

nucleus can be excited by X-rays in the energy range $[E, E+\mathrm{d}E]$. The phonon-creation/annihilation side bands of $S(E)$ are analogous to the Stokes and anti-Stokes lines observed by optical spectroscopies. The ratio $S(-E)/S(E)$ is universally given by the Boltzmann factor, that is, $S(-E) = \exp[-\beta E]S(E)$, with $\beta = 1/(k_\mathrm{B}T)$, temperature T, and Boltzmann's constant k_B. This relationship is known as "detailed balance" and is an intrinsic feature of all NRIXS spectra. The partial DOS is extracted by a mathematical inversion procedure from $S(E)$. Here, "partial" refers to the selection that has taken place by observing only vibrations of the resonant isotope.

Cross Section

Excitation probabilities can be calculated with Fermi's golden rule, which gives the transition rate Λ_{ni} for changes from the initial state $|\Phi_i\rangle = |\chi_i\rangle|\phi_i\rangle$ to an intermediate state $|\Phi_n\rangle = |\chi_n\rangle|\phi_n\rangle$ under the influence of a monochromatic X-ray field of energy $\bar{E}$, amplitude $\boldsymbol{a}$, and wave vector $\boldsymbol{k}$

$$\Lambda_{ni} = \frac{2\pi}{\hbar}\,|\langle\Phi_n|\hat{H}_\mathrm{int}|\Phi_i\rangle|^2\delta(E_{ni}-\bar{E}) \qquad [4]$$

The energy difference of the states is given by E_{ni}, and the interaction Hamiltonian can be expressed by

$$\hat{H}_\mathrm{int} = \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\hat{\boldsymbol{r}}}\boldsymbol{a}\cdot\hat{\boldsymbol{J}}(-\boldsymbol{k}) \qquad [5]$$

where $\hat{\boldsymbol{J}}$ is the spatial Fourier transform of the nuclear current operator in the center of mass frame, and the position of the center of mass is given by $\boldsymbol{r}$. One obtains for the cross section

$$\sigma(E,\boldsymbol{k}) = \frac{1}{|\boldsymbol{a}|^2}\sum_n\langle\Lambda_{ni}\rangle_i = \frac{\pi}{2}\,\sigma_\mathrm{N}\Gamma S(E,\boldsymbol{k}) \qquad [6]$$

where $E = \bar{E} - E_0$ is the energy of the incident X-rays relative to the nuclear transition energy. The angle brackets indicate an average over all initial states that may be present, for example, in a thermal distribution. The last term is defined by

$$S(E,\boldsymbol{k}) = \int\frac{\mathrm{d}t}{2\pi\hbar}\,\mathrm{e}^{\mathrm{i}Et/\hbar}\langle\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\hat{\boldsymbol{r}}(t)}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\hat{\boldsymbol{r}}(0)}\rangle \qquad [7]$$

This is the excitation probability density mentioned earlier, and here it is expressed as a self-correlation function of the position of a resonant isotope. For solid materials, $S(E,\boldsymbol{k})$ shows a sharp peak with width Γ around the nuclear transition energy E_0, that is, around $E=0$. The existence of this peak is tantamount to recoilless absorption of X-rays by the nucleus, the Mössbauer effect. In fact, $\Gamma S(0) = f$, the Lamb–Mössbauer factor or probability for recoilless absorption. The value of f varies approximately between 0.05 and 0.9 for solids at room temperature but vanishes for liquids and gases. The estimate for absorption "on resonance" is then

$$\sigma(0) \approx \frac{\pi}{2}\,\sigma_\mathrm{N} f \qquad [8]$$

With the exception of the elastic peak, $S(E)$ is expected to be a smooth function in energy, extending over an energy range that may be estimated by the Debye energy Θ. From eqn [7] one obtains $\int S(E)\mathrm{d}E = 1$, and with this normalization, one can estimate for the "off resonance" region $\Theta S(E) \approx 1-f$ providing

$$\sigma(E\neq 0) \approx \frac{\pi}{2}\,\sigma_\mathrm{N}(1-f)\frac{\Gamma}{\Theta} \qquad [9]$$

A quantitative estimate for ^{57}Fe in metallic form gives in units of the photoelectric cross section

$$\sigma(0) \approx 560\ \sigma_\mathrm{pe} \quad \sigma(E\neq 0) \approx 0.0002\ \sigma_\mathrm{pe} \qquad [10]$$

The change of cross section by six orders of magnitude when moving away from the transition energy is dramatic. The large "on resonance" value permits conventional energy-resolved Mössbauer spectroscopy. The observation of the phonon sidebands via the small "off resonance" value requires the use of time discrimination.

Observation

Imagine a resonant nucleus that was somehow excited. The nucleus will decay into the ground state either by emission of an X-ray photon or by transferring the excitation energy to the electron shell. In the latter case, an electron is expelled, and the hole is quickly filled by other electrons with the emission of fluorescence X-rays. All these decay products are emitted with some delay relative to the time of excitation of the nucleus, and the average delay time is given by the natural lifetime. **Figure 3** illustrates the time evolution of the scattered intensity of a material containing resonant nuclei after excitation with an SR pulse. If the energy of the incident X-ray is close to the nuclear transition energy, nuclei are excited, and delayed emission of X-rays can be observed. If only the delayed photons are counted while tuning the energy of the incident X-ray pulses, an event rate that is proportional to $\sigma(E)$ is expected to be measured. The normalized data then provide $S(E)$. An example of data collected from a metallic foil of ^{57}Fe is shown in **Figure 6**. The low background shows that the time-discrimination trick removes all nonnuclear scattering of the X-rays very effectively.

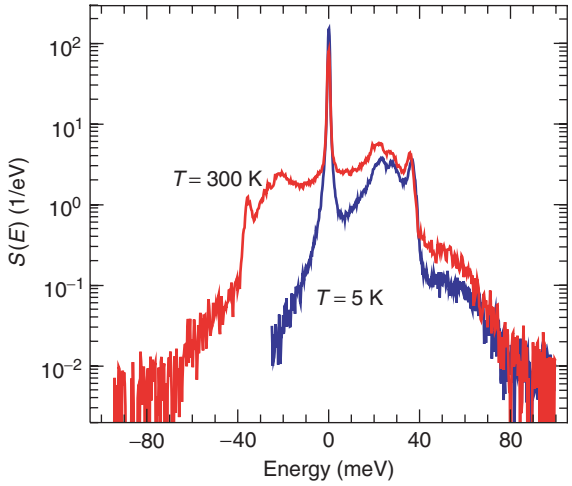

Figure 6 Phonon excitation probability density from NRIXS data of an iron foil at two temperatures. Energy zero corresponds to the nuclear transition energy of 14.4125 keV of the ^{57}Fe isotope. At low temperatures, phonon annihilation (negative energy values) is inhibited.

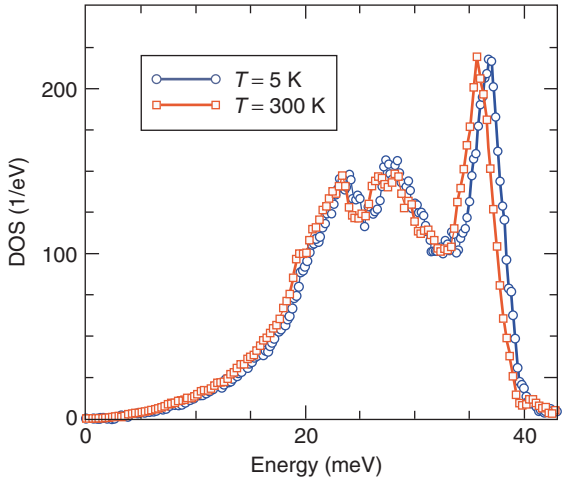

Figure 7 The DOS of iron metal (b.c.c.) at two temperatures. The curves show $3g$ calculated from the data shown in **Figure 6** using eqn [11].

Phonon Density of States

In many cases, an expansion of the interatomic potential around the equilibrium positions of the atoms in a solid is quite accurately described by a quadratic dependence on the atomic displacements. In this quasiharmonic approximation, the equation of motion for the atomic motions can be integrated. The excitation probability can then be rewritten in a physically meaningful way as

$$S(E) = f\delta(E) + \sum_{n=1} S_n(E)$$

$$S_1(E) = \frac{fE_R}{E(1-\exp(-\beta E))}\, g(|E|) \qquad [11]$$

$$S_n(E) = \frac{1}{nf} \int S_{n-1}(E')S_1(E-E')\ \mathrm{d}E'$$

where the individual terms S_n correspond to n-phonon contributions. The delta-distribution term describes elastic scattering. The probability for this process is described in terms of the Lamb–Mössbauer factor f. The probability $\mathrm{d}P_1$ to create ($E>0$) or annihilate ($E<0$) one phonon of energy E is given by the first-order term, that is, $\mathrm{d}P_1 = S_1(E)\,\mathrm{d}E$. The second-order term incorporates the participation of two phonons with energies that add to E. For a given inverse temperature β, all terms in eqn [11] are generated from the partial DOS $g(E)$. The measurement provides $S(E)$, and an inversion of eqn [11] gives $g(E)$. **Figure 7** shows the DOS of iron metal.

Synchrotron Mössbauer Spectroscopy

In solids, the probability that NRS occurs without change in the vibrational state is often appreciable and was introduced previously as the Lamb–Mössbauer factor f. In terms of the phonon excitation probability density of eqn [7], $f = \Gamma S(0)$ with corresponding transitions indicated in **Figure 5**. Now that vibrational transitions are excluded, slight energy differences of the nuclear levels become visible and measurable. The nuclear-level splitting is caused by the electronic environment and is known as hyperfine interaction. The exclusion of phonon excitations results in elastic coherent scattering. This process is described by a differential scattering cross section that is strongly peaked in certain directions and, in particular, the direction of the incident X-rays (nuclear forward scattering).

Level Splitting

Figure 8 shows transitions of a ^{57}Fe nucleus under the influence of an electric field gradient (EFG) or a magnetic field. The energy levels of the isolated nucleus are twofold and fourfold degenerate, respectively. The presence of an EFG, which is created by the electronic environment and couples to the quadrupole moment of the nucleus, partly removes the degeneracy. In the case of an axially symmetric EFG, the energy splitting for spin quantum numbers $I>1/2$ and $m = -I, \ldots, I$ is given by

$$E_m = \Delta\, \frac{3m^2 - I(I+1)}{2I(2I-1)} \qquad [12]$$

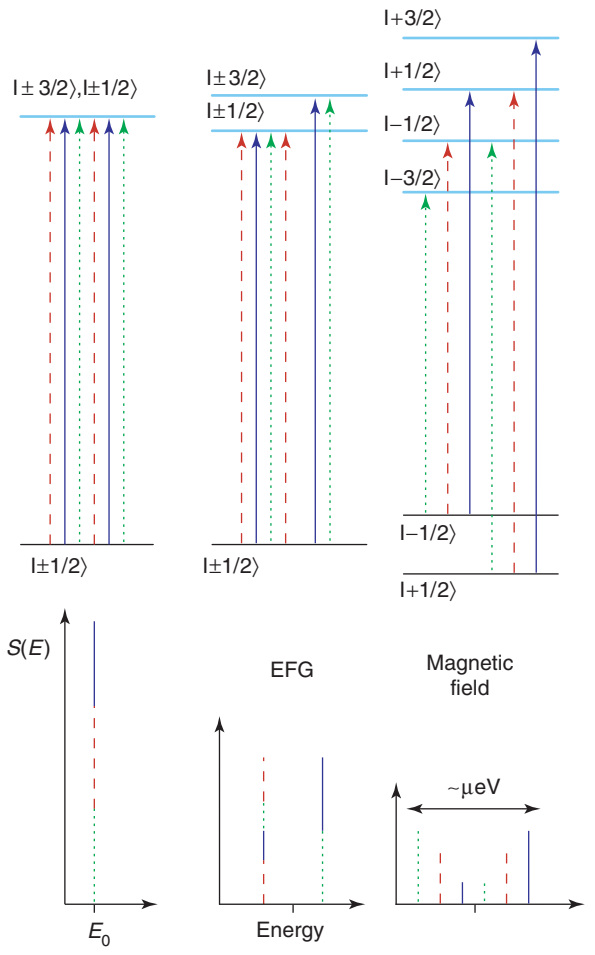

Figure 8 Nuclear level splitting of ^{57}Fe by interactions with electrons. The presence of an EFG or a magnetic field leads to several nuclear transitions separated by up to several μeV. The ground and excited state have spin quantum numbers of 1/2 and 3/2, respectively.

where Δ is called the electric quadrupole splitting. For the ^{57}Fe case, one obtains a characteristic two-line pattern with $E_{\pm 3/2} - E_{\pm 1/2} = \Delta$.

The presence of the magnetic field imprints unidirectional symmetry, which removes the degeneracy completely. The energy splittings are given by

$$E_m = -\mu B \frac{m}{I}, \quad m = -I, \ldots, I \qquad [13]$$

where μ and I are the magnetic moment, and spin of the nuclear state respectively, B is the magnetic field at the nucleus, and m is the spin-projection quantum number. The 14.4125 keV transition of ^{57}Fe has M1 multipolarity, and the individual transitions shown in **Figure** 8 follow dipole selection rules, that is, $|m_e - m_g| \leqslant 1$. This results in a characteristic six-line pattern.

In addition to the interactions discussed above, one expects a renormalization of the energy of nuclear levels due to the presence of *s*-electrons in the nuclear volume. The observable result is a slight shift of the transition energy that is proportional to the density of the *s*-electrons in the nuclear volume. This so-called isomer shift can only be measured by comparison of different materials, for example, for ^{57}Fe the isomer shift is normally given relative to ^{57}Fe nuclei in iron metal at ambient conditions.

Index of Refraction

SMS is an elastic coherent process, and all possible nuclear sublevels can be excited simultaneously by a short X-ray pulse with sufficient bandwidth. The different nuclear transitions are then analogous to a set of oscillators with slightly different energies that are excited in phase at a given instant. Shortly, after the X-ray pulse has passed, the de-excitation begins, also in phase, but soon the increasing phase difference leads to destructive interference and then again to a constructive interference. This process leads to oscillations in the emission of the scattered radiation that depend directly on the nuclear-level splitting and thus on the hyperfine interactions. In a transmission geometry, SMS is usually described by an energy-dependent contribution to the index of refraction

$$n(E) = \frac{\hbar c}{2E} \rho \sigma_N f \sum_l \frac{W_l}{z_l(E) - i} \qquad [14]$$

where ρ is the number density of resonant nuclei, σ_N is the nuclear resonant cross section, and f is the Lamb–Mössbauer factor. The sum is over all sublevels of nuclear ground and excited states. The function $z_l = 2(E_l - E)/\Gamma$ depends on the energy difference between excited and ground states E_l and the nuclear level width Γ. The weight of each resonance is given by W_l with the normalization $\sum_l W_l = 1$. The weights depend on the directions of the hyperfine fields relative to the direction and the polarization of the SR. For simplicity, their tensor character is ignored here. Then, the transmission of monochromatic X-rays of energy E through a sample of thickness D is given by

$$T(E) = T_0 \exp\left[-\eta \sum_l \frac{W_l}{z_l^2(E) + 1}\right] \qquad [15]$$

where $\eta = \rho \sigma_N f D$ is called "effective thickness" of the platelet. The factor T_0 accounts for electronic absorption. The time response to an SR pulse is expressed by

$$\frac{dI}{dt} = T_0 \tau \left| \mathscr{F}\left(\exp\left[i \frac{2\pi D}{\lambda} n(E) \right] - 1 \right) \right|^2 \qquad [16]$$

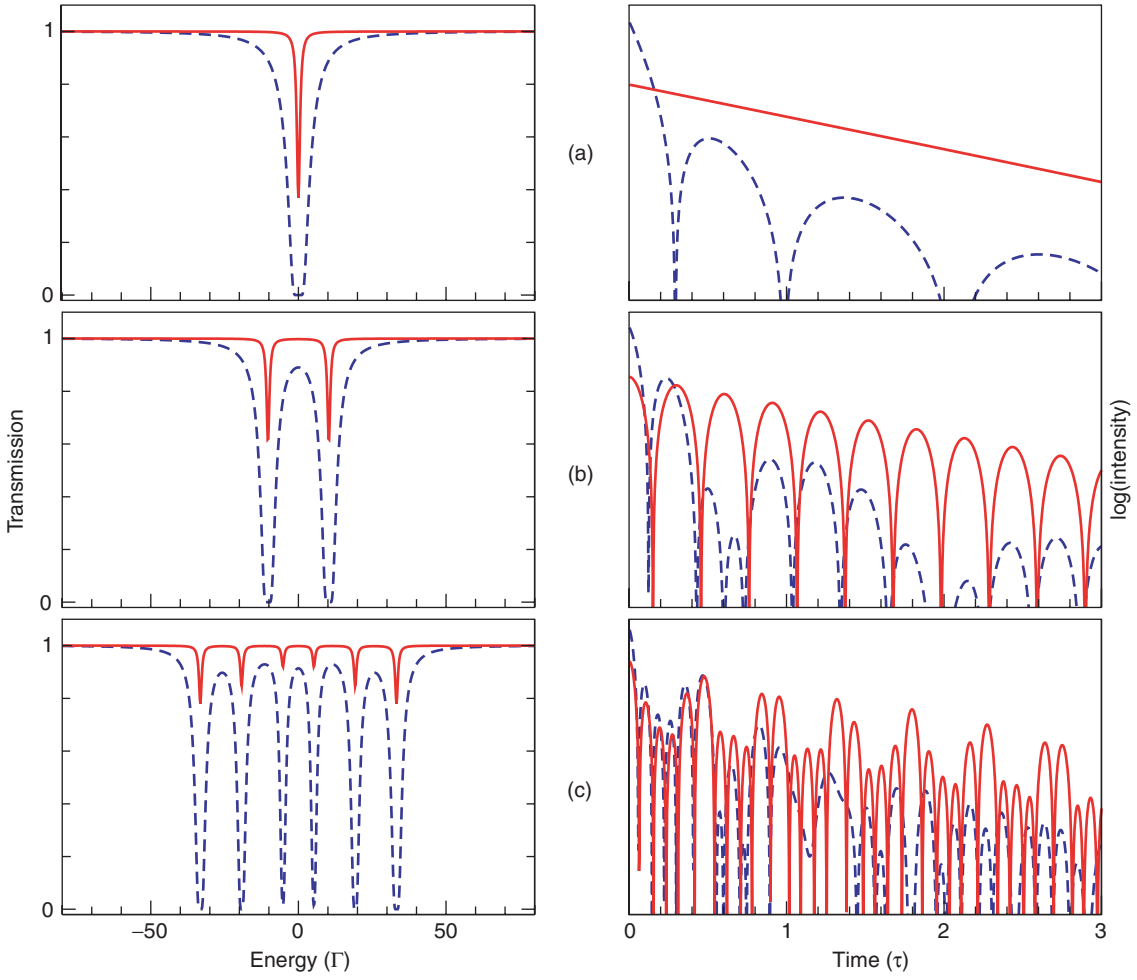

Figure 9 SMS spectra in energy and time. Calculations used eqns [15] and [16] with small ($\eta = 1$, solid lines) and large ($\eta = 50$, dashed lines) effective thicknesses. Panel (a) displays the case without hyperfine fields; panels (b) and (c) show spectra characteristic for an EFG and a magnetic field, respectively. Time spectra (right side) were normalized to identical area.

where λ is the X-ray wavelength and $\mathscr{F}$ symbolizes a Fourier transformation. The primary application of SMS is the determination of hyperfine interaction parameters. The transmission spectra are easier to interpret if the effective thickness is small. Large values of η lead to a self-absorption effect, that is, a broadening of the absorption lines in the energy spectra and a faster decay in the time spectra accompanied by aperiodic oscillations. The influence of the effective thickness is demonstrated in **Figure 9** by calculations using eqns [15] and [16].

Experimental Procedure

A schematic of the typical experimental setup that can be found at third-generation SR facilities is shown in **Figure 10**. The X-ray source consists of electron bunches that are orbiting in the storage ring and periodically pass through an undulator. The

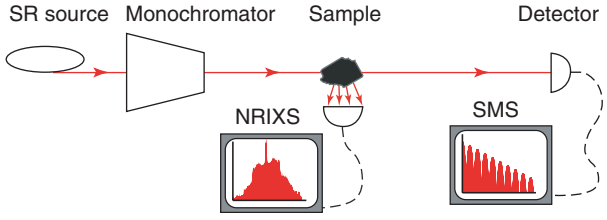

Figure 10 Experimental setup for NRIXS and SMS.

X-rays are monochromatized in two steps using a premonochromator and a high-resolution monochromator.

For NRIXS measurements, the energy bandwidth determines the resolution of the phonon spectra of the samples. The high-resolution monochromator is tuned around the nuclear transition energy, and the X-rays excite the nuclei in the sample. The re-emitted radiation is observed with an avalanche photodiode

detector that is placed as close as possible to the sample but away from any strong coherent scattering directions. The integrated delayed counting rate is recorded.

For SMS measurements, the energy bandwidth should be as small as practicably achievable with reasonable efficiency. The high-resolution monochromator is tuned to the nuclear transition energy and kept as stable as possible. X-rays that are transmitted through the sample excite the resonant nuclei coherently and are observed with an avalanche photodiode detector that is placed far enough, away from the sample to avoid contamination from incoherent scattering. The delayed events are mapped as a function of elapsed time between arrival of an SR pulse and detection of transmitted X-ray photon – this constitutes the time spectrum of the nuclei in the sample.

Scattering, Rayleigh

R Piazza, Politecnico di Milano, Milan, Italy
V Degiorgio, Università di Pavia, Pavia, Italy

Introduction

Rayleigh scattering (RS) is the elastic spreading of electromagnetic radiation from bound electrons, after they have been excited to virtual states far from resonances. Therefore, it differs from resonant fluorescence, molecular Raman scattering, and Brillouin scattering in condensed media, which are discussed elsewhere in this encyclopedia. Thomson scattering can be seen as a particular case of RS from free electrons, but is not further discussed in this article (neither is its relativistic Compton counterpart). Molecular RS plays a primary role in atmospheric optics accounting for the blue color of the sky and a large number of optical phenomena ranging from rainbows to fogbows, glories, halos, coronae, blue sun and moon, and the white color of clouds and snow, to cite only a few. A comprehensive discussion of atmospheric scattering has been made by M J G Minnaert in 1954 and D K Lynch and W Livingston in 1995.

Yet, probably, the most interesting applications of RS concern scattering from mesoscopic objects, either in the form of aerosols or suspensions of colloidal particles with a size ranging from a few nanometers to a few micrometers. Scattering from pollutant airborne particles has, for instance, crucial consequences on re-irradiation of solar energy from the lower atmosphere. Measurements of the scattering properties of dispersed particles yield primary information on colloid size, morphology, and interactions. Chances of obtaining photonic bandgap crystals often rely on the peculiar scattering properties of metal-coated colloids. Finally, by exploiting radiation forces associated to scattering, particles can be easily manipulated using noninvasive "optical tweezers," allowing one to design template surfaces of interest in photonics. Although, fluid systems are primarily dealt with, it is also important to point out that the attenuation due to RS sets severe limits to the useful wavelength range for light propagation in optical fibers.

This article is organized as follows. After a basic analysis of elastic molecular scattering, the key role of fluctuations in RS from condensed media is pointed out, and a fluctuation approach to shortly derive RS from simple fluids and mixtures is applied. The final and largest part is devoted to particle RS and its exploitation. Besides specific applications, however, the main message of which an attempt is made to convey is the following: "every deviation of light from rectilinear propagation, including diffraction and even geometrical refraction, can be ultimately seen as a consequence of Rayleigh scattering." As will be seen, the optical theorem, linking the refractive index to scattering properties, and the large-particle limit of Mie scattering, yielding classical diffraction and eventually geometric optics, justify this strong statement.

Molecular Rayleigh Scattering

First, recall the basic geometry of a scattering experiment. As incident field, what will always be taken is a plane wave having a wave vector $\boldsymbol{k}_\mathrm{i}$, with $|k_\mathrm{i}| = k = 2\pi/\lambda$ (where λ is the wavelength in the medium), linearly polarized along $\hat{\boldsymbol{n}}_\mathrm{i}$. Measurements consist in detecting the light scattered along the direction set by the wave vector $\boldsymbol{k}_\mathrm{s}$ that, together with $\boldsymbol{k}_\mathrm{i}$, fixes the scattering plane. Since Rayleigh scattering is elastic, one must have $|k_\mathrm{s}| = k$, and therefore the scattering vector $\boldsymbol{q} \equiv \boldsymbol{k}_\mathrm{i} - \boldsymbol{k}_\mathrm{s}$ has magnitude $q = 4\pi/\lambda \sin \vartheta/2$, where ϑ is the angle in the scattering plane between $\boldsymbol{k}_\mathrm{i}$ and $\boldsymbol{k}_\mathrm{s}$ (the azimuth angle with respect to the normal to the scattering plane will conversely be denoted by φ). In some measurements, a specific polarization component of the scattered field along $\hat{\boldsymbol{n}}_\mathrm{s}$ may be selected with a polarizer.

Probably, the simplest way to estimate elastic scattering from molecules is the elegant dimensional argument originally devised by Rayleigh in 1871 that, restated in modern terms, goes as follows: "Provided that the molecular dimensions are much smaller than λ, so that the scatterer essentially "sees" a spatially uniform, time-varying field, the scattered and incident fields will be proportional." Their dimensionless ratio $E_\mathrm{s}/E_\mathrm{i}$ may, in principle, depend on λ, the velocity of light c, the volume V of the scatterer, the dielectric constants $\varepsilon_\mathrm{P}, \varepsilon_\mathrm{M}$ of the materials constituting the particle and the surrounding medium, and the distance r of the observation point from the scattering volume. Since c is the only quantity that contains time, it should not appear in $E_\mathrm{s}/E_\mathrm{i}$. Similarly, ε_P and ε_M must appear only as a homogeneous function f of the ratio $\varepsilon_\mathrm{P}/\varepsilon_\mathrm{M}$. Since molecular polarizability α is linearly proportional to V, so must be E_s. Finally, in the radiation zone the scattered field will be a spherical wave, so that $E_\mathrm{s} \propto r^{-1}$. Therefore, the simplest dimensionless combination is $E_\mathrm{s}/E_\mathrm{i} = Vr^{-1}\lambda^{-2} f(\varepsilon_\mathrm{P}/\varepsilon_\mathrm{M})$, and for the scattered intensity one must have

$$I_\mathrm{s} = \frac{V^2}{r^2\lambda^4} f^2\left(\frac{\varepsilon_\mathrm{P}}{\varepsilon_\mathrm{M}}\right) I_0 \qquad [1]$$

where I_0 is the incident intensity, giving both a strong preferential scattering of short wavelengths (accounting for the hue of the sky and for the sun reddening at dawn and setting) and the remarkable dependence on molecular volume (yielding, for spheroidal molecules, a sixth power dependence on the radius).

For a molecular scatterer of size $d \ll \lambda$, a formal analysis can be performed by solving the Helmoltz equation for the vector potential in a far-field (radiation) zone $r \gg \lambda \gg d$, expanding the solution in multipoles, and retaining only the lowest (electric dipole) order. Within this approximation, the incident field induces a dipole $\boldsymbol{p} = \boldsymbol{\alpha}\boldsymbol{E}_\mathrm{i}$, where in general, the molecular polarizability $\boldsymbol{\alpha} = \alpha_{ij}$ is a tensor (so that $\boldsymbol{p}$ and $\boldsymbol{E}_\mathrm{i}$ are not necessarily parallel). The induced dipole irradiates a spherical wave at the same frequency and with amplitude given by

$$\boldsymbol{E}_\mathrm{s}(\boldsymbol{r}) = \frac{k^2}{4\pi\varepsilon_0} (\hat{\boldsymbol{r}} \times \boldsymbol{p} \times \hat{\boldsymbol{r}}) \frac{\exp(\mathrm{i}kr)}{r} \qquad [2]$$

If, for simplicity, one assumes that the molecule has a scalar polarizability α, so that $p \equiv |\boldsymbol{p}| = \alpha E_\mathrm{i}$, the scattered intensity (irradiance) is given by

$$I_\mathrm{s} = \frac{\varepsilon_0 c}{2} \overline{\boldsymbol{E}_\mathrm{i}^* \boldsymbol{E}_\mathrm{i}} = \frac{\pi^2\alpha^2 \sin^2\gamma}{\varepsilon_0^2\lambda^4 r^2} I_0 \qquad [3]$$

where γ is the angle between $\boldsymbol{p}$ and the direction of propagation of the scattered field. Equation [3] is consistent with the general prediction of eqn [1], since α is proportional to the scattering volume and, as later discussed in the text, depends only on the particle and solvent dielectric constants.

The simple classical analysis that was made is fully adequate for treating most of the problems involving molecular RS. For what concerns quantum effects, what is first noticed is that RS is a two-photon process requiring full quantization of the radiation field. A simple quantum analysis of RS can be made starting from the two-level Bloch equations, or from a more general multilevel perturbation theory leading to the Kramers–Heisenberg (KH) formula, which has the advantage of treating on the same footing as Rayleigh, Thomson, and inelastic Raman scattering, allowing explicit evaluation of the scattering cross sections from the matrix elements (while phenomenological coefficients are needed in the classical approach). The KH formula also yields quantum corrections to classical RS cross sections: however, far from resonances the latter are negligible, so that a fully classical approach is used in what follows.

Scattering and Fluctuations

The former single-scatterer approach to RS may however be misleading, missing a fundamental point: indeed, a uniform distribution of molecules will not scatter light at all, since the phases of the scattered fields are uniformly distributed in $[0, 2\pi]$. Therefore, the total scattered field vanishes for all except the forward direction where, adding to the incident beam, leads to a phase delay of the transmitted beam, modifying (as shall be better seen below) the refractive index of the medium. Exceptions are ordered

arrays of the scatterers, where Bragg peaks appear due to breaking of continuous translational symmetry. Scattering therefore always requires fluctuations. A very general approach to the problem can be made by treating the scattering medium as a continuum where, in order to account also for optical anisotropy effects, local dielectric (and therefore, refractive index) fluctuations are introduced by means of a tensor $\delta\boldsymbol{\varepsilon}(\boldsymbol{r},t)$, and deriving a wave-propagation equation in weakly inhomogeneous media. By assuming that the scattered field is much smaller than the incident field, and decomposing the dielectric fluctuations in spatial Fourier components as

$$\delta\boldsymbol{\varepsilon}(\boldsymbol{q},t) = \int \mathrm{d}V \delta\boldsymbol{\varepsilon}(\boldsymbol{r},t)\,\exp(\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}) \qquad [4]$$

where r gives the position of the scattering element with respect to an arbitrary origin O in the scattering volume. The instantaneous scattered field amplitude reaching a detector placed at a distance R from O the scattering volume, after passing through a polarizer with transmitting axis set along $\hat{\boldsymbol{n}}_\mathrm{f}$, is given by

$$E_\mathrm{s}^{if}(R,t) = -\frac{k^2 E_0}{4\pi\varepsilon_0 R}\,\delta\varepsilon_{if}(q,t)\,\exp[\mathrm{i}(k_\mathrm{s}R-\omega t)] \quad [5]$$

where $\delta\varepsilon_{i,f} \equiv \hat{\boldsymbol{n}}_\mathrm{i}\cdot\delta\boldsymbol{\varepsilon}(\boldsymbol{q},\boldsymbol{t})\cdot\hat{\boldsymbol{n}}_\mathrm{f}$. The time-averaged detected intensity is

$$I_\mathrm{s}^{if}(\boldsymbol{q}) = \frac{k^4 I_0}{16\pi^2\varepsilon_0^2 R^2}\langle|\delta\varepsilon_{if}|^2\rangle \qquad [6]$$

and is therefore proportional to the mean square fluctuation of the dielectric constant with the same spatial frequency.

In order to find a connection with the molecular approach, which is particularly useful when dealing with scattering from dispersed particles, it can simply be assumed that the local dielectric constant depends explicitly only on the local molecular number density $\rho(\boldsymbol{r},t)$ (see the next section for a discussion) writing $\delta\boldsymbol{\varepsilon}(\boldsymbol{r},t) = \boldsymbol{\alpha}(t)\rho(\boldsymbol{r})$, where $\boldsymbol{\alpha}(t)$ is the molecular polarizability tensor, depending on time because of molecular rotations. Expressing the local density fluctuations as a sum of delta functions over the molecular positions $\boldsymbol{r}_i(t)$ as $\delta\rho(\boldsymbol{r},t) = \sum_i \delta(\boldsymbol{r}-\boldsymbol{r}_i) - \bar{\rho}$, where $\bar{\rho}$ is the average number density, and with $\alpha_{if}(t) \equiv \hat{\boldsymbol{n}}_f\cdot\boldsymbol{\alpha}(\boldsymbol{q},t)\cdot\hat{\boldsymbol{n}}_f$, one can immediately see that

$$\delta\varepsilon_{if}(\boldsymbol{q},t) = \alpha_{if}(t)\left\{\sum_i \exp[\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}_i(t)] - N\delta(q)\right\} \qquad [7]$$

where the second term (coming from $\bar{\rho}$) is simply the $q=0$ contribution from the N molecules. Provided that molecular orientations and translations are uncorrelated (so that the amplitude and phase averages factorize), from eqn [6], one therefore obtains

$$I_\mathrm{s}^{if}(\boldsymbol{q}) = \frac{k^4 N I_0}{16\pi^2\varepsilon_0^2 R^2}\langle|\alpha_{if}|^2\rangle S(q) \qquad [8]$$

where

$$S(q) = N^{-1}\sum_{i,j}\langle\exp[\mathrm{i}\boldsymbol{q}\cdot(\boldsymbol{r}_i-\boldsymbol{r}_j)]\rangle \qquad [9]$$

is the static structure factor. To make things clearer, an ideal gas where particle positions are uncorrelated is considered. Then $\langle\exp[\mathrm{i}\boldsymbol{q}\cdot(\boldsymbol{r}_i-\boldsymbol{r}_j)]\rangle = \delta_{i,j}$, so that $S(q)=1$ and I is proportional to N. It is noticed that this apparently "trivial" scaling with N, holds true only because (Poisson) density fluctuations in an ideal gas are proportional to $\sqrt{N}$: for interacting systems, it is no longer so. It is important to recall that the typical q-range over which structural features of simple fluids develop is much larger than the range probed by light scattering, which therefore essentially measures only $S(0) = Vk_\mathrm{B}T\rho^2\chi_T$, where χ_T is the isothermal compressibility (the situation is however very different for suspensions of mesoscopic particles, where the structural spatial scales are often of the order λ).

Rayleigh Scattering from Pure Fluids and Fluid Mixtures

In liquids, fluctuations of the local dielectric constant can be expanded in terms of any two thermodynamic variables whose fluctuations are uncorrelated, for instance, temperature T and density ρ. Since experimentally, for most simple liquids, $(\partial\varepsilon/\partial T)_\rho \approx 0$, RS is in fact mostly due to density fluctuations. In order to derive RS effects in simple fluids, it is however more convenient taking pressure p and entropy S as independent variables, and using a fluctuating hydrodynamics approach. This amounts to linearizing the continuity for small fluctuations, Navier–Stokes, and heat equations and finding their normal modes. Since in the continuity equation ρ is coupled to the fluid velocity $\boldsymbol{v}$ only through $\nabla\cdot\boldsymbol{v}$, density fluctuations are uncoupled to transverse velocity modes, which, therefore, cannot be detected by light scattering. In addition to two propagating pressure modes (corresponding to absorption or excitation of sound waves, giving rise to Brillouin scattering), the solution of linearized mode equations yields a thermal diffusive mode, corresponding to the frequency-unshifted Rayleigh peak having a width $\Delta\omega = D_\mathrm{T}q^2$, where D_T is the thermal diffusivity,

and an amplitude proportional to the difference $c_p - c_v$ of the specific heats at constant pressure and volume. For many liquids, and in particular for water, $c_p - c_v$ is rather small, and therefore RS is fairly weak (at variance to a widespread belief, the bluish appearance of thick water layers on ice blocks is not due primarily to scattering, but to a much stronger absorption effect due to an overtone vibrational peak close to the red edge of the visible spectrum; D_2O, for which the absorption shifts to higher λ due to isotope effects, indeed is much more transparent).

In binary liquid mixtures new modes appear due to the presence of an additional conserved variable, namely the concentration c of one of the two species, adding a hydrodynamic mass diffusion equation. The analysis is much simpler as discussed by B J Berne and R Pecora in 1976 if pressure fluctuation, and therefore effects on Brillouin peaks, are neglected, so that the problems amount to solving by Laplace transforming the linearized form of the coupled equations for the fluctuations δc, δT

$$\begin{aligned}\frac{\partial(\delta c)}{\partial t} &= D\left[\nabla^2(\delta c) + \frac{k_T}{T}\nabla^2(\delta T)\right] \\ \frac{\partial(\delta T)}{\partial t} - \frac{1}{c_p}k_T\left(\frac{\partial\mu}{\partial c}\right)\frac{\partial(\delta c)}{\partial t} &= D_T\nabla^2(\delta T)\end{aligned} \qquad [10]$$

where D is the mass diffusion coefficient, μ is the chemical potential of the mixture, and k_T is the thermal diffusion ratio, quantifying coupling of mass and heat transport through the so-called Soret effect. Solution of eqn [10] yields two diffusive modes where thermal and concentration fluctuations are, in general, mixed: in practice, however, since $D \ll D_T$ (for most liquids $D_T \simeq 10^{-3}\ \mathrm{cm^2\,s^{-1}}$, while D varies between $10^{-5}\ \mathrm{cm^2\,s^{-1}}$ for simple mixtures and $10^{-6} - 10^{-8}\ \mathrm{cm^2\,s^{-1}}$ for macromolecular solutes) the two modes are almost decoupled. The peak due to concentration fluctuation has an extremely narrow width $\Delta\omega = Dq^2$ and an amplitude proportional to $(\partial\mu/\partial c)^{-1}$ (for dilute solutions, this means that RS is proportional to the osmotic compressibility).

Scattering from Dispersed Particles

Statement of the Problem

The important case of elastic scattering from dispersed particles is discussed here. Only particles made of an optically isotropic material, that is with a scalar polarizability are considered first. In a far field, the scattered field $E_s(r,t)$ is an amplitude-modulated spherical wave, which can be written as

$$E_s(r,t) = S(\vartheta,\varphi)\,\frac{\exp[i(kr-\omega t)]}{ikr}\,E_0 \qquad [11]$$

where a term i has been factorized out, just for convenience, and the dimensionless scattering function $S(\vartheta,\varphi)$ has been introduced, which is, in general, a complex quantity: $S \equiv F(\vartheta,\varphi)\exp[i\phi(\vartheta,\varphi)]$. The scattered intensity can, therefore, be written in terms of the incident intensity I_0 as

$$I = \frac{F(\vartheta,\varphi)^2}{k^2r^2}\,I_0 \qquad [12]$$

By integrating $r^2 I_s$ over the solid angle Ω, the scattering cross section is therefore found to be

$$\sigma_s = \frac{1}{k^2}\int \mathrm{d}\Omega F(\vartheta,\varphi)^2 \qquad [13]$$

If, besides scattering, the particle absorbs part of the radiation with an absorption cross section σ_A, the total extinction cross section will be given by $\sigma_{ext} = \sigma_s + \sigma_A$.

The previous definition can be generalized to account for scattering from optically anisotropic particles by writing

$$\begin{bmatrix} E_s^{\perp} \\ E_s^{\parallel} \end{bmatrix} = \frac{\exp[ik(r-z)]}{ikr}\begin{bmatrix} S_1 & S_2 \\ S_3 & S_4 \end{bmatrix}\begin{bmatrix} E_i^{\perp} \\ E_i^{\parallel} \end{bmatrix} \qquad [14]$$

where z is the particle coordinate along the direction of the incident beam with respect to an arbitrary origin.

Specific forms for the scattering matrix (S) are dictated by particle symmetry as discussed by H C van de Hulst in 1981: for instance, it is diagonal for spherical particles made of an optically isotropic material and symmetric for nonchiral particles.

The Optical Theorem (OT)

A simple, but extremely useful relation connects the total scattering cross section to the scattering amplitude in the forward direction (the direction of the incident beam, once again taken as z). Forward scattering is rather peculiar. At any finite angle, the total scattering from N spatially uncorrelated particles is a vector sum of random components, and therefore a Gaussian complex random variable. In full analogy with what has been seen for RS from ideal gas, the total scattered field is then proportional to $\sqrt{N}$ and the scattered intensity to N. This means that the individual particle cross sections add, $\sigma_s = \sum \sigma_s^{(i)}$. However, it is easy to show that all scattering contributions in the forward direction add in phase, so

that one must sum field amplitudes, not intensities, with $S(0) = \sum S^{(i)}(0)$. van de Hulst, in 1981, has shown that the forward scattering contribution for a thin slab of thickness δ containing ρ particles per unit volume is given by $dE_s = -[2\pi\rho\delta S_0/k^2]E_i(z,t)$, where S_0 is the value of the scattering function in the forward direction. The propagation equation for the spatial part of the total field $E = E_i + E_s$ is therefore

$$\frac{dE(z)}{dz} = \left(ik + \frac{2\pi\rho}{k^2} S_0\right) E(z) \qquad [15]$$

yielding

$$E(z) = E_0 \exp[ikz(1 + i2\pi\rho S_0/k^3)] \qquad [16]$$

Identifying eqn [16] with the general expression $E(z) = E_0 \exp(i\tilde{n}kz)$, where $\tilde{n} = n + in'$ is the complex refractive index, one has

$$\begin{aligned} n &= 1 + (2\pi\rho/k^3)\ \mathrm{Im}(S_0) \\ n' &= -(2\pi\rho/k^3)\ \mathrm{Re}(S_0) \end{aligned} \qquad [17]$$

connecting the refractive index of the medium to the presence of scattering. Provided that the particles are nonabsorbing, the transmitted intensity is given by $I(z) = I_0 \exp[-2k\ \mathrm{Im}(\tilde{n})]$, so that the extinction coefficient (power loss) per unit volume is $\gamma = 2kn'$. The extinction cross section is finally given by $\sigma_{ext} = \gamma/\rho$, one finally has

$$\sigma_{ext} = \frac{\gamma}{\rho} = -\frac{4\pi}{k^2}\ \mathrm{Re}(S_0) \qquad [18]$$

which is the usual form of the OT. Apparently, this rather curious result, summing up scattering in all directions only in terms of zero-angle scattering, has been independently "rediscovered" and extended by many authors, totally unaware of previous results, both for classical electromagnetic scattering and in quantum electrodynamics.

Scattering Regimes

The full solution of the electromagnetic scattering for particles of arbitrary size and composition is very elaborate, even for the simplest case of homogeneous spheres. It is however useful considering some specific approximation yielding simple explicit expressions for the scattering function. Both the external incident field and the internal field within the particle are required. The refractive indices of the particle and of the surrounding medium ("solvent") shall be denoted by n_P and n_s, the wavelength of the incident radiation in vacuum by λ_0 (so the wave vector is $k_{ext} = 2\pi n_s/\lambda_0$ for the external field, and $k_{int} = 2\pi n_P/\lambda_0$ within the particle), and a characteristic particle size by a.

Particles small compared to the wavelength This is what is called the Rayleigh regime in the strict sense. Both the external and the internal fields are required to be essentially uniform over the particle size. This means that the phase shifts $k_{ext}a$ and $k_{int}a$ have to be small, or $a \ll \lambda_0/2\pi n_s, a \ll \lambda_0/2\pi n_P$ (the second condition is generally more restrictive-it is to be noted in particular that it excludes strongly absorbing particles, whatever their size). The situation is then completely analogous to molecular Rayleigh scattering. If the particle is made by an optically isotropic material so that its polarizability is scalar, the amplitude of the scattered field is given by eqn [3] while, by integrating eqn [3] and dividing by the incident intensity, the scattering cross section is found as

$$\sigma_s = k^4\alpha^2/6\pi\varepsilon_0^2 \qquad [19]$$

A note of caution however concerns particle polarizability, which has to be interpreted as the excess optical polarizability with respect to an equal solvent volume. Noticing that, when the incident field is vertically polarized (perpendicular to the scattering plane), $\gamma \equiv \pi/2$, while if it is horizontally polarized $\gamma \equiv \pi/2 - \vartheta$, the full scattering matrix is found to be

$$\boldsymbol{S} = \frac{ik^3\alpha}{4\pi\varepsilon_0} \begin{bmatrix} 1 & 0 \\ 0 & \cos\vartheta \end{bmatrix} \qquad [20]$$

Specific expressions for polarizability can be found by solving the electrostatic problem for a uniform field. For instance, for dielectric spheres of radius a, made of a material with dielectric constant ε_P,

$$\alpha = 4\pi\varepsilon_0 \frac{\varepsilon_P/\varepsilon_s - 1}{\varepsilon_P/\varepsilon_s + 2} a^3 = 4\pi\varepsilon_s \frac{n_P^2 - n_s^2}{n_P^2 + 2n_s^2} a^3 \qquad [21]$$

Since $S(0) = S_{1,2} = ik^3\alpha/4\pi\varepsilon_0$, from the OT one has $\sigma_{ext} = (k/\varepsilon_0)\ \mathrm{Im}(\alpha)$, so one should have reduction of the incident power only for absorbing particles. This apparent contradiction only means that to evaluate total cross sections via the OT, one must go beyond the Rayleigh approximation, so to obtain a nonvanishing real part of $S(0)$.

The previous result can be extended to small optically anisotropic particles. For simplicity, it is assumed that the particle is made of a uniaxial birefringent material. The polarizability tensor, referred to the particle optical principal axes X, Y, Z, has only two independent components, that shall be denoted as $\alpha_{||} \equiv \alpha_X$ and $\alpha_\perp \equiv \alpha_Y = \alpha_Z$. Assuming for

convenience x as the direction of the scattered field and z as the normal to the (x, y) scattering plane, the two most common experimental configurations are the VV and VH geometries. In both of them the incident field is vertically polarized, but while in the VV scheme the vertical component I_{VV} of the scattered intensity is measured, the orthogonal ("depolarized") I_{VH} component is detected in the VH scheme. I_{VV} and I_{VH} can be found by evaluating $\hat{\boldsymbol{n}}_z \cdot \boldsymbol{\alpha} \cdot \hat{\boldsymbol{n}}_z$ and $\hat{\boldsymbol{n}}_y \cdot \boldsymbol{\alpha} \cdot \hat{\boldsymbol{n}}_z$, after the particle polarizability tensor has been re-expressed in the laboratory fixed frame, in terms of the average particle polarizability $\bar{\alpha} = (\alpha_{||} + 2\alpha_{\perp})/3$ and of the particle optical anisotropy $\beta = \alpha_{||} - \alpha_{\perp}$. Defining $\bar{n}_P^2 = \bar{\alpha}/V + 1$ and (provided that the optical anisotropy is small) $\Delta n = \beta/2\bar{n}V$, and assuming that $\bar{n}_P \approx n_s$, the final expression, after subtracting the solvent polarizability $\alpha_s = (n_s^2 - 1)V$, is

$$\begin{aligned} I_{VV} &= CV\bar{n}_P^2[(\bar{n}_P - n_s)^2 + (4/45)(\Delta n)^2] \\ I_{VH} &= CV\bar{n}_P^2(\Delta n)^2/15 \end{aligned} \qquad [22]$$

where C does not depend on particle or solvent optical properties. Notice that both I_{VH} and the second term on the right-hand side of the expression for I_{VV} do not depend on n_s, so that scattering is present even in "best index matching" conditions $n_s = \bar{n}_P$. These contributions are the direct analogs, in depolarized Rayleigh scattering, of the incoherent cross section for neutron scattering. **Figure 1** shows the experimental results for optically anisotropic particles in water.

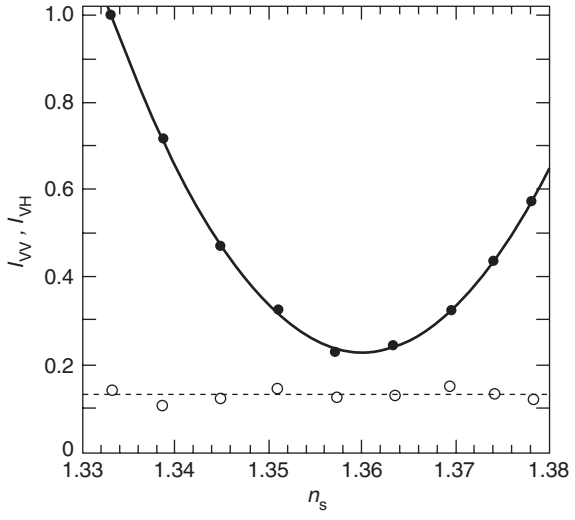

Figure 1 Experimental values for I_{VV} (•) and I_{VH} (○) (normalized to their values for water suspensions) as a function of the solvent refractive index n_s for optically anisotropic colloidal spheres made of the partially crystalline polymer perfluoro-alkylvinylether (PFA). The parabolic fit to I_{VV} yields an average particle refractive index $\bar{n}_P \simeq 1.36$ and an optical anisotropy $\Delta n \simeq 0.03$. As discussed in the text, I_{VH} does not depend on n_s.

Rayleigh–Gans–Debye scattering Most dispersed particles do not fulfill the strict requirements of the "pure" Rayleigh regime. A much more useful approximation can be obtained by letting the incident field vary, even appreciably, over the particle length scale, but requiring that "the internal field does not appreciably differ from the incident one," both in amplitude and in phase. Weak amplitude changes simply imply $|n_P - n_s| \ll 1$, while tuning of the phases requires the optical path with or without the particles to be comparable, or

$$\frac{2\pi}{\lambda}|n_P - n_s|a \ll 1 \qquad [23]$$

which, for $a > \lambda/2\pi$, is the more restrictive criterion framing the Rayleigh-Gans-Debye (RGD) regime. Notice that even particles with size $a \gg \lambda$ may satisfy eqn [23], provided that they are sufficiently "faint." Equating the internal and external fields amounts to neglecting effects on any given volume element δV of the fields scattered by the surrounding, so that the RGD regime is the equivalent of the first Born approximation in quantum scattering. Each δV can, therefore, be considered as an independent elementary Rayleigh scatterer, and the total scattered field is obtained by summing over all volume elements, taking into account the phase of each scattering contribution (note that the phase shift of a wave scattered by an element placed at $\boldsymbol{r}$ compared to the contribution from a volume element centered around an arbitrary origin is $\Delta\varphi = \boldsymbol{k}_i \cdot \boldsymbol{r} - \boldsymbol{k}_s \cdot \boldsymbol{r} = \boldsymbol{q} \cdot \boldsymbol{r}$). Summing up over all volume elements, and allowing for nonuniformity of the particle refractive index by expressing $n_P = n_P(\boldsymbol{r})$, one obtains

$$\begin{bmatrix} S_1(\vartheta) \\ S_2(\vartheta) \end{bmatrix} = \frac{\mathrm{i}n_s k^3 V}{2\pi} F(q) \begin{bmatrix} 1 \\ \cos\vartheta \end{bmatrix} \qquad [24]$$

where

$$F(q) = \frac{1}{V}\int_V \mathrm{d}^3 r[n_P(\boldsymbol{r}) - n_s]\exp(\mathrm{i}\boldsymbol{q} \cdot \boldsymbol{r}) \qquad [25]$$

By introducing the "characteristic function" $\chi(\boldsymbol{r}) = 1$ if $\boldsymbol{r} \in V$ and zero otherwise, $F(q)$ is seen to be the spatial Fourier transform of the distribution of the refractive index mismatch. For the special case of a particle with uniform refractive index distribution and vertical incident polarization, the scattered

intensity is then given by

$$I(q) = I_0 \frac{V^2 k^4}{4\pi^2 R^2} (n_P - n_s)^2 P(q) \qquad [26]$$

where

$$P(V) = \frac{1}{V^2} \left| \int_V \exp(i\boldsymbol{q} \cdot \boldsymbol{r}) \right|^2 \qquad [27]$$

called the particle "form factor" is readily seen to represent an "intraparticle" structure factor. Scattering pattern in the RGD approximation can therefore be evaluated by a straight geometrical integration: for homogeneous spheres, for instance, $F(q)$ is simply proportional to the spherical Bessel function $J_{3/2}(qa)$, and an analytical expression can also be found for ellipsoids, long rods, and thin disks. RGD scattering considerably extends the class of particles for which an easy analysis is feasible. A particularly interesting situation is colloidal fractal aggregation induced by the addition of salt. Fractal clusters grow with time, soon becoming much larger than λ, but they also became more and more "tenuous." Therefore, their average refractive index becomes more and more matched with the solvent, and it can be shown that, asymptotically, RGD conditions are always fulfilled.

Mie scattering The exact solution for RS from an arbitrary sphere was obtained in 1908, with a real mathematical "tour de force," by Gustav Mie. Here only the main feature of the results are described, commenting on some general aspects. First of all, all solutions are fixed. The general solution is fixed only by two parameters, namely $m = n_P/n_s$ and the dimensionless size $x = ka = 2\pi n_s a/\lambda$, and is formally given by

$$\begin{aligned} S_1 &= -\sum_n \frac{2n+1}{n(n+1)} (a_n \pi_n + b_n \tau_n) \\ S_2 &= -\sum_n \frac{2n+1}{n(n+1)} (a_n \tau_n + b_n \pi_n) \end{aligned} \qquad [28]$$

where $\pi_n(\vartheta) = P_n^1(\cos\vartheta)/\sin\vartheta$ and $\tau_n(\vartheta) = \mathrm{d}P_n^1(\cos\vartheta)/\mathrm{d}\vartheta$ give, in terms of the associate Lagrange functions $P_n^1(\cos\vartheta)$, the angular distribution of the scattered light. The amplitude coefficients a_n and b_n are complicated functions of m and x. What is important to point out, however, is that their leading behavior is $a_n \sim x^{2n+1}$, $b_n \sim x^{2n+3}$, so that, for small particles, taking into account only the first terms is sufficient. By increasing n, the functions π_n and τ_n display in a polar diagram an increasing number of lobes, changing in direction and sign with n. For large particles, therefore, the sum of many terms tends to cancel out scattering at most angles. The only exceptions are the lobes that are present for all n around $\vartheta = 0°$ and $\vartheta = 180°$, the latter however alternating in sign. As a result, large particles tend to scatter predominantly forward, with a residual backscattering cone (so one gets dazzled by backlighted drops on a windshield). For very large particles, the forward lobe has a width $\Delta\vartheta \sim \lambda/a$, witnessing the merging of Mie scattering with the classical diffraction theory. **Figure 2** compares the full Mie and approximate RGD solutions for polystyrene latex spheres in water.

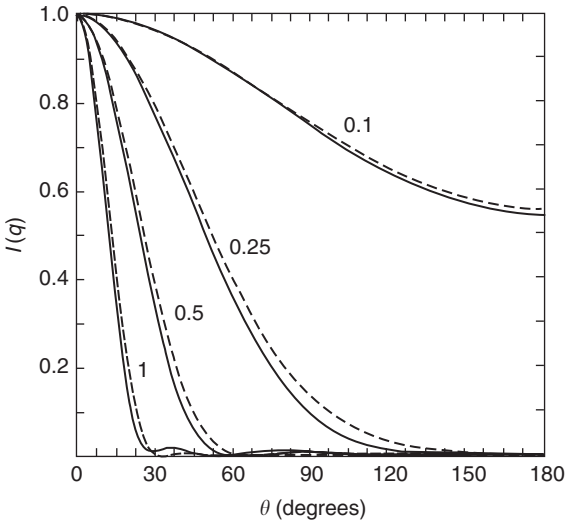

Figure 2 Normalized scattering intensity vs. scattering angle ϑ for polystyrene spheres ($n_P = 1.59$) in water for $\lambda_0 = 633$ nm. For each value of the ratio a/λ, indicated close to the curves, the full and dotted lines are, respectively, the numerical result from Mie theory and corresponding RGD analytical solution.

The coefficients a_n and b_n are finite for all real values of x. However, for strongly absorbing particles, they often present complex poles with very small values of the imaginary part. These "quasiresonances" lead to strong enhancement of specific modes, and are responsible for the beautiful colors often observed in suspensions of metallic colloids.

By exploiting the OT, the total extinction cross section can be obtained directly as a sum over the coefficients a_n, b_n:

$$\sigma_{ext} = \frac{2\pi}{k^2} \sum_n (2n+1)\, \mathrm{Re}(a_n + b_n) \qquad [29]$$

For small particles, σ_{ext} goes as λ^{-4} as in the RGD approximation, but by increasing x it tends to level off with substantial oscillations. In particular, for a specific (narrow) particles size range, it may happen that in the visible region σ_{ext} increases with λ (see **Figure 3**). This takes place for instance, when

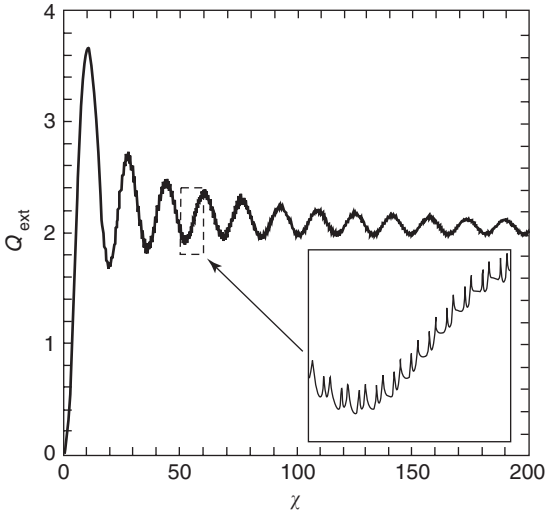

Figure 3 Extinction efficiency factor $Q_{ext} = \sigma_{ext}/\pi a^2$ for polystyrene spheres in water as a function of x (varied by fixing $\lambda =$ 560 nm and increasing a). The steep rise at small x corresponds to the RGD regime, $Q \sim x^4$, while the rich substructure at higher x, shown in the inset, derives from the large number of contributing Mie modes. "Blue moon" effects may take place in the regions where $dQ_{ext}/dx < 0$.

volcanic bursts eject huge quantities of large particles in the atmosphere, giving rise to the effect of a blue sun or moon (as the name suggests, a rare event indeed).

The strong propensity to forward scattering for large particles also allows one to explain a puzzling fact about extinction. As shown in **Figure 3**, in the limit $x \to \infty$, eqn [29] yields a value for σ_{ext} which is twice the particle geometric cross section $\sigma_g = \pi a^2$, that is, the particles subtract twice the expected power from the incident beam. This is not an artifact, but a real effect; what happens, however, is that half of the scattered power is concentrated in the forward lobe, so that it is collected by any finite-size detector as the eye. Such an intuitive geometrical optic concept as "shadow" is therefore based on subtle scattering effects.

A final consideration concerns transfer of momentum by radiation pressure, which is of primary importance both for optical levitation and for particle trapping by laser tweezers. For nonabsorbing particles, it is easy to show that the radiation pressure is given by $p_{rad} = I_0(\sigma_s/\sigma_g)(1 - \langle \cos\vartheta \rangle)$, where $\langle \cos\vartheta \rangle$ is averaged over the scattering pattern distribution. For $a \ll \lambda$, one obtains $\langle \cos\vartheta \rangle \simeq 0$, and the radiation pressure increases approximately as a^4. However, for very large particles $\sigma_s/\sigma_g \to 2$ and $\langle \cos\vartheta \to 1 \rangle$, so that radiation pressure decreases. Depending on the size and material composition of the particle, there is therefore an optimal λ for efficient momentum transfer.

The limit of geometrical optics A brilliant result by van de Hulst in 1981 yields a rigorous link between scattering and simple "ray optics": in the limit $x \gg 1$, a term of order n in the Mie expansion is mapped into a ray passing at a distance $(n+1)\lambda/2\pi$ from the particle center (the number of "distinguishable" rays must be finite: a single "ray," to be meaningful must be straight over a length $l \geqslant \lambda$, so that, because of diffraction, it must have a minimum spot area of the order of λ^2). The Mie coefficients can then be split into two equal parts leading, respectively, to diffuse the refraction–reflection effects and to the forward diffraction cone. Obviously, classic ray optics is found to be incorrect near caustics and focal point.

Dynamic Rayleigh Scattering

Rayleigh scattering from dispersed particles is not exactly elastic. Particles in suspensions undergo a Brownian motion, so that the phase (and, for optically anisotropic particles, also the amplitude see [7]) of the scattered field in eqn [2] depends on time. This slow phase modulation leads to a spectral broadening $\Delta\omega$ that is usually "extremely" small, typically $\Delta\omega/\omega \ll 10^{-9}$. Therefore, $\Delta\omega$ cannot be resolved even by sophisticated interferometric methods, since it is much smaller than the intrinsic spectral broadening on any source. A brilliant solution is looking at "intensity" fluctuations measured by a "quadratic" detector (photodiode, photomultiplier, CCD). Quadratic detection indeed introduced a "replica" of the spectrum shifted to the base band (as in homodyne radio systems) that can be easily extracted. Even more, this scheme does not require an incident light with strict temporal coherence (lasers are actually used, but only because of their brilliance). This clever idea stands at the root of "intensity correlation spectroscopy" (ICS, also called "dynamic light scattering"), allowing one to obtain the particle size from the behavior of the intensity time-correlation function $g(t) = \langle I(0)I(t) \rangle$ measured by a digital correlator. A comprehensive analysis of ICS has been made by B J Berne and R Pecora in 1976.

Scattering, Resonant

C Vettier, Institut Laue Langevin, Grenoble, France

Introduction

In its simplest form, the scattering of X-rays by atoms and molecules can be approximated in terms of the classical scattering of electromagnetic radiation (X-rays) by a free electric charge which was first solved by J J Thomson. In this approximation, only electrons orbiting around the nuclei contribute to the scattering. Other charges, such as protons which make up the nuclei, are not considered here.

Electrons are generally located in atomic bound states when they form atoms. These bound states are at the origin of the resonant effects. Suppose that electrons are loosely bound to atoms and that they are distributed over a volume comparable with atomic dimensions and the wavelength of the X-ray radiation. In this case, the amplitude of scattering by an atom is given by the so-called atomic scattering factor, which contains information about the spatial density of the electronic shells around the nucleus. Atoms arranged in a crystalline array scatter coherently and the amplitudes scattered by different scattering centers can be added; the constructive interferences lead to diffraction peaks (Bragg scattering) whose positions and intensities are analyzed to reconstruct the structure of the scattering medium. If atoms are distributed at random, the scattered intensities are added; a similar situation occurs in the case of incoherent or Compton scattering where the radiation is scattered inelastically.

The following sections deal with the coherent X-ray scattering only. The general expression for elastic scattering of X-rays from a collection of atoms is

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = r_\mathrm{e}^2 \left| \sum_n \mathrm{e}^{\mathrm{i}K\cdot r_n} f_n(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega) \right|^2$$

where $\boldsymbol{k}$ and $\boldsymbol{k}'$ are the incident and scattered wave vectors of the photons, $\boldsymbol{K} = \boldsymbol{k} - \boldsymbol{k}'$ is the photon momentum transfer or scattering vector, and $\hbar\omega = \hbar c|\boldsymbol{k}|$ is the photon energy. $r_\mathrm{e} = e^2/mc^2 \approx 2.8 \times 10^{-15}$ m is the classical electron radius which measures the magnitude of the scattering. $f_n(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ represents the scattering amplitude of the nth atom (or atomic scattering factor) and is expressed in "electron units." A knowledge of $f_n(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ is a prerequisite to crystal structure determination when analyzing diffracted intensities. The resonant effects occur when the photon energy is varied through absorption edges, which correspond to transitions between electronic states. These transitions alter the $f_n(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ dramatically because the energy dependence of the atomic scattering factors $f_n(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ occurs in resonant denominators. The following sections describe these phenomena and their consequences for applications.

Coherent X-Ray Scattering

The complete derivation of X-ray scattering amplitudes requires the use of quantum principles. X-rays are represented by a quantized electromagnetic field. For an electron of mass m and spin $\boldsymbol{s}$ in a field of vector-potential $\boldsymbol{A}$ and scalar potential Φ, the appropriate form of the interaction Hamiltonian is

$$H = \frac{1}{2m}\left(p - \frac{e}{c}\boldsymbol{A}\right)^2 - \frac{e\hbar}{2mc}\,\boldsymbol{s}\cdot B - \frac{e\hbar}{2(mc)^2}\,\boldsymbol{s}\cdot E \times \left(p - \frac{e}{c}\boldsymbol{A}\right)$$

This Hamiltonian includes the electron kinetic energy and the interactions with the electromagnetic field, Zeeman coupling, and spin–orbit term. In the Zeeman term $B = \nabla \times \boldsymbol{A}$, while the spin–orbit term contains $E = -\nabla\Phi - (1/c)(\partial\boldsymbol{A}/\partial t)$. The vector potential $\boldsymbol{A}(\boldsymbol{r})$ is linear in the photon creation and annihilation operators. At $\boldsymbol{r}_j$, the position of the jth

electron, $\boldsymbol{A}(\boldsymbol{r})$ can be expanded in terms of the photon creation and annihilation operators, $C(\boldsymbol{k}\sigma)$ and $C^{+}(\boldsymbol{k}\sigma)$ with a quantization volume V:

$$\boldsymbol{A}(\boldsymbol{r}_j) = \sum_{q\sigma}\left(\frac{2\pi\hbar c^2}{V\omega_{\boldsymbol{k}}}\right)^{1/2}[\varepsilon_\sigma C(\boldsymbol{k}\sigma)\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_j} + \varepsilon_\sigma^{*}C^{+}(\boldsymbol{k}\sigma)\mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_j}]$$

where $\varepsilon_\sigma \equiv e(\boldsymbol{k}\sigma)$ denotes the two transverse unit polarization vectors (label $\sigma = 1, 2$) associated with the wave $\boldsymbol{k}$; $\hbar\omega_{\boldsymbol{k}}$ is the energy of the wave $\boldsymbol{k}$. Since a scattering event conserves the number of photons, the linear terms in $\boldsymbol{A}$ lead to scattering in the second order while only quadratic terms in $\boldsymbol{A}$ induce scattering in the first order.

The spin–orbit term in H is of the order of vc; therefore, the Hamiltonian H can be further reduced by omitting linear terms in $\boldsymbol{A}$ which contribute to the scattering in the second order.

Finally, the interaction between an electron and the electromagnetic field can be written as

$$H' = \frac{e^2}{2mc^2}\boldsymbol{A}^2 - \frac{e}{mc}p\cdot\boldsymbol{A} - \frac{e\hbar}{mc}\boldsymbol{s}\cdot\nabla\times\boldsymbol{A} - \frac{e^2\hbar}{2(mc^2)^2}\boldsymbol{s}\cdot\frac{\partial\boldsymbol{A}}{\partial t}\times\boldsymbol{A}$$

The first term, $H_1^{'}$, in the equation above corresponds to the classical Thomson scattering term. The second, $H_2^{'}$, which is linear in $\boldsymbol{A}$, is at the origin of the resonant or anomalous X-ray scattering. The last two terms, $H_3^{'}$ and $H_4^{'}$, which contain the spin of electrons lead to magnetic X-ray scattering.

Fermi's golden rule is used to calculate the scattering cross section or the scattering amplitude $f(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$. It is assumed that the total system photon + scattering medium evolves from the initial state $|i\rangle = |a\rangle|\boldsymbol{k}\sigma\rangle$ with photon $|\boldsymbol{k}\sigma\rangle$ and the medium in a state of energy E_a to a final state $|f\rangle = |b\rangle|\boldsymbol{k}'\sigma'\rangle$ with photon $|\boldsymbol{k}'\sigma'\rangle$ and the medium in a state of energy E_b. The transition probability p is given by Fermi's golden rule up to the second order:

$$p = \frac{2\pi}{\hbar}\left|\langle f|H'|i\rangle + \sum_c \frac{\langle f|H'|c\rangle\langle c|H'|i\rangle}{E_i - E_c}\right|^2 \times \delta(E_i - E_f),$$
$$E_i = E_a + \hbar\omega_{\boldsymbol{k}} \qquad E_f = E_b + \hbar\omega_{\boldsymbol{k}'}$$

As mentioned above, only the terms in H' that are quadratic in $\boldsymbol{A}$ contribute to scattering in the first-order approximation, whereas the terms linear in $\boldsymbol{A}$ contribute to the second-order perturbation. As a result, $H_1^{'}$ and $H_4^{'}$ contribute to the nonresonant scattering; in contrast, $H_2^{'}$ and $H_3^{'}$, treated in the second-order perturbation, lead to scattering terms containing energy-dependent denominators at the origin of the resonant effects. In the following, only coherent elastic scattering in which the final state $|b\rangle$ of the scattering medium is the same as the initial state $|a\rangle$ with $\hbar\omega_{\boldsymbol{k}} = \hbar\omega_{\boldsymbol{k}'} = \hbar\omega$ is considered.

The photon part of the matrix can be calculated, and by summing over all electrons at positions j, the scattering amplitude by an atom can be written as

$$f_{\sigma'\sigma}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega) = -\sum_a p_a\left[\left\langle a\left|\sum_j \mathrm{e}^{\mathrm{i}\boldsymbol{K}\cdot\boldsymbol{r}_j}\right|a\right\rangle \varepsilon_{\sigma'}^{\prime *}\cdot\varepsilon_\sigma - \mathrm{i}\frac{\hbar\omega}{mc^2}\boldsymbol{B}\cdot\left\langle a\left|\sum_j \boldsymbol{s}_j\mathrm{e}^{\mathrm{i}\boldsymbol{K}\cdot\boldsymbol{r}_j}\right|a\right\rangle + \frac{1}{m}\sum_c\left(\frac{\langle a|O^{+}(\boldsymbol{k}')|c\rangle\langle c|O(\boldsymbol{k})|a\rangle}{E_a - E_c + \hbar\omega - i(\Gamma_c/2)} + \frac{\langle a|O(\boldsymbol{k})|c\rangle\langle c|O^{+}(\boldsymbol{k}')|a\rangle}{E_a - E_c - \hbar\omega + i(\Gamma_c/2)}\right)\right]$$

Note that the scattering amplitude is polarization dependent. It is generally represented by 2×2 matrices with the two transverse polarization states as basis vectors. In the following, the polarization index σ is dropped for the sake of simplicity.

The sum is taken over all possible initial states $|a\rangle$ of the scattering medium with probability p_a. The $\boldsymbol{B}$ polarization factor is expressed in terms of the incident and scattered unit wave vectors and polarization vectors:

$$\boldsymbol{B} = \varepsilon'^{*}\times\varepsilon + (\hat{\boldsymbol{k}}'\times\varepsilon'^{*})(\hat{\boldsymbol{k}}'\cdot\varepsilon) - (\hat{\boldsymbol{k}}\times\varepsilon)(\hat{\boldsymbol{k}}\cdot\varepsilon'^{*}) - (\hat{\boldsymbol{k}}'\times\varepsilon'^{*})\times(\hat{\boldsymbol{k}}\times\varepsilon),$$
$$\hat{\boldsymbol{k}} = \frac{\boldsymbol{k}}{|\boldsymbol{k}|} \qquad \hat{\boldsymbol{k}}' = \frac{\boldsymbol{k}'}{|\boldsymbol{k}'|}$$

The intermediate states $|c\rangle$ correspond to an electron excited into a previously unoccupied state and leaving a hole in the core level $|a\rangle$. Such excited states have a finite lifetime $1/\Gamma_c$; Γ_c is the natural width of the intermediate state $|c\rangle$, which is determined by all radiative and nonradiative de-excitations of $|c\rangle$. The operators $O(\boldsymbol{k})$ are given by: $O(\boldsymbol{k}) = \sum_j \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_j}\{\boldsymbol{p}_j\cdot\varepsilon - i\hbar\varepsilon\cdot(\boldsymbol{k}\times\boldsymbol{s}_j)\}$, where $\boldsymbol{p}_j$ and $\boldsymbol{s}_j$ are the momentum and the spin of the jth electron; these operators depend on the polarization geometry.

Further manipulations of $f_n^{\mathrm{res}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ to separate the nonresonant from the pure resonant

scattering lead to

$$f_n(\boldsymbol{k},\boldsymbol{k}',\hbar\omega) = f_n^{\text{nonres}}(\boldsymbol{K}=\boldsymbol{k}-\boldsymbol{k}') + f_n^{\text{res}}(\boldsymbol{k},\boldsymbol{k}',\hbar\omega)$$

with

$$f_n^{\text{nonres}}(\boldsymbol{K}) = -\sum_a p_a \left[\left\langle a \left| \sum_j e^{i\boldsymbol{K}\cdot\boldsymbol{r}_j} \right| a \right\rangle \varepsilon'^{*}\cdot\varepsilon - i\frac{\hbar\omega}{mc^2} \left\langle a \left| \sum_j e^{i\boldsymbol{K}\cdot\boldsymbol{r}_j} \left(\frac{i\boldsymbol{K}\times\boldsymbol{p}_j}{\hbar K^2}\cdot(\varepsilon'^{*}\times\varepsilon) + \boldsymbol{B}\cdot\boldsymbol{s}_j \right) \right| a \right\rangle \right]$$

and

$$f_n^{\text{res}}(\boldsymbol{k},\boldsymbol{k}',\hbar\omega) = -\sum_a p_a \left(-\frac{1}{m}\sum_c \frac{E_a-E_c}{\hbar\omega} \times \frac{\langle a|O^{+}(\boldsymbol{k}')|c\rangle\langle c|O(\boldsymbol{k})|a\rangle}{E_a-E_c+\hbar\omega-i(\Gamma/2)} + \frac{1}{m}\sum_c \frac{E_a-E_c}{\hbar\omega} \frac{\langle a|O(\boldsymbol{k})|c\rangle\langle c|O^{+}(\boldsymbol{k}')|a\rangle}{E_a-E_c-\hbar\omega+i(\Gamma/2)} \right)$$

Nonresonant Scattering

The first term in $f_n^{\text{nonres}}(\boldsymbol{K})$ gives the classical Thomson charge scattering from electrons. The polarization dependence of the charge part is simple, that is, $f_n^{\text{nonres charge}}(\boldsymbol{K}) = -\rho_n(\boldsymbol{K})\varepsilon'^{*}\cdot\varepsilon$, where $\rho_n(\boldsymbol{K})$ is the Fourier transform of the charge density: the atomic charge scattering is a diagonal tensor which implies that polarization of X-rays is not rotated by charge scattering. The quantity $\rho_n(\boldsymbol{K})$ can be estimated from *ab initio* calculations based on model electronic wave functions as discussed below.

The second term in $f_n^{\text{nonres}}(\boldsymbol{K})$ corresponds to magnetic X-ray scattering with two contributions, one from the electron spin and the other from the electron momentum. The matrix elements containing the electron momentum can be rewritten explicitly in terms of the Fourier transform of the atomic orbital magnetization density $\boldsymbol{L}_n(\boldsymbol{K})$. This leads to

$$f_n^{\text{nonres magnetic}}(\boldsymbol{K}) = -i\frac{\hbar\omega}{mc^2}\left(\frac{1}{2}\boldsymbol{L}_n(\boldsymbol{K})\cdot\boldsymbol{A} + \boldsymbol{S}_n(\boldsymbol{K})\cdot\boldsymbol{B}\right)$$

where $\boldsymbol{S}_n(\boldsymbol{K})$ is the Fourier transform of the spin density of the nth atom and $\boldsymbol{A}$ is another polarization vector:

$$\boldsymbol{A} = 2(1-\hat{\boldsymbol{k}}\cdot\hat{\boldsymbol{k}}')(\varepsilon'^{*}\times\varepsilon) - (\hat{\boldsymbol{k}}\times\varepsilon)(\hat{\boldsymbol{k}}\cdot\varepsilon'^{*}) + (\hat{\boldsymbol{k}}'\times\varepsilon'^{*})(\hat{\boldsymbol{k}}'\cdot\varepsilon)$$

The nonresonant magnetic scattering is much weaker than the charge scattering as indicated by the prefactor $\hbar\omega/mc^2$; the ratio of the magnetic to the charge scattering is given by

$$\left|f_n^{\text{nonres magnetic}}/f_n^{\text{nonres charge}}\right|^2 \approx \left(\frac{\hbar\omega}{mc^2}\right)^2\left(\frac{\rho_n^{\text{magnetic}}}{\rho_n}\right)^2$$

where ρ_n^{magnetic} is the Fourier transform of the "magnetic" electron density. For typical scattering experiments performed with X-ray energies around $\hbar\omega \approx 5$–$10\,\text{keV}$ (compared to $mc^2 \approx 511\,\text{keV}$), this ratio is $\sim 1\times10^{-6}$. This makes the observation of nonresonant magnetic X-ray scattering difficult, even when using powerful X-ray sources such as synchrotron sources. However, it is worth noting that the charge part, the spin part, and the orbital momentum part of $f_n^{\text{nonres}}(\boldsymbol{K})$ have different polarization dependences through $\boldsymbol{A}$ and $\boldsymbol{B}$, which not only allows the discrimination of magnetic and charge scattering but permits the full separation of the spin and momentum contributions to magnetic moments. There, synchrotron sources play a key role because they produce highly polarized X-ray beams.

If resonant effects could be ignored, then the atomic scattering factor for X-rays would not vary with the photon energy and there would not be any absorption. However, this approximation cannot be justified in all cases of practical importance: even when using standard X-ray sources in laboratories, Cu K-α radiation ($\hbar\omega \approx 10\,\text{keV}$) is often used to investigate the structure and properties of materials containing other $3d$ elements of the periodic table which have absorption edges in the same energy range.

Resonant X-Ray Scattering

The denominators in $f_n^{\text{res}}(\boldsymbol{k},\boldsymbol{k}',\hbar\omega)$ which contain the photon energy $\hbar\omega$ lead to resonant effects when the photon energy is tuned near any natural absorption energy of the scattering atoms, $E_c - E_a$. A schematic single-electron energy-level diagram in **Figure 1** illustrates the resonant scattering process. The incident photon virtually excites an electron from the ground state $|a\rangle$ into an unoccupied state above the Fermi level creating a hole in the core level; the excited electron then decays by filling the core hole and emitting a photon. The same intermediate electronic states contribute to the white lines in X-ray spectroscopy.

The different atomic absorption edges are labeled according to the core level $|a\rangle$, the final state of the excited electron being ignored. In a filled atomic shell (n,l) the total momentum is zero; however, as soon as a hole is created, it acquires a momentum

$j = l \pm (1/2)$. This j value can be used as an index to label the core level $|a\rangle$. **Table 1** shows the correspondence between the accepted nomenclature and the core levels.

Further levels with $n = 4, 5, 6$ are labeled similarly with letters N, O, and P. All levels with the same n are grouped together: the core electrons in the inner shells are hydrogen-like electrons and their energies are given in a first approximation by

$$-\frac{me^4}{2\hbar^2}\frac{Z^2}{n^2} = 13.60\frac{Z^2}{n^2}$$

in eV units, and depend on n only. Relativistic spin–orbit effects induce the separation of j multiplets for a given n; for example, L_1 and L_2 have a different energy than L_3. Terms with different l values but same n and j are separated due to intra-atomic electron interactions, which modify the Coulomb potential from the nucleus. Values for the absorption edges have been tabulated for elements of the periodic table in various chemical environments and valence states. The values of the K edges vary from 16 eV for hydrogen, 7.1 keV for iron to 115 keV for uranium, while L_3 edges range from 700 eV in the $3d$ series to 17.2 keV for uranium. **Table 2** gives a list of absorption edge energies for selected chemical elements.

Typical values for the energy line width are $\sim$1–10 eV, which leads to a fast scattering process in the 10^{-16} s range but sufficiently slow so that the excited states can be considered as quasistationary.

The resonant part of the scattering amplitude has three fundamental properties:

1. First, there are additional terms in the scattering amplitude which are known as dispersion correction terms. Normally, the atomic scattering factor is written as: $f = f_0 + \Delta f' + i\Delta f''$ where f_0 is the nonresonant atomic scattering factor. $\Delta f'$ and $\Delta f''$ are the real and imaginary parts of the dispersion correction given by $f_n^{\mathrm{res}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$. The imaginary part of $f_n^{\mathrm{res}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$, $\Delta f''$ which is positive, leads to X-ray absorption by the scattering medium. Similarly, the complex refractive index for X-rays $n = 1 - \alpha - i\beta$ is related to $f = f_0 + \Delta f' + i\Delta f''$:

$$\alpha = r_e \frac{\lambda^2}{2\pi} N(f_0 + \Delta f') \quad \text{and} \quad \beta = r_e \frac{\lambda^2}{2\pi} N\Delta f''$$

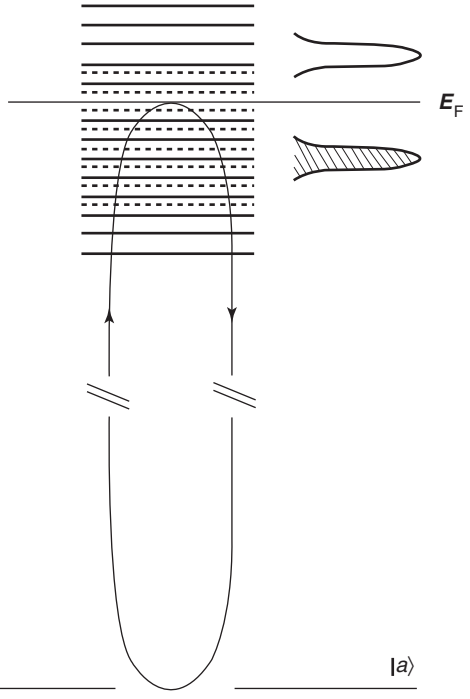

Figure 1 Schematic diagram showing the resonant process: the incident photon excites an electron in ground state $|a\rangle$ into an available state near the Fermi level $\boldsymbol{E}_F$. The intermediate state $|c\rangle$ contains a hole in $|a\rangle$ and an extra electron near $\boldsymbol{E}_F$. In an elastic scattering process, the excited electron in $|c\rangle$ decays back into $|a\rangle$, emitting a scattered photon with the same energy as the incident photon.

Table 1 Nomenclature of absorption edges

Table 2 Selected resonances for characteristic chemical species. The transition process for dipolar ($E1$) and quadrupolar ($E2$) transitions are indicated. Resonant energies are given in keV; the corresponding X-ray wavelengths are given in Å

Chemical elements		*Resonance process*			*Resonant energy* (keV)	*Wavelength* (Å)
3*d* Transition metal	Fe	$E1$	$p \leftrightarrow d$	L_2, L_3	0.71	17.5
		$E1$, $E2$	$s \leftrightarrow p,d$	K	7.1	1.5
5*d* Transition metal	Pt	$E1$	$p \leftrightarrow d$	L_2, L_3	11.5–13	1.08–0.95
		$E1$, $E2$	$s \leftrightarrow p,d$	K	78.4	0.16
4*f* Rare earth	Gd	$E1$	$d \leftrightarrow f$	M_4, M_5	1.22–1.19	10.2–10.4
		$E1$, $E2$	$p \leftrightarrow d,f$	L_2, L_3	7.9–7.2	1.57–1.72
5*f* Actinides	U	$E1$	$d \leftrightarrow f$	M_4, M_5	3.7–3.5	3.35–3.54
		$E1$, $E2$	$p \leftrightarrow d,f$	L_2, L_3	20.9–17.2	0.59–0.72

where λ is the X-ray wavelength and N is the atomic density. Resonant effects induce large changes in the refraction of X-rays.

2. Second, resonant amplitudes depend on the polarization geometry and the local site symmetry of the "edge" atoms in crystals. The anisotropic resonant scattering amplitude must be represented by a second-rank tensor. The anisotropy of the tensorial macroscopic refraction index n gives rise to X-ray optical effects similar to those observed in the visible light range. All local symmetry-breaking effects can play a role: the local symmetry of specific sites, crystal lattice distortions, and even the onset of magnetic moments.
3. Finally, it should be noted that the resonant process is highly selective. Resonant energies characterize chemical elements in well-defined valence states (**Table 2**) and the resonances are rather narrow; therefore, only "edge" atoms in materials, that is, those atoms where edges are excited by the incident X-rays, contribute to these resonant intensities. Furthermore, as shown below, selection rules specify which electronic shells can contribute to resonances, hence the electronic shell selectivity.

Resonant Scattering Amplitudes

The magnitude of the resonant scattering is given by the matrix elements in $f_n^{\mathrm{res}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$. The operators $O(\boldsymbol{k})$ contain electron spin and momentum operators. However, for photon energy larger than 10–100 eV, the magnetic transitions induced by the spin operators are much weaker than the electric transitions induced by the electron momentum operators. Therefore, the spin operators can be omitted in $f_n^{\mathrm{res}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ and electric transitions only are involved in connecting to the intermediate states. The resonant contributions to the coherent scattering amplitude can be written in terms of various approximations following the expansion $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_j} \approx 1 + \mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_j + (1/2)\left(\boldsymbol{k}\cdot\boldsymbol{r}_j\right)^2$ in the operator $O(\boldsymbol{k}) \approx \sum_j \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_j}\,(\boldsymbol{p}_j\cdot\varepsilon)$. Dipole and quadrupole approximations are retained as the leading terms, bearing in mind that dipolar matrix elements are normally larger than the quadrupolar ones for the transitions that they allow. The importance of the transition amplitude is determined by overlap integrals of the occupied orbitals in the initial state and the new occupied orbitals in presence of the core hole in the intermediate states: these are matrix elements $\langle c|r^L|a\rangle$, where $L = 1.2$ for dipole and quadrupole transitions. Selection rules exist which restrict the possible intermediate states depending on the nature of the transition: a dipolar electric transition is associated with a change ΔL in the orbital momentum and no change in spin, whereas a quadrupolar electric transition involves $\Delta L = 2$. Returning to **Figure 1**, if a transition metal of the $3d$ series near the K edge is considered, dipolar transitions ($\Delta L = 1$) will involve electronic excited states in the $4p$ bands, whereas quadrupolar ($\Delta L = 2$) terms would involve the available $3d$ states. Similarly, resonant effects at the L_3 edge of a rare-earth element in the $4f$ series will include the $5d$ electronic bands via dipolar transitions and the more localized $4f$ states via quadrupolar transitions.

The detailed comparisons of dipolar and quadrupolar contributions to the resonance depend on the origin of the resonant process.

Sensitivity to Local Symmetry

The outer electronic shells of the intermediate states are sensitive to the local symmetry of atomic sites, and the atomic scattering amplitude depends on the relative orientation of the incident X-ray polarization with respect to local symmetry axis. Therefore, near a resonance, the atomic scattering factors contain resonant terms which reflect the local symmetry of the atomic sites; atomic scattering factors are no longer scalar and diffraction may exhibit birefringence. This anisotropy of the anomalous scattering leads to spectacular effects, such as the appearance of otherwise "forbidden" reflections as discussed below.

Although the leading resonant terms are due to multipolar electric transitions, resonant X-ray scattering is sensitive to local magnetic moments. The spin–orbit coupling, which couples the spin of the available electronic levels to the orbital momentum, makes overlap integrals depend on the net magnetic polarization of the electronic bands. As a result, resonant scattering also provides information on magnetic properties.

Dispersion Corrections

The dispersion corrections, that is, the dependence of the atomic scattering power on the photon energy, had remained a deep concern for crystallographers who had viewed these corrections as an annoyance. Indeed, dispersion effects are strongly dependent on the electronic structure of atoms and ions in solids; furthermore, close to the resonances, the local symmetry and environment can lead to new and large effects. Nevertheless, the advent of synchrotron radiation sources has opened new fields of activity in variable-wavelength methods, and crystallography experiments offer better understanding and more accurate estimates for these corrections. These developments have brought renewed interest, both from the theoretical and the experimental side, to

tackle the problem of dispersion corrections. Several attempts had been made to calculate the full atomic scattering factor using models for atomic electrons, such as the Thomas–Fermi model or self-consistent-field methods. The early methods had ignored the fact that electrons occupy definite energy levels within atoms. The presence of the absorption edges were reproduced by including damped oscillators to introduce dispersive corrections to the atomic scattering factors.

The current theoretical approaches for the calculation of corrections include classical, nonrelativistic, and relativistic theories. It should be noted that these calculations assume an isolated neutral atom with spherical symmetry. Most of these approaches ignore the changes in X-ray polarization during scattering. Refined relativistic calculations have provided a detailed understanding of the scattering process and have assessed the validity of simpler approaches. Values for $\Delta f'$ and $\Delta f''$ have been tabulated using different calculation methods and can be compared with experimental determinations.

The experimental techniques to determine the corrections rely on the measurements of macroscopic properties, such as the refractive index and the linear absorption coefficient. These methods involve dispersion corrections at zero photon momentum transfer $\boldsymbol{K} = 0$.

The imaginary part $\Delta f''$ is obtained through measurement of the linear absorption coefficient. The real part $\Delta f'$ can be obtained through the Kramers–Kronig inversion of the experimental data for $\Delta f''$ obtained over a sufficiently broad range of photon energies. More accurate methods involve the measurement of optical index X-ray interferometry, total reflection of X-rays, and refraction of X-rays through prisms.

For isolated absorption edges, $\Delta f'$ takes negative values at low energies reaching a minimum at the edge (where $\Delta f''$ reaches a maximum), and approaching small positive values at higher energies. The values for $\Delta f'$ at absorption edges can be very large: in the $3d$ series, $\Delta f'$ reaches $-9\ r_e$ at the edge (theories predict $-13.5\ r_e$) to be compared to the 29 electrons in Cu atoms.

Other techniques measure intensities of Bragg reflections from crystalline materials as a function of the photon energy or the variation of intensities within a diffraction peak due to the interferences between transmitted and reflected X-ray waves as predicted by the dynamical theory of X-ray diffraction. These measurements provide data on the dispersion corrections at the finite scattering vector $\boldsymbol{K}$. However, the $\boldsymbol{K}$ dependence of the dispersion corrections is not established.

Anisotropy of Resonant Scattering

Away from resonance, the nonresonant scattering amplitude $f_n^{\text{nonres charge}}$ does not depend on the relative orientation of the crystal axis with respect to the polarization vectors: diffracted intensities are not sensitive to rotations of the crystal about the scattering vector $\boldsymbol{K}$ (azimuthal scans or Renninger scans). This property is exploited to detect artifacts (such as multiple scattering) in collecting diffraction data. However, this property is no longer valid near absorption edges. In general, the dispersion corrections must be taken as second-rank tensors, which are compatible with the symmetry of the chemical bonding of the atomic sites in crystals. Consequently, the scattering cross section $d\sigma/d\Omega$ takes a tensorial form. In absorption and transmission experiments, this leads to birefringence and pleochroism effects. In diffraction experiments at an absorption edge, the intensity and polarization of diffracted peaks depend on the rotation of the crystal about the scattering vector $\boldsymbol{K}$ as shown in **Figure 2**.

A special consequence of the anisotropy of $f_n^{\text{res}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ is the violation of extinction rules due to equivalent crystal sites with different orientations of their local axis. Due to the anisotropy of $f_n^{\text{res}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$, edge atoms, which occupy equivalent crystal sites related by a screw-axis or glide-planes, do not have the same scattering power at resonance. As a result, the usual rules for absent reflections based on space groups symmetry are no longer

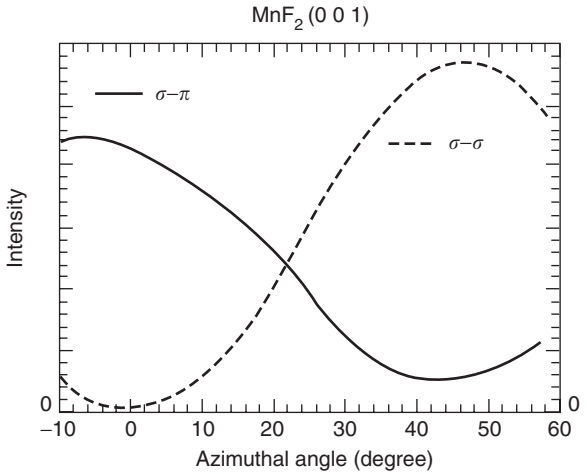

Figure 2 Rotation of the sample about the scattering vector $\boldsymbol{K}$ (azimuthal scan) at the K-edge on manganese at the forbidden reflection (0 0 1) in manganese difluoride, MnF_2. Such a reflection would be forbidden by the crystal symmetry of the MnF_2 structure if the atomic scattering factor of manganese were spherical. At resonance, atomic factors are not spherical; scattered intensities with different polarizations vary with the orientation of the crystal axis with respect to the X-ray polarization vectors (azimuthal angle).

rigorous: diffraction peaks which would be forbidden away from resonance can be observed when the photon energy is tuned near the absorption edges. The "forbidden" Bragg reflections provide information on the partial structure of the edge atoms.

Magnetic Resonant Scattering

Magnetooptics phenomena (Faraday rotation and magnetooptic Kerr effect) with visible light and infrared radiation clearly demonstrate that electromagnetic radiation interacts with magnetic moments. These phenomena involve the refraction index, which is related to the $\boldsymbol{K} = 0$ part of the scattering amplitude. However, in the X-ray range away from resonances, it can be seen that the polarization vectors $\boldsymbol{A}$ and $\boldsymbol{B}$ which enter $f_n^{\text{nonres magnetic}}(\boldsymbol{K})$ vanish at $\boldsymbol{K} = 0$. The X-ray refraction index differs strongly from unity only near absorption edges due to the anomalous part of the scattering amplitude: this is where polarization rotation effects and magnetic scattering effects can be detected.

Resonant magnetic scattering originates from the dependence of $f_n^{\text{res}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ on the magnetization at site n. This happens if the overlap integrals depend on the local magnetic moment or if the energies of intermediate levels $|c\rangle$ are split by exchange interactions. The magnetic sensitivity arises from the combination of spin–orbit couplings which must be present in one of the two levels involved at the resonance and exchange interactions.

The following example illustrates the effect (**Figure 3**): if the ground state $|a\rangle$ of the atom has a single hole in the $4f$ shell ($l = 3$) and, therefore, carries a localized magnetic moment, the direct application of Hund's rule shows that the empty electronic orbital is characterized by $m_l = -2$, $m_s = -1/2$, which is also a quantum state with $j = 7/2$, $m_j = -7/2$. At the M_5 edge (initial state in the 3 $d_{5/2}$ band), dipolar transitions contribute with $\Delta L = 1$ and $\Delta M_L = -1$ only; this corresponds to a circular left-handed polarization. The other two transitions, $\Delta M_L = 1$ and $\Delta M_L = 0$, are not allowed. If all sites have their magnetic moments aligned in the same direction, left-handed circularly polarized photons with proper energy will excite this transition and will be absorbed by the assembly of magnetic atoms, whereas the other polarizations, linear and right-handed circular, would not interact. This is the origin of X-ray magnetic dichroism. Similar effects will take place in the scattering process. Estimations in this idealized case have shown that the magnetic resonance scattering amplitude could reach 100 in electron units, giving extremely large effects in X-ray absorption and diffraction.

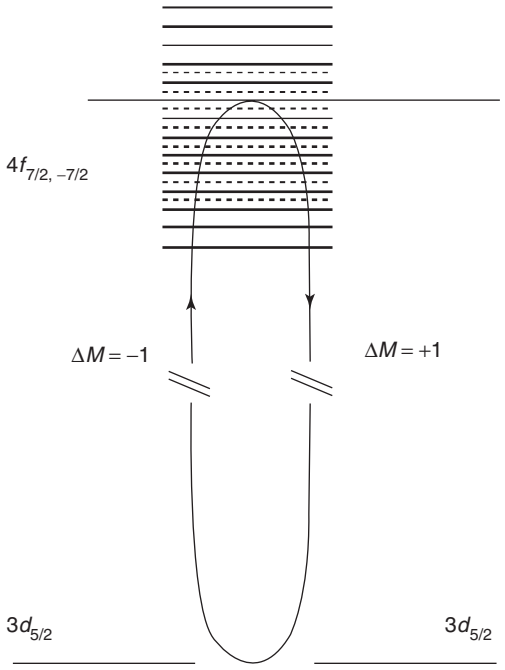

Figure 3 Schematic diagram showing magnetic sensitivity of the resonant process: only the $\Delta M = -1$ transition is allowed at the transition leading to X-ray dichroism in absorption experiments.

If the edge energy $E_c - E_a$ is split by exchange interactions, that is, depending on the spin state of the intermediate electronic level $|c\rangle$, then the transition probabilities also depend on the change in momentum ΔM_L induced by the incident radiation. As a result, X-ray dichroism and magnetic scattering will also appear.

If the momentum transfer $\boldsymbol{K}$ corresponds to the magnetic periodicity of the material, the sum over intermediate states for all atoms is nonzero, which leads to resonant magnetic Bragg peaks. The resonant scattering is superimposed on nonresonant scattering: the two scattering amplitudes interfere to produce the total cross section $\mathrm{d}\sigma/\mathrm{d}\Omega$.

Large resonant enhancements of magnetic scattered intensities have been observed at the $L_{\text{II, III}}$ edges of rare earths (10- to 100-fold enhancements) and $M_{4,5}$ edges of actinides (several orders of magnitude enhancements) as illustrated in **Figure 4**. A fundamental difference between $f_n^{\text{nonres magnetic}}(\boldsymbol{K})$ and $f_n^{\text{res}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ is that $f_n^{\text{nonres magnetic}}(\boldsymbol{K})$ contains the spin and the orbital contributions to the magnetic moment, whereas $f_n^{\text{res}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ is sensitive to the orientation of the local moment only. However, there exist sum rules for $\Delta f''$ which allow one to extract values for the orbital moment and for the spin.

The largest resonant enhancements observed at the $M_{4,5}$ edges of actinides result from strong dipole transitions, which couple the d core levels directly

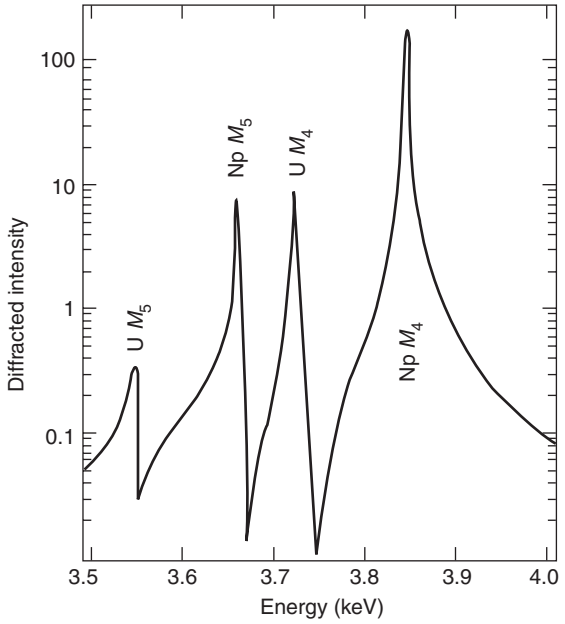

Figure 4 Photon energy dependence of magnetic diffraction intensity from a material containing two magnetic elements, uranium and neptunium. Neptunium and uranium are clearly distinguishable and well separated. Tuning the photon energy to one edge makes the diffraction sensitive to neptunium or uranium magnetic properties. The resonant intensities are enhanced by 5 orders of magnitude compared to intensities observed in the nonresonant regime far above the edges.

to the unfilled magnetic $5f$ electronic shell. The size of the magnetic resonance is a combination of the overlap integrals discussed above and the magnetic polarization of the intermediate states. The weaker enhancements observed at the $L_{2,3}$ edges of rare earths are explained by the fact that dipole transitions couple to $5d$ bands, which are more spin-polarized than the $4f$ shells, which carry the magnetization in rare earths. In such a case, quadrupolar transitions can be comparable to dipolar terms because they couple the core level ($2p$) directly to the strongly spin-polarized $4f$ states. **Table 2** lists resonant processes which are of importance for resonant magnetic scattering experiments.

The properties of resonant magnetic X-ray scattering lead to important applications. The large size of the scattering amplitude allows minute samples and even surfaces to be studied in magnetic scattering experiments. The chemical selectivity of the resonant process is illustrated in **Figure 4**: tuning the photon energy through the absorption edges of different chemical species makes it possible to distinguish the magnetic moments that reside in different elements. Similarly, the electronic sensitivity allows the distinction of the contributions from the d, f or even itinerant p electronic states to magnetization.

Corresponding effects can be observed in X-ray spectroscopy. Restricting the resonance to dipolar transitions, $f_n^{\text{res, dipole}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ can be written as

$$f_n^{\text{res, dipole}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega) = F^{(0)}\varepsilon'^{*} \cdot \varepsilon - iF^{(1)}(\varepsilon'^{*} \times \varepsilon)z_n + F^{(2)}(\varepsilon'^{*} \cdot z_n)(\varepsilon \cdot z_n)$$

where z_n is the quantization axis at the site n. The $F^{(I=0,1,2)}$ are the resonant matrix elements and contain the resonant denominators. The first term in $f_n^{\text{res, dipole}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ is independent of z_n and does not contribute to the magnetic scattering; it is the usual anomalous X-ray scattering term which contributes to white lines in the fluorescence signal. The second term in $f_n^{\text{res, dipole}}(\boldsymbol{k}, \boldsymbol{k}', \hbar\omega)$ leads to X-ray circular dichroism in X-ray spectroscopy experiments, and the third term contributes to X-ray linear dichroism.

Future Directions

Resonant scattering processes have opened new dimensions to X-ray scattering. The sensitivity to local symmetries and the selectivity properties of the resonant scattering amplitude become new tools to exploit the potential offered by the properties of synchrotron radiation: tunability of the energy and of the polarization of the X-ray beams.

Introduction

The clusters of atoms and molecules are somewhat intermediate in several aspects (number of constituent atoms N, size, basic properties, etc.) between simple atoms and molecules on one side and macroscopic aggregates (bulk solids) on the other side. The advent of clusters as stable or at least reproducible nanosystems composed of a number of atoms ranging roughly between 10 and 10^4 (consequently with average size up to a few nanometers, so that quite often the term nanoparticles is used to indicate them) took place gradually with the parallel development and refinements of techniques to master and study their properties.

When an increasing number of atoms are progressively aggregated to form clusters, the evolution from atomic-like to bulk-like behavior is ascertained to have happened in many different ways, depending on the kind of atoms, the growth conditions, and the environment. Useful and general schemes of classification have been proposed. Now the question may arise: are there clear-cut borderlines between single atoms or molecules and very small clusters on one side, and also between relatively bigger aggregates and bulk solids on the other side? While it is generally accepted that the main properties of more extended aggregates ($N \sim 10^3$–10^4) gradually tend to bulk values, the situation appears to be rather more complex on the former borderline. It can be safely stated that the molecules are characterized by a definite composition and also a definite structure; clusters on the contrary may contain a variable number of atoms and for a given N, may exhibit many possible structures, some of them more stable than the other ones. If N is progressively increased, it is found that more stable structures exist in correspondence to specific numbers, which are called "magic numbers."

On general grounds, it is evident that recent advances in growth techniques (lithography, film deposition, molecular beam epitaxy, etc.) have opened the way to new and rich developments of physics: this is based on the fact that size and length scales characterizing the nanosystems described here are now comparable to or smaller than typical lengths (such as, electron mean free path and exciton radius) which have been playing an essential role in the various phenomena taking place in macroscopic condensed matter.

Clusters: Size-Related Typical Quantities

The investigation of the structures in the nanometer domain presents rather challenging aspects in terms of experimental characterization and theoretical calculations for the prediction and/or interpretation of their basic properties. To summarize in one sentence, it can be stated that space confinement plays a key role in modeling and tuning the physical properties of nanocrystals. This statement is supported with a few considerations:

- limitation of the validity of effective-mass approximation below a given size, and of the *ab initio* molecular dynamics approach above a certain number of constituent atoms ($N > 10^2$);
- strong redistribution of the electronic density of states, and blue-shift of the main spectral structures when the size is smaller than the excitonic radius for semiconductors;
- discretization of the electronic density of states in metals, and modification of transport properties when the number of constituent atoms does not exceed a few tens;
- the breaking of the $k = 0$ selection rule due to the uncertainty principle $\Delta x \Delta k = 1$ (where Δx and Δk are the uncertainty on position and wave vector, respectively), and the related possibility of exploring the ω versus k dispersion curve, also away from $k = 0$;
- strong modification of the main properties when N_s/N (where N_s is the number of surface atoms, and N the overall number of atoms) becomes relevant;
- strong effects of surface scattering in the ultrafast electron dynamics, when the size is smaller than the mean free path with consequences on the thermalization times of the electron gas, and
- modification of the surface plasmon energy due to space confinement.

The appreciation of the relevant length scales (between 0.1 nm and 0.1 mm) over which the phenomena are evidenced is an important prerequisite to a more detailed understanding of the new physics. The length scales are set by different aspects:

1. there are those measured on an atomic scale, associated with the deposition of the constituent materials;

2. scales are set by the achievement of lithography and technology processes in order to stabilize and integrate nanostructures in application-oriented configurations;
3. typical lengths are set by physical principles (diameter of excitons, radius of cyclotron orbits) as cited above, and
4. other lengths are associated with scattering coherence (mean free path, surface quality, etc.), and are derived from the optical or electronic properties.

From Bulk to Nanoregime

Two completely different approaches have been adopted in the last two decades to prepare three-dimensionally confined structures or clusters. The first approach (top-down) is based on patterning and etching techniques in order to obtain space-limited systems starting from macroscopic samples. In fact, originally the fabrication methods of quantum wires and dots were based on lateral patterning of two-dimensional heterostructures, by combining fine-line lithography with wet and chemical etching. However, lithographic patterning introduces irregularities in the shape of the nanostructures, and mechanical damage cannot be avoided. The second one (bottom-up) is related to the aggregation and self-organization of single atoms and molecules to form clusters in the nanometer range via evaporation/condensation processes.

One of the most conspicuous examples of a stable cluster is certainly represented by the "buckyball" C_{60} molecule. The forces binding the clusters together are of different types, depending on the specific material; for instance, Coulomb forces are responsible for NaCl clustering, covalent forces for C_{60} and Si aggregates, van der Waals forces for rare-gas agglomeration, and metallic bonds in the case of metals. This implies, of course, that a wide variety of approaches must be adopted to grow and study them. However, instead of trying to give a detailed picture of the very ample spectrum of possible systems that can be obtained with their specific features, one can state the general principles that characterize the behavior of the clusters.

In general terms, one can summarize the evolution of the main properties with size as follows:

1. irregular or strongly oscillating size-dependence of structural, energetic, electronic, and electromagnetic observables, in connection with the existence of the magic numbers for clusters with very small N ($<10^2$);
2. if the size is increased ($N>10^2$), a smooth and continuous evolution of the properties toward bulk values is observed. The behavior of a generic property is shown in **Figure 1**.

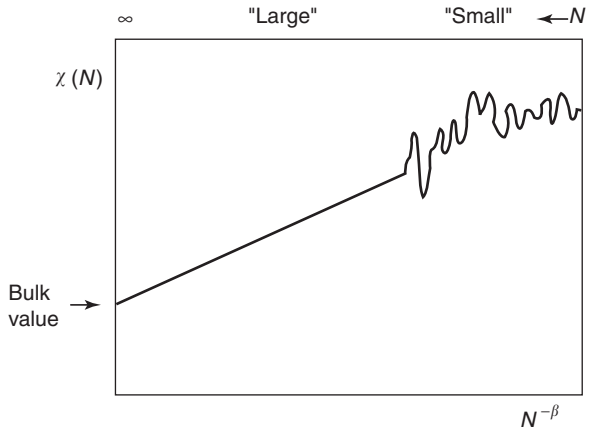

Figure 1 Schematic representation of the behavior of a general property of a cluster vs. size.

In the N region (2), a qualitative description of the size-dependence of a property can be expressed by the relationship

$$\chi(N) = \chi(\infty) + AN^{-\beta}$$

where A is a constant and β can vary between 0 and 1. $\chi(\infty)$ represents the bulk value, which is usually determined quite easily from experiments or reliable simulations. Specific examples amenable to this equation are:

1. the cohesive energy of a metal cluster in a metal-drop model,
2. the ionization potential of van der Waals clusters in the case of an impurity state in a rare-gas cluster,
3. melting temperature of a nanoparticle as compared to the bulk value, and
4. confinement of Wannier excitons where the energies of the excitonic nth levels are expressed by the above relationship.

Adequate theoretical studies of these systems require, in general, rather sophisticated and complex computational procedures and methods. In principle, at least in the simplest cases, one uses the same theoretical tools generally applied to study molecules; the quantum mechanical methods range from *ab initio* variational calculations of the entire electronic structure to more approximate methods related to the use of "effective potentials." However, recent developments are bringing important new contributions to the treatment of more complex systems. In

this respect, mention may be made of: (1) the Monte Carlo method, which allows one to explore, by statistical sampling, the accessible phase space of configurations and momenta of particles, and (2) molecular dynamics for solving, by means of numerical simulation, the simultaneous equation of motion of all the atoms of a cluster (if one has a reliable potential).

Basically, the starting approach in studying clusters and small aggregates consists in selecting a structure, and then calculating the consequent total energy. By repeating the calculations for all possible geometries, one determines the ground state, characterized by the lowest energy among all configurations. However, while these results have been quite satisfactorily obtained in molecular physics for some decades through the well-known and standard quantum mechanical method of calculating the exact wave functions of electrons and ions, nontrivial difficulties arise when the systems are given by a relatively large number of atoms; in this case, the number of local energy minima increases dramatically with size and the problem tends to be practically insoluble.

Among the several approaches adopted, it is worth stressing the methods based on a combination of density functional and molecular dynamics. The next two sections will be devoted to more specific treatments given separately to semiconductor and metallic clusters/nanosystems.

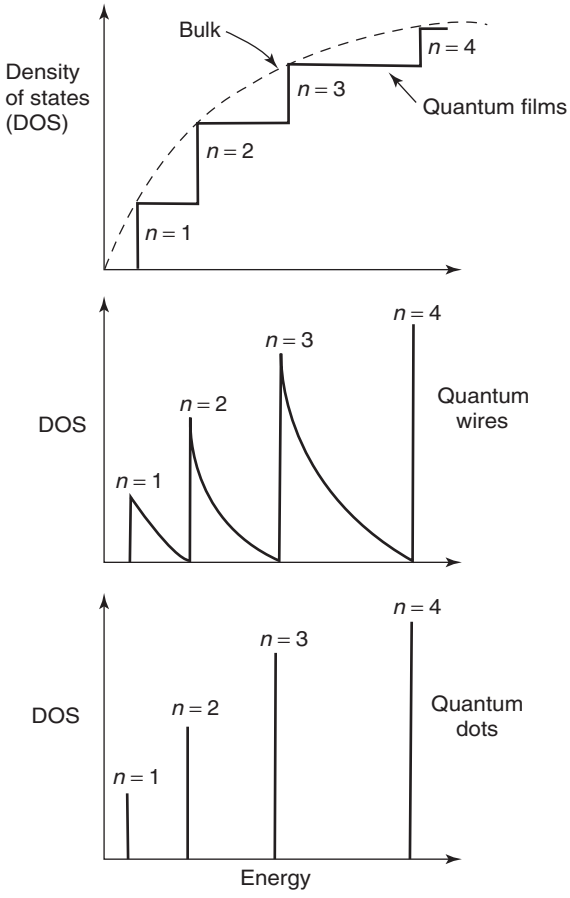

Figure 2 Effect of dimensionality on the electronic density of states: quantum films, which are confined in one dimension (as compared to bulk), quantum wires, and quantum dots (confined in two and three dimensions, respectively).

Semiconductor Clusters

Recently, a lot of emphasis has been given to semiconductor clusters or "quantum dots" (QDs, also called nanocrystals), and in particular to their quantum behavior deriving from space confinement. These nanosystems are characterized by sizeable effects on the electron density of states, with respect not only to bulk, but also to quantum wells and quantum wires.

As a matter of fact, in a more general framework three regimes of quantization can be defined depending upon whether the charge carriers are confined in one, two, or three dimensions. Confinement in one dimension creates structures that have been termed quantum wells. This is because such structures could be described by the elementary quantum mechanics of a particle in a one-dimensionally confined box. The carrier confinement in two dimensions produces quantum wires, and confinement in three dimensions produces quantum dots. The dimensionality of confinement affects many aspects of quantization; for example, **Figure 2** shows the effect on the density of states.

Remarkable developments related to applications of these type of systems have been reported in literature, and are being extensively discussed in state-of-the-art applied research.

To introduce the basic electronic properties of quantum dots (and their consequent spectroscopic behavior), it is to be assumed that one deals with a simple two-band semiconductor with parabolic, isotropic, direct bands (eventually spin degenerate). In addition, an effective mass approximation (EMA) is used: as it has been proved, this would imply that one considers dot sizes larger than a given value, which is well above 1 nm. Consider the case of spherical quantum dots with radius R. For spherical potential wells, the kinetic energy of a quantum mechanical particle takes discrete values and scales as the square of the inverse radius

$$E_{e,nl} = E_g + \frac{\hbar^2}{2m_e^*}\left[\frac{k_{nl}}{R}\right]^2$$

$$E_{h,nl} = E_g + \frac{\hbar^2}{2m_h^*}\left[\frac{k_{nl}}{R}\right]^2$$

where E_g is the fundamental energy gap, m^* is the effective mass, and the subscripts e and h refer to electrons and holes, respectively. It is usual to refer to the n, l electron or hole eigenstate as ns, np, nd, etc., where s, p, d correspond to $l = 0$, 1, 2, respectively. The lowest confined state of a single electron–hole pair has its energy increased with respect to the bulk gap by

$$\Delta E = \frac{\hbar^2}{2m_r}\left(\frac{\pi}{R}\right)^2$$

where the reduced mass m_r is given by

$$m_r = \frac{m_e^* m_h^*}{m_e^* + m_h^*}$$

To introduce scaled quantities, the exciton Rydberg energy E_R is used:

$$E_R = \frac{\hbar^2}{2m_r a_B^2}, \quad \text{with } a_B = \frac{\varepsilon' \hbar^2}{m_r e^2}$$

where a_B is the exciton Bohr radius, and ε' is the background dielectric constant. Then,

$$\Delta E = E_R\left(\frac{\pi a_B}{R}\right)^2$$

For small quantum dots, the confinement-induced energy shift is large in comparison to the exciton binding energy.

Important new aspects of quantum confinement can be evidenced by switching from the fundamental bandgap to higher-energy structures, such as E_1 and E_2. For example, a blue-shift effect is obtained in the optical absorption spectra measured on nanocrystals of germanium (see **Figure 3**), a paradigmatic case of indirect gap semiconductor, with different values of the radius R.

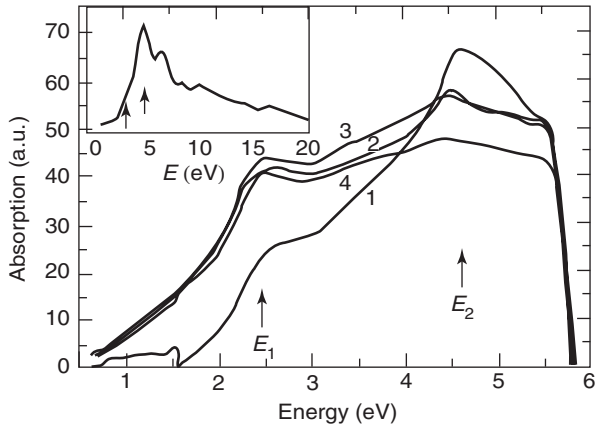

Figure 3 Optical absorption spectra of Ge nanoparticles in the E_1 and E_2 interband transition spectral region, with radii varying from 1.2 (sample 1) to 6.5 nm (sample 4). Inset: calculated $k \cdot p$ absorption spectrum for bulk Ge.

In general, E_2 transitions come from different k points in the Brillouin zone. Although a blue-shift of spectral structures is generally observed in confined systems, the quantitative explanation of the E_2 shift goes beyond the simple effective-mass models. As calculated by Wang and Zunger for Si quantum dots, the confinement shift of the spectral structures does not necessarily grow as $1/R^2$ but, in any case, it increases faster than the electron–hole Coulomb attraction, which behaves as $1/R$, so that the excitonic enhancement of absorption is expected to be less important in the quantum dots compared to the bulk.

The E_1 spectral structure presents a different behavior, characterized by the interplay of the reduction of the joint density of states (k is no more a good quantum number, the notion of interband transition between parallel bands becomes meaningless) and of the excitonic nature. The overall effect is given by a reduction of the oscillator strength accompanied by the weakening of the excitonic structure.

Recent calculations of the electronic structure of quantum dots display more and more sophisticated approaches, where the dot is viewed as a new structure rather than a perturbation on the bulk material. This is made possible computationally by a series of innovations rendering a 10^3–10^6 atom problem tractable within a pseudopotential framework. The approach starts from the bulk band structure and treats nanostructures of all dimensionalities on an equal footing; it captures the correct atomistic structures, strain and symmetry, including surface effects, and incorporates Coulomb and exchange effects without any further approximations. It can be applied to "free-standing," for example, colloidal dots as well as to embedded ("self-assembled") dots.

Since quantum dots allow one to study the electronic properties at the extreme limits of zero dimension, their behavior appears to be transferable into novel device concepts.

One of the most investigated aspects obviously concerns the optical properties of QDs that are relevant in optoelectronic devices. First, the luminescence line width from excitons in single QDs is ultranarrow up to elevated temperatures, proving that the density of electronic states is δ-function like, similar to the density of states in an atom. A potential significant point for applications is the realization of efficient QD luminescence at 1.3 μm wavelength at room temperature, and is coupled to favorable properties for QD lasers: low, temperature-insensitive threshold current, high gain, and differential gain. From the first laser presented in 1994 by Bimberg and Grundmann, which exhibited zero-dimensional

properties until 120 K, significant further progress has occurred. Laser operation at room temperature of a single sheet of dots on their ground state can be prevented by gain saturation in connection with sufficiently high optical losses – for example, in short cavities. Such an effect can be circumvented by incorporating more QDs into the cavity by vertical stacking. In vertical-cavity surface emitting lasers (VCSELs) incorporating QD stacked layers as active medium, the matching of the cavity passband with the QD optical density of states exhibits laser operation at room temperature on their ground state. When structural anisotropy of self-ordered dots is exploited, laser emission of polarized light from VCSELs can occur.

In addition, both quantum confinement and strong Coulomb interaction have strong effects on transport. The few-electron regime is accessible in vertical dot devices, which contain a dot located between source and drain contacts by means of heterostructure tunnel barriers. When a dot is coupled to a reservoir, the addition of an extra electron raises the electrochemical potential of the dot, and the one-by-one change of the number of electrons leads to conductance oscillations (Coulomb oscillations) as a function of gate voltage. The oscillation period is usually constant when a dot contains many electrons and equals e/C, where C is the total capacitance and e is the elementary electron charge. In a few-electron dot, the e–e interactions and quantum confinement effects become so strong as to modify the Coulomb oscillations remarkably. The absolute value N of the electrons can be identified by starting from the zero-current region (Coulomb-blockade region); then the current shows clear Coulomb oscillations where each period corresponds to a change of exactly one electron in the dot. When N becomes smaller than 20, an increasing irregularity is found and the oscillation period depends strongly on N.

Metal Clusters

In the case of metals also, new effects are expected due to space confinement. Already in the 1930s, Frölich had pointed out that the continuous distribution of the electronic density of states in the conduction band tends to break up into discrete states when the size of the metal becomes sufficiently small. The problem was quantitatively formulated by Kubo in the 1960s, and since then, considerable efforts have been made to get experimental evidence of the quantum effects.

In general terms, if the particles are so small that the conduction band breaks up into discrete levels separated by energies which are large compared to thermal energies, the Drude expression is no longer valid. It must be replaced by a more realistic, quantum mechanically derived dielectric function. The simplest quantum mechanical model that can be used is that of free electrons in a cubic potential well with infinite sides. The formal advantages of this model are clear: analytic expressions can be obtained at all stages in the calculation. Perhaps, a serious disadvantage is related to the high degree of symmetry and therefore of degeneracy in the electronic states, a degeneracy which probably will not be found in nature.

The one-electron wave functions of this model are well known:

$$\psi_{lmn} = \left(\frac{8}{L^3}\right)^{1/2} \sin\left(\frac{l\pi x}{L}\right) \sin\left(\frac{m\pi y}{L}\right) \sin\left(\frac{n\pi z}{L}\right)$$

where L is the length of one edge of the potential well, and l, m, n are positive integers. The corresponding energy levels are

$$E_{ijk} = E_0(l^2 + m^2 + n^2)$$

where

$$E_0 = \frac{\pi^2 h^2}{2mL^2}$$

A nontrivial aspect of the discretization of the electronic energy levels in metals is related to the gap or energy separation between two consecutive levels:

$$\Delta E = \frac{E_F}{N^{1/3}}$$

where E_F is the Fermi energy, and N the number of constituent atoms. It is evidently hard to have energy separation larger than either the thermal energies or the widths of the levels (as induced by defects, inhomogeneities, etc.), already when $N > 50$–100 atoms, that is, when the size becomes ~ 0.5–1 nm. This makes a remarkable difference with respect to semiconductors, where clearly observable quantum effects show up when the size becomes smaller than the excitonic radius a_0, that is, already ~ 5–10 nm in some cases.

The discretization of the electronic energy levels in the conduction band implies that the Drude model is no longer valid in very small nanoclusters. A clear distinction comes out with respect to large clusters or bulk metals, where plasmon-like excitations are based on almost elastic processes for the involved electrons due to field-induced coherent oscillations superimposed on their k vectors. The individual electrons can gain only small amounts of energy of the

order of $\Delta E = h\omega/N_e$, where N_e is the number of participating electrons in the cluster. This energy becomes important in small clusters ($\Delta E \sim 0.1$ eV for $N_e \sim 100$) and hot electrons are produced. The smaller the cluster, the hotter the electrons and in such a case, it is preferable to speak of collective electron excitations rather than of plasmons.

In the case of spherical clusters embedded in a dielectric matrix (ε_m), if the complex dielectric function $\varepsilon(\omega)$ of the particles is known, the average dielectric function $\langle \varepsilon \rangle$ of the composite medium describes completely the optical response of the layer. For small volume fraction of the particles, f, one can write the imaginary part of $\langle \varepsilon \rangle$ as

$$\langle \varepsilon \rangle_2 = 9f\varepsilon_m^2 \frac{\varepsilon_2(\omega)}{(\varepsilon_1(\omega) + 2\varepsilon_m)^2 + \varepsilon_2(\omega)^2}$$

which is expressed in terms of ε and ε_m.

As a consequence, a resonance can be expected at a frequency ω_s given by $\varepsilon_1(\omega_s) = -2\varepsilon_m$. This is the so-called surface plasma resonance of the effective medium embedding the small spherical particles. For small particles, scattering of electrons off the surface gives an appreciable contribution to the total reciprocal lifetime:

$$\tau^{-1} = \tau_0^{-1} + \frac{v_F}{L_{eff}}$$

where τ_0, v_F, and L_{eff} are, respectively, the electron lifetime in the bulk, the Fermi velocity, and a measure of the size of the particle. Actually, the width of the observed plasma resonances in clusters has been generally well explained by this model. The additional term on the right-hand side accounts for the behavior of the plasma resonance (at least in terms of size-related broadening) in a rather wide-size range (or number of constituent atoms $N \gg 100$). The effects due to the size variation on τ are observable also in correspondence to the size domain, where the electronic energy level distribution is quasicontinuous.

This has a remarkable effect, for example, on the ultrafast electron dynamics in metal nanoparticles. During irradiation with ultrashort laser pulses (from picoseconds to femtoseconds timescale), a change is induced in the electron energy distribution due to the formation of a low-density nonthermalized high-energetic electron population. The acquired energy is redistributed by electron–electron (e–e) and electron–phonon collisions. The electron thermalization usually occurs on a subpicosecond timescale; therefore, a hot Fermi distribution with a temperature $T_e > T_0$ (where T_0 is the initial sample temperature) is formed. The hot electron system thermalizes with the lattice through electron–phonon collisions and other interactions, mainly with the nanoparticle surface, with characteristic decay times.

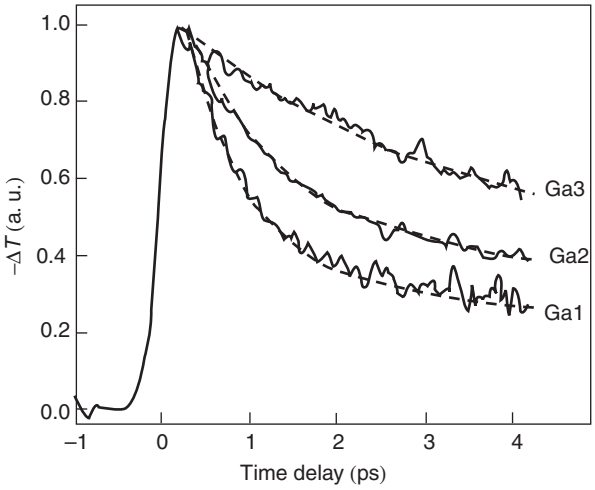

Figure 4 Time-resolved transmittivity changes ΔT in Ga nanoparticles embedded in a dielectric transparent matrix, as a function of probe time delay. Sample labels are Gan where n indicates the equivalent mass thickness of deposited Ga (in nanometers), the average radius of the nanoparticle being $R \sim 4n$.

The evident consequence is represented by a thermalization time which is size-dependent: the smaller the particle, the faster the thermalization (for example, the behavior of gallium nanoparticles, **Figure 4**). In fact, if R becomes comparable or smaller than the bulk electron mean free path, the electron oscillates inside the spherical potential well of the particle with a frequency $v = v_F/R$. In sufficiently small particles, this frequency can be larger than the Debye frequency, so that the bulk electron–phonon interaction (which is a resonant process) may become ineffective. In this case, the electrons dissipate the excess energy through generation of surface vibrational modes (currently defined "capillary waves"). In the case of gallium, the mean free path at 77 K is $l \sim 15$ nm. For smaller particles, the electron scattering with the surface takes place and the corresponding charge oscillation frequency $v = 1.82 \times 10^{14}\,s^{-1}$ turns out to be much larger than the Debye frequency $v_D = 6.6 \times 10^{12}\,s^{-1}$.

Metallic nanophase systems are also promising for applications in connection with the ease of growth combined with the wide flexibility in tuning electronic/thermodynamic properties. Applications of these systems include switching elements between different tunable states driven by an external force (optical or electrical pulses), and also the effect of phase transitions (in particular, melting) on their linear and nonlinear optical response.

Nomenclature

a_B	exciton Bohr radius (m)
C	capacitance (F)
e	electron charge (C)
E_F	Fermi energy (eV)
E_g	energy gap for semiconductors (eV)
E_R	exciton Rydberg energy (eV)
k	wave vector (m^{-1})
m^*	effective mass (kg)
R	cluster radius (m)
t	electron lifetime (s)
ν	frequency (s^{-1})
ν_D	Debye frequency (s^{-1})
ν_F	Fermi velocity (ms^{-1})
ε	dielectric function ($C^2N^{-1}m^{-2}$)
ω	angular frequency (s^{-1})

Semiconductor Compounds and Alloys, Electronic States of

J C Phillips, Rutgers University, Piscataway, NJ, USA

Like their predecessors, tetravalent elements (Si and Ge), semiconductor compounds (GaAs, InP, etc.), and alloys ((Al, Ga)As, (Ga, In) (P, As), etc.) based on tetrahedrally coordinated structures are the most studied and best understood materials in condensed matter physics. Like Si and Ge, they generally share eight valence electrons per cation/anion pair, and their formula can be written as A^NB^{8-N}. In addition to these "octet" semiconductors, there are also compounds and alloys with the formula A^NB^{10-N}, such as PbTe, that have a rock salt (octahedrally coordinated) structure, as well as many other predominantly covalent materials with more complex formulas, such as As_2Se_3, $GeSe_2$, etc. This article emphasizes the electronic states in the simplest octet case, partly because most of the applications are found there. Similar principles apply to the electronic states of all these materials, and the results are most impressive for the simplest cases. The ongoing progress of semiconductor science will probably lead to similar successes for other semiconductors as well.

Chemical Bonding in Octet Compounds

Because of their tetrahedrally coordinated structures, the electronic states of octet compounds and alloys can be described approximately as superpositions of Pauling's sp^3 hybrid atomic orbitals (**Figure 1**). In a diatomic structure there are two kinds of such hybrids, those pointing toward and away from the nearest neighbors, corresponding to bonding (valence) and antibonding (conduction) band states. When the two atoms in the unit cell are different and have different electronegativities, the covalent bonds found in elemental semiconductors (Si, Ge) become partially ionic. For many decades, the question of how to define the ionic and covalent fractions of chemical bonds was open and considered by many to be unanswerable, but this problem was solved for the octet compounds by Phillips' dielectric theory. It turns out that not only the electronic states but also almost all the physical properties of octet semiconductors are smooth functions (usually linear) of ionicity defined dielectrically, thus microscopically justifying much of Pauling's heuristic discussion of chemical bonding in molecules and solids, and explaining its many great successes.

In semiconductors, there are many energy gaps between the valence and conduction band states, the

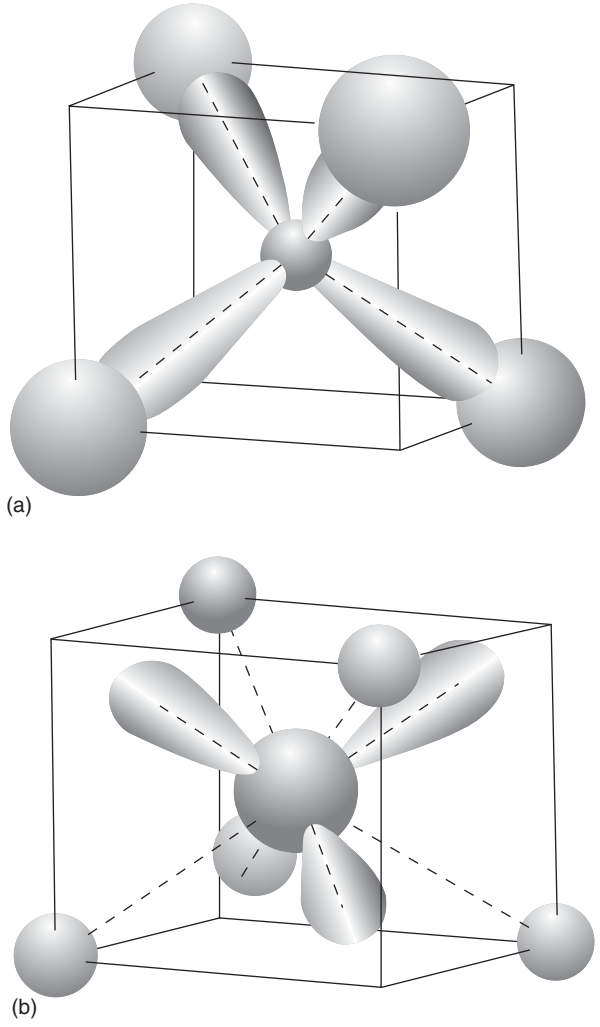

Figure 1 (a) Directed bonding and (b) antibonding orbitals in $A^N B^{8-N}$ semiconductors. The A atoms are represented by smaller spheres and are more electropositive, while the B atoms are represented by larger spheres and are more electronegative. The bonding orbitals have lower energy both because they are directed toward their nearest neighbors (covalency) and because they are centered predominantly on the more electronegative ion (ionic effect). These apparently qualitative effects are represented quantitatively (accuracy ~1%!) by the energy gaps E_h and C. (Reproduced from Phillips JC (1973) *Bonds and Bands in Semiconductors*. New York: Academic Press, with permission from Elsevier.)

most important one for transport properties being the smallest gap. However, all the gaps follow chemical trends that are best described in terms of the average gap E_g defined dielectrically

$$\varepsilon(0) = 1 + A(\hbar\omega_p/E_g)^2 \qquad [1]$$

where A is a fixed number of order unity that corrects for band dispersion, and ω_p is the plasma frequency defined in terms of the valence electron density n_0 by

$$\omega_p^2 = 4\pi n_0 e^2/m \qquad [2]$$

Of course, in most cases, the average gap E_g is much larger than the smallest gap $E_{min} = E_0$. For example, in (Si, Ge) the gaps in electron volts are $E_g = (12.5, 11.5)$ and $E_{min} = (1.1, 0.7)$.

All the gaps follow chemical trends as functions of ionicity similar to those followed by the average gap, which is decomposed into its covalent or homopolar (E_h) and ionic or charge transfer (C) parts according to the Cartesian relation

$$E_g^2 = E_h^2 + C^2 \qquad [3]$$

The covalent gap E_h is a function only of the lattice constant, and is easily interpolated for compounds from the values of C, Si, Ge, and (gray) Sn. The ionic gap C is then obtained either from the known values of $\varepsilon(0)$ in the octet compounds, or from the analytic systematics of E_h and C obtained from other compounds. In horizontal series such as Ge, GaAs, and ZnSe, composed of elements from the same period, where the lattice constant changes are very small, it is found that C is proportional to $N - 4$. Thus, C behaves as a dielectrically defined electronegativity difference.

Pseudopotential Form Factors

The actual wave functions in semiconductors are not described accurately by the hybrid atomic orbitals shown in **Figure 1**, but they are described very accurately outside the atomic cores by superpositions of several hundred plane waves. The surprising aspect of these wave functions is that they can be derived from Cohen–Chelikowsky pseudopotential form factors $V_p(q)$ that depend on only a few parameters/atoms (if they are derived empirically from observed optical spectra) or that can be calculated from atomic potentials very precisely with no adjustable parameters; the values obtained empirically or from first principles are in excellent agreement. That is why one says that pseudopotentials are "transparent, reliable and transferable (TRT)." (Aside: this is a rare, virtually unprecedented, occurrence in quantum theory.) Without pseudopotentials, the knowledge and understanding of electronic states in solids would still be in a primitive, disorganized, and erratically inaccurate state.

Comparing the screened pseudopotentials for Al and Si shown in **Figure 2**, normalized to the free-electron Fermi energy E_F, it is to be noted that the form factors $V_p(q)$ of these adjacent elements in the

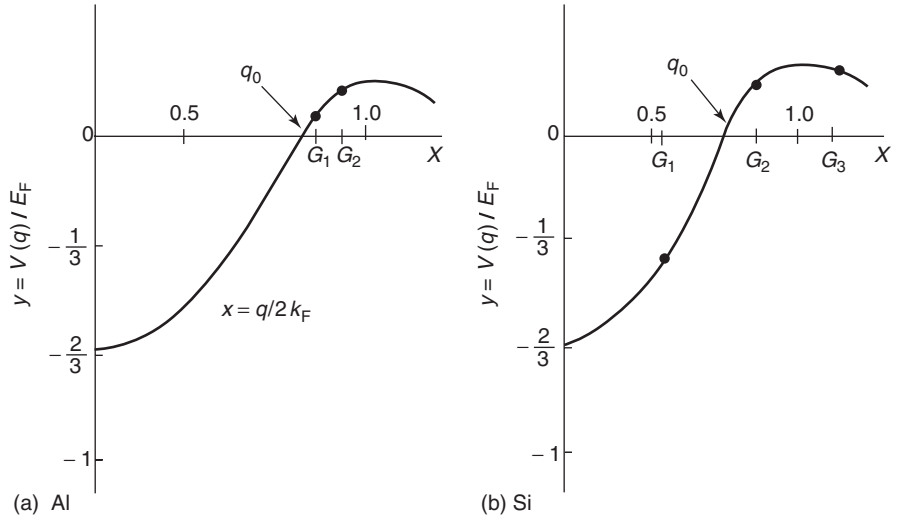

Figure 2 The electronic structures of solids arise from a complex interplay of electronic interactions at atoms and interatomic interactions between multiply scattered waves. Two such radically different materials as Al, a nearly free-electron metal, and Si, the semiconductor that is the basis of microelectronics, appear to have quite similar TRT pseudopotential form factors. The most striking differences arise because the reciprocal lattice vectors G_i are different for close-packed Al and tetrahedrally coordinated Si, leading to different values for $V(G_i)$, marked by the solid circles. However, a close examination of the form factors reveals other differences as well. Note that the number of valence electrons alone does not account for the differences in physical properties: Pb, like Si, is tetravalent, but it has the same close-packed crystal structure as Al. A close examination of the TRT pseudopotential calculations shows that the G that is largely responsible for this difference is $G_2 = (220)$, because $V(G_2)$ reverses the sign between Si and Pb. (Reproduced from Phillips JC (1973) *Bonds and Bands in Semiconductors*. New York: Academic Press, with permission from Elsevier.)

periodic table as functions of $x = q/k_F$ appear at first to be quite similar, as one would expect from the fact that their atomic cores are isoelectronic. A closer inspection shows that the nodal value q_0 is smaller for Si than for Al, and the repulsive overshoot (due to exclusion of valence electrons from the atomic cores) is slightly larger. Most striking, however, are the positions of the reciprocal lattice vectors labeled G_i. In Al, with its close-packed 12-fold coordinated structure, the first two G's lie in the repulsive region beyond q_0, and covalent bonding is not possible. However, for Si q_0 lies well inside k_F and is large in magnitude and negative, favoring the formation of covalent bonds.

Thus far the atomic orbital and pseudopotential descriptions are quite similar. Now, however, a miracle happens. The covalent and ionic parts of the average energy gap are described quite accurately by

$$E_h/2 = V_s(G_2) + [V_s(G_1)]^2/\Delta T \qquad [4]$$

$$C/2 = 2V_s(G_1)V_a(G_1)/\Delta T \qquad [5]$$

where ΔT is a free-electron energy difference that depends only on the lattice constant, and $V_{s,a}(G) = V^A(G) \pm V^B(G)$. These energy gaps are central to understanding chemical trends in the electronic states of A^NB^{8-N} compound semiconductors and their alloys. They have been derived from tabulated atomic pseudopotential form factors without elaborate calculation. Their transferability has been tested elegantly for the series Mg_2X (X = Si, Ge, Sn), with a triatomic cubic fluorite structure and many new reciprocal lattice vectors, with the results shown in **Figure 3**. TRT successes of this kind are unique to pseudopotentials.

Ionicity

Given the covalent or homopolar (E_h) and ionic or charge transfer (C) energy gaps, one defines the bond ionicity as $f_i = C^2/(E_h^2 + C^2)$. Almost all bulk properties of A^NB^{8-N} compound semiconductors and their alloys are linear functions of f_i. (Strictly speaking, this statement has been tested only for 17 (!) compounds. These are: Si, Ge, AlSb, GaP, GaAs, GaSb, InP, InAs, InSb, ZnS, ZnSe, ZnTe, CdS, CdSe, CdTe, and CuCl. High-quality samples are gradually becoming available for AlN and GaN, and these should soon join the list.) The largest database against which the bond ionicity has been tested is 70 octet compounds that are either tetrahedrally or octahedrally coordinated. Success in predicting this fundamental covalent/ionic structural dichotomy had eluded all other attempts, but the parameter-free dielectric approach is completely successful, as shown in **Figure 4**.

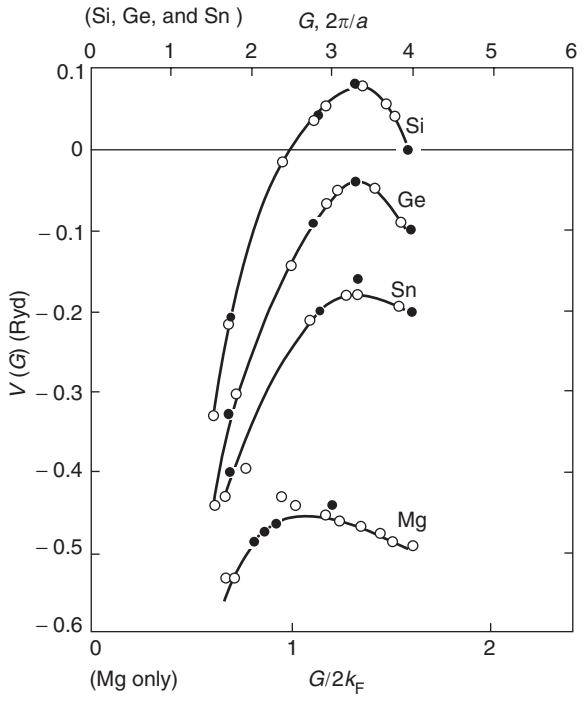

Figure 3 To test the assumption that pseudopotential form factors are transferable, self-consistent electronic structures were calculated for the X elements shown, and for the compound semiconductors Mg_2X. Values of the form factors derived from elemental band structures are represented by filled circles, while values for the compounds are marked by the empty circles. The overall consistency is spectacular, and validates the TRT description. Figure 4 Values of E_h and C for ~70 octet compounds, including both tetrahedral semiconductors and octahedral insulators. The line corresponding to $f_i = C^2/(E_h^2 + C^2) = 0.785$ (5) separates the two classes exactly. (Reproduced from Phillips JC (1973) *Bonds and Bands in Semiconductors*. New York: Academic Press, with permission from Elsevier.)

Charge Densities

The pseudoatom charge densities calculated using several hundred plane waves are in excellent agreement with X-ray results, after subtraction of the chemically uninteresting core background. A surprising feature of the charge densities is the appearance of a bond charge between the atoms. In elemental cases (diamond, Si, Ge, gray Sn), this charge is, of course, situated halfway between two atoms, but for compounds it moves closer to the anion. The displacement is linear in the ionicity f_i. Alternatively, one can integrate the excess charge density above the background. As shown in **Figure 5**, this excess charge extrapolates to zero as f_i approaches the critical ionicity derived in **Figure 4**.

Energy Bands of Octet Compounds

The energy bands of compound semiconductors have been calculated with great precision over a wide energy range (detailed comparisons with experiment cover an energy range of 10–20 eV) using the pseudopotential form factors illustrated in the next paragraph. The same form atomic factor occurs in many compounds, and the variations from one compound to another for the same atom are so small as to be scarcely perceptible. Two kinds of form factors have been used: semi-empirical and self-consistent first-principle, including in some cases corrections for many-electron correlation and exchange. To illustrate the differences between elemental band structures and compound band structures, one can compare (**Figure 6**) the energy bands of Ge and GaAs, which are quite similar because the main change in the crystal potential comes from the ionic potential C produced by the difference between Ga and As. The most important difference is that the smallest energy gap $E_{min} = E_0$ is indirect in the elemental semiconductors Si and Ge, that is, the valence and conduction band edges lie at different points in the crystal

momentum space k, but it is direct in most compound semiconductors, where both edges fall at $k = 0$. Almost all optical applications, including the most important one, multi-quantum well lasers, require a direct optical gap. The gap at $k = 0$ is denoted conventionally by E_0', that is associated with states near the (1 1 1) Brillouin zone face by E_1, and that is associated with states near the (2 0 0) Brillouin zone face by E_2.

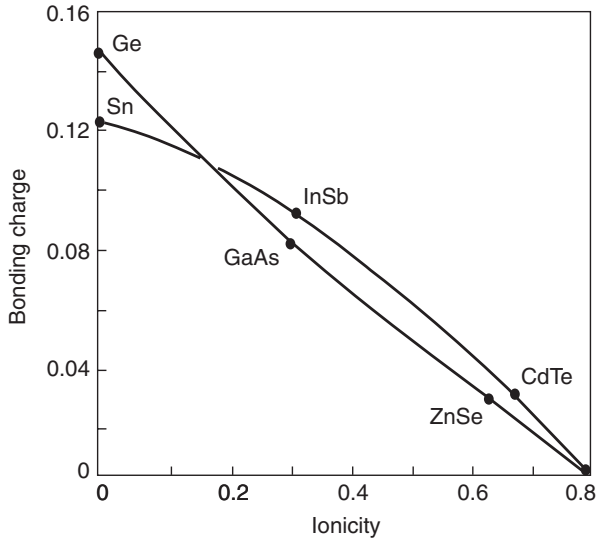

Figure 5 The bond charge as a function of dielectric ionicity for two isoelectronic series of octet semiconductors (third and fourth periods) clearly extrapolates to zero for the critical ionicity derived in **Figure 4**. (Reproduced with permission from Walter JP and Cohen ML (1971) *Physical Review* 4B: 1877; © American Physical Society.)

Elastic Constants and Phonons

The pseudopotential theory yields phonon spectra $\omega_i(q)$ for semiconductors by a convolution of the pseudopotential form factors in the conventional dynamical matrix theory, but this must be done on a case-by-case basis. More interesting are the general trends in the normalized shear modulus, shown in **Figure 7**; it is nearly linear in the ionicity f_i, except for collapsing in the Cu halides as the ionicity approaches the critical value 0.785 (**Figure 4**) for transition to the rock salt structure.

Fundamental Optical Spectra

At first sight, the optical spectra of semiconductors seem to be uninformative, because the energy bandwidth is large compared to the spacing of structures generated by crystal symmetry. However, modern TRT pseudopotential calculations yield very accurate energy bands, and oscillator strengths are routinely

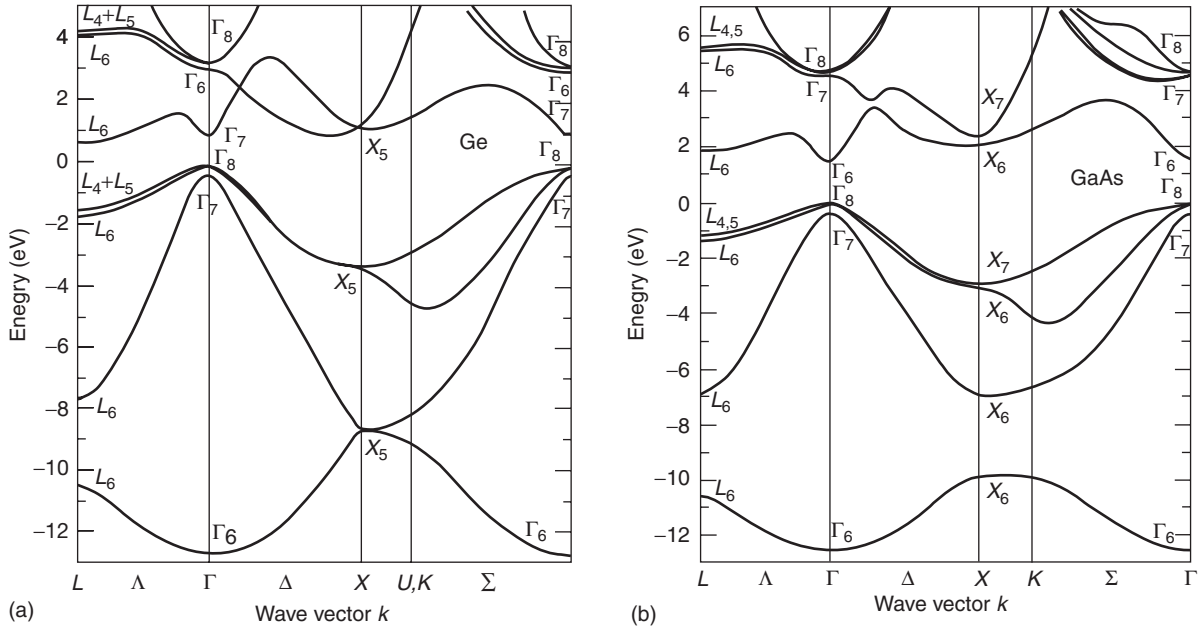

Figure 6 The energy bands of Ge and GaAs over an energy range of ~20 eV are quite similar; all the important differences in their physical properties stem from scarcely perceptible shifts in energies of their lowest conduction bands at the symmetry points Γ, *X*, and *L* in crystal momentum space *k*. These shifts, ~0.3 eV, are accurately predicted by TRT pseudopotential band structures, as these are calculated with an accuracy ~0.03 eV over the entire range of 20 eV. Accuracies of this kind are generally not achieved in quantum calculations even for polyvalent atomic spectra. (Reproduced with permission from Chelikowsky and Cohen (1973) *Physical Review Letters* 31: 1582; © American Physical Society.)

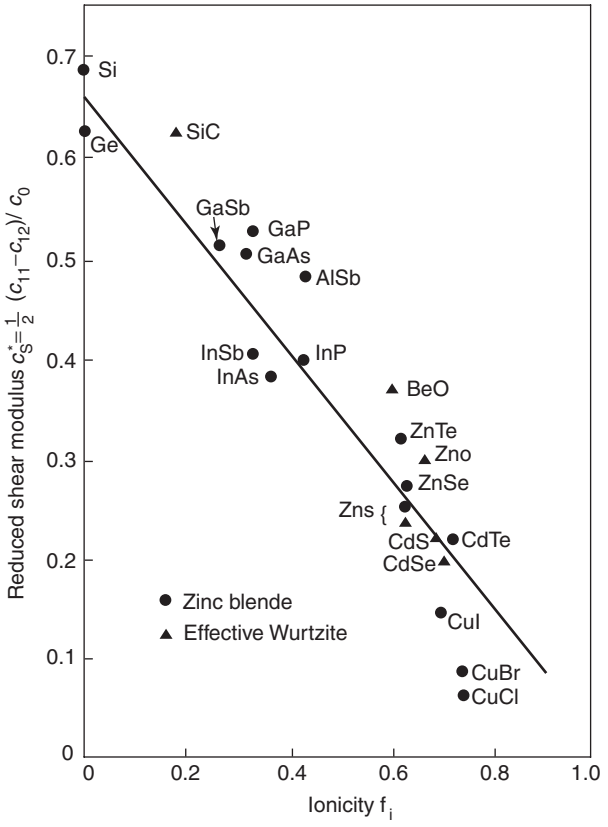

Figure 7 Increasing ionicity in octet compound semiconductors reduces the bond charge (**Figure 5**) and leads to the archetypical tetrahedral-octahedral phase transition (**Figure 4**). It also dramatically reduces the resistance of the open tetrahedral structure to shear. As shown here, this reduction appears to extrapolate to zero at $f_i = 1$, but in the Cu halides, there is a dramatic collapse as f_i approaches the critical value 0.785. This means that although there is a large volume change at the transition, so that it is technically first order, quantum mechanically it appears to be continuous, that is, second order, presumably because the bond charge (**Figure 5**) extrapolates to zero for the critical ionicity derived in **Figure 4**. (Reproduced from Phillips JC (1973) *Bonds and Bands in Semiconductors*. New York: Academic Press, with permission from Elsevier.)

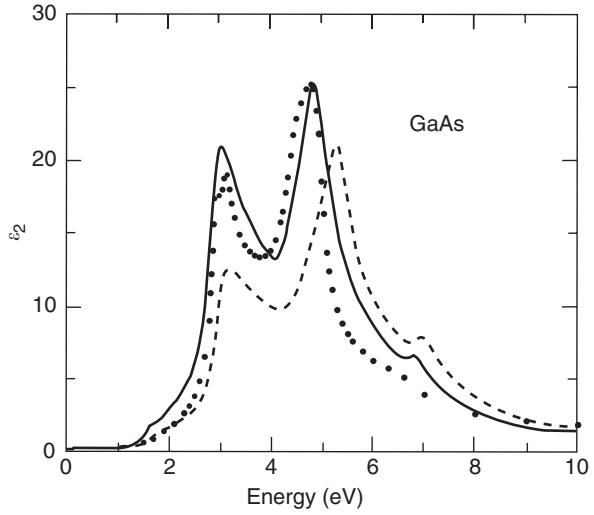

Figure 8 TRT pseudopotential calculations of the reflectance spectrum of GaAs (including oscillator strength redistribution to lower energies caused by interactions between excited electrons and holes) are in excellent agreement with experiment. (Reproduced with permission from Rohlfing M and Louie SG (1998) Electron–hole excitations in semiconductors and insulators. *Physical Review Letters* 81: 2312; © American Physical Society.)

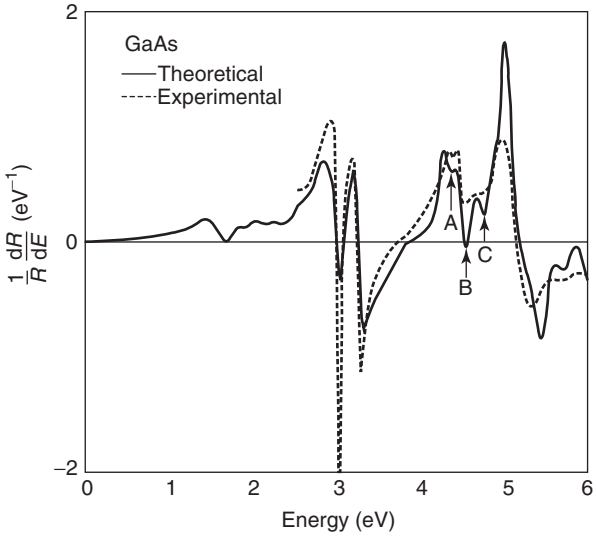

Figure 9 The derivative of the reflectance spectrum shown in **Figure 8** has also been calculated by one-electron TRT pseudopotentials; this derivative is less sensitive to many-electron interactions than the original spectrum, and the calculated results are in spectacularly good agreement with experiment. (Reproduced from Ricardo, Zucca RL, Walter JP, Shen YR, and Cohen ML (1970) *Solid State Communications* 8(8): 627–632, with permission from Elsevier.)

calculated including corrections for the Coulombic final state (excitonic) interactions. The resulting optical spectra agree so well with experiment (see **Figure 8** for GaAs) that often the discrepancies result merely from experimental problems with sample surfaces. Moreover, lock-in modulation methods uncover the fine structure in the reflectivity spectra (see **Figure 9** for GaAs) with an improvement in resolution of at least a factor of 10, as well as doubling the number of identified symmetry transitions. The static dielectric constant $\varepsilon_1(0)$ is connected to the absorptive dielectric function $\varepsilon_2(\omega)$ through the Kramers–Kronig relation as an integral over $\varepsilon_2(\omega)$. Thus if the average energy gap is $E_g^2 = E_h^2 + C^2$, then all the symmetry-derived peaks in $\varepsilon_2(\omega)$ should follow similar trends, using the same values of the dielectric electronegativity difference C. This is indeed the case; there are small downward shifts in peak energies relative to one-electron calculations, but

most of these are already incorporated into the definition of C from $\varepsilon_1(0)$, which itself includes similar corrections.

Electronic States of Defects

The most common defects in compound semiconductors are vacancies and antisite defects (i.e., A ions on B sites). The energies of formation and the electronic states associated with these defects depend on the position of the Fermi energy (the doping level) and strain. These energies can be estimated very accurately using pseudopotentials. The antisite defect energies are at least ten times smaller than the vacancy energies, and are comparable to thermal energies at growth temperatures. Thus antisite defects are the most important defects in most compound semiconductors. An example is strain at quantum well interfaces. Macroscopically, one would expect that such interfaces would be most stable when strain-free. In practice, a small amount of interfacial misfit is found to be optimal. This misfit may suppress diffusion of antisite defects; it is larger, for example, in InP-based cases (large antisite size difference) than in GaAs-based cases (small antisite size difference). Empirically, in manufacturing devices, the presence of these defects is reduced by the use of proprietary (confidential) methods. In other words, here science and technology are separated by important business considerations.

Surfaces and Interfaces

Another technologically important topic is the nature of the electronic states at surfaces and interfaces. The chemistry of these states is different in compound semiconductors than in elemental semiconductors. In the most important case – Schottky barriers between metals and compound semiconductors such as GaAs – the interface states for a midgap Fermi energy are taken mainly from the metal and the conduction band of the semiconductor.

PbS or A^NB^{10-N} Compounds

The two extra electrons outside the sp^3 octets are an extra s^2 lone pair associated with the cation: other examples of these compounds are GeTe, SnSe, SnTe, PbSe, and PbTe, as well as the elemental materials As, Sb, and Bi. The crystal structure is usually rock salt (sixfold coordinated). The weakly bound s^2 electrons produce strong absorption in the infrared region ($\sim$0.2 eV). The spin–orbit splittings of heavy elements such as Pb and Te are larger than the energy gaps, and produce unusual band structures calculated again very accurately by pseudopotential methods, in excellent

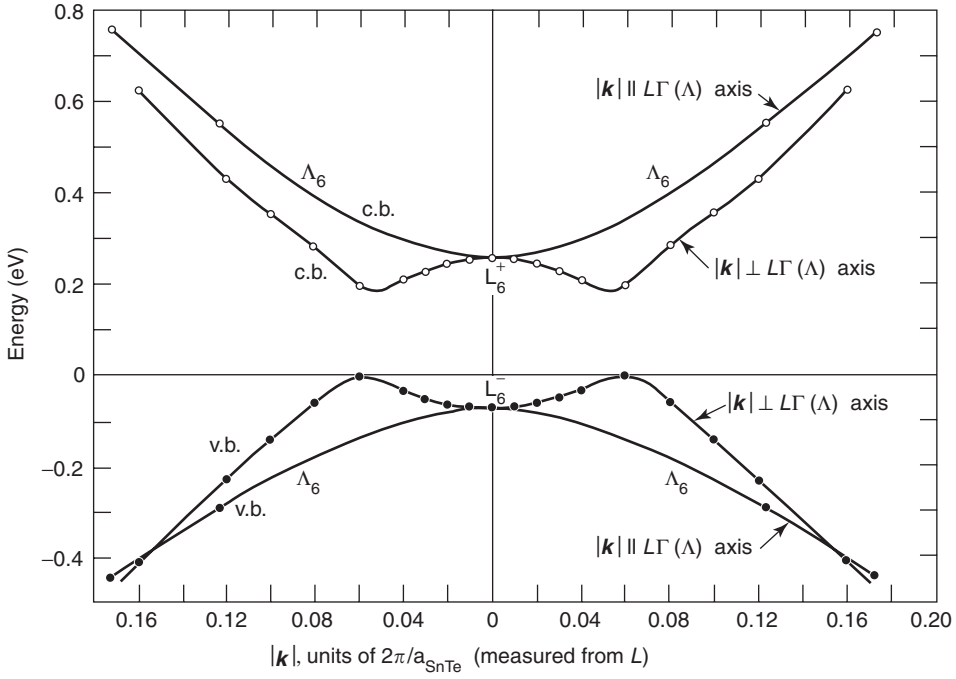

Figure 10 The structure of the energy bands of SnTe near the energy gap is complex. The complexity is caused by a combination of factors, including inversion of energy levels relative to octet compounds by the presence of lone pair electrons, and very large spin–orbit splittings. (Reproduced from Tung YW and Cohen ML (1969) *Physics Letters A* 29(5): 236–237, with permission from Elsevier.)

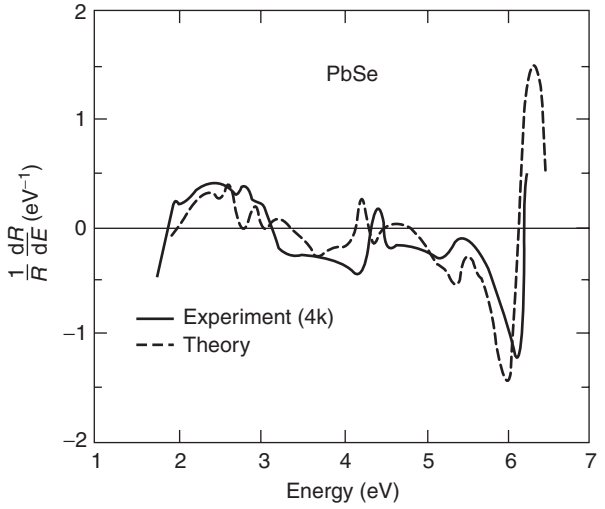

Figure 11 The modulated (derivative) reflectivity spectra of A^NB^{10-N} compounds calculated by one-electron TRT pseudopotentials are also in spectacularly good agreement with experiment. The example shown here is PbSe. (Reproduced with permission from Kohn SE, Yu PY, Petroff Y, Shen YR, Tsang Y, *et al.* (1973) *Physical Review B* 8:1477–1488; © American Physical Society.)

agreement with optical data. The band structures of these compounds can be quite complex, as illustrated for the example of SnTe in **Figure 10**. Again TRT pseudopotential derivative reflectivity spectra are in excellent agreement with experiment, as shown for the example of PbSe in **Figure 11**.

Ternary Octet Compounds

Further refinements and additional tunability (sometimes called band-structure engineering) are possible in two ways: through alloying (next paragraph) and through supercell formation (ternary compounds), the most important example being the octet chalcopyrite compounds $A^{II}B^{IV}C_2^V$ ($CuB^{III}C_2^{VI}$) which are pseudo III–V (II–VI) compounds with tetragonally distorted structures. Phase diagrams and accordingly sample preparation are complex in the chalcopyrites, in order for the cations to order on their respective sublattices in a unique polytype. Thus, the TRT pseudopotential theory has played a very important part in the development of these materials.

Electronic Structures of Alloys

The most important optical materials in practice (see following section) are semiconductor III–V alloys. The energy bands and optical transitions of these alloys are given approximately by linear interpolation between the corresponding structures of their end point pure compounds, as one would expect from a random distribution of ions on the alloying sublattices (ideal solution). (Note that ions alloyed on a sublattice are second nearest neighbors and hence interact much more weakly than atoms alloyed on the entire lattice, for instance, in (Si, Ge) alloys.) However, small curvatures are observable, and are of great practical importance for bandgap tunability; the curvatures are successfully predicted by treating the alloys as regular solutions.

Applications

As noted above, many compound semiconductors have electronic structures with valence and conduction band edges at $k = 0$ (the Brillouin zone center, often denoted conventionally by Γ), so that their lowest energy optical transitions are direct, a necessary condition for semiconductor quantum well lasers. The quantum wells themselves enhance the overlap between excited electron and hole wave functions, increasing oscillator strengths, lowering lasing thresholds, and increasing laser intensities. The transparency window of silica-based optical fibers is fixed by nature in the near infrared, and because of bandgap engineering it is possible to design semiconductor lasers that emit light at any desired wavelength in this window. The actual alloys used are quaternary (In, Ga) (P, As) alloys, and it is semiconductor multiquantum well lasers based on these alloys that have revolutionized civilization in the twenty-first century. The lifetimes of these lasers are fixed mainly by the quality of interfaces (semiconductor and semiconductor-metal). Other compound semiconductors are utilized in many other applications as far infrared detectors, and light emitting diodes are now manufactured over a wide range of colors up to the ultraviolet ((InGa)N).

Semiconductor Devices

T Takahashi, University of Tokyo, Tokyo, Japan

Introduction

Semiconductor devices are key devices in modern electronics, and are roughly categorized into electronic devices and optical devices. The main applications as electronic devices are junction diodes, transistors, and memories, which are widely used in large-scale integrated circuits (LSI), as well as power devices such as thyristors and so on. As optical devices, light emitting diodes (LEDs), laser diodes (LDs), and photo detectors (PDs) are utilized in optical display and communication systems, while solar cells are important for energy conservation. In the following sections, the basic principles of these devices are described.

Junction Diodes

A junction of *p*-type and *n*-type semiconductors makes a diode structure as shown in **Figure 1**. Electrons or holes are the majority carriers in the *n*-type or *p*-type semiconductor, respectively. In the thermal equilibrium condition, the electrons in the *n*-type region near the *p–n* junction interface diffuse toward the *p*-type region because of the concentration gradient, and the holes in the *p*-type region diffuse vice versa. Then a depletion region or a space charge region, where no free carriers exist, appears. If one assumes an ideal *p–n* junction, which is very abrupt and the depletion completely occurs as shown in **Figure 2**, the built-in potential V_{bi} that appears across the junction is given by

$$V_{bi} = \tfrac{1}{2} E_m (x_p + x_p)$$

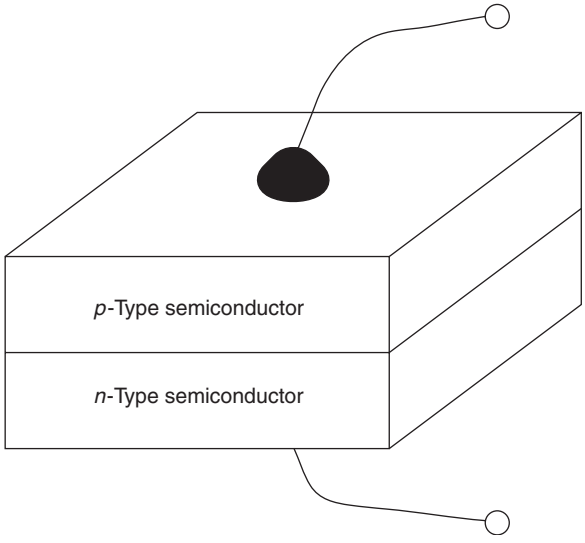

Figure 1 A schematic illustration of a *p–n* junction diode.

where

$$E_m = \frac{qN_A x_p}{\varepsilon_s} = \frac{qN_D x_n}{\varepsilon_s}$$

and the depletion region width W is given by

$$W = \sqrt{\frac{2\varepsilon_s}{q}\left(\frac{N_A + N_D}{N_A N_D}\right) V_{bi}}$$

(here, q is the unit charge and ε_s is the dielectric constant).

When a positive bias V is applied to the *p*-type region with respect to the *n*-type region, the holes in the *p*-type region easily move into the *n*-type region, and the electrons in the *n*-type region move in the opposite direction. Thus a large current flows across the junction. Such a bias condition is called a forward bias. When, on the other hand, the bias condition is inversed, which is called a reverse bias, the majority carriers are not able to move at all. Then the

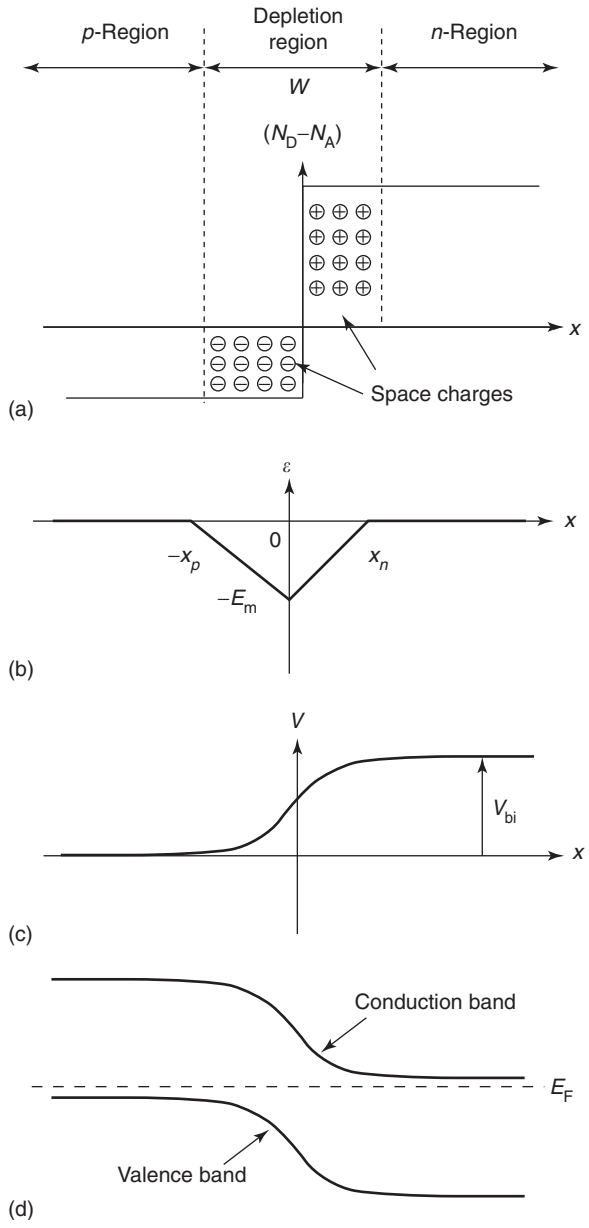

Figure 2 (a) Space charge distribution, (b) electric field distribution, (c) potential variation, and (d) energy band diagram of an ideal *p–n* junction in thermal equilibrium condition.

total current density J flowing across the junction is given by $J = J_s(e^{qV/kT} - 1)$, where J_s is the saturation current density, k is the Boltzmann constant and T is the temperature. Therefore, the diode has asymmetric current–voltage characteristics against the bias voltage V as shown in **Figure 3**, and the diode device achieves a rectification property for alternating currents. This rectification effect in the *p–n* junction is very important in most semiconductor devices because it can control the current flow by blocking undesirable current leakage. In the real *p–n* junction diode, however, a voltage breakdown occurs at a high reverse bias, which gives the reverse bias tolerance of the diode, also shown in **Figure 3**.

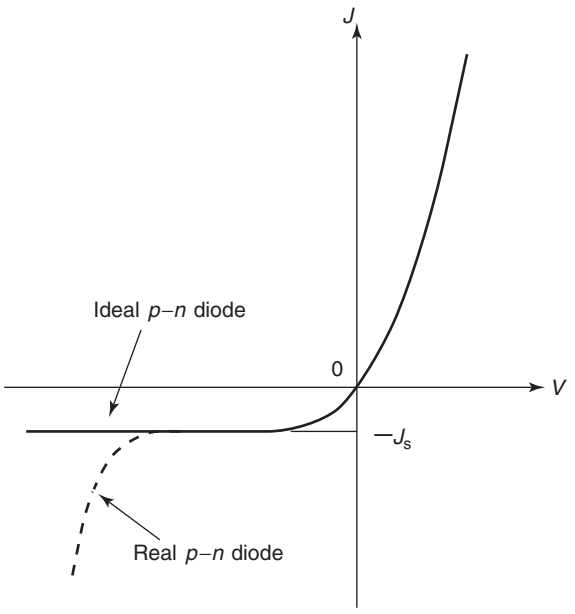

Figure 3 Current voltage characteristics in the *p–n* junction diode.

Bipolar Transistors

The bipolar transistor which was invented by a research group at Bell Laboratories in 1947 has become one of the most important semiconductor devices today. It consists of two *p–n* junctions, that is, *p–n–p* or *n–p–n* structures as shown in **Figure 4**. These three regions are called emitter, base, and collector. In the symbols of the *p–n–p* and *n–p–n* transistors, the arrow indicates the direction of current flow under normal operating conditions, where forward and reverse biases are applied to the emitter–base and collector–base junctions, respectively. The specific features in the bipolar transistor are the very thin base and the highly doped emitter. The latter brings a high injection of carriers into the base region, where the injected carriers becomes the minority, while those carriers pass through the base region into the collector with a very small recombination rate owing to the former feature. Therefore, the collector current I_C can be represented by the emitter current I_E as $I_C = \alpha I_E$, where α is slightly less than 1. In general, a forward bias V_{EB} is applied to the emitter–base junction, but the collector–base bias V_{CB} is in a reverse bias condition. Since the collector junction is highly and reversely biased, the power amplification against the input power to the emitter junction is achieved. In the following discussion, the *p–n–p* transistor is considered but an appropriate

change of polarities makes the results applicable to the *n–p–n* transistor. The basic model for the bipolar transistor is the Ebers–Moll model, in which the transistor is represented by two diodes connected face to face and two current sources. A circuit diagram in the Ebers–Moll model for the *p–n–p* transistor is illustrated in **Figure 5**. In this model, a current I_R flowing through the collector–base diode determines a current value from the current source in the emitter side, and a current I_F through the emitter–base diode determines a current from the current source in the collector side. Here, amplitudes of current gain α_R and α_F that are barely less than 1.

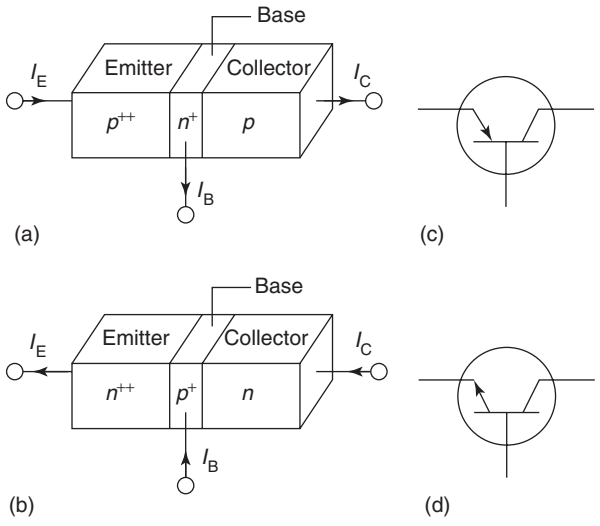

Figure 4 Schematic illustrations of (a) *p–n–p*, (b) *n–p–n* bipolar transistors and their symbols (c–d).

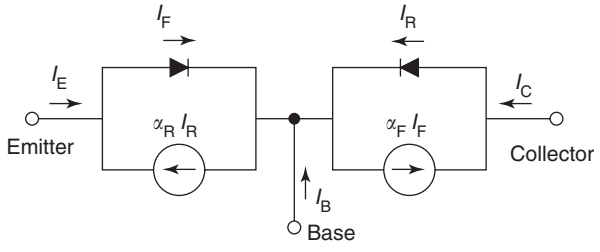

Figure 5 A circuit diagram of the Ebers–Moll model of the *p–n–p* bipolar transistor.

There are three configurations of the bipolar transistors as shown in **Figure 6**. In the common-base configuration, where the base lead is used as a common terminal for input and output, a signal is inputted to the emitter–base junction that is forwardly biased, while a load resistance is connected to a side of the reversely biased collector–base junction to extract an output signal. The common-base configuration is suited for a low input impedance circuit. According to the Ebers–Moll model, the collector current I_C is given by $-\alpha_F I_F$ because I_R is almost zero. In this configuration, therefore, only voltage amplification is obtained without current amplification. On the other hand, the common-emitter configuration, in which the emitter lead is used as a common terminal, is most widely used, and the current amplification as well as the voltage amplification is achieved because the collector current I_C is given by $I_C = \alpha_F I_B/(1-\alpha_F)$ and the collector–base junction is still reversely biased. On the contrary, the common-collector configuration gives only a current gain without the voltage amplification, which is useful as an impedance converter. The typical output characteristics for the bipolar transistor in the common-base and common-emitter configurations are illustrated in **Figure 7**.

Since a current density strongly depends on the *p–n* junction cross section, and a switching speed is determined by the base region thickness in the bipolar device, they can easily be improved by using a large junction cross section and a thin base region, respectively. Therefore, bipolar devices are also suited for high speed and/or power devices. The three *p–n* junctions in series, such as *p–n–p–n* or *n–p–n–p* structures, are used in three- or four-terminal devices, in which bistable operations with low-power dissipation is possible. These devices are called thyristors and are applicable in high-current, high-voltage, or high-power switching devices.

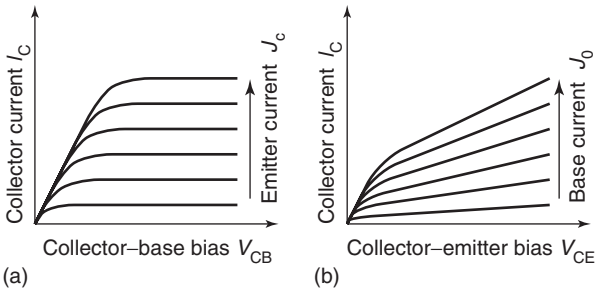

Figure 7 Typical output characteristics for the bipolar transistor in the (a) common-base, and (b) common-emitter configurations.

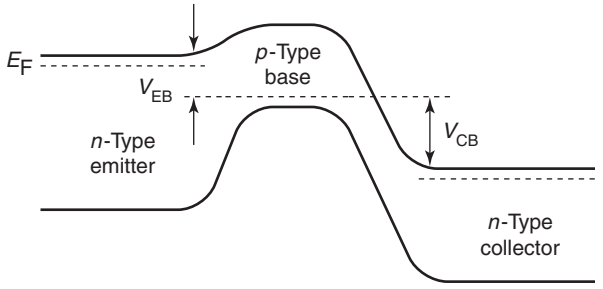

Figure 8 A schematic of the *n–p–n* heterobipolar transistor.

One may change one or all the lead materials in the bipolar devices in order to be different from others as shown in **Figure 8**; such devices are called heterobipolar devices. In heterobipolar devices, many performances are well improved. For instance, (1) high-emitter efficiency owing to the blockade of the hole injection (the minority carrier injection for the emitter) from the base into the emitter by the high barrier in the valence band, (2) low-voltage drop at the emitter–base junction, and (3) high-frequency response owing to a high-current gain and low-base resistance because heavy doping in the base region is possible without degrading emitter efficiency.

Field Effect Transistors

Similar to the bipolar transistor, a field effect transistor (FET) has three terminals, called source, gate, and drain. There are some variations of FET structures as illustrated in **Figure 9**. In the junction FET(JFET), which was the first proposed of all FET devices, the gate bias voltage varies the depletion region width at the *p–n* junction under the gate to control a channel conductance. In the metal–semiconductor FET (MESFET), a Schottky junction is formed between a gate metal and a channel semiconductor, and the depletion width is varied by the gate voltage. On the other hand, a metal-insulator-semiconductor (MIS) structure, in which an insulator

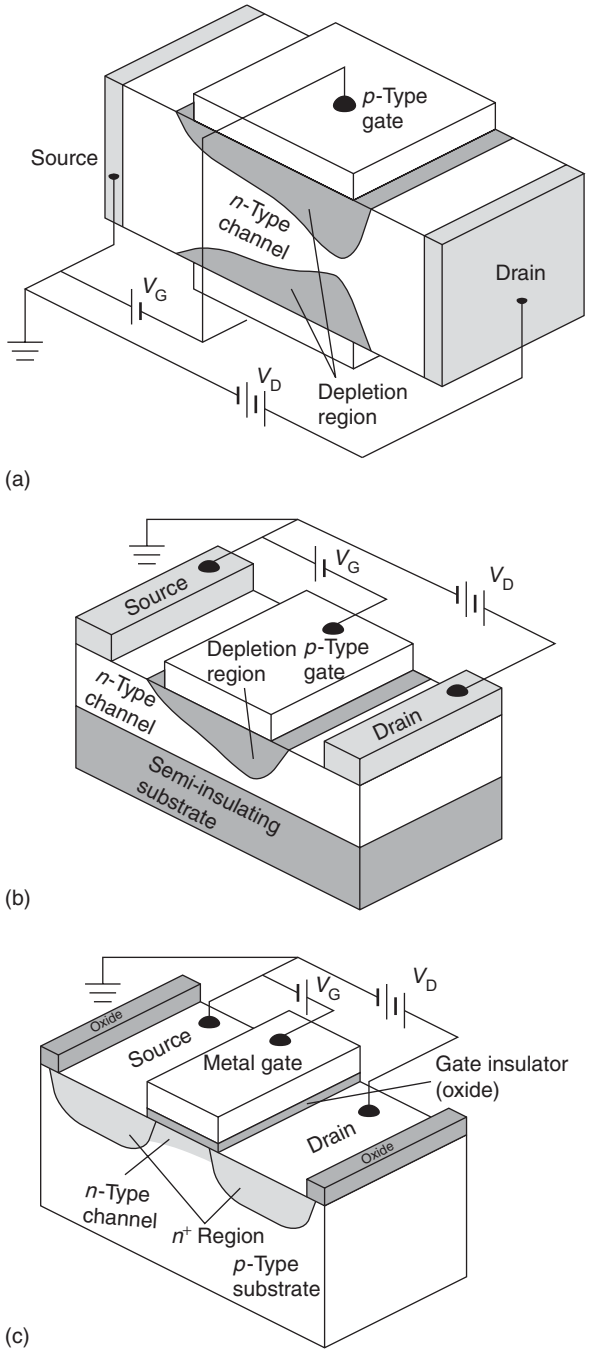

Figure 9 Some variations of the FETs; (a) a JFET, (b) a MESFET, and (c) a MISFET. In the case of using an Si dioxide film as an insulator, the FET is specially called a MOSFET.

film is inserted under the gate electrode to prevent current leakage between the gate and the channel, is suited for FET devices. Especially, silicon dioxide is widely used as an insulator in silicon FETs, which are called metal-oxide–semiconductor FET (MOSFET). In contrast to the bipolar transistor in which both positive and negative charges play important roles, only unipolar charges flow in the FET channel. Thus

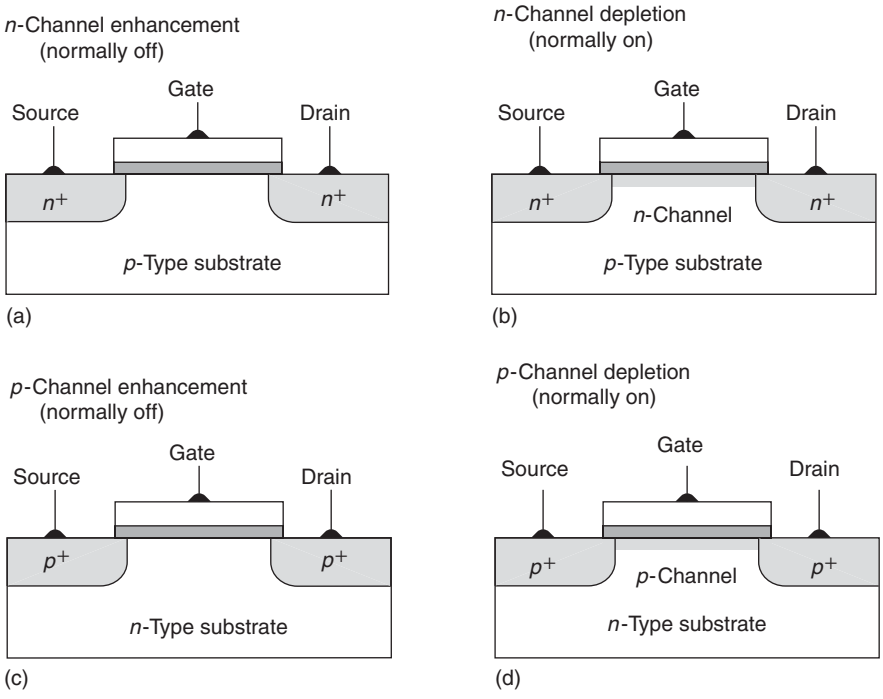

Figure 10 Four basic types of MOSFETs at zero gate voltage.

the FET is classified into either an *n*-channel or a *p*-channel FET. It is also possible to categorize MOSFET by the conductivity at zero gate bias into a normally-off type or a normally-on type as shown in **Figure 10**. If the channel conductance is very low at the zero gate bias and a positive bias to the gate is required to form a conductive *n*-channel, this type is called the normally-off (or enhancement) *n*-channel MOSFET. The MOSFET, in which the *n*-channel is sufficiently conductive even at the zero gate bias and one has to apply a negative bias to the gate to reduce the channel conductance by depleting the channel carriers, is the normally-on (or depletion) *n*-channel MOSFET. Similarly, there are the normally-off (enhancement) and normally-on (depletion) *p*-channel MOSFETs.

Now, a complementary use of the *p*-channel and *n*-channel MOSs in series, for instance, the normally-on *p*-channel and the normally-off *n*-channel MOSs, forms a complimentary MOS (CMOS) configuration as shown in **Figure 11**. In the CMOS, a low-input voltage (typically, $V_{low} = 0\,V$) keeps the *n*-channel enhancement MOS (normally-off) in the "off-state" (highly resistive) and the *p*-channel depletion MOS (normally-on) in the "on-state" (highly conductive). Therefore, an output is equal to the high source voltage. In contrast, a high input (typically, $V_{high} = 5\,V$) turns the *n*-channel MOS into an "on" state and the *p*-channel MOS into an "off" state, and therefore,

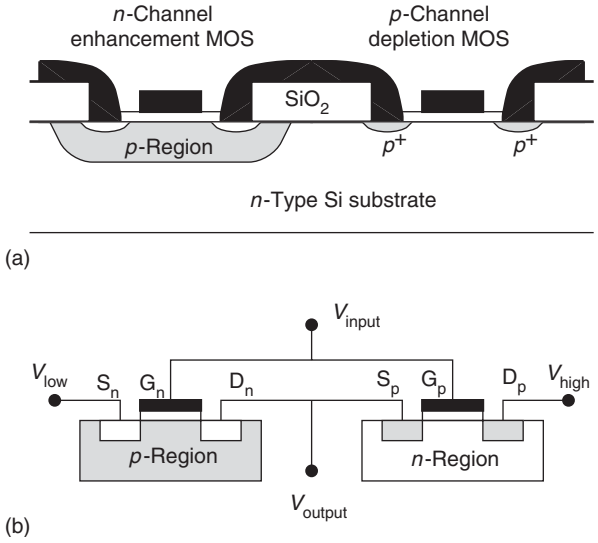

Figure 11 (a) A schematic of the CMOS structure, and (b) its equivalent electrical scheme.

the output becomes low level. Thus an inverter operation is realized by the CMOS configuration. In addition, a steady current passing through both the *n*-channel and *p*-channel MOSs can be sufficiently suppressed and the passing current only flows at the switching period, resulting in a very low power consumption in the circuits. Moreover, since the FET suits a planar configuration, CMOS transistors are mostly used in an integrated circuit (IC) or LSI.

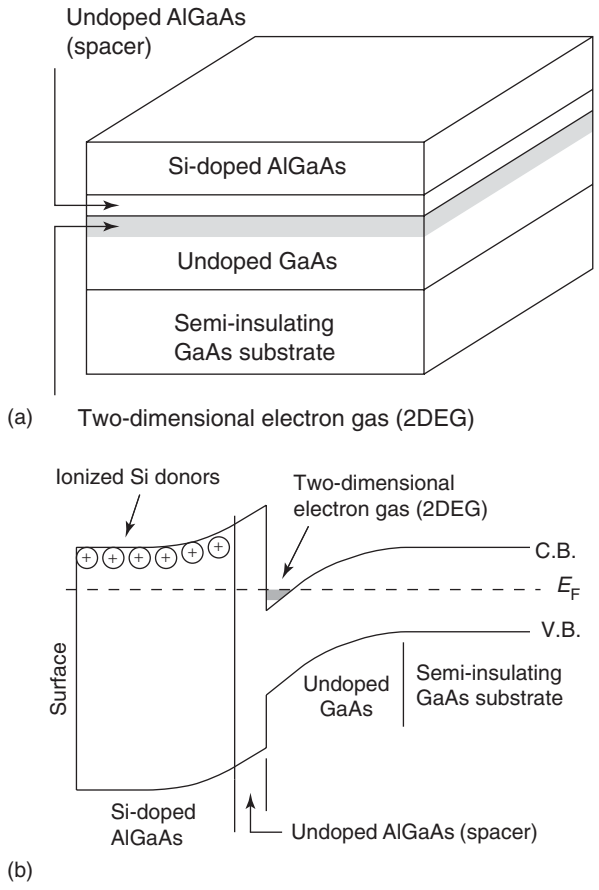

Figure 12 (a) A device structure, and (b) an energy band diagram of the HEMT realized by using the semiconductor hetero-structures.

By using compound semiconductor hetero-structures and a modulation doping technique, a high electron mobility transistor (HEMT) was realized as shown in **Figure 12**. The potential confinement of electrons at the heterointerface gives rise to a two-dimensional electron gas (2DEG). In the 2DEG system, the electron scattering probability is reduced because the states that the electrons can occupy are limited. In addition, the modulation doping also reduces the electron scattering rate by impurities because of a spatial separation between the conducting electrons and the impurities. Owing to these two effects, very high electron mobility is achieved in the HEMT device. Consequently, the HEMT device is practically used in high-speed applications.

Memories

Another key device for the LSI circuits is a memory device. A conventional memory cell needs capacitors, in which data are stored as charges, and the memory devices can be categorized into volatile and nonvolatile types. The volatile memory allows a very high access rate though it consumes a large quantity of power for keeping data, a typical device of which is a dynamic random access memory (DRAM). The DRAM, therefore, is suited for main memories in the LSI circuits. In order to integrate a lot of DRAMs in the LSIs, a deep-trench structure is used for keeping capacitance sufficiently large. In the nonvolatile one, on the other hand, the access time is relatively long but data can be kept without power consumption; typical devices are floating gate RAM (FRAM) and static RAM (SRAM), which are applied to mobile telephones, for instance.

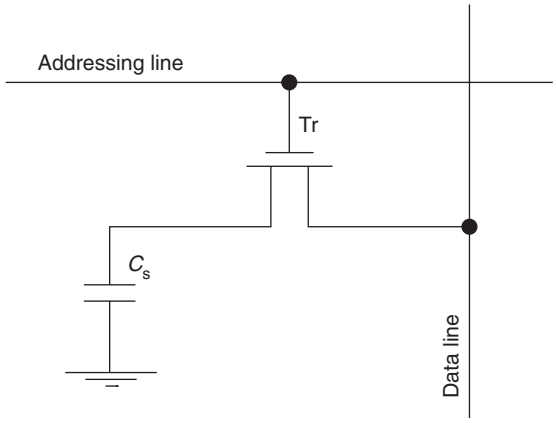

Figure 13 A schematic of a one-bit memory cell in the simplest DRAM.

In most of the cases, the memory is fabricated by the compatible process of CMOS technologies. To access the memory, charging or discharging the capacitor is done for writing or reading, respectively, through the transistor connected to an addressing line. **Figure 13** shows a one-bit memory cell in the simplest DRAM. For writing, the transistor channel is opened by an appropriate bias applied to the addressing line with a high bias applied to the data line, and subsequently the capacitor C_s is charged. For reading, on the contrary, the transistor channel is also opened and a voltage appearing in the data line is detected. If the capacitor has been charged, a certain value of voltage appears, while no voltage appears when no charge has been stored in the capacitor. These two states correspond to "1" and "0" as one bit in the binary logic.

Photodetectors and Photodiodes

Semiconductor photodetectors can detect optical signals through electronic processes. Light incident on a semiconductor excites electrons from the valence band to the conduction band, if the photon energy of the incident light exceeds a semiconductor

bandgap energy, and, then, a current or a voltage is generated in the semiconductor. Thus, the photodetector acts as a current source or a voltage source under the light illumination.

Generally, photodiodes consist of *p–n* or *p–i–n* (*i* means an intrinsic layer) structures. An electric field, existing at the depletion region around the *p–n* interface or the intrinsic region, is very important to separate photogenerated electron–hole pairs. The thin depletion region leads to a high-speed operation but low quantum efficiency (a ratio of the generated electron–hole pairs to the incident photons), while the thick one leads to the opposite. The basic operation mode of the *p–i–n* photodiode is illustrated in **Figure 14**. When the reversal bias applied to the *p–i–n* structure enhances a separation rate of the photogenerated electron–hole pairs, a high-speed operation is possible even if the depletion region is thick enough to achieve a high quantum efficiency. Especially, when a very high electric field is applied in the thick intrinsic region, secondary ionization occurs and thus the number of electrons and holes dramatically increases, resulting in quite high efficiency, which is called an avalanche photodiode (APD).

The detectable wavelength range of the photodiode is an important parameter. The long-wavelength cutoff is determined by the bandgap of the semiconductor material used in the photodiode because of the lower photon energy light, which means that a wavelength, longer than the bandgap cannot be absorbed in the semiconductor. On the other hand, the absorption coefficient for a short-wavelength light is quite high, so such a light is absorbed very near the surface. Since, the carrier recombination occurs very frequently via the surface states, most of the photocarriers recombine without either being collected in the *p–n* junction or contributing to the current. This limits the short-wavelength cutoff in photodiodes.

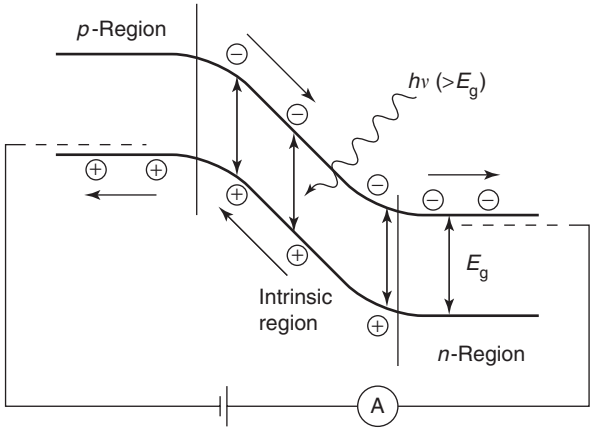

Figure 14 Basic operation mode of the *p–i–n* photodiode.

Solar Cells

A similar *p–n* diode structure in the photodiode can be used as a solar cell, which works as an electricity source. In particular, a detectable wavelength range in the solar cell is well optimized to fit the spectrum of sunlight. The photocarriers generated in the *p–n* diode are extracted as a current source, while photovoltage appears between the *p*- and *n*-type semiconductor ends due to the photocarrier separation. A current–voltage curve in the *p–n* diode changes under the light illumination as shown in **Figure 15**. The property of the solar cell is characterized by three important parameters; the short-circuit current I_{SC}, the open-circuit voltage V_{OC}, and the maximum power rectangle P_M. High I_{SC} and V_{OC}, resulting in large P_M, are desirable. Since the photoabsorption spectrum of Si material matches the incident sunlight spectrum to some extent, Si is one of the best materials for solar cells. Si solar cells have already been used as alternative energy resources in both high- and low-power applications.

Light Emitting Diodes

When the electron–hole pair disappears by recombination, it should convert its energy to other constituents because of the energy conservation law. In direct transition semiconductors such as GaAs, photons whose energy corresponds to the recombination energy are emitted, while phonons are emitted, in

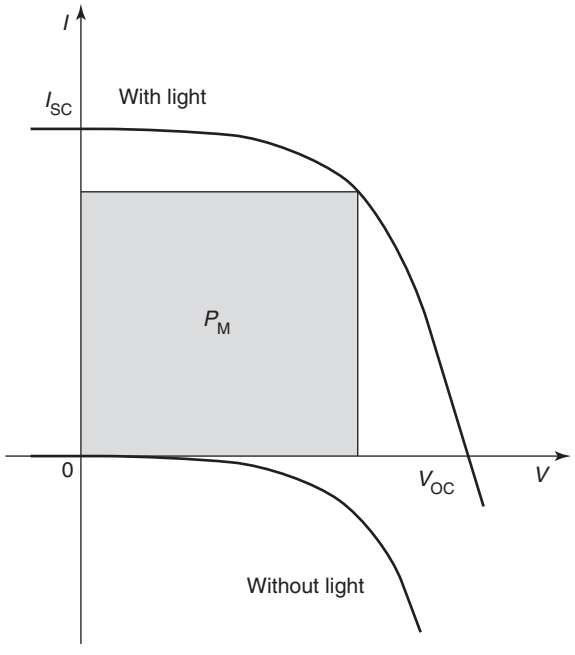

Figure 15 Typical current–voltage characteristics in the *p–n* solar cell with or without the light illumination.

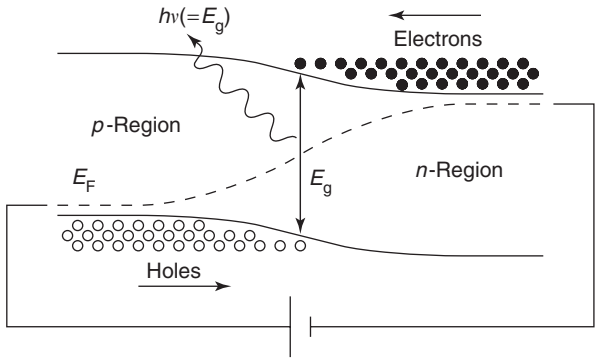

Figure 16 Electron and hole injections through *n*-type and *p*-type regions, respectively, in the LED. The emitted photon energy is almost equal to the bandgap energy.

most cases, in indirect transition semiconductors, and the semiconductor materials are heated. Especially where electrons and holes are intentionally injected from electrodes, a current–light conversion is achieved in the direct transition semiconductors. The *p–n* or *p–i–n* diode structures are suited for devices similar to photo detectors, and they are called LEDs. The electrons supplied from the *n*-type region and the holes from the *p*-type region recombine near the *p–n* interface or in the intrinsic region with light emission as illustrated in **Figure 16**. Since most electrons and holes distribute at the conduction and valence band edges, respectively, the emitted photon energy is almost equal to the bandgap energy. Therefore, the wavelength of the emitted light can be selected by an appropriate choice of the semiconductor materials. Especially by using compound semiconductors, the wavelength of the LED can be tuned in a wide range, for instance, from orange to near-infrared through red wavelengths by $A1_xGa_{1-x}As$ or $GaAs_{1-x}P_x$ materials with various mole fraction x. Very recently, green or blue LEDs were achieved by GaN-related materials. As a result, semiconductor LEDs can realize full color display devices.

Laser Diodes

In LEDs, the light is emitted through a spontaneous recombination process of the electron–hole pairs. On the other hand, the electron–hole recombination is stimulated if there exists a light whose photon energy is same as the recombination energy. This stimulated recombination process plays an important role in lasers. Since the basic structure of the semiconductor laser is almost same as that of the LED, semiconductor lasers are often called laser diodes (LDs). The difference between LDs and LEDs is that the LDs have a cavity for lasing as shown in **Figure 17**. In the cavity, the light travels back and forth and is

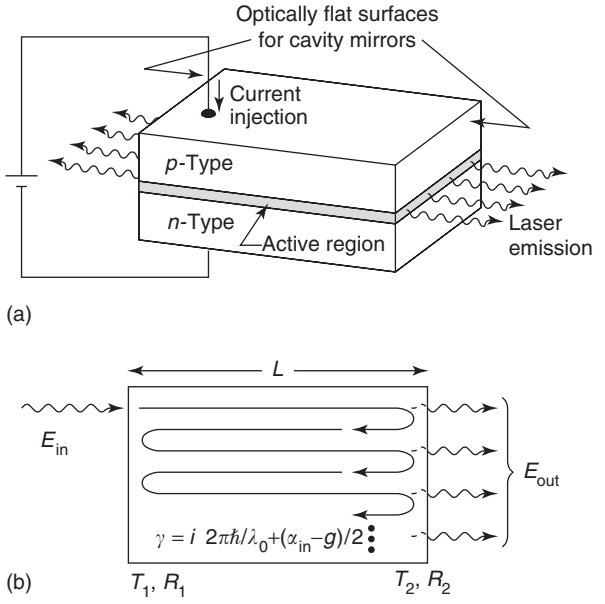

Figure 17 (a) A schematic of the LD where a laser cavity is added to the LED structure to achieve the laser oscillation, and (b) a model of light traveling in the laser cavity.

amplified by the stimulated emission. It is assumed that an incident plane wave to the cavity is $E_{in} = E_0 e^{j(\omega t - kx)}$, reflectances for input and output mirrors are R_1 and R_2, transmittances for the input and output mirrors are T_1 $(=1-R_1)$ and T_2 $(=1-R_2)$, respectively, and a parameter representing a change in both amplitude and phase for one way in the cavity is γ. Then the total output E_{out} is given by

$$\begin{aligned} E_{out} &= E_{in}T_1T_2e^{-\gamma L} + E_{in}T_1T_2R_1R_2e^{-3\gamma L} \\ &\quad + E_{in}T_1T_2R_1^2R_2^2e^{-5\gamma L} + \cdots \\ &= E_{in}T_1T_2e^{-\gamma L}(1 + R_1R_2e^{-2\gamma L} \\ &\quad + R_1^2R_2^2e^{-4\gamma L} + \cdots) \\ &= E_{in}T_1T_2e^{-\gamma L}\frac{1}{1 - R_1R_2e^{-2\gamma L}} \end{aligned}$$

If $1 - R_1R_2e^{-2\gamma L} = 0$ is satisfied, a finite output is obtained even when $E_{in} = 0$, and this is the oscillation condition for lasers. Now, γ can be rewritten as $\gamma = i2\pi\bar{n}/\lambda_0 + (\alpha_{in} - g)/2$ where $\lambda_0, \bar{n}, \alpha_{in}$, and g are the wavelength in vacuum, the refractive index, the cavity internal loss, and the optical gain in the cavity, respectively. Therefore, one can introduce the following equations from the amplitude and phase condition for lasing:

$$\begin{aligned} &R_1R_2\exp[(g - \alpha_{in})L] = 1 \\ &\quad - 2i(2\pi\bar{n}/\lambda_0)L = i2m\pi \quad (m = 1, 2, 3, \ldots) \end{aligned}$$

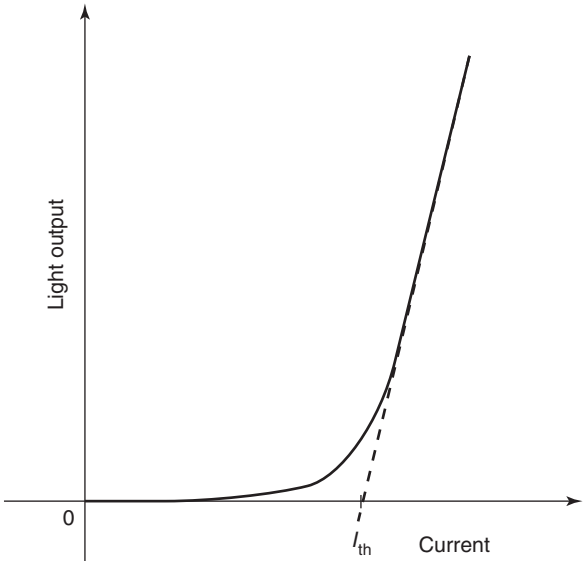

Figure 18 Typical current–light characteristics in the LD.

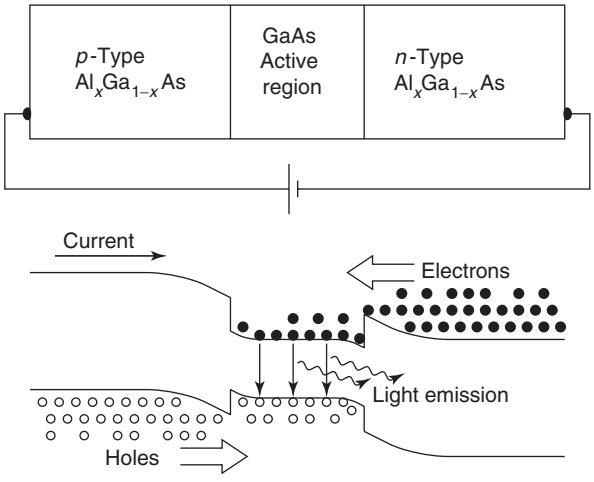

Figure 19 A double heterostructure to confine the carriers in the active region efficiently.

From the former equation, the threshold gain for lasing is given as $g = \alpha_{in} + (1/L)\ln R_1R_2$, and the longitudinal mode of lasing light wavelength is given as $\lambda = 2L/m$ from the latter one. Consequently, if the amplifying gain owing to the carrier injection from outside is high enough to exceed the cavity losses (summation of internal loss and mirror loss), a laser emission occurs, that is, some threshold current is needed to achieve the laser emission. Above the threshold, the laser output power strongly increases as an increase of the injected current, as schematically illustrated in **Figure 18**. Since, on the other hand, the lasing wavelength is determined by the cavity length, the emitted light from the LDs is very coherent, very monochromatic, and highly directional, similar to other lasers such as solid-state lasers and gas lasers. The greatest advantage in LDs is their compactness in size. In order to confine the carriers in the active region where a stimulated recombination occurs, double heterostructures are widely used as shown in **Figure 19**. The active region, in which the bandgap is tuned to be a desirable photon energy, is sandwiched by the barrier regions which have wider bandgaps than the active region and are oppositely doped to inject electrons and holes separately. Such active and barrier regions also act as core and clad regions for a waveguide structure, respectively, owing to the difference in refractive index. As a result, the traveling light wave and the injected carriers are effectively confined in the active region, which contributes to the high emission efficiency in the LDs.

When electrons are confined in very fine quantum well (QW) heterostructures, a 2DEG is formed similar to the HEMT device. As illustrated in **Figure 20**, the electron density of states in the 2DEG system looks like a staircase, so the electron distribution in the 2DEG is more concentrated near the band edge than that in the three-dimensional free electron

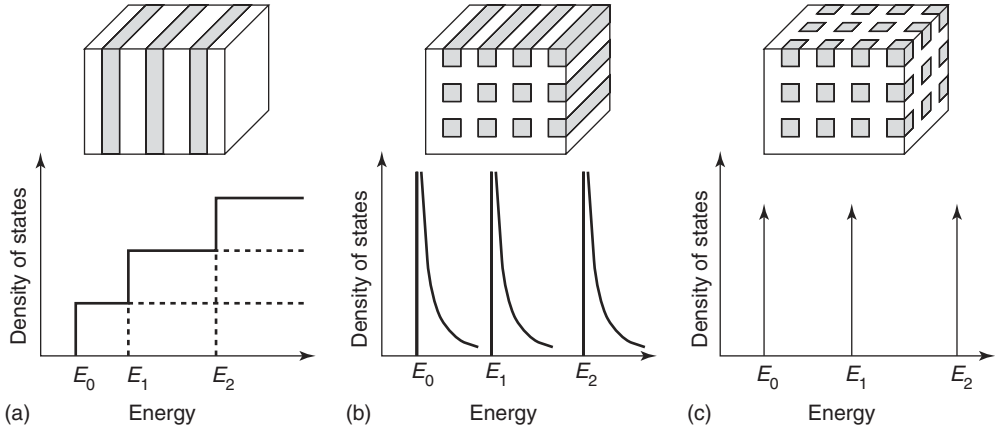

Figure 20 Schematics of the electron density of states in (a) two-dimensional, (b) one-dimensional, and (c) zero-dimensional electron gas systems in the QW, QWI, and the QD, respectively.

system, which well raises the current–light conversion efficiency in the QW. As a result, many improvements in the laser characteristics, such as low threshold current, high modulation frequency, and narrow spectrum line width, are realized. In addition, by adopting lower-dimensional electron systems in quantum wires (QWI) and quantum dots (QD), more improvements are expected owing to their sharper density of states, as illustrated in **Figure 20**.

Wide Bandgap Materials

For semiconductor devices such as Si, Ge, GaAs, InP and their compounds have widely been used since the invention of the bipolar transistor. Their bandgaps are 1–2 eV, resulting in most of the applications for optic devices being limited in the yellow, red, and infrared regions. However, according to the recent progress in crystal growth, it has been possible to fabricate the $A1_xGa_{1-x}N$ materials that have a wide bandgap, over 3 eV. By using them, green or blue light emission is realized. In addition, wide-gap materials have high voltage tolerance compared with the narrow-gap materials such that high electric fields can be applied to accelerate electrons, which brings about a possibility for very high-speed operations. Therefore, $A1_xGa_{1-x}N$ materials are very hopeful for electronic devices as well.

Semiconductor Heterojunctions, Electronic Properties of

M Peressi, University of Trieste, Trieste, Italy

Introduction

Semiconductor heterojunctions are built by joining, at a planar face, two semiconductors formed by different chemical elements but usually with similar lattice structure and chemical binding, as schematically indicated in **Figure 1**. From the simple heterojunction constituted by two thick slabs of different materials, which presents only one interface, different heterostructures can be formed – from the double heterojunction showing confinement properties for the charge carriers to the repeated heterojunctions (multiple quantum wells and superlattices) and new artificial structures based on sequences of alternating different semiconductors of varying thickness (10–1000 Å).

Semiconductor heterojunctions show peculiar electronic properties giving rise to physical phenomena of a quantum mechanical nature, some of them not possible even in any "natural" bulk material. These peculiar electronic features are determined by the spatial profile of the electronic bands, which is in turn controlled both by intrinsic characteristic of constituent semiconductors, such as lattice constants, energy gaps, doping, and extrinsic features such as chemical and structural details in the interface

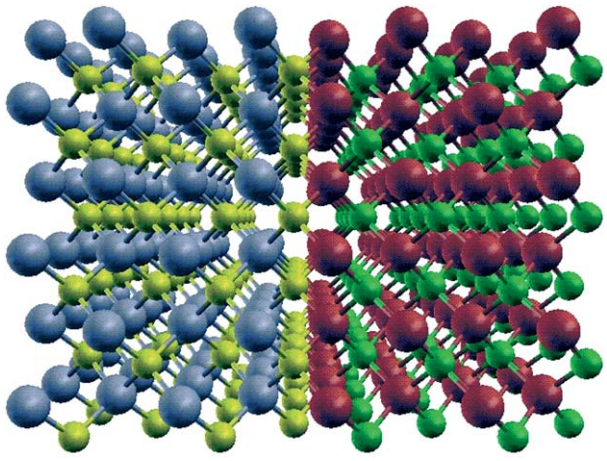

Figure 1 Stick-and-ball model of an abrupt semiconductor heterojunction between two zinc blende semiconductors with no-common ions. The interface is (0 0 1) oriented. (Adapted from Sorba L, *et al.* (1992) Structure and local dipole of Si interface layers in AlAs–GaAs heterostructures. *Physical Review B* 46: 6834.)

region, where the bands exhibit discontinuities (see **Figure 2**). The spatial profile of the electronic bands can be used to properly tailor the space-charge distribution and the behavior of the charge carriers both in the growth direction (transport properties) and in the potential wells parallel to the interface planes (confinement properties), giving the semiconductor heterojunctions a crucial role in modern electronic and optoelectronic devices.

The introduction of heterojunctions dates back to almost 50 years ago. Herbert Kroemer and Zhores I Alferov obtained the Nobel Prize in Physics in 2000 "for developing semiconductor heterostructures used in high-speed- and opto-electronics." In 1957, Herbert Kroemer published the first proposal for a heterostructure transistor. His theoretical work showed that heterostructure devices could offer superior performance compared to conventional transistors. In 1963, H Kroemer and Zhores I Alferov independently proposed ideas to build semiconductor lasers from heterostructure devices, using a double heterostructure to confine carriers. Alferov built the first semiconductor laser from gallium arsenide and aluminum arsenide in 1969.

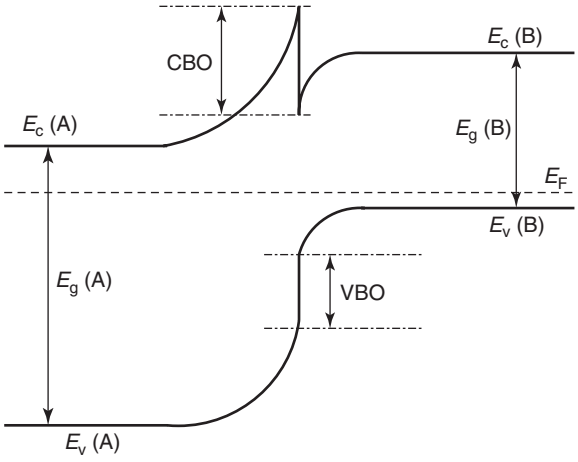

Figure 2 Schematic spatial profile of the valence and conduction bands along the growth direction for a semiconductor heterojunction, with band bending due to space-charge effects and definition of band offsets, VBO and CBO.

The traditional semiconductor heterojunctions involve elements of the central portion of the periodic table, starting from Si and GaAs. Si- and GaAs-based technology is the most mature, but many other III–V and II–VI binary compounds as well as alloys are used nowadays, the choice depending on the particular application. Among alloys, perhaps the most widely studied and used is $Al_xGa_{1-x}As$, in particular, in its interface with GaAs.

High-quality semiconductor interfaces are easily built from two semiconductors which are isovalent and lattice-matched, but more generally they can be also heterovalent (involving semiconductors of different groups) and lattice-mismatched, with slightly different lattice parameters. With the addition of nitrides of II(IV)–VI compounds and of magnetic semiconductors to the most conventional ones, the range of the lattice constants and of the energy gaps which is covered by the different constituents used to form heterostructures is very large, as indicated by **Figure 3**,

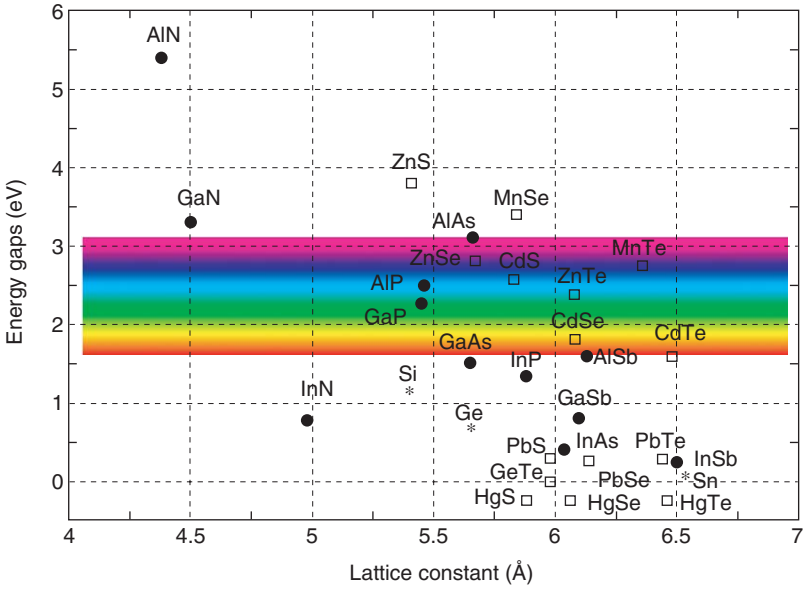

Figure 3 Energy gaps vs. lattice constants for various IV (stars), III–V (closed circles), II(IV)–VI (open squares) zinc blende semiconductors. The visible electromagnetic spectrum is also indicated.

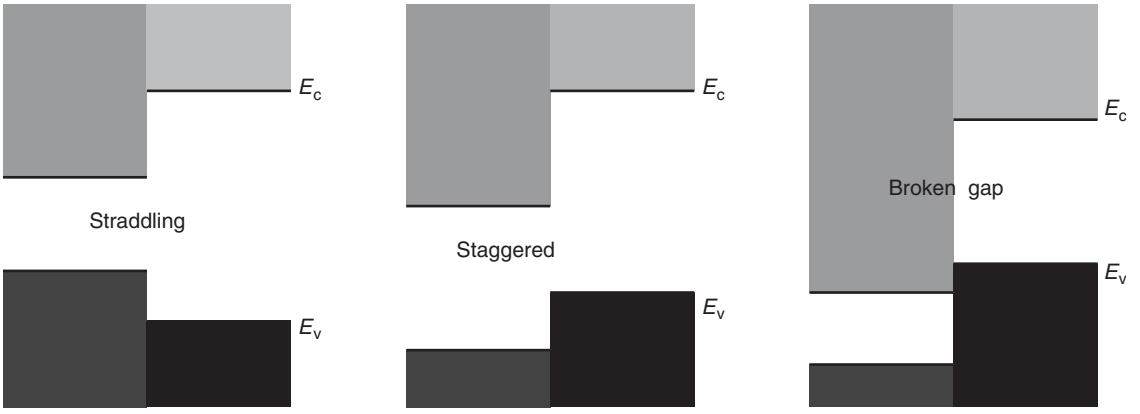

Figure 4 Schematic possible types of band alignments: (a) straddling, (b) staggered, and (c) broken gap. Flat bands are represented, as the focus is on a region which is of the order of 10 atomic units, and the band bending is negligible at this scale.

suggesting possibilities for new fundamental physics and device applications.

Thanks to the improvement of experimental techniques such as molecular beam epitaxy (MBE) and metal–organic chemical–vapor deposition (MOCVD), it is possible to grow high-quality pseudomorphic heterostructures without misfit dislocations or other defects, also with semiconductors with a rather small lattice mismatch (i.e., less than a few percent), and with different but almost commensurate structures.

A heterojunction indicated with A/B typically corresponds to a particular growth order: B is the substrate and A the epilayer. Another specific feature that is usually indicated is the crystallographic growth axis, which determines the interface plane.

Electronic Properties: Band Alignments

The spatial profile of the electronic bands is mostly determined by the band discontinuities at the interface. The bandgap difference ΔE_g, normally existing between the constituent materials, is shared among valence and conduction bands, thus giving rise to the valence and conduction band offsets (VBO and CBO):

$$\Delta E_g = \mathrm{VBO} + \mathrm{CBO} \qquad [1]$$

There are different types of band lineups which are possible, schematically indicated in **Figure 4**. The straddling or type-I lineup characterizes, for instance, the GaAs/$Ga_xAl_{1-x}As$ interface. Modern optoelectronic devices – including quantum well lasers – are based on such a lineup, typically with a double or repeated heterojunction, where the charge carriers are both confined in the slab of material with the lowest energy gap (see **Figure 5**). Other types of lineups are the staggered or type-II and the broken-gap or type-II-misaligned lineups, which could be preferred for some specific applications.

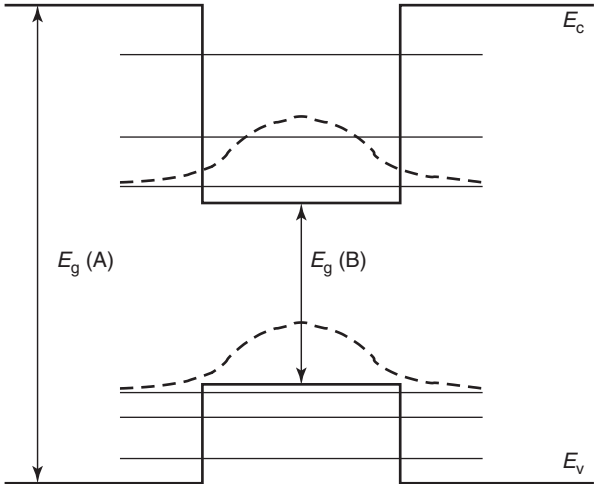

Figure 5 Confinement of electrons and holes in the slab of a material with the lower gap in a double semiconductor heterostructure with straddling-type band alignment.

Extensive theoretical and experimental work has targeted the problem of band alignments since a long time. In particular, an important and general issue widely debated is whether the band discontinuities are essentially determined by the bulk properties of the constituents, or if some interface-specific phenomena, such as crystallographic orientation and abruptness, may affect them in a significant way. A large joint experimental and theoretical/computational effort has been performed to finally clarify, quite recently, the physical mechanisms which give rise to the band alignment. Several books and review articles are available on the subject, as indicated in the "Further reading" section. Some of them are focused on the problem of band offset engineering, that is, on the possibility of controlling the interfaces thus

providing a way to manipulate the band lineups and tune the transport properties across the junctions.

Measuring Band Offsets

Several experimental techniques are available for measuring energy band discontinuities, including optical and transport measurements. Since the late 1970s, spectroscopic techniques have emerged as a fundamental tool for investigating heterojunctions on a microscopic scale. In photoemission spectroscopy, for instance, a direct measurement of the band discontinuities can be done by comparing specific core-level binding energies E_{cl} with respect to valence band top edges E_v in bulk samples with those from the heterostructure:

$$\begin{aligned}\mathrm{VBO} = &[E_{cl}(\mathrm{Ga}\ 3d) - E_v(\mathrm{GaAs})] \\ &- [E_{cl}(\mathrm{Al}\ 2p) - E_v(\mathrm{AlAs})] + \Delta E_{cl} \qquad [2]\end{aligned}$$

An example is schematically shown in **Figure 6** for the AlAs/GaAs(0 0 1) interface.

Predicting Band Offsets

Theoretical and numerical investigations based on different approaches have contributed toward predicting band offset values and identifying the basic mechanism responsible for band offsets. These investigations can be divided mainly into two classes: (1) models and approaches making simplifying and sometimes drastic approximations in describing the interface, but retaining important physical concepts, and (2) accurate computational predictions based on fully self-consistent *ab initio* approaches, which allow one to fully take into account the interface details, such as orientation, abruptness, and defects.

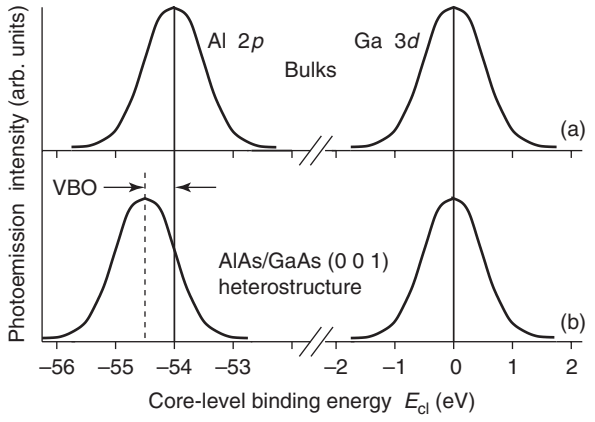

Figure 6 Example of a photoemission measurement of the band offset at the semiconductor heterojunction AlAs/GaAs(0 0 1). Core-level binding energy distribution curves for Al 2*p* and Ga 3*d* states referred to the corresponding AlAs and GaAs valence band top edges are schematically drawn. The zero of the energy scale is arbitrarily taken at the center of the Ga 3*d* emission peak. The variation of the separation ΔE_{cl} of the core level peaks from the case of the two bulks, considering the topmost valence bands of the two materials aligned (a) and the heterojunction (b) is a direct measurement of the VBO.

In general, no universal energy scale exists on which the band structures of the different semiconductors can be easily and uniquely referred, but simple and old models based on intrinsic reference levels have been widely used and have given successful predictions for a number of heterostructures: from the oldest models by Anderson, Frensley, and Kroemer, based on the difference between the electron affinities of the two semiconductors and the concept of charge neutrality levels, to Tersoff's model emphasizing the role of interface dipoles. More refined quantum mechanical approaches, based on the envelope function concept or using the tight-binding method have also been widely and successfully applied. They are reviewed in the books cited above.

The second class of theoretical/computational investigations, more recent, includes *ab initio* approaches, which are based on the solution of quantum mechanical equations for the system under consideration without any use of empirical parameters. This seemingly unaffordable task has been made feasible, thanks to the density-functional theory (DFT) proposed by Walter Kohn, who received the Nobel Prize in Chemistry in 1998 for the same, and for its approximations for practical applications, such as the local-density approximation. DFT has proven to yield reliable results, at an acceptable computational cost, on the electronic ground-state properties of complex crystalline systems, allowing a meaningful comparison with experiment or even accurate predictions of quantities not yet accessible experimentally, with an extremely useful predictive power.

In *ab initio* approaches, semiconductor heterostructures are normally modeled using periodically repeated supercells with a limited number of atoms. The relevant effects due to the presence of the interface are confined in a small region, and the bulk features of the charge density distribution and electrostatic potential are completely recovered within a few atomic units from the interface. This justifies the concept of abrupt discontinuities of the electronic bands across the interfaces which is used in the schematic diagrams of electronic band profiles.

The supercell self-consistent calculations provide the electronic charge density distribution and the corresponding electrostatic potential, as shown in **Figure 7**. Filtering out the microscopic oscillations

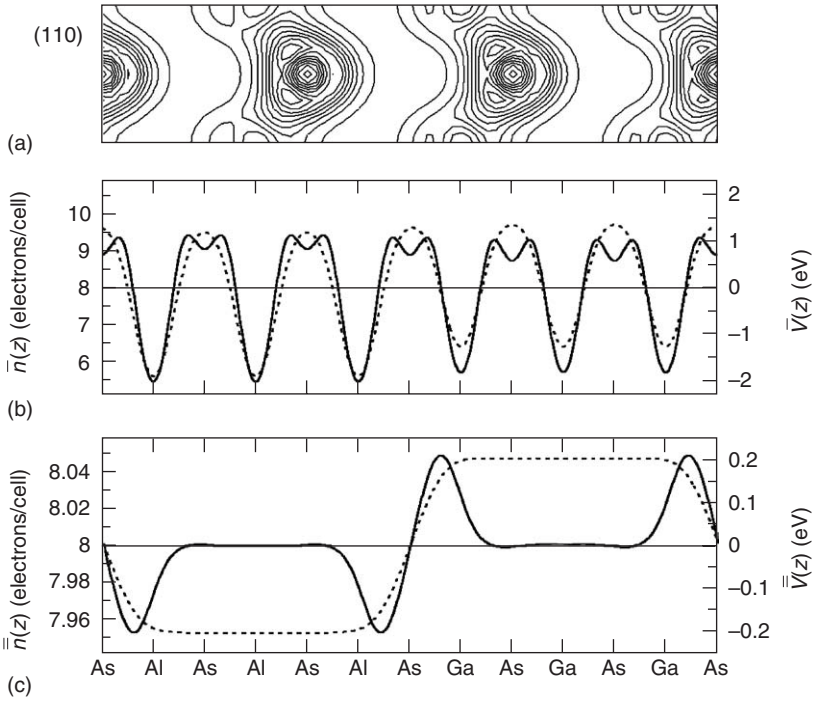

Figure 7 Contour plot of the valence electron density distribution (a) for GaAs/AlAs(0 0 1) heterojunction over a (1 1 0) plane containing the growth axis and centered on the interface anion. Profiles of the electron density and of the electrostatic potential along the growth direction averaged over planes parallel to the interface ($\bar{n}(z)$and $\bar{V}(z)$) (b), and further averaged along the growth direction with a filter equal to the periodicity of bulks ($\bar{\bar{n}}(z)$ and $\bar{\bar{V}}(z)$) (c).

with the bulk-like periodicity, one can unambiguously define an "interface dipole" and extract a potential difference across the interface, ΔV, which, in principle, depends on the interface structural and chemical details. The final band offsets VBO and CBO are determined by the difference ΔE_v and ΔE_c between the relevant band edges in the two materials, measured with respect to the average electrostatic potential in the corresponding bulk crystals:

$$\mathrm{VBO} = \Delta V + \Delta E_v \qquad [3]$$

$$\mathrm{CBO} = \Delta V + \Delta E_c \qquad [4]$$

When the two semiconductors constituting the heterostructure are rather similar (in structure and chemical composition), their differences can be quite minute with respect to the typical bulk variations, and a low-order perturbation approach is appropriate.

The state-of-the-art theoretical approaches allow one not only to compute band discontinuities accurately but also to obtain an insight into the atomic-scale mechanisms which determine the band lineups, and interpret and predict their trends. However, the predictive capability of theoretical schemes is actually limited by the difficulty in predicting the actual atomic-scale arrangement at the interfaces, and their kinetic versus thermodynamic character.

Band Offset Trends

Some peculiar trends in band offsets at semiconductor heterojunctions have been clarified, thanks to the large joint experimental and computational effort: at lattice-matched isovalent heterojunctions, the band offsets depend only on the bulk properties of the two materials, whereas at heterovalent heterojunctions they crucially depend on the interface orientation and other microscopic details. These results are briefly reviewed and justified in the following section.

Lattice-Matched Semiconductor Interfaces

Isovalent semiconductor heterojunctions The GaAs/AlAs heterojunction is the simplest prototype of lattice-matched common-anion heterojunctions. The different cations are isovalent; therefore, the induced potential drop across the interface is only due to the electronic charge. Measurements and accurate numerical investigations show that the VBO and CBO are independent of the interface orientation and abruptness. These results can also be generalized to isovalent no-common-ion heterojunctions such as InAs/GaSb and InP/$Ga_{0.47}In_{0.53}As$, where the lattice-matching conditions result from a balance between the differences of the cationic and anionic core radii, and consequently an important microscopic and configuration-dependent interfacial strain may establish.

Consequences of the bulk-like character of the VBO and CBO are the commutativity and transitivity relationships, which are valid, at least approximately, in the whole class of isovalent semiconductor heterojunctions:

$$\mathrm{VBO}(A/B) = -\mathrm{VBO}(B/A) \qquad [5]$$

$$\mathrm{VBO}(A/B) = \mathrm{VBO}(A/C) + \mathrm{VBO}(C/B) \qquad [6]$$

Heterovalent semiconductor heterojunctions For the sake of clarity, the reader is referred to the case of Ge/GaAs as the simplest prototype of heterovalent semiconductor heterojunctions, but similar considerations apply to other heterojunctions characterized by a valence mismatch between the constituent atoms, such as those among ZnSe, Ge, and GaAs.

In the (1 1 0) direction, each atomic plane is characterized by the same average ionic charge, so that an abrupt junction does not carry ionic charge contribution and the lineup is due only to the electrons. At variance, ideally abrupt interfaces along a polar direction such as (0 0 1) would be charged and hence thermodynamically unstable, as already emphasized first by Harrison in 1978. The simplest neutral and stable interfaces one can envision are terminated by one mixed plane of anions or cations, $As_{0.5}Ge_{0.5}$ or $Ga_{0.5}Ge_{0.5}$ (see **Figure 8**). These two interfaces are stoichiometrically inequivalent, and, because of ionic point charges contribution due to the different valence of the atoms involved (Ge vs. Ga, Ge vs. As), they also correspond to different band offsets. Elementary electrostatics together with a linear response theory predict that the screened ionic point-charge contribution to the offsets is equal in magnitude and opposite in sign for the two interfaces: $\Delta V_{\mathrm{ionic}} = \pm \pi e^2 / 2 a_0 \langle \varepsilon \rangle$, where a_0 is the lattice parameter involved and $\langle \varepsilon \rangle$ a proper average of the dielectric constants of the constituents. The maximum predicted possible variation with interface composition of the band offset at these interfaces is thus $\pi e^2 / a_0 \langle \varepsilon \rangle \approx 0.8$ eV for Ge/GaAs. For ZnSe/Ge, where the valence difference between the constituting elements is twice, the maximum possible variation would be $2\pi e^2 / a_0 \langle \varepsilon \rangle \approx 1.3$ eV.

In general, the atomic interdiffusion which may also occur across the interface over several atomic planes, depending on the growth conditions, reduces the point-charge contribution to the offset, and the observed variations of the offsets are smaller. However, for heterovalent heterostructures deviations from the commutativity and transitivity rule definitely beyond the experimental resolution, up to ≈ 0.5 eV, are observed, and these are a clear fingerprint of the formation of inequivalent interfaces.

Lattice-Mismatched Semiconductor Interfaces

In lattice-mismatched heterojunctions, the band offsets are affected by the stress state of the two materials, depending on the substrate. In pseudomorphically grown heterostructures, the epilayer accommodates its mismatch with the substrate with an almost homogeneous strain and a lattice constant $a_\perp$ along the growth direction, which essentially depends on its elastic properties and on the mismatch with the substrate. The strain state of the epilayer affects the band edges with a combined effect of shift and split. The former affects the averages of the band edge manifolds, calculated with respect to the reference electrostatic potential, and depends on the hydrostatic component of the strain, that is, on the relative volume change with respect to the cubic unstrained material. Splitting effects depend on the orientation and sign of the strain (tensile or compressive). The total variation of the VBO with strain also includes the variation of the electrostatic potential lineup ΔV.

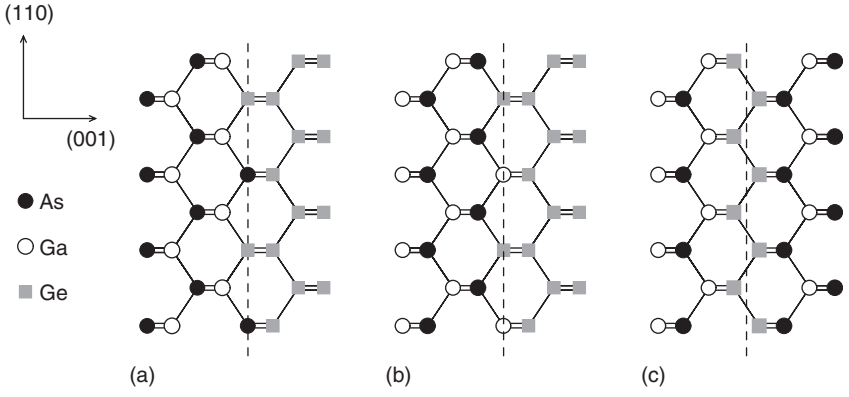

Figure 8 Atomic configurations for the two simplest neutral Ge/GaAs interfaces (a), (b), and for a Ge bilayer embedded in GaAs (c). (Adapted from Sorba L *et al.* (1992) *Physical Review B* 46: 6834.)

The simplest case of lattice-mismatched heterojunctions is Si/Ge, which is an example of isovalent homopolar interfaces. The predicted variation of the VBO at this heterojunction is ~ 0.5 eV, changing the substrate from Si to Ge. Larger effects could be, in principle, possible at heterovalent lattice-mismatched heterojunctions, such as Si/GaAs, or in presence of larger lattice mismatches. However, the difficulty of growing high-quality lattice-mismatched heterojunctions drastically limits their formation and their use in practice.

Band Offset Engineering

In bulk semiconductor technology, one of the most important and widely used features has been the possibility of intentionally varying the electronic properties by alloying and doping. For semiconductor heterojunctions, a similarly important challenge is to control and artificially modify the band offsets.

As already mentioned, the VBO and CBO at lattice-matched isovalent semiconductor heterojunctions are mostly determined by the bulk properties of the constituents, and interface details such as orientation and stoichiometry play a very minor role, whereas at heterovalent heterojunctions they are very sensitive to these extrinsic features. As a consequence, heterovalent heterojunctions seem to be ideal candidates as tunable heterojunctions, while using only isovalent materials, it seems that the only way to tune the offset is to act on their bulk properties with strain or with alloying.

Actually, the peculiarity of heterovalent interfaces leads naturally to a practical way for modifying the offset also at isovalent heterojunctions, or even for creating an offset at a homojunction. For instance, joining together the two inequivalent interfaces Ge/GaAs(0 0 1) (Ge–As and Ge–Ga terminated), one has the following sequence of atomic planes: $\cdots$As–Ga–As–$Ge_{0.5}Ga_{0.5}$–$Ge_{0.5}As_{0.5}$–Ga–As–Ga$\cdots$. Therefore, using the difference between the VBOs of these two inequivalent interfaces, a net potential drop $\Delta V = \pi e^2/a_0 \langle \varepsilon \rangle$ is predicted across the mixed bilayer. This potential drop is the same that would result from a microscopic capacitor whose plates are placed at a distance $a_0/4$, and carry a surface charge $\sigma = e/a_0^2$. The above sequence of atomic planes can also be thought of as due to the transfer of a proton per atomic pair from the As to the Ga planes.

This viewpoint is easily generalized to arbitrary concentrations of Ge in a pair of consecutive compensated GaAs planes, Ge_xGa_{1-x} and Ge_xAs_{1-x}, to ensure local charge neutrality. The maximum potential drop would be, in principle, $\Delta V_{\max} = 2\pi e^2/a_0 \langle \varepsilon \rangle$ for the case $x = 1$, that is, for an entire Ge bilayer embedded (see **Figure 8**). The above results can be further generalized to the heterojunctions, for example, doping a GaAs/AlAs interface with ultrathin layers of Si or Ge. In this case, the interlayer contribution can reduce or increase the intrinsic VBO according to the growth sequence. These predictions have been indeed experimentally confirmed for Si interlayers at GaAs/AlAs and AlAs/GaAs (0 0 1) junctions and analogous effects have also been observed in other systems.

Localized Interface States

Another important issue in the heterojunction electronic structure concerns the presence of localized interface states in heterojunctions, their origin, and their role in determining the electronic characteristics of the junctions. The existence of localized interface states is generally claimed whenever anomalous features are observed in photoemission, optical, or transport measurements. Their unambiguous identification, however, is a difficult task in experiments. Reflectance anisotropy spectroscopy has been recently applied to a few interfaces and seems to be a promising tool for more direct investigations.

The electronic states of a heterojunction can be extended everywhere, localized in one material or the other (acting as a quantum well), or localized at the interface. The true interface states are not degenerate with bulk Bloch states, decay exponentially away from the interface, and exist only in the mutual energy gaps. The comparison of the band structures of the two bulk materials with the spectrum of the heterojunction allows one to identify those states which do not belong to the bulk band structures, and are, therefore, candidates to be interface states. Localized electronic states can be successfully identified in numerical investigations also by the local density of states: far from the interface on the two sides of the junction, it yields the bulk densities of states of the two materials, whereas its deviations with respect to the constituting bulk state densities in the interface region would indicate the presence of states which are localized there.

Interface states can have different physical origins. In some cases, they are associated with defects which typically arise at junctions between two morphologically different phases (e.g., cubic and wurtzite). But localized electronic states can also occur, in principle, at semiconductor heterojunctions with constituents having the same or similar structure but different chemical properties. Simple electron-counting schemes indicate that the valence mismatch between neighboring atoms from opposite sides of the junction could result in localized interface states

corresponding to donor or acceptor bonds. Therefore, heterovalent heterojunctions, which exhibit such kind of bonds in the interface region, are natural candidates for the existence of localized interface states. Localized states have been experimentally detected at diamond/zinc blende interfaces, for example, Ge/ZnSe, at zinc blende/zinc blende heterovalent interfaces, for example GaAs/ZnSe, and even at isovalent no-common-ion interfaces, for example, BeTe/ZnSe.

Accurate calculations predict that interface electronic states critically depend not only on the type of heterojunction (i.e., heterovalent rather than isovalent), but on the particular atomic-scale morphology of the interface.

Semiconductor Heterostructures and Spintronics

The word "spintronics" denotes electronic-like heterostructures where the relevant physical quantity is the spin of the carriers and its interactions with external magnetic fields, rather than the charge of holes and electrons and the associated electronic properties.

Semiconductor heterostructures using carrier spin as a new degree of freedom offer new functionality with respect to conventional junctions. A large effort is currently devoted to integrate traditional III–V and II–VI semiconductors with ferromagnetic semiconductors or, more generally, with other ferromagnetic materials including metals and half-metals. There are, however, several advantages using all-semiconducting devices: interface properties, such as lattice matching and band offsets, are more understood and controllable, and the integration with the existing conventional semiconductor technology is easier. The diluted ferromagnetic semiconductors are semiconductor compounds where a fraction of the constituent ions is replaced by magnetic ions. This is the case, for instance, of (Ga,Mn)As, which has received particular attention: Mn is a heterovalent substitutional impurity for Ga in GaAs (valence II with respect to the valence III of Ga), and therefore, it can be used as a source of spin-polarized holes. An Mn content up to 5% is sufficient to make (Ga,Mn)As ferromagnetic.

Furthermore, there is the possibility of a good integration of half-metals with conventional semiconductors: these are materials that have only one occupied band at the Fermi level, and behave as a metal in one spin channel and as a semiconductor in the other. Current effort, both experimental and theoretical, is nowadays devoted to predict those particular heterostructures where half-metallicity is also maintained in the presence of the interface.

Semiconductor Lasers

M-C Amann, Technische Universität Munchen, Garching, Germany

Introduction

Even though more than four decades have passed since the first demonstration of lasing in semiconductors, the pace of development of new and further improved semiconductor lasers continues to be rather high. Judging by their economic impact, semiconductor lasers can be considered today as the most important type of laser. From the beginning, the development of semiconductor lasers has been closely connected with the progress of semiconductor technology and device physics. Hence, the invention of semiconductor heterostructures as well as the straightforward implementation of quantum effects together with improved epitaxial techniques have had a decisive impact on the evolution of these lasers. Besides the physical background and the various device concepts, a proper treatment of semiconductor lasers has to particularly include a description of the relevant materials and their fabrication technology.

After a brief review of the conditions for laser action in semiconductors, this article gives an overview of the most relevant semiconductor materials and material systems. Besides the materials, it is also shown that the various choices among the various laser structures makes this laser class well suited for a vast number of applications. The stationary, dynamic, and spectral characteristics of state-of-the-art semiconductor lasers are presented in the next section and a brief discussion on single-frequency and vertical-cavity surface-emitting semiconductor lasers completes this article.

Population Inversion and Gain in Semiconductors

A fundamental concept in laser physics is to achieve population inversion between two discrete states in a nonequilibrium physical system, so that the stimulated emission can overcome absorption and losses yielding a net optical gain. In a semiconductor, however, the energy states for electrons and holes are continuously distributed within energy bands that are separated by forbidden bands as schematically shown in **Figure 1** for a direct semiconductor, where the width of the forbidden band is denoted as bandgap energy E_g. The population of these bands is governed by the Fermi distribution characterized by the Fermi level at which the population probability equals 0.5. A population inversion can be achieved by heavily pumping the semiconductor via a current injection. As shown in **Figure 1**, the nonequilibrium electron and hole distributions can be described by two equilibrium Fermi distributions with two Fermi levels E_{Fc} and E_{Fv} for the conduction and valence bands, respectively. This is possible due to the fast relaxation of the carriers within the bands,

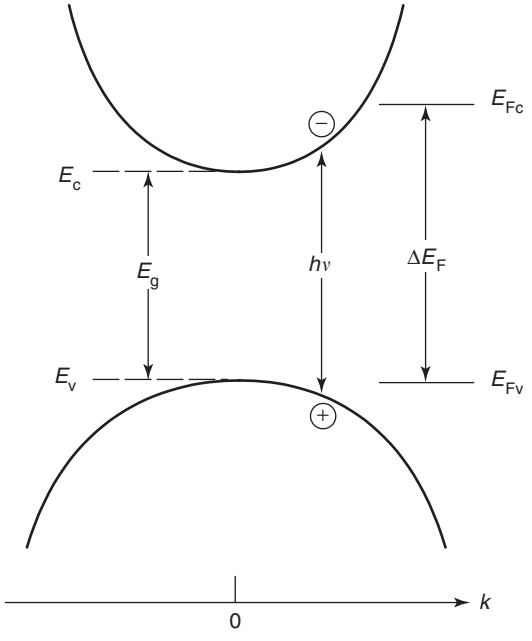

Figure 1 Schematic diagram of energy bands and quasi-Fermi levels of an inverted semiconductor illustrating the Bernard and Duraffourg condition.

hence, E_{Fc} and E_{Fv} are named quasi-Fermi levels. In 1961, Bernard and Duraffourg derived the condition for population inversion in semiconductors essentially stating that the energy difference $\Delta E_F = E_{Fc} - E_{Fv}$ needs to exceed the bandgap energy, and the photon energy $\hbar\omega$ is between ΔE_F and E_g:

$$\Delta E_F > \hbar\omega \geqslant E_g$$

The Bernard and Duraffourg condition requires that the population of at least one band is degenerate, that is, the carrier density exceeds the effective density of states N_c and N_v of the conduction and/or the valence band, respectively. This means that the semiconductors are operated in the high-injection regime, since N_c and N_v are rather large. In GaAs, for instance, at room temperature, $N_c \cong 4 \times 10^{17}$ cm^{-3} and $N_v \cong 8 \times 10^{18}$ cm^{-3}. Normally, undoped active regions are applied, so that the electron and hole densities are equal causing the conduction band to become degenerate. While, in principle, population inversion is possible in direct and indirect semiconductors, a sufficient gain to overcome internal absorption losses can hardly be achieved in indirect semiconductors.

For injection levels exceeding the threshold as defined by the Bernard and Duraffourg condition, an optical gain due to stimulated emission by the inverted band occupation occurs. The injection level at which this gain exactly compensates the material losses, such as free-carrier absorption or scattering losses, is defined as the transparency threshold. At even higher injection, the increasing gain may also compensate the mirror losses of an optical cavity enabling laser operation. It should be noted that inverted semiconductors may provide very large optical gain g up to the order of 1000 cm^{-1}, exceeding that of any other optical gain medium.

Semiconductor Heterostructures

Laser operation in homojunction semiconductors is difficult to achieve because of the high current densities required to achieve optical gain. For low-threshold operation, it is therefore necessary to reduce the volume of the active region in which the injection occurs and to exclude optical absorption in the surrounding semiconductor regions. This goal can most effectively be achieved by applying semiconductor heterostructures, in which semiconductors with different bandgap energy are combined. The most effective among them is the so-called "double heterostructure," in which the active region is completely embedded into p- and n-doped semiconductors with a larger bandgap energy as shown schematically in **Figure 2**. The double heterostructure provides two essential features relevant for laser operation:

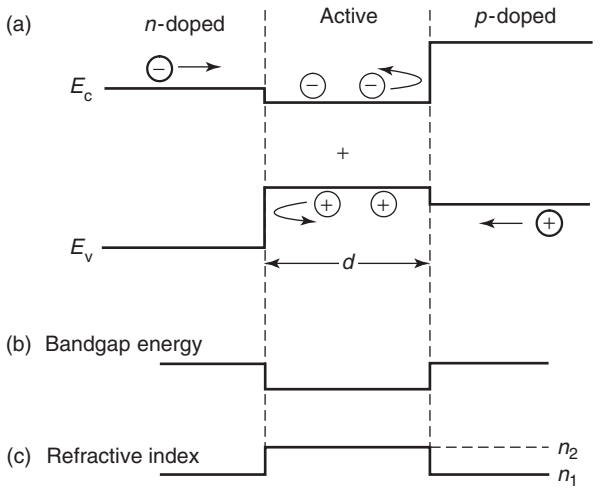

Figure 2 Schematic illustration of (a) semiconductor double heterostructure, (b) spatial profiles of bandgap energy, and (c) refractive index.

1. *Carrier confinement*. This almost completely concentrates electrons and holes within the active region even for active regions having thickness in the nm-regime.
2. *Optical confinement*. This yields optical waveguiding, establishing a slab waveguide with the active region as core because of the smaller refractive indices of the higher bandgap energy semiconductors sandwiching the active region.

Compared to the carrier confinement, the optical confinement as measured by the optical confinement factor

$$\Gamma = \frac{\text{mode power carried in active layer (region)}}{\text{total mode power}}$$

is not as complete for small dimensions, and the optimal radiation-matter interaction in the active region occurs where Γ/d is maximal. Depending on the material constants, accordingly, active region thicknesses are usually $\sim$100 nm.

Further, an improved optical gain performance shows the quantum-well (QW) structures, in which the active region thickness is reduced to below the de Broglie wavelength ($\sim$30 nm). In QWs, the quantization of the electronic states along the normal layer results in a two-dimensional (2D) electron (and hole) gas with a modified density of states that makes the inversion population possible for smaller injection levels. The density of states in the valence band can

additionally be modified by introducing elastic strain that lifts the degeneracy of light and heavy valence bands, so that only one of the two valence bands needs to be inverted yielding still smaller thresholds. Extending the quantization to the other two dimensions, one obtains quantum wire and quantum dot structures, corresponding to one-dimensional (1D) and zero-dimensional (0D) electron (hole) systems with distinct threshold reduction. In case of the quantum dot, atom-like discrete states appear to make this kind of gain medium rather similar to atomic laser media. In general, reducing the dimensionality of the carrier systems results in reduced thresholds and smaller temperature dependence of the optical gain. Because of the significant advantages achieved with double heterostructures, all modern laser diodes normally comprise a QW double heterostructure.

Semiconductor Heterostructure Material Systems

The benefits of the semiconductor heterostructure can be exploited only if the composite crystal exhibits a high crystalline quality. This generally requires that all constituents of the heterostructure have the same lattice constant a_0, while the difference in bandgap energy should be large (several hundred meV). The lattice-matching requirement strongly limits the possible semiconductor combinations because semiconductor heterostructures are almost entirely grown on binary substrates. This is because binary substrates, such as GaAs or InP, are unambigous chemical compounds in contrast to, for example, $In_xGa_{1-x}As$ and typically provide more than an order of magnitude of better thermal conductivity than ternary (or quaternary) compounds because of the nonoccurance of alloy scattering of the phonons.

Lattice-matched double heterostructures, therefore, consist of ternary and quaternary (or even quinternary) compounds grown on binary substrates. The lattice-matching condition can be found from Vegard's law which states that the lattice constant of a compound can be calculated as a linear interpolation between the constituting binaries. For a quaternary compound $A_xB_{1-x}C_yD_{1-y}$, where A and B, and C and D each share the same sublattice, the lattice constant is

$$a_0(A_xB_{1-x}C_yD_{1-y}) = xya_0(AC) + x(1-y)a_0(AD) + (1-x)ya_0(BC) + (1-x) \times (1-y)a_0(BD)$$

On the other hand, the bandgap energy of a compound shows a more complicated and nonlinear dependence on composition. As a consequence, with a proper choice of semiconductor materials, rather large bandgap energy differences can be achieved with lattice-matched compounds making numerous heterostructure combinations possible. Semiconductor lasers are nowadays made from numerous III–V and other compound semiconductors covering the entire visible as well as the infrared regime up to $\sim 100\,\mu m$ wavelength.

Stripe Laser Diodes

A schematic drawing of the basic stripe-geometry semiconductor laser structures is depicted in **Figure 3**. All of them comprise a transverse (vertical, x-axis) double heterostructure to define the vertical extension of the laser-active area with a pn-junction at or in the active layer. A laser current is fed via stripe

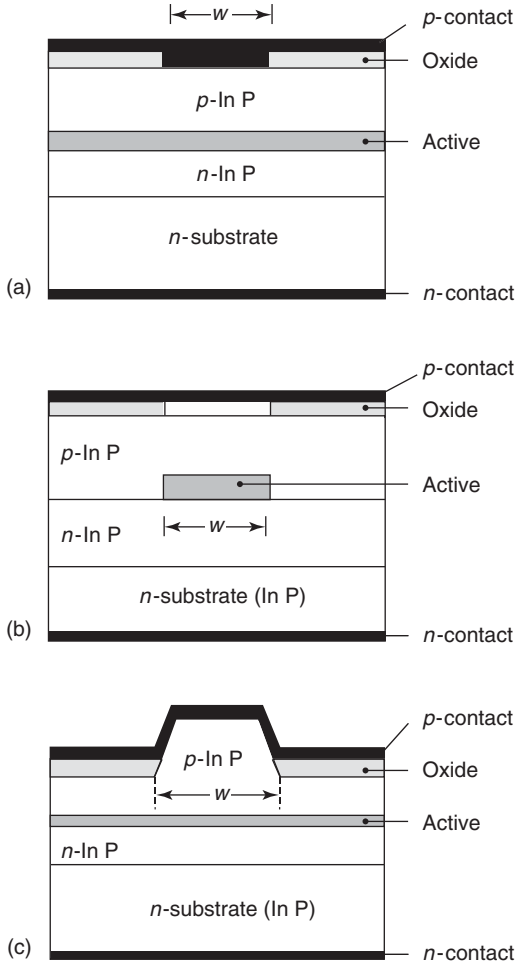

Figure 3 The three different lateral waveguiding types (a) Gain-guiding (GG), (b) index-guiding (IG), and (c) quasi-index-guiding (QIG).

contacts on the top and bottom of the laser chips. Three basic types of lasers can be distinguished: gain-guided (GG), index-guided (IG), and quasi-index-guided (QIG) laser structures, where the guiding relates to the in-plane (lateral) waveguiding along the y-axis. While the transverse waveguiding (x-axis) is accomplished by index guiding via the double heterostructure, the lateral waveguiding may either be done (1) simply by the lateral gain profile in the active layer (GG), (2) similar to the transverse direction by a lateral double heterostructure (IG), or (3) by a partial lateral replacement of part of the structure by a lower index material without attaching the active layer (QIG). While the GG lasers require the lowest technological effort and generally show an excellent long-term stability because of the nonmodified active layer, the IG lasers exhibit the smallest thresholds and optimum laser performance; however, the lateral removal of part of the active layer may worsen the reliability. Often a reasonable compromise are the QIG lasers that, in all aspects, show the behavior in between the other two structures. An optical feedback is provided by the cleaved end-facets of the laser chips, which for typical refractive indices of the semiconductors (2.5–3.5) show a reflectivity $\sim 30\%$ against air. Due to the large gain of the semiconductor laser, this comparatively small mirror reflectivity can be compensated for by laser lengths of the order of several hundred micrometers.

Waveguiding in Laser Diodes, Effective Refractive Index, and Confinement Factor

The transverse double heterostructure represents an optical slab waveguide with the schematic index profile shown in **Figure 2c**. Depending on the active layer (core) thickness d and the index profile, this slab may carry one or more guided transverse electric (TE) and transverse magnetic (TM) modes, respectively. For a sufficiently thin active layer,

$$d < \frac{\lambda}{2\sqrt{n_2^2 - n_1^2}}$$

only the fundamental TE- and TM-modes are guided, which is normally aimed for.

The optical gain which the modes acquire, that is, the mode gain g_m, is the product of the active region material gain g and the optical confinement factor Γ for the particular mode. For a given slab waveguide, the (fundamental) TE-mode exhibits a larger confinement than the (fundamental) TM-mode. Also, the facet reflectivity shows a certain polarization dependence favoring the TE-modes as well. As a consequence, semiconductor lasers normally operate in the fundamental transverse TE-mode. In a good approximation, the confinement factor for the fundamental TE-mode is

$$\Gamma \cong \left[1 + \left(\frac{d_0}{d}\right)^2\right]^{-1} \quad \text{with } d_0 = \frac{\lambda}{2\pi}\sqrt{\frac{2}{n_2^2 - n_1^2}}$$

A further mode property is the effective refractive index n_{eff}, that describes the mode propagation along the waveguide in analogy with a plane wave in a homogeneous medium, with the refractive index equal to n_{eff}. The effective refractive index, which is the ratio of the propagation constant β and the free-space wave number k_0, is between n_1 and n_2.

Considering complex refractive indices $n = n' + jn''$, where the imaginary part is related to the material gain (or loss) g as $n'' = g/2k_0$, it is obvious that the gain in the active region leading to the mode gain produces a slightly complex propagation constant and a complex effective refractive index with imaginary part equal to $n'' = \Gamma g/2k_0$.

Besides transverse profiles of the real part of n, those of the imaginary part of n may also produce optical waveguiding. This explains why the lateral gain profile constitutes a waveguide for laser radiation in the GG lasers. For common gain values, however, the GG mechanism is much smaller than IG, with the consequence that the maximum stripe width w for lateral single-mode operation is much larger in the GG lasers than in their IG counterparts.

Output Power versus Current Characteristic

A representative plot of an optical output power versus current characteristic for a semiconductor laser is shown in **Figure 4**, together with the principal current-dependent carrier density in the active region. Relevant parameters of this characteristic are threshold current I_{th}, output power P, and differential quantum efficiency η_d. The threshold current is related to the active region volume V_a and the spontaneous recombination rate R at lasing threshold carrier density N_{th}

$$I_{\text{th}} = eV_a(N_{\text{th}})$$

where e is the elementary charge. The active region gain $g(N_{\text{th}})$ at injection level N_{th} yields a mode gain that equals the total losses α_{tot} comprising internal losses (e.g., absorption and scattering) α_i and the

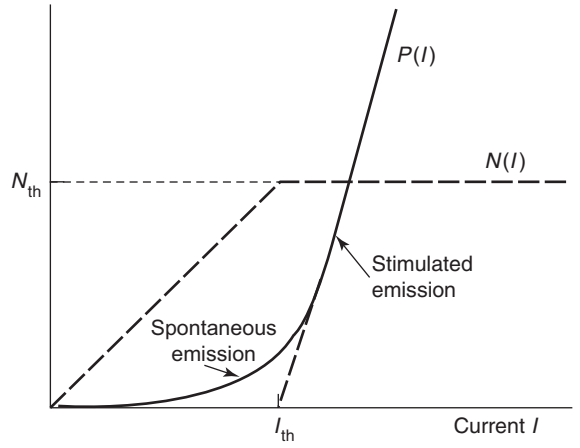

Figure 4 Schematic profile of optical output power P and carrier density in active region N vs. current in a semiconductor laser.

mirror losses α_m:

$$\Gamma g = \alpha_i + \alpha_m \text{ with the mirror losses}$$

$$\alpha_m = \frac{1}{2L} \ln \frac{1}{R_1 R_2}$$

where L is the laser length, and R_1 and R_2 are the front facet mirror reflectivities. For a symmetric laser with $R_1 = R_2 = R$, the optical output power per facet (above threshold) is

$$P(I) = \frac{h\nu}{2e} \frac{\alpha_m}{\alpha_{tot}} (I - I_{th})$$

and the differential quantum efficiency reads

$$\eta_d = \frac{dP/h\nu}{dI/e} = \frac{\ln 1/R}{2\alpha_{tot} L}$$

Emission Spectrum and Beam Properties

With state-of-the-art semiconductor technology, it is possible for most emission wavelengths to fabricate narrow-stripe laser waveguides that carry only one transverse and one lateral mode each. Even though the length of semiconductor cavities (typically 0.1–1 mm) is orders of magnitude smaller than that of most other laser types, the length-(effective)-refractive-index-product is still of the order of several thousand wavelengths. Therefore, the longitudinal mode spacing

$$\Delta\lambda = \frac{\lambda^2}{2n_g L} \quad (n_g : \text{group (effective) index})$$

is very small against the spectral width of the active region gain characteristic, which in terms of energy is of the order of the thermal energy ($k_B T$). As a consequence, the mode gains of the modes near the gain peak are only slightly different, so that the usual Fabry–Perot-type semiconductor lasers generally emit in many longitudinal modes. The purity of the spectrum can be described by the side-mode suppression ratio (SMSR) that measures the ratio of the dominant mode to the next strongest one. Given the mode gain difference Δg_m between the two strongest modes, the SMSR of a symmetric semiconductor laser ($R_1 = R_2$), under stationary conditions, is proportional to the power in the dominant mode P according to

$$\text{SMSR} = \frac{2P\Delta g}{h\nu n_{sp} v_g \alpha_{tot} \alpha_m}$$

where n_{sp} is the spontaneous emission coefficient (typically 2), that is specific for semiconductor lasers taking into account the incomplete inversion of the bands, and v_g is the group velocity. Truly single-mode lasers, that is, single-frequency lasers, show an SMSR > 30 dB, that is, three orders of magnitude, requiring a Δg of 0.01–0.1 cm^{-1}, which generally cannot be accomplished solely by the spectrally dependent active region gain. Single-frequency laser diodes, therefore, need additional wavelength selective elements such as Bragg reflectors as shown below.

An important spectral parameter, particularly for single-frequency semiconductor lasers, is the spectral line width of the mode(s). As with other lasers, the line width is obtained by the Schawlow–Townes formula; however, due to the gain-phase coupling in semiconductor lasers, the Schawlow–Townes formula must be completed yielding the so-called "Schawlow–Townes–Henry line width formula"

$$\Delta\nu = \frac{h\nu v_g^2 \alpha_{tot} \alpha_m n_{sp}}{8\pi P} (1 + \alpha_H^2)$$

where α_H is Henry's line width enhancement factor describing the gain-phase coupling accompanying carrier density changes in the active region which has the form

$$\alpha_H = -2k_0 \frac{\partial n'/\partial N}{\partial g/\partial N}$$

The physical origin for nonzero α_H is the nonsymmetric gain versus wavelength characteristic of semiconductor gain media. While the gain-wavelength characteristics of most other laser materials are symmetric, the asymmetry in semiconductors yields nonvanishing changes of the refractive index at the gain maximum, that is, at the laser wavelength,

during the occurence of gain changes, for instance, during relaxation oscillations or after each spontaneous emission event into the lasing mode(s). It should be noted that α_H is significantly smaller for QW lasers, particularly for strained QW lasers, than for bulk lasers. In case of the recently developed quantum dot lasers, α_H approaches zero because of the almost completely symmetric atom-like gain-wavelength characteristic.

The radiation beam of normal laser-diodes is transversely single-mode and nearly diffraction limited. In this case, the near-field and far-field widths depend on each other as

$$\Delta\Phi = \arctan\left(\frac{2\lambda}{\pi W}\right)$$

where $\Delta\Phi$ and W are the full width at half maximum (FWHM) of the far-field and near-field angles, respectively. Because of the narrow stripe widths of transversely single-mode semiconductor lasers (typically 0.5–3 μm at 1–2 μm emission wavelength), the diffraction-limited far-field width is of the order of several tens of degrees, in contrast to most other laser types.

Dynamic Properties and Noise

The dynamic properties of laser diodes are relevant for their use as a direct current-modulated light source in high-speed data transmission applications. Thereby, the two limiting cases of a linear response at a small-signal modulation and a nonlinear response at a large-signal (generally pulse) modulation are of great interest.

Modulating the laser around average current I and average output power P per facet, respectively, the small-signal modulation response $H(\omega)$ can be described by the transfer function of a damped second-order low-pass filter

$$H(\omega) = \frac{1}{1 - (\omega/\omega_r)^2 + j(\omega/\omega_d)}$$

where the relaxation and damping circular frequencies ω_r and ω_d are given as

$$\omega_r = \frac{1}{\tau_s}\sqrt{\frac{2a\Gamma}{\nu_g\alpha_m\alpha_{tot}h\nu V_a}P} \quad \text{and} \quad \omega_d = \frac{\tau_s}{\gamma}\omega_r^2$$

respectively. Here, the linear gain parameter $a = \partial g/\partial N$ and the photon lifetime in the cavity $\tau_s = (\nu_g\alpha_{tot})^{-1}$ appear, and γ is

$$\gamma = \frac{aS}{\alpha_{tot}} + \frac{\tau_s}{\tau_d} + \frac{n_{sp}\Gamma}{V_a S}$$

with τ_d being the differential carrier lifetime in the active region determined by the total spontaneous emission rate and nonradiative recombination processes (typically several nanoseconds). S is the photon density in the active region corresponding to output power P

$$S = \frac{2\Gamma}{\nu_g\alpha_m h\nu V_a}P$$

With an increase in the laser current or output power, respectively, the relaxation frequency as well as the damping frequency increases. The absolute value of the modulation response versus frequency f is shown in **Figure 5** for a typical 1.55 μm wavelength InGaAsP laser in comparison with an LED made from the same semiconductor material. It is usual to measure $|H(\omega)|$ in decibels, that is, $10\log|H(\omega)|$. The characteristic 3-dB bandwidth is only slightly larger than the relaxation resonance, so that the latter can be used as a reasonable measure for the modulation bandwidth.

The large-signal pulse modulation can be described by rather accurate approximations for the turn-on delay τ_{on}

$$\tau_{on} \cong \tau_d \frac{I_{on} - I_{off}}{I_{on} - I_{th}}$$

for $I_{off} < I_{th} < I_{on}$: off-state below threshold

$$\tau_{on} \cong \frac{\sqrt{2}}{\omega_r}\ln\frac{P_{on}}{P_{off}}$$

for $I_{th} < I_{off} < I_{on}$: off-state above threshold

where switching occurs from $P_{off}(I_{off})$ to $P_{on}(I_{on})$. While for lasers biased below threshold, the τ_{on} delay

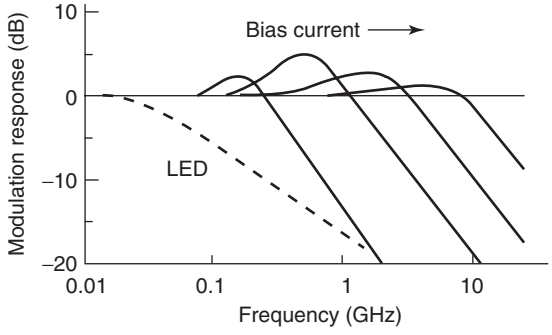

Figure 5 Absolute value $|H(f)|$ of the modulation response of a laser diode.

is of the order of the comparatively long differential carrier lifetime τ_d, τ_{on} delays ~ 0.1 ns can be obtained with an above-threshold bias.

Besides the phase noise that determines the modal line width, an intensity noise occurs in semiconductor lasers. This is usually described in terms of the relative intensity noise (RIN)

$$\mathrm{RIN(in\ dB\ Hz^{-1}}) = \frac{1}{\Delta f} \log\left(\frac{\Delta P}{P}\right)^2$$

where ΔP denotes the power fluctuations of the laser output within bandwidth Δf. The RIN shows a frequency dependence similar to the modulation response with typical low frequency values $\sim 135\,\mathrm{dB\,Hz^{-1}}$.

Single-Frequency Semiconductor Lasers

Semiconductor lasers can be made single-frequency lasers by introducing additional wavelength-selective elements into the laser cavity that select only one of the longitudinal modes. This is commonly accomplished with Bragg gratings monolithically integrated into the laser structure. As shown in **Figure 6**, the gratings may either replace the laser mirrors and are therefore put at one or both laser facets (distributed Bragg reflector (DBR) laser with a longitudinal integration of grating) or may homogeneously be collocated with the active region over the entire laser length (distributed feedback (DFB) laser with a transverse integration of grating). To avoid interference with the end facet reflection, antireflection coatings are normally applied onto those facets of DBR lasers where the gratings provide the feedback. In DFB lasers, therefore, both facets need an antireflection coating to suppress these interferences.

The Bragg gratings are made by periodic thickness variations of a grating layer sandwiched between layers of different refractive indices, so that the thickness variations result in effective refractive index variations Δn_{eff} of the same periodicity. In the DBR laser, the Bragg grating introduces a wavelength-dependent mirror loss with a minimum loss or maximum reflectivity at the (free-space) Bragg wavelength

$$\lambda_B = 2n_{eff}\Lambda$$

where Λ is the grating period, (**Figure 6b**). In the interesting regime around the Bragg wavelength, the wavelength-dependent reflectivity can be calculated by the coupled-mode theory yielding

$$R(\lambda) = \left|\frac{\kappa \sinh(sL_B)}{j\Delta\beta \sinh(sL_B) + s\cosh(sL_B)}\right|^2$$

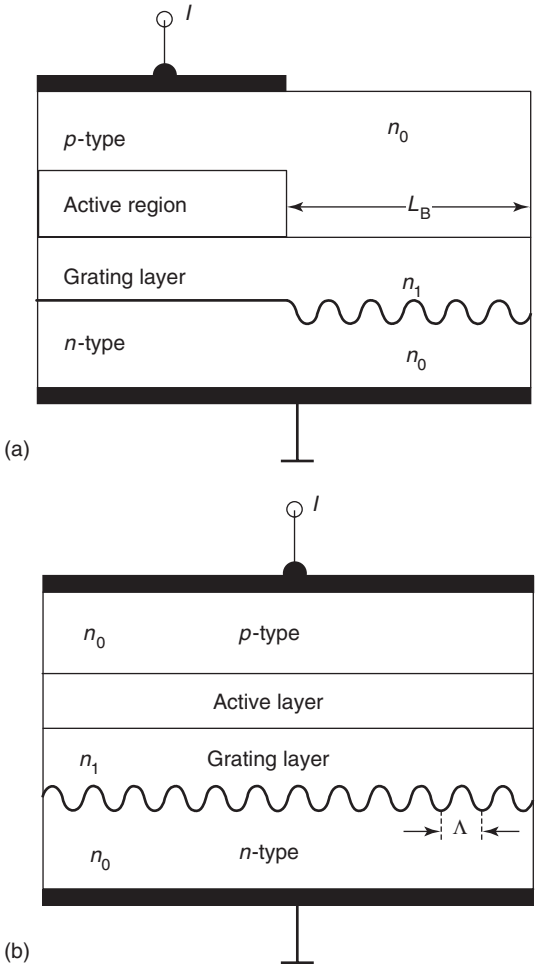

Figure 6 (a) DBR (longitudinal integration), and (b) DFB (transverse integration) single-frequency semiconductor laser structures.

where κ, the coupling coefficient of the grating describing the strength of the grating feedback has the form

$$\kappa = \frac{k_0 \Delta n_{eff}}{4}$$

and $\Delta\beta$ is the deviation of the wave vector $k_0 n_{eff}$ from the wave vector at the Bragg wavelength k_B and is thus a measure of the difference $\Delta\lambda = \lambda - \lambda_B$

$$\Delta\beta = k_0 n_{eff} - k_B \cong -\frac{2\pi n_{eff}}{\lambda_B^2}\Delta\lambda$$

L_B is the grating length, and $s = \sqrt{\kappa^2 - \Delta\beta^2}$. At the Bragg wavelength, the reflectivity is maximal and is given by

$$R(\lambda_B) = \tanh^2(\kappa L_B)$$

For most DBR semiconductor lasers, it is possible to achieve κL_B-products of the order 1 or more and thus

to realize reasonable reflectivities exceeding even the facet reflectivity of the semiconductor–air interface in the Fabry–Perot semiconductor lasers. However, the relative spectral position of the Bragg wavelength and the longitudinal mode spectrum is not controlled well in DBR lasers, particularly, if a wide operation temperature range is considered with resulting relative shifts of both against each other. The wavelength control and stability is much better in the DFB lasers because the longitudinal DFB laser modes are intrinsically related to the Bragg wavelength, and the grating and the active region are spatially not separated, so that any index changes in the active region or the grating layer may not change this relationship. As a consequence, DFB lasers have become commercial single-frequency lasers, while more sophisticated DBR devices have gained importance in the area of wavelength-tunable semiconductor lasers. Properly designed DFB lasers show excellent single-frequency performance with SMSR well exceeding 30 dB.

Vertical-Cavity Surface-Emitting Semiconductor Lasers

Vertical-cavity surface-emitting lasers (VCSELs) are relatively new semiconductor lasers in which the laser cavity is not along the wafer plane but vertical to it. Consequently, the length of the gain region along which the optical gain compensates internal and mirror losses is drastically reduced to the thickness of the active region (e.g., 50 nm) instead of its length (e.g., 500 μm). Because of the large optical gains achievable with semiconductors, it is possible to realize a sufficient gain along a gain path length of only 5–50 nm for the compensation of the losses of high-reflective mirrors. A schematic illustration of the basic VCSEL geometry is shown in **Figure 7**. Top and bottom mirrors of the VCSEL consist of several ten quarter-wavelength semiconductor layer pairs with alternating refractive index that can precisely be fabricated with molecular beam epitaxy (MBE) or metal-organic vapor-phase epitaxy (MOVPE).

The cavity length of VCSELs is of the order of the wavelength and thus orders of magnitude shorter than that of the edge-emitting lasers. Accordingly, the laser performance shows substantial differences, such as a longitudinal single-mode operation or the onset of quantization effects of the optical field.

Using thin QW active layers, the thickness d of the active region can be made much thinner than a quarter wavelength in the semiconductor, that is, $\lambda/4n$, so that by placing the active region in a maximum of the field intensity $|E|^2$ as shown in **Figure 7**, the gain is twice as large for the long active regions in edge-emitting layers, where the gain works on the

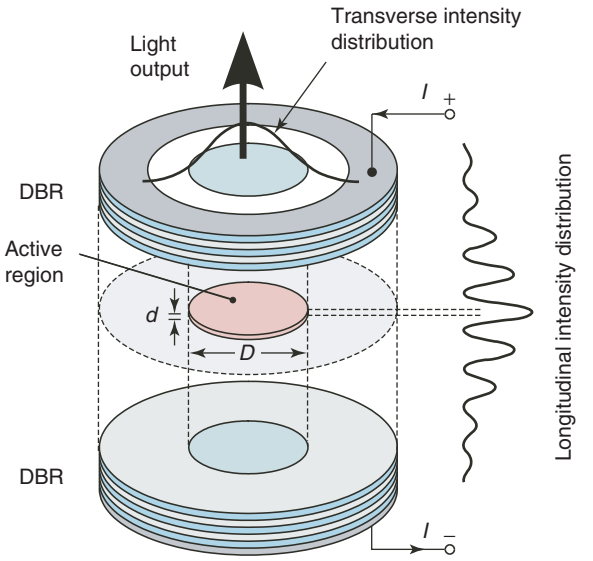

Figure 7 Schematical illustration of principal vertical-cavity surface-emitting laser (VCSEL) structure.

averaged field intensity, including nodes of $|E|^2$ as well. The threshold condition for this design, therefore, reads (note the factor of 2)

$$2dg = \alpha_i L_{\text{eff}} + \frac{1}{2} \ln \frac{1}{R_1 R_2}$$

where the effective cavity length L_{eff} is the vertical extension of the standing wave within the 1/e-decay on both ends. Due to the ultra-small d, the mirror reflectivities need to be near unity, typically $>99\%$. This can be achieved by DBRs made of alternating (and conductive) semiconductor layers of different composition yielding different refractive indices. Mathematically, the peak reflectivity of such a DBR at the Bragg wavelength is expressed as

$$R = \left[\frac{1 - (n_0/n_2)(n_2/n_1)^{2N}}{1 + (n_0/n_2)(n_2/n_1)^{2N}}\right]^2$$

where N is the number of layer pairs in the DBR, n_0 and n_2 are the refractive indices of the medium outside the VCSEL (e.g., air: $n_0 = 1$) and the inner semiconductor region respectively, and n_1 is the refractive index of the second semiconductor in the DBR. With refractive index differences up to 5–10% in usual semiconductor material systems (GaAlAs/GaAs, InGaAlAs/InP), several ten-layer pairs give reflectivities of the order 99.5–99.9% against air. With these high reflectivities, the laser threshold can be achieved with reasonable active region gains ~ 500–$1000\,\text{cm}^{-1}$. Up to now, room-temperature continuous-wave VCSELs have successfully been demonstrated for the wavelength ranges 850–1000 nm in Ga(In)AlAs/GaAs,

1.2–1.3 μm in GaInNAs/GaAs, and 1.3–2.0 μm in AlGaInAs/InP.

The lateral diameter of the active region can be kept small enough to favor single transverse-mode operations and is typically $\sim$3–10 μm. As a consequence of the small active region volume, the threshold currents of VCSELs are rather small, typically <1 mA, even though the threshold current density might be quite large to obtain the required large threshold gain. Another consequence of the small active region is that the output power of a VCSEL is accordingly small, typically of the order of a few milliwatts, which is, however, sufficient for the vast majority of applications in communications, measurements, and sensing.

Nomenclature

a_0	lattice constant (nm)
c	vacuum speed of light (cm s^{-1})
d	thickness of active region (μm)
D	diameter of circular active region in VCSEL (μm)
e	elementary charge (As)
E_c	conduction band edge energy (eV)
E_{Fc}	quasi-Fermi level in conduction band (eV)
E_{Fv}	quasi-Fermi level in valence band (eV)
E_g	bandgap energy (eV)
E_V	valence band edge energy (eV)
f	frequency (Hz)
g	optical material gain (cm^{-1})
h	Planck's constant (VAs^2)
H	modulation response
I	current (mA)
I_{th}	laser threshold current (mA)
k	wave vector (cm^{-1})
k_0	free-space wave vector $k_0 = 2\pi/\lambda$ (cm^{-1})
k_B	wave vector at Bragg wavelength (cm^{-1})
L	laser length (μm)
L_B	length of Bragg grating (μm)
$n = n' + jn''$	complex refractive index
n_{eff}	effective refractive index of a waveguide mode $n_{eff} = \beta/k_0$
n_g	group refractive index
n_{sp}	spontaneous emission coefficient (typically 1–2)
N	carrier density (cm^{-3})
N_c	effective density of states in conduction band (cm^{-3})
N_{th}	carrier density at laser threshold (cm^{-3})
N_v	effective density of states in valence band (cm^{-3})
P	optical power (mW)
R	recombination rate (cm^{-3} s^{-1}), mirror reflectivity (dimensionless)
RIN	relative intensity noise (dB Hz^{-1})
S	photon density (cm^{-3})
SMSR	side-mode suppression ratio (dB)
V_a	active region volume (cm^3)
v_g	group velocity (cm s^{-1})
w	stripe width (μm)
W	full width at half maximum (FWHM) (μm) of laser near-field
α	optical loss coefficient (cm^{-1})
α_H	Henry's line width enhancement factor
α_i	intrinsic optical loss (cm^{-1})
α_m	mirror loss (cm^{-1})
α_{tot}	total optical loss $\alpha_{tot} = \alpha_i + \alpha_m$ (cm^{-1})
β	propagation constant (cm^{-1})
Γ	confinement factor of an optical mode
ΔE_F	difference of quasi-Fermi levels, E_{Fc}–E_{Fv} (eV)
$\Delta\Phi$	FWHM of laser far-field (rad,^{o})
κ	coupling coefficient of Bragg grating (cm^{-1})
Λ	(Bragg) grating period (nm)
λ	wavelength (μm)
λ_B	Bragg wavelength (μm)
ν	frequency (Hz)
τ_d	differential carrier lifetime (s)
τ_{on}	turn-on delay time (s)
τ_s	photon lifetime (s)
ω	circular frequency (s^{-1})
ω_d	damping circular frequency (s^{-1})
ω_r	relaxation circular frequency (s^{-1})

Semiconductor Nanostructures

B Voigtländer, Forschungszentrun Jülich GmbH
Jülich, Germany

Introduction

Two conceptually different methods are used to fabricate semiconductor nanostructures. In the top–down approach, lithography is used to fabricate nanostructures. In the bottom-up approach, small nanostructures form by self-organization during epitaxial growth. The greatest advantage of the top–down approach is the large variety of different structures, which can be generated by lithographic methods. In the case of the bottom-up approach, the variety of structures is much more limited. Islands, wires, rods, and rings have been fabricated bottom-up. However, the bottom-up approach offers the unique opportunity to fabricate very small nanostructures down to the one-digit nanometer range beyond the limits of current lithography techniques. Another advantage of self-organized fabrication of semiconductor nanostructures is the inherent parallel approach, in which billions of nanostructures are generated in parallel.

The focus of this article is the self-organized growth of semiconductor structures with lateral dimensions below 100 nm. Semiconductor quantum-well structures are nanostructures in the growth directions and not lateral nanostructures, and will not be considered in this article. The actual growth techniques used to fabricate the nanostructures like molecular beam epitaxy (MBE) and chemical vapor deposition (CVD) will be considered in separate articles. The methods used to analyze the nanostructures are scanning tunneling microscopy (STM), scanning force microscopy (AFM or SFM), transmission electron microscopy (TEM), and low energy electron microscopy (LEEM). Different properties of semiconductor nanostructures, and the applications of self-organized nanostructures in devices are discussed elsewhere in this encyclopedia. As examples for the self-organized growth of nanostructures, material systems such as Si/Ge and GaAs/InAs are used predominantly.

After introducing the self-organized semiconductor nanoislands grown on planar substrates, the aligned growth on prestructured samples is discussed. Subsequently, self-organized nanowires grown on facetted surfaces and the growth of monolayer thick wires by step-flow growth are presented. Finally, the growth of nanowires by vapor liquid solid (VLS) epitaxy and hybrid systems, where nanowires aligned to lithographically defined structures are fabricated, are presented.

Physical Principles of Self-Organized Growth

Semiconductor nanostructures can be fabricated by self-organization using heteroepitaxial growth, which is the growth of a material B on a substrate of a different material A. In heteroepitaxial growth, the lattice constants of the two materials are often different. The lattice mismatch for the two most commonly used material systems Si/Ge and GaAs/InAs is 4.2% and 7%, respectively (schematically shown in **Figure 1a**). This lattice mismatch leads to a buildup of elastic stress in the initial two-dimensional (2D) growth in heteroepitaxy. In the case of Ge

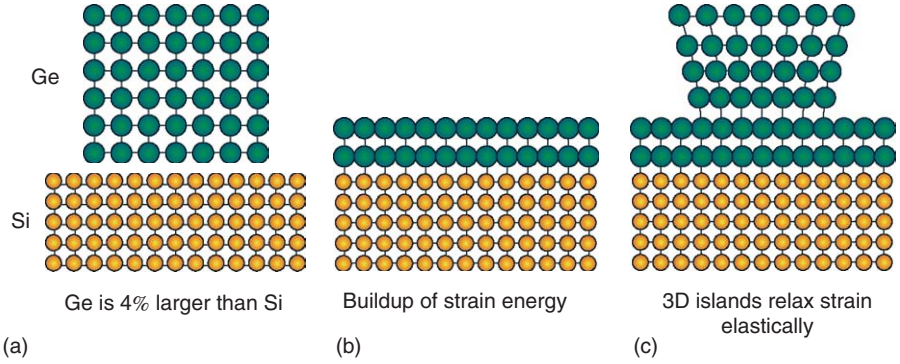

Figure 1 (a) Schematic representation of Si and Ge crystals with different lattice constants, (b) buildup of elastic strain energy during 2D growth with Ge confined to the Si lattice constant, and (c) elastic relaxation by formation of 3D islands (Stranski–Krastanov growth). In the upper part of the 3D island, the lattice constant relaxes towards the Ge bulk constant. The usual form of the 3D islands is a pyramid and not like the one shown in this schematic sketch.

heteroepitaxy on Si, the Ge is confined to the smaller lattice constant of the Si substrate, that is, the Ge is strained to the Si lattice constant. This results in a buildup of elastic stress (**Figure 1b**). One way to relax this stress is the formation of 3D Ge islands. In the 3D islands, only the bottom of the islands is confined to the substrate lattice constant. In the upper part of the 3D island, the lattice constant can relax to the Ge bulk lattice constant and reduce the stress energy this way (**Figure 1c**). This growth mode characterized by the formation of a 2D wetting layer and the subsequent growth of (partially relaxed) 3D islands is called Stranski–Krastanov growth mode.

The driving force for the formation of self-organized semiconductor nanoislands in heteroepitaxial growth is the buildup of elastic strain energy in the stressed 2D layer. As a reaction to this, a partial stress relaxation by the formation of 3D islands can lower the free energy of the system. The process of island formation close to equilibrium is a trade-off between elastic relaxation by formation of 3D islands which lowers the energy of the system and an increase of the surface area which increases the energy. Apart from the formation of 3D islands, there is another process which can partially relax the stress of a strained 2D layer: the introduction of misfit dislocations. This corresponds to the removal of one lattice plane of a compressively strained 2D layer. If a lattice plane is removed in regular distances in the 2D layer, a misfit dislocation network forms.

Depending on the growth parameters, temperature, and growth rate, the self-organized growth can be close to equilibrium or in the kinetically limited regime. Close to equilibrium, that is, at high-growth temperatures or low-deposition rates, the occurring morphology (strained layer or 3D islands or a film with dislocations) is only determined by the energies of the particular configurations. The morphology with the lowest energy will be formed. If the growth is kinetically limited, the activation barriers are important. For instance, an initially flat strained layer can transform to a morphology with 3D islands or to a film with dislocations. What actually happens depends on the kinetics of the growth process, that is, on the activation energy for formation of 3D islands compared to the activation energy for the introduction of misfit dislocations.

Semiconductor Nanoislands

Stranski–Krastanov growth occurs in InAs/GaAs growth. An example of InAs nanoislands grown on a GaAs substrate is shown in the atomic force microscopy image in **Figure 2**. The InAs islands were grown by MBE at a growth temperature of 800 K. The width

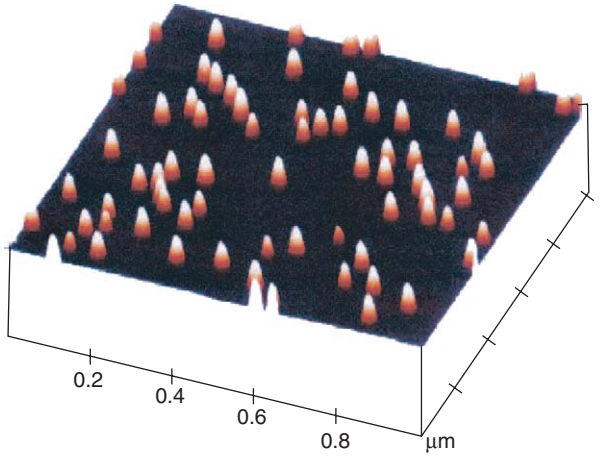

Figure 2 InAs nanoislands grown on a GaAs surface imaged by AFM. (Courtesy of A Lorke; reproduced with permission from Warburton RJ (2002) *Contemporary Physics* 44: 351; © Taylor & Francis Ltd. (http:www.tandf.co.uk).)

of the islands is 20 nm and the height 6 nm with a density of $10^{10}\,\mathrm{cm}^{-2}$. The challenges in the growth of these semiconductor islands are to grow islands of the desired size and density and with a high-size uniformity. In general, a higher growth temperature generally leads to the formation of larger islands; a higher growth rate leads to the formation of smaller islands. The size of the islands increases with the coverage. Often the density of the islands saturates at an early stage of the growth. These are general trends which may depend on the material system and the particular deposition technique. In some cases (self-limiting growth), the size of the islands saturates and the density increases with coverage. This kind of growth mode leads to a high-size uniformity of the islands. The size uniformity achieved in self-organized growth of semiconductor islands can be as small as $\sim 10\%$. For optoelectronic applications, the nanoislands have to be capped (i.e., embedded in a semiconductor to prevent oxidation of the islands under ambient conditions where the optic measurements are performed) and care has to be taken that they change their shape and composition during the capping process. The confinement of charge carriers in all three directions gives rise to atomic-like energy levels. Quantum dot lasers operating at room temperature have now been realized. The islands grown on a flat substrate are usually not ordered laterally due to the random nature of the nucleation process. In the following sections, it is shown how nucleation at specific sites can be achieved.

Lateral Positioning of Nanoislands by Growth on Templates

On homogenous substrates, the location of the nanostructured islands formed were not predictable due

to the stochastic nature of the nucleation process. It is desirable to position islands at specific (preselected) locations. This is desirable if the islands are used as functional units of nanoelectronic devices. Electric contacts can be structured easier when the location of an island is predefined. The approaches are now discussed where island nucleation occurs not randomly, but at specific locations. These predefined locations are usually specific sites on regularly prestructured substrates. Examples of such prestructured substrates are: regularly stepped substrates, facetted substrates, a regular arrangement of dislocations, or long-range surface reconstructions.

An example of ordered nucleation at a prestructured substrate is shown in **Figure 3**. Here Ge islands nucleate above dislocation lines. An SiGe film is grown on an Si(0 0 1) substrate. At the interface between the SiGe film and the substrate, dislocations form. The driving force for the formation of the dislocations is the relief of elastic strain, which arises due to the different lattice constants between the Si substrate and a Ge/Si film on this substrate. Due to the crystal structure of the substrate, the dislocations are aligned in straight lines along the two perpendicular high-symmetry directions of the substrate. During annealing, the dislocations form a relatively regular network, due to a repulsive elastic interaction between the dislocations. **Figure 3** shows growth of Ge islands on this prestructured substrate. Rows of islands grow preferentially above the dislocation lines. The nucleation of Ge islands is more favorable at the relaxed areas above the dislocations, which have a lattice constant closer to that of Ge than the strained areas of the SiGe film, where the lattice constant is confined to that of the Si substrate. Islands have a lower energy if they grow with their natural lattice constant compared to growth at a different lattice constant (strained islands). This leads to a preferred nucleation of Ge islands above the dislocations. The nucleation does not occur randomly at the surface, but simultaneously at sites which have the same structure. This can lead to a narrower size distribution than for the growth on unstructured Si(0 0 1) substrates.

In the case of the growth on a prestructured substrate, another process of self-organization occurs (before the growth of islands) during the formation of the regular arrangement of the defect structures. Here, it is often a repulsive elastic interaction, which leads to a regular distance between steps or dislocations under equilibrium conditions. Since island nucleation occurs at the defect sites, the distances are determined by the distances of the defects. Nucleation at predefined defect sites has two advantages over the random nucleation. First, the islands are located at specific sites and second, the size distribution is narrower due to simultaneous nucleation at sites with identical environment.

Vertical Stacking of Nanoislands

A nucleation of nanoislands preferentially above existing ones can be achieved when a new layer of Ge (InAs) islands is grown on top of an Si (GaAs) spacer layer. If the spacer layer is sufficiently thin, the nucleation of islands occurs just above pre-existing islands. This vertical stacking of islands is shown in **Figure 4** and can be explained as follows: the lattice constant of the top part of the Ge islands is increased close to the bulk constant. Subsequent Si deposition leads to an increased lattice constant of the Si spacer layer just above the Ge islands. Upon the nucleation

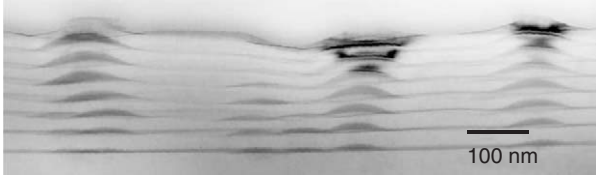

Figure 4 Cross-sectional TEM image of a stack of Ge islands in 40 nm thick Si spacer layers. The islands are aligned on top of underlying islands. (Reproduced from Vescan L (1998) *Thin Solid Films* 336: 244, with permission from Elsevier.)

of the next Ge island layer, Ge islands nucleate preferentially at locations on the Si spacer layer where the lattice constant is closest to the Ge lattice constant. This is just the case above the Ge islands. The residual strain field of the Ge islands in the lower layer seeds the nucleation in the upper layer. It was observed that the size uniformity of the 3D islands in subsequent layers is improved.

Semiconductor Nanowires

Nanowires on Facetted Surfaces

Some surfaces such as the Si(1 1 3) surface are known to facet, that is, to form alternating regions with a very high step density (step bunches) alternating with flat surface regions. Subsequent growth of Ge can result in preferential growth of nanowires in the step-bunch region. This effect is even more pronounced in Si/Ge multilayers. In **Figure 5**, a cross-sectional TEM image of a stack of five alternating depositions of Ge and Si is shown. Ge nanowires with a thickness of $\sim$4.5 nm and a width of $\sim$100 nm are formed. The formation of these nanowires is explained as a strain relaxation effect of Ge growing at the step-bunch regions where it can relax the elastic strain more effectively than on a compact 2D layer. After growth of an Si buffer layer, the next SiGe wire structure nucleates above the previous one. This is a strain-induced effect similar to the one shown for the vertical stacking of the islands.

Monolayer Thick Wires at Step Edges

Regular surface steps can be used to fabricate monolayer thick Ge wires using step-flow growth. Pre-existing step edges on the Si(1 1 1) surface are used as templates for the growth of 2D Ge wires at the step edges. When the diffusion of the deposited atoms is sufficient to reach the step edges, these deposited atoms are incorporated exclusively at the step edges and the growth proceeds by a homogenous advancement of the steps (step-flow growth mode). If small amounts of Ge are deposited, the steps advance only some nanometers, and narrow Ge wires can be grown. A key issue for the controlled fabrication of nanostructures consisting of different materials is a method of characterization, which can distinguish between the different materials on the nanoscale. In case of the important system Si/Ge, it has been difficult to differentiate between Si and Ge due to their similar electronic structure. However, if the surface is terminated with a monolayer of Bi, it is possible to distinguish between Si and Ge. **Figure 6a** shows an STM image after repeated alternating deposition of 0.15 atomic layers of Ge and Si, respectively. Due to the step-flow growth, Ge and Si wires are formed at the advancing step edge. Both elements can be easily distinguished by the apparent heights in the STM images. It turns out that the height measured by the STM is higher on areas consisting of Ge (red stripes) than on areas consisting of Si (orange stripes). The assignment of Ge and Si wires is evident from the order of the deposited materials (Ge, Si Ge, Si and Ge, respectively in this case). The initial step position is located right from the grown Ge wires. The step edge has advanced towards the left after the growth of the nanowires. The reason for the height difference in STM between Si and Ge is the different electronic structure of a Ge–Bi bond compared to an Si–Bi bond. The apparent height of Ge areas is $\sim$0.1 nm higher than the apparent height of Si wires (**Figure 6b**). The width of the Si and Ge wires is $\sim$3.5 nm as measured from the cross section (**Figure 6b**). The nanowires are 2D with a height of only one atomic layer (0.3 nm). Therefore, the cross section of a 3.3 nm wide Ge nanowire contains only 21 atoms (**Figure 6c**). The height difference arises due to an atomic layer of Bi which was deposited initially. The Bi floats always on top of the growing layer because it is less strongly bound to the substrate than Si or Ge. The Si/Ge wires are homogenous in width over larger distances and have a length of several thousand nanometers. Different widths of the wires can be easily achieved by different amounts of Ge and Si deposited.

Free-Standing Semiconductor Nanowires Grown by Vapor Liquid Solid Growth

In the VLS method, small catalytic nanoparticles (often gold) induce the growth of a homogenous rod of a semiconductor, with the diameter of the rod determined by the nanoparticle. The gold nanoparticles can be fabricated by heating a thin evaporated gold

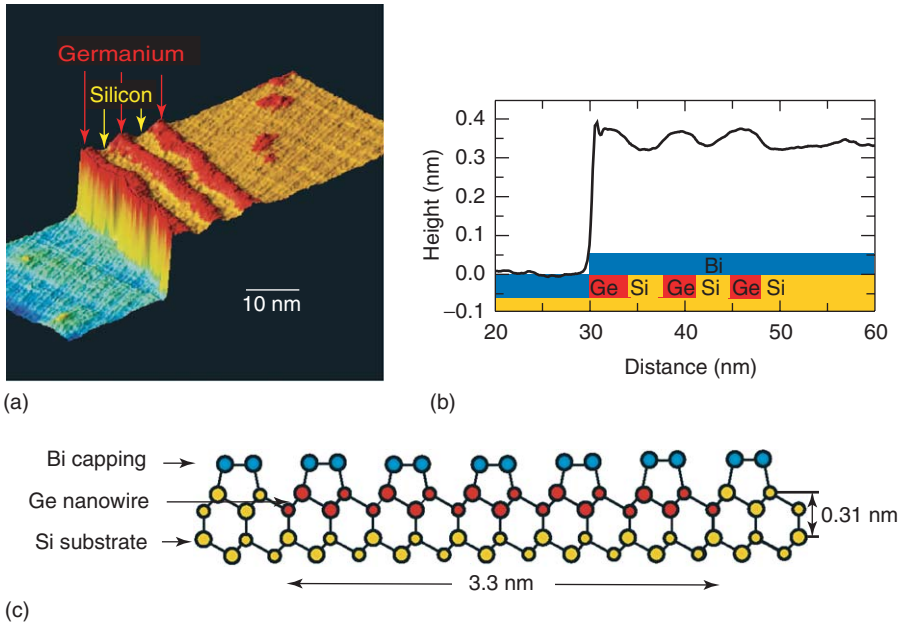

Figure 6 (a) STM image of 2D Ge/Si nanowires grown by step flow at a pre-existing step edge on a Si(1 1 1) substrate. Si wires (orange) and Ge wires (red) can be distinguished by different apparent heights. (b) The cross section shows the dimensions of the Si and Ge nanowires. The width of the wires is 3.5 nm and the height is only one atomic layer (0.3 nm). (c) Atomic structure of a 3.3 nm wide Ge wire on the Si substrate capped by Bi. The cross section of the Ge wire contains only 21 Ge atoms. film, which breaks up and reshapes into nanoscale droplets. Alternatively, gold aerosol nanoparticles with sizes of a few tens of nanometers are used. The gold nanoparticles form a eutectic alloy with the substrate material (for instance, GaAs). Using MBE or metallorganic vapor phase epitaxy, nanowires can be grown. These nanowires are different from the ones discussed so far, in that they are free-standing on the substrate and grow vertically. The previously considered nanowires were epitaxially grown along their length on the substrate or even embedded into the substrate during growth.

The VLS method was used for the Si/Ge and the GaAs material system. This growth method can even be used to grow semiconductor heterostructures within the nanowires with atomically sharp interfaces. **Figure 7** shows an InAs nanowire (green) with several InP barriers (red). The rapid alternation of the composition is controlled by the supply of precursor atoms to the eutectic melt supplied as molecular beams. Of particular interest is the fact, that the very small cross section allows efficient lateral relaxation of the nanowire, thereby providing freedom to combine materials with very different lattice constants to create heterostructures within the nanowire. The problem of incorporation of misfit dislocations, when a critical thickness is exceeded, does not occur due to the small lateral size of the nanowires. The

VLS method is also used to grow semiconductor heterostructures, not along the wire, but radial heterostructures, the so-called core-shell structures.

The synthesis of Si/Ge core-shell nanowires by chemical vapor deposition is achieved by the following

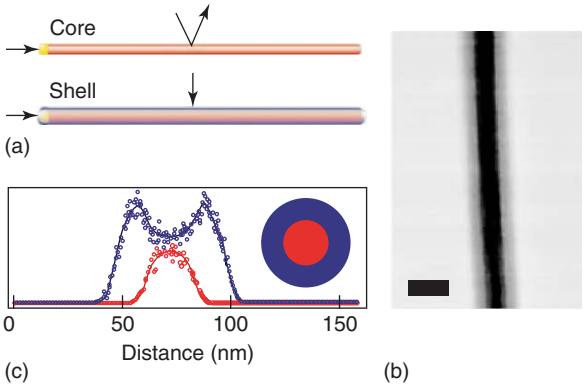

Figure 8 (a) Schematic of the core-shell growth of a radial Ge/Si structure (b) TEM image of a Ge/Si core-shell nanowire. Scale bar is 50 nm. (c) Elemental mapping along the cross section showing the Ge (red circles) and Si (blue circles) concentrations. process schematically shown in **Figure 8a**. Initially a Ge nanowire is grown by vapor phase epitaxy growth from a gold nanoparticle. In this case, the substrate serves only as a support and the nanowires are not epitaxially connected to the substrate. The deposition temperature is chosen so low that no germane (GeH_4) is decomposed along the wire and radial growth is suppressed. Only axial growth occurs by the VLS mechanism at the gold nanoparticle. Subsequently, a boron-doped Si shell is grown by CVD. The addition of diborane serves to lower the decomposition temperature of silane (SiH_4) and "turns on" the radial growth. **Figure 8b** shows a TEM image of the Ge core (imaged darker) and the Si shell (lighter gray) with a diameter of $\sim$50 nm. The elemental TEM cross-sectional mapping shown in **Figure 8c** shows the radial chemical composition in a wire (core diameter 26 nm, shell thickness 15 nm). By oxidation of a shell of the radial heterostructure, it is possible to build a coaxially gated nanowire transistor.

Hybrid Systems – Combination of Lithography and Self-Organized Growth

In hybrid methods, self-organization is combined with lithographic patterning. In this approach, self-organization is used to form nanostructures on a smaller scale than the one accessible by lithography. Most importantly, the hybrid methods provide a direct contact of nanostructures formed by self-organization to lithographically patterned structures. As an example, the self-organized growth of Ge islands in oxide holes is shown in **Figures 9a–9d**. The staring

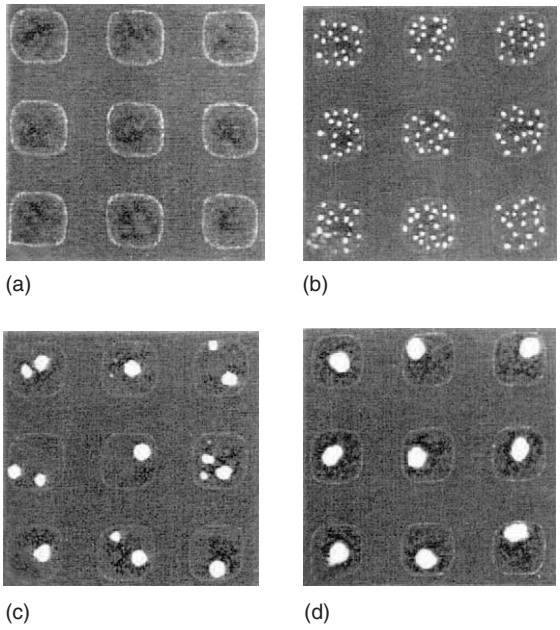

Figure 9 (a–d) Growth of Ge islands in holes on an oxidized Si substrate. (Reproduced with permission from Kim ES, Usami N, and Shiraki Y (1999) *Semiconductor Science and Technology* 14: 257; © IOP Publishing Limited.)

surface is a silicon substrate with a thin oxide layer at the surface. Electron lithography is used to remove the oxide and form holes of a diameter of 0.5 μm where the bare Si surface is exposed. Self-organized growth of Ge leads to the formation of Ge islands, which can be smaller than the size scale of the electron beam lithography. The gas phase growth of Ge is selective, that is, Ge only grows inside the holes in the oxide and not on the oxide itself. **Figure 9** shows the nucleation of Ge islands in the holes in the oxide for different growth temperatures. At lower temperatures, the island density is so large that several islands nucleate in one oxide hole. If the temperature is increased finally, only one Ge island nucleates in each oxide hole. The size of the Ge island is smaller than the lithographically defined oxide hole. This approach is called lithographic downscaling. However, the positioning of the islands is not perfect. As seen in **Figure 9d**, the position of the Ge island inside the oxide hole is not defined but is rather randomly in the center or at the corner of the oxide hole. Due to the fact that the Ge does not grow on the oxide, the edges of the oxide hole are not sinks for deposited Ge atoms. Therefore, the Ge adatom concentration is homogenous across the hole, and the nucleation of the Ge island is random within the oxide hole. If the edges of the hole were sinks for Ge atoms (for instance, if the edges of the hole consisted of Si), the adatom density would have a maximum at the center of the hole and the nucleation of the Ge islands

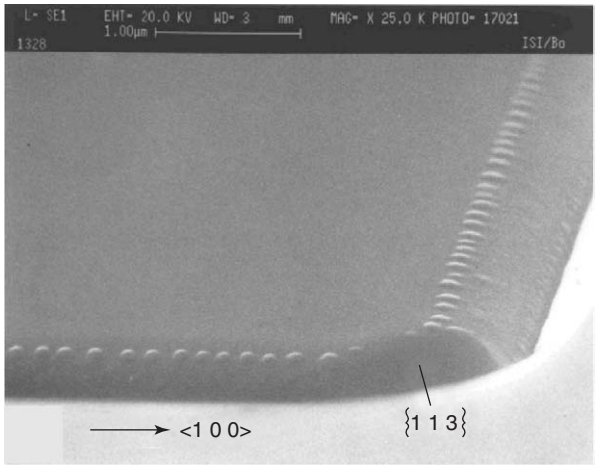

Figure 10 Regular alignment of Ge islands at the edge of a mesa which was fabricated by optical lithography. (Reproduced from Vescan L (1989) *Journal of Crystal Growth* 194: 173, with permission from Elsevier.)

would occur preferentially at the center of the oxide holes.

A simple structure formed by lithographic methods is a mesa (from the Spanish table), which is a flat terrace separated from the rest of the wafer by trenches. A silicon mesa structure is imaged by electron microscopy and shown in **Figure 10**. It has been observed that the growth of Ge on this mesa leads to preferential nucleation of Ge islands at the mesa edges. **Figure 10** shows a regular alignment of Ge islands along the mesa edges. This preferred nucleation of islands at the convex part of the surface profile is quite unexpected. Considering the surface curvature alone, the chemical potential is lowest at locations with a concave curvature. Atoms diffuse toward the lower chemical potential, that is, to the concave parts of the surface. This reasoning is true for homoepitaxy. In heteroepitaxy, another contribution is important: the strain-dependent contribution to the chemical potential. The convex regions are most favorable for strain relaxation of the strained Ge wetting layer covering the Si substrate. Therefore, the strain contribution to the chemical potential has a minimum at convex edges. In the current case, this strain-induced contribution to the chemical potential overwhelms the curvature contribution and leads to a minimum in the total chemical potential at the convex edges. Therefore, these convex edges with a minimum in the chemical potential provide a favorable nucleation site for Ge islands.

Also, nanowires can be fabricated, aligned to lithographically defined structures. V-grooves can be defined by lithography and anisotropic wet chemical etching with a low-etch speed for the crystal plane forming the side facets of the V-groove. The formation

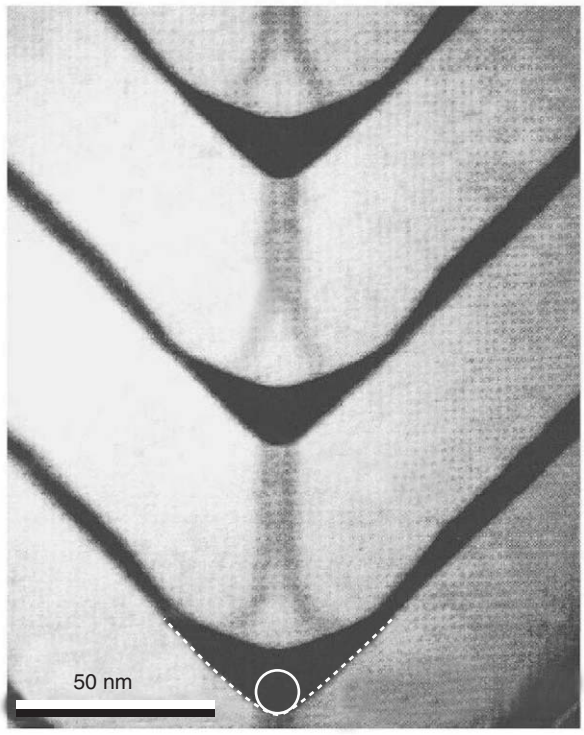

Figure 11 Cross-sectional TEM image of vertically stacked GaAs nanowires and AlGaAs barriers aligned along a lithographically defined V-groove. (Reproduced with permission from Gustafsson A, Reinhardt F, Baisiol G, and Kapon E (1995) *Applied Physics Letters* 67: 3673; © American Institute of Physics.)

of nanowires at the bottom of the V-groove is induced by the self-limiting nature of the growth front of AlGaAs on the grooved substrate. Vertically stacked arrays of GaAs/AlGaAs nanowires exhibiting 5–10% size uniformity have been demonstrated (**Figure 11**). The layer structure consists of GaAs nanowires separated by $Al_{0.42}Ga_{0.58}As$ barriers. The formation of the crescent-shaped GaAs wires is based on the formation of slow-growing side facets along the V-grooves. The migration of adatoms away from these side-walls toward the V-groove bottom produces the concave surface profiles in the corners of the V-grooves.

Semiconductor Optics

G C La Rocca, Scuola Normale Superiore, Pisa, Italy

Introduction

Even though the paramount role of semiconductors, and of silicon above all, in modern technology is mainly due to their use in electronic microdevices, the optical properties of these materials are also of great interest. In particular, many applications of semiconductors are based on optoelectronic effects: the transformation of light in electric current (photovoltaic devices), and the transformation of electric current in light (semiconductor light emitting diodes and lasers). Of course, the spectroscopy of semiconductors has been, and continues to be, a subject of crucial relevance from the viewpoint of basic science as it allows a detailed study of the electronic structure of these materials. The field is still in great expansion, also due to the possibility of growing layers of different materials on top of each other by molecular beam epitaxy in order to engineer their electronic and optical properties.

The following concentrates on bulk properties rather than on heterostructures, and the focus is on the optical part of the spectrum due to interband electronic excitations (possibly assisted by phonon participation). After discussing general concepts related to the linear optical response functions, the corresponding absorption spectra are considered as they are much less sensitive than luminescence to extrinsic effects. Excitonic and polaritonic phenomena are also touched upon. Finally, the role of external perturbations on the optical properties is discussed (modulation spectroscopy).

The Dielectric Function

Semiconductors are characterized by an energy gap of the order of the electronvolt (see **Table 1**) and correspondingly by an absorption edge in the near infrared or in the visible below which they are nearly transparent and above which they are almost opaque. Actually, a direct measurement of the absorption is rather difficult as it is so strong when the frequency is higher than the threshold frequency that no radiation goes through the semiconductor, except in the case of extremely thin layers. This difficulty can be overcome when the optical quality of the surfaces makes it possible to measure by ellipsometry, both the real and the imaginary part of the dielectric function as a function of the light frequency. Alternatively, a measurement of the reflectivity over a large frequency range with sufficient accuracy and the application of the Kramers–Kronig relations allows one to determine the real and the imaginary part of the reflection coefficient. From this, the dispersion and the absorption can be obtained, establishing the bases for the experimental determination of the optical response of semiconductors and of its theoretical interpretation in terms of the electronic band structure.

It may be recalled that the normal incidence reflection coefficient, defined as the ratio between the electric field of reflected and incident wave, is related to the complex index of refraction $\tilde{n}$ by the Fresnel relation

$$r = \frac{E_r}{E_i} = \frac{\tilde{n} - 1}{\tilde{n} + 1} = |r|e^{i\theta} \qquad [1]$$

and taking the logarithm

$$\log r = \log |r| + i\theta \qquad [2]$$

Since this is an analytic function of the frequency ω in the upper complex plane $\omega + i\eta$, the following

Table 1 Energy gap values (in eV) of cubic semiconductors at room temperature

	AlSb (i)	CdTe (d)	GaAs (d)	GaP (i)	GaSb (d)
E_g	1.52	1.45	1.43	2.26	0.71
	Ge (i)	InAs (d)	InP (d)	InSb (d)	Si (i)
E_g	0.67	0.35	1.35	0.18	1.14

(d) = direct gap; (i) = indirect gap.

Kramers–Kronig relation holds true:

$$\theta(\omega) = -\frac{2\omega}{\pi}\,\mathscr{P}\int_0^\infty \frac{\log|r(\omega')|}{\omega'^2-\omega^2}\,\mathrm{d}\omega' \qquad [3]$$

and from the measured reflectivity $|r(\omega')|^2$, $\theta(\omega)$ can be obtained, and consequently the real and imaginary parts of $\tilde{n} = n + \mathrm{i}k$ can be derived from [1].

This amounts to the knowledge of dispersion and absorption since the complex dielectric function is related to $\tilde{n}$ by

$$\tilde{\varepsilon} = \varepsilon_1 + \mathrm{i}\varepsilon_2 = \tilde{n}^2 \qquad [4]$$

The dissipation is related to the imaginary parts, since the absorption coefficient is given by

$$\alpha(\omega) = \frac{2k\omega}{c} = \frac{\varepsilon_2\omega}{nc} \qquad [5]$$

while the real part $n(\omega)$ gives the dispersion.

To relate the measured optical constants to the electronic structure, the coupling dipolar interaction between the electromagnetic radiation and the electrons is to be considered:

$$H'(\boldsymbol{r}) = \mathrm{e}\boldsymbol{E}\cdot\boldsymbol{r} \qquad [6]$$

where $\boldsymbol{E} = \boldsymbol{E}_0\mathrm{e}^{-\mathrm{i}\omega t} + \boldsymbol{E}_0^*\mathrm{e}^{-\mathrm{i}\omega t}$ denotes the electric field of the radiation, and $\boldsymbol{r}$ is the position of the electron which can make a transition between different electronic states. One may recall that the transition probability per unit time between an occupied lower initial state $|i\rangle$ and an empty higher final state $|f\rangle$ is given by the Fermi golden rule

$$P^{(1)}_{i\to f} = \frac{2\pi}{\hbar}\,|\langle f|H'|i\rangle|^2\delta(E_f - E_i - \hbar\omega) \qquad [7]$$

In the case of semiconductors, one must sum over all occupied initial states (valence bands) and empty final states (conduction bands) in the unit volume to compute the electromagnetic power dissipated at a given frequency

$$W(\omega) = \frac{1}{V}\sum_{i,\,f}\hbar\omega P^{(1)}_{i\to f} \qquad [8]$$

where V is the crystal volume. The absorption coefficient is by definition

$$\alpha(\omega) = \frac{\text{dissipated power per unit volume}}{\text{incoming flux}} = \frac{W(\omega)}{(cnE^2/2\pi)} \qquad [9]$$

The imaginary part of the dielectric function, rather than the absorption coefficient, can be directly calculated as it does not depend on the real part of the index of refraction. From the above expressions, one obtains for the dissipative function

$$\varepsilon_2(\omega) = 4\pi^2\sum_{c,v}\int\frac{2\mathrm{d}\boldsymbol{k}}{(2\pi)^3}\,|\langle\psi_{ck}|e\boldsymbol{r}|\psi_{vk}\rangle|^2 \times\delta(E_c(\boldsymbol{k}) - E_v(\boldsymbol{k}) - \hbar\omega) \qquad [10]$$

where the wave functions and their energies are given by a band structure calculation, the integration is over the first Brillouin zone and a factor of 2, assuming spin degeneracy has been included. Here, as the wave vector of light $2\pi/\lambda$ is much smaller than the size of the Brillouin zone π/l, being l the lattice constant, only allowed 'vertical' transitions between electronic states having the same $\boldsymbol{k}$ have been considered.

The real part $\varepsilon_1(\omega)$ is then obtained from the Kramers–Kronig dispersion relation

$$\varepsilon_1(\omega) = 1 + \frac{2}{\pi}\mathscr{P}\int_0^\infty\frac{\omega'\varepsilon_2(\omega')}{\omega'^2-\omega^2}\,\mathrm{d}\omega' \qquad [11]$$

and from the complex dielectric function, the optical dispersion and absorption properties follow. One may finally recall that since most semiconductors of interest (e.g., those in **Table 1**) are cubic, their optical response is isotropic as assumed here.

Interband Transitions

The optical absorption in crystals is mostly due to interband transitions, that is, to the promotion of electrons from occupied valence bands to empty conduction bands. Because of the energy conserving δ-function in [10], a singular behavior of the response functions is obtained in the vicinity of the critical points of the Brillouin zone (van Hove singularities), where for a given couple of conduction and valence bands

$$\boldsymbol{\nabla}_k(E_c(\boldsymbol{k}) - E_v(\boldsymbol{k})) = 0 \qquad [12]$$

In fact, near a critical point it is often a good approximation to consider the transition dipole matrix element as a constant. Then, the integral in [10] is simply proportional to the joint density of states $J(\omega)$:

$$J(\omega) = \int\frac{2\mathrm{d}^3k}{(2\pi)^3}\,\delta(E_c(\boldsymbol{k}) - E_v(\boldsymbol{k}) - \hbar\omega) = \frac{2}{(2\pi)^3}\int_{S(\omega)}\frac{\mathrm{d}^2k}{|\nabla_k(E_c(\boldsymbol{k}) - E_v(\boldsymbol{k}))|} \qquad [13]$$

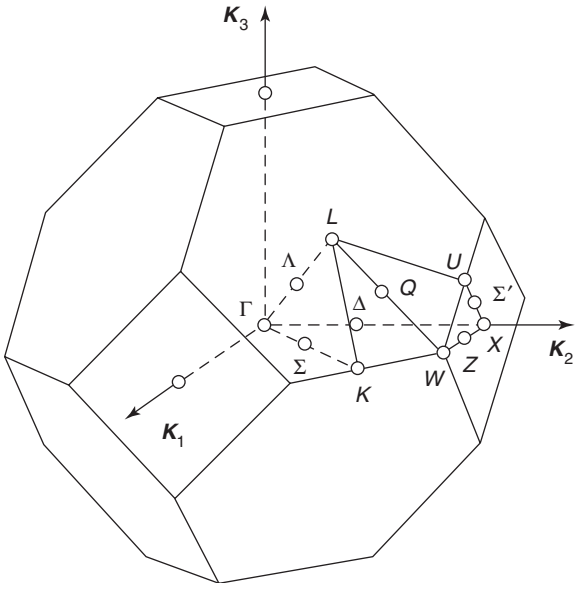

Figure 1 Brillouin zone of cubic semiconductors (f.c.c. lattice); lines and points of high symmetry are indicated.

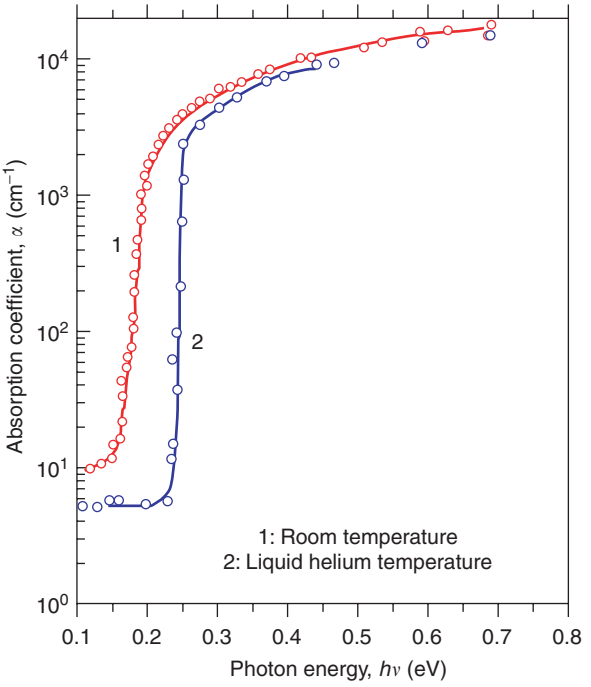

Figure 2 Absorption edge of InSb. (From the database NSM maintained by the Ioffe Institute.)

where the two-dimensional integral is over a surface $S(\omega)$ in $\boldsymbol{k}$-space for which $E_c(\boldsymbol{k}) - E_v(\boldsymbol{k}) = \hbar\omega$.

The location of critical points in the Brilluoin zone is mainly (but not completely) determined by symmetry considerations. For cubic semiconductors, the points Γ, X, L, and W in the Brilluoin zone (see **Figure 1**) are always critical points; other critical points usually occur along lines or planes of symmetry, but critical points at a generic wave vector $\boldsymbol{k}$ cannot be excluded. van Hove singularities have been found in the optical spectra of all semiconductors, and this has allowed the identification of the critical point transition peaks and the verification of the band structure.

A direct gap semiconductor is characterized by having both the conduction band minimum and the valence band maximum at the same wave vector $\boldsymbol{k}$ (typically the Γ point at $\boldsymbol{k} = 0$). When the optical transition between them is allowed, the absorption edge at a frequency corresponding to the bandgap E_g is due to the fact that the joint density of states vanishes for $\hbar\omega < E_g$ and increases sharply for $\hbar\omega \simeq E_g$. In particular, assuming a parabolic dispersion of the conduction and valence band states for $\hbar\omega \geqslant E_g$

$$J(\omega) \propto \sqrt{\hbar\omega - E_g} \qquad [14]$$

This result correctly describes the gross features of the absorption edge for allowed interband transitions in direct gap semiconductors. As an example, the absorption spectrum of InSb near its direct gap is shown in **Figure 2** exhibiting a well-pronounced absorption edge and becoming opaque at frequencies $\hbar\omega > E_g$ with an absorption coefficient $\alpha \approx 10^4$ cm^{-1}.

In **Figure 3**, the entire experimental excitation spectrum of Ge (the lowest gap of which is indirect, see below) is compared to that computed, as described above, from a pioneering band structure calculation based on empirical pseudopotentials. In this classical example, not only have the critical points been identified, but also the full band structure has been put to test obtaining a satisfactory agreement with the measured data. From the calculation of the dipole matrix elements at all points of the Brillouin zone and for all possible transitions to higher conduction bands, it can be concluded that most of the absorption is due to transitions to the lowest empty conduction bands. This fact can also be proved by verifying the f-sum rule in the optical range

$$\int_0^{\omega_M} \omega\varepsilon_2(\omega)\, d\omega \simeq \frac{2\pi^2 e^2 n_{\text{eff}}}{m} \qquad [15]$$

where in this case the frequency ω_M is just above the spectrum in the visible region, and n_{eff} is about equal to the number of valence electrons which take part in the optical transitions (8 per unit cell in elemental semiconductors such as Ge).

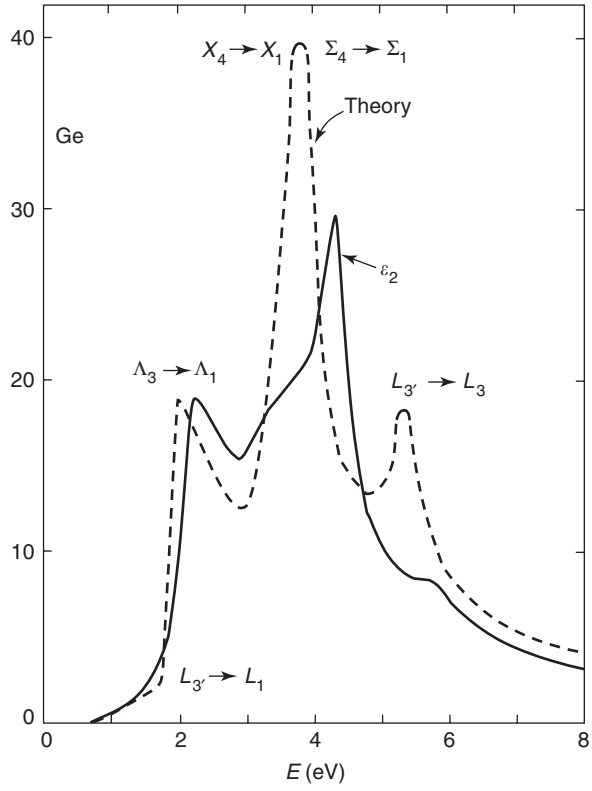

Figure 3 Imaginary part of the dielectric function of Ge: the solid line is experimental, the dashed one theoretical; optical transitions at critical points are identified. (From Brust D, Phillips JC, and Bassani F (1962) Critical points and ultraviolet reflectivity of semiconductors. *Physics Review Letters* 9: 94.)

Phonon-Assisted Transitions

Differently from the case of direct gap semiconductors such as GaAs and InSb, for Si and Ge, while the top of the valence band is still at the center of the Brillouin zone (Γ point), the minimum of the conduction band occurs away from Γ (close to the X point along the Δ line in Si, at the L point in Ge). This has been clearly observed by cyclotron resonance experiments, but it also shows in the optical properties, because the electron–phonon interaction makes an optical transition possible between different points of the Brillouin zone, the missing (pseudo) momentum being provided by the phonon emitted or adsorbed.

The probability of an indirect transition can be calculated in the second-order perturbation theory taking the perturbation interaction to be the sum of [6] and the electron–phonon interaction. Assuming constant matrix elements involving the states near the extrema which give the strongest contribution, one obtains

$$\varepsilon_2(\omega) \propto \left(n_{q_o v_o} + \frac{1}{2} \pm \frac{1}{2}\right) \int\int \frac{2\,\mathrm{d}\boldsymbol{k}_1\,\mathrm{d}\boldsymbol{k}_2}{(2\pi)^6} \times \delta(E_c(\boldsymbol{k}_1) - E_v(\boldsymbol{k}_2) \pm \hbar\omega_{v_o}(\boldsymbol{q}_o) - \hbar\omega) \quad [16]$$

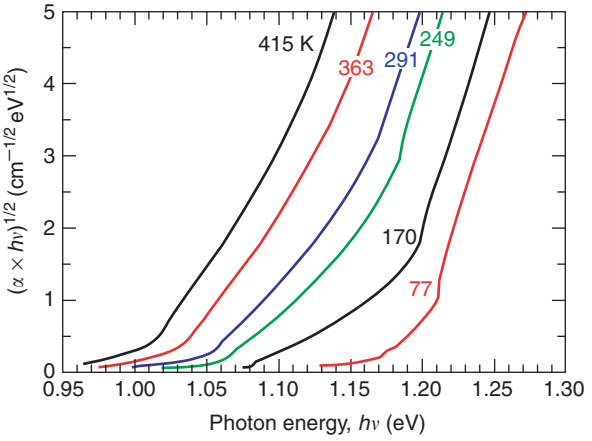

Figure 4 Indirect absorption edge of Si at various temperatures. (From the database NSM maintained by the Ioffe Institute.)

where "$\pm$" refers to the creation or destruction of a phonon of mode v_o with the wave vector $\boldsymbol{q}_o$, which connects the valence band maximum and the conduction band minimum.

The summation over the final electronic states above the edge ($\hbar\omega_o$) gives an energy dependence which is different from that of direct transitions, and precisely

$$\begin{aligned} &\varepsilon_2(\omega) = 0 \quad \text{when} \quad \omega < \omega_o \\ &\varepsilon_2(\omega) \propto (\omega - \omega_o)^2 \quad \text{when} \quad \omega > \omega_o \end{aligned} \quad [17]$$

Furthermore, different edges occur in correspondence to each phonon, and their values depend on the fact that the phonons are absorbed or emitted. At low temperature, one can only create phonons, and consequently the edge occurs at higher energy

$$\hbar\omega_o = E_g + \hbar\omega_{v_o}(\boldsymbol{q}_o) \quad [18]$$

At higher temperature, phonons can also be absorbed with a temperature-dependent probability given by the Bose–Einstein factor, and the edge is shifted to lower energy

$$\hbar\omega_o = E_g - \hbar\omega_{v_o}(\boldsymbol{q}_o) \quad [19]$$

Indirect transitions are responsible for the weak absorption tail in Si and Ge, which reflects their conduction band structures. **Figure 4** shows the absorption tail of Si; a fit to the profile of the indirect edge gives the frequency of the phonons which make the transition possible. At higher energies, when allowed direct transitions set in, the contribution of phonon-assisted indirect transitions to the absorption is negligible.

Excitons and Polaritons

The discussion above neglects the attractive interaction between the electron promoted into the conduction band and the hole left behind in the valence band. However, their motion is correlated and, in particular, they can be bound into the Wannier–Mott excitonic states with an energy below that of the single-particle energy gap. Due to the large dielectric constant ($\varepsilon_o \approx 10$) and the small reduced mass ($\mu = (m_e m_h)/(m_e + m_h) \approx 0.1\, m_o$) typical of semiconductors, the exciton radius a_o is much larger than the lattice constant and the binding energy correspondingly small. In the first approximation, an exciton turns out to be a "rescaled hydrogen atom" with binding energies depending only on the principal quantum number n:

$$E_n = E_g - \frac{R^*}{n^2},$$
$$R^* = \frac{\mu e^4}{2\varepsilon_o^2 \hbar^2} = \frac{\hbar^2}{2\mu a_o^2} = \frac{e^2}{2\varepsilon_o a_o} \qquad [20]$$

the exciton Bohr radius a_o being larger than 1 nm and the effective Rydberg R^* being typically ~ 10 meV. Thus, the exciton absorption lines are typically prominent only at low temperatures, as shown for GaAs in **Figure 5**.

The optical resonances below the bandgap corresponding to the excitonic bound states can be described by the following complex dielectric constant:

$$\varepsilon(\omega) = \varepsilon_b + \sum_n \frac{f_n}{(E_n/\hbar)^2 - \omega^2 - i\gamma_n \omega} \qquad [21]$$

where ε_b is a background dielectric constant, γ_n a phenomenological line width (e.g., due to phonon scattering), and the oscillator strength f_n is proportional to the square of the dipole matrix element between valence and conduction band extrema and inversely proportional to the exciton volume ($f_n \propto (n a_o)^{-3}$).

In correspondence to the excitonic resonances, when damping processes are small compared to the exciton–photon coupling, the electromagnetic waves propagating in the crystal hybridize with the exciton polarization giving rise to polariton states, that is, the proper modes of Maxwell's equations with the dielectric function given in [21]. Their dispersion law is obtained from

$$\omega^2 = \frac{c^2}{\varepsilon(\omega)} k^2 \qquad [22]$$

giving two branches (upper and lower polaritons) accompanied by a region of anomalous dispersion with a strongly reduced group velocity, as shown for GaAs in **Figure 6**. In polar semiconductors, having strong infrared absorption lines due to optical phonons, phonon–polariton states are similarly formed.

Modulation Spectroscopy

In an experimental spectrum, for example, of the reflectivity, the van Hove singularities such as those shown in **Figure 3** might be difficult to identify. As an example, the optical reflectivity of Si in **Figure 7** exhibits quite a smooth behavior as a function of frequency. However, the possibility of employing a phase-sensitive detection technique in conjunction with a periodic modulation of an external perturbation improves, on the one hand, the signal-to-noise

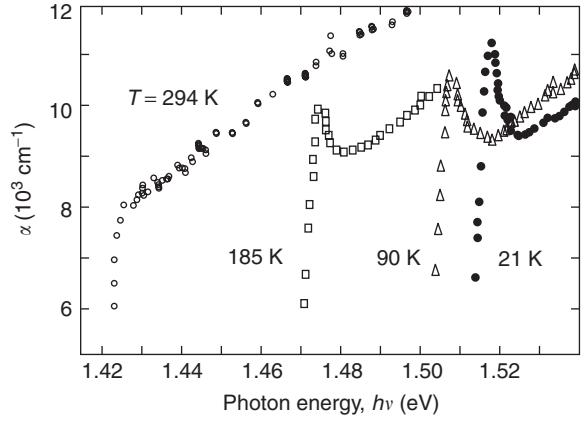

Figure 5 Excitonic absorption in GaAs, at room temperature the exciton peak is no longer observed. (From the database NSM maintained by the Ioffe Institute.)

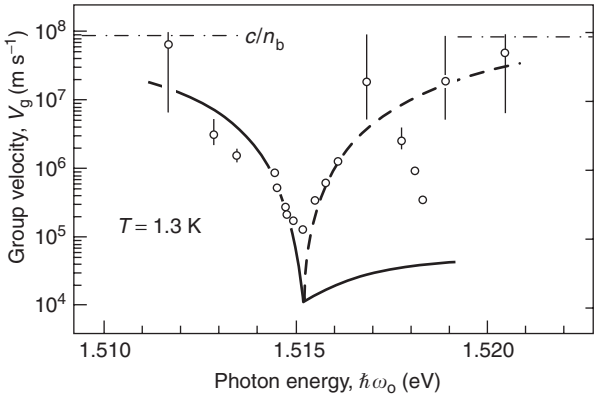

Figure 6 Exciton–polariton group velocity in GaAs, the solid and dashed lines are the theoretical values for the lower and upper polariton branch, respectively. (From Ulbrich RG and Fehrenbach GW (1979) Polariton wave packet propogation in the exciton resonance of a semiconductor. *Physics Review Letters* 43: 963.)

ratio by several orders of magnitude and, on the other hand, allows to enhance the sharp features of a spectrum with respect to a smoothly varying background. Modulation spectroscopy allows one to directly measure derivative spectra showing very clearly the stronger singularities in the first (and higher order) derivatives of, say, the reflectivity as a function of frequency.

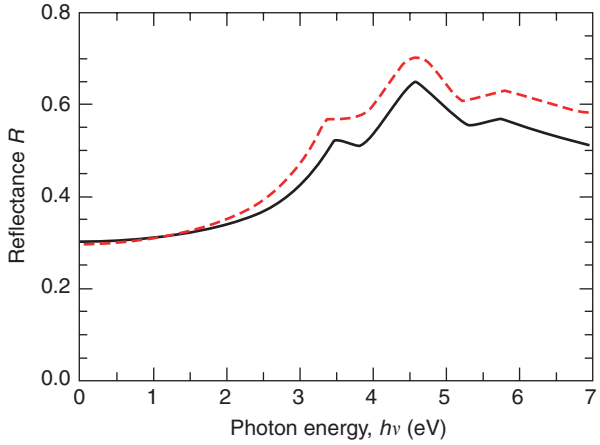

Figure 7 Reflectivity spectrum of Si: dashed line is experimental, solid line is theoretical (based on an empirical pseudopotential band structure calculation). (From the database NSM maintained by the Ioffe Institute.)

Thus, from the experimental point of view, much information on the properties of semiconductors can be obtained by measuring changes induced by externally applied perturbations. The latter can preserve the symmetry of the crystal (as for hydrostatic pressure or temperature changes) or lower it (as for uniaxial stress or electric and magnetic fields), in which case detailed information on the symmetry properties of the critical points of the electronic bands can be obtained. For instance, the reflectivity of Ge ~ 2.2 eV is dominated by interband transitions involving states along the Λ line in the Brillouin zone: uniaxial stress along the [0 0 1] direction does not split the degeneracy among the eight [1 1 1] valleys, whereas uniaxial stress along the [1 1 1] direction induces a difference between the two of them along the stress axis and the other six; in the latter case, a polarization dependence of the reflectivity is observed.

One of the most common techniques of modulation spectroscopy is electroreflectance, in which the

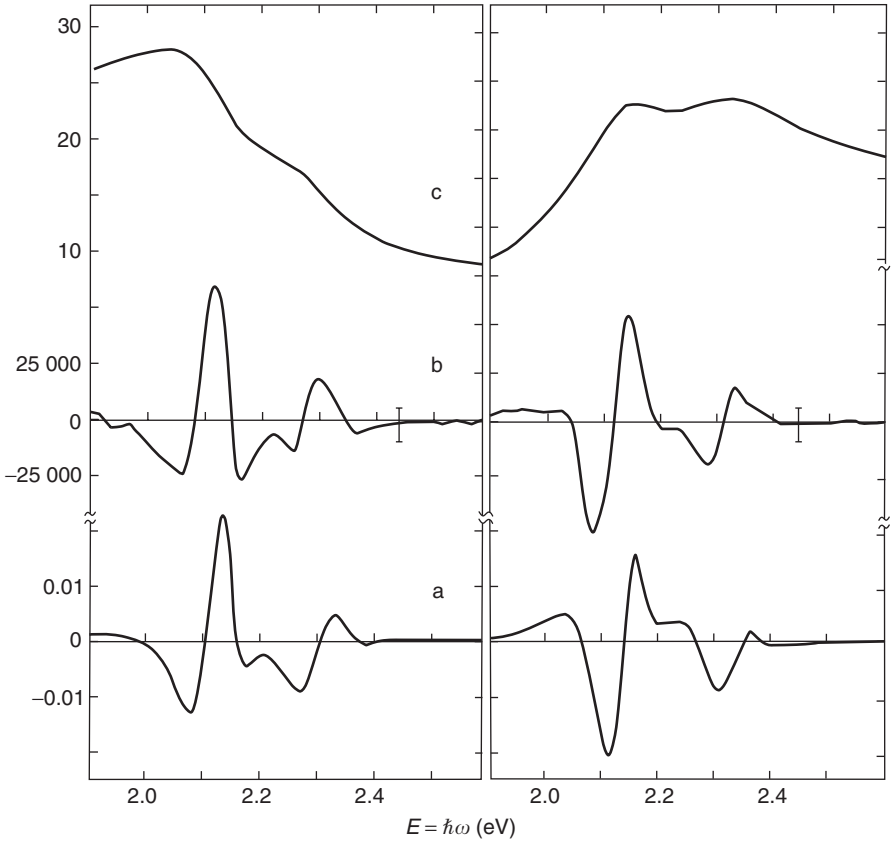

Figure 8 Real part (left panels) and imaginary part (right panels) of the dielectric function of Ge at the E_1 and $E_1 + \Delta_1$ gaps from (a) low-field electroreflectance compared to (b) the third-order derivatives as in eqn [23] calculated from (c) ellipsometric data. (From Aspnes DE (1972) Direct verification of the third-derivative nature of electroreflectance spectra. *Physics Review Letters* 28: 168.)

reflectivity is measured while applying an AC electric field parallel or perpendicular to the sample surface. The changes in optical constants measured by electroreflectance modulation spectroscopy have a very simple interpretation in the regime of low applied fields. In this case, as shown in **Figure 8**, the spectra are simply proportional to the third derivative of the respective optical constant with respect to frequency according to

$$\Delta\varepsilon(\omega) \propto \frac{e^2F^2}{\mu\hbar}\,\frac{1}{\omega^2}\,\frac{\mathrm{d}^3}{\mathrm{d}\omega^3}\,(\omega^2\varepsilon(\omega)) \qquad [23]$$

where F is the electric field and μ the reduced mass of the relevant interband transition. The electroreflectance spectra (**Figure 8a**) show much sharper features than those obtained by ellipsometry (**Figure 8c**).

Introduction

A general introduction to semiconductors has been provided elsewhere in this encyclopedia. In order to theoretically describe electronic transitions induced in a semiconductor by a radiation field, it is first essential to model the energy eigenstates in a crystal. Therefore, this article begins with a brief review of the fundamental assumptions on which the description of the states of an ideal crystal is based. The effect of different types of impurities, such as acceptors, donors, and isoelectronic impurities, which enrich the spectrum of semiconducting crystals, is considered next. These are particularly important both from the fundamental and technological points of view. Finally, excitonic states, which appear in the crystal spectrum when electronic transitions between valence and conduction bands occur, are addressed. Once the full spectrum is understood, transitions induced by the radiation are discussed. These bear a strong analogy with atomic transitions, in particular concerning the selection rules. This article is restricted to radiation frequencies close to the fundamental gap, which, for a semiconductor, is typically of the order of a few electron volts.

Electronic Band Structures of Crystals: The Basic Approximations

A crystal consists of a very large number of atoms arranged in a regular lattice. The lattice structure of crystals implies that their properties are invariant under translations in space. In fact, the lattice of any crystal can be built from a fundamental cell, called unit cell, by spatial translations along the three fundamental axes.

In order to obtain the energy levels and the states of a solid, a number of approximations are introduced. First, the adiabatic (Born–Oppenheimer) approximation, according to which the electrons adiabatically follow the slower motion of the nuclei, allows separation of the equation of motion into two coupled problems for the nuclei and the electrons. The approximation relies on the fact that nuclei have a mass four orders of magnitude larger than the electron mass and, consequently, that the velocity of the motion of the nuclei around their equilibrium positions in the lattice is several orders of magnitude smaller than that of the electrons. The wave function of the crystal is then represented as the product of two wave functions, one for the nuclei and the other for the electrons, respectively. In the adiabatic approximation, the Schrödinger equation for electrons is solved in the potential of the nuclei, which

are frozen in their equilibrium positions. The equation for the nuclei is then averaged over the electron motion, which contributes only as a global potential term. From the viewpoint of transitions between electronic states, the equation for the electronic part of the wave function should be solved, which is a difficult many-electron problem. Therefore, a second approximation – the one-electron or Hartree–Fock approximation – is introduced. The wave function of N electrons is written as the antisymmetrized product of N one-electron wave functions, which is expressed as a determinant (the Slater determinant).

This approximation implies that the electron–electron correlations are neglected. The energies and states of electrons in the crystal are then calculated by a variational method using the Slater determinants as a basis. The corresponding Euler equations have the form of a nonlinear Schrödinger equation with two self-consistent potentials resulting from the electron–electron direct (Hartree) and exchange (Fock) interaction, respectively. The Hartree–Fock approach briefly sketched above leads to quite cumbersome calculations. Therefore, the so-called band approximation is introduced. In this case the basic equation describing the electrons in the crystal is

$$\left[\frac{p^2}{2m} + V(\boldsymbol{r})\right]\psi_n(\boldsymbol{k},\boldsymbol{r}) = E_n(\boldsymbol{k})\psi_n(\boldsymbol{k},\boldsymbol{r}) \qquad [1a]$$

where the nonlocal potential has been approximated by a local one. Here, $V(\boldsymbol{r})$ is a periodic potential, invariant under all symmetry operations of the crystal. It is the same for all states and is expressed as follows:

$$V(\boldsymbol{r}) = V_{\text{electron-lattice}} + V_{\text{Coulomb}} + V_{\text{exchange}} + V_{\text{correlation}} \qquad [1b]$$

In particular, the Coulomb and exchange components of $V(\boldsymbol{r})$ are calculated using the charge distribution of the ground state. The last term describes an approximation to the correlation energy, which is in general assumed to be proportional to a non-integral power of the charge density. In the section on excitons, the limitation of such an approximation is discussed. The solutions of eqn [1] with periodic boundary conditions are eigenfunctions of the Bloch type, that is, $\psi_n(\boldsymbol{k},\boldsymbol{r}) = e^{i\,\boldsymbol{k}\cdot\boldsymbol{r}}u_n(\boldsymbol{k},\boldsymbol{r})$, where $u_n(\boldsymbol{k},\boldsymbol{r})$ is a periodic function, with the periodicity of the lattice, and the wave vector $\boldsymbol{k}$ belongs to the first Brillouin zone. The eigenvalues $E_n(\boldsymbol{k})$ describe the energy bands of the crystal. In a semiconductor, in particular, two bands, called "valence" and "conduction" band, respectively, are well separated, in energy by the an energy gap E_g. Typically, the energy gap in a semiconductor varies between 0.5 eV and 2 eV at room temperature. A very useful model in this context is the two-band model, which neglects all bands, except the valence and conduction bands.

Impurity States

The theory sketched so far has considered the states of a perfect crystal. However, there are situations in which this picture must be refined, for example, when foreign atoms (impurities) are introduced into the crystal lattice. Two specific examples are the donor and acceptor impurities, and the isoelectronic impurities, which change the optical properties of the semiconductor without changing the carrier density.

Shallow Impurities

The effective-mass method for shallow impurities is illustrated in the case where a foreign atom (donor), which can release an electron in the conduction band of the host crystal, is introduced into the lattice. The translational periodicity of the lattice is broken and an additional potential originating from the presence of the impurity atom is introduced. In the one-electron approximation, the Schrödinger equation can be written as

$$\left[\frac{p^2}{2m} + V(\boldsymbol{r}) + U(\boldsymbol{r})\right]\Phi(\boldsymbol{r}) = E\Phi(\boldsymbol{r}) \qquad [2]$$

where $V(\boldsymbol{r})$ is, as usual, the potential of the perfect lattice and $U(\boldsymbol{r})$ is the additional potential due to the impurity. The very common case in semiconductor physics is considered where the electronic states are very weakly bound to the impurity, for example, in the case for donor impurities such as arsenic or phosphorus in germanium. The eigenvalue problem [2] is solved under the following assumptions.

1. The unperturbed conduction band $E_c(\boldsymbol{k})$ is non-degenerate, has an extremum at $\boldsymbol{k} = \boldsymbol{k}_0$, and is well separated from the other bands. The corresponding unperturbed Bloch state is denoted by $\psi_c(\boldsymbol{k},\boldsymbol{r}) = e^{i\,\boldsymbol{k}\cdot\boldsymbol{r}}u_c(\boldsymbol{k},\boldsymbol{r})$.
2. The perturbation potential $U(\boldsymbol{r})$ is weak with respect to E_g and its interband matrix element can be disregarded.
3. $U(\boldsymbol{r})$ is a slowly varying function over the crystal cell, that is, for the Fourier transform of the potential the inequality $\tilde{U}(\boldsymbol{k}) \gg \tilde{U}(\boldsymbol{k}+\boldsymbol{G})$, where $\boldsymbol{G}$ is a reciprocal lattice vector and $\boldsymbol{k}$ belongs to the first Brillouin zone, holds.

4. The periodic part of the Bloch functions is slowly varying as a function of $\boldsymbol{k}$, that is, $u_n(\boldsymbol{k},\boldsymbol{r}) \approx u_n(\boldsymbol{k}_0,\boldsymbol{r})$.

It should be noted that the usual perturbation theory cannot be used because the unperturbed eigenvalues $E_n(\boldsymbol{k})$ depend continuously on the wave vector $\boldsymbol{k}$. The solution of [2] is expanded in terms of unperturbed Bloch functions,

$$\Phi(\boldsymbol{r}) = \frac{V}{(2\pi)^3} \sum_n \int \varphi(\boldsymbol{k}) \psi_n(\boldsymbol{k},\boldsymbol{r})\, \mathrm{d}\boldsymbol{k} \qquad [3]$$

Substituting [3] into [2] and projecting the obtained equation on the unperturbed state $\psi_c(\boldsymbol{k},\boldsymbol{r})$, one obtains the following equation for the envelope function $\varphi(\boldsymbol{k})$:

$$[E_c(\boldsymbol{k}) - E]\varphi(\boldsymbol{k}) + \frac{V}{(2\pi)^3} \times \int \mathrm{d}\boldsymbol{k}' \langle \psi_c(\boldsymbol{k}) | U | \psi_c(\boldsymbol{k}') \rangle \varphi(\boldsymbol{k}') = 0 \qquad [4]$$

Substituting in the matrix element of [4], the approximation for the periodic part of the Bloch function, that is, $u_n(\boldsymbol{k},\boldsymbol{r}) \approx u_n(\boldsymbol{k}_0,\boldsymbol{r})$, as a consequence of the assumptions introduced above, one obtains $\langle \psi_c(\boldsymbol{k}) | U | \psi_c(\boldsymbol{k}') \rangle = \tilde{U}(\boldsymbol{k} - \boldsymbol{k}')$, which is the Fourier transform of the perturbing potential $U(\boldsymbol{r})$. For an isotropic and parabolic conduction band $E_c(\boldsymbol{k})$ with an effective mass m_c the Fourier transform of [4] takes the form

$$\left[-\frac{\hbar^2 k^2}{2m_c} + U(\boldsymbol{r}) \right] F(\boldsymbol{r}) = E\, F(\boldsymbol{r}) \qquad [5]$$

where $F(\boldsymbol{r})$ is the Fourier transform of the envelope function $\varphi(\boldsymbol{k})$.

For the special case of a screened Coulomb potential $U(\boldsymbol{r}) = -e^2/\varepsilon(0)r$, where $\varepsilon(0)$ is the static dielectric constant and $F(\boldsymbol{r})$ is a hydrogenic function. The binding energy in the ground state is the effective Rydberg $\mathrm{Ry}^* = \mathrm{Ry}\, m_c/m\varepsilon(0)^2$. For typical semiconductors, $\mathrm{Ry}^* \approx 10\,\mathrm{meV}$. The expression of the impurity wave function in terms of the envelope function is given by [3]. After expanding the Bloch function around the extremum $\boldsymbol{k}_0$ and performing the integration over $\boldsymbol{k}$, one obtains, in first order,

$$\Phi(\boldsymbol{r}) = F(\boldsymbol{r}) \psi_c(\boldsymbol{k}_0,\boldsymbol{r}) \qquad [6]$$

This result represents a useful introduction to the exciton problem, which is discussed in detail in the next section. In fact, the exciton, which results from the interaction of an electron in the conduction band and a hole in the valence band, is described through an extension of the approach outlined here.

Isoelectronic Impurities

Isoelectronic impurities are substitutional impurities whose valence state contains the same number of electrons as the valence state of the atom they replace. Therefore, in contrast to acceptors and donors, they do not contribute any additional charge to the host semiconductor. The isoelectronic impurities are classified by their solubility and by the presence of discrete levels. Impurities characterized by discrete levels and limited solubility are said to be of the first kind, whereas impurities that are widely soluble and continuously change the band edge are said to be of the second kind.

Examples of isoelectronic impurities of the first kind are GaP:N with N_P (nitrogen impurity in gallium phosphide, where N_P specifies that a nitrogen atom replaces a phosphorus atom), CdS:Te with Te_S, ZnTe:O with O_{Te}, and AgBr:I with I_{Br}. The last of these impurities is the basic component of a photographic film. These impurities are also called isoelectronic traps. $Ga_{1-x}In_xAs$ and $Ga_{1-x}Al_xAs$ are examples of isoelectronic impurities of the second kind. These ternary compounds are of special importance because their bandgap can have a range of values. Isoelectronic traps are used in order to enhance the optical properties of indirect-gap materials and are thus widely used in the development of LEDs and lasers.

The isoelectronic impurities are neutral impurities and the perturbing potential associated with is short range, in contrast to the long-range Coulomb potential of donors and acceptors. As a consequence, these impurities have a finite number of discrete levels. Isoelectronic impurities provide scattering and trapping centers for free carriers and excitons. Intuitively, the impurity traps a carrier (electron or hole) and the latter is then trapped by Coulomb interaction with this complex. A particularly interesting case is that of iodine, which traps a hole from an electron–hole pair, thus leaving the electron available for the creation of the latent image in photographic emulsions. The binding energy of the isoelectronic impurities is calculated in the framework of the so-called Koster–Slater formalism.

In contrast to the case of the electronic state of donors, where the perturbing potential is a slowly varying function over the crystal cell, for isoelectronic impurities the perturbing potential is short ranged. For example, in the case of AgBr, if a bromine atom is substituted by chlorine, only when the electron is very close to the impurity, it "feels" the

difference between bromine and chlorine atoms. The donor impurity model has to be modified in order to describe isoelectronic impurities. The starting point is eqn [4], as in the case of donor states. In the present case, the matrix element $\langle \psi_c(\boldsymbol{k})|U|\psi_c(\boldsymbol{k}')\rangle$ is, in first approximation, a constant independent of $\boldsymbol{k}$ and $\boldsymbol{k}'$ and is denoted by W_c; eqn [4] then reads as

$$[E_c(\boldsymbol{k}) - E]\varphi(\boldsymbol{k}) + W_c \frac{V}{N(2\pi)^3} \times \int d\boldsymbol{k}'\, \varphi(\boldsymbol{k}') = 0 \qquad [7]$$

Equation [7] for $[E_c(\boldsymbol{k}) - E] \neq 0$ is transformed into

$$1 + W_c/\varepsilon_c(E) = 0 \qquad [8a]$$

with

$$1/\varepsilon_c(E) = (2\pi)^{-3} \frac{V}{N} \int d\boldsymbol{k} \frac{1}{[E_c(\boldsymbol{k}) - E]} \qquad [8b]$$

Figure 1 plots $\varepsilon_c(E)$ for energies outside the conduction band. The horizontal lines indicate the constant W_c. The eigenvalue equation [8] has a solution only for sufficiently large $|W_c|$. In this case the energy E^* of the bound state is a solution of

$$\varepsilon_c(E) + W_c = 0 \qquad [9]$$

while the wave function of the bound state reads

$$\Phi^{(E^*)}(\boldsymbol{r}) = A \frac{V}{(2\pi)^3} \sum_n \int \frac{1}{[E_c(\boldsymbol{k}) - E^*]} \times \psi_n(\boldsymbol{k}, \boldsymbol{r})\, d\boldsymbol{k} \qquad [10]$$

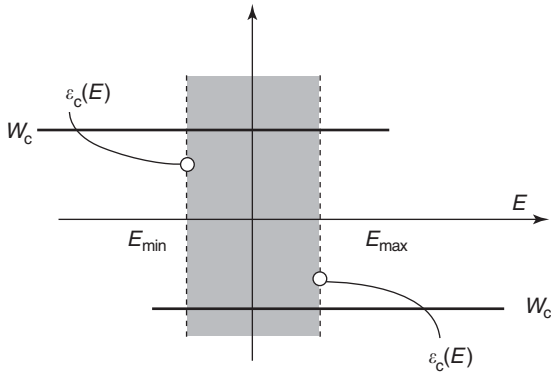

Figure 1 Graphic solution of eqn [8a] for two different values of the matrix element W_c.

For example, the above formulation yields a binding energy of iodine in AgBr to be 26 meV.

Excitons in Bulk Systems

Excitons appear when an electron excited from the valence band into the conduction band interacts with the positive excess charge (the "hole") left in the valence band after the transition. If one restricts consideration to a two-band model, the band index n indicates the valence and conduction bands, which are labeled by "v" and "c," respectively. The ground state of the crystal, in this approximation, is thus given by

$$\Phi(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N) = \frac{1}{\sqrt{N!}} \mathrm{Det}\{\psi_v(\boldsymbol{k}_1, \boldsymbol{r}_1), \ldots, \psi_v(\boldsymbol{k}_N, \boldsymbol{r}_N)\} \qquad [11]$$

where all the electrons are assumed to occupy valence band states. It should be noted that the number of k-values in the Brillouin zone of the reciprocal space is equal to the number of electrons, N. Furthermore, the ground state of the system is always a totally symmetric state with respect to the symmetry group of the crystal lattice and, in particular, its wave vector is zero. For simplicity, the spin degree of freedom is neglected in the simplified treatment that follows.

In order to derive the excited states of the system, consider first "promoting" one electron from the valence to the conduction band. The relevant Slater determinant is

$$\Phi_{k_m, k'_m}(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_N) = \frac{1}{\sqrt{N!}} \mathrm{Det}\{\psi_v(\boldsymbol{k}_1, \boldsymbol{r}_1) \cdots \psi_c(\boldsymbol{k}'_m, \boldsymbol{r}) \cdots \psi_v(\boldsymbol{k}_N, \boldsymbol{r}_N)\} \qquad [12]$$

where $\psi_c(\boldsymbol{k}'_m, \boldsymbol{r})$ is the wave function of an electron in the conduction band. The many-electron state has a total wave vector $\boldsymbol{k} = \boldsymbol{k}'_m - \boldsymbol{k}_m$, while its energy is given by $E_c(\boldsymbol{k}'_m) - E_v(\boldsymbol{k}_m)$. The state [12], however, is not a good first excited state. In fact, it has been assumed that the potential $V(\boldsymbol{r})$ appearing in [1] is constructed in a self-consistent way by minimizing the expectation value of the total Hamiltonian over the ground state [11]. When an electron is promoted from the valence band to the conduction band, the total charge density is modified with respect to the ground state and, consequently, the state [12] can be considered only as the zero-order approximation of the first excited state. The first-order state is obtained as a linear combination of Slater determinants of the

type [12] which diagonalize the total Hamiltonian. Explicitly, one can write, for an exciton trial function with zero wave vector $\boldsymbol{k}$,

$$\Phi_{\text{exc}} = \sum_{k'} \varphi(\boldsymbol{k}')\Phi_{\boldsymbol{k}',\boldsymbol{k}'} \qquad [13]$$

Normalization of [13] gives

$$\sum_{k'} |\varphi(\boldsymbol{k}')|^2 = 1 \qquad [14]$$

The coefficients $\varphi(\boldsymbol{k})$ are chosen by minimizing the expectation value of the total Hamiltonian. Using the same approximation as already used in the impurity problem, that is, $u_n(\boldsymbol{k},\boldsymbol{r}) \approx u_n(\boldsymbol{k}=0,\boldsymbol{r})$, the eigenvalue equation reads

$$[E_{\text{c}}(\boldsymbol{k}) - E_{\text{v}}(\boldsymbol{k}) - E]\varphi(\boldsymbol{k}) + \sum_{k''} \varphi(\boldsymbol{k}')V(\boldsymbol{k},\boldsymbol{k}') = 0 \qquad [15a]$$

with

$$V(\boldsymbol{k},\boldsymbol{k}') = \int \mathrm{d}\boldsymbol{r}_1\, \mathrm{d}\boldsymbol{r}_2\, \psi_{\text{c}}^*(\boldsymbol{k},\boldsymbol{r}_1)\psi_{\text{v}}(\boldsymbol{k},\boldsymbol{r}_2) \times \frac{e^2}{|\boldsymbol{r}_1 - \boldsymbol{r}_2|}\psi_{\text{c}}(\boldsymbol{k}',\boldsymbol{r}_1)\psi_{\text{v}}^*(\boldsymbol{k}',\boldsymbol{r}_2) \qquad [15b]$$

Here, the exchange contribution, which is small, has been neglected. Elementary solutions of [15] can only be found for two particular forms of the potential $V(\boldsymbol{k},\boldsymbol{k}') = V_1(\boldsymbol{k})V_2(\boldsymbol{k}')$ and $V(\boldsymbol{k},\boldsymbol{k}') = V(\boldsymbol{k}-\boldsymbol{k}')$. In the first case, the solution describes the localized Frenkel–Peierls excitons, while, in the second case, the solution describes delocalized Wannier excitons. Frenkel–Peierls excitons are found, for example, in solid rare gases or alkali halides. In the following, the discussion is restricted to Wannier excitons as found, for example, in copper oxide and in III–V compounds such as GaAs.

Theory of Wannier Excitons

In order to consider the case of a Wannier or weakly bound exciton in more detail, assume that its wave function extends over a region much larger than the lattice period. Equivalently, the coefficients $\varphi(\boldsymbol{k})$ in [13] can be assumed to involve only a small range of k-values around zero. This hypothesis depends, of course, on the material under consideration and may be justified only *a posteriori*. Therefore, it is convenient to use an effective-mass description of the energies and Bloch states involved in the exciton wave function, that is,

$$E_{\text{c}}(\boldsymbol{k}) = E_{\text{g}} + \frac{\hbar^2 k^2}{2m_{\text{c}}} \quad \text{and} \quad E_{\text{v}}(\boldsymbol{k}) = -\frac{\hbar^2 k^2}{2m_{\text{h}}} \qquad [16]$$

where E_{g} is the fundamental gap of the semiconductor, m_{c} and m_{h} are the effective masses associated with the conduction and valence band, respectively.

The Fourier transform of the integral eqn [15a] with the kernel $V(\boldsymbol{k},\boldsymbol{k}') = V(\boldsymbol{k}-\boldsymbol{k}') = e^2/|\boldsymbol{k}-\boldsymbol{k}'|^2$ yields a hydrogen-like Schrödinger equation for the function

$$F(\boldsymbol{r}) = \Omega^{-1/2} \sum_{k} \varphi(\boldsymbol{k})\exp[\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}] \qquad [17]$$

analogous to the case of shallow impurities (see eqn [5]). In this equation, V/N is the normalization volume. In this case, the total wave vector of the exciton state is zero. Thus, under the assumptions introduced here, a simple picture of the exciton states is that of an electron which forms a hydrogenic atom with a positive charged hole in the valence band. The hole is ideally the vacancy left by the promoted electron. In reality, this derivation shows that the exciton is strictly a many-body effect, which goes even beyond the Hartree–Fock approximation. Nevertheless, the hydrogen-atom picture is very effective and is widely used. It requires, however, an important modification in order to be quantitatively predictive. In a realistic situation, the electric field between the two charges, which form the exciton, is screened by the presence of all the other electrons in the material. This screening originates from the polarization of the medium around the charges. The virtual transitions to the excited states of the system are responsible for this polarization. Only the transitions to the lower conduction band have been included in the present model. In principle, all the electron states belonging to different bands must be included to obtain the effect of screening. A quite surprising result is that this correction can be taken into account simply with the introduction of a dielectric constant $\varepsilon(0)$ screening the electron–hole Coulomb interaction term of the exciton hydrogen-like Schrödinger equation. In most of the small-gap semiconductors, the dielectric constant is rather large and takes values around 10. The two parameters that characterize a hydrogenic system that is, the effective Rydberg and the effective Bohr radius, can be written as

$$\text{Ry}^* = \mu e^4/2\varepsilon(0)^2\hbar^2, \qquad a_{\text{B}}^* = \hbar^2\varepsilon(0)/\mu e^2$$

where μ is the reduced mass of the electron–hole system. The electron–hole exchange interaction, which has been neglected so far, can be taken into account in first-order perturbation theory. This interaction is short-ranged and does not require a screening dielectric constant as in the case of the

Coulomb term. Due to the small effective masses of the conduction and valence bands in most small-gap semiconductors, and the large dielectric screening, the effective Rydberg is typically of the order of few meV only.

Optical Transitions

The interactions between radiation and electrons in the crystal may introduce transitions from the ground state to some excited electronic states. These transitions may occur to higher-energy bands for direct-gap semiconductors or the impurity or excitonic states. The threshold energy for direct interband transitions is given by the energy gap, while the transitions to impurity and exciton states are similar to atomic transitions and occur for energies smaller than the energy gap. Electronic transitions at optical frequencies are well described in the framework of the dipole approximation. The electron–field interaction has the form $e\boldsymbol{r} \cdot \boldsymbol{E}_0 \cos(\omega t)$ for a monochromatic field, where $e\boldsymbol{r}$ is the dipole operator. The contribution of the exciton or impurity states to the absorption coefficient is related to the transition probability from the ground state to the excited state induced by the radiation. The transition probability is a function of the exciting field amplitude $|\boldsymbol{E}_0|$ and is calculated with perturbation theory leading to a series expansion in powers of $|\boldsymbol{E}_0|^2$. The nth term in this expansion is denoted as n-photon process. Here only the one- and two-photon processes are considered. First consider the one-photon processes which occur under the resonance condition only. The transition probability depends on the envelope function $\varphi(\boldsymbol{k})$ and on the matrix element $\boldsymbol{M}(\boldsymbol{k}) = e\langle \psi_c(\boldsymbol{k}, \boldsymbol{r})|\boldsymbol{r}|\psi_v(\boldsymbol{k}, \boldsymbol{r})\rangle$ of the dipole operator between the valence and the conduction band wave functions taken at the same wave vector $\boldsymbol{k}$. For weakly bound impurities or Wannier excitons, the envelope function is peaked around $\boldsymbol{k} = 0$ and thus the transition probability is proportional to $|\boldsymbol{E}_0|^2|\boldsymbol{M}(\boldsymbol{k} = 0)|^2|F(\boldsymbol{r} = 0)|$, where $F(\boldsymbol{r})$ is defined in [5] and [17] for impurities and Wannier excitons, respectively. The excited states considered being hydrogen-like, the transitions are allowed to s-like states only. A typical absorption spectrum is shown in **Figure 2** for the case of GaAs.

The optical absorption and emission spectra of isoelectronic impurities show a characteristic series of peaks, which arise from the strong electron–phonon interaction. The strength of the interaction is due to the localization of the wave function of the electron in the impurity and to the strong gradient of the wave function in this region. The absorption and emission spectra have mirror-symmetric shapes and, in general, display a partial overlap. The isoelectronic trap ZnTe:O, whose absorption and emission spectra are specular, as indicated in **Figure 3**, represents an exception to this behavior.

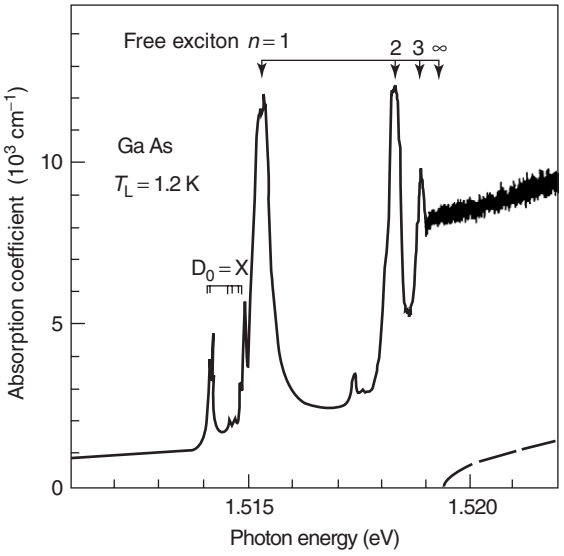

Figure 2 Absorption spectrum of GaAs at 1.2 K near the band edge. The $n = 1$, 2, 3 free-exciton peaks as well as impurity lines [D_0–X] of excitons bound to donors are shown. (Weisbuch C and Ulbrich R, unpublished, adapted from Ph.D. thesis of Weisbuch C, University of Paris 7, 1977.)

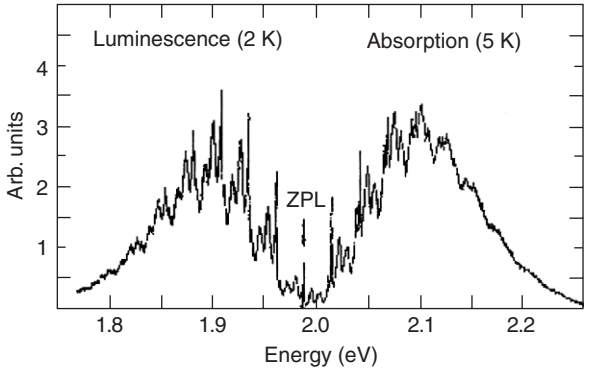

Figure 3 Absorption and luminescence spectra of CdTe:O at 2 K. ZPL indicates the zero phonon line. (Adapted from Schwendimann P, *et al.* (1992) Theoretical description of light amplification in ZnTe:O: a vibronic-laser material. *Physical Review B* 46: 7479–7485.)

When interband transitions are forbidden, that is, $\boldsymbol{M}(\boldsymbol{k} = 0) = 0$, it is necessary to take the next order in the wave vector $\boldsymbol{k}$ in the expansion of $\boldsymbol{M}(\boldsymbol{k})$ around $\boldsymbol{k} = 0$: $\boldsymbol{M}(\boldsymbol{k}) \propto \boldsymbol{k}$. In this case, the transition probability is proportional to

$$|\boldsymbol{E}_0|^2|\boldsymbol{k}|^2\left|\frac{\partial F(\boldsymbol{r})}{\partial \boldsymbol{r}}|_{r=0}\right|^2$$

and, therefore, the p-states can be reached. Indeed, the absorption spectrum of the yellow exciton in Cu_2O as presented in **Figure 4** does not contain the $n = 1$ transition line.

When one-photon transitions are forbidden, and for intense enough excitation field, two-photon transitions may occur, provided that the resonance condition $E^{\text{exciton}} = 2\hbar\omega$ is satisfied. The two-photon transition is also realized when two beams of different frequencies are used. In this case, the resonance condition $E^{\text{exciton}} = \hbar\omega_1 + \hbar\omega_2$ is fulfilled.

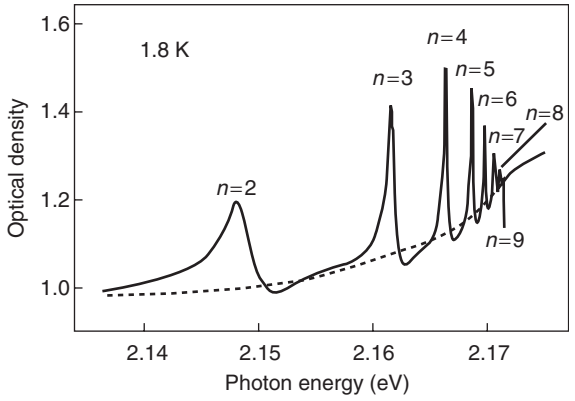

Figure 4 Absorption spectrum of the "yellow" exciton in Cu_2O at 1.8 K. Since transitions are allowed only to p-states of this exciton, the $n = 1$ state is forbidden. (Adapted form Shindo K, *et al.* (1974) Exciton-LO phonon scattering in Cu_2O. *Journal of the Physical Society of Japan* 36: 753–758.)

Cu_2O is particularly interesting because the one-photon transition can excite only the p-states, while the two-photon transition may excite s- and d-states, as indicated in **Figure 5**.

Finally, for strong photon–exciton coupling, the perturbation theory fails. The interacting photons and excitons have to be treated on the same footing, as indicated in the next section.

Polaritons

The absorption and emission spectra of semiconductor crystals have been considered in the above section. The present section outlines how the optical response of a semiconductor is modified when the propagation of the radiation field in the semiconductor is considered. Due to the presence of excitons, the propagation of radiation in a direct semiconductor shows a peculiar dispersive behavior. This is best understood through the solution of Maxwell's equations in presence of a linear polarization. The linear response of the exciton with eigenfrequencies $\omega(\boldsymbol{k})$ is given by the dielectric function $\varepsilon(\boldsymbol{k}, \omega) = \varepsilon_\infty + 4\pi f^2/(\omega^2(\boldsymbol{k}) - \omega^2)$, where ε_∞ is the background dielectric constant and f is the oscillator strength corresponding to the transition from the ground state to the 1s state. It is calculated in first-order perturbation theory corresponding to the one-photon processes discussed above. The fundamental

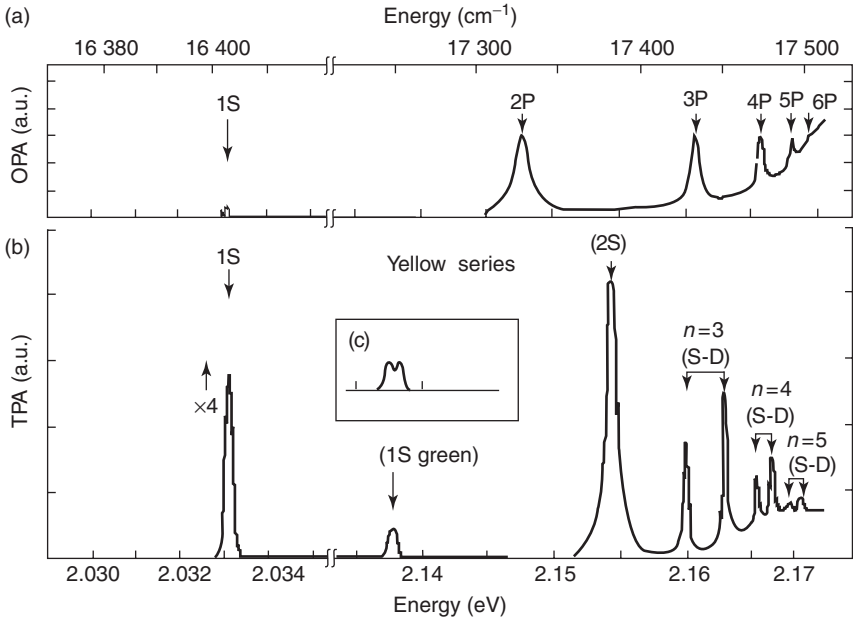

Figure 5 The one- and two-photon spectrum of Cu_2O. (a) "Yellow" exciton. One-photon data at 4.2 K. (b) "Yellow" exciton. Two-photon data at 4.5 K. (c) Splitting of the 1s green line in a magnetic field. (Adapted from Fröhlich D, *et al.* (1979) Assignment of the even-parity excitons in Cu_2O. *Physical Review Letters* 43: 1260.)

equation is then obtained via the Maxwell equations and reads $\nabla \times \nabla \times \boldsymbol{E} + \varepsilon(\boldsymbol{k}, \omega) k^2 \boldsymbol{E} = 0$. The solution of this equation for transverse modes, that is, $\nabla \cdot \boldsymbol{E} = 0$, is obtained when considering a plane-wave solution of the electric field,

$$\varepsilon(\boldsymbol{k}, \omega) = \varepsilon_\infty + \frac{\varepsilon(\boldsymbol{k}, 0) - \varepsilon_\infty}{1 - \omega^2/\omega^2(\boldsymbol{k})} = \left(\frac{c\boldsymbol{k}}{\omega}\right)^2 \quad [18]$$

For each value of k, this is a biquadratic equation whose solutions correspond to two transverse modes, called upper and lower polariton modes, propagating through the crystal. These modes, displayed in **Figure 6**, correspond to mixed exciton–photon states.

The upper-branch polariton (photon polariton) asymptotically approaches the dispersion of the free photon, whereas the lower-branch polariton (exciton polariton) similarly approaches the exciton dispersion. Polaritons are observed indirectly through nonlinear spectroscopic tools (Raman scattering, two-photon absorption). A direct observation of polariton photoluminescence is not very promising. Indeed, a polariton is a well-defined state of the crystal for any value of the wave vector, owing to its translational invariance. On the crystal surface, the translational invariance is broken and all polariton modes are mixed. Therefore, it is not possible to resolve the polariton luminescence as a function of the wave vector with sufficient accuracy.

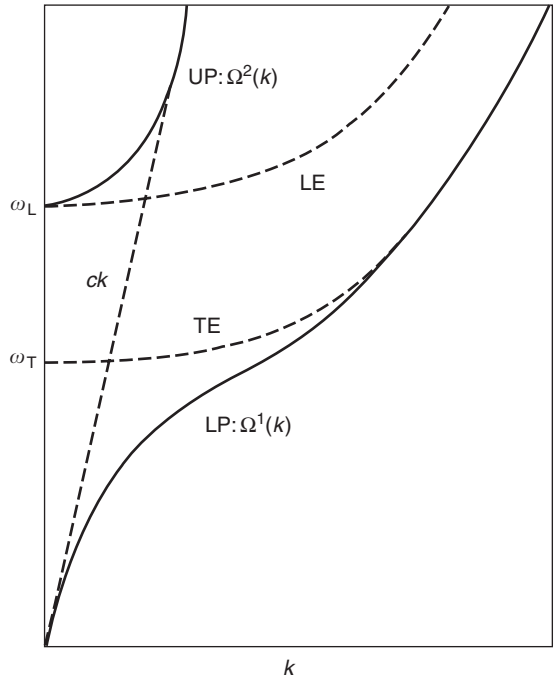

Figure 6 Schematic representation of the upper (UP) and lower (LP) polariton originated from Wannier excitons. The transverse (TE) and longitudinal (LE) excitons are also indicated as well as the radiation mode. (Adapted from Bassani F, *et al.* (1986) Microscopic quantum theory of exciton polaritons with spatial dispersion. *Il Nuovo Cimento* 7D: 700–716.)

The situation changes when lower-dimensional semiconductor structures like quantum wells, quantum wires, or quantum dots are considered. Consider the case of a quantum well. Because of the symmetry breaking in the direction of the growth of the quantum well, a single two-dimensional exciton, with a fixed in-plane momentum, acquires a radiative line width due to the coupling to the component of the three-dimensional electromagnetic field. This effect can be exploited by embedding the quantum well in a semiconductor microcavity consisting of two dielectric high-reflectivity mirrors. In this structure, only one photon mode couples to the exciton due to the large energy spacing between the cavity modes, and polaritons appear as a consequence of this interaction, which can be detected in the optical response. Microcavity polaritons form the basis of several important linear and nonlinear optical properties that have been the object of many studies in recent years.

Nomenclature

a_B^*	effective Bohr radius (cm)
e	electron charge (esu $= g^{1/2} cm^{3/2} s^{-1}$)
$\boldsymbol{E}_0$	electric field (esu $= g^{1/2} cm^{-1/2} s^{-1}$)
$E_c(\boldsymbol{k})$	energy eigenvalue of the conduction band
E_g	semiconductor energy gap (eV)
$E_n(\boldsymbol{k})$	energy eigenvalue of the nth band
$E_v(\boldsymbol{k})$	energy eigenvalue of the valence band

f	oscillator strength (s^{-2})
$F(\boldsymbol{r})$	Fourier transform of the envelope function
$\boldsymbol{k}$	wave vector
m_c	conduction band effective mass (g)
m_v	valence band effective mass (g)
$\boldsymbol{p}$	moment
Ry	Rydberg (eV)
$U(\boldsymbol{r})$	impurity potential
$\tilde{U}(\boldsymbol{k})$	Fourier transform of $U(\boldsymbol{r})$
$u_c(\boldsymbol{k},\boldsymbol{r})$	periodic part of the conduction Bloch wave function
$u_n(\boldsymbol{k},\boldsymbol{r})$	periodic part of the Bloch wave function
$u_v(\boldsymbol{k},\boldsymbol{r})$	periodic part of the valence Bloch wave function
$V(\boldsymbol{r})$	periodic potential
$\varepsilon(0)$	dielectric constant
$\varepsilon(\boldsymbol{k},\omega)$	dielectric function
ε_∞	background dielectric function
$\Phi(r)$	wave function in presence of an impurity
$\varphi(\boldsymbol{k})$	envelope function
$\psi_c(\boldsymbol{k},\boldsymbol{r})$	wave function of the conduction band
$\psi_n(\boldsymbol{k},\boldsymbol{r})$	Bloch wave function of the nth band
$\psi_v(\boldsymbol{k},\boldsymbol{r})$	wave function of the valence band
μ	electron–hole reduced mass (g)

Semiconductors, General Properties

G Margaritondo, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

The main characteristics of semiconducting materials are briefly reviewed. First, semiconductors are treated in the context of the one-electron band structure defining the differences with respect to metallic conductors. The same framework is then used to present basic notions, such as the effective mass, the mobility, intrinsic and doped materials, and donors and acceptors. The fundamental mechanism of rectification by p–n junctions and a short description of the main properties of selected group IV and III–V semiconducting materials – including direct-gap and indirect-gap cases – are then presented. Finally, a short introduction of the optical properties of semiconductors and their use in light emitting devices and photon detectors is presented.

Introduction: Insulators and Semiconductors

All solids fall into broad classes as far as electrical conduction is concerned: metallic conductors, superconductors, insulators, semiconductors, etc. The insulating character can be caused by electron–electron interactions, for example, in the Mott insulators. In a one-electron theoretical framework, a solid is an insulator if the Fermi level falls within the forbidden gap that separates the valence band and the conduction band. At a temperature $T = 0\,\mathrm{K}$, no electron is found in the conduction band and the valence band is completely filled. Because of the symmetry of the valence-band states, the overall current created by the filled valence band is zero.

For $T > 0\,\mathrm{K}$, some electrons can be excited above the gap and into the conduction band leaving behind empty valence-band states. Such "free" electrons have energies close to those of empty states, so that low-energy excitations – required for electrical conduction – become possible. Furthermore, the empty valence-band states also contribute to conduction. The insulator thus becomes a conductor, although with a much lower conductivity than that of a metallic conductor.

For a finite temperature, the number of electrons thermally excited into the conduction band increases as the gap width E_g decreases. For E_g values below $\sim 2.5\,\mathrm{eV}$, the material is called a "semiconductor" rather than an insulator.

Semiconductors are the well-known protagonists of the modern microelectronics industry. This is primarily due to three factors: (1) the possibility of controlling their conduction properties by "doping" them with suitable impurities; (2) the possibility of electrically and chemically passivating their surface with ultrathin layers of insulating materials, thereby making it possible to integrate a huge number of microdevices into a single semiconductor slice; (3) other functions parallel to electrical conduction, such as light emission and absorption that can be exploited for specialized devices.

Doping is the most important of the three factors. In order to understand how it works, the conduction mechanism in all of its aspects must be analyzed first. This includes the role of both the conduction-band (free) electrons and the valence-band empty states.

Effective Mass, Electrons and Holes

Consider (**Figure 1a**) a simplified one-dimensional scheme of the band structure of a semiconductor. The electron energy E is plotted as a function of the

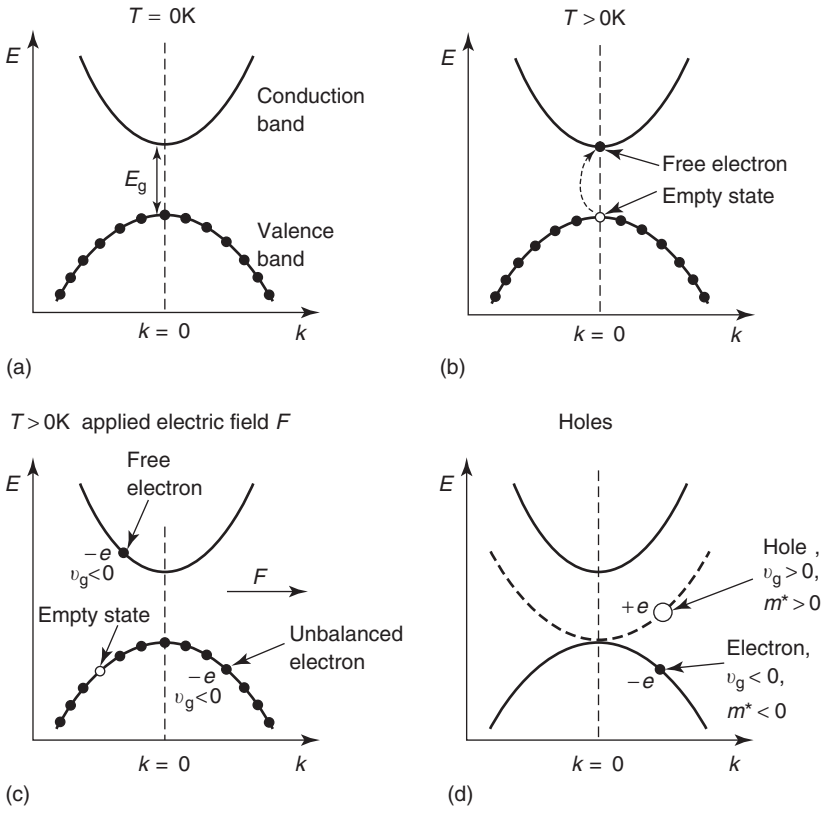

Figure 1 (a) Simplified one-dimensional scheme of the valence and conduction bands of a semiconductor: E is the electron energy and k is the wave number. At $T = 0\,\mathrm{K}$, the valence band is completely filled, the conduction band is empty, and there is no conduction. (b) Thermal excitation of an electron to the conduction band leaving an empty state in the valence band. (c) An external electric field F is applied in the positive direction of k: the conduction-band electron is subject to a negative force $-eF$ that causes a decrease in the group velocity $v_g \propto \mathrm{d}E/\mathrm{d}k$ and, therefore, a shift of the electron toward the negative side of the k-axis. The electron has negative charge and negative v_g; therefore, its contribution to the current is in the positive direction as the electric field F. In parallel, all electrons in the valence band are subject to the force $-eF$. Since their effective mass $m^* \propto 1/(\mathrm{d}^2E/\mathrm{d}k^2)$ is negative, v_g increases, and the electrons in the valence band shift in the negative k-direction, bringing with them the empty state. The "unbalanced" electron symmetric to the empty state has negative charge and negative group velocity; thus, it again produces current in the same direction as the electric field. (d) The effects of the empty valence-band state can be visualized in terms of a "hole" with positive charge $+e$, positive effective mass $-m^*$, and positive group velocity $|v_g|$: the dashed line shows its dispersion curve.

k-vector (in one dimension, the wave number k); note that $\hbar k$ is the momentum p or, more precisely, the "crystal momentum" in the Bloch theorem framework. It can be seen that at $T = 0\,\mathrm{K}$, the valence band is completely filled and the conduction band empty, corresponding to no conduction.

At $T > 0\,\mathrm{K}$, some electrons are thermally promoted into the conduction band. **Figure 1b**, for simplicity, shows only one of such electrons and the corresponding empty state in the valence band. **Figure 1c** shows the corresponding situation when an external electric field F is applied in the positive direction of k. The conduction-band electron is subject to a force $-eF$, moving to a negative value of k.

The effect of such a force can be treated based on the fundamental equation of mechanics,

$$-eF = \hbar \frac{\mathrm{d}k}{\mathrm{d}t} \qquad [1]$$

and based on the definition of group velocity,

$$v_g = \frac{1}{\hbar}\frac{\mathrm{d}E}{\mathrm{d}k} \qquad [2]$$

Equation [2] gives, in fact,

$$\begin{aligned}\mathrm{d}v_g/\mathrm{d}t &= (1/\hbar)(\mathrm{d}^2E/(\mathrm{d}k\ \mathrm{d}t)) \\ &= (1/\hbar)(\mathrm{d}^2E/\mathrm{d}k^2)(\mathrm{d}k/\mathrm{d}t)\end{aligned}$$

Combined with eqn [1], this becomes

$$-eF = m^*\frac{\mathrm{d}v_g}{\mathrm{d}t} \qquad [3]$$

that is, an equation of Newtonian form except that the electron mass is replaced by an "effective mass"

m^* defined as

$$m^* = \frac{\hbar^2}{(\mathrm{d}^2E/\mathrm{d}k^2)} \qquad [4]$$

In first approximation, the $E(k)$ curve near the minimum of the conduction band has a parabolic form and its second derivative is a positive constant, so that m^* is nearly constant as the real electron mass although different in value.

According to eqn [3], the effect of the force $-eF$ is a decrease of v_g that corresponds indeed to a shift of the electron toward the negative side of the k-axis, as seen in **Figure 1c**. The shift does not continue indefinitely since at a certain point, the effects of the external electric field are countered by the scattering mechanisms responsible for resistivity.

The contribution of the conduction-band electron to the overall current equals its charge $-e$ multiplied by its group velocity v_g. The electron in **Figure 1c** has negative charge and negative group velocity; therefore, its contribution to the current is in the positive direction – the same direction as the electric field F.

Consider now the empty valence-band state in **Figure 1b**. When completely filled, the valence band does not contribute to the current since the electrons moving in one direction are balanced by those moving in the symmetrically opposite direction. The $k = 0$ empty state in **Figure 1b** does not change this situation.

When an external electric field is applied (**Figure 1c**), all electrons in the valence band are subject to the force $-eF$. The effects are again described by eqn [3]. Note that near a maximum of the $E(k)$ curve, the effective mass (eqn [4]) is "negative" rather than positive. Thus, a negative force $-eF$ causes a positive derivative $\mathrm{d}v_g/\mathrm{d}t$ and an increase of the group velocity $v_g \propto \mathrm{d}E/\mathrm{d}k$. This means that all the electronic states in the valence band shift in the negative direction of the k-axis and bring the empty state with them as shown in **Figure 1c**.

The valence-band electron symmetric to the empty state is no longer balanced and produces a net current. This "unbalanced" electron has negative charge and negative group velocity; thus, it produces a positive current, again in the direction of the electric field as the conduction-band electron. The overall current is given by the sum of two contributions in the same direction, one from the conduction band and the other from empty states in the valence band.

The effects of the empty valence-band states can be treated in terms of the so-called "holes." This notion is suggested by the fact that the "unbalanced electron" in **Figure 1c** – with negative charge $-e$, negative m^*, and negative v_g – has the same effect on the current as a hypothetical particle ("hole") with positive charge $+e$, positive effective mass $-m^*$, and positive group velocity $-|v_g|$. The dispersion curve for this "hole" is shown in **Figure 1d**. The behavior of holes is easier to visualize than that of unbalanced electrons: the "hole" picture is, therefore, universally adopted when describing semiconductor properties.

In a more realistic picture, the top of the valence band and the bottom of the conduction band correspond to a maximum and a minimum of the three-dimensional surface $E(\boldsymbol{k})$, where $\boldsymbol{k}$ is the k-vector. The effective mass is not a scalar quantity but a tensor. Furthermore, several $E(\boldsymbol{k})$ surfaces can be found near the valence-band top or the conduction-band bottom, corresponding to different effective masses of the corresponding electrons and holes.

Mobility

The previous discussion leads to the following form of the total current density created in a semiconductor by an external electric field F:

$$j = -nev_e + pev_h \qquad [5]$$

where n and p are the free-electron density and the hole density; v_e is the average free-electron group velocity caused by the combined effect of the applied field F and of the scattering mechanisms responsible for the resistivity (i.e., scattering by impurities or defects and lattice vibrations); and v_h is the corresponding average group velocity for holes. Note that v_e and v_h are opposite to each other; thus, the two terms on the right-hand side of eqn [5] are in the same direction.

In first approximation, both v_e and v_h are proportional to the applied field F:

$$v_e = \mu_e F; \quad v_h = \mu_h F \qquad [6]$$

The parameters μ_e and μ_h are called "electron mobility" and "hole mobility." In a three-dimensional picture, the mobilities can have directional character.

The combination of eqns [5] and [6] gives

$$j = (-ne\mu_e + pe\mu_h)F \qquad [7]$$

The term in parentheses corresponds to the conductivity. Equation [7] implies two basic differences between a semiconductor and a simple metal. The first is the presence of two contributions to the conductivity, one from free electrons and the other from holes. The second difference is the effect of temperature. In a simple metal, the temperature primarily affects the mobility: as the temperature increases, the mobility decreases and so does the conductivity. In a

semiconductor, the temperature affects both the mobilities and the carrier densities n and p. The second effect dominates, producing an increase of the conductivity as the temperature increases.

Doping

What determines the free-electron concentration n and the hole concentration p in a semiconductor? Assume, for now, that the forbidden gap contains no impurity-related states. Each hole corresponds to an empty state in the valence-band electron that, in turn, corresponds to a free electron in the conduction band. This implies that $n = p$.

The free-electron concentration n is determined by the number of occupied states in the conduction band, determined by the Fermi–Dirac distribution and specifically by the position of the Fermi level E_F within the gap. Similarly, the position of E_F determines the hole concentration p. The condition $n = p$ requires E_F to be not too far from the middle of the gap (**Figure 2a**).

It can be shown that under rather general conditions (law of mass action), the product np is a function of the temperature, independent of the position of E_F in the gap. The conductivity of a semiconductor depends on the total concentration of available carriers, $n + p$. For a given temperature, np =constant, and the case $n = p$ corresponds to the minimum value of $n + p$.

Therefore, to increase the total carrier concentration, the condition $n = p$ must be violated. This can be done by doping the material with impurity atoms.

Consider, for example (**Figure 2b**), arsenic impurities in a silicon crystal. The chemical bonds in the pure crystal are formed by sp^3 hybridization of four $3s$ and $3p$ valence electrons for each atom. An atom forms chemical bonds with four nearest neighbors; thus, each bond involves two electrons, one for each atom. The molecular bonding states of these electrons form the valence band, whereas the antibonding states form the conduction band.

Suppose now that one silicon atom is replaced by an arsenic atom with five rather than four valence electrons (**Figure 2b**). Four of them form chemical bonds with neighboring silicon atoms and contribute to the conduction- and valence-band states. The fifth electron is not engaged in chemical bonding: its state

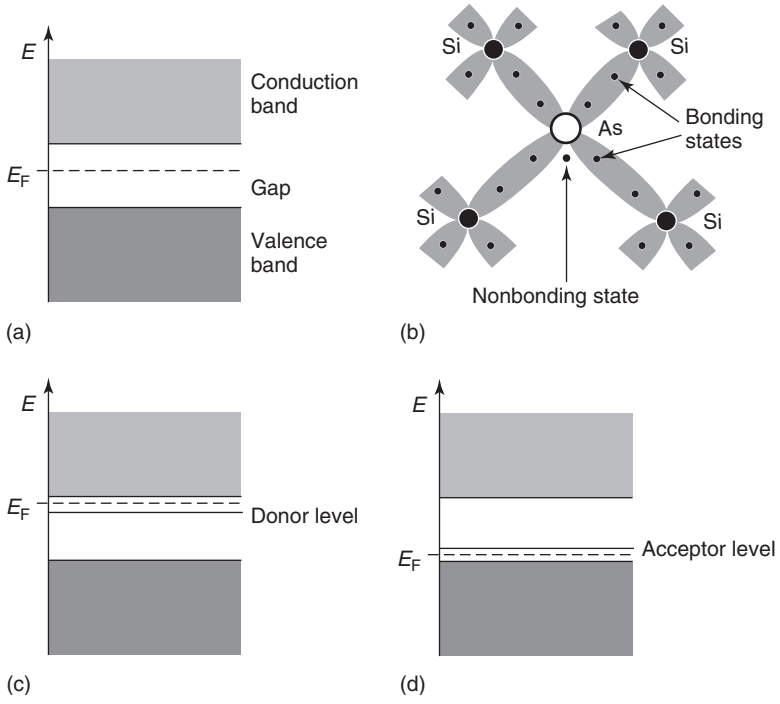

Figure 2 (a) In a semiconductor free from impurities, the condition $n = p$ implies that the Fermi level E_F is close to the middle of the gap. (b) Chemical bonds for an arsenic impurity in a silicon lattice. In pure Si, each bond engages two electrons, one per atom: all four valence electrons of a tetrahedrally coordinated Si atom are thus engaged. Arsenic has five valence electrons and the fifth one is not engaged in chemical bonds. (c) The corresponding nonbonding arsenic state has an energy level inside the gap and near the bottom of the conduction band. Electrons can be thermally promoted from this level to the conduction band: arsenic is thus a "donor" of electrons. (d) Symmetrically, a three-valent impurity, such as gallium, has an energy level near the top of the silicon valence band and can inject a large number of holes in the valence band acting as an "acceptor."

is nonbonding and its energy is intermediate between the bonding and antibonding states, that is, it falls in the forbidden gap separating the valence band from the conduction band (**Figure 2c**).

Because of the nonbonding character, this electron can be easily freed from the impurity and promoted to the conduction band. This implies that the impurity energy level is close to the bottom of the conduction band, as seen in **Figure 2c**. Thermal excitation allows the impurity to "donate" electrons to the conduction band, so that the arsenic in silicon is called a "donor" impurity.

Note that at $T = 0\,\mathrm{K}$, there is no thermal excitation at all: the donor electron states are all filled and the conduction band states are empty. This implies (**Figure 2c**) that the Fermi level is no longer close to the midgap but between the donor impurity level and the bottom of the conduction band.

Doping by donors leads to a large concentration of concentration n of impurity-donated free electrons; the $n = p$ rule is then broken and the total carrier density $n + p$ is larger than the minimum value. The material is called an "n-type" semiconductor, whereas an impurity–free sample with $n = p$ is called an "intrinsic" semiconductor.

A symmetric mechanism enables three-valent ("acceptor") impurities, such as gallium, to inject a large number of holes in the silicon valence band, producing a "p-type" sample. In this case (**Figure 2d**), the impurity has an empty nonbonding state near the top of the valence band that can capture thermally excited electrons from the valence band. This produces empty states in the valence band and, therefore, increases the hole density p. At $T = 0\,\mathrm{K}$, the Fermi level is found to be between the top of the valence band and the acceptor impurity level.

More sophisticated mechanism enables impurities with the same valence as the replaced atoms to also act as donors or acceptors. One good example of these "isoelectronic" impurities is provided by five-valent nitrogen replacing five-valent arsenic in GaAs.

The presence of impurities in a semiconductor is difficult to avoid, so that the samples naturally tend to be doped n-type or p-type. Suitable technologies must be used to control the doping level and change its character from p to n and vice versa. Particularly difficult is to obtain samples with low impurity concentrations so that $n = p$, the total carrier concentration $n + p$ is low, and the material is insulating rather than conducting. Practically speaking, the $n = p$ condition can be achieved by seeking equal concentrations of donors and acceptors rather than low donor and acceptor concentrations. A material of this kind is said to be "compensated."

Current Rectification by a *p–n* Junction

The control of transport properties by doping is a key ingredient in the manufacture of semiconductor devices. A simple example is qualitatively discussed here: the p–n junction, which is a fundamental building block of many devices. A p–n junction consists of a semiconductor sample with two different regions, one n-type and the other p-type (**Figure 3a**). In practice, such a system can be fabricated starting from a sample of one type and then changing the doping of part of it with a suitable procedure such as gas-phase exposure.

As seen in **Figure 3b**, the band diagram of the system includes an n-type region (similar to **Figure 2c**) and a p-type region (similar to **Figure 2d**), separated by an intermediate area called the "depletion" region. Elementary thermodynamics requires the Fermi level (which corresponds to the free energy function) to be the same everywhere in the sample. As a consequence, in the depletion region, E_F tends to be close to the midgap and the situation is similar to that in **Figure 2a**. This corresponds to low conductivity because of the low total carrier density: the "depletion" of carriers justifies the name of the region.

Note that free electrons trying to cross from the n-region to the p-region face an energy barrier E_B that prevents them from doing so. Similarly, holes in the p-region cannot cross into the n-region because of a symmetric barrier.

Imagine now that an external voltage bias is applied to the junction trying to create a current. A bias in the "forward" direction (**Figure 3c**), positive on the p-region and negative on the n-region, decreases the E_B barrier, making it easier for electrons to overcome it: a current is thus created. A symmetric analysis leads to the same conclusion for holes. On the contrary, a "reverse" bias (**Figure 3d**) increases the barrier and makes it even more difficult for carriers to cross the junction so that no or very little current is created.

The overall effect corresponds to the rectifying diode behavior shown in **Figure 3e**. Under rather idealized hypotheses, this behavior can be described by the equation

$$I = I_0\left[\exp\left(\frac{eV}{\eta kT}\right) - 1\right] \qquad [8]$$

where I is the current and V the applied voltage bias, k the Boltzmann constant, and η the so-called "ideality factor" ($\eta = 1$ for the most ideal case); note that for a strong reverse (negative) bias, $I \sim -I_0$, the so-called "saturation current."

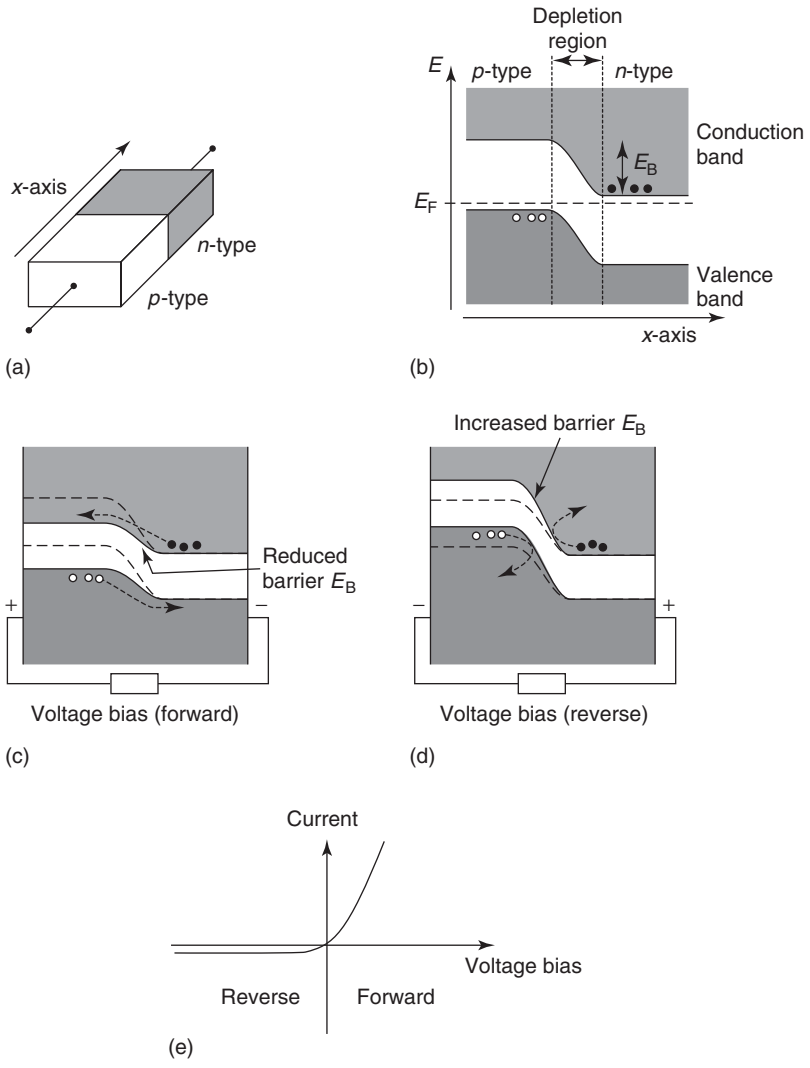

Figure 3 (a) A *p–n* junction consists of a semiconductor sample with two different regions, *n*-type and *p*-type. (b) In the corresponding band diagram, the *n*-region (similar to **Figure 2c**) and the *p*-region (similar to **Figure 2d**) are separated by a "depletion" region. There, E_F tends to be close to the midgap as in **Figure 2a**, corresponding to low conductivity. Free electrons trying to cross the depletion region are blocked by the energy barrier E_B; a symmetric conclusion is valid for holes. (c) An external voltage bias applied in the "forward" direction decreases the barrier E_B, making it easier for electrons and holes to overcome it and generating a current. (d) A "reverse" bias increases E_B and generates no current. (e) The corresponding typical current–voltage curve of a rectifying diode.

This description is, of course, oversimplified. However, it is suitable to understand the basic facts and, in particular, the crucial role of doping in the fabrication of devices. In modern microelectronics, other building-block devices are fundamentally important in addition to the *p–n* junction, in particular, the field-effect transistor.

Examples of Important Semiconductors

The most important semiconductors for industrial applications are the elemental group IV materials, such as silicon and germanium, and some III–V binary compounds, such as GaAs, GaP, InP, and GaN. Other classes of compounds include interesting semiconductors for specialized applications but none of them has a technological impact comparable to group IV or III–V materials. Furthermore, the microelectronics industry is dominated by the silicon-based technology, whose impact in market terms, is much stronger than all the other semiconductors put together. This is due to several factors – in particular passivation, crystal growth, and crystal refinement – that greatly facilitate silicon-based manufacturing and make it possible to reach advanced performance, extreme miniaturization, and massive integration.

Silicon and Germanium

Both these elemental semiconductors have the cubic structure of diamond shown at the top of **Figure 4**. Each atom is tetrahedrally bound to four nearest neighbors.

The band structures of the two materials are shown in the middle and bottom parts of **Figure 4**. Specifically, the three-dimensional dependence of the energy E on the k-vector is shown along two high-symmetry crystallographic directions of $\boldsymbol{k}$, $\langle 1\,1\,1 \rangle$ and $\langle 1\,0\,0 \rangle$.

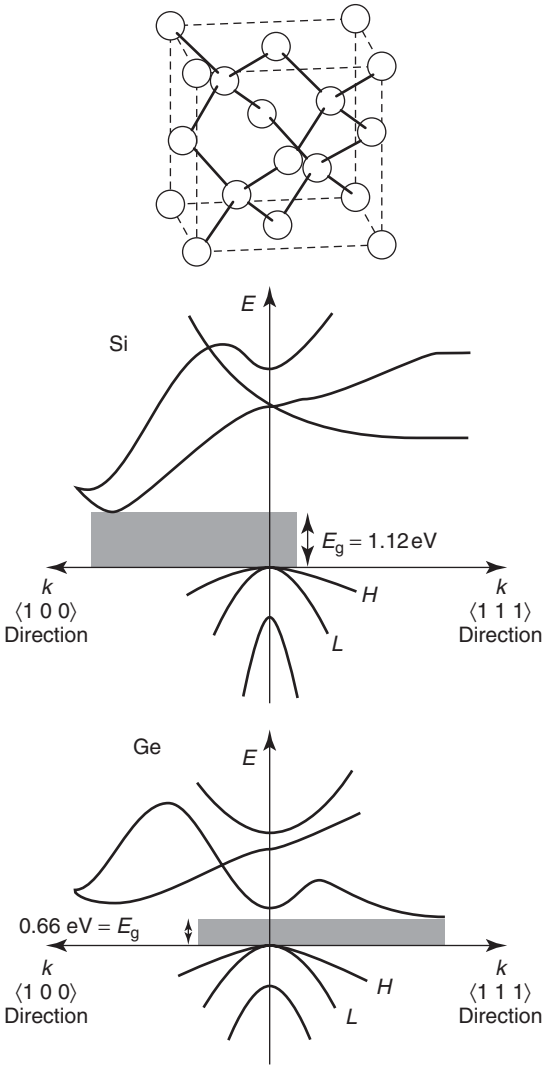

Figure 4 Top: the characteristic tetrahedrally coordinated cubic diamond crystal structure of silicon and germanium. Middle: band structure of silicon along the $\langle 1\,1\,1 \rangle$ and $\langle 1\,0\,0 \rangle$ directions of $\boldsymbol{k}$. Note that an "indirect" gap occurs when the conduction-band minimum is at a different $\boldsymbol{k}$-position than the valence-band maximum. Bottom: the band structure of germanium with its indirect gap. Also, note for both band structures the presence of a "heavy hole" band (H) and of a "light hole" band (L), with different curvatures and, therefore, different effective masses.

It is important to note that for both band structures, the bottom of the conduction band and the top of the valence band of germanium occur at two different values of the k-vector. The corresponding gaps are called "indirect," whereas, when the bottom of the conduction band and the top of the valence band occur at the same k-value, the gap is said to be "direct" as seen in the GaAs band structure in **Figure 5**.

The direct or indirect character of the gap strongly influences the physical properties of the material. For example, the excitation of electrons across the gap implies no change of the k-vector for a direct gap, whereas the contrary is true for an indirect gap. This also implies that the excitation across an indirect gap requires a change in the crystal momentum and therefore, a suitable third party, such as a lattice vibration, to guarantee the conservation of the crystal momentum.

It should also be noted that for both the Si and the Ge band structures, there are two $E(\boldsymbol{k})$ curves near the top of the valence band. Holes can belong to either curve and can have two different effective

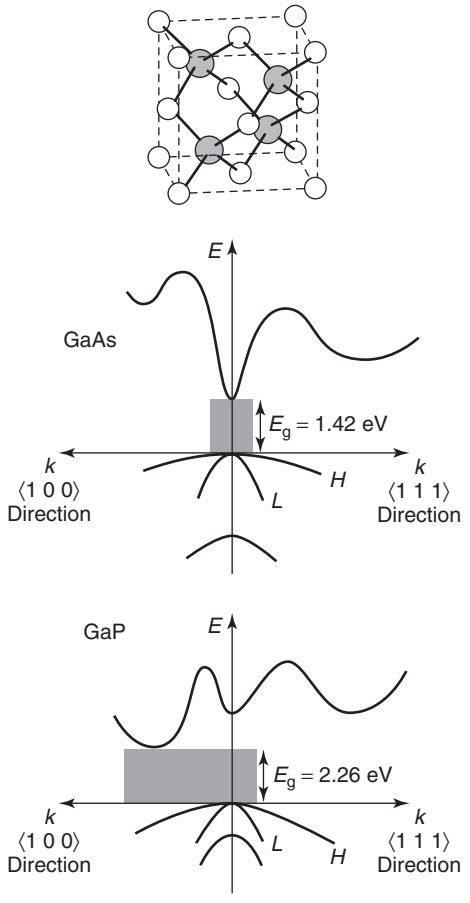

Figure 5 Top: the zinc blende crystal structure of many III–V semiconductors. Middle and bottom: the band structures of GaAs and GaP with their direct and indirect gaps, respectively.

masses. Equation [4] shows that the effective mass is proportional to the reciprocal of the curvature of $E(\boldsymbol{k})$. Therefore, a small curvature means a large effective mass and vice versa. Accordingly, the two valence-band $E(\boldsymbol{k})$ curves are called "heavy hole" band (H) and "light hole" band (L).

The following are the values of some important parameters of Si and Ge (the effective masses are expressed in terms of free electron mass m_e):

	Si	Ge
E_g (300 K)	1.12 eV	0.66 eV
Electron effective masses	0.98, 0.19	1.59, 0.08
Hole effective masses (heavy and light)	0.49, 0.16	0.33, 0.04

The two values for the electron effective masses correspond to the "longitudinal" and "transverse" effective mass. This distinction corresponds to the fact that the conduction-band minimum is not isotropic in three dimensions and that the second derivative in the denominator of eqn [4] is different in different directions. The longitudinal mass corresponds to the derivative along the crystallographic direction where the minimum occurs, whereas the transverse mass refers to directions perpendicular to it.

III–V Compounds

Materials in this class exhibit a wide spectrum of properties of interest for practical applications. **Figure 5** (top) shows the typical zinc blende crystal structure of many III–V compounds. This structure is closely related to that of diamond, with two atomic species rather than one.

The middle and bottom parts of **Figure 5** show the band structures of two particularly important III–V semiconductors, GaAs and GaP. There are some similarities with respect to the Si and Ge band structures of **Figure 4**, such as the heavy-hole band and the light-hole band. Note that the gap is direct in the case of GaAs and indirect for GaP.

There are some important parameters for GaAs, GaP, and for two other important III–V semiconductors, InP and GaN (in the zinc blende structure, GaN is also found in the wurtzite structure):

	GaAs	GaP	InP	GaN
E_g (300 K)	1.42 eV	2.26 eV	1.34	3.3 eV
Electron effective mass	0.06	0.22	0.08	0.13
Hole effective mass	0.51, 0.108	0.79, 0.14	0.6, 0.09	1.3, 0.19

Light Emission and Absorption

The presence of a forbidden gap in the band structure of a semiconductor has an immediate impact on its optical properties: without taking into account the impurities, electronic transitions cannot cause the emission or absorption of photons of energy smaller than E_g. Note, from the previous section, that the gaps of Si and Ge correspond to the energies of infrared photons, such as those of GaAs and InP. On the contrary, the GaP gap falls in the visible and the GaN gap near the border between the ultraviolet and visible regions.

Figure 6 shows the absorption coefficient of silicon plotted in the photon energy range near the gap-width value E_g. It is seen that the absorption has indeed a rapid increase at the E_g-threshold. Note that silicon is an indirect-gap material: the edge would be even sharper for a direct-gap semiconductor. The form of the absorption coefficient after the threshold can be justified in terms of the available initial and final states for the photon-excited transitions of electrons from the valence band to the conduction band.

The symmetric process of photon emission takes place if electrons are injected in the conduction band. The transition from the excited conduction-band states to unoccupied valence-band states can be visualized as the "recombination" of electrons and holes.

Real optical processes are often more complicated than suggested by the above picture. For example, this is a one-particle picture that includes no interaction between the electrons. In reality, the electrons do interact, in particular, the free electrons in the

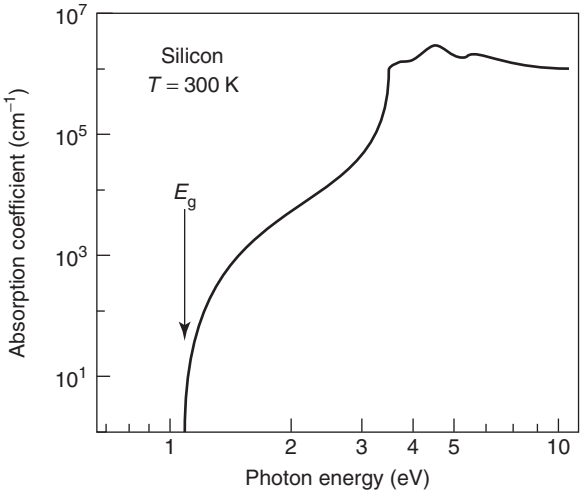

Figure 6 Absorption coefficient of silicon plotted in the photon energy range near the gap-width value E_g. Note the steep threshold related to E_g.

conduction band and the electrons in the valence band. This causes the so-called "excitonic effects."

The simplest case of the excitonic effects is the formation of "Wannier excitons," in which the interaction is visualized as the formation of bound states between free electrons in the conduction band and holes in the valence band. A Wannier exciton can thus be imagined as a hydrogen-atom system in which the proton is replaced by a much lighter hole. The Wannier electron–hole pair is sufficiently delocalized to treat the system in terms of electron and hole effective masses (the contrary is true for the opposite limit of localized "Frenkel" excitons). In the hydrogenic picture, the proton mass is replaced by the reduced-mass combination of the effective masses. Furthermore, the vacuum dielectric constant is replaced by the dielectric constant of the semiconducting material.

The excitation of an electron from the valence band can take place in two different ways: either by forming an exciton or by entirely freeing the electron into the conduction band. The latter situation corresponds to the ionization continuum of the hydrogenic exciton, whereas the former corresponds to its 1*s* ground level. Correspondingly, in the absorption spectrum, the "continuum" above the E_g edge is preceded by an exciton absorption line (or by a series of lines corresponding to different hydrogenic levels). The detection of excitonic lines requires sufficient spectral resolution and low temperature to avoid thermal broadening; otherwise, the excitonic effects are only observed as modifications of the one-electron absorption spectrum.

Figure 7a shows a typical excitonic line absorption spectrum taken on GaAs at low temperature. Note the temperature-induced shift of the E_g edge with respect to the values reported above.

The situation becomes more complicated when the gap is not direct as for GaAs, but indirect. As already mentioned, the optical transitions must be assisted by a suitable "third party" to guarantee the conservation of the (crystal) momentum. Lattice vibrations (i.e., phonons) can play such a role. **Figure 7b** shows the absorption edge of indirect-gap GaP with several features related to the intervention of specific phonons that absorb part of the photon energy and provide the necessary momentum.

Excitonic effects also affect the photon emission processes. Such processes are very important for the realization of "optoelectronic" devices, such as light-emitting diodes (LEDs) and semiconductor lasers. In most cases, in such devices the so-called "bound" excitons, those related to impurities, are the ones that are more significant.

Impurity levels in the forbidden gap allow the absorption and emission of photons of energy smaller

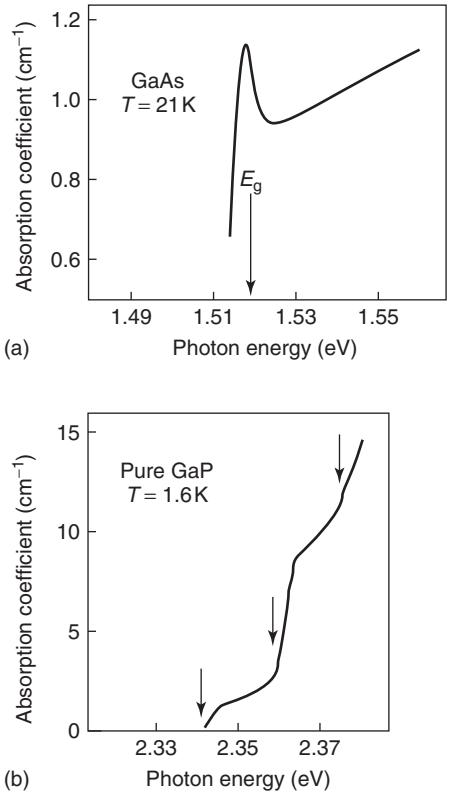

Figure 7 (a) The excitonic line in the low-temperature absorption spectrum of GaAs. (b) Absorption edge of indirect-gap GaP. The arrows mark spectral features related to specific phonons that guarantee momentum conservation.

than the gap. This has important repercussions on the corresponding optoelectronic devices. Consider, for example, the case of GaP: its room-temperature gap, 2.26 eV, would correspond to the "green" visible photons. The corresponding LEDs would produce light with excellent visibility since the peak of the human eye response occurs for such photons.

Unfortunately, the emission of photons from pure GaP is rather ineffective, since the indirect gap requires the intervention of phonons, and this leads to lower electron–hole recombination rates. Doped GaP is much more effective and is commonly used in LEDs. However, its emission no longer occurs in the green but at lower photon energies in the red, where the human eye is less efficient.

It is also possible to remove the effects of the GaP indirect gap by using an intermediate composition between GaP and direct-gap GaAs, that is, $GaAs_{1-x}P_x$. With a suitable choice of the concentration (the x-value), the material has a direct gap. However, the gap width is shifted from the "green" value of GaP toward the infrared value of GaAs and the emitted photons are once again at lower energies than the green.

From this brief discussion, it is clear that the ideal material for LEDs should have a very large gap and should be suitable for doping with different types of impurities. Such impurities would correspond to optical transitions at different photon energies smaller than the gap, ideally covering the entire visible spectrum. In this way, a single material could emit different colors and could be used in integrated devices for variable color emission.

Among the III–V semiconductors, the best candidate for this role is GaN. It is seen, indeed, that its gap falls near the visible–ultraviolet border. Doped with suitable impurities, GaN could emit blue light as well as light at lower photon energies.

The technology of GaN, unfortunately, is much less developed than that of GaAs or GaP (not to mention the extremely sophisticated technology of silicon). In recent years, however, substantial improvements have led to the fabrication of efficient GaN-based blue-emitting devices. Further improvements are foreseen so that the GaN technology is quite promising for versatile optoelectronic devices.

Figure 8a schematically shows a simple type of LED based on a forward-biased *p*–*n* junction. As noted already, the forward bias lowers the barriers for electrons and holes. Electrons from the *n*-region can cross the junction into the *p*-region, where they find a large density of holes. The electron–hole recombination causes the emission of photons.

Symmetrically, the reduced barrier for holes enables some holes to move from the *p*-region to the *n*-region. There, they find a large density of free electrons: once again, the electron–hole recombination can give rise to photon emission.

The *p*–*n* junction is also the building block of another important optoelectronic device: the light detector or photodiode. **Figure 8b** schematically shows how it operates. In this case, the *p*–*n* junction is reverse biased, so that normally very little current flows through it.

When a photon beam with photon energy larger than the gap width illuminates the junction, photon absorption can excite electrons into the conduction band of the *p*-type region. Some of these photo-injected free electrons reach the interface region where they find a suitable voltage to move into the *n*-type region. In this way, the photon beam produces a photocurrent that can reveal its arrival on the diode.

For solar cells, some photodiodes are optimized for the detection of a large part of the solar spectrum. They allow the direct conversion of solar energy into electric power, providing an interesting alternate source of energy of increasing importance.

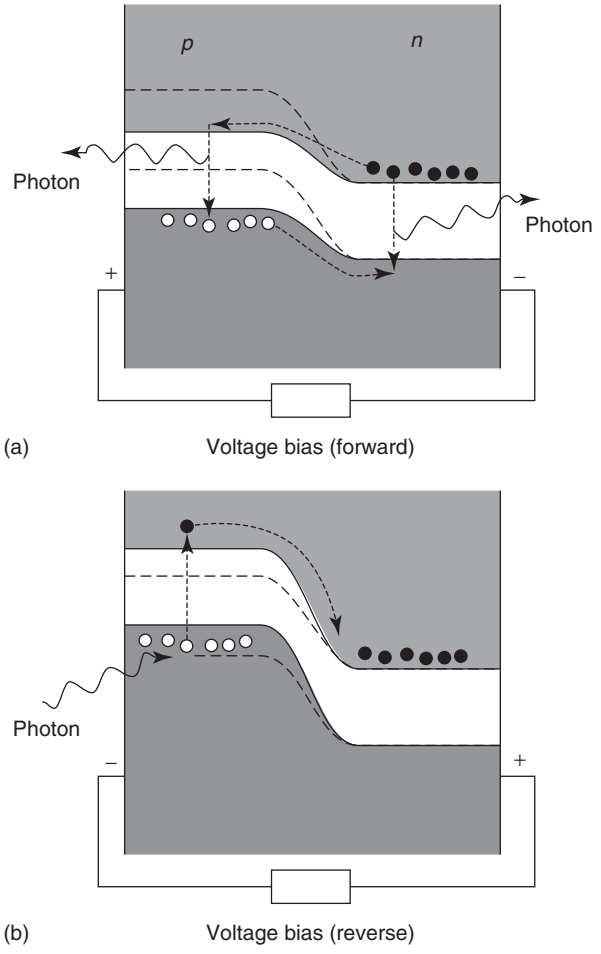

Figure 8 Simple types of semiconductor optoelectronic devices based on the *p*–*n* junction. (a) The forward bias of LED lowers the barriers for electrons and holes that can cross the junction reaching the opposite region, recombining and emitting photons. (b) Due to the reverse bias in the photodiode, very little current normally flows through the device. When photons with energy larger than the gap illuminate the junction, they can excite electrons into the conduction band of the *p*-type region. Some of these free electrons reach the interface region where they find a suitable voltage to move into the *n*-type region. The photons thus produce a current that is used to detect them.

Introduction

The so-called information or computer superhighway has led in modern society to a transformation comparable to the industrial revolution of the nineteenth century. This recent informatic revolution developed in the second half of the twentieth century as a consequence of the scientific knowledge of the microscopic world, conceptually based on quantum mechanics, and originated from the understanding of the electronic processes in a particular class of solids, known as semiconductors.

The existence of materials of this kind, which are poor insulators as well as poor conductors, had been noticed by Alessandro Volta (1745–1827) in the course of his studies on electricity at the end of the eighteenth century. The most common compounds of this kind were Ag_2S, PbS (galena), ZnS, CdS, ZnSe, and CdSe. Today, the most important semiconductor is silicon (Si), introduced by Antoine–Laurent Lavoisier (1743–1794) at the end of the eighteenth century as a component of sand (silex), and isolated by Joseph–Louis Gay–Lussac (1778–1850) and Jöns Jacob Berzelius (1779–1848) at the beginning of the nineteenth century.

The theoretical understanding of the physical phenomena which occur in semiconductors started in the 1930s and was developed throughout the rest of the last century, leading to new concepts of fundamental relevance, particularly in the field of many-body physics and light–matter interaction, and opening the way to new applications with the extreme miniaturization of the electronic and optoelectronic devices. At present, the semiconductor industry plays a crucial role in the economic system of every technologically advanced country, and is in constant growth because it satisfies the ever-increasing need to execute complex calculations, and to store and transmit information.

The development of the scientific and social history which led to these results is a fascinating subject and a prominent example of the strict interplay between physics and technology. An attempt has been made to briefly indicate its main points.

The Origins

The first observation of a poorly conducting behavior is due to Stephen Gray (1666–l736) who noticed how wet cork put in contact with charged glass is able to attract objects. The concept of electrical conductor (conducteur d' électricité) was subsequently introduced by Jean-Théophile Desaguiliers (1683–1744) in a communication to the Académie Royale des Belles Lettres et Arts (Bordeaux, 1742).

However, it was Volta who found, during his studies on the transport of electricity from one body to another, that a large number of substances were poor insulators and poor conductors. He introduced the notion of imperfect conductor for such materials using the term semi-insulators (semicoibenti) to define substances "which are actually permeable to the electric fluid, but oppose a strong resistance to its passage."

When intense electrical currents became available thanks to Volta's pile, Humphry Davy (1778–1829), the father of electrochemistry, could carry out experiments on the conductivity of common metals (Cu, Ag, Fe, Pt, etc.), observing that in all of them it decreases with increasing temperature. His pupil Michael Faraday (1791–1867) extended the conductivity measurements to nonmetallic materials (oxides, carbonates, sulfates) and, in particular, to HgI_2, and discovered that the increase of temperature produces in them a great increase of the conductivity, contrary to what happens in metals. The data of Faraday and later data on Ag_2S and Cu_2S by Johann

Wilhelm Hittorf (1824–1914) have been reexamined by George Busch, who found that they were in agreement with an exponential increase of conductivity with increasing temperature, as shown in **Figure 1**.

Understanding this phenomenon was the subject of a long debate. Contrary to the case of ionic crystals where the electrical conductivity was due to the flow of ions made possible by vacancies as found by Jakov I Frenkel, Carl Wagner, Walter Schottky, Walter Jost, and Robert W Pohl in the early 1920s, in the case of these materials no appreciable weight change was observed at the electrodes. It is useful to remember that the current density can be written as

$$\boldsymbol{J} = \sigma \boldsymbol{E} = ne\mu \boldsymbol{E} \qquad [1]$$

where the conductivity σ depends on the density n of the charge carriers and on their mobility μ. To understand the process of electrical conduction, it is necessary to measure with precision, besides the charge e, the density of carriers n. This became possible after 1879, thanks to the discovery by Edwin H Hall (1855–1938) that the current in the presence of a magnetic field perpendicular to the flux direction produces an electric field orthogonal to them and proportional to the current and to the magnetic field such as to compensate the deflecting Lorentz force. The proportionality constant is given by $1/nec$ and from its measurement, the sign and density of the charge carriers can be obtained, taking the elementary charge for e. This was crucial to determine that in metals and semiconductors the electrical current is carried by electrons, as shown by Carl V E Riecke (1845–1915) in 1901 at the University of Göttingen, who found that the charge-to-mass ratio obtained from the Hall effect measurements was consistent with the value e/m found by Joseph J Thompson in 1898 for electrons in vacuum. While Riecke and Paul Drude (1863–1906) formulated the model of free-electron conductivity in metals, Johann Koenigsberger (1874–1946) introduced, in 1913, the assumption that in semiconductors the conductivity is thermally activated with a material-dependent activation energy.

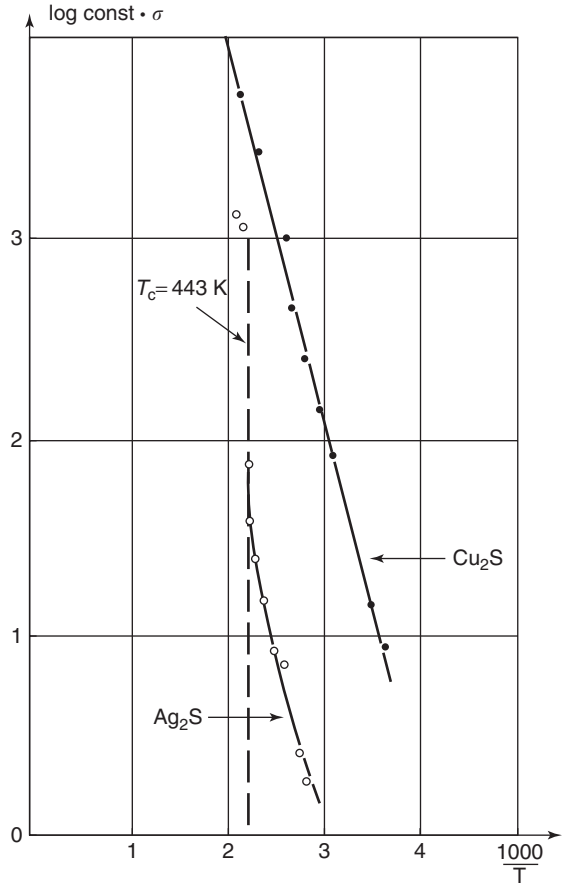

Figure 1 Conductivities of Cu_2S and Ag_2S as a function of temperature. It is to be noted that the change of slope in Ag_2S at $T_c = 443$ K is due to a phase transition.

An important and, for a long time, unexplained result was found by Karl Baedeker (1877–1914) in CuI in 1909, and later on by Orso Maria Corbino (1876–1937) in other substances: the Hall constant changed sign and showed an anomalously low concentration of carriers, yet with a large current. Now it is known that this is due to the presence of two types of carriers (negative electrons and positive holes), both of which contribute to the current, but partly compensate each other in the Hall effect.

The early studies of semiconductors were particularly challenging because the experimental results were poorly reproducible due to the uncontrolled presence of impurities. This gave the semiconductor physics a bad reputation, to the point that Wolfgang Pauli (1900–1958) called it "dirty physics." Only the possibility of producing relatively pure substances during and after the second World War allowed one to overcome such problems and start the modern physics of semiconductors.

Two important properties of semiconductors were empirically discovered in the nineteenth century. Ferdinand Braun (1850–1918), the discoverer of cathode rays and who shared the Noble prize with Marconi in 1909, observed in 1874 the rectifying behavior of galena and of other semiconducting crystals, namely the fact that in a metal–semiconductor contact, the current flows easily only in one direction and not in the opposite one. William G Adams and Richard E Day, in 1877, discovered the photovoltaic effect in Se, that is the appearance of a potential difference (open circuit) or of an electrical current (closed circuit) due to the absorption of light.

Both effects were used for important technological applications: the rectifying diodes were used as efficient detectors of radiowaves, and photovoltaic devices were used as exposimeter in the photographic process.

Detectors of Electromagnetic Waves

The electromagnetic waves, produced by Guglielmo Marconi (1874–1937) and co-workers, were initially detected by the coherer, a glass tube containing loose metal filings or mercury drops making contact with two electrodes; in the presence of the electric field of the wave, the conductivity increased and the tube acted as a detector. At the beginning of the last century, semiconductor rectifiers were used in order to obtain the electroacoustic transformation of radio waves and to allow earphones to be used. Though less sensitive than the coherer, crystal diodes soon came to be of general use as radiowave detectors. They were later substituted by vacuum tubes, which had better performances and gave more reproducible results. The vacuum tube also gave the possibility of amplifying the current, using a grid (triode). However, semiconductor diodes were never completely abandoned as they required no additional circuitry to produce the electron current.

Semiconductor diodes came to acquire utmost importance when it was necessary to detect microwaves of a few centimeters of wavelength for which vacuum tubes were not adequate. In particular, the use of silicon crystal and tungsten diodes in connection with the development of radar technology was introduced in 1939 by two young British, Denis Robinson and H W B Skinner, who also employed such diodes as nonlinear elements in a heterodyne circuit to reduce the frequency of the return signal and allow for subsequent amplification.

During the war, further progress was made in the US at the Radiation Laboratory of MIT and at the Du Pont company by producing silicon and germanium crystals of high purity doped with controlled amounts of impurities. A historical *I–V* curve of a silicon–tungsten diode is shown in **Figure 2**.

At the same time as at General Electric, at the University of Pennsylvania and at the Bell Telephone Laboratories, a research program was started on germanium, a semiconductor similar to silicon, but with a higher carrier mobility. In this case, very precise measurements of the Hall effect and the activation energy were made. The conductivity activation energy in the intrinsic regime was found to be 0.33 eV, while at lower temperatures, it was determined by the impurity content. Similar results were valid also for silicon, with an activation energy of 0.6 eV.

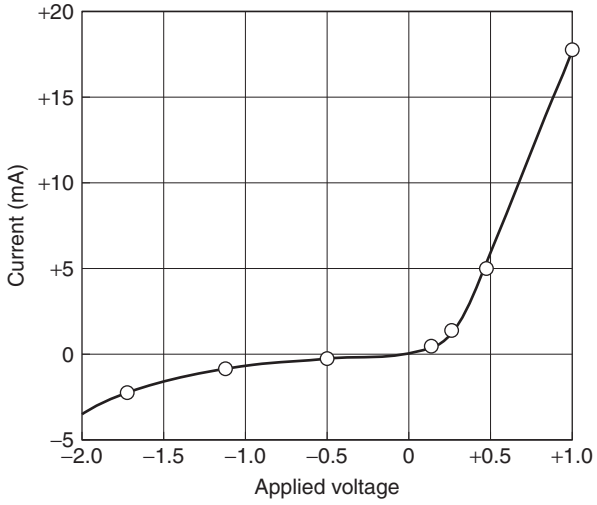

Figure 2 Historical *I–V* curve of a silicon–tungsten diode. (Adapted from Torrey HC and Whitner CA (1948) *Crystal Rectifiers*. McGraw-Hill.)

Since then, the technological interest for semiconductor crystals became predominant, and special attention was focused on crystals of group IV as well as III–V and II–VI compounds of particular simple symmetry (each atom at the center of a regular tetrahedron). Semiconductor physics after the second World War, was mainly developed by the group of Frederick Seitz at the University of Pennsylvania, and of Karl Lark-Horovitz at Purdue University, as well as at Bell Laboratories, clearly indicating the interest in the use of germanium in telecommunications.

Theory of Electronic Processes

The theoretical understanding of electronic processes in semiconductors developed gradually after the advent of quantum mechanics in the 1920s. The basic concept is that energy bands are available states for electrons in crystals. A theorem proved by Felix Bloch (1905–1983) in 1928 shows that the eigenfunctions of the Schrödinger equation in a crystal, and the corresponding available energies depend on the good quantum number $\boldsymbol{k}$ in reciprocal space. Such $\boldsymbol{k}$-vectors are uniformly distributed in the first Brillouin zone of the reciprocal space and their number equals that of the elementary cells in the crystal (half the number of atoms in Si and Ge, which have two atoms per unit cell). The energy values available to the electrons are organized in bands $E_n(\boldsymbol{k})$, each $\boldsymbol{k}$-vector corresponding to a de Broglie wavelength $\lambda = 2\pi/k$ and a momentum $\hbar\boldsymbol{k}$ of the electron. Such energy bands can be associated to the atomic states to which they would reduce if the interatomic distance were greatly increased.

The second basic concept is the exclusion principle introduced by Pauli in 1925 which states that each state can be occupied by one electron only (two electrons if spin is taken into account). Such a principle was formulated to account for the chemical properties of the atoms, but it turned out to explain the electronic properties of metals, insulators, and semiconductors, as shown conceptually by Alan H Wilson in 1931 while he was at Lipsia in the group of Werner Heisenberg. At zero temperature, in fact, electrons fill up the states of lower energy up to the Fermi level. At higher temperature, they follow the Fermi statistical distribution and some of them occupy higher electronic states. The totally filled bands cannot give any contribution to the current flow because of the exclusion principle. In metals, the Fermi level is inside a partly occupied band, and this allows the electron of that energy to transfer onto nearby empty levels with a behavior similar to that of free electrons. In insulators, totally occupied bands are separated from empty ones by an energy gap E_g, sufficiently wide to prevent the presence of electrons in higher bands at any temperature below the melting point. Semiconductors are insulating at very low temperatures, but their energy gap E_g is sufficiently narrow (typically less than 2 eV) so that at high temperatures a number of electrons per unit volume can be in the normally empty conduction band above the Fermi level. Such electrons behave as electrons in metals and are responsible for a current flow in the presence of an applied electric field.

For the purpose of illustration, **Figure 3** shows the energy bands of silicon computed with appropriate mathematical techniques in the 1950s by various authors (C Herring, F Hermann, T O Woodruff, F Bassani), and computed since then again and again with ever-increasing accuracy. One can observe that the eight valence electrons per unit cell (four for each of the two atoms) fill up all the states of the four lowest bands up to the maximum $\Gamma_{25'}$ at $\boldsymbol{k} = 0$, and the gap $E_g = 1.2$ eV separates these states from the conduction band minimum in the Δ direction at

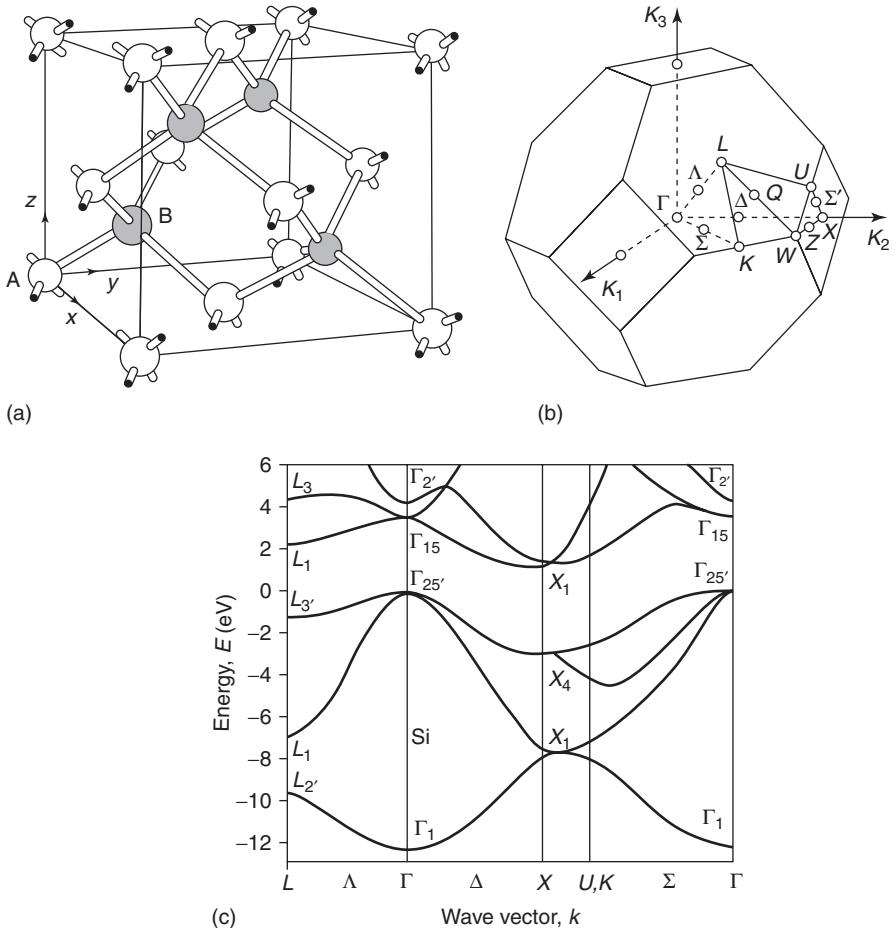

Figure 3 Structure of the zinc blende lattice: in Si both dark and light sites are occupied by Si atoms, in GaAs they are occupied by Ga and As atoms respectively; (b) Brillouin zone of the zinc blende lattice with the indication of points and lines of high symmetry; (c) Electronic band structure of silicon: the valence band maximum is the $\Gamma_{25'}$ state and the conduction band minimum is along the Δ line.

$\boldsymbol{k} = (2\pi/a)(0.8, 0, 0)$, a being the lattice constant. In this case, the gap is said to be indirect and the lifetime of electrons and holes is long because their recombination requires the participation of a phonon to preserve momentum. In other semiconductors having a direct gap, such as GaAs, optical recombination is allowed without phonon participation and has a much higher probability. Analogous results have been obtained experimentally and theoretically for all semiconductors of interest.

Another fundamental concept is that of a "hole" of electron, introduced by Heisenberg for atoms and by Rudolf Peierls for solids in 1931: an empty electronic state in a band otherwise totally occupied behaves like a positively charged particle and thus contributes to the current. The concept is analogous to that of the antiparticles of Dirac, the positrons, but in this case the effective mass m^* of electrons and holes are different as they are determined by the curvature of the bands $E_n(\boldsymbol{k})$ at the minimum of the conduction band and at the maximum of the valence band, respectively. In fact, the behavior of electrons near the band extrema is determined by the relation

$$E(\boldsymbol{k}) = E_0 \pm \frac{\hbar^2 k^2}{2m^*} \qquad [2]$$

where $+$ or $-$ refer to the minimum or maximum of the respective bands. The existence of holes explains the anomalous Hall effect mentioned above which had remained a mystery for decades.

In an intrinsic semiconductor, the concentration of electrons in the conduction band equals that of holes in the valence band, and they are given by

$$n_e = n_h = C\, e^{-E_g/(2K_B T)} \qquad [3]$$

where the prefactor depends on the effective masses and weakly on temperature. This explains the measured values of the activation energies which is half the energy gap (1.2 eV for Si, 0.66 eV for Ge).

In the case of doped semiconductors, as first suggested by Wilson, the impurities which substitute atoms of the lattice introduce additional electrons when their chemical valence exceeds that of the substituted atom, and introduce holes in the opposite case. For instance, group III impurities (B, Al) in Si and Ge introduce holes and group V impurities (P, As) electrons. Such holes or electrons are bound to the impurity atoms, but the attraction is very small because the dielectric constant screening the Coulomb interaction is large (typically >10) and the effective mass is small. Such states are then partly ionized and most of the additional electrons and holes are in the conduction or valence bands at room temperature. This explains why the amount of doping allows one to control the type of conductivity and its values. One can obtain semiconductors of n-type (with negative carriers) and of p-type (with positive carriers). The mobility μ has a much smaller influence on the conductivity with respect to the carrier density n; the latter can change by orders of magnitude and is controlled by the amount of doping (extrinsic regime) or by temperature (intrinsic regime).

This simple conceptual scheme was made available in the first half of the century, but its definite success is due to accurate research carried out in the second half of the century, particularly on the semiconductors Si and Ge. Among the main protagonists of the successful explanation of the electronic processes in semiconductors are, besides the aforesaid scientists, Walter Kohn and Charles Kittel. Kohn developed the density-functional theory to include many-body effects in the energy band calculations. Kittel developed the cyclotron resonance technique in semiconductors, which consists in producing transitions with microwaves between quantum levels induced by magnetic fields and measuring the corresponding absorption peaks. The cyclotron frequency separating the levels is eB/m^*c, which allows the experimental determination of the effective masses.

Transistor, Integrated Circuits, and Microprocessors

First of all, the band theory allowed the understanding of current rectification in the metal–semiconductor junction as due to a potential barrier at the interface produced by a migration of electrons from the side of an n-type semiconductor to the side of the metal (W Schottky, 1939). Such a potential barrier, shown in **Figure 4a** for the n-type case (an analogous situation occurring also for holes in p-type semiconductors), allows the passage through the interface of only those electrons having a higher energy. An applied external field would change the height of the potential barrier lowering it for one polarity and increasing it for the other. The number of electrons that can overcome the interface barrier varies by the factor $e^{\pm eV/K_B T}$; as a consequence, there is a great increase of the current only in the direction in which the barrier is lowered. For the same reason, as shown in **Figure 4b**, one obtains rectification at a junction between n-type and p-type semiconductors where the potential barrier is due to the fact that the Fermi level is near the conduction band or the valence band in n-type and p-type semiconductors, respectively. In 1958, Leo Esaki discovered that current can also be obtained by a tunnel effect for sufficiently high

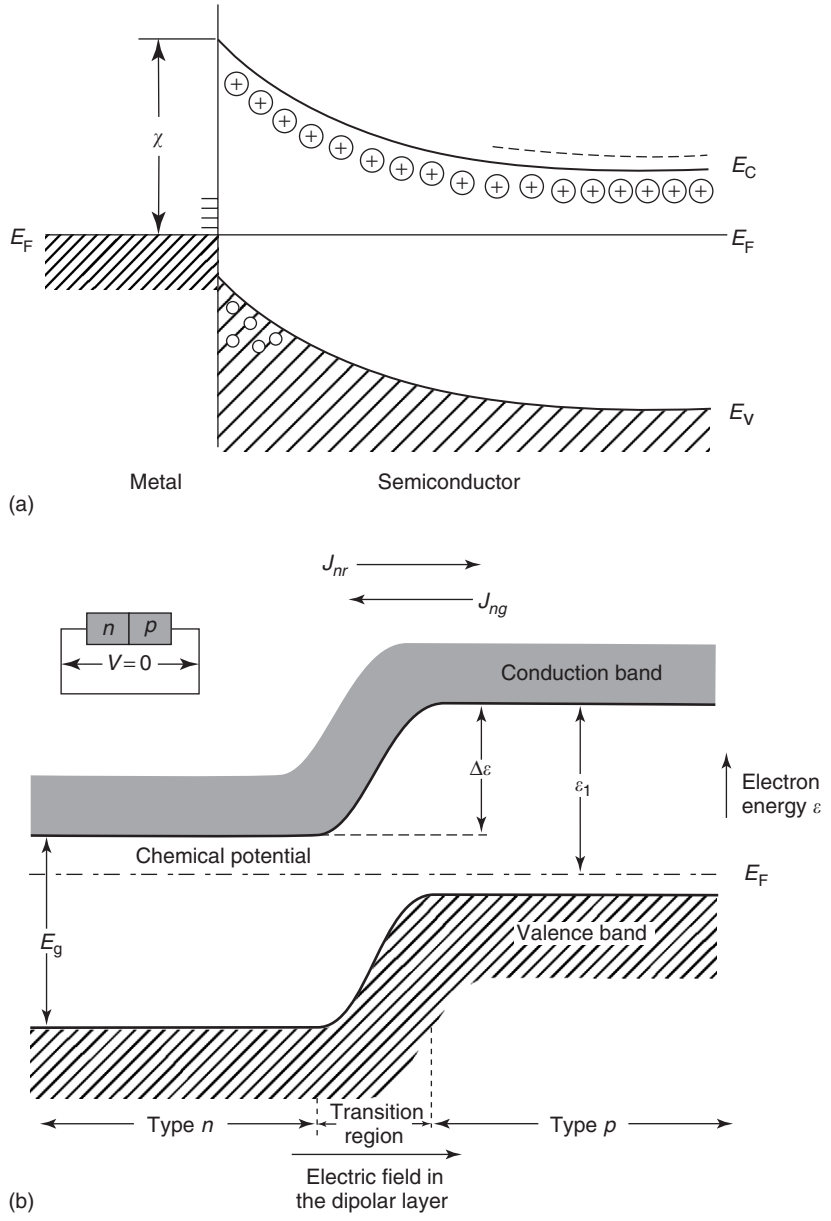

Figure 4 (a) Schematic diagrams of a metal–semiconductor Schottky barrier, and (b) schematic diagram of a *p–n* junction.

electric fields in the direction in which, normally, the diode would not conduct.

It was natural to expect that this type of knowledge could lead to a device similar to the triode, and thus allow amplification of the current. Such a device was created by J Bardeen, W H Brattain, and W Shockley in 1947 at the Bell Telephone Laboratories of Murray Hill. It consists of two junctions, one metal–semiconductor and the other semiconductor–metal, very close to each other as shown in **Figure 5a**. A small current in the base gets amplified into a large current flowing through the collector. The name "transistor" was proposed by J R Pierce of Bell Telephone Laboratories because the large swing of the collector-to-base voltage (load circuit) driven by a small variation of the base-to-emitter current implies a resistance transfer. A second type of transistor was soon invented by Shockley combining two semiconductor junctions, for example in the scheme *n–p–n* as shown in **Figure 5b**. In this case, the first *n–p* junction acts as the emitter-to-base junction and the second one as the base-to-collector junction. Again, the base current is amplified into the collector current. This bipolar junction transistor was immediately used as a substitute for amplifying vacuum tubes with hot emitting filaments in electronic circuits and computers, its main advantages being the compact dimensions and the limited power dissipation.

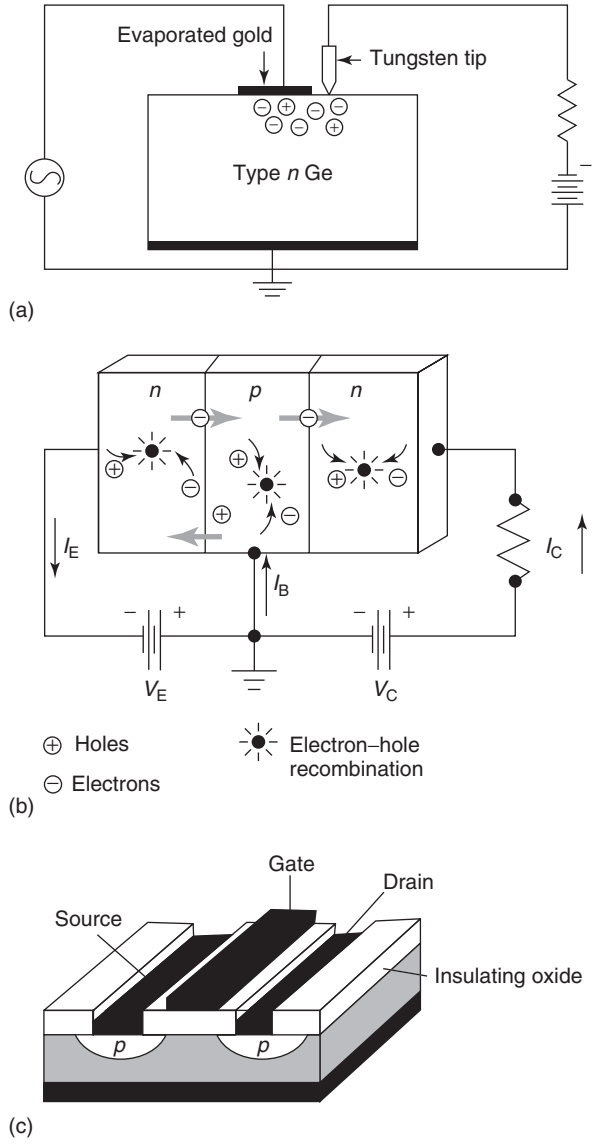

Figure 5 (a) Scheme of the point-contact transistor; (b) scheme of the *n*–*p*–*n* transistor; (c) scheme of a MOSFET.

A further development was the field-effect transistor (FET) suggested by Bardeen in 1950 and developed by G C Dacey and I M Ross in 1953. In this case, a voltage is applied to the base (also called gate) generating a field that attracts or repels charge carriers favoring or impeding the current flow from the emitter (also called source) to the collector (also called drain). A metal-oxide field-effect transistor (MOSFET) can be realized exploiting the surface oxide to isolate the contacts and building the device on a single surface of a monocrystal of Si, as shown in **Figure 5c**.

FETs, and particularly the MOSFETs, are the basic ingredients of the planar integrated circuits that have opened the way to the miniaturization of electronics. The connecting wires are substituted by the metal evaporated in the channels engraved in the oxide and capacitors, resistors, and transistors are properly inserted at the semiconductor surface.

The advantage of using a planar architecture explains the almost exclusive use of silicon as the basic material of the electronic industry as its oxide is an excellent insulator, and is not igroscopic as germanium oxide. The development and mass production of these semiconductor "chips" have led to the informatic revolution of the second half of the twentieth century. The first complete circuit system obtained by chemical processing on the surface of a silicon monocrystal eliminating the need of connecting metal wires was realized by Jack Kilby (Texas Instruments) and Robert Noyce (Fairchild Semiconductors) in 1959. In the 1970s, the first memory devices were developed by introducing on the gate of a MOSFET an isolated metallic substrate which can trap or release electrons by a tunnel effect under the application of an electric field, thus switching the device on and off. As a consequence of the above developments at Texas Instruments, at Fairchild Semiconductors and at the new Intel company, a complete microprocessor (including logical and memory devices) was realized on a single chip with a diameter of $\sim$1 inch (Federico Faggin, 1972).

Such results have been obtained through the driving force of strong industrial companies which allowed continuous technological improvements and large-scale production. The rapid growth of the field also favored the development of new companies, entirely dedicated to the production of semiconductor devices, concentrated in the region that became known as Silicon Valley in California.

These events give a vivid example of the close connection among science, technology, and industry in modern society. The development of microprocessors is still in progress, the increase of the number of transistors per unit area on a single chip following the so-called Moore's law of doubling each year, reaching more than a billion units per chip in 2002. At the same time, there has been a large increase in the cost of a single factory and a large decrease in the cost of a single chip, while the semiconductor industry production has enormously increased reaching a total worldwide market value of a thousand billion dollars per year.

Laser and Photonic Devices

Semiconductors are also very important for their optical properties which allowed the development of microlasers and other photonic devices. Optical transitions corresponding to the absorption (emission) of

light occur when an electron is excited from the valence band to the conduction band (an electron from the conduction band recombines with a hole). As mentioned before, such processes are most probable when such transitions are vertical ($\Delta \boldsymbol{k} = 0$) because the photon momentum (h/λ) is negligible with respect to that of electrons ($\hbar k \simeq \hbar/a$). As a consequence, direct gap semiconductors, such as GaAs, are the most useful ones to develop photonic devices.

The photovoltaic effect is exploited in the solar cell, which allows the transformation of photon energy into electrical power following photon absorption at the junction, as indicated in the scheme shown in **Figure 6**. One observes that the reverse process, in which a current is converted into light, takes place in a junction working as a light emitting diode (LED).

The first silicon solar cell was realized by D M Chaplin, C S Fuller, and G L Pearson (in 1954) with a conversion efficiency of the solar spectrum of 6%. Later on, the efficiency reached 24% in GaAs. The theoretical limit in bulk materials is due to the fact that photons, with an energy higher than the gap, convert only part of it into electrical power, the rest being thermally dissipated in the semiconductor. To overcome this limitation, solar cells based on graded gap materials are being developed.

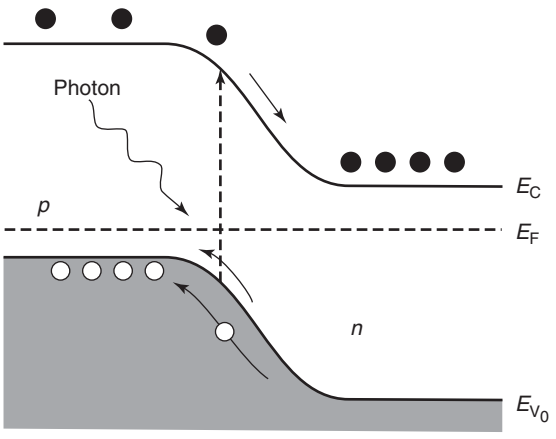

Figure 6 Scheme of a *p–n* junction solar cell.

In the 1960s, semiconductor lasers were first developed using heavily doped GaAs *p–n* junctions by R N Hall and N Holonyak at General Electric, by M I Nathan at IBM, and by T M Quist at MIT. The basic idea is to obtain population inversion in the electronic system; the applied electric field driving the current produces a spatial superposition of heavily *n*-type and *p*-type doped regions, as indicated in **Figure 7**. While electrons and holes recombine, population inversion is maintained by the continuous injection of carriers (electrical pumping). Furthermore, the surfaces of the semiconductor itself act as mirrors forming an optical cavity which allows for optical gain and laser action. An important development has been the heterostructure laser realized by Z Alferov (1969). The advantages of semiconductor lasers with respect to gas lasers are the reduced dimensions, the small power consumption, and the low cost. The frequencies of the light emitted can be chosen using semiconductors with different energy gaps, from the infrared (InSb) to the ultraviolet (GaN).

Heterostructures and Low-Dimensional Devices

In the last two decades of the last century, semiconductor physics received a new incentive from the realization of artificial crystals in which the chemical composition is controlled at the atomic level, some parts being made of one semiconductor and other parts by a different one (heterostructures). Such substances are produced by epitaxial growth from

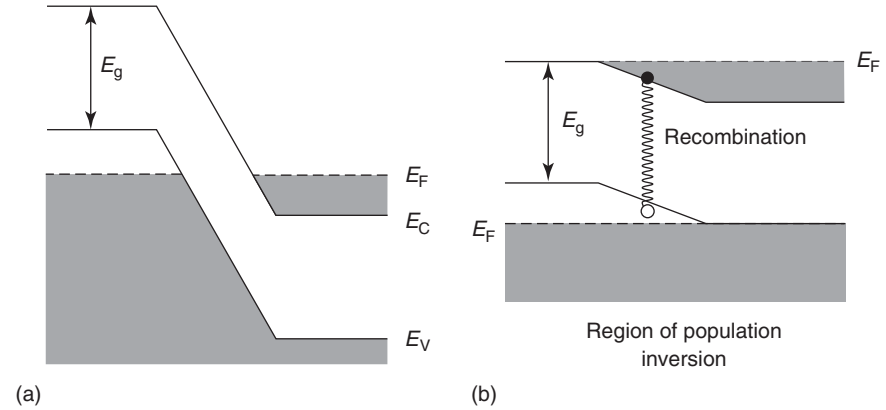

Figure 7 Scheme of a semiconductor junction laser: (a) without the applied electric field; (b) with the applied field, in working condition.

molecular beams (MBE) impinging under ultrahigh vacuum on a heated substrate, or by other growth techniques such as chemical vapor deposition (CVD). These heterostructures are not thermodynamically stable, but once produced, have a practically infinite lifetime at room temperature.

The first of such nanostructures is the superlattice, introduced by L Esaki and R Tzu in 1970, made of sequences of N atomic planes of semiconductor A with lattice constant a, and M atomic planes of semiconductor B with lattice constant b, giving rise to a large periodicity $Na + Mb$ in the growth direction. In this direction, the possible values of the wave vector $\boldsymbol{k}$ are greatly reduced and the energy bands are correspondingly narrow (minibands).

Other nanostructures can be obtained by inserting some planes of a semiconductor of a lower gap inside a semiconductor of a larger gap. Then, electrons and holes tend to be confined in the lower gap material forming two-dimensional subbands, each associated to a discrete level produced by quantum confinement (quantum well). In such a case, by controlling the thickness of the well, one can control the frequency of the optical transitions between subbands, thus obtaining lasers of desired frequency, infrared detectors, etc.

The first experimental observation of optical transitions in a quantum well is due to R Dingle (1974), and since then, there has been a continuous development in photonic nanostructures. The two-dimensional confinement of the electronic states also has a profound influence on transport properties and this has led to unexpected phenomena, such as the quantum Hall effect. At a low temperature and in a high magnetic field, the Hall resistance of a two-dimensional electron gas in the inversion layer of a silicon MOSFET or in a quantum well shows as a function of the magnetic field, well-defined plateaus, from which the universal quantum of resistance h/e^2 can be obtained (V Klitzing, 1982).

One can also realize quantum confinement in two directions producing quantum wires with one-dimensional subbands, or quantum confinement in all three directions producing quantum dots with discrete atomic-like levels (see the scheme in **Figure 8**).

A further nanostructure is the microcavity, obtained when a semiconductor of width comparable to half the wavelength of light in the material is sandwiched by totally reflecting layers (metallic mirrors or dielectric Bragg mirrors), as shown in **Figure 9**. In such a system, one obtains a concentration of light of wavelength which can be chosen in resonance, for instance, with a quantum well optical transition to which it is strongly coupled (C Weisbuch, 1992).

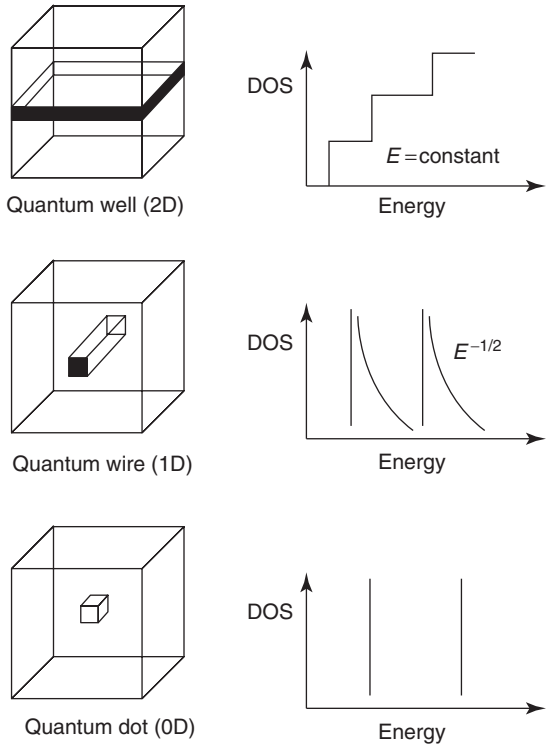

Figure 8 Nanostructures with quantum confinement in 1, 2, or 3 dimensions.

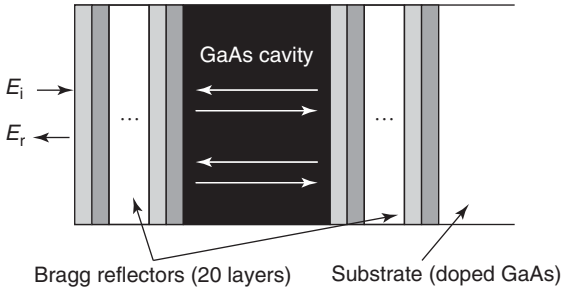

Figure 9 Semiconductor microcavity with distributed Bragg reflectors.

The use of nanostructures for the production of a number of important optical effects is now pursued. An important example is the quantum cascade laser originally proposed by R Suris and R Kazarinov in 1971 and realized for the first time by F Capasso at the Bell Telephone laboratories in 1994. In this unipolar device, quantum wells and superlattices are alternated in great numbers and displaced in energy by the applied electric field driving electrons through the structure. The complex design is such that each flowing electron makes many transitions and, in the proper regime for population inversion and laser action, emits many laser photons. Recent developments by A Tredicucci and co-workers at the Scuola

Normale Superiore in Pisa (2002) have led to a laser with high spectral quality in the frequency region of the terahertz (see **Figure 10**), which is of great interest for the spectroscopic detection of complex molecules and for the possibility of penetrating through most substances.

Conclusions

The history of semiconductors, from Volta's times to the present day, has witnessed many extraordinary results in fundamental and applied physics. Since the Nobel prize awarded for the discovery of the transistor, more than ten other Nobel prizes have acknowledged milestone achievements in semiconductors physics. One can anticipate that this field will continue to produce important results in the future. The theoretical limit of the miniaturization of solid-state electronic devices down to the atomic level has not yet been reached. In photonics, the new nanostructures are very promising not only for laser light production, but also for nonlinear optics and coherent control in microcavities and hybrid organic–inorganic structures. Finally, the development of computers and quantum computers based on photons as well as on electrons is a very ambitious goal that will be reached only through major developments in semiconductor physics and nanotechnology.

Semiconductors, Impurity and Defect States in

H Ikoma, Tokyo University of Science, Tokyo, Japan

Introduction

The role of mobile charge carriers is a key factor in semiconductor device operations. These free carriers are supplied by doping semiconductors with certain kinds of impurities. The electrical properties of semiconductors can thus be controlled by adding a small amount of impurities. However, some other impurities and crystal defects often have detrimental effects on the performance of the device. These impurities and defects create discrete energy levels in the bandgap of the host semiconductor, and exert various influences (usefully or detrimentally) on the semiconductor characteristics. Therefore, a knowledge of the electronic structure of the impurities and defect states in semiconductors is very important.

Structural and Electrical Properties of Impurities and Crystal Defects

Impurity atoms normally substitute the atoms of the host semiconductor (substitutional impurity atom).

However, some of them, especially those with small atomic radii, often enter the interstitial site in the host crystal lattice (interstitial impurity atom). On the other hand, the well-known point defects – the vacancies (lattice points where atoms are lacking) and the interstitials (atoms of the host semiconductor occupying the interstitial sites) – are examples of the intrinsic crystal defects. These point defects sometimes generate a complex center such as the Frenkel defect (the pair of vacancy and interstitial atoms in the neighboring lattice sites). There are two types of impurities and defects from the electrical point of view. One of them supplies free electrons and the other provides holes in the host crystal. The former is called donor and the latter, acceptor. For example, when V-column elements such as P and As are doped in Si (IV-element), one excess valence electron is easily liberated (the impurity atom is ionized) in the Si lattice even at room temperature because of the low binding energy between the electron and the impurity atom. Also, when a III-element such as B is introduced into Si, one valence electron is deficient so that one hole is created and easily released in the Si lattice at room temperature due to their very low binding energy. These impurities, having very low binding (ionization) energies are termed shallow impurities (shallow donor and shallow acceptor). If Si is doped with VI-elements (S, Se, and so on) or II-elements (Zn, Cd, and so on), two free electrons or two holes per impurity atom, respectively, are created (double donor and double acceptor). On the other hand, some impurity elements (and crystal defects) have very high binding energies so that electrons or holes are not easily liberated in the host crystal at room temperature. These impurities with high binding energies are called deep impurities. Heavy metals such as Fe, Ni, and Cu in Si, for example, are deep impurities. In compound semiconductors, the same impurity atom behaves both as a donor and an acceptor depending on its occupied site (amphoteric impurities). The Si atom in GaAs behaves as a donor if it occupies the Ga site and as an acceptor when it substitutes the As atom. When IV-elements (Ge, C, etc.) are doped in Si, they also behave as donors or acceptors although there are cases when they are not electrically active. These impurities are called isoelectronic impurities. With doping of the impurities in semiconductors, the discrete energy levels are normally generated in the bandgap of the host semiconductor. For shallow donors and acceptors, these energy levels are located very near the bottom of the conduction band and the top of the valence band, respectively. On the other hand, the energy levels for the deep impurities occur near the middle of the bandgap.

Theory of the Electronic States of the Shallow Impurities

Shallow impurities can be theoretically treated using the effective mass approximation and the hydrogen atom model. Consider the case of the donor (the acceptor can also be considered similarly). The excess electron moves in an orbit round the impurity ion due to the Coulomb interaction between them in the host crystal, just like the hydrogen atom. The Coulomb potential is much smaller than that in the hydrogen atom due to the screening effect of the valence electrons (the change of the valence electron distributions around the impurity ion) in the crystal lattice. The screened Coulomb potential is written as $U = Zq^2/\varepsilon_s r$, where Z is the valence number of the impurity ion, q the electronic charge, ε_s the dielectric constant of the host semiconductor and, r is the distance between the electron and impurity ion. The screening effect is effectively represented by the dielectric constant ε_s. Thus, the electron is very loosely bound by the impurity ion (very low binding energy) and its wave function extends in the wide range of the crystal lattice. Hence, the electron moves feeling both the periodic potential of the host crystal and the screened Coulomb potential. The effect of the periodic potential on the motion of electrons is well described in terms of the "effective mass" m^*, that is, electrons in the periodic potential of crystal behave as if they are free electrons with their mass m^* being different from that (m_0) in a vacuum. Therefore, the electrons in the orbital round the shallow impurity ions can be considered as electrons with an effective mass m^* moving in the screened Coulomb potential U. The fundamental Schrödinger equation for these electrons is written as follows:

$$\left[\left(\frac{\hbar}{2m_0}\right)\nabla^2 + (V - U)\right]\Psi(\boldsymbol{r}) = E\Psi(\boldsymbol{r})$$

Here, $\nabla^2 = (\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2)$ is an operator, $\Psi(\boldsymbol{r})$ the wave function of the electron, $\boldsymbol{r} = \boldsymbol{r}(x, y, z)$ the position vector of the electron, V and U the periodic potential in the perfect crystal and the screened Coulomb potential, respectively, and E is the energy of the electron. In the case of $U = 0$ (perfect crystal), the solution of the above equation is given by the Bloch wave function $\Psi n\boldsymbol{k}(\boldsymbol{r}) = \exp(\mathrm{i}\boldsymbol{k}\boldsymbol{r})u_{n\boldsymbol{k}}(\boldsymbol{r})$, where $\exp(\mathrm{i}\boldsymbol{k}\boldsymbol{r})$ is the wave function of the free electron (plane wave) extending to the whole crystal, and $u_{n\boldsymbol{k}}(\boldsymbol{r})$ is the function having the periodicity of the crystal lattice with n and $\boldsymbol{k}$ being the quantum number specifying the energy bands and the wave number vector, respectively. For applying the effective mass approximation to the shallow

impurity problem, the wave function $\Psi(\boldsymbol{r})$ is expanded by the Bloch functions or their Fourier transforms (the Wannier functions) and substituted in the equation. Thus, the following equation is obtained:

$$\left[\frac{\hbar}{2m^*}\nabla^2 - U\right]\Phi(\boldsymbol{r}) = E\Phi(\boldsymbol{r})$$

This equation is the same as that for the hydrogen atom except for the difference in the electron mass. The wave functions of the electrons are given as the product of $\Phi(\boldsymbol{r})$ and the function which has the periodicity of the crystal lattice. The above equation is for the case of the isotropic conduction band (in which the effective mass is the same for all crystal orientations). For example, some compound semiconductors such as GaAs and InP have this type of conduction bands. On the other hand, the conduction bands are anisotropic in semiconductors such as Si, Ge, and GaP, that is, the effective mass is different in different crystal orientations. The valence bands of most semiconductors have degeneracy in which the energies of the "heavy" holes and the "light" holes coincide at the top of the band. For these cases, the above equation should be modified to take the anisotropy or degeneracy of the band structures into consideration. The details of the same are not discussed here.

The solution of the above equation is well known for the "hydrogen atom." The electronic states of the hydrogen atom are specified by the principal (Bohr) quantum number n, the angular momentum quantum number l, the magnetic quantum number m, and the spin quantum number s. The principal quantum number n is the positive integer and the angular momentum quantum number $l \leqslant n-1$ for each n value. The magnetic quantum number m is given as $m = l, l-1, l-2, 0, \ldots, -l-1, -l (l \geqslant m \geqslant -l)$ and the spin quantum number $s = \pm 1/2$. The electronic states corresponding to $l = 0$, 1, and 2 are called s, p, and d states, respectively. Then the state of $n = 1$ and $l = 0$ is called as the 1s state (the ground state: the state of the lowest energy). The higher energy states (the excited states) are thus called as 2s ($n = 2$, $l = 0$), 2p($n = 2$, $l = 1$), 3s($n = 3$, $l = 0$), 3p($n = 3$, $l = 1$), 3d($n = 3$, $l = 2$) states and so on. The energies E_n of these states obtained from the above equation are given as

$$E_n = -E_0/n^2 \quad (n = 1, 2, 3, \ldots)$$
$$E_0 = (\varepsilon_0/\varepsilon_s)^2 (m^*/m_0) E_H$$

Here E_0 is the energy of the ground (1s) state and, ε_0 and ε_s are the dielectric constants of the vacuum and semiconductor respectively. E_H is given as

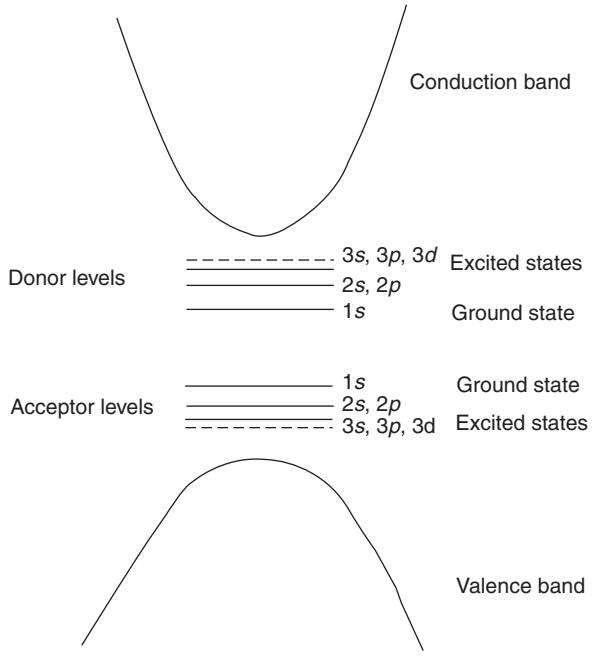

Figure 1 Shallow impurity level scheme in the wave number (k) space.

$E_H = (1/\varepsilon_0)^2 (q^4 m_0/2\hbar^2) = 13.6$ eV and is the ground-state energy of the real hydrogen atom (the Rydberg constant). From the above equations, it is obvious that the energy E_n is only dependent on the principal quantum number n (degenerate with respect to the other quantum numbers l, m, and s) in the case of the isotropic conduction band. For the donor and acceptor, respectively, the ionization energies (the binding energies) E_D and E_A from the ground state can be calculated as $E_D = E_C - E_0$ and $E_A = E_V - E_0$, where E_C and E_V are, respectively, the energies of the bottom of the conduction band and the top of the valence band. In **Figure 1**, the shallow impurity levels are schematically shown.

The wave function is $\Phi_{1s}(r)$ of the ground state is written in the following:

$$\Phi_{1s}(r) = (1/\pi)^{1/2} (1/a^*)^{3/2} \exp(-r/a^*)$$

Here, it is assumed that $Z = 1$. a^* is the Bohr radius given as $a^* = (\varepsilon_0 m^*)(\hbar^2/m_0 q^2)$ and represents the extent of the electronic wave function in the real crystal space. The wave function exhibits a sharp decrease at $r \gg a^*$. The wave functions of some excited states are as follows:

$$\Phi_{2s}(r) = (1/\pi)^{1/2} (1/2a^*)^{3/2} [2 - (r/a^*)] \exp(-r/2a^*)$$

$$\Phi_{2p}(r) = (1/\pi)^{1/2} (1/2a^*)^{3/2} (r/\sqrt{3}) \exp(-r/2a^*)$$

In these excited states, the electron wave functions show a strong decay as

$$r \gg 2a^*$$

Experimental Determination of the Shallow Energy Levels

The energy levels of shallow impurities can be determined accurately using the infrared absorption measurements at very low temperatures. It is well known that electrons bound to a hydrogen atom can be excited to higher energy levels by the absorption of light. Similarly, electrons captured by shallow impurity levels are transferred to higher energy levels by absorbing infrared light. These optical transitions are allowed only when the difference (Δl) in the angular momentum quantum numbers (l) between two related energy levels is 1 ($\Delta l = 1$) (the selection rule). Thus the electrons can be excited from the $1s$ (ground) state to the $2p$, $3p$, $4p$, … (excited) states. However, the transitions $1s \rightarrow 2s$, $1s \rightarrow 3s$, … (and so on) are not allowed. The absorption peaks of the infrared light are very sharp because these energy levels are completely discrete. By measuring the infrared absorption spectrum at very low temperature (~ 4.2 K), one can accurately determine the energies between the ground state and many excited states. The excited levels with very large principal quantum numbers n are located very close to the conduction or valence band edge so that one can determine the ground-state ($1s$) level and any excited ($2p$, $3p$, …) levels measured from the band edge (ionization energies). In **Table 1**, some examples of the measured shallow donor and acceptor levels (ionization energies) in Si are shown together with the calculated ones. The agreement between the measured and calculated values is excellent.

Table 1 Some examples of the ionization energies of the ground states of shallow donors and acceptors

Theory of the Electronic States of the Deep Impurities (or Defects)

For the deep impurities, electrons (or holes) are very tightly bound to the impurity atom nucleus due to the highly localized core potential. The motion of the bound electrons (or holes) is strongly affected by this core potential and the wave functions of these carriers are also highly localized around the impurity atoms (or defect centers). Therefore, both the effective mass approximation and the hydrogen atom model cannot be applied to the deep level cases. The tight binding approximations, such as the linear combination of atomic orbitals (LCAO) method, are suitable to treat the deep-level problem. Since the core potentials are not small, the conventional perturbation theory is not applicable and the Green-function approach is useful to solve the fundamental Schrödinger equation. The Schrödinger equation describing the motion of the electron bound to the deep impurity is given as follows:

$$(H_0 + U)\Psi(\boldsymbol{r}) = E\Psi(\boldsymbol{r})$$

Here, H_0 is the Hamiltonian operator for the perfect crystal and U is the localized potential due to the deep impurity atom. In order to solve the above equation, the impurity potential U needs to be determined. However, this is very difficult for the following reason. In many cases of deep impurities, the impurity atoms are slightly displaced from the lattice point of the host semiconductor, and a microstrain is induced around the impurity atoms. It is assumed that if the impurity atom occupies the lattice point (as is the case for shallow impurities), a shallow energy level of E_D is generated. When this impurity atom is somewhat displaced from the lattice point (the lattice relaxation occurs), a deep energy level E_0 is assumed to be created. Also, a lattice relaxation energy (strain energy) E_L occurs. If $E_0 + E_L$ is higher than E_D, it is energetically stable to form the deep level with a small displacement of the impurity atom from the lattice point rather than the shallow levels. If the mixed semiconductor crystal AlGaAs is doped with Si, a deep-level center (called the DX center) is created while Si atoms act as shallow donors in GaAs. This DX center is considered to be as the above stated case. In order to determine the impurity potential U, the effect of the lattice relaxation should be taken into account exactly, which, however, is a very difficult problem. Many calculations have been performed by assuming various forms of the impurity potential U. The wave function $\Psi(r)$ is expanded in terms of the sp^3 atomic orbital functions (Φ_j) as $\Psi = \sum_j a_j \Phi_j$ (LCAO). Then the Schrödinger equation is

solved using the Green-function approach under the various assumptions of the impurity potentials. However, quantitative comparisons between the calculated and observed energy levels are difficult because of the difficulty in including the lattice relaxation effect in the analysis.

There are some cases of deep levels, in which the energy level merges into the conduction or the valence band of the host semiconductor. This level is called the resonant level. The existence of this level affects the band structure of the host crystal because the density of states of the impurities are superposed to those of the conduction or the valence band. With doping of the isoelectronic impurities, this resonant level is often observed. These resonant energy levels can also be calculated using the above Green-function approach.

Experimental Determination of the Deep Energy Levels

The deep level transient spectroscopy (DLTS) is the most powerful tool to determine deep energy levels. This method is based on the measurements of the transient electrical capacitances of the metal–semiconductor (Schottky) contact as the pulsed reverse bias voltage is applied. The transient Schottky capacitance $C(t)$ is written as follows.

$$C(t) = C_\infty \left[1 - \left(\frac{N}{2}\right)\exp\left(\frac{-t}{T}\right)\right]$$

Here $N = N_T/(N_D + N_T)$, N_T and N_D are the density of the deep impurity and the shallow donor, respectively. $C_\infty = \{[(\varepsilon_s\varepsilon_0/2)(V + V_D)]\ (N_D - N_T)\}^{1/2}$, ε_s and ε_0 are the dielectric constant of the semiconductor and a vacuum, respectively, and V_D is the diffusion potential of the Schottky contact. The relaxation time τ can be written as $e_n = 1/\tau$, where e_n is the electron (or hole) emission coefficient of the deep impurity and given as $e_n \propto C_n \exp[-(E_C - E_T/kT)]$ because electrons (and holes) are emitted from the deep levels by thermal activation. Here, C_n is the capture cross section of the deep impurity, E_T and E_C are the deep impurity energy level and the bottom of the conduction band, respectively. T and k are the absolute temperature and the Boltzmann constant, respectively. If the transient capacitance $C(t)$ is measured as a function of temperature T, the temperature dependence of e_n is obtained. From the plot of $\ln e_n$ versus $1/T$ (the Arrhenius plot), the deep energy level E_T can be easily determined. The capture cross section C_n and the deep impurity density N_T are at the same time determined. The famous example of the deep level is the EL2 center observed in the semi-insulating GaAs single crystal which is the cause of the high resistivity. The ionization energy of this EL2 center was measured to be $0.7 \sim 0.8$ eV (located near the middle of the bandgap of GaAs).

Introduction

An insulator is distinguished from a metal by its vanishing DC conductivity at low temperature. In contrast to what happens in metals, the electronic charge in insulators and semiconductors (and quite generally nonmetals) cannot flow freely under an applied DC field, but instead undergoes static polarization. Within classical physics, this qualitative difference is attributed to the nature of the electronic charge: either "bound" (Lorentz model for insulators) or "free" (Drude model for metals). In other words, electrons are localized in insulators and delocalized in metals. Switching to quantum physics, this clear-cut distinction is apparently lost. In most textbooks, the insulating/metallic behavior is explained by means of the band structure theory, focusing on the position of

the Fermi level of the given material: either in a bandgap (insulators), or across a band (metals). The one-electron approximation is the main paradigm of the band theory in solids. It consists of an electron assumed to be acted on by the field of the fixed atomic cores plus an average field arising from the charge distribution of all the other outer-shell electrons.

The one-electron model for solids is generally quite adequate as confirmed by several experiments on a wide variety of materials showing a good agreement with theory. This is particularly true in semiconductors and insulators when investigated by optical experiments. These experiments provide ample evidence for direct and indirect gaps, as well as for excitonic states.

This article addresses some basic features of insulators and semiconductors from the perspective of the optical and infrared properties. The article is organized as follows: starting with a broad introduction of the characteristic features of semiconductors and insulators, a few general concepts of the electronic band structure, such as the single-particle gap and the interband transitions, are addressed. The phenomenological Lorentz model is emphasized, which is a useful tool in order to describe the relevant energy scales and absorptions in semiconductors, such as the already mentioned gap and electronic transitions in general as well as the phonon modes and the impurity/defect states. In fact, optical studies can also shed light on the role of doping in semiconductors. The second part of this article then discusses, as an example, a prototype semiconducting/insulating material, focusing the attention on its experimental optical response. An outlook to some challenging issues in the present basic research of semiconductors and insulators concludes this article.

Electronic Interband Transitions: A Few Concepts

From a microscopic point of view, one can state that the excitation of one electron from the valence band (v) to the conduction band (c) (**Figure 1**) leads to an extra electron with momentum $\boldsymbol{k}_1$ in the conduction band, leaving a hole with momentum $\boldsymbol{k}_2$ in the valence band. In a crystal, momentum conservation requires that

$$\boldsymbol{k}_1 = \boldsymbol{k}_2 + \boldsymbol{K} \qquad [1]$$

where $\boldsymbol{K}$ is the reciprocal lattice vector. Neglecting Umklapp process, the so-called vertical direct transitions occur for $\boldsymbol{k}_1 = \boldsymbol{k}_2 = \boldsymbol{k}_0$ such that the excitation energy $\hbar\omega_0$ satisfies the relation:

$$\hbar\omega_0 = \varepsilon_c(\boldsymbol{k}_0) - \varepsilon_v(\boldsymbol{k}_0) \qquad [2]$$

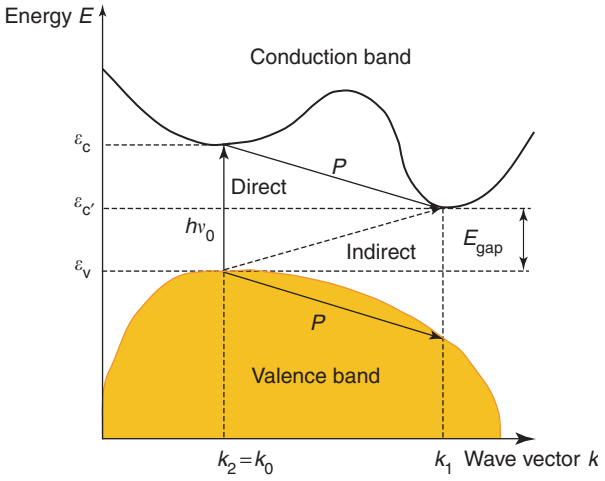

Figure 1 Transitions between occupied (valence) and unoccupied (conduction) bands in an insulating material. A direct transition at $\boldsymbol{k}_0$ and an indirect (phonon assisted) one between $\boldsymbol{k}_2$ and $\boldsymbol{k}_1$ are shown. $\boldsymbol{P}$ stays for the phonon momentum. The direct transition occurs at $\hbar\omega_0 = \varepsilon_c - \varepsilon_v$, while the indirect excitation occurs at $E_{gap} = \varepsilon'_c - \varepsilon_v$.

due to the energy conservation (**Figure 1**). The optical response is fully described by the complex dielectric function ($\tilde{\varepsilon}(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$). For direct interband transitions, it can be shown that the imaginary part ε_2 of $\tilde{\varepsilon}(\omega)$, describing the absorption spectrum, is given by

$$\varepsilon_2(\omega) = 8\left(\frac{\pi e}{m\omega}\right)^2 |p_{cv}|^2 J_{cv} \qquad [3]$$

where p_{cv} is the electric dipole transition matrix element and

$$J_{cv} = \frac{1}{8\pi^3}\int_S \frac{dS}{|\nabla_k \varepsilon_{cv}|_{\varepsilon_{cv}=h\nu}} \qquad [4]$$

is the so-called combined or joint density of states. J_{cv} accounts for both available initial and final states involved in the electronic interband transition, and can be extracted from the electronic band structure. The integral is over a surface S of $\boldsymbol{k}$ vectors for which $\varepsilon_{cv} = \varepsilon_c - \varepsilon_v = \hbar\omega$. The critical points, where

$$\nabla_k \varepsilon_{cv} = \nabla_k [\varepsilon_c(k) - \varepsilon_v(k)] = 0 \qquad [5]$$

are called van Hove singularities in the joint density of states, which usually coincide with excitations at high symmetry points in the electronic band structure. This is the case for photon energies $\hbar\omega_0$ for which the two energy bands separated by $\varepsilon_{cv} = \hbar\omega_0$ are parallel at a particular $\boldsymbol{k}$ vector. At those k-points, van Hove singularities lead to peculiar absorption peaks and band edge features in the excitation spectrum and consequently determine the prominent

structures in the imaginary part ε_2 (eqn [3]) of the dielectric function, thus of the absorption coefficient.

In a large number of semiconductors, the energy maxima in the valence and minima in the conduction band do not occur for the same momentum $\boldsymbol{k}_0$, but for different momenta $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$ (**Figure 1**). Optical direct transitions between these states cannot take place due to momentum conservation; however, such transitions become possible when the excitation of phonons is involved. For instance, one scenario involves the creation of a photon for wave vector $\boldsymbol{k}_2$ and the subsequent phonon emission, which absorbs the energy and momentum, necessary to reach the conduction band at momentum $\boldsymbol{k}_1$ (**Figure 1**):

$$\boldsymbol{k}_1 = \boldsymbol{k}_2 + \boldsymbol{P} \qquad [6]$$

with $\boldsymbol{P}$ the wave vector of the phonon involved. These processes are known as indirect (phonon assisted) transitions. An opposite process can also contribute to the absorption spectrum (**Figure 1**). Such indirect transitions have several distinct characteristics when compared with direct transitions. For instance, the absorption increases with frequency as the square of the energy difference:

$$\varepsilon_2(\omega) \sim N_{\mathrm{P}}(E_{\mathrm{gap}} - \varepsilon_{\mathrm{P}} \pm \hbar\omega)^2 \qquad [7]$$

(with ε_{P} the phonon energy and N_{P} the phonon occupation number) instead of the square root dependence for direct transitions near the band edge (E_{gap} represents here the direct gap):

$$\varepsilon_2(\omega) \sim (\hbar\omega - E_{\mathrm{gap}})^{1/2} \qquad [8]$$

obviously with $\hbar\omega > E_{\mathrm{gap}} \pm \varepsilon_{\mathrm{P}}$ (eqn [7]) or $\hbar\omega > E_{\mathrm{gap}}$ (eqn [8]). Second, the indirect absorption is strongly temperature dependent, reflecting the phonon population factor (N_{P}). These differences make the distinction between direct and indirect optical transitions in analyzing measured spectra relatively straightforward.

The smallest possible energy for which an electronic transition occurs defines the insulating or semiconducting single-particle bandgap E_{gap} (**Figure 1**). Insulators can be then classified as direct or indirect gap materials depending on whether the interband transition at E_{gap} occurs at $\boldsymbol{k}_0$ or between $\boldsymbol{k}_2$ and $\boldsymbol{k}_1$ (**Figure 1**), respectively. **Table 1** gives a few examples of band semiconductors, with their direct or indirect gap values. The single-particle bandgap is therefore the central feature in insulators or semiconductors. At $T = 0$ the valence band is full, whereas the conduction band is empty (**Figure 1**), so that the Fermi level lies between these bands. A zero DC conductivity follows at $T = 0$.

Table 1 Energy gap (E_{gap}) at 300 K of selected semiconductors

Material	E_{gap} (eV)	*Gap*
Si	1.12	i
Ge	0.67	i
InSb	0.16	d
GaAs	1.4	d
GaP	2.2	d
C (diamond)	5.5	i

"i" indicates an indirect gap and "d" a direct one.

The Phenomenological Lorentz Model

The simplest and general situation that mimics the transition between different bands corresponds to the electronic direct transition between a ground state (valence band) and excited states (conduction band) of identical atoms. The excitation induced by the electromagnetic fields can be treated using the time-dependent Schrödinger equation. In a perfect crystal, the total crystal potential felt by the electrons has the periodicity of the crystal lattice and the solutions of the Schrödinger equation are the well-known Bloch functions. Thorough descriptions of this approach, finally leading to an explicit form of eqn [3], can be found in the specialized literature.

In order to highlight the relevant optical fingerprints in band semiconductors or insulators, the so-called Lorentz model is employed. While phenomenological, this model catches the main features in and allows extracting several useful parameters from the optical response of semiconductors. By assuming the response of a classical harmonic oscillator, the electrons in the Lorentz model are bound to the nucleus of the atom (like a small mass bound to a large mass by a spring). Such a classical dispersion theory leads to the following expression of the complex dielectric function:

$$\tilde{\varepsilon}(\omega) = \varepsilon_1(\omega) + \mathrm{i}\varepsilon_2(\omega) = \varepsilon_\infty + \frac{\omega_{\mathrm{p}}^2}{(\omega_0^2 - \omega^2) - \mathrm{i}\Gamma\omega} \qquad [9]$$

where $\hbar\omega_0$ is the resonance energy of the bound electron, Γ is the damping and ω_{p}^2 is the oscillator strength. The analogy with the quantum mechanical treatment identifies $\hbar\omega_0$ with the energy difference between two electronic states involved in the transition (like the insulating gap) and ω_{p}^2 as a measure of the relative probability of the transition.

Figure 2 displays the real ε_1 (dispersive) and imaginary ε_2 (absorptive) part of $\tilde{\varepsilon}(\omega)$ for one single absorption, which exactly occurs at ω_0. The full width of the region of anomalous dispersion in ε_1 is Γ (see **Figure 2**). For $\Gamma \ll \omega_0$, there is little dispersion and in this limit the full width of the ε_2 curve at half

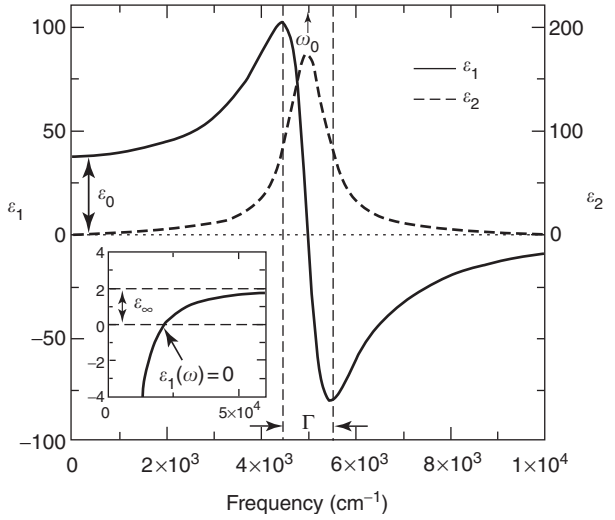

Figure 2 Real (ε_1) and imaginary (ε_2) part of the complex dielectric function calculated after the Lorentz model for one single harmonic oscillator (eqn [9]). The parameters are $\varepsilon_\infty = 2$, $\omega_0 = 5000\,\mathrm{cm}^{-1}$, $\Gamma = 1000\,\mathrm{cm}^{-1}$, and $\omega_p = 3 \times 10^4\,\mathrm{cm}^{-1}$. The static dielectric constant $\varepsilon_1(\omega \to 0) = \varepsilon_0$ (eqn [10]) is indicated. The inset is a blowup of $\varepsilon_1(\omega)$ at high frequencies, showing the zero-crossing $\varepsilon_1(\omega) = 0$ and the high-frequency limit $\varepsilon_1(\omega \to \infty) = \varepsilon_\infty$ of the real part of the dielectric function. Here and elsewhere in this article, the photon energy is expressed as frequency in a wave number (cm^{-1}) so that $1\,\mathrm{eV} = 8.065\,48 \times 10^3\,\mathrm{cm}^{-1}$.

maximum is also given by Γ. The real part ε_1 is characterized by the $\omega \to 0$ limit, the so-called static dielectric constant ε_0 (**Figure 2**):

$$\varepsilon_0 = \varepsilon_\infty + \frac{\omega_p^2}{\omega_0^2} \qquad [10]$$

and, by the $\omega \to \infty$ limit, coinciding with the optical constant ε_∞ (inset of **Figure 2**). For a material with a discrete number of Lorentz harmonic oscillators at high frequencies (representing, e.g., interband transitions), each of such oscillators will contribute to ε_0 in an additive way. Therefore, ε_∞ phenomenologically takes into account the static contribution from those high-frequency (energy) excitations.

From the well-known relations of the classical electrodynamics, one can evaluate the optical functions ($\mu = 1$):

$$\varepsilon_1 = n^2 - k^2 \qquad [11]$$

$$\varepsilon_2 = 2nk = \frac{4\pi\sigma_1}{\omega} \qquad [12]$$

where n is the refractive index, k is the absorption coefficient, and σ_1 is the real part of the optical conductivity.

From the experimental point of view, several techniques allow to reach those fundamental quantities. One way is to extract these optical functions

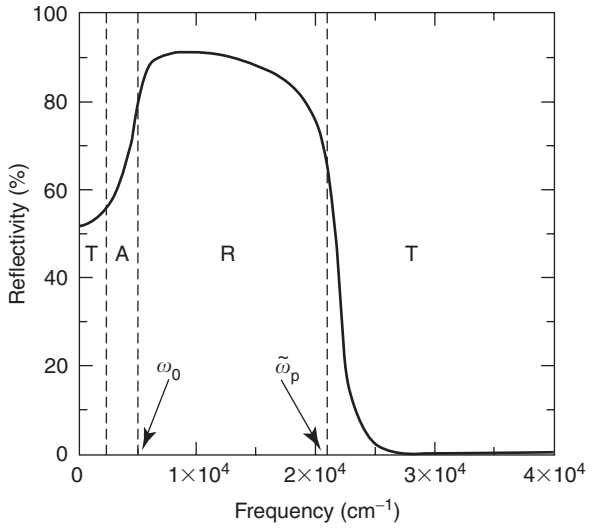

Figure 3 Optical reflectivity for an insulating material calculated with eqns [9], and [11]–[13] within the Lorentz model for one single (e.g., gap-like) excitation (same parameters as in **Figure 2**). T stands for transparent, A for absorption, and R for reflection.

from the measurement of the optical reflectivity, defined as

$$R = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2} \qquad [13]$$

When the reflectivity is known in a broad spectral range, extending over several decades in photon energy, one can perform reliable Kramers–Kronig (KK) transformations. The KK transformations are classical dispersion relation based on the causality principle, and relate the phase Θ of the complex reflectance $\tilde{r} = \sqrt{R}e^{i\Theta}$ to the measured magnitude R. When the phase Θ is known, one can then calculate all optical functions, by solving the equation

$$\sqrt{R}e^{i\Theta} = \frac{(1-\tilde{n})}{(1+\tilde{n})} \qquad [14]$$

with respect to n and k ($\tilde{n} = n + ik$) and using eqns [11] and [12].

For the purpose of illustration, **Figure 3** displays the typical shape of $R(\omega)$ for an insulator, as calculated within the Lorentz model for one single (gap) excitation after eqns [9], and [11]–[13]. Starting from zero frequency in the region for $\omega < \omega_0$, one has $\varepsilon_2 = 0$ and $\varepsilon_1 > 1$ so that $k \sim 0$ and $\varepsilon_1 = n^2$. Thus, this is a region of high transparency (T), and no absorption takes place. By further increasing the frequency, there is, on the contrary, strong absorption (A), while for $\omega > \omega_0$ the electrons of the insulators respond as if they were free electrons (R). This is because the photon energy is

much greater than the binding energy $\hbar\omega_0$ of the electron, which is ultimately excited to the continuum. Therefore, in this latter region the $R(\omega)$ spectrum looks like the one of a metal. If $\Gamma \to 0$, it follows that $R(\omega) \to 100\%$, which is also called the "Reststrahlen" or total reflection region. At frequencies of the order of $\tilde{\omega}_p \approx \omega_p/\sqrt{\varepsilon_\infty}$, there is a sharp drop of $R(\omega)$. $\tilde{\omega}_p$ also defines the frequency where the material is again transparent (T)!

In passing, it is mentioned that the metallic behavior is obtained within the Lorentz model by setting $\omega_0 = 0$ in eqn [9]. In that case $R(\omega) \to 100\%$ (total reflection) for $\omega \to 0$ and the (sharp) drop at high frequency (i.e., $\omega \sim \tilde{\omega}_p$) of **Figure 3** would then correspond to the so-called plasma edge (see "Further reading" section for more details about the optical response of a metal).

The phenomenological presentation, adopted so far, considered one single electronic excitation coinciding with the insulating gap. In general, the absorption spectrum is further characterized by other excitations, the origin of which can be rather different, depending on the spectral range where those excitations appear. At higher energies, for instance, electronic interband transitions are possible. Below the lowest possible electronic interband transition (gap), in the so-called transparent region, one can detect various types of excitations such as the phonon modes due to the lattice vibrations or collective excitations. Excitons and impurity states can represent another important contribution to the absorption spectrum of semiconductors. Excitons are brought about by the Coulomb interaction and consist of an electron–hole pair which can be mobile. It does not contribute to the DC conductivity but can be excited by the electromagnetic field. Alternatively, Coulomb interactions between an impurity potential and electrons lead to bound states localized to the impurity potential sites. In all cases, the resulting excitations can be described simply by borrowing concepts developed for the energy levels of single atoms. These excitations appear as an absorption resonance, and similarly to the electronic interband excitations, can be described with dedicated Lorentz harmonic oscillators. Therefore, one can reconstruct the whole absorption spectrum of insulators by adding as many Lorentz harmonic oscillators as needed for each excitation.

Example of an Insulating System: EuS

Figure 4 shows the reflectivity and **Figure 5** the real part $\sigma_1(\omega)$ of the optical conductivity of EuS, which is chosen as an example for a typical insulating

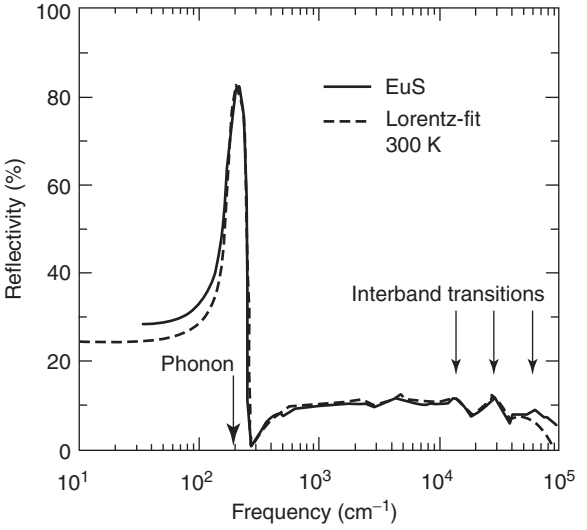

Figure 4 Optical reflectivity of EuS measured from the far infrared up to the ultraviolet (note the logarithmic energy scale). The infrared active phonon mode at 200 cm^{-1} is clearly seen. The dashed line is a Lorentz phenomenological fit (eqns [9], and [11]–[13]). The fit parameters are: $\varepsilon_\infty = 1.64$ for the optical dielectric constant, $\omega_{0ph} = 181\,\text{cm}^{-1}$, $\Gamma_{ph} = 13\,\text{cm}^{-1}$, $\omega_{p-ph} = 395\,\text{cm}^{-1}$ for the resonance frequency, damping and oscillator strength of the phonon, $\omega_{01} = 1.54 \times 10^4\,\text{cm}^{-1}$, $\Gamma_1 = 4444\,\text{cm}^{-1}$, $\omega_{p1} = 9587\,\text{cm}^{-1}$, $\omega_{02} = 3 \times 10^4\,\text{cm}^{-1}$, $\Gamma_2 = 1.2 \times 10^4\,\text{cm}^{-1}$, $\omega_{p2} = 2.24 \times 10^4\,\text{cm}^{-1}$, $\omega_{03} = 6.3 \times 10^4\,\text{cm}^{-1}$, $\Gamma_3 = 6.2 \times 10^4\,\text{cm}^{-1}$, $\omega_{p3} = 7.5 \times 10^4\,\text{cm}^{-1}$, for the resonance frequencies, dampings and oscillator strengths of the interband transitions. The frequency position for each Lorentz harmonic oscillator is indicated by arrows.

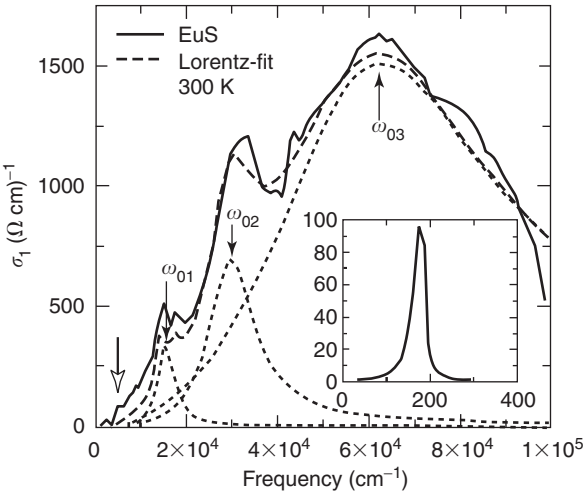

Figure 5 Real part $\sigma_1(\omega)$ of the optical conductivity of EuS obtained by KK transformation of the reflectivity $R(\omega)$ in **Figure 4**. A linear frequency scale has been used in order to emphasize the spectral range relevant for the interband transitions. The white arrow marks the onset of absorption at $\sim 5000\,\text{cm}^{-1}$. The Lorentz-fit (eqns [9] and [12]) with an appropriate number of harmonic oscillators (the single fit components are shown by dashed lines) can reproduce the interband transitions very well. The arrows identified the resonance frequencies ω_{0j} for the interband transitions within the Lorentz fit. The inset emphasizes $\sigma_1(\omega)$ in the far infrared, with the dominant phonon mode absorption. The fit parameters are the same as in **Figure 4**.

material. Eu chalcogenides have received tremendous interest from scientists all over the world. One obvious reason was the hope of using these magnetic semiconductors industrially, for example, in the form of fast, light beam addressable memory systems in computers, as magneto-optical modulators, and as magnetic-field-activated electronic switches. The hope for applications dwindled when one realized that upon doping, the magnetic-ordering temperatures could not be raised up to room temperature. However, the purely academic interest in magnetic semiconductors, especially the Eu chalcogenides, continued to be an enormous driving force, because the materials turned out to be model substances for studying magnetism. It is beyond the scope of this article to elaborate further on the interesting physics of these materials. Thus, attention is limited to the phenomenological discussion of the optical spectra, in order to illustrate the concepts developed above and also as an example for the successful application of the Lorentz model.

$R(\omega)$ (**Figure 4**) is typical for an insulator since it saturates to a constant value for $\omega \to 0$. On the one hand, one can clearly recognize the strong absorption feature at $200\,\mathrm{cm}^{-1}$ in $R(\omega)$, which is ascribed to the infrared phonon mode of the f.c.c. rocksalt structure of EuS. On the other hand, above 0.5 eV ($\sim 4000\,\mathrm{cm}^{-1}$) several absorption features can be identified. These latter absorptions can be better observed in $\sigma_1(\omega)$ (**Figure 5**). In this respect, **Figure 5** emphasizes the near infrared–ultraviolet spectral range, characterized by several peaks for the electronic interband transitions involving 4*f*, 3*p*, and 5*d* states. Of particular interest is the onset of absorption at $\sim 0.62\,\mathrm{eV}$ ($\sim 5000\,\mathrm{cm}^{-1}$) which is ascribed to the excitation between the localized $4f^7$ levels in the ^7F_J configuration and the bottom of the extended $5d(t_{2g})$ band (see white arrow in **Figure 5**).

From the phenomenological point of view, one can describe the absorptions in $\sigma_1(\omega)$ (phonon and electronic interband transitions) with *ad hoc* Lorentz harmonic oscillators. The total $\tilde{\varepsilon}(\omega)$ was obtained by adding four Lorentz harmonic oscillators (eqn [9]): one for the phonon and three for the electronic interband transitions (see parameters in the caption of **Figure 4**). **Figures 4** and **5** demonstrate the great fit quality achieved for both $R(\omega)$ and $\sigma_1(\omega)$ within the Lorentz model. The extracted parameters can then be used in order to achieve information about the intrinsic physical properties of the investigated material and can be compared with other measured quantities. For instance, the excitation energy $\hbar\omega_{0j}$ (**Figure 5**) can be compared with the allowed electronic interband transitions from the band structure calculations. The oscillator strengths ω_{pj} can be related to the transition probability and the excitation selection rules.

Insulators and Semiconductors: Topics of Interest

It should noted be that the picture considered so far for insulators applies only to a crystalline material (**Table 1**), within the independent-electron approximation. This is a very limited class of insulators indeed. In some materials, the insulating behavior is dominated by disorder (Anderson insulators), in some it is dominated by electron correlation (Mott insulators). Therefore, the band picture is grossly inadequate for a large number of insulators. To conclude this chapter, some aspects and topics are mentioned briefly, partially being still matter of debate and unsettled issues, which are of interest in semiconductors and/or insulators research. The interest from the perspective of the optical properties is particularly emphasized.

The dimensionality of the electronic structure plays an essential role in shaping the properties of solids. It is well known that metallic materials with linear-chain-like structure are characterized by a quasi-one-dimensional electronic structure and are therefore unstable. This favors a so-called nesting of the Fermi surface, which leads through a metal–insulator phase transition to a broken symmetry ground state, known as charge (**Table 2**) or spin density wave state, depending on whether the electron–phonon or the electron–electron interaction dominates. These phase transitions induce the opening of an insulating gap in the excitation spectrum, which can be detected optically.

Optical properties also reveal essential information on the nature of the phase transition and the related ground state. Indeed, the leading role played by the correlation effects in driving the phase transitions can be directly studied by analyzing the frequency dependence of the optical conductivity. For a one-dimensional band insulator, it is expected that

Table 2 Transition temparature T_c and single-particle energy gap E_{gap}, obtained from the DC resistivity, for some linear chain compunds with CDW ground state

Material	T_c(K)	E_{gap} (K)
KCP	189	1400
$K_{0.3}MoO_3$	183	920
TaS_3	215	1600
$NbSe_3$	145 and 60	700
$(TaSe_4)_2I$	263	3000

the optical conductivity will display a sharp singularity at the gap edge and will decay after the expression $\sigma_1(\omega) \sim (\omega - E_{gap})^{-1/2}$. Toward high frequencies, the decay is expected to follow the powerlaw $\sigma_1(\omega) \sim \omega^{-3}$ if the lattice is assumed to be rigid and only Umklapp scattering or of the single-period lattice potential is possible, or as $\sigma_1(\omega) \sim \omega^{-2}$ when coupling to phonons is included. A strongly frequency-dependent optical conductivity has indeed been found in several one-dimensional or nearly one-dimensional semiconductors, such as $K_2[Pt(CN)_4]Br_{0.3}3H_2O$ (better known as KCP) and $(NbSe_4)_3I$. For the latter material, a stronger dependence ($\sigma_1(\omega) \sim \omega^{-4.25}$, instead of ω^{-3}) was found, presumably due to the narrow band, with the bandwidth comparable to the optical frequencies where the measurements were made.

Electron–electron interactions may modify this picture further. Such interactions lead, in strictly one dimension, to an electron gas which is distinctively different from a Fermi liquid. In not strictly but only nearly one dimension, such interactions (Umklapp scattering process) lead to a (Mott) gap, and the features predicted by theory are expected to be observed only at high photon energies. These features include a power-law dependence of the conductivity, with the exponents on ω different from -3. Experiments on highly anisotropic materials, such as the linear chain Bechgaard salt $(TMTSF)_2PF_6$, have been interpreted as evidence for such a novel, so-called Tomonaga–Luttinger liquid.

Another topic of particular importance is the study of the optical response associated with impurity states or defects in semiconductors (as in the case of phosphorus doped silicon Si : P), mainly because of industrial purposes. Extrinsic conduction associated with such impurity states is a standard issue for solid-state physics, and transport effects which depend on the impurity concentration are also well studied. For small concentrations, these impurity states are localized to the underlying lattice, but an insulator–metal transition occurs at zero temperature as the impurity concentration increases. The optical properties are very sensitive to the defect/impurity concentration, so that one can follow very precisely concentration-induced metal–insulator transitions.

This survey is far from being exhaustive. The quoted references should allow, as "Further reading," to widen the reader's perspectives on this vast topic.

Nomenclature

E_{gap}	energy gap (K or cm^{-1})
J_{cv}	joined density of states
$R(\omega)$	reflectivity
$\varepsilon(\omega)$	dielectric function
$\sigma_1(\omega)$	real part of optical conductivity ($(\Omega\,cm)^{-1}$)
ω	frequency in wave number ($1\,eV = 8.065\,48 \times 10^3\,cm^{-1}$)

Semi-Empirical and Empirical Calculations

M-H Whangbo, North Carolina State University, Raleigh, NC, USA

Introduction

In understanding the relationships between crystal structures and physical properties of solid-state materials, it is essential to know their electronic structures. Electronic structure calculations can be carried out either at first principles or at semi-empirical levels. What level of calculations is appropriate for a system under investigation depends on what kind of answers one seeks from calculations. For quantitative predictions, there is no substitute for first-principles electronic structure calculations. For the purpose of understanding qualitative trends, however, semi-empirical electronic structure calculations can be sufficient and expedient.

Electronic structure calculations for a many-electron system lead eventually to an effective one-electron Hamiltonian H^{eff} and its matrix representation. To construct this Hamiltonian, one needs the one-electron wave functions to be determined as eigenfunctions of H^{eff}. As a consequence, it is necessary to construct H^{eff} in terms of trial one-electron wave functions and improve H^{eff} using its eigenfunctions iteratively until a self-consistent-field (SCF) convergence is achieved. In calculating the matrix representation of H^{eff}, first-principles electronic structure calculations execute SCF adjustments of H^{eff} without simplifying approximations, while semi-empirical calculations introduce such approximations. Semi-empirical methods are divided into two groups, that is, one that requires SCF adjustments of H^{eff} and the other that does not.

The crudest, but the most useful and versatile, semi-empirical method of electronic structure calculations is the extended Hückel tight-binding (EHTB) method. This method does not take electron–electron repulsion into consideration, so that it does not require any SCF adjustment of H^{eff}. Despite this simplicity, the EHTB method has been indispensable in uncovering structure–property relationships in all kinds of materials, from molecules to solids, from organic to inorganic compounds. The EHTB method is also indispensable in understanding the trends in spin exchange interactions and magnetic structures of various magnetic solids, although these properties are a manifestation of electron correlation that is neglected in the EHTB method. This article examines the essential features of the EHTB method and discusses why this crude method can be used to describe the electronic structures of not only metallic but also magnetic insulating solids.

Extended Hückel Tight-Binding Method

For a discrete molecule with a set of valence atomic orbitals $\{\chi_1, \chi_2, \chi_3, \ldots, \chi_m\}$, the molecular orbitals ψ_i $(i = 1,2, \ldots, m)$ are expressed as linear combinations of these atomic orbitals:

$$\psi_i = \sum_{\mu=1}^{m} C_{\mu i}\chi_\mu$$

The molecular orbitals ψ_i are the eigenfunctions of the effective one-electron Hamiltonian H^{eff}:

$$H^{\text{eff}}\psi_i = \mathrm{e}_i\psi_i$$

In the EHTB method, the explicit form of H^{eff} is not specified but its matrix representation $H_{\mu\nu} = \langle \chi_\mu | H^{\text{eff}} | \chi_\nu \rangle$, in atomic orbital basis, is defined semi-empirically. The diagonal element $H_{\mu\mu}$ is approximated by the valence state ionization potential (VSIP) of the atomic orbital χ_μ, that is, $H_{\mu\mu} = -\text{VSIP}$. The off-diagonal elements $H_{\mu\nu}$ $(\mu \neq \nu)$ are approximated by the Wolfsberg–Helmholz formula, $H_{\mu\nu} = KS_{\mu\nu}(H_{\mu\mu} + H_{\nu\nu})/2$, where $S_{\mu\nu}$ is the overlap integral $S_{\mu\nu} = \langle \chi_\mu | \chi_\nu \rangle$ and $K = 1.75$. In the weighted Wolfsberg–Helmholz approximation, the coefficient K is replaced with another coefficient K', which is given by $K' = K + \Delta^2 + \Delta^4(1 - K)$, where $\Delta = (H_{\mu\mu} - H_{\nu\nu})/(H_{\mu\mu} + H_{\nu\nu})$. The weighted Wolfsberg–Helmholz approximation is used to reduce the extent of counter-intuitive orbital mixing. The energies e_i and the atomic orbital coefficients $C_{\mu i}$ of the molecular orbitals ψ_i are obtained by solving the set of simultaneous equations:

$$\sum_{\mu=1}^{m} (H_{\mu i} - \mathrm{e}_i S_{\mu i})C_{\mu i} = 0, \quad i = 1, 2, \ldots, m$$

To calculate the electronic structure of an extended solid having a set of valence atomic orbitals $\{\chi_1, \chi_2, \chi_3, \ldots, \chi_m\}$ per unit cell, it is necessary to define the corresponding set of Bloch orbitals $\{b_1(\boldsymbol{k}), b_2(\boldsymbol{k}), b_3(\boldsymbol{k}), \ldots, b_m(\boldsymbol{k})\}$ for any given wave vector point $\boldsymbol{k}$:

$$b_\mu(\boldsymbol{k}) = \frac{1}{\sqrt{N}} \sum_{\boldsymbol{R}} \exp(\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{R})\chi_\mu(\boldsymbol{r} - \boldsymbol{R}), \quad \mu = 1, 2, \ldots, m$$

where N is the number of unit cells in the magnetic solid, $\boldsymbol{R}$ is the lattice vector, and $\chi_\mu(\boldsymbol{r} - \boldsymbol{R})$ is the atomic orbital χ_μ located at the lattice vector $\boldsymbol{R}$. Then,

the crystal orbitals $\psi_i(\boldsymbol{k})$ of an extended solid are written as linear combinations of the Bloch orbitals:

$$\psi_i(\boldsymbol{k}) = \sum_{\mu=1}^{m} C_{\mu i}(\boldsymbol{k}) b_\mu(\boldsymbol{k})$$

The crystal orbitals $\psi_i(\boldsymbol{k})$ are the eigenfunctions of the effective one-electron Hamiltonian H^{eff}: $H^{\text{eff}}\psi_i(\boldsymbol{k}) = \mathrm{e}_i(\boldsymbol{k})\psi_i(\boldsymbol{k})$ Once the matrix elements $H_{\mu\nu}(\boldsymbol{k}) = \langle b_\mu(\boldsymbol{k})|H^{eff}|b_\nu(\boldsymbol{k})\rangle$ and $S_{\mu\nu}(\boldsymbol{k}) = \langle b_\mu(\boldsymbol{k})|b_\nu(\boldsymbol{k})\rangle$, in Bloch orbital basis, are determined using the EHTB approximation, the energies $\mathrm{e}_i(\boldsymbol{k})$ and the Bloch orbital coefficients $C_{\mu i}(\boldsymbol{K})$ of the crystal orbitals $\psi_i(\boldsymbol{k})$ are calculated by solving the set of simultaneous equations:

$$\sum_{\mu=1}^{m}(H_{\mu i}(\boldsymbol{k}) - \mathrm{e}_i(\boldsymbol{k})S_{\mu i}(\boldsymbol{k}))C_{\mu i}(\boldsymbol{k}) = 0, \quad i = 1, 2, \ldots, m$$

To fully specify the electronic structure of a given solid, one needs to solve the above equation for a set of $\boldsymbol{k}$ points lying in the first Brillouin zone (FBZ), which gives rise to energy bands.

Atomic Orbital Parameters

In EHTB calculations, the valence atomic orbitals χ_u are approximated by Slater-type orbitals (STOs). A single-zeta (SZ) STO, χ_μ, is defined by

$$\chi_\mu \propto \boldsymbol{r}^{n-1}\exp(-\zeta \boldsymbol{r})Y(\theta, \phi)$$

where n is the principal quantum number, ζ is the exponent, and $Y(\theta, \phi)$ is the spherical harmonics. In a double-zeta (DZ) STO, a linear combination of two exponential functions is used:

$$\chi_\mu \propto \boldsymbol{r}^{n-1}[c_1\exp(-\zeta_1 \boldsymbol{r}) + c_2\exp(-\zeta_2 \boldsymbol{r})]Y(\theta, \phi)$$

Thus, the semi-empirical parameters of EHTB calculations are the ζ values for SZ STOs, the ζ_1, ζ_2, c_1, and c_2 values for DZ STOs, and the VSIP values of the valence atomic orbitals. These values can be taken from results of atomic electronic structure calculations using the Hartree–Fock method.

In general, results of EHTB calculations depend more sensitively on the exponents of STOs than on their VSIPs. For compounds consisting of transition metal elements M and main group elements L, it was customary to represent the *d*-orbitals of M by DZ STOs, the *s*/*p* orbitals of M by SZ STOs, and the *s*/*p* orbitals of L by SZ STOs (hereafter referred to as DZ/SZ calculations). However, a better agreement with experiment and with first-principles electronic structure calculations is achieved with EHTB calculations in which the *s*/*p* orbitals of main group elements L are also represented by DZ STOs (hereafter referred to as DZ/DZ calculations), regardless of whether a system under consideration is metallic or magnetic insulating. For conducting salts of organic donor molecules, which consist of only main group elements, use of DZ STOs for the main group elements also provides a better description of their electronic structures than does that of SZ STOs.

Metallic versus Magnetic Insulating States of Extended Solids

A metallic compound has one or more partially filled bands. For example, consider a one-dimensional (1D) chain with one electron and orbital per site (**Figure 1a**), which has a half-filled band. In the metallic state, the levels of the half-filled band below the Fermi level are each doubly filled while those above the Fermi level are each empty as shown in **Figure 1b**. Thus, the wave vectors of the FBZ are divided into two sets, those leading to the filled band levels and those leading to the empty levels. The boundary surface between these two sets of wave vectors are known as the Fermi surface. The transport properties of a metal are mainly governed by the

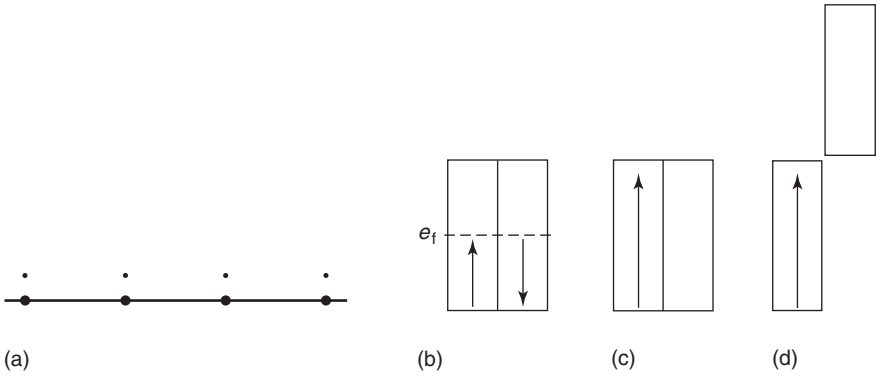

Figure 1 Metallic and magnetic insulating states of a 1D chain with one electron and one orbital per site: (a) schematic representation of a 1D chain; (b) metallic state; (c) magnetic insulating state in non-spin-polarized representation; and (d) magnetic insulating state in spin-polarized representation.

electrons around the Fermi level and hence around the Fermi surface. The charge density wave instability of a low-dimensional metal, which is analogous to the Jahn–Teller instability of a discrete molecular system, is likely to occur when its Fermi surface is nested.

A magnetic insulating state also possesses one or more partially filled bands. For example, in the magnetic insulating state of a half-filled band system, all the band levels are each singly occupied as shown in **Figure 1c**. From the viewpoint of spin-polarized representation, the latter is equivalent to filling all the up-spin band levels singly filled while leaving all the down-spin band levels unoccupied. In spin-polarized electronic band structure calculations for this formally ferromagnetic insulating state, the up-spin and down-spin bands become split in energy (**Figure 1d**). The metallic and magnetic insulating states are similar in that they possess one or more partially filled bands, but they differ in the way the band levels are occupied. Given the bandwidth of the 1D chain as W and the on-site repulsion as U, the metallic state is more stable than the magnetic insulating state if $W > U$, while the reverse is true if $W < U$.

Strengths, Weaknesses, and Utility

EHTB calculations cannot be used to predict either the optimum structure of a system or the relative energies of a system with different electron configurations. For systems of known geometry, however, EHTB calculations provide invaluable information about their electronic properties. In EHTB calculations, the total energy of a system is given by the sum of its occupied orbital energies. Thus, EHTB calculations predict that a solid with a partially filled band is always metallic, in disagreement with experiment. If EHTB calculations give a narrow partially filled band for a solid, one should expect that the solid might be a magnetic insulator rather than a metal. Similarly, for a molecule with two electrons to fill its HOMO and LUMO, EHTB calculations predict that the closed-shell singlet state is always more stable than the triplet state, in disagreement with experiment. When EHTB calculations give a small HOMO–LUMO gap for a molecule, one should expect that the ground state of the molecule might be a triplet state (see below).

Results of EHTB calculations do not depend on the number of electrons in a system, because electron–electron repulsion is not included in the EHTB method. This apparent shortcoming provides several advantages that no first-principles theory can ever match:

1. The "frontier" bands (i.e., the highest-occupied and lowest-unoccupied bands) of a complex system can be well approximated by that of its appropriate fragment. For instance, in an organic conducting salt (BEDT-TTF)$_2$X with mononegative anion X^- (BEDT-TTF–bis(ethylenedithio)tetrathiafulvalene), layers of the (BEDT-TTF)$_2^+$ cations alternate with layers of the X^- anions (**Figure 2**). The frontier bands of (BEDT-TTF)$_2$X are associated with the cation layers so that the electronic structure of a (BEDT-TTF)$_2$X salt is well approximated by that of an isolated cation layer. Similarly, in the monophosphate tungsten bronze, $(PO_2)_4(WO_3)_8$, the corner-sharing WO_6 octahedral layers are separated by PO_4 tetrahedra (**Figure 3**). The frontier bands of $(PO_2)_4(WO_3)_8$ are associated with the WO_6 octahedral layers so that the electronic structure of $(PO_2)_4(WO_3)_8$ is well approximated by that of an isolated WO_6 octahedral layer.
2. The local electronic structure of a transition metal ion M surrounded with n main group ligand atoms L in its first coordination sphere is well

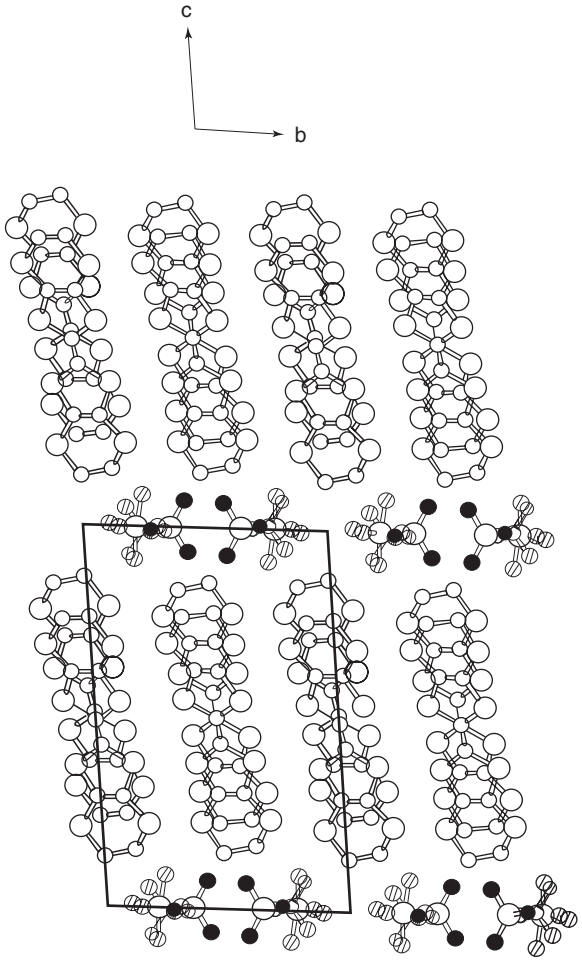

Figure 2 Projection view of the organic conducting salt, β''-(BEDT-TTF)$_2$SF$_5$CH$_2$CF$_2$SO$_3$, showing the alternation of the [(BEDT-TTF)$_2$]$^+$ cation and the [SF$_5$CH$_2$CF$_2$SO$_3$]$^-$ anion layers.

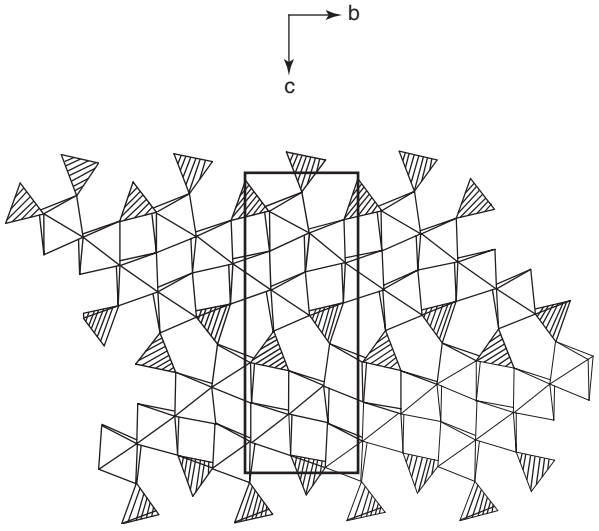

Figure 3 Projection view of the monophosphate tungsten bronze, $(PO_2)_4(WO_3)_8$, showing that the corner-sharing WO_6 octahedral layers are condensed with the PO_4 tetrahedra (shaded).

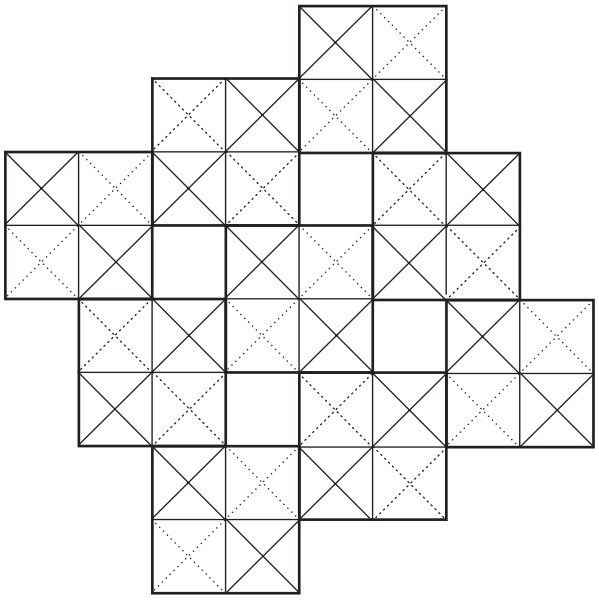

Figure 4 Condensation pattern of the V_4O_9 layers of CaV_4O_9. Each small square with solid (dotted) diagonal lines represents a VO_5 square pyramid having the apical oxygen atom above (below) the basal plane, and the large square made up of four small squares represents a plaquette.

approximated by the *d*-block electronic structure calculated for an isolated complex ML_n. For the purpose of electron counting in the *d*-block levels, each ligand is treated as a closed shell anion. For example, the magnetic oxide CaV_4O_9 is made up of edge- and corner-sharing VO_5 square pyramids (**Figure 4**), and the vanadium and oxygen atoms of CaV_4O_9 have the oxidation states $+4$ and -2, respectively. Thus, a spin monomer (i.e., a structural unit containing one spin site) is represented by the $(VO_5)^{6-}$ cluster, while a spin dimer (i.e., a structural unit containing two spin sites) is represented by the $(V_2O_8)^{8-}$ cluster for edge-sharing square pyramids and by the $(V_2O_9)^{10-}$ cluster for corner-sharing square pyramids (**Figure 5**). The highly charged anion state of these species does not present any computational problem in EHTB calculations, unlike the case of first principles and semi-empirical calculations requiring SCF adjustments of H^{eff}.

3. EHTB calculations are simple and hence enable the study of molecular and extended solids that are too large to study using first-principles electronic structure calculations.

In general, there are two ways of introducing electron correlation in electronic structure calculations, namely, the configuration interaction (CI) wave function and the density-functional theory (DFT) methods. In the CI wave function method, the Hartree–Fock equations solve the exact Hamiltonian (i.e., the molecular Hamiltonian) with approximate many-body wave functions (i.e., Slater determinants). The exact solution can be achieved through systematic improvements in the form of many-body wave functions such as CI wave functions. In this approach, atomic orbitals and hence molecular orbitals play the role of basis functions used to improve the form of many-body wave functions. In the DFT method, however, approximations are introduced only in the exchange-correlation operator. The density-functional equations solve an approximate many-body Hamiltonian with exact wave functions, and DFT approaches the exact solution by improving the exchange-correlation operator. Therefore, unlike the case of the CI wave function method, orbital concepts as practiced by chemists remain valid in DFT. Results of DFT electronic structure calculations are readily interpreted by employing the concepts of orbital interactions on the basis of EHTB calculations.

Low-Dimensional Metallic Compounds

A large number of low-dimensional metallic compounds, which include transition-metal oxides, transition-metal chalcogenides, organic conducting salts,

etc., have been examined by EHTB calculations. In the following, the band dispersion relations, the density of states, and the Fermi surfaces for two examples that illustrate the utility of EHTB calculations are calculated. These calculations get the Fermi surface topology approximately correct, but underestimate the effective mass.

The cation layers of the organic conducting salt β''-(BEDT-TTF)$_2$SF$_5$CH$_2$CF$_2$SO$_3$ are well separated (**Figure 2**). In each cation layer, there are four BEDT-TTF molecules per unit cell. The band dispersion relations and the density of states calculated for a single cation layer using the SZ STOs for all the atoms of BEDT-TTF molecules are shown in **Figures 6a** and **6b**, respectively. For simplicity, only the four highest occupied bands, derived mainly from the HOMOs of the BEDT-TTF molecules, are shown. With the oxidation state $[(\text{BEDT-TTF})_2]^+$, there are six electrons to fill these four bands leading to partially filled bands. The Fermi surfaces associated with the partially filled bands, shown in **Figure 6c**, consist of four wavy lines. Therefore, the SZ STO calculations predict that β''-(BEDT-TTF)$_2$SF$_5$CH$_2$CF$_2$SO$_3$ is a 1D metal. **Figures 7a–7c** show the dispersion relations, the density of states, and the Fermi surfaces calculated for a single cation layer using the DZ STOs for the carbon and sulfur atoms of BEDT-TTF. It is noted that the bandwidth from the DZ STO calculations is about twice as wide as that from the SZ STO calculations. The Fermi surfaces of the DZ STO calculations consist of two wavy lines and a closed pocket centered at the X point. Namely, the DZ STO calculations predict that β''-(BEDT-TTF)$_2$SF$_5$CH$_2$CF$_2$SO$_3$ has both 1D and 2D metallic character, in agreement with the experiment.

Figure 3 shows that a unit cell of the monophosphate tungsten bronze, $(PO_2)_4(WO_3)_8$, has two corner-sharing WO_6 octahedral layers separated by PO_4 groups. **Figures 8a** and **8b** present the band dispersion relations and the density of states obtained for a single octahedral layer from the DZ/SZ calculations, respectively. For simplicity, only the t_{2g}-block bands are shown. The Fermi surfaces associated with the partially filled bands are shown in **Figure 8c**. The corresponding plots obtained for a single WO_6 octahedral layer from the DZ/DZ calculations are presented in **Figure 9**. The bandwidth from the DZ/DZ calculations is about twice as wide as that from the

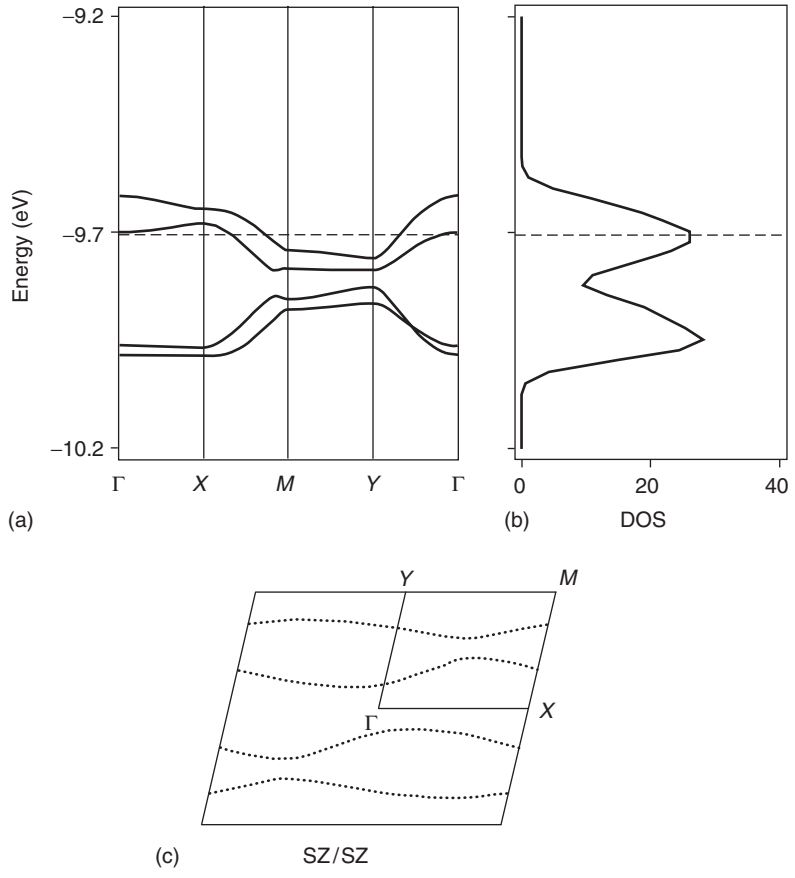

Figure 6 Electronic band structure calculated for a cation layer of β''-(BEDT-TTF)$_2$SF$_5$CH$_2$CF$_2$SO$_3$ using the SZ STOs. (a) Band dispersion relations; (b) density of states; (c) Fermi surface.

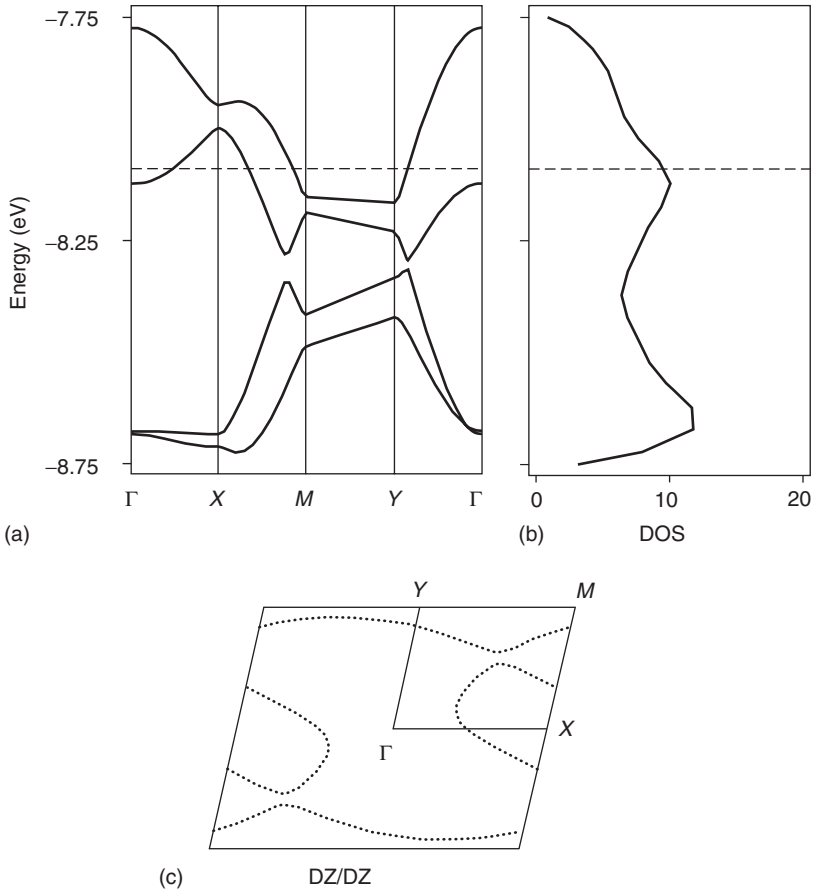

Figure 7 Electronic band structure calculated for a cation layer of β''-(BEDT-TTF)$_2$SF$_5$CH$_2$CF$_2$SO$_3$ using the DZ STOs. (a) Band dispersion relations; (b) density of states; (c) Fermi surface.

DZ/SZ calculations, but the Fermi surfaces from the two calculations are similar. The band dispersion relations, the density of states, and the Fermi surfaces obtained for the 3D lattice of $(PO_2)_4(WO_3)_8$ using the DZ/DZ calculations, presented in **Figure 10**, are very close to those obtained for a single WO_6 octahedral layer using the DZ/DZ calculations. This is so because the interaction between the adjacent WO_6 octahedral layers is weak.

Spin Dimer Analysis of Spin Exchange Interactions

Low-energy excitations of a magnetic solid with localized spins are probed by magnetic susceptibility and neutron scattering measurements, and are analyzed using a spin Hamiltonian defined in terms of a set of spin exchange parameters J. The nature and values of the spin exchange parameters deduced from this analysis depend on what spin exchange paths one includes in the spin Hamiltonian. Strongly interacting spin exchange paths of a magnetic solid are determined by the overlap between its magnetic orbitals (i.e., singly occupied molecular orbitals). Since the magnetic orbitals are anisotropic in shape, the strength of a spin exchange path is not necessarily determined by the shortness of the distance between the magnetic ions. Therefore, in interpreting results of magnetic susceptibility and inelastic neutron scattering measurements, it is crucial to employ a set of strongly interacting spin exchange paths chosen on the basis of proper electronic structure considerations. Otherwise, one may end up interpreting the magnetic properties of a system in terms of a spin lattice model quite irrelevant for the system. Spin dimer analyses based on extended Hückel tight-binding calculations provide a reliable and expedient means to estimate the relative strengths of spin exchange interactions.

In essence, electron localization is responsible for spin exchange interactions of magnetic solids. Consider that a spin dimer has two equivalent spin sites with one electron and one orbital per site (**Figure 11a**).

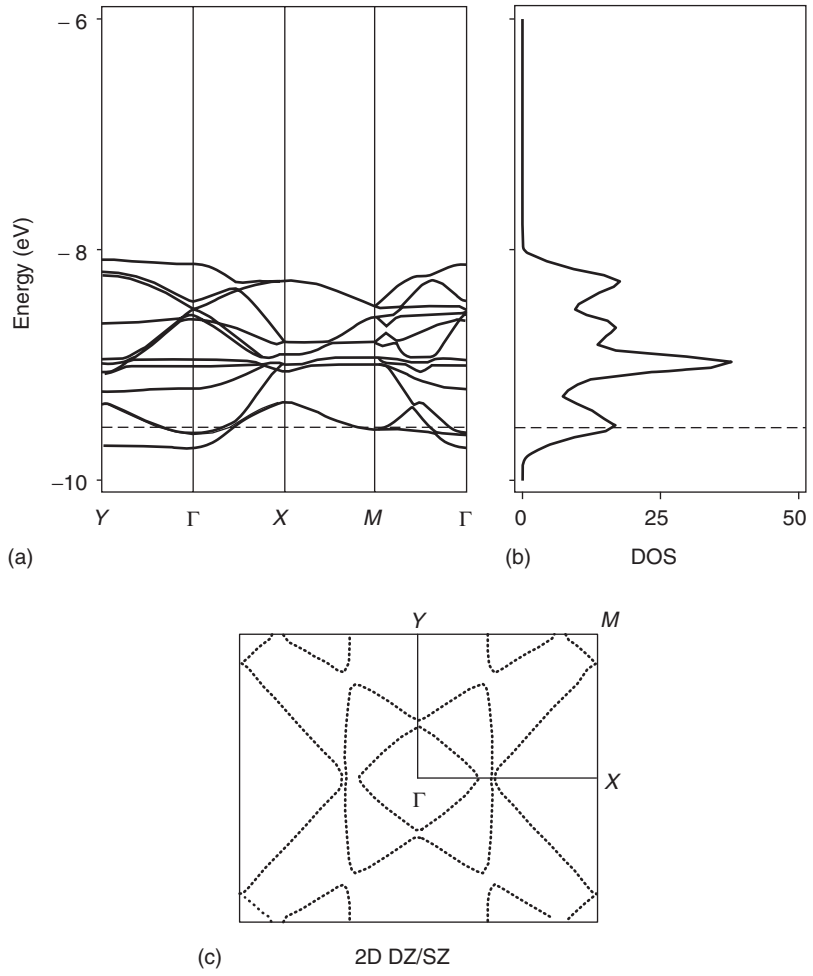

Figure 8 Electronic band structure obtained for a single WO_6 layer of $(PO_2)_4(WO_3)_8$ using the DZ/SZ-STO calculations. (a) Band dispersion relations; (b) density of states; (c) Fermi surface.

The interaction between the two magnetic orbitals χ_1 and χ_2 (representing the spin sites 1 and 2, respectively) leads to two molecular levels ψ_1 and ψ_2 with energies e_1 and e_2, respectively. Three electron configurations of interest for this spin dimer are the triplet configuration Φ_T and the singlet configurations, Φ_1 and Φ_2 (**Figures 11b–11d**). When chemical bonding interaction between the spin sites is weak, the orbital energy difference $\Delta e = e_2 - e_1$ is small, and the two electrons of the dimer are considered as localized. In this case, the two singlet configurations Φ_1 and Φ_2 become close in energy, so the CI between Φ_1 and Φ_2 becomes strong and the ground singlet state Φ_S is described by the linear combination:

$$\Phi_S = C_1\Phi_1 - C_2\Phi_2$$

where the mixing coefficients C_1 and C_2 have the same sign and are similar in magnitude. Using this CI wave function, the energy difference between the triplet and singlet electronic states, $\Delta E = E_S - E_T$, is expressed as

$$\Delta E = 2K_{12} - \frac{(\Delta e)^2}{U_{\text{eff}}}$$

where K_{12} is the exchange repulsion integral between χ_1 and χ_2, and U_{eff} is the effective on-site repulsion.

If the spin dimer is described by the Heisenberg spin Hamiltonian $\hat{H} = -J\hat{S}_1 \cdot \hat{S}_2$, it is found that the spin exchange parameter J is equal to $E_S - E_T$. Therefore,

$$J = \Delta E = 2K_{12} - \frac{(\Delta e)^2}{U_{\text{eff}}}$$

so that the spin exchange parameter J can be written as $J = J_F + J_{AF}$, where

$$J_F = 2K_{12} > 0$$

$$J_{AF} = -\frac{(\Delta e)^2}{U_{\text{eff}}} < 0$$

In general, the exchange integral K_{12} is a small positive number so that the spin exchange cannot be

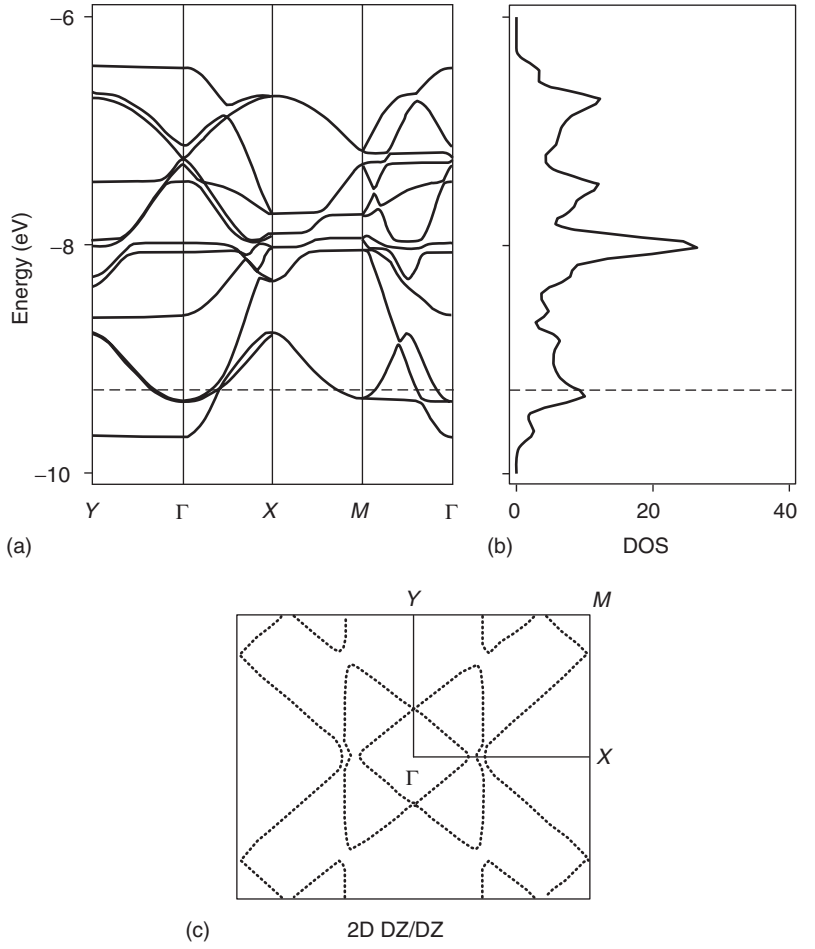

Figure 9 Electronic band structure obtained for a single WO_6 layer of $(PO_2)_4(WO_3)_8$ using the DZ/DZ-STO calculations. (a) Band dispersion relations; (b) density of states; (c) Fermi surface.

ferromagnetic (i.e., $J>0$) unless the antiferromagnetic term J_{AF} either vanishes or is very small in magnitude. For various spin exchange paths of a magnetic solid, the U_{eff} term is nearly constant so that the variation of the J_{AF} values is mainly governed by that of the $-(\Delta e)^2$ values. For an antiferromagnetic exchange interaction (i.e., $J<0$), the J_{AF} term dominates over the J_F term. Since the J_F term is a small positive number, trends in spin exchange interactions can be discussed on the basis of the trends in the corresponding $-(\Delta e)^2$ values obtained from EHTB calculations for spin dimers.

When two adjacent spin sites have M unpaired spins, the overall spin exchange parameter J is then described by

$$J = \frac{1}{M^2}\sum_{\mu=1}^{M}\sum_{\nu=1}^{M} J_{\mu\nu}$$

Therefore, the trends in spin exchange parameters can be discussed in terms of the sum of the spin orbital interaction energy squares:

$$\left\langle (\Delta e)^2 \right\rangle = \frac{1}{M^2}\sum_{\mu=1}^{M}\sum_{\nu=1}^{M} (\Delta e_{\mu\nu})^2$$

Then, the antiferromagnetic component of the overall spin exchange parameter J of the spin dimer can be written as:

$$J_{AF} = -\frac{\left\langle (\Delta e)^2 \right\rangle}{U_{eff}}$$

To illustrate the utility of the spin dimer analysis based on EHTB calculations, two examples are considered. The magnetic properties of 3D perovskites $KNiF_3$ and $KCuF_3$ as well as the layered perovskites K_2NiF_4, K_2CuF_4, and La_2CuO_4 were extensively studied both theoretically and experimentally. These compounds are made up of corner-sharing ML_6 octahedra. As summarized in **Figure 12a**, the experimental J values of these compounds are almost

quantitatively reproduced by the J values obtained from first-principles electronic structure calculations. **Figure 12b** shows that the experimental J values and the $\langle(\Delta e)^2\rangle$ values obtained from EHTB calculations have a good linear relationship. The vanadium oxide, CaV_4O_9, consists of V_4O_9 layers that are made up of VO_5 square pyramids containing V^{4+} (d^1) ions as shown in **Figure 4**. The spin exchange parameters of CaV_4O_9 are known for four exchange paths from the neutron inelastic scattering and magnetic susceptibility studies and from first-principles electronic structure calculations (**Table 1**). From the calculated $(\Delta e)^2$ for these exchange paths, one can estimate the exchange parameters using the relationship $-(\Delta e)^2/U_{\text{eff}}$, where the U_{eff} value of 1.587 eV is chosen to reproduce the strongest J value. Clearly, the relative strengths of the four experimental J values are very well reproduced by the $-(\Delta e)^2/U_{\text{eff}}$ values (**Table 1**).

Importance of Super-Superexchange Interactions

For extended magnetic solids in which magnetic transition metal ions M are surrounded with main elements L, the spin exchange interactions between adjacent metal ions take place via M–L–M superexchange (SE) and M–L…L–M super-superexchange (SSE) paths. On a qualitative level, the trends in the signs and magnitudes of SE interactions are discussed in terms of Goodenough–Kanamori rules. In the past, SSE interactions have been neglected because there was no simple qualitative rule by which to recognize when their strengths were significant. **Figure 13a** shows that the magnetic orbital of a V^{4+} (d^1) ion is given by the V $3d_{xy}$ orbital that makes π-antibonding interactions with the p orbitals of the four ligands L in the basal plane. As depicted in **Figure 13b**, the strength of an SSE interaction between two such magnetic orbitals increases with increasing the overlap between the p-orbital tails of the L…L contacts in the two V–L…L–V paths. This interaction becomes stronger as the L_4 ring formed from the two L…L contact units is more planar and rectangular, as the basal planes of the two spin monomers are more coplanar, and as the L…L contacts are shorter and lie within the van der Waals distance. When the latter conditions are met, an SSE interaction can be stronger than an SE interaction, as found for $(VO)_2P_2O_7$. A similar situation is also found for spin exchange interactions involving Cu^{2+} (d^9) ions. The magnetic orbital of a Cu^{2+} (d^9) ion is the Cu $3d_{x2-y2}$ orbital that makes sigma antibonding interactions with the p orbitals of the four ligands L (**Figure 14a**). As depicted in **Figure 14b**, the strength of an SSE interaction between two such magnetic orbitals increases with increasing the overlap between the two p-orbital tails of the L…L contact in one Cu–L…L–Cu path. This interaction becomes stronger as both ∠Cu–L…L bond angles become

Figure 14 (a) Magnetic orbital of a CuL_4 square plane, in which the Cu $3d_{x2-y2}$ orbital makes σ-antibonding with the ligand p orbitals on the basal plane; (b) arrangement of two adjacent magnetic orbitals in an SSE interaction having a linear Cu–L…L–Cu path.

larger and as the L…L distance becomes shorter and lies within the van der Waals distance. For instance, in the magnetic oxides, $CuWO_4$ and $CuMoO_4$-III, the strongest spin exchange interactions are the SSE interactions involving the most linear Cu–O…O–Cu paths, in which the O…O distances of these paths are in the range of 2.4 Å, which is considerably shorter than the van der Waals distance, and the two ∠Cu–O…O angles of these paths are identical and are close to 165°.

As described above, an SSE interaction can be stronger than any SE interaction. Therefore, assigning strongly interacting spin exchange paths of magnetic solids should be based on appropriate electronic structure considerations. When a magnetic solid consists of other magnetic ions with more than one unpaired spin, the relative strengths of SE and SSE interactions should be estimated with appropriate electronic structure calculations, for which EHTB calculations have been found invaluable.

Concluding Remarks

Although the semi-empirical EHTB method is based on very crude approximations, it facilitates one to extract invaluable information about metallic as well as magnetic insulating solids of known crystal structures. It is also useful in interpreting results of first-principles electronic structure calculations in terms of simple chemical concepts such as overlap, symmetry, and orbital interaction.

Nomenclature

$b_\mu(\boldsymbol{k})$	Bloch orbital at a wave vector $\boldsymbol{k}$
$C_{\mu i}$	coefficient for the atomic orbital χ_μ in molecular orbital ψ_i
$C_{\mu i}(\boldsymbol{k})$	coefficient of the $b_\mu(\boldsymbol{k})$ in crystal orbital $\psi_i(\boldsymbol{k})$
e_j	molecular orbital energy
$e_i(\boldsymbol{k})$	crystal orbital energy at a wave vector $\boldsymbol{k}$
H^{eff}	effective one-electron Hamiltonian
$H_{\mu\nu}$	interaction energy matrix element $\langle \chi_\mu \vert H^{\text{eff}} \vert \chi_\nu \rangle$
J_{AF}	antiferromagnetic component of a spin exchange parameter J
J_{F}	ferromagnetic component of a spin exchange parameter J
J, $J_{\mu\nu}$	spin exchange parameters between two magnetic orbitals
K_{12}	exchange repulsion integral
$S_{\mu\nu}$	overlap matrix element $\langle \chi_\mu \vert \chi_\nu \rangle$

U	on-site repulsion
U_{eff}	effective on-site repulsion
W	bandwidth
$Y(\theta,\phi)$	spherical harmonics
$\langle(\Delta e)^2\rangle$	sum of the spin orbital interaction energy squares
Δe, $\Delta e_{\mu\nu}$	orbital energy spilt associated with the interaction between magnetic orbitals
ζ	exponent of an exponential function of a slater type atomic orbital
χ_μ	valence atomic orbital
Φ_{i}	electron configuration
Φ_{S}	singlet state
Φ_{T}	triplet state
ψ_i	molecular orbital
$\psi_i(\boldsymbol{k})$	crystal orbital at a wave vector $\boldsymbol{k}$

Sensors

A D'Amico and C Di Natale, University of Roma "Tor Vergata," Rome, Italy

All the living beings of our planet, in different ways, display highly complex integrated biological systems (biosensors) that are used to profitably interact with the environment where they exist. The loss of efficiency of these indispensable biosystems or even their absence (lack), is reflected in a reduction of outliving capacity and, as a consequence, in a slow-down of the evolutionary processes. For this reason, these biosensors are of paramount importance. For example, in the constant effort dedicated to imitate Nature, in order to construct apparatuses of particular importance such as robots to be used for hard and precision works, man tries to construct, using available and updated technologies, sensors able to exceed the performance of the biological analogs.

In the last two decades, along with the developments in microelectronics and microsystems, a variety of sensors for the detection of physical, chemical, and biological measurands have been fabricated, and the effort is still in an evolutionary phase due to the ever-growing technological level. These are used to characterize and control the so-called generalized environment (GE) where living beings grow and develop their intrinsic knowledge. Examples of GE are: atmosphere, lands, waters, drops of biological liquids, cells, vehicles, buildings, outer space, etc.

In designing new sensors or even sensor systems, one should keep in mind the strategy adopted by Nature, especially in the case of evolved animals. Most of the sensing systems are formed by a large number of small sensors. It seems that Nature tends to reduce the dimensions of the single sensor in order to achieve, at small dimensions, one peculiar property and use a matrix of these sensors to gain another property useful at macroscopic level. As an example, consider the eye. The single-photon sensor is made small enough to determine the single-pixel resolution at a given distance; then a huge number of these high-performance sensors are used in order to have the possibility of seeing a rather large sight frame (extended field of view).

New-generation sensors are solid-state devices fabricated by microelectronic technologies able to read the GE and give responses of either the electrical or the optical type, suitable for both successive preprocessing and final actions of monitoring, storing, and control. They can measure physical parameters such as force, acceleration, strain, torque, vibration, position, velocity, pressure, temperature, ion concentration in solutions (Na^+, Ca^{++}, K^+, etc.), and a variety of volatile compounds, such as H_2, CO, CO_2, SO_2, etc. Also utilizing enzymes, antibodies, or chemically sensitive molecules designed *ad hoc*, they can improve sensitivity and resolution versus particular chemical or biological species.

Sensors being highly complex devices, their study and development can only be performed at multidisciplinary level using knowledge ranging from solid-state physics, chemistry, microelectronics, to biology, interfaces, electrochemistry, nanocorrosions, etc. This may be justified by taking into account some of the most important characteristics that must be satisfied by sensors: high sensitivity and resolution, low noise, robustness, compatibility with microelectronic technologies, and noncontaminability; finally, for all applications regarding human bodies, biocompatibility does represent the most important requirement. All these characteristics cannot, in practice, be satisfied, simultaneously, and an acceptable compromise should always be found so that sensors for specific tasks can be designed more easily.

In this article, for the sake of clarity, the following terminology is used:

1. *Physical sensors*: devices able to sense physical quantities.
2. *Chemical sensors*: devices able to sense chemical quantities.
3. *Biological sensors*: devices able to sense biological quantities.

4. *Biosensors*: devices having sensing parts made by biological materials. Here one may distinguish among:

   (a) Chemical biosensors: devices having sensing parts made by biological materials and sensitive to chemicals.
   (b) Biological biosensors: devices having sensing parts made by biological materials and sensitive to biomaterials.
   (c) Physical biosensors: devices having sensing parts made by biological materials and sensitive to physical quantities.

Numerous effects may be derived from the interactions between the chemically interactive material (CIM) and the GE. The most relevant for the CIMs are: heat generation followed by a temperature increase; changes of one of the following parameters: electronic charge, mass, conductivity, refractive index, work function, photon emission. Many transducers available today are able to utilize one or more of the above-mentioned effects.

A variety of CIMs are available for chemical and biosensing, such as: metal oxide semiconductors (SnO_x, TiO_x, Ta_2O_5, IrO_x, WO_2, etc.), metals (Pt, Pd, Ni, Ag, Cr, Sb, K, etc.), ionic conductors (ZrO_2, LaF_x, CaF_x, CeO_2, Nasicon, etc.), polymers (polypyrrole, polyphenylacetylene, cellulose, polyurethane, polycarbonate, porphyrines, phthalocyanines, polysiloxanes, etc.), enzymatic systems (glucose-oxidase, lattosio-oxidase, urease, anti-IgG, anilisteria, etc.).

It is also interesting to mention that a sensor, incorporating an appropriate transducer, can be seen as an energy-to-energy convertor, where the possible energies at the input and output, may be any of the following: electrical, magnetic, optical, chemical, mechanical, thermal, or nuclear. In this context, the following sensor conversion phenomena give us the various possibilities available for the design of new sensing devices: biochemical, bioelectric, biomagnetic, electroacoustic, elastomagnetic, elastoelectric, electrochemical, photochemical, magnetoelectric, magnetooptic, photoelastic, photoelectric, photomagnetic, thermoelectric, thermomagnetic, thermoelastic, and thermooptic.

It is also useful to mention the most important types of measurable quantities which are related to the nine application areas listed below:

1. *Acoustic*: amplitude, phase, polarization, spectra, power, and harmonic distortion.
2. *Biological*: concentration, type of molecules, functionality, and affinity.
3. *Chemical*: concentration, type of molecules, functionality, and affinity.
4. *Electric*: current, charge, potential, electric field, power, phase, polarization, resistivity, conductivity, permittivity, and permeability.
5. *Magnetic*: magnetic field, magnetic flux, permeability, and phase.
6. *Mechanical*: force, moment, torque, stress, strain, viscosity, linear position, angular position, linear velocity, angular velocity, acceleration, mass, density, flow, stiffness, and compliance.
7. *Optical*: amplitude, phase, polarization, refractive index, spectra, power, wave velocity, phase velocity, and harmonic distortion.
8. *Radiation*: frequency, wavelength, intensity, energy, power, and spectra.
9. *Thermal*: temperature, thermal conductivity, thermal resistance, specific heat, and flux.

In order to evaluate the characteristics of a sensor, suitable descriptors must be considered, e.g.:

(a) *Response curve* (*RC*). It represents the output response as a function of the measured quantity applied to its input. For instance, in the case of a chemical sensor based on change in conductivity (G) with respect to the change of the input quantity, it is recommended to use the following notations for the output response: G (conductance), G/G_0 (relative conductance), $(G - G_0)/G_0$ (relative change of the conductance).

(b) *Sensitivity* (*S*). It is defined as the derivative of the response (which is a function of the operating point) with respect to the measured quantity (M). With reference to the three above-mentioned cases, one has $S = \mathrm{d}(G)/\mathrm{d}M$, $S = \mathrm{d}(G/G_0)/\mathrm{d}M$, $S = \mathrm{d}((G - G_0)/G_0)/\mathrm{d}M$.

In the case of a linear response without offset the above three relationships of sensitivity simplify as follows: $S = G/M$, $S = (G/G_0)/M$, $S = ((G - G_0)/G_0)/M$.

In the case of a piecewise linear response, for each of the segments, the sensitivities can be further simplified as $S = \Delta G/\Delta M$, $S = \Delta(G/G_0)/\Delta M$, $S = \Delta((G - G_0)/G_0)/\Delta M$.

(c) *Resolution* (*R*). It is defined as the magnitude of the measured quantity which gives a signal-to-noise ratio equal to 1 and can be expressed in a simplified form as follows

$$R = \text{noise voltage}/S$$

which means that sensors having the same noise present a better resolution when the sensitivity is higher.

In the following, the basic principles of the most important sensors are illustrated through the use of

some figures which schematically indicate (not to scale) their shapes.

Figure 1 shows a pyroelectric sensor, which is sensitive to heat rate delivered during the sensing action. A slice of pyroelectric material, such as $LiTaO_3$ or $LiNbO_3$, is covered by two thin-film metallic contacts, and a CIM is deposited on one of them (e.g., platinum if one would like to detect ammonia). A change in dipole moment induced by external temperature changes develops either an open circuit voltage or a loaded circuit current as output signal. Temperature changes as low as 10^{-6} K are possible using this sensor.

Figure 2 schematically shows a metal oxide semiconductor (MOS) structure, which is sensitive to electronic charges, where, as an example, the gate has been covered by a thin film of palladium. In the presence of hydrogen, through a catalytic action, electrical dipoles grow at the palladium–silicon dioxide interface, which controls the source drain current of the MOS structure. In this way, the output voltage at the drain can be related to the amount of the adsorbed and absorbed hydrogen occurring during the catalytic process itself. About 10^{-9} C represents the minimum charge variation allowed at the gate to obtain the minimum readable signal.

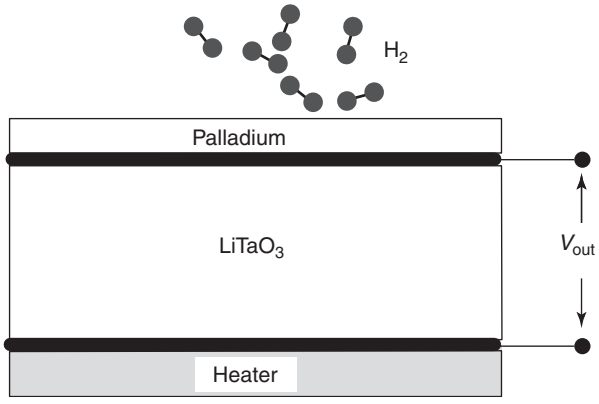

Figure 1 Schematic of a chemical sensor based on the pyroelectric effect. The interaction between airborne hydrogen and palladium results in a variation of temperature of the metal film. The underlying pyroelectric material changes its polarization state according to the temperature variation. As output, a voltage drop across the pyroelectric material is observed. To the nature of the pyroelectric effect, the output voltage is proportional to the derivative of the temperature. The heating system helps to speed up the catalithic reaction between the CIM and the volatile compound.

Figure 3 shows a differential surface acoustic wave sensor which is sensitive to mass changes occurring along the surface wave path. Usually, a CIM sensitive to one or more volatile compounds is deposited as a thin film on the surface of one of the two surface acoustic wave (SAW) devices, while the other acts as a reference. During the CIM–gas interaction, the acoustic–electric properties of the CIM change, inducing a delay in the propagating surface wave. If the SAW sensors are included in an oscillating circuit, this delay produces a change in the frequency. So, the output frequency of the sensors can be related to the concentration of the adsorbed gas. Suitable propagation modes present in the SAW structure can be used for the detection of either ions or neutral molecules even in liquids.

Figure 4 shows a bulk acoustic wave (BAW) sensor, sensitive to mass changes of the adsorbing layer, made by a quartz slice included in an oscillating circuit. The surface of this device is usually coated by a CIM. During adsorption–desorption processes, the overall quartz mass change induces a frequency variation of the oscillator which can be related to the concentration of the volatile compound. Small quantities of gas molecules (ppm), corresponding to nanograms, can be detected by this sensor. Temperature stability is the

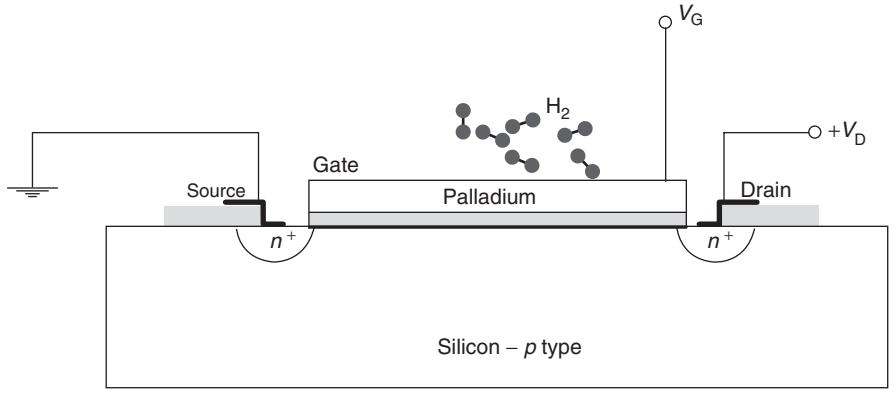

Figure 2 Conceptual scheme of a ChemFET for gas detection. In this particular example, the usual gate is replaced by a film of palladium. As a consequence of the absorption of hydrogen molecules, a number of dipoles are formed at the metal–oxide interface. This results in a detectable change of the source drain current.

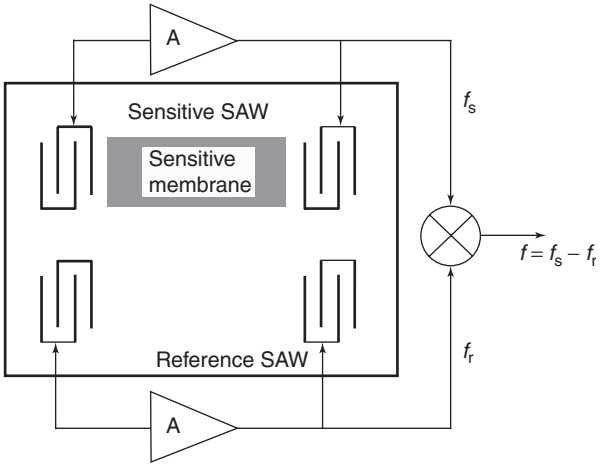

Figure 3 Schematic assembly of a SAW chemical sensor. In this configuration, two SAWs are used as delay lines in feedback configuration with two amplifiers. The propagation path of the acoustic wave in the upper SAW is modified by a chemically sensitive layer. This layer can absorb molecules from the environment and this interaction results in a modification of the acoustic wave propagation conditions. The other SAW is left uncoated and used to compensate any variation different from the chemical interaction. The output quantity is the frequency of the output signal obtained as the difference of the frequencies of the oscillators incorporating the two SAWs.

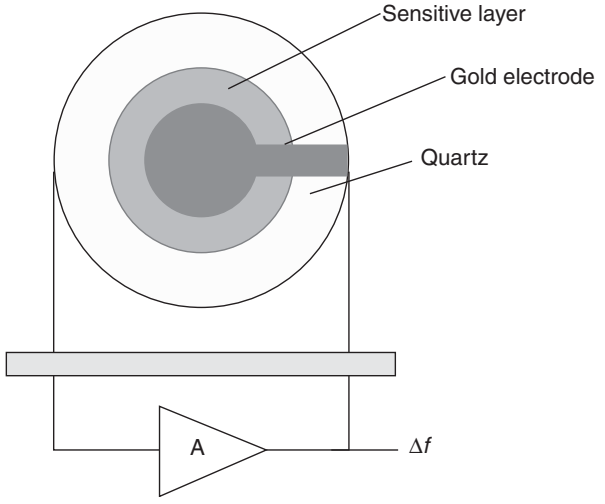

Figure 4 Scheme of a BAW sensor. The sensor is formed by a piezoelectric slab cut along some defined crystal axis. The quartz disk is electrically contacted by metallic electrodes. The mechanical oscillation frequency, sensitive to the gravitating mass, is matched by the piezoelectric effect with the electrical resonance frequency driving and electronic oscillator. The frequency of the output signal is then proportional to the gravitating mass. The chemical sensitivity is given by the sensitive layer deposited onto the quartz surface.

most important constraint to be considered and controlled during the sensing operation.

Figure 5 shows an ion-selective field effect transistor (ISFET) sensitive to the electronic charge, which

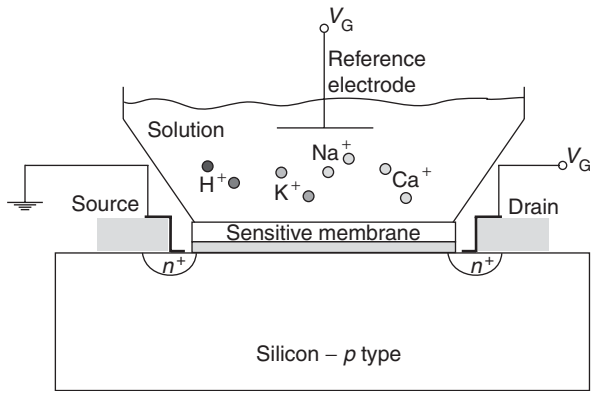

Figure 5 Schematic diagram of the ISFET sensor. In this sensor the usual gate of a MOSFET device is replaced by the sensitive membrane, the electrolytic solution, and the reference electrode. The scope of the device is, as in the case of ChemFET, to bring charged molecules at the oxide – "gate-like" interface in order to alter the current flowing from the drain to source contacts.

can detect the amount of ion concentration in a liquid. In this device, the reference gate is immersed into the liquid and the metal gate is replaced by a CIM suitable for liquids able to adsorb ions. As an example, valynomicine is a well-known CIM for the detection of potassium ions. The presence of ions inside the membrane induces a change of the source drain current which represents the useful output signal. ChemFETs (also GasFETs) belong to the same family; here the gate may be a catalytic metal able to adsorb a certain volatile compound. As an example, a palladium gate would give the possibility of detecting hydrogen or ammonia, even at room temperature. ENFETs have the gate covered by an enzyme able to adsorb biochemical species. The intrinsic operative mechanism is always the same: a charge is needed to be deposited inside the CIM or at the CIM–silicon dioxide interface in order to change the flat-band voltage of the basic device and, as a consequence, to change the output current.

Figure 6 shows a Mach–Zehnder optical interferometer used as a chemical sensor. Here, one branch of the interferometer is covered by a CIM, while the other represents the reference. During the adsorption–absorption and desorption processes, the CIM changes its refractive index and the light at the output turns out to be dependent on the changed optical path of the modified branch. In this device, changes of the refractive index of 10^{-4} can practically be detected, allowing detection capabilities, with respect to gases, of a few ppm.

Figure 7 shows the schematic diagram of a sensor based on conductivity change. These devices have the sensing part made from semiconductor oxide materials such as SnO_x. These materials, which behave

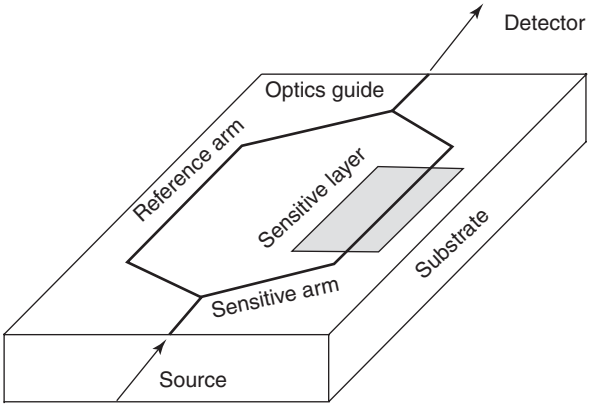

Figure 6 Schematic diagram of the Mach–Zehnder interferometer; the entering light is split into two arms and summed before the output. In order to turn the device into a chemical sensor, it is necessary to coat one of the arms with some material that after the absorption of molecules, changes its dielectric constant. It results in a modification of the optical length of the arm and, due to the interference process, in a modulation of the intensity of the output light.

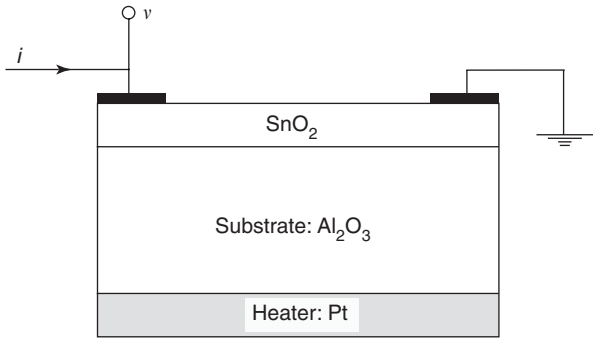

Figure 7 Schematic view of a SnO_2 based chemical sensor. The presence of the heater is necessary in order to bring and maintain the sensitive material at a temperature in the range 250–400°C. At these temperatures, the catalytic processes leading to sensitivity toward both reducing and oxidizing gases are active and the sensor can change its electric resistance.

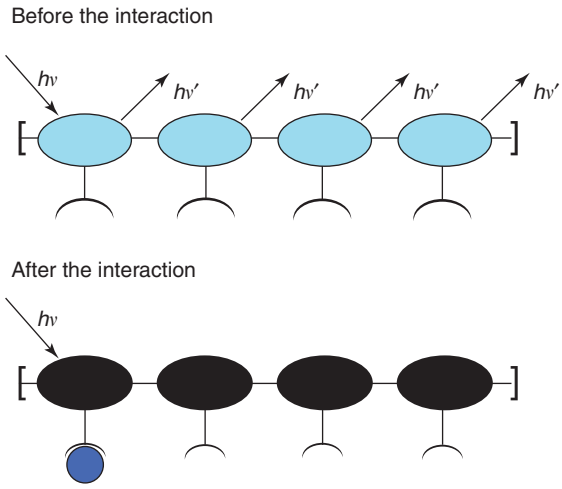

Figure 8 Effect of conjugated polymers. These polymers are formed by linking together fluorescent monomers. The effect of the polymer is that the excitation can travel along the polymer chain inducing a collective fluorescence. If each monomer is functionalized with a receptor able to bind molecules from the environment, the binding of only one molecule is enough to stop the excitation propagation along the chain, quenching the fluorescence of all the fluorescent molecules in the polymer. It provides an amplification of the binding event enhancing the total sensitivity greatly.

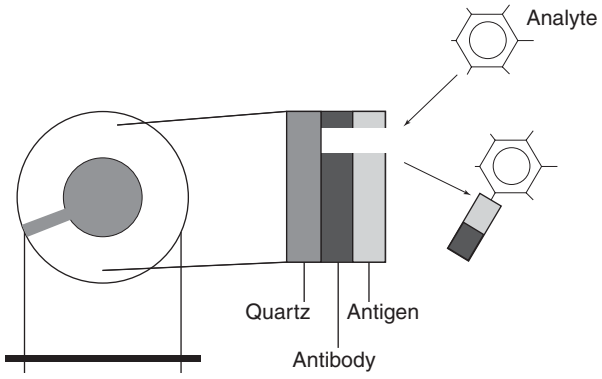

Figure 9 Biosensor based on quartz microbalance sensor. Usually, such sensors measure the mass of the absorbed analyte. In this arrangement, the action of the analyte is to remove a portion of the coating from the quartz surface. Since the removed molecules are heavier with respect to the analyte, this results in a sort of amplification of the sensor sensitivity toward the analyte. It should be remarked that successive exposure to the analyte reduces the amount of coating, and in turn the limited lifetime of the sensor.

like semiconductors, may be doped at the surface by different metals (e.g., gold, palladium, platinum, or copper) in order to enhance their sensitivity compared to volatile compounds and must operate at temperatures ranging from ~200 up to 500°C. Minimum detectable concentrations could be in the ppm range.

Figure 8 shows a chemical biosensor based on the phenomenon of luminescence quenching. A suitable biomaterial which acts as a CIM and is able to emit luminescence light in the visible range under, for instance, ultraviolet excitation, deactivates its luminescence centers by the presence of a given chemical compound. The output-quenched signal is detected by a photon-sensitive device (a solid-state photomultiplier, for instance) allowing rather high resolution values to be obtained, in the ppb range in already proven cases.

Figure 9 shows a schematic diagram of another chemical biosensor utilizing the effect of mass changes. The transducer is represented by a quartz resonator covered by an antigen–antibody structure sensitive to a given analyte, for instance, as that emitted by plastic mines. The presence of such an

analyte takes a piece of antigene out of the transducer inducing a rather strong mass variation which is detected by a frequency change. In this context, a useful strategy consisting of using two quartz resonators, one of which is considered as reference, permits one to reduce the effects of common unuseful parameters such as pressure, temperature, and humidity.

Insofar as physical sensors are concerned, a large number of them have been developed in the last few decades. They are devices able to detect physical quantities, such as photon intensity, pressure, temperature, strain, rotation angles, magnetic and electric field, and refractive index, etc.

Temperature sensors are physical sensors showing sensitivity either to temperature or to temperature changes (thermocouples and thermopiles, thermistors, diodes, and transistors), or to temperature changes only (pyroelectric devices).

Figure 10 shows a schematic of a thermopile made, for example, by two thermocouples. The thermopile output is represented by a voltage proportional to the temperature difference between the hot and cold junctions, the latter representing the reference. This type of a physical sensor is characterized by the minimum noise level, and temperature differences as low as 10^{-4}°C can be detected, even at room temperature.

Thermistors are devices where the material used (metals or semiconductors) shows an exponential resistivity change versus the temperature. Some of them display sensitivity values so high as to give the possibility of detecting even 10^{-5}°C.

Diodes and transistors have an intrinsic sensitivity to temperature; in fact, the diode currents (for the diode) and the collector currents (for the transistor) are exponential functions of the temperature. In a semilogarithmic scale, the plot of the currents versus the diode voltage (or versus the base emitter voltage) has a slope that is directly temperature-dependent. For these devices, temperature resolutions of 10^{-2}°C are possible.

Pyroelectric devices characterized by ferroelectric materials, such as $LiTaO_3$ show an output voltage proportional to the temperature rate, and may allow detection of sinusoidal temperature variation as low as 10^{-6}°C.

Figure 11 shows a schematic diagram of a pressure sensor fabricated by the micromachining technology. The basic principle relies on a membrane where four piezoresistors, used in a full-bridge configuration, are located at the position of larger strain. Once the pressure is applied, the piezoresistors are activated and a voltage can be detected at the bridge output. This voltage can be related to the pressure values.

Figure 12 shows another useful solution for a pressure-integrated sensor. Here a plate belonging to a capacitor is displaced by the applied pressure, and the detection is performed by the capacitance measurement through a suitable circuit, which is eventually fully integrated in the same substrate. Among them, infrared sensors (IR) have been the most important, especially for their strategic use, because they allow night vision with high efficiency, and also because they are useful in detecting underskin cancer. IR radiation is usually classified as near infrared

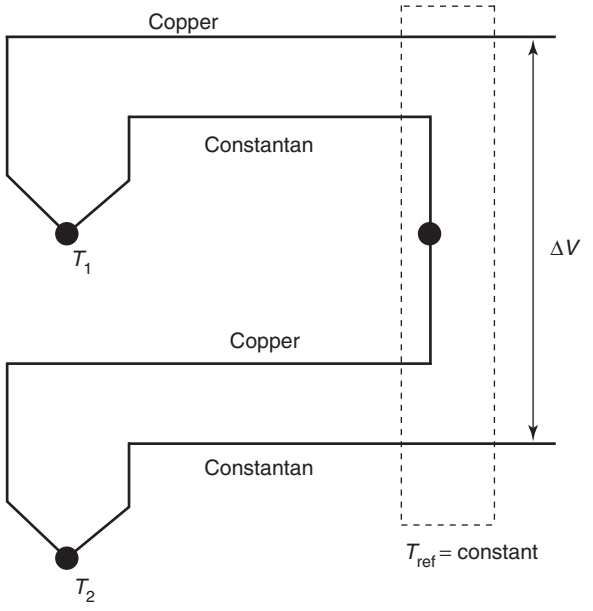

Figure 10 Two thermocouples are connected in series to show the working principle of the thermopile. The resulting voltage drop across the first and the last conductor provides a measure of the mean temperature of the hot nodes (T_1 and T_2 in figure) with a thermoelectric power, that is, the thermoelectric power of the single thermocouple multiplied by the number of couples forming the thermopile.

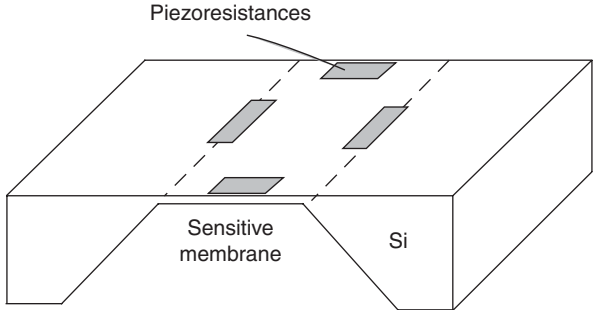

Figure 11 Arrangement of a micromachined fabrication of a pressure sensor. The sensitive membrane moves according to the pressure difference experienced by the two sides of the membrane. The four piezoresistors are assembled in order to provide negative and positive response to the same pressure signal. This arrangement takes the maximum advantage from the Wheatstone bridge configuration leading to a linear relation between output signal and pressure variation and maximum sensitivity.

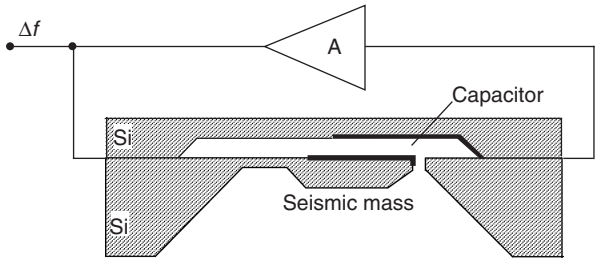

Figure 12 Scheme of an accelerometer based on the capacitive transduction of the position of a seismic mass. The value of the capacitance can then be transformed into a signal frequency by a suitable oscillator circuit.

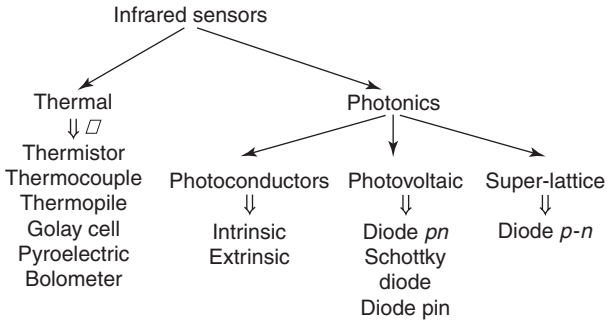

Figure 13 Classification of IR sensors according to the thermal (flat band responsivity) and photonic (narrow band responsivity) detection principle.

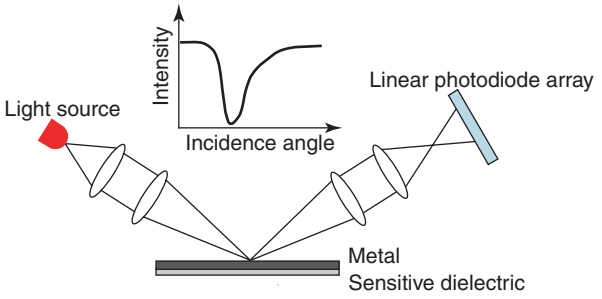

Figure 14 Schematic arrangement of a surface plasmon resonance measurement setup. The light source is condensed through a lens series in order to span a range of incidence angles. Reflected light is recollected on a linear photodiode array. In the inset, a typical response is shown.

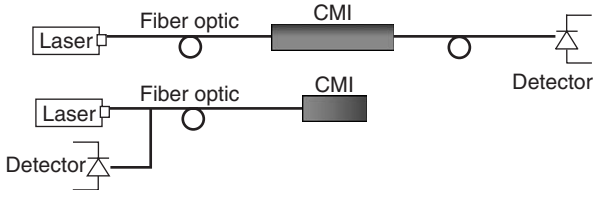

Figure 15 Two possible arrangements of fiber optic chemical sensors are shown in the figure. Both the setups are based on the interaction of chemicals with a sensitive material coating the fiber cladding. In the second case, a fiber bundle is used to collect back the light in order to keep the light source and detector in the same position.

(0.8–2 μm), medium infrared (2–14 μm), and far infrared (14–100 μm). Among these regions, the so-called IR windows are present. They represent wavelength intervals where the adsorption coefficient in air is very low. The window that ranges between 8 and 12 μm is very important, because it represents an easy propagation path of that radiation generated by a room-temperature blackbody.

Figure 13 shows some categories of the wide family of IR devices. The important difference between thermal and photonic sensors is worth mentioning. The former gives a flat response versus wavelength, while the latter does present a pass-band-like response. Photoconductor IR sensors change their conductivity in the presence of IR radiation and a current must be injected through them in order to get a voltage signal, while photovoltage IR sensors behave as IR solar cells and generate a voltage without any polarization current. Important IR photonic materials are PbS, PbTe, PbSe, CdTe, $PbSn_xTe_{(1-x)}$, and $HgCd_xTe_{(1-x)}$. Above 8 μm, many IR sensors must be cooled in order to give an acceptable signal-to-noise ratio, but some of them, such as thermopiles and pyroelectric sensors, can operate at room temperature even up to 12 μm.

Figure 14 shows a schematic diagram of a sensor able to detect the changes of refractive index of a given material. It is based on the surface plasmon resonance effect. Surface plasmons are charge waves propagating along a given metal surface. In this geometry (Kretschmann geometry), light penetrates a prism and impinges on a metal surface with a certain angle of incidence. An evanescent wave is locally generated, which propagates through the film itself. It then generates, under suitable resonance conditions related to the light frequency and incident angle, on the other side of the film, the plasmons. The presence of a liquid with a certain refractive index may be detected by analyzing the intensity change of the light out of the prism. Bioliquids have been succesfully analyzed by this method.

Optical fiber sensors also represent a powerful tool for the development of robust, reliable, low-cost, and sensitive sensors with a high degree of immunity toward electromagnetic interferences. Optical fiber sensors may be configured in order to measure physical parameters (temperature, pressure, strain, electric current, rotation, etc.) or chemical parameters (e.g., composition, concentration, etc). Different types of optical fibers can be utilized in this context: monomode, multimode, and others supporting polarized propagation light. The basic structure of an optical fiber chemical sensor is shown in **Figure 15**.

It is necessary to have a laser, an optical fiber, suitably treated, and a detector. In **Figure 15**, the central part of the fiber is covered by a CIM and, in presence of a given volatile compound (VOC) compatible with the CIM, the detector may experience a change of the light intensity. This effect can be correlated to the concentration of the VOC. In other configurations, the sensitive part is located at one of the fiber extremes, while the other extreme is used either to send a pulse of light for a certain time or to receive the response which carries information about the CIM–VOC interaction.

Artificial Olfaction Systems

One of the most ambitious applications of chemical sensors is concerned with artificial systems that are able to reproduce the functions of the natural chemical senses: olfaction and taste.

Senses necessary to life as interfaces between living beings (both animal and vegetables) and the surrounding world allow living beings to interact with the environment and adapt themselves to it. Traditionally, in humans, five senses are identified: sight, hearing, touch, taste, and olfaction. It is very interesting to note that senses can be further classified according to the nature of the things sensed. From this point of view, it is possible to distinguish the physical senses (hearing, sight, and touch) from the chemical senses (taste and olfaction). A great difference between the two groups exists, and it concerns the treatment of the perceived information. Indeed, in humans it is common to communicate hearing or visual experiences while communication of olfactive or gustative perceptions is not as common. These semantic differences have corresponding difficulties in the technological capability to reproduce the functions of natural senses. For instance, hearing and sight have largely been studied and several technological similii are currently available (such as cameras and microphones). On the other hand, only in the last few years the possibility of designing artificial systems able to mimic chemical senses began to be considered.

The first ideas about artificial olfaction came in the 1960s, but the breakthrough occurred during the 1980s when some researchers argued that the behavior of chemical sensors was rather similar to that of olfaction receptors. Then, the possibility of assembling a number of such devices allowed one to construct a sort of artificial olfaction, which was soon nicknamed "an electronic nose."

Many chemical sensors, such as those previously illustrated, share with the natural receptor an important feature: they are not selective. This means that their signal cannot be related to one specific volatile compound, but rather to the global nature of the compounds present in the air. Indeed, natural olfaction does not provide analytical information about the inhaled air, but olfaction provides signals to the brain in order to allow the individual to give a sort of qualitative description of the sniffed air. In practice, natural olfaction makes use of a large number of different receptors, where none of them is selective, but the totality of the ensemble makes the individual selective to thousands of different odors.

During the 1990s, the research and development of electronic noses grew, involving a large number of researchers. Electronic noses have been demonstrated to be able to classify and distinguish different odors (e.g., to distinguish different wines), and to identify, after proper training, unknown samples (e.g., to identify the denomination of a particular wine). A sort of standard model of an electronic nose can be found by looking at the extent of technological implementation of the original idea. This is based on an array of sensors, from a few units in the case of metal-oxide chemoresistors or quartz microbalances up to thousands of fluorescent beads micromechanically carved on a single optic fiber.

Disregarding the working principle and the technological fabrication, sensors are required to be "globally sensitive" and, at the same time, sensors with a range of selectivity properties must be produced. In this way, each sensor provides different information contributing to the global identification of samples. Another important characteristic of the electronic nose is data analysis. Multicomponent analysis techniques are utilized to infer from the sensor signals the properties of the measured sample. Among these techniques, the most utilized are those derived from chemometrics, namely, the algorithms and methods used in chemistry to analyze data of spectral

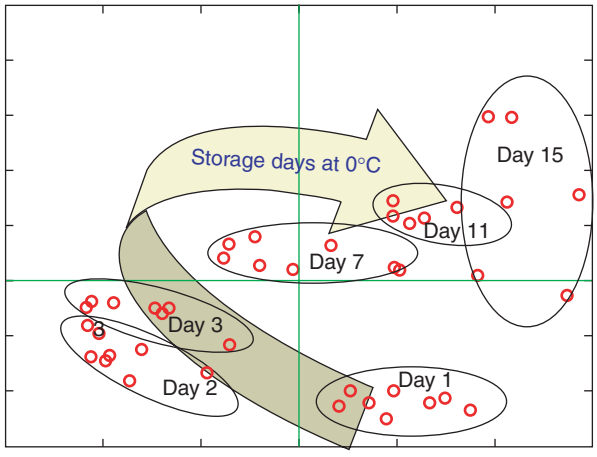

Figure 16 Result of a typical electronic-nose measurement aimed at characterizing the process of spoilage in fish.

instruments (e.g., spectrophotometry and gas chromatography). Also, neural networks have been used extensively, and these have contributed to enhancing the properties of artificial olfaction systems.

Data analysis usually results in maps where odors are plotted in order to study their similarities and differences. As an example, **Figure 16** represented below shows a typical result obtained in the analysis of food. The same principle of electronic nose has also been applied to arrays of sensors operating in liquid samples giving rise to the so-called "electronic tongue." This system has been found to be efficient in environmental (e.g., the detection of various ionic species in ground waters) and food applications (e.g., different coffee brands and spoilage processes in fruit juices).

Shubnikov–de Haas and de Haas–van Alphen Techniques

W Biberacher, Walther-Meissner-Institut, Garching, Germany

The de Haas–van Alphen (dHvA) and Shubnikov–de Haas (SdH) effects describe oscillatory components of the magnetization and conductivity, respectively, of a metal as a function of an applied magnetic field at low temperatures. The oscillations are periodic in a reciprocal magnetic field. It is the most accurate method to determine the contours of the Fermi surface of a metal or semimetal, but also gives information on other physical properties of electrons such as effective mass, scattering time, and spin-splitting factor.

Historical Introduction

The first experimental and theoretical manifestation of this effect dates back to 1930. In this year, L D Landau developed the quantum mechanical calculation of the diamagnetism of conduction electrons and mentioned the possibility of oscillatory effects there. But he believed, it was unobservable at that time. In the same year, L V Shubnikov and W J de Haas published an oscillatory behavior of the magnetoresistance in bismuth, and at the end of this year de Haas and P M van Alphen reported the observation of an oscillatory magnetization in the same material. Three years later, R Peierls developed a quantitative theory of the oscillations in Bi based on Landau's formulation of the energy levels of electrons in a magnetic field. In 1939, D Shoenberg determined the Fermi surface of Bi using the theoretical calculations of Landau. Shoenberg came to be the leading scientist in this field for several decades.

It was only around 1950 that general interest was seen in these oscillatory effects. In 1947, dHvA oscillations were detected in zinc, the first observation in a metal other than Bi. Soon after, it became clear that

this effect could be observed in nearly every polyvalent metal, if crystals of high quality were available.

In the beginning of the 1950s, three important theoretical advances were made: first, the influence of the electron spin was worked out as a damping factor of the oscillation amplitude, second, R B Dingle could show that electron scattering broadens the Landau levels. This should change the oscillations in a way similar to a rise in temperature. The most important contribution was first published by L Onsager. He showed that the dHvA frequency is connected with the geometry of the Fermi surface and gives the extremal cross section of the Fermi surface perpendicular to the magnetic field. But this breakthrough could not be exploited immediately: at that time only low-frequency oscillations of the rather complex Fermi surfaces of polyvalent metals could be experimentally observed. On the other hand, band structure calculations were not yet good enough to show all details of a Fermi surface.

Around 1950, typical laboratory magnets produced fields up to 3 T. The very few water-cooled high-power magnets available at that time suffered from their instability. It was clear that higher and/or more stable magnetic fields are needed. Shoenberg, therefore, started working with pulsed fields up to 10 T and was soon able to observe high-frequency oscillations also in polyvalent metals, and even made the first observations in monovalent metals.

On the basis of prior theoretical work, I M Lifshitz and A M Kosevich developed a complete theory of the dHvA effect in 3D metals published in 1956. Together with improved band structure calculations starting from 1960, dHvA oscillations were investigated in all metals and compared with the theoretical band structure.

Although the basic investigations of the metallic elements are more or less completed, the dHvA and SdH effects are still of high use in the investigation of new compounds. Important examples are heavy fermion systems and low-dimensional conductors such as organic metals or artificially grown 2D electron systems.

Basic Theoretical Models

Landau Quantization

The physical reason for the oscillatory effects in a magnetic field can be easily understood in the model of a free electron gas confined to a cube of length L. (The electron spin is neglected first.) The Schrödinger equation for free electrons in a magnetic field is given by

$$\frac{1}{2m_e}\left(\frac{\hbar}{i}\nabla - eA\right)^2 \Psi = E\Psi$$

where m_e is the electron mass, e is the electron charge, and $\boldsymbol{A}$ is the vector potential of the magnetic field $\boldsymbol{B}$. Landau showed in 1930, that for a magnetic field applied in the z-direction the energy is given by

$$E = \left(n + \frac{1}{2}\right)\hbar\omega_c + \frac{\hbar^2}{2m_e}k_z^2$$

with $n = 0, 1, 2, \ldots$, $\omega_c = eB/m_e$ being the cyclotron frequency and $k_z = 2\pi n_z/L$ $(n_z = 0, \pm 1, \pm 2 + \cdots)$ the wave vector in the z-direction. If one compares this to the solution of a free electron gas without a magnetic field, where $E = \hbar^2 k^2/2m_e$, it is seen that the wave vector in the x,y-plane perpendicular to the magnetic field is no longer quasicontinuous, but takes only discrete values

$$k_{x,y} = \sqrt{(n + 1/2)2m_e\omega_c/\hbar}$$

All permitted states lie on concentric tubes parallel to the magnetic field called Landau cylinders. The energy levels belonging to a certain n are highly degenerate. The degeneracy D is given by

$$D = \frac{eBL^2}{h}$$

This is the ratio between the magnetic flux BL^2 through the sample and the flux quantum h/e. The degeneracy is equal to the number of states contained in the adjacent interval of width $\hbar\omega_c$ of the electron spectrum in a zero field, that means, the adjacent states condense to the Landau tubes.

The cross-sectional areas of the Landau cylinders $S_k = \pi k_{x,y}^2$ are proportional to the applied magnetic field, that means, the Landau tube for a certain n increases as the field is increasing. In zero field, the electronic states are filled up to the Fermi level. In an increasing magnetic field, subsequent Landau levels pass through the Fermi energy and become depopulated (see **Figure 1**). This gives an oscillatory dependence to the free energy of the electronic system and to all other quantities derived from it. From the linear dependence of S_k on B, it can be easily derived that the oscillatory component must be periodic in $1/B$ with the frequency F of the oscillations given by the extremal cross section S_{extr} of the Fermi surface, as was first pointed out by Onsager:

$$F = \frac{h}{e}S_{extr}$$

Lifshitz–Kosevich (LK) Formula

In 1956, Lifshitz and Kosevich published a theory of the magnetic susceptibility of conduction electrons in a metal with an arbitrary dispersion law. The

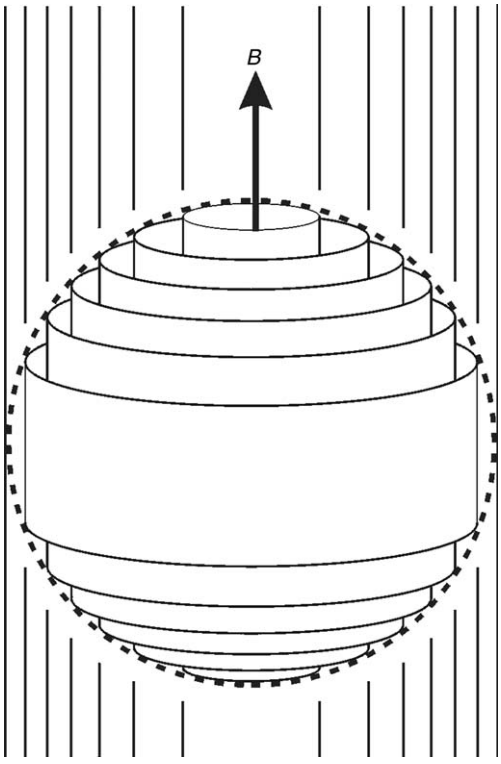

Figure 1 Schematic drawing of a spherical Fermi surface with Landau cylinders.

oscillatory part of their solution turned out to be a complete description of the experimental results of the dHvA-oscillations measured in moderate magnetic fields and is still the standard to compare experiment with theory. They calculated the thermodynamic potential Ω of a gas of quasiparticles. The magnetization is then given by the thermodynamic relation:

$$\boldsymbol{M} = -(\mathrm{grad}_{\boldsymbol{B}}\Omega)_{T,\mu}$$

The contributions to the oscillatory part come exclusively from the vicinity of the extremal orbits of the Fermi surface. For a certain extremal orbit, the oscillatory magnetization M parallel to the applied magnetic field is given by

$$M \propto \frac{F}{m}\left(\frac{B}{\partial^2 A_k/\partial k_z^2}\right)^{1/2} \sum_{p=1}^{\infty} \frac{1}{p^{3/2}} R_\mathrm{T} R_\mathrm{D} R_\mathrm{S} \times \sin\left[2\pi p\left(\frac{F}{B} - \gamma\right) \pm \frac{\pi}{4}\right]$$

F is the dHvA frequency, m is the cyclotron mass, $\partial^2 A_k/\partial k_z^2$ is the curvature of the cross-sectional area of the Fermi surface at the extremal orbit along the field direction, the factors R_T, R_D, and R_S are damping factors according to impurity scattering, temperature and spin, and γ is a value close to 0.5. The sign of the phase $\pi/4$ is dependent on the geometry: if the extremal orbit is a minimum, the sign is $+$; for a maximum, it is $-$. In normal situations, the cyclotron energy $\hbar\omega_\mathrm{c}$ is much smaller than the Fermi energy and the oscillatory magnetization is dominated by the first harmonic in the summation over p.

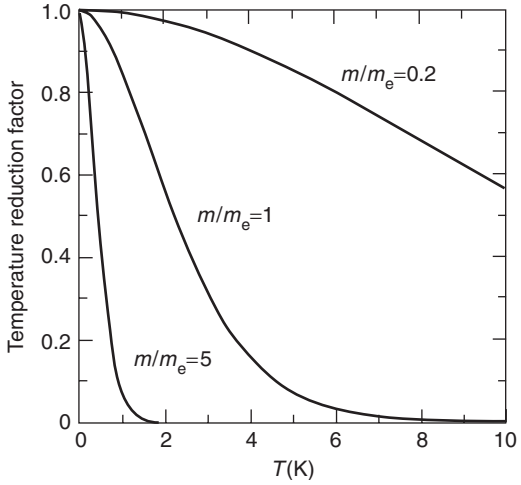

Figure 2 Temperature reduction factor of the fundamental frequency according to the Lifshitz–Kosevich theory at a magnetic field of 15 T for different values of the cyclotron mass.

In general, Fermi surfaces can be quite complicated and contain more than one extremal orbit. In that case, the total oscillatory component is a sum over all the contributions, each of which follows the LK formula, but with different parameters.

Without the reduction factors R_i the LK formula gives the idealized situation, where finite temperature, finite electron relaxation time, electron spin and other complications are neglected. At finite temperature, the occupation probability of a certain state with energy E is given by the Fermi Dirac function:

$$f(E) = \frac{1}{(1 + \exp((E - E_\mathrm{F})/kT))}$$

where k is the Boltzmann constant and E_F is the Fermi energy. This is a step function for $T = 0$ K but is smeared out by kT around E_F at finite temperature. This smearing leads to a reduction of the dHvA amplitude by the temperature reduction factor R_T:

$$R_\mathrm{T} = \frac{2\pi^2 pkmT/\hbar eB}{\sinh(2\pi^2 pmkT/\hbar eB)}$$

Typical dependencies of the reduction factor on the temperature at a magnetic field of 15 T are given in **Figure 2** for several values of the normalized cyclotron mass m/m_e.

Real crystals are always imperfect in some respect. This leads to a finite relaxation time τ of electrons, which is equivalent to a broadening of the Landau

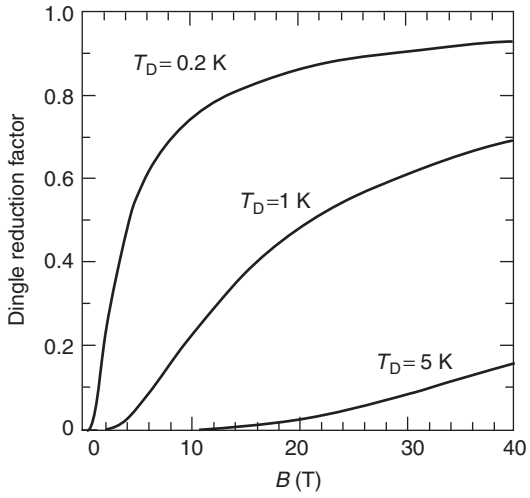

Figure 3 Dingle reduction factor of the fundamental frequency according to the Lifshitz–Kosevich theory for different values of the Dingle temperature. The cyclotron mass is set equal to the free electron mass.

levels. If this broadening is described by a Lorentzian distribution, the reduction of the oscillation amplitude is given by

$$R_D = \exp\left(\frac{-\pi p}{\omega_c \tau}\right)$$

This directly shows that the relaxation time must be long enough for the electron to complete a cyclotron orbit. The effect of impurities is similar to an increase in sample temperature. The reduction factor is generally given as

$$R_D = \exp\left(-\frac{2\pi^2 pmkT_D}{\hbar eB}\right)$$

with T_D being the so-called Dingle temperature, $T_D = \hbar/2\pi k\tau$. The influence of T_D on the oscillation amplitude is shown in **Figure 3** for free electrons ($m = m_e$). In samples with Dingle temperatures higher than a few kelvin, oscillations are hard to detect. Additional damping can be caused by sample and field inhomogeneities, mosaic spread, bending and strain on the sample, etc.

In a magnetic field, the spin degeneracy of the energy levels is lifted and each Landau level is split into two at energies $E \pm \frac{1}{2}\Delta E$ where

$$\Delta E = g\mu_B B$$

Here $\mu_B = e\hbar/2m_e$ is the Bohr magneton and g is the spin-splitting factor, which takes the value 2.0023 for free electrons. On increasing the field, the split Landau levels pass the Fermi surface at different field values. Therefore, a phase difference between these two oscillations arises and leads to a reduction of the amplitude by

$$R_S = \cos(\tfrac{1}{2}p\pi gm/m_e)$$

For free electrons the spin reduction factor is just $(-1)^p$, since the spin-splitting is equal to the Landau level spacing. In special cases, if $pgm/m_e = 1, 3, 5, \ldots, R_s$ becomes zero and the oscillation amplitude vanishes. This is called a spin-zero. The relation also shows that in the spin-zero of the fundamental frequency ($p = 1$), the second harmonic becomes maximal.

Other Oscillatory Quantities

The standard method for the determination of Fermi surfaces of metals is the dHvA effect. But as mentioned above, the dHvA oscillations were derived from oscillations of the thermodynamic potential Ω. Therefore, it is clear that all other physical properties derived from Ω show an oscillatory behavior in a high magnetic field and there are many experimental investigations of these effects. Examples are the specific heat, magnetostriction, elastic properties, and the chemical potential. Oscillations of the chemical potential play an important role in quasi-two-dimensional (Q2D) systems as discussed later. In 3D systems, they are usually weak and can be neglected in most cases. Another important quantity, which can be derived from the thermodynamic potential or calculated in a similar way, is the density of states at the Fermi energy.

There are oscillatory effects which cannot be described by thermodynamic relations alone since they involve nonequilibrium properties. The most famous example for it is the SdH effect, the oscillatory property of the magnetoresistance. As mentioned above, magneto-oscillations were first observed in the magnetoresistance of Bi in 1930. But it turned out that the SdH effect is very weak in normal metals and hard to detect there. In recent years the SdH effect has been of high importance, since it is easy to observe in Q2D electron systems such as quantum well structures or organic metals.

The theory of the SdH effect is complicated since it involves the problem of electron scattering in a magnetic field. In 1959, E N Adams and T D Holstein calculated the oscillatory conductivity for two different scattering mechanisms and found similar results in both cases. They concluded that the exact nature of scattering is not very crucial. Their result for the case of phonon scattering and high quantum number is the following:

$$\frac{\tilde{\sigma}}{\sigma} = \frac{R_T \frac{5}{2}\tilde{N}}{N_0}$$

where $\tilde{\sigma}$ is the oscillatory part of the conductivity, σ the steady conductivity, R_T the temperature reduction factor and $\tilde{N}, N_0$ are the oscillating and steady parts of the density of states at the Fermi energy, respectively. This result can be understood qualitatively by an argument of Pippard: the probability of scattering is proportional to the number of states in which the electrons can be scattered. Therefore, the conductivity is related to the oscillations of the density of states. The SdH effect is described by the same reduction factors as the dHvA effect. R_S and R_D are already involved in $\tilde{N}$. Finally, one should mention that the oscillatory part of the density of states and thus the oscillatory conductivity is proportional to the derivative of the magnetization dM/dB.

Two-Dimensional Case

The above mentioned theories for the dHvA and SdH effect were calculated for an isotropic case, that is, for a spherical Fermi surface. It turned out that they can also describe anisotropic systems with ellipsoidal or even warped cylindrical Fermi surfaces well. But in the pure 2D case, the theory is no longer applicable. From a theoretical point of view, it turned out that the 2D case is in some respect more difficult to calculate than the 3D one, and up to now, analytic solutions are available only for limiting cases.

Typical examples for Q2D electron systems are layered metallic compounds. The energy spectrum is usually given by

$$E_k = \frac{\hbar^2}{2m}(k_x^2 + k_y^2) - 2t\cos(k_z d)$$

with t being the interlayer transfer integral, k_z the wave vector perpendicular to the layers, and d the interlayer distance. This yields a cylindrical Fermi surface with a slightly oscillating cross section along the k_z direction (warping). In the case of $2t \gg \hbar\omega_c$, the system can be well described within the LK theory. In that case, there exists a minimal and a maximal cyclotron orbit and one expects two nearby frequency components in the dHvA spectrum (see **Figure 4**).

When the transfer integral becomes comparable to the Landau level separation, the LK theory is no longer appropriate and for $2t \ll \hbar\omega_c$, the system is very near to the pure 2D case. In that case, the whole Fermi surface is extremal and one expects large oscillations. It is also clear that the assumption of a field independent chemical potential is, generally speaking, no longer valid. For a constant number of electrons, one would rather expect jumps in the chemical potential periodic in $1/B$. In the extreme 2D case, the Fermi energy lies between two Landau levels. The chemical potential is fixed to the highest occupied Landau level and when this level is depopulated by increasing the field, the chemical potential will jump to the next lower Landau level. A sawtooth form of the magnetization oscillations is expected for that case and was indeed observed in artificially grown 2D electron gases. The other limiting case of a fixed chemical potential can be fulfilled by oscillations of the total number of electrons due to an infinite reservoir. This situation is probably given in some organic metals where a Q1D band is present beside the 2D one.

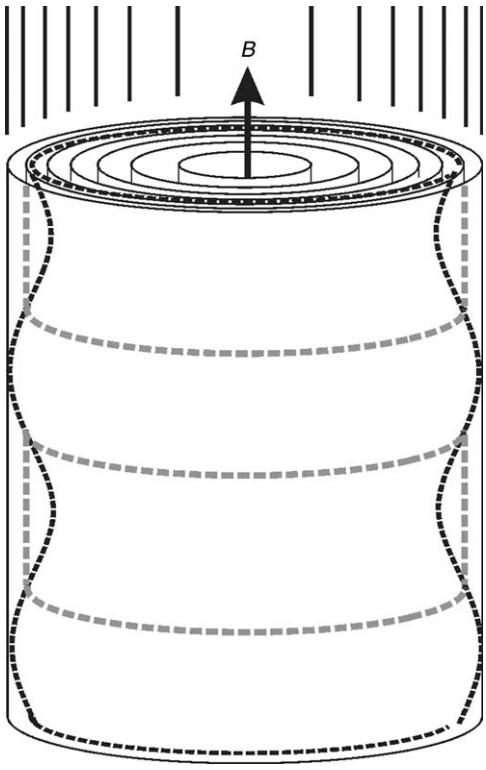

Figure 4 Slightly warped cylindrical Fermi surface (black dashed line) of a Q2D metal with Landau cylinders. The magnetic field is applied perpendicular to the conducting plane.

Analysis of Data

In a typical experimental investigation of the quantum oscillations, the first quantity to derive is the oscillation frequency. The oscillatory signal measured in a certain interval of the magnetic field and plotted against $1/B$ is transformed by a Fourier transformation into a power spectrum. This gives the frequencies of the different extremal orbits of the Fermi surface and – if present – their higher harmonics. Repeating this procedure for different field directions allows one to reproduce the complete Fermi surface. One should mention that the frequency only gives the cross section of the extremal orbit, but cannot show the deviations from a circular form.

A comparison with the LK theory gives further information. If the oscillation amplitude is measured at different temperatures, a least-square fit of the temperature reduction factor to the experimental data directly yields the effective cyclotron mass m of this extremal orbit. The magnetic field dependence of the oscillation amplitude at constant temperature is given by the product of the Dingle factor R_D and B^n, where n depends on the experimental method. Knowing the effective mass m from the temperature dependence, one can extract the Dingle temperature by a least-square fit of the field dependence.

Finally, the spin reduction factor R_S can be used to determine the spin-splitting factor g. In most cases, there is an intrinsic ambiguity in the determination of the g-factor and only a series of possible values can be derived. A special situation is given in the layered organic metals. Due to the relatively high effective mass m and the angular dependence of m, usually a whole series of angles appears, where the oscillation amplitude vanishes due to R_S. This allows one to determine the product gm/m_e without ambiguity.

Special Cases

Magnetic Interaction, Condon Domains

Normally, the oscillating part of the magnetization $\mu_0\tilde{M}$ is much smaller than the applied magnetic field B_a. Therefore, in the LK theory the inner magnetic field B_i was taken as the applied field B_a. In some cases (very pure metals with large Fermi surfaces, low temperature), this assumption is no longer valid as was first observed by Shoenberg in very pure samples of gold. To analyse his data, he started with the LK-equation for the first harmonic and replaced B by B_i. He could show that the condition

$$a = \mu_0 \left| \frac{d\tilde{M}}{dB} \right| \ll 1$$

must be fulfilled for the LK theory to be fully applicable. If the factor a is smaller than 1 but of the same order of magnitude, the observed oscillations show an increased harmonic content and, if several different orbits are involved, the occurrence of combination frequencies is expected. In these cases, one has to take into account the demagnetization factor n of the sample shape also.

If the factor a becomes larger than 1, the magnetization of the sample is no longer a single-valued quantity of the applied field. This is thermodynamically unstable and leads to jumps in the magnetization. As first proposed by Condon, under this condition a sample with a demagnetization factor $n > 0$ will split up into magnetic domains with two different values of the magnetization. The existence of these domains could be shown by NMR and muon spin rotation experiments. Up to now, clear evidences for Condon domains are reported in high-quality samples of silver, beryllium, white tin, aluminum, and lead.

Magnetic Breakdown and Quantum Interference

The Fermi surface of a metal can be completely described within the first Brillouin zone. Any constant energy surface exceeding this zone belongs to higher bands and can be folded back to the first Brillouin zone. It was therefore very exciting, when in the beginning of the 1960s, Priestly reported the observation of a dHvA orbit in Mg, which was considerably larger than the hexagonal cross section of the Brillouin zone. The explanation for this observation was given by Cohen and Falicov, who pointed out that electrons could tunnel from one band to another, if the bandgap E_g between these two bands is sufficiently small and the magnetic field strong enough. It is evident that this could happen, when the bandgap is comparable to or smaller than the Landau level separation $\hbar\omega_c$, but Blount could show that the much weaker condition

$$\hbar\omega_c \geqslant \frac{E_g^2}{E_F}$$

is valid, with E_F being the Fermi energy. Since typically $E_g/E_F \ll 1$, magnetic breakdown could happen in quite low magnetic fields.

For the theoretical description of magnetic breakdown, a simple hypothetical model of a free electron gas in a 1D crystal potential was introduced as shown in **Figure 5**. At the zone boundary, a small gap opens and the Fermi surface consists of a closed (α-orbit) and an open part. At very high magnetic fields, electrons can tunnel through the gap and a new much larger closed orbit (β-orbit) is observed. At intermediate magnetic fields, a complicated spectrum with sum and difference frequencies of α- and β-orbits will appear. The case – first thought as hypothetical – was in the meantime verified in artificial heterostructures and in organic metals such as (BEDT-TTF)$_2$Cu(NCS)$_2$ and is of high interest at present.

In systems, where magnetic breakdown is present, one often finds a striking difference in the frequency spectrum of dHvA and SdH oscillations. The SdH oscillations typically show additional frequencies not present in dHvA. These differences can often be described by quantum interference effects as introduced first by R W Stark and C B Friedberg: it is possible to have magnetic breakdown between orbits, along which electrons move in the same direction; if

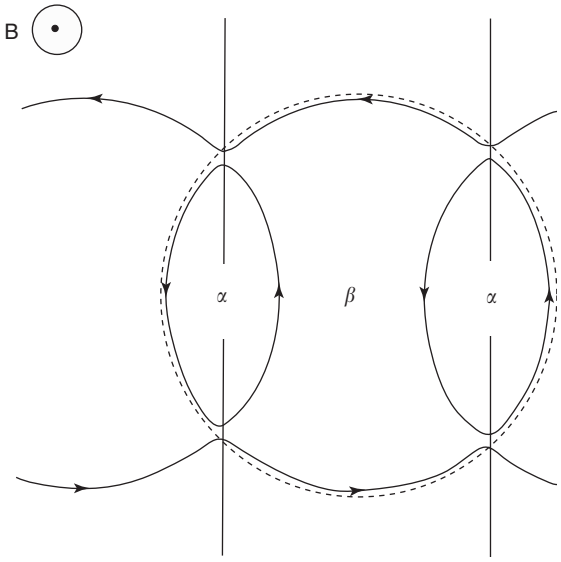

Figure 5 Model Fermi surface for magnetic breakdown: at small fields the carriers are fixed to the closed α-orbit or the open orbit above and below, at high magnetic fields the carriers can tunnel through the gap and a larger closed orbit (β-orbit, dashed line) becomes dominant.

electrons moving from point A to B can travel along two different paths connected by magnetic breakdown, interference effects yield an oscillatory contribution in transport measurements with the frequency determined by the area between the two paths. Since this represents not a closed orbit, these frequencies are not detected in thermodynamic quantities such as dHvA oscillations.

Experimental Techniques

Orders of Magnitude

Quantum oscillations are periodic in the reciprocal magnetic field. Therefore, the unit of the oscillation frequency is tesla (T). Typical values range from a few T to $\sim 50\,000$ T. Low-frequency oscillations are easier to detect and can be often observed up to temperatures of 10–20 K. The observation of high-frequency oscillations requires usually low temperatures ($T < 4$ K), and high and homogeneous magnetic fields. (The oscillation period of a 50 kT frequency amounts to 20 μT at $B = 1$ T.) The observation of oscillations in the heavy fermion compounds needs dilution fridge temperatures for detection. This can be easily verified by calculation of the temperature reduction factor R_T with high effective cyclotron masses.

Optimal relative amplitudes of the oscillatory magnetization $\mu_0 M/B$ are $\sim 10^{-5}$, which is comparable to steady susceptibilities of weakly magnetic materials. The sensitivity of magnetization experiments is often improved by measuring dM/dB (see below). The oscillations in the resistivity are experimentally observed mainly in semimetals and under magnetic breakdown conditions. In recent years, the SdH effect plays an important role in layered metals and quantum well structures. In both cases, the oscillatory amplitude can exceed the background resistance in high magnetic field considerably.

Magnetic fields are typically produced nowadays by superconducting magnets. The maximum field available in laboratories lies between 8 and 20 T. Higher steady magnetic fields can be obtained in some high-field magnet laboratories running high-power (typically, 10–25 MW)-resistive or superconducting-resistive hybrid magnets. These laboratories are usually open for users and can offer magnetic fields between 20 and 45 T. For even higher magnetic fields, some pulsed field facilities are operated. For the study of metallic samples, they can produce magnetic field pulses of duration between a few ms and 1–2 s with maximal fields between 35 and 70 T.

de Haas–van Alphen Techniques

The above mentioned magnitude of the oscillatory effect shows that the standard techniques for measuring small magnetic susceptibilities are often sufficient for the observation of the dHvA effect. But for observation in less favorable circumstances, techniques with very high sensitivity are needed. It should also be mentioned that the high degree of field homogeneity required for the observation of high-frequency oscillations makes the Faraday method less suitable. The two mostly used methods are discussed in the following.

Pickup coil techniques This technique is similar to the well-known mutual inductance method for AC-susceptibility measurements. The sample is placed in a pickup coil system consisting of two identical coils connected in series with opposite signs so that the voltage induced by a changing magnetic field is zero. If a sample is placed in one of the coils, the induced voltage will be

$$U \propto (dM/dB)(dB/dt)$$

The proportionality constant is determined by the geometry. For the arrangement of the two balanced coils, many possibilities exist. Due to limited space of high homogeneity in a magnet, the two coils are often wound one after the other on the same coil core. In the standard laboratory method, the applied magnetic field B is superimposed by an oscillatory contribution $b(t) = b_0 \cos(\omega t)$, with typical frequencies ω

lying between 20 Hz and a few kHz. The oscillation amplitude b_0 can be appropriately chosen for the system under consideration. It should be smaller or comparable to the period of the dHvA oscillation. The modulation field method allows the use of phase-sensitive detection via lock-in amplifiers, which considerably improves the signal-to-noise ratio. In addition, this allows detection at different harmonics of the modulation frequency.

The signal amplitude of the different harmonic contributions A_p of the LK theory is given by

$$U_p^{(k)} \propto k\omega J_k\left(\frac{2\pi pFb_0}{B^2}\right)A_p$$

for detection at the kth harmonic of the modulation signal, J_k is the kth order Bessel function. Some disadvantage of this method is the fact that the weight of the harmonics is changed: in case of high harmonic content, the observed waveform deviates from the real one and has to be recalculated. On the other hand, this can be used for suppressing a certain harmonic by working near the corresponding Bessel function zero, and therefore having increased sensitivity for other weak oscillations.

The changing magnetic field may be also produced by a pulsed magnetic field. In that case, the induced voltage is first amplified and then recorded by a fast data acquisition system. In both methods, a self heating of the sample due to eddy currents must be avoided.

Torque method If the Fermi surface of a given metal deviates from spherical symmetry, that is, if the characteristic frequency F of an extremal orbit is dependent on the field orientation, there exists a torque about any axis perpendicular to the magnetic field given by

$$\tau = -\frac{1}{F}\frac{\mathrm{d}F}{\mathrm{d}\theta}BVM$$

where, θ determines the angle between the magnetic field B and a characteristic direction in the plane perpendicular to the torque axis, V is the volume of the sample, and M is the parallel magnetization as given by the LK formula. The torque vanishes for some symmetry directions of the crystal, where either $\mathrm{d}F/\mathrm{d}\theta$ vanishes or two related parts of the Fermi surface cancel each other. In practice this is often not a problem, since the missing angular range is very small and can be easily interpolated. In case of large oscillations, the torque should be measured by a feedback system to avoid problems due to slight changes of the sample orientation (torque interaction). A strong advantage

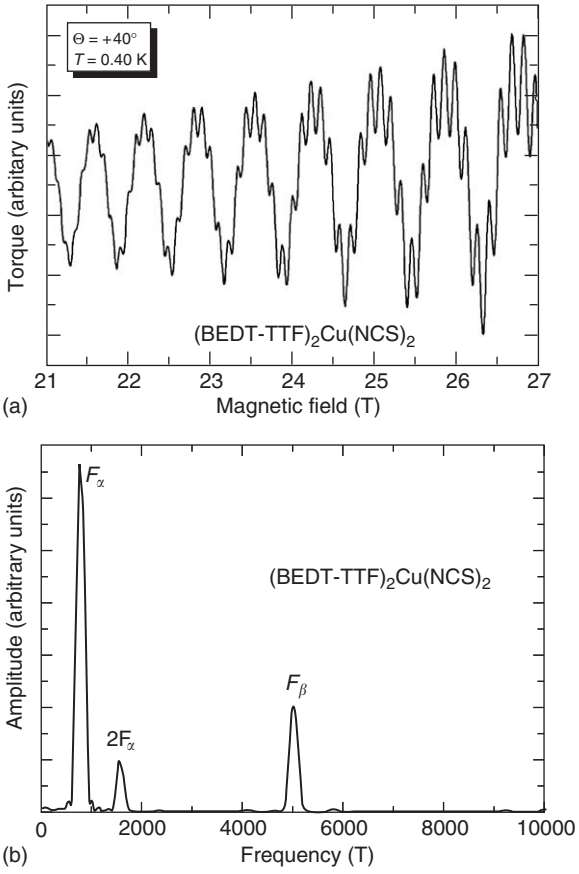

Figure 6 (a) Magnetic torque oscillations in very high magnetic fields showing magnetic breakdown. The sample is a small ($m = 80\,\mu g$) single crystal of the organic Q2D metal κ-(BEDT-TTF)$_2$Cu(NCS)$_2$. The tilt angle between the direction of magnetic field and the normal to the conducting layers is 40°. (b) Corresponding Fourier transform of the data in (a). The spectrum clearly shows the first and second harmonic of the α-orbit and the breakdown frequency F_β (see **Figure 5**).

of this method is the robust and easy set-up and the ease of calibrated measurements. Calibrated measurements are of importance for determining the curvature factor of the extremal orbit in the LK formula. A typical example of an oscillatory magnetic torque is shown in **Figure 6**.

The torque method is one of the first techniques applied by Shoenberg already in 1939, but is still in use in many cases. Whereas the first experiments used the torsion of a wire and optical detection, most of the present devices are based on capacitive detection of the torque. In a simple arrangement, the sample is placed on a small platform on a cantilever. The displacement of the platform is determined by a measurement of the capacitance between the platform and a fixed plate. Adding a calibration coil to the platform allows calibrated measurements. Nowadays, such cantilever spring torquemeters can be fabricated from a silicon wafer using lithographic

techniques. Miniature devices of this kind were even used in pulsed field experiments.

Shubnikov–de Haas Techniques

Measurements of resistance always require a four wire arrangement: a current is applied to the sample via two contacts and the voltage drop between two other contacts is measured. For absolute measurements of the resistivity, the sample should be in a well-defined geometry to assure homogeneous current flow. The application of an AC- current with typical frequencies between 10 and a few hundred Hz allows phase-sensitive detection via a lock-in amplifier. For low-temperature experiments, the current must be small enough to avoid self-heating of the sample.

As mentioned above, the SdH effect is hard to detect in pure metallic elements. At present many SdH studies are carried out in 2D systems. In artificially produced 2D layers, the geometry is easy to adjust by using suitable masks. The typical arrangement is a rectangular bar with current contacts at both short sides and typically two additional contacts on both sides for voltage measurements. This allows one to measure the resistance and Hall effect at the same time. (For the calculation of the conductivity of a pure 2D system, both quantities are needed). In bulk-layered metals the in-plane resistance is often difficult to determine, since the crystals are usually very tiny and the arrangement of well-defined contacts with a homogeneous current distribution is difficult to accomplish. Therefore, most researchers use the interplane resistance for the determination of the SdH effect in these compounds. In that case, a current and a voltage contact are placed on both the large sides of a crystal. Due to very high anisotropy in the resistance (10^3 and more) in these compounds, the interplane resistivity is measured with high accuracy.

Silicon, History of

F Seitz, Rockefeller University, New York, NY, USA
N G Einspruch, University of Miami, Coral Gables, FL, USA

In 1781, Henry Cavendish discovered that water is not a primary chemical element, as had been believed for millennia, but a compound formed by the combination of hydrogen and oxygen. This discovery provided Antoine Laurent Lavoisier with insight concerning the true nature of the elements and stimulated him to undertake extensive experimental investigations in a search to identify as many elements as possible. His views were formalized in 1789 by the publication of a two-volume treatise (**Figure 1**) that provided the platform for the evolution of modern chemistry.

In his search for new elements, Lavoisier commonly attempted to reduce with hydrogen what were presumably compounds of the elements, a procedure that was particularly successful with the heavy metal oxides. In the course of this work, he decided that the mineral quartz was probably the oxide of an interesting element, but failed in his attempts to reduce it. A quarter of a century later, the distinguished Swedish chemist Joens Berzelius (**Figure 2**) finally achieved that goal. The newfound element ranked as an oddity. While it had some of the characteristics of a metal, such as a somewhat shiny metallic luster and the ability to conduct electricity, its conductivity was poor compared to that of silver and copper and decreased rather than increased as the temperature was lowered.

Since no immediate use was found for it, early samples of silicon were in the main assigned an honored place within exhibits of the chemical elements. However, the situation with respect to silicon changed radically during the last quarter of the nineteenth century, by which time professional chemists, well-trained

in scientific methods, were in charge of research and development in fields such as metallurgy, ceramics, enamels, pigments, and dyes, replacing the ancient breed of investigators who had depended with some degree of success upon tradition, hunches, and mysticism. There was, for example, much interest at this time in the study of the magnetic properties of iron and its alloys that were being used in electric generators, motors, and transformers for many power-handling applications. Systematic research disclosed the existence of a family of iron–silicon alloys whose magnetic properties were much better than those of pure iron for many purposes. Moreover, relatively modest additions of silicon to some forms of steel could confer superior properties in matters such as toughness. In any event, silicon had finally become a very useful element in technical application and was beginning to be produced commercially at a level of ~98% purity.

During this same period, two other developments that were to influence the use of silicon in fields of technology occurred. First, a young German physicist, Dr. Ferdinand Braun (**Figure 3**), decided to extend prior research carried out earlier by Michael Faraday on the electrical properties of materials that were neither good insulators nor good electrical conductors. His target group included some ionic crystal, such as salts that permit ionic conductivity, and what are now called semiconductors, which were found

Figure 3 Ferdinand K Braun who discovered rectification in semiconductors in 1874, soon after completing his doctorate. He became one of the foremost leaders in the field of radio technology during his time. He demonstrated the important role that resonant circuits can play in long-distance transmission. He shared a Nobel Prize with Marconi in 1909. (Courtesy of the Tuesday Morning Club of Tübingen, the library of the University of Tübingen.)

Figure 4 Reginald A Fessenden, the prolific Canadian inventor who invented amplitude modulation (AM) radio, introduced rectification and the heterodyne principle which made it possible to alter the frequencies of electromagnetic waves. He was also responsible for the first two-way wireless transmission across the Atlantic Ocean on a steady basis and for the invention of sonar. (Courtesy of the Fessenden collection of the Archives of the State of North Carolina in Raleigh, North Carolina.)

eventually to conduct electronically. Both types of substance are distinguished by the fact that their electrical conductivity decreases toward zero at sufficiently low temperatures. Working with specimens of semiconductors, particularly with heavy metal sulfides, Braun discovered crystal rectification in 1874, that is, asymmetrical flow of current in a crystalline specimen for a given voltage when applied in opposite directions. In the course of his investigations, he demonstrated that it was a surface effect, Ohm's law connecting the current and field strength being valid in the bulk of the specimen.

The second significant development was Heinrich Hertz's production of electromagnetic radiation in the meter and shorter range of wavelength with hand-fabricated condensers, inductance, and antennae. This generated widespread interest in the possibility of long-range transmission and reception of such waves, a goal that was led in a very dynamic way by Guglielmo Marconi.

Initially, the propagation of an electromagnetic wave was detected by means of an ingenious device known as the coherer, invented in 1890 by the French physicist Edouard Branly. The coherer contained a bundle of metallic needles that aligned parallel to one another when an electromagnetic wave passed through the needles, thereby altering the collective electrical conductivity of the bundle.

Apparently, at some time toward the end of the 1890s, the prolific Canadian inventor Reginald A Fessenden (**Figure 4**) discovered that one can hear the electromagnetic pulses with earphones of the type used in telephones, provided one rectifies the electric current produced by the signals so that the resulting

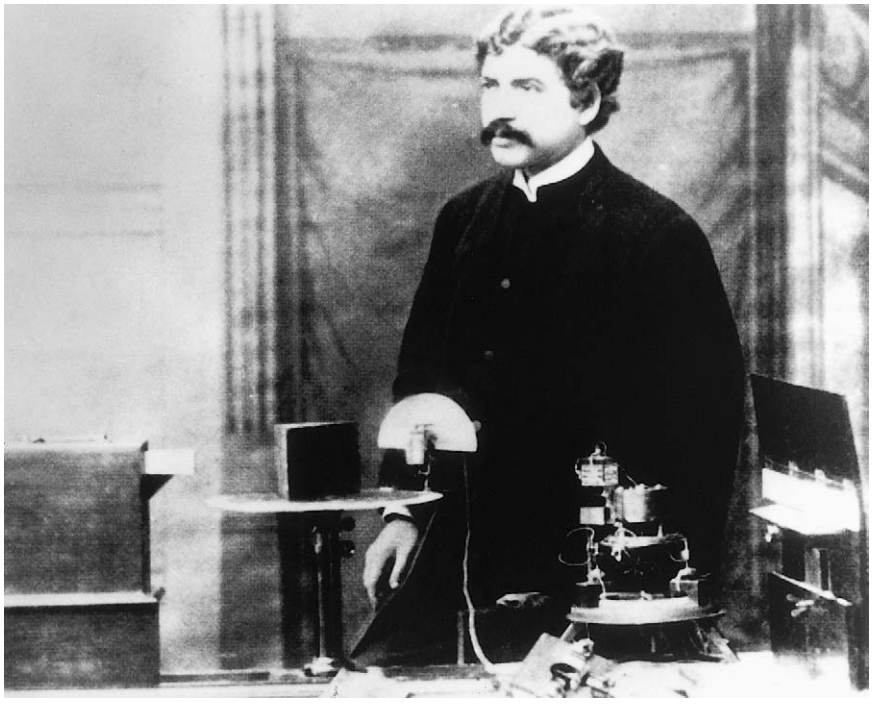

Figure 5 Jagadish C Bose who was at Cambridge University in England when Hertz published his papers on the generation of electromagnetic waves. Bose immediately began research in the centimeter and millimeter range of wavelengths. He invented many items of apparatus that were later re-invented in the 1930s, during the early days of microwave radar. He was the first person to employ a semiconductor (galena) as a rectifier. (Courtesy of the Jagadish Chandra Bose Research Institute, Calcutta, India.)

pulse contains frequencies in the audible range to which the earphones could respond. He invented a rectifier consisting of a wire dipped in an electrolytic solution. Soon after, a brilliant young Indian physicist, Sir Jagadish Chandra Bose (**Figure 5**), who was studying at Cambridge University when Hertz published his research and had done much to improve the coherer, patented the use of crystalline lead sulfide (the mineral galena), a rectifying semiconductor of the type discovered by Braun, as a replacement for the electrolytic device. This represented a very significant milestone in the development of solid-state electronics. Incidentally, Marconi was greatly assisted in his work by a very competent group of electrical engineers of the Italian Navy, who kept abreast of most technical developments in the field. He presumably used a semiconductor rectifier in his first successful transatlantic transmission in 1901.

In 1900 the American Telephone and Telegraph Company (AT&T) served only local communities because of limitations in the distance over which copper wire would transmit voice messages without amplification. The principal city was New York. The management of the company soon decided, however, that it should develop a national network in order to provide more uniform, consolidated service throughout the country. As a result, AT&T began to assemble an excellent technical staff to assist in determining the best route to follow. The range of possibilities included use of a wireless system. Dr. G W Pickard (**Figure 6**), a member of the technical staff who had become interested in the possibility of employing wireless communication, decided to see if there was a crystalline rectifier that was superior to galena. It is reported that he investigated more than a thousand compounds. In any case, carefully selected crystals of the commercially available grade of silicon turned out to have the best properties of all the specimens included in his search. The management of AT&T permitted him to set up an independent company to market the silicon rectifiers he developed.

In the meantime, many scientists began to study the properties of the electron beams (cathode rays) that could be produced in a vacuum from a negatively charged electrode. One of the investigators, John A Fleming, showed that a device containing such an electron source and a positively charged collecting electrode could serve as a rectifier. Subsequently, Dr. Lee De Forest demonstrated that one could add a third electrode to Fleming's rectifier and use it to modulate the magnitude of the collected current. With appropriate feedback, De Forest's triode could be used as the basis for creating an electronic amplifier or an oscillator. Since vacuum technology was fairly primitive at the time, the early versions of the two devices behaved in an

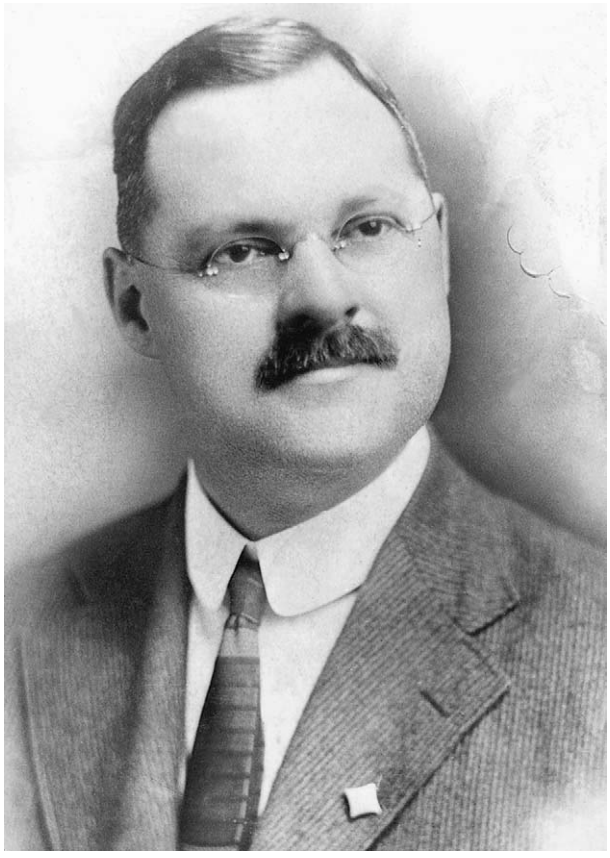

Figure 6 G W Pickard who, in 1905 while working for AT&T, made a thorough search among available semiconductors to find the best rectifier. He concluded that silicon was the preferred choice and began marketing units that contained good specimens. unpredictable manner and were generally treated as interesting curiosities.

However, the technical staffs of AT&T and the General Electric Company, as well as scientists and engineers in other countries, recognized the importance of the principles involved in De Forest's invention and began to improve both vacuum tube diodes and triodes. By 1915, the telephone system established by AT&T, which incorporated greatly improved vacuum tube relay-amplifiers, was able to span the continent. By the end of World War I, essentially the entire field of electronics was in the hands of vacuum tube experts. Semiconductors were almost forgotten, although inexpensive cuprous oxide and selenium rectifiers were widely used to rectify ordinary fifty- or sixty-cycle current for special purposes, such as providing rectified current to vacuum-tube filaments. As amusement, individuals in their early teens commonly made simple, inexpensive crystal-detector radio receivers that enabled them to listen to local broadcasting stations using earphones. Galena was generally used as a rectifier in such sets. Many older boys entered the world of vacuum tube technology when they could afford to acquire such tubes.

Fortunately, semiconductors were not completely forgotten since they display two important characteristic properties: they do not need a specially designed cathode and associated energy source since some conduction electrons become free at ambient temperatures; as such, semiconductors could be fabricated into monolithic devices whose useful lifetime was not determined by burn-out or other factors that influence vacuum tubes. In continuous operation at full power, a typical vacuum tube has a lifetime of $\sim$1000 h. To overcome this major limitation, a number of individuals attempted to develop a triode analog of the De Forest tube using semiconductors prior to World War II. Some inventors succeeded in obtaining conceptual design patents for proposed devices, but none were actually "reduced to practice."

One of the individuals who took this issue very seriously in the 1920s was Dr. Mervin J Kelly (**Figure 7**), who was then in charge of the production of vacuum tubes at the Western Electric Company, the

manufacturing arm of AT&T. He was thoroughly conscious of the limitations of vacuum tubes and was captivated by the thought of replacing, or at least complementing, them by semiconductor devices. He decided that if he were ever made Head of the Bell Telephone Laboratories, he would establish a team to explore semiconductor-based technology fully. He became head of the Laboratories in the mid-1930s and, in keeping with his plans, hired Dr. William S Shockley, a doctoral graduate of the Massachusetts Institute of Technology, to join forces with Dr. Walter H Brattain, who was already at the Laboratories, in characterizing the properties of various semiconductors. While they made a preliminary study of cuprous oxide, they were diverted to other problems as World War II approached. Kelly's plan was forced to await the end of the war.

Research and development in the field of radar was a major activity among scientists and engineers during World War II. Although many significant investigations were carried out earlier, the first microsecond pulsed radar was developed in 1932 by an ingenious engineer, Dr. Hans E Hollmann, who used it to study the reflections of electromagnetic waves from the ionosphere in the upper atmosphere of the Arctic region – the layers that make transmission of radio waves in the kilohertz and lower megahertz region of the radio spectrum possible over long distances on the curved earth. He observed the reflected pulses on an oscilloscope with a synchronized time sweep and found that he could pick up features of the landscape such as mountain ranges. The German Navy used this knowledge to produce its first radar system soon thereafter. It operated with wavelengths in the vicinity of 2.4 m. Dr. Robert Page achieved the first comparable development in the US at the Naval Research Laboratory in 1939, delays in funding having retarded research that was initiated in the 1920s.

It should be added that Hollmann so distrusted Hitler and his plans for world conquest that he discontinued all research that might be employed in offensive warfare and focused on medical applications of electronics. While making the shift, however, he wrote a two-volume treatise in the field of high-frequency electronics that was by far the most advanced work of its kind when it appeared in 1936. At the end of the war, he migrated to the US at the invitation of the government and became an expert consultant to industry during the early development of transistor technology.

In the meanwhile, the British, French, and Russians were pursuing the development of radar for their own military needs. In addition to carrying on research in the meter range that was to be used in the long-range perimeter defense of their island, the British were eager to increase the resolution of radar images and decrease the size and weight of equipment for airborne and other critical uses. To achieve this purpose, they extended their research to the decimeter and centimeter range of wavelengths. Consequently, a young English engineer, Denis M Robinson (**Figure** 8), who had been employed in servicing British television transmitters, which had broadcast programs several times a week until 1939, found himself seconded to a secret laboratory in Scotland by The Telecommunications Research Establishment (TRE), the agency that was guiding radar development in Britain. He was instructed to produce a radar system that could operate at a wavelength of 10 cm.

Figure 8 Denis M Robinson who decided early in WWII, and after reading the treatise on microwave technology written by Hans Hollmann, to search for a semiconductor that could serve as a suitable heterodyne mixer in the 10 cm range of wavelengths. He joined forces with HWB Skinner who determined that commercially available silicon would serve their immediate purpose adequately. (Courtesy of the book *Five Years at the Radiation Laboratory* (Massachusetts Institute of Technology, 1946). Reprinted by IEEE in International Microwave Symposium, 1991.)

The means to generate and transmit such radiation was already available. Devising appropriate equipment to process and display the return signal, however, presented a problem. What Robinson needed most was a nonlinear device, or "mixer," that had the capability of converting the reflected return signal to a frequency that could be handled by available amplifiers and the auxiliary equipment involved in display. There was no

available vacuum tube, such as a rectifier, that could serve as a mixer in the low centimeter range. Developing one during wartime would take valuable time with an uncertain outcome. He went to a University library nearby and found Hans Hollmann's two-volume treatise mentioned above. This treatise asserted that crystal rectifiers could be useful as rectifying detectors in the centimeter range of wavelengths. Robinson remembered the use of galena from his teen years and decided to team up with Dr. H W B Skinner, previously at the University of Bristol and later also at TRE. The latter was much more familiar with the so-called solid-state devices than Robinson was. After some deliberate investigations, Skinner ascertained that selectively chosen specimens of silicon, available in its somewhat variable impure metallurgical form, would provide the answer to their immediate problem of fabricating a mixer. It is interesting to note that Dr. R S Ohl, working in the field of microwave research at the Bell Telephone Laboratories in close cooperation with Dr. G C Southworth, had recently come to the same conclusion in a search for a suitable detector, thereby reaffirming the conclusion reached by his former colleague, Dr. G W Pickard, some thirty years earlier at the start of wireless communication.

When the government of France fell before the advancing German army in May of 1940, a high-level group of French scientists and engineers had been involved in research on a very advanced form of microwave generator known as the cavity magnetron. It operated at wavelengths in the vicinity of 16 cm. At one of the last possible moments, Maurice Ponte, one of the leaders of the French group, flew their working model to England, where it added significantly to the development of the magnetron being carried on there. The French, it turned out, had not yet faced up to the problem of searching for the best heterodyne mixer in that wavelength range and marveled in their turn at the effectiveness of the silicon diodes that the British were using.

Once France had fallen and Britain was isolated from any immediate help from the continent, Winston Churchill decided that he must form the closest possible relationship with the US, which was still formally neutral but was preparing to become fully armed. As a positive step, Churchill offered to share with the US all secret technical research with which Britain was involved, including its developments in radar. President Franklin D Roosevelt readily agreed to the plan and established an Office of Scientific Research and Development within the Executive branch of the government.

In further keeping with Churchill's suggestion, Roosevelt selected two highly respected scientists to head the office, namely James B Conant and Vannevar Bush, the former from Harvard and the latter from the Massachusetts Institute of Technology (MIT). One of their first steps was to create the Radiation Laboratory, a radar research and development center, at MIT, to supplement on a large scale what the British had already been developing, with particular focus on applications in the microwave region. Dr. Lee A DuBridge, an already distinguished younger scientist-administrator, was selected to be the director; he would remain so throughout the war. The laboratory was rapidly staffed by a highly selective group of scientists and engineers, many from the top ranks of university faculties.

Most of the staff of the Radiation Laboratory were not familiar with semiconductors other than in a very peripheral way, such as the crystal radio sets of their early teen years. To them, the British-made silicon rectifier-mixers that were used for frequency conversion of the returning radar signals were both a curiosity and an abomination because of the great variability of the metallurgical-grade silicon used as starting material. Many on the staff felt that they should take the time to develop vacuum tube rectifiers that would operate in the microwave region.

Fortunately, DuBridge was familiar with research on crystalline solids and called on one of the authors of this article (FS) to see if a way to salvage the situation could be found. An excellent physical chemist, Dr. C Marcus Olson (**Figure 9**), in the Pigments Department of the DuPont Corporation near Wilmington, Delaware, found that he could produce a form of silicon that was uniformly pure to several parts in one hundred thousand by reacting purified silicon chloride with comparably pure metallic zinc. When this form of the element was properly treated with controlled additions of other elements that influenced its electrical conductivity, it could be used to produce highly satisfactory silicon diodes on a mass-production basis (**Figure 10**). Moreover, DuPont was prepared to manufacture the purer grade of silicon in practical quantities.

Once this point was reached, the Radiation Laboratory added a semiconductor section under the leadership of Dr. Henry C Torrey. It followed progress in industrial production and administered an extended research program, including research on diodes made from the semiconductor germanium, the sister-element to silicon, which found very special uses in situations in which the rectifier experienced high reverse voltages. Both semiconductors permitted conductivity by both negative and positive carriers depending upon the addition of small controlled quantities of foreign elements, known as "dopants." The positive carriers ("holes") were associated with a dearth of electrons in what normally are fully occupied shells or bands of

Figure 9 Dr. CM Olson (center), on the staff of the Pigments Department of the DuPont Company. During the early part of World War II he developed a procedure for producing elemental silicon that was sufficiently pure to permit routine mass production of silicon diodes. (Courtesy of CM Olson.)

electron states in silicon. The empty states are equivalent to bubbles in a fluid, which will move opposite to the direction of any applied forces that cause acceleration of the fluid. The two types of conductors were designated *n*-type (negative) and *p*-type (positive), respectively.

When World War II ended, Dr. Kelly returned to the secret pursuit of a semiconductor triode armed with an increased staff and the extensive new knowledge of semiconductors gained during the war. Shockley was appointed head of the group and had the good fortune to attract John Bardeen, a highly experienced engineer-physicist who possessed strong background knowledge in solid-state science, as part of the team. Brattain who knew Bardeen well joined him in a remarkably productive working partnership (**Figure 11**).

As a first step, Shockley attempted to develop what later became known as the field-effect transistor in which the density of carriers in the bulk semiconductor is altered by application of an electric field transverse to the direction of current. He failed to achieve the desired effect and turned to other matters, leaving his colleagues to carry on. Bardeen suspected that the failure was a result of a temperature-related shift in surface charge that compensated the applied field within the bulk of the semiconductor. He and Brattain demonstrated this by repeating the experiment at temperatures sufficiently low so that the surface charges would be frozen. Much later, means of stabilizing the surface charge at normal operating temperatures were found and the resulting "field effect transistor" became an important member of the transistor family.

Figure 12 Gordon K Teal who successfully pursued the development of monocrystalline silicon-based transistors, first at the Bell Telephone Laboratories and then at Texas Instruments. (Courtesy of The American Institute of Physics Emilio Segre Visual Archives.)

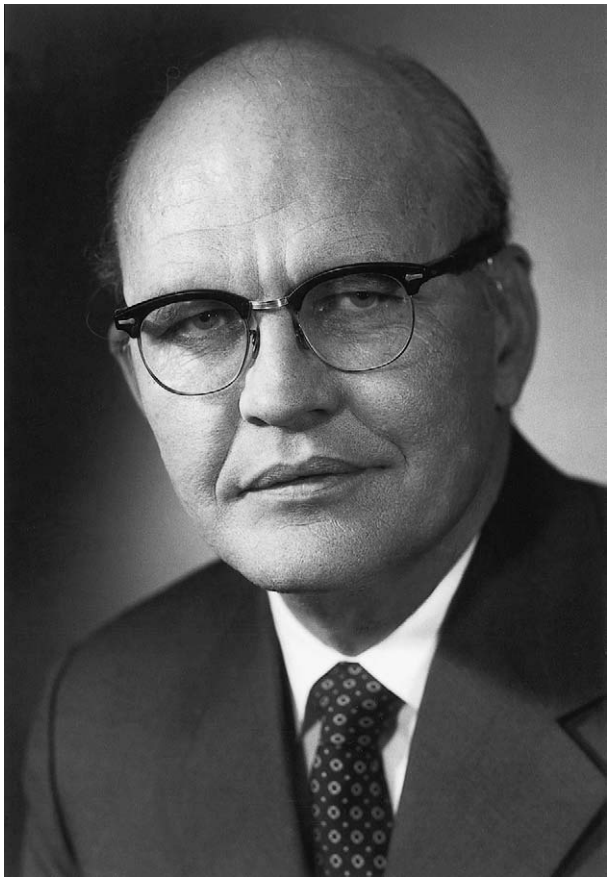

Figure 13 J S Kilby who invented the integrated circuit and received a Nobel Prize for it. (Courtesy of Kilby JS.)

While extending this research in December of 1947, Bardeen and Brattain invented, partly by chance, what became known as the "point-contact transistor." It was the first truly amplifying semiconductor triode. Shockley returned to research in this field at this point and invented what became known as the "discrete *p–n* junction transistor." The principles involved in its operation were to play a major role in the development of electronics during the next decade.

In the course of events, one of the members of the Laboratories developed a method for purifying germanium to a very high level that was particularly applicable to that element. As a consequence, Shockley mandated that all research on transistors under his direction be carried out with crystals of germanium. A courtly strong-minded Texan on the staff, Dr. Gordon K Teal (**Figure 12**), aware of the superior chemical and physical properties of silicon from wartime research, began to produce single crystals of it surreptitiously in his laboratory. Teal shifted his activity to Texas Instruments Incorporated, in Dallas, Texas, in 1953 when that company obtained a license from AT&T to produce transistors. The company gave him a warm welcome in his pursuit of the work on silicon. Methods were soon found to purify silicon to parts per billion and to improve crystal perfection, which Teal knew to be very important. The element became the mainstay of production of transistors, particularly when the beneficial characteristics of its relatively

Figure 14 A single crystal ingot of silicon having a diameter of 300 mm. Such an ingot is sliced horizontally into circular wafers whose surfaces become the site of integrated circuits. (Courtesy of H Fusstetter of Wacker and Siltronics AE.)

stable oxide were fully appreciated. Nevertheless, much research continued to be carried out with germanium. In fact, discrete transistors made of silicon or germanium were manufactured throughout much of the 1950s.

The invention of the integrated circuit by Jack Kilby (**Figure 13**) in 1958, led to previously unforeseen increases in circuit complexity, eventually at very low cost – a process requiring a good part of a decade. It was not clear at first whether such circuits, which permitted the creation and interlinking of vast arrays of transistors on a single silicon chip, would find uses other than in military applications where a premium price might be acceptable. By the mid-1960s, however, the most farsighted manufacturers began to express optimism. For example, in 1964 Patrick E Haggerty, the President of Texas Instruments, published a paper in the Proceedings of the Institute of Electrical and Electronics Engineers in which he stated that if the remaining problems of large-scale production were resolved in an economical manner, one could expect devices based on the use of integrated circuits to become "pervasive" in human affairs, creating a revolution in such matters as information processing, communications, and controls. A year later Dr. Gordon E Moore, then at Fairchild Semiconductor and later a founder of Intel, had the foresight and courage to predict that the cost of integrated circuits would soon go through a period in which the cost per transistor would be halved about every eighteen months, accelerating their use. Widespread applications of the device finally reached Moore's expansive stage by the end of the 1960s, along with the rapid growth in sophistication of the technology associated with design of operating systems and applications software, the linchpins of the computer era. The end of the evolution of this field is not yet in sight. All evidence suggests that silicon will continue to play an unending role in electronics (**Figure 14**).

Single-Molecule Methods in Biophysics

Y Ishii and T Yanagida, CREST, Suita, Osaka, Japan

Introduction

Biomolecules such as DNA and proteins assemble into molecular machines and networks in biosystems such as cells. The functions performed in molecular machines and biosystems reflect the characteristic features of the biomolecules. Recent developments in molecular cell biology have allowed the biomolecules and their roles to be identified. Advances in structural biology have allowed the basic static structures to be determined with atomic resolution. These molecules, however, act in a kinetic and dynamic fashion, when they function. To understand the underlying mechanism of the functions it is therefore essential to monitor the dynamic and kinetic behaviors of biomolecules under their normal working conditions.

In conventional ensemble measurements faint signals from individual molecules are accumulated from a large number of molecules. In the averaging process the signals are amplified and the S/N ratio increased but some of the information such as the dynamic, kinetic, and fluctuating properties of biomolecules is hidden. Recent developments in lasers, detectors, and other techniques have made it possible to detect faint signals from individual molecules. These techniques have allowed the behavior of the individual biomolecules to be detected without averaging. The single-molecule measurements have provided unique information, which was not possible to obtain in the conventional ensemble measurements. The information is important particularly in elucidating the mechanisms underlying the function of biomolecules and biosystems.

Single-Molecule Fluorescence Imaging

Single-molecule measurement techniques include the imaging and manipulation. Single molecules can be visualized by attaching a fluorescent marker. Fluorescence is the technique in which only the molecules that have been marked are visualized. The unnecessary signals such as light scattering are filtered out by using different wavelengths for the excitation and observation. Following the visualization of single

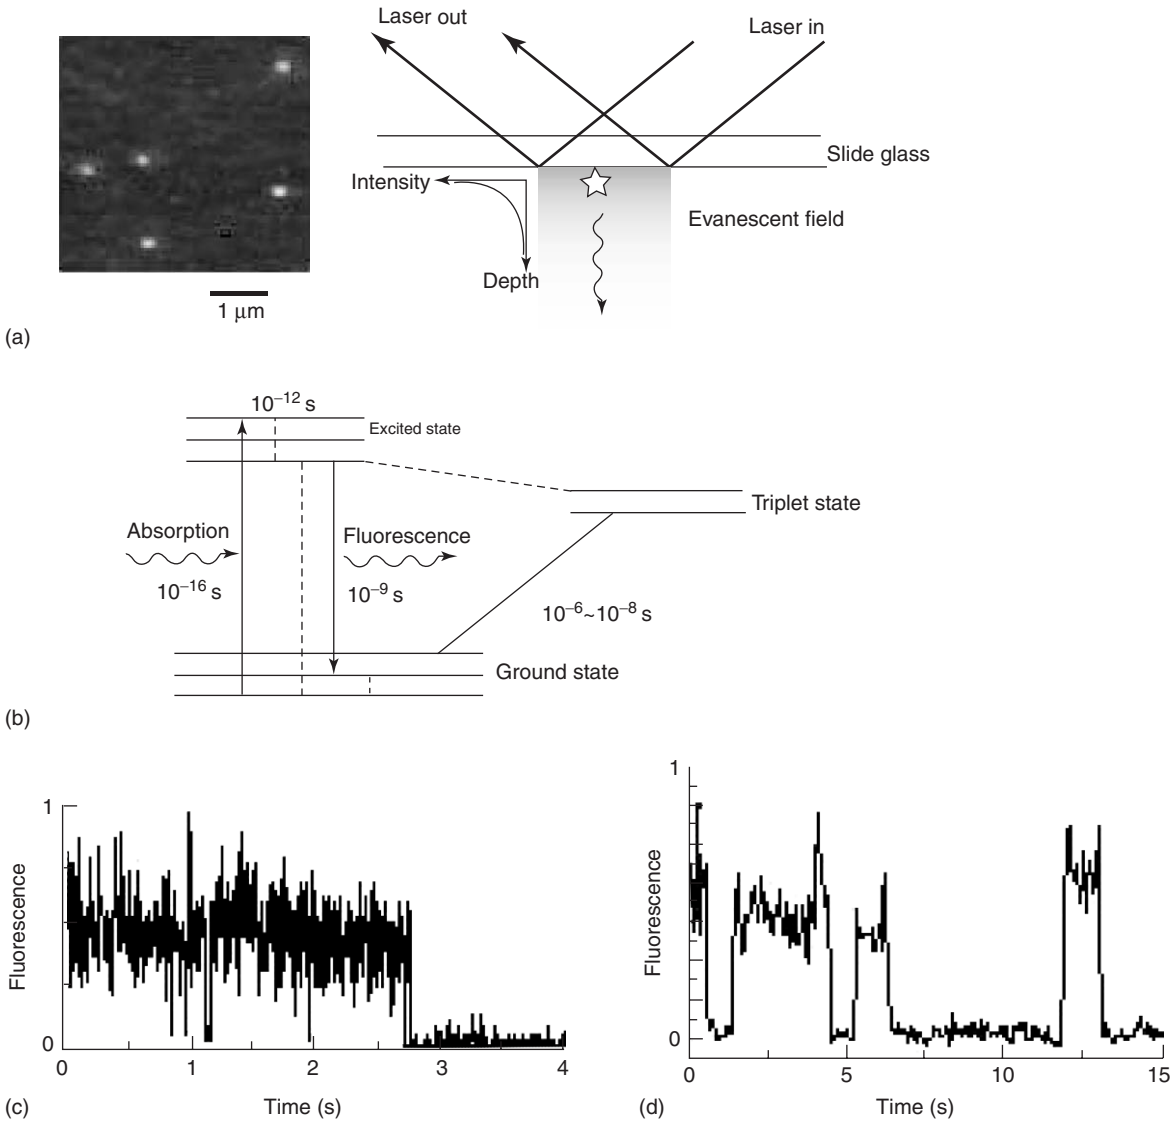

Figure 1 Imaging single fluorescent molecules. (a) Fluorescence images from single fluorophores using total internal reflection fluorescence (TIRF) microscopy: (left) single spots come from single fluorophores; (right) a schematic diagram of TIRF microscopy. (b) Mechanism of fluorescence emission. Three electronic states (ground, excited, and triplet states) contain several vibrational levels (horizontal lines). Transitions between these states (straight or dashed vertical lines) occur when fluorophores interact with light (wavy lines) or in radiationless process. The order of the time constants is indicated. (c, d) Typical time record of fluorescence from single fluorophores including photobleaching (c) and blinking (d).

fluorophores in dry air, visualizing single fluorophores attached to active biomolecules was accomplished in aqueous solution in 1995. For the measurements of active biomolecules at work, it was essential to measure biomolecules in similar condition in which they work, that is, in aqueous solution. The fluorescence in aqueous solution, is however, low mainly because of "quenching" caused by the collision of surrounding water molecules.

Since the fluorescence from single fluorophores is faint, it is essential to reduce the background noise to increase the S/N ratio. This was achieved by local illumination. Total internal reflection fluorescence (TIRF) microscopy was the most appropriate method to image single molecules (**Figure 1a**). When a laser is irradiated onto a surface between different refractive index media from the high diffractive index medium at angles greater than a critical angle, it is completely reflected. At the same time the laser generates electromagnetic fields called evanescent fields only in the vicinity of the interface to a depth of ~ 100 nm in the medium of low refractive index. For example, a laser is incident through a slideglass and the evanescent field is generated on the surface in the aqueous sample solution. The fluorophores on the glass surface can be visualized over the irradiated areas. Other scanning

probe microscopy such as confocal microscopy and near-field microscopy can also be used to visualize single molecules. TIRF microscopy is advantageous over other microscopy techniques for the systems where molecules move on the surface.

Single biomolecules are observed as fluorescent spots. Fluorescence spots are accumulations of photons emitted from single molecules. A single photon results from a single cycle of excitation and emission (**Figure 1b**). When fluorescent molecules are excited by an excitation light, the electronic state of the molecules is shifted from a ground state to an excited state using the energy of a photon of the excitation light. The molecules return to the ground state via emission of fluorescence with a lifetime in the order of nanoseconds or return via radiationless processes. The wavelength of fluorescence is longer than that of excitation light because energy is lost due to the rapid relaxation of the vibration levels within the excitation and ground states after the absorption and emission of light, respectively. The fluorescence intensity has been determined through the probabilities for adsorbing excitation light and emitting fluorescence presented by an absorption coefficient and a quantum yield, respectively. This process occurs stochastically and the emission of photons is random with time. The number of photons acquired in a measurement time or fluorescence intensity fluctuates with time. In general, the width of the fluctuation is $\sim N^{1/2}$ when the number of the photons for the signal is N. The S/N ratio increases with the number of photons.

After a fluorescent molecule emits a large number of photons, it suddenly ceases to emit photons (**Figure 1c**). This process is irreversible and is known as photobleaching. In the case of tetramethylrhodamine (TMR) or Cy3 which is used for single-molecule measurements, the photobleaching occurs after a molecule emits approximately 100 thousand to 1 million photons. The sudden drop of the fluorescence observed in the recording time is characteristic of single molecules and has been used as a test whether the fluorescence spots observed come from single molecules. The fluorescence from a single fluorophore drops in a single step and that from two molecules in two steps. Photobleaching occurs stochastically and the time for the photobleaching is distributed in an exponential manner. In agreement with this distribution, the fluorescence intensity decreases gradually with time due to the photobleaching in ensemble measurements. The photobleaching time shortens with an increase in laser power. The number of photons that single molecules emit until the photobleaching event is characteristic for each fluorescent dye. Oxygen is known to accelerate the photobleaching process so an oxygen scavenger system is useful in single-molecule measurements.

Blinking, an event in which the fluorescence is turned on and off reversibly, is more or less found in almost all fluorescent dyes (**Figure 1d**). The dark state which lasts from about a millisecond to a second is thought to be related to a triplet state. The power of the laser affects the interval time between the dark states but does not affect the duration time in the dark state. Blinking does cause problems in interpreting the data. It is difficult to discriminate blinking from the turning on–off of the fluorescence signals originating from the changes in the biomolecule systems. In general, blinking depends on the power of the laser but the fluorescence changes originated from biomolecules do not. Blinking does not depend on the solution conditions whereas the fluorescence changes originated from changes in biomolecules occur depending on the solution conditions. The blinking may or may not occur under conditions used for the ensemble measurements. In the single-molecule measurements, intense excitation light is used so that single fluorophores are excited very frequently. In the ensemble measurements, if blinking occurs, it would be hidden.

In the fluorescence images, the spots from molecules of nanometer size appear as large as the order of the wavelength (several hundred nanometers) due to the diffraction limit of the light. Molecules which exist within ~ 100 nm cannot be distinguished. For measurements, the concentration of the protein must be lower in order to distinguish individual spots. It is difficult to discriminate two separate fluorescence spots at this resolution; however, it is possible to determine the change in the position of single spots with greater resolution. Recently, the positions have been determined with an accuracy of 10 nm with the assumption of the distribution of the fluorescence around the molecules. The determination of the spatial resolution is dependent on the standard deviation of the distribution of photons.

There are only a limited number of fluorescent dyes that are suitable for the single-molecule measurements. The dyes must have a high intensity (high absorption coefficient and high quantum yield), a high stability against photobleaching, and a high stability against blinking. Many organic compounds such as TMR and Cy3 have been used to attach specifically to biomolecules. Natural fluorescent proteins have been used to fuse to proteins. Green fluorescent protein (GFP) and its mutants, which have different fluorescent colors, can also be used. Quantum dots are new materials which can prolong the photobleaching time. Further development of fluorescent dyes remains a very important research topic for single-molecule measurements.

Imaging the Association and Dissociation Events

Using single-molecule imaging it is possible to visualize the binding and dissociation of fluorescently labeled molecules to partner molecules at a fixed position. If fixed molecules are labeled with different fluorescent dyes, the position of the molecules that are fixed can be marked. At the location of the fixed molecules, fluorescent spots appear when the molecule binds and disappears when it dissociates. When the fluorescent molecules are free in solution, they undergo rapid Brownian movement. They are not observed as spots but contribute to the background noise. The concentration required to successfully image the binding of single molecules is limited below tens of nM. Thus, it is difficult to measure the binding with an affinity below $10^6\,M^{-1}\,s^{-1}$ with this assay. The duration time from the appearance of the fluorescence to its disappearance is related to the dissociation rate. The time from the disappearance of the fluorescence to the reappearance of the fluorescence signal due to the binding of the next molecule is related to the association rate. The association rate depends on the concentration of the molecules. At lower concentrations, the time between events is longer and single cycles of binding and detachment are more easily identified. The duration time varies from event to event and the decay time can be calculated from histograms. In equilibrium, the ratio of the two rates gives an association constant. The association constant can also be presented by the ratio between the sum of the duration time in the bound and unbound states.

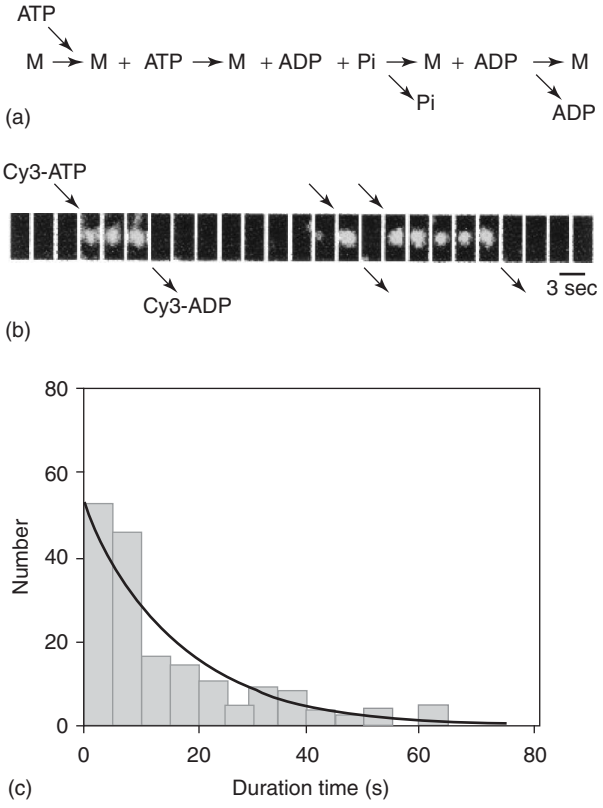

Figure 2 Imaging chemical reaction of single ATP molecules. (a) Chemical reaction of the ATP hydrolysis to ADP and inorganic phosphate (Pi) by myosin (M). (b) Time record of the ATP fluorescence image at the position of a single myosin molecule. (c) A histogram of the duration time for the ATP turnover. The data were fit to a single exponential curve with the decay time of $0.045\,s^{-1}$.

Some enzymatic reactions involve the binding and unbinding of the ligand. The ATP hydrolysis cycle includes the binding of ATP and dissociation of ADP after the hydrolysis of ATP to ADP (**Figure 2a**). Fluorescently labeled ATP (Cy3-ATP) was added to myosin molecules attached on the surface of slide-glass (**Figure 2d**). The duration time from the binding to the dissociation event could be well fitted to the single exponential decay and the average duration time gave the turnover time of ATP, which corresponds to the ATP hydrolysis rate at the limit of saturating ATP concentration (**Figure 2c**). The energy released from the ATP hydrolysis is utilized as a fuel for the function of many molecular machines including molecular motors. The visualization of this reaction is important for the studies on the function of these molecular machines.

Detecting the Dynamics of the Biomolecules

The fluorescence emission processes are sensitive to the environmental changes near the fluorophores. The techniques monitoring these changes have been developed as fluorescence spectroscopic methods. When fluorophores are attached to protein molecules, the structural changes occurring in the protein molecules are sensed by fluorescence through the environmental changes of the fluorophores. The changes in the protein structure cannot be resolved directly in fluorescence microscopy because of the diffraction limit. It is possible to monitor the changes in the structure of single molecules by combining the spectroscopic methods with single-molecule imaging. In addition to the structural changes, changes such as the interaction with other molecules, which affect the state of the fluorophores, can also be monitored.

The environmental changes alter the energy levels of the excited and ground states of the fluorophores by altering their electronic states. These changes are detected as changes in the fluorescence spectrum. For the fluorescence spectrum the number of photons emitted is measured as a function of wavelength (**Figure 3a**).

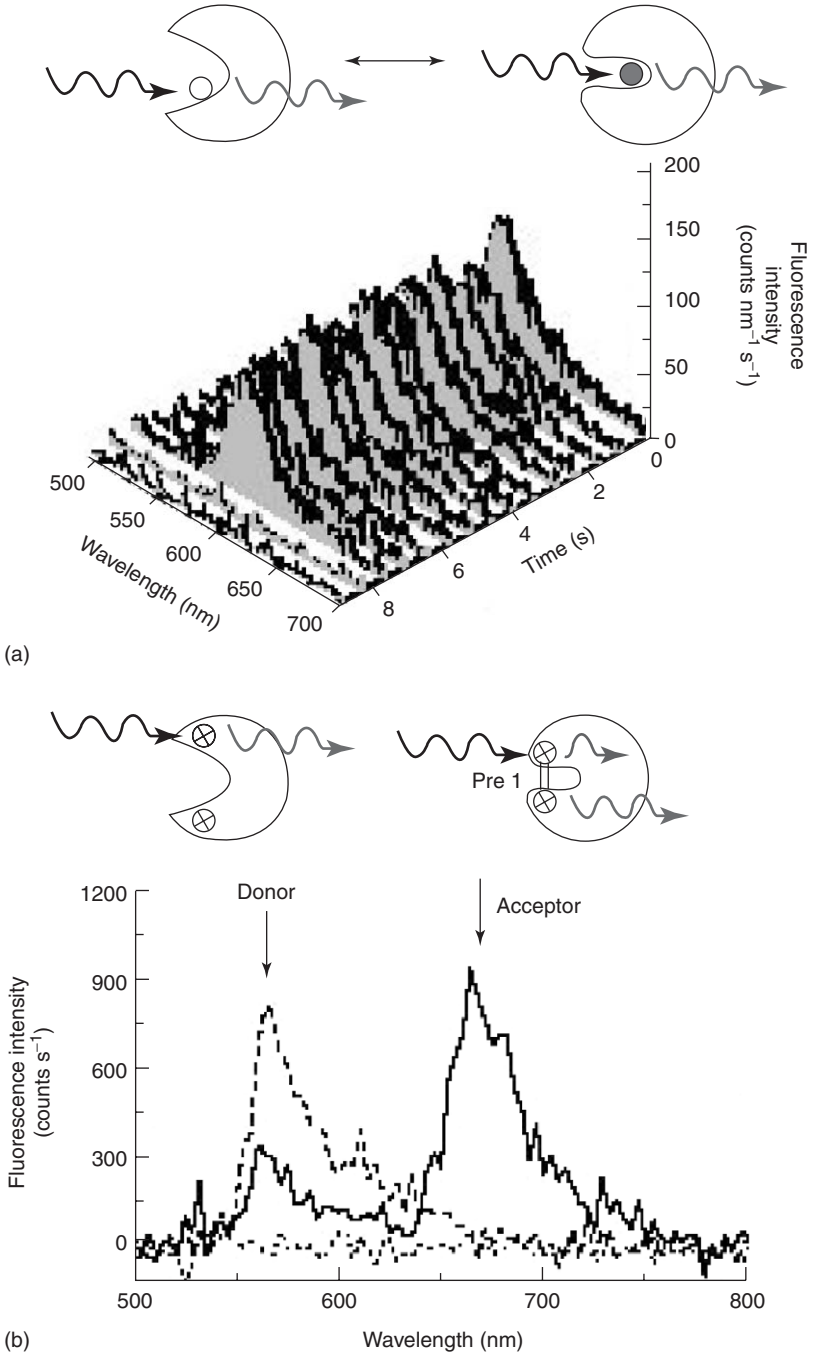

Figure 3 Spectroscopic methods to monitor the dynamic changes of single protein molecules. (a) Fluorescence spectrum method. The time record of the fluorescence spectrum from TMR attached to a single myosin molecule. (b) Fluorescence resonance energy transfer (FRET) method. The fluorescence spectra of FRET were taken from single tropomyosin molecules (straight line). The spectrum in broken line was taken after the donor was photobleached and the spectrum in dashed line was after both the donor and acceptor were photobleached.

The changes in the fluorescence spectrum are depicted by several parameters. The fluorescence intensity is one of these parameters. However, the fluorescence intensity is variant and it is difficult to compare the intensity between different measurements, because the intensity depends on the instruments, experimental conditions, and preparation of the sample. In contrast, the wavelength is an invariant number. The determination of the peak wavelength is useful when the position of the spectrum shifts. The microenvironmental changes affect the spectral changes including the hydrophobicity, the structure of water, and the

electronic potential created by the charges around the fluorophores.

Absorption and emission take place through the interaction of photons with the absorption and emission dipole moments of the fluorophores, respectively. The polarity of the fluorescence against the polarized excitation light reflects the relaxation of the dipole moment during the lifetime of the fluorescent dyes in the order of nanoseconds. When the fluorescent dyes attached to biomolecules are allowed to rotate, rotational relaxation of the dye molecules can be measured. The relaxation of the rotational Brownian motion is affected by the microenvironment and the protein structure. When the dye molecules are attached tightly to large biomolecules, the mode of the rotational motion or flexibility of the local regions of biomolecules can be measured. Fluorescent dyes attached tightly to the motor protein molecule probes can be used to detect structural changes during movement, with single-molecule measurements.

Fluorescence resonance energy transfer (FRET) is a more direct method to monitor changes in the geometrical relationship between two different fluorophores attached on the biomolecules in the nanometer order (**Figure 3b**). When the donor fluorophore is excited, the excited energy is transferred to the acceptor through the dipole–dipole interaction, resulting in the emission of fluorescence from the acceptor. The efficiency of the FRET depends on the geometry between the two dyes, but primarily on the distance between the two dyes. This method can be used to measure the structural changes in biomolecules and the changes in the interaction between two molecules. The fluorescence lifetime is also sensitive to the microenvironment of probes and the FRET efficiency.

The accumulation of a number of photons is necessary for a single data point. These data are then analyzed to obtain the fluorescent parameters. In addition to the stochastic nature of the fluorescence emission process, the process for detecting photons is stochastic. Whether the origin of the stochastic process is quantum mechanics or a statistical mechanism, the detection of a single photon does not have any physical basis. For example, in the measurements of FRET, single photons are detected as either a donor or acceptor. When a number of photons are measured, the distribution of the donor and acceptor can be obtained and the ratio of the donor and acceptor gives the FRET efficiency. The measurement time must be sufficient to acquire the appropriate number of photons for statistical analysis and at the same time short enough to monitor the dynamic changes if any exist. Changes that occur faster than the acquisition time are averaged.

For spectroscopic measurements it is possible to measure and compare more than two parameters at the same time. For example, the fluorescence spectrum includes several parameters such as the peak position, fluorescence intensity, and the half-width of the spectral band. The interpretation of the data, however, is complex. The conclusion reached will depend on the parameter being investigated. One parameter may not distinguish two states but another parameter will. The use of multiple parameters is necessary for a more solid conclusion. The measurements of the structural changes in proteins are similar. The choice of parameters and the position of the labeling is critical. There is currently no general theory that describes which parameters can describe the structural and state changes of proteins.

Studies using these technologies have shown that many proteins are in equilibrium between multiple conformations in solution; individual molecules have different conformation and the conformation of individual molecules changes spontaneously with time in the time range of 100 ms or even $\sim$1 s. Proteins are the main constituents of molecular machines and are responsible for their functions. This dynamic picture of the structure of a particular protein may play an important role in their functioning.

Detection of the Movement of Single Molecules

It is possible to trace the motion of fluorescently labeled molecules if the molecules move at an appropriate speed, that is, hundreds of $\mathrm{nm\,s^{-1}}$ to several $\mu\mathrm{m\,s^{-1}}$. Brownian movement of fluorescently labeled proteins and lipid molecules on biomembranes can be monitored for both artificial and natural cell membranes. In living cells, the movement reflects the structures of the cell membrane and their interactions with molecules of the cytoskeleton, which is important in relation to their functions.

For the advancement of studies on molecular motors, it is essential that the movement of these motors be visualized. In 1985, the sliding movement of fluorescently labeled actin filaments on myosin fixed on a slideglass was visualized for the first time using purified proteins under a microscope. Since then it has been demonstrated that single fluorescently labeled molecular motors move smoothly along protein tracks fixed on a slideglass. Kinesin and certain types of myosin can move for long distances without dissociating.

Larger and brighter probes instead of single fluorophores are advantageous for the detection of these molecules. Fluorescent beads attached to myosin and

kinesin showed that linear molecular motors move along track proteins. A fluorescently labeled actin filament attached to a rotary motor protein F1 as a marker has allowed the visualization of this rotary motion, providing the first direct evidence for the existence of rotary motors. In this motor the rotational motion is tightly coupled to the hydrolysis of ATP, and was found to be very efficient: the work done at each step was almost the same as the energy released from the hydrolysis of a single ATP molecule.

Manipulation of Molecular Motors and the Unitary Steps

The manipulation techniques have been used to carry out measurements under well-controlled conditions. Glass microneedles or beads trapped by a laser have been developed to catch single molecules and manipulate them. For example, single motor proteins attached to beads trapped by a laser can be brought into contact with single filaments of the track proteins (**Figure 4**). These systems can also be used for the mechanical measurements of molecular motors, because the displacement can be determined with high resolution and glass microneedles and laser traps have similar properties to a spring. These probes exert a spring force to pull the molecules back to the original position when they are displaced. Thus, motor molecules attached to a large probe move against the spring force until the force of molecular motors and the spring force are balanced and then the movement stops. The displacement of large probes has been measured using a divided photodiode with nanometer and milliseconds accuracy. The measurement of the displacement of the probes gives the displacement of molecular motors, if the probes attach tightly to the proteins and follow the quick movement of the molecular motors. To measure the displacement without disturbance due to Brownian motion of the probes, the stiffness of the measurement system, in general, must be high. Compliant linkages between the probes and the proteins make the system less stiff. To allow the probes to follow the rapid movement of the motors, the friction coefficient of the probes must be low.

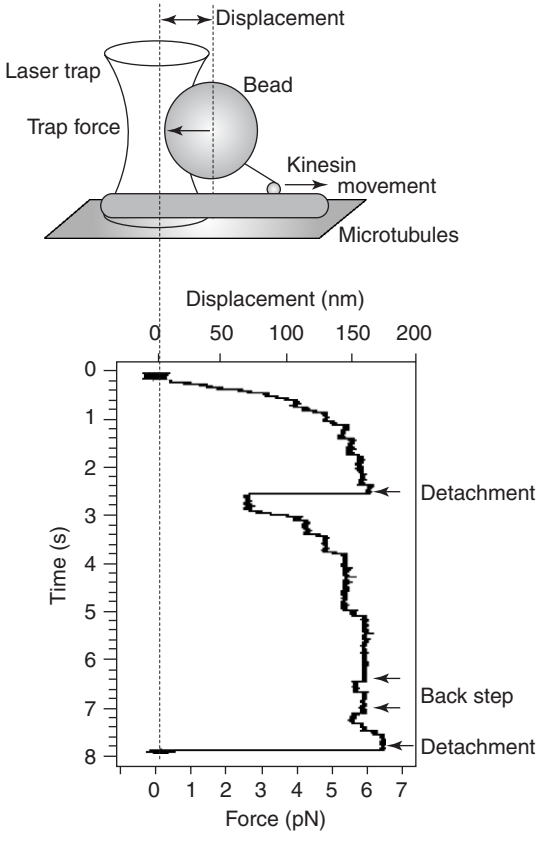

Figure 4 Measuring the stepwise movement of a single kinesin molecule: (top) a single kinesin molecule attached to a bead is trapped by a laser. The movement of single kinesin molecules along microtubules is monitored by measuring the movement of a bead; (bottom) typical record of the displacement of kinesin.

The movement of motors is fueled by the energy released from the hydrolysis of ATP. Using single-molecule measurements within an accuracy of nanometer and milliseconds, the unitary steps of single motor molecules using the energy of single ATP molecules have been identified. Kinesin and unconventional myosin V and VI move in a stepwise manner along protein tracks for long distances without dissociating. This processivity is consistent with their function of transporting cellular organelles for long distances. In the case of kinesin, the step size during hydrolysis of single ATP molecules is 8 nm, corresponding to the periodicity of the tubulin heterodimers in a microtubule (**Figure 4**). The movement occurs against an increasing load until the movement ceases at the stall force of 7 ~ 8 pN. Thus, a kinesin walks on tubulin-heterodimers using its two heads in an alternating hand-over-hand fashion.

Myosin moves along actin filaments. In the case of myosin V and VI, the processive movement has been observed with the step size of 35 nm, which corresponds to the pitch of the two-stranded helical filament of actin. Muscle myosin, in contrast to kinesin and some unconventional myosin, dissociates every ATP hydrolysis cycle. Single myosin molecules have been found to generate mean displacements of 5–25 nm at nearly zero load and mean forces of 3–5 pN at high loads (**Figure 5a**). It was difficult to determine the individual step size of muscle myosin because the starting position of the displacements cannot be determined due to the effects of Brownian movement of beads attached to actin filaments. Instead of the

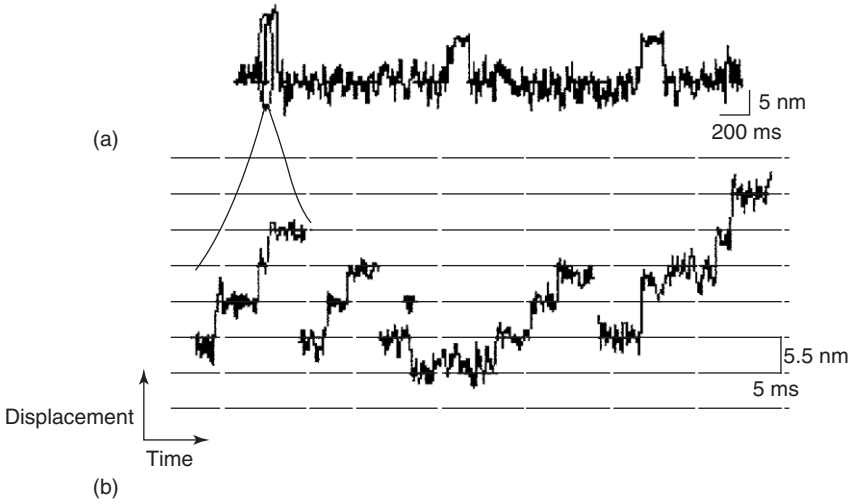

Figure 5 Stepwise movement of myosin measured using a fine scanning probe microscope. Single myosin molecules were attached to a tip of a microneedle and brought into contact with actin filaments. The trace is plotted in a different timescale. Part (b) is an expansion of (a).

manipulating actin filaments, the manipulation of single myosin molecules with a very fine scanning probe has provided a measurement system for the displacement and force generation processes with a high spatial and temporal resolution. With this measurement system, it was found that the displacements were coupled to the ATP hydrolysis and each displacement contained several distinct steps (**Figure 5b**). Each step was 5.5 nm in size, and corresponded to the distance between adjacent monomers in an actin filament. The steps took place stochastically and some of them ($<10\%$ of total steps) were in the backward direction. These results cannot be explained by the widely accepted model of structural change in which the displacement results from structural changes in the myosin coupled to the ATP hydrolysis reaction. Rather it has been suggested that a myosin head can walk along the actin monomers arranged in a filament utilizing Brownian motion. The mechanisms underlying the movement of myosin is still controversial and various measurements have been attempted from the viewpoints of the structure–function relationship.

Monitoring the Chemical Reactions

The functions in the biosystems take place in series of events. In single-molecule measurements, the series of events can be detected without interruption. In ensemble measurements, individual steps are measured separately and the entire processes reconstructed using this information. The kinetic parameters are determined by synchronizing the reactions of constituent molecules using stop flow, flash photolysis, or other transient kinetic methods. In single-molecule measurements, the reaction time varies from event to event reflecting the stochastic nature of the reactions. The rate constants, which characterize the reaction, are determined using the data from individual events.

The data obtained in the single-molecule measurements must be consistent with the data in the ensemble measurements. The data of single-molecule measurements contain more information than those of ensemble measurements. Data points from individual single molecules align with time. The time correlation data are discussed in relation to the memory effects of biomolecules. In flavoenzyme, which catalyzes the oxidation of cholesterol by oxygen, the enzymatic turnover is dependent on previous turnovers.

The series of events are described using several different parameters obtained from different measurements. It is unlikely that all the steps can be detected using single parameters obtained experimentally. In the ATP hydrolysis reaction, the fluorescence of ATP senses only the binding and dissociation events but not the hydrolysis steps or any other of the chemical steps. The mechanical measurement detects the displacement, association, and dissociation of the motor molecules but not any of the chemical steps. The chemical and mechanical parameters, which are separately measured, are however related to each other. Any change in the chemical reactions will influence the time record of the mechanical reactions. Changes in the ATP concentration change the mechanical trace. Time records of single parameters are influenced by the changes in other parameters that cannot be directly detected. Thus, the coupling between two parameters can be studied.

Direct Determination of Coupling Between Two Different Events

A more direct way of relating different events is to measure several parameters simultaneously. In single-molecule measurements, the individual measurements, in which the kinetic steps have not been averaged, can be directly compared. In the case of the molecular motors, the coupling between the ATP hydrolysis reaction as an input of the energy and mechanical work as the output has been determined (**Figure 6**). The ATP hydrolysis cycle is measured by measuring the binding and dissociation cycle of fluorescent ATP and the displacement of myosin using a laser trap. It has been suggested that the rising phase of the displacement record is not always coupled to the chemical reactions but instead is delayed. The energy released from the hydrolysis of ATP is then stored and used afterwards for the generation of the force.

With regard to the relationship between two events, the structure–function relationship is a fundamental question that needs to be addressed. In many proteins, the function can be explained by structural changes in the proteins. These changes are usually based on the atomic structures obtained from crystallographic studies. The relationship between structure and function has been studied by measuring the function using mutated proteins. Now that the structural changes of single protein molecules can be detected, the structure–function relationship will be experimentally studied in a more direct manner.

From Single Molecules to a Biosystem

Single-molecule measurements have been extended to monitoring single molecules in cells. Using TIRF microscopy it is possible to image both the basal and apical surfaces of cells. Incident laser light is totally internally reflected at the apical surface between the cytoplasm and the cell culture medium, where the diffractive indices are different. Other microscopy such as confocal microscopy has been used especially to image locations other than at the cell surfaces.

Cells perform their function in response to the external stimuli. At early processing stages, that is, from stimulation to function, the ligands bind to their receptors on the surface of cells and the signals are transmitted through a cascade of signaling proteins. In this process, many different kinds of molecules participate and chain reactions take place in a spatially organized fashion. Single-molecule measurements have been a powerful technique to explore early signal transduction systems. *Dictyostelium* amoeba exhibits chemotaxis along a gradient of adenosine 3′,5′-monophosphate (cAMP). The binding of fluorescent cAMP

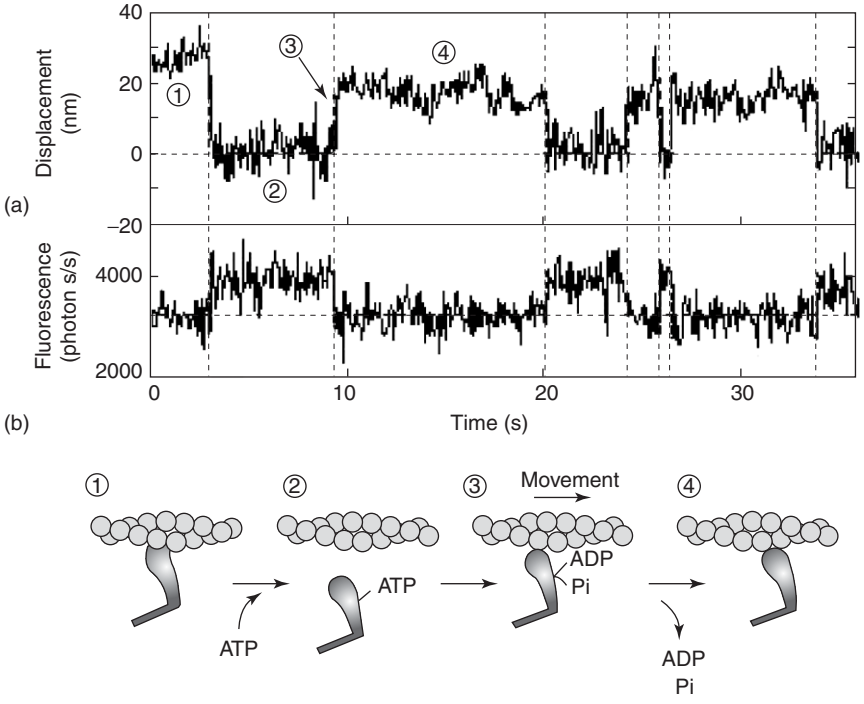

Figure 6 Direct determination of mechanochemical coupling of myosin. (a) The displacement of a single myosin molecule along an actin filament was measured using a laser trap method. (b) The fluorescence of Cy3-ATP was monitored at the same time. A schematic drawing of the interaction of myosin and actin is shown at the bottom.

to its receptor has been visualized at single-molecule level (**Figure 7**). It was found from observations of the dissociation rate constants that a receptor in the anterior half of the moving cells became activated when there was a difference in the cAMP concentration gradient compared to the posterior half.

In this process, in addition to the binding of the ligands, the activation, structure, and interaction of protein processes can be visualized using single-molecule imaging. Dimerization was visualized by measuring the fluorescence intensity and phosphorylation was visualized using fluorescent monoclonal antibody.

Concluding Remarks

Single-molecule measurements have allowed the measurements of the properties of biomolecules hidden in averaged measurements involving over large numbers of molecules. Dynamic, kinetic, and fluctuating properties of biomolecules, which are important in elucidating the mechanism of their function have been revealed. Using fluorescence microscopy the behavior of biomolecules at work can be measured. Both temporal and spatial information is included in the fluorescence microscopy measurements. It is possible to detect the behaviors of biomolecules in complicated systems, allowing the function of biomolecules to be imaged in living cells.

Using single-molecule measurements it is possible to monitor series of events in real time. To interpret the kinetic data, it is necessary to analyze large numbers of molecules from individual events. These complicated procedures are necessary because the energy used for the function of molecular machines is similar to the thermal energy. The energy released from the ATP hydrolysis is approximately 20 times the thermal energy. Biomolecules of nanometer size are largely disturbed by thermal energy. Thus, it is highly likely that the single-molecule measurements of biomolecules are influenced by thermal disturbances. It is an intriguing question as to how biomolecules work efficiently under situations of thermal energy disturbances. The mechanism that the biomolecules harness the thermal energy rather than being disturbed has been suggested from single-molecule measurements. These properties most likely give the systems flexibility in their function.

To measure the properties of single molecules, probes are attached. The effects of the probes on the activity can be examined by comparing the function with molecules that have no probe attached. However, it is difficult to ascertain what the effects of the probes on the properties of the biomolecules are as revealed by single-molecule measurements. *In situ*, the molecular motors move without the aid of beads or microneedles and proteins change their structure in the absence of fluorescent probes. Different probes may disturb biomolecules in different ways. Biomolecules may behave with different restrictions in different systems. Thus, measurements with different probes and in different systems may be helpful in understanding the effects of the probes.

In single-molecule measurements it is possible to monitor states that occur less frequently compared with other states. In ensemble measurements, the majority states contribute largely and the minority states are neglected. This is not to say, however, that the states that occur more frequently are most important and the states that occur less frequently are not important in the biological processes. The single-molecule measurement in cells show that the binding of a small number of ligands is sufficient to stimulate

the cells. It is possible that the minority state plays an important role even though only a small population of molecules is involved. Thus, single-molecule measurements will play an important role in the future of biosciences.

Small Particles and Clusters, Optical Properties of

T Arai and K Matsuishi, University of Tsukuba, Tsukuba, Japan

Introduction

Mesoscopic particles of nanometer size are considered to be the intermediate phase which bridges between crystals and molecules and/or atoms. Appearance of various kinds of new properties – such as quantum size effects of electronic and phonon states, variations in shape and crystal structure, an increase of optical nonlinearity, a change in the selection rule of the optical transition, and an increase of surface effects – is expected in the mesoscopic particles.

This article focuses on the optical properties of small-size particles of semiconductors, ionic crystals, and metals.

Semiconductors and Ionic Crystals

Quantum Size Effects of Electronic States

The lowest excitation energy state of an electron in an ionic crystal and a semiconductor is the exciton state. The exciton can be treated as a "particle." Hence, in a first approximation the exciton will be considered as a particle in a spherical-shaped potential well. The wave function of the infinitesimally small particle with mass M in a spherical-shaped potential well with radius R is expressed by a spherical Bessel function, and the eigenenergies measured from the bottom of the potential well are given as follows:

$$\Delta E(R) = \frac{\hbar^2}{2M}\left(\frac{\phi}{R}\right)^2 \qquad [1a]$$

where $\phi/\pi = 1,\ 1.43,\ 1.83, \ldots$ give $1S$-state, $1P$-state, $1D$-state, …, respectively. Thus, the translational energies become discontinuous and increase. When the effective Bohr radius of the exciton, a_B^*, is much smaller than the radius of the particle, the exciton retains its size and can be treated as a particle. This case is called the exciton confinement or the weak confinement regime and eqn [1a] can be used with a small modification. The energy difference between the bulk exciton and the confined exciton is given by the following equation:

$$\Delta E(R) = \frac{\hbar^2}{2(m_e^* + m_h^*)} \times \frac{\phi^2}{[R - \eta(\sigma)a_B^*]^2} \qquad [1b]$$

where $\eta(\sigma)$ is a function of the ratio of the effective mass of the hole, m_h^*, to that of the electron, m_e^*. The term $\eta(\sigma)a_B^*$ expresses a dead-layer effect. That is, the exciton cannot exist within a distance less than $a_B^*/2$ from the wall of the potential well.

On the contrary, when the potential well radius R is comparable to or smaller than a_B^*, the exciton size diminishes and its internal motion is modified strongly. The exciton energy is also quantized. Therefore, the mass in eqn [1b], $m_e^* + m_h^*$, should be changed to the reduced mass of the exciton, μ, given by

$$\frac{1}{\mu} = \frac{1}{m_e^*} + \frac{1}{m_h^*}$$

This case is called the individual-confinement or the strong-confinement regime.

When the Coulomb energy in the exciton becomes equal to the energy of the relative motion of the exciton, the confinement state changes from the "exciton confinement" to the "individual confinement." The transition between the two states occurs when

$$\frac{\hbar^2\pi^2}{2\mu a_B^{*2}} \geqslant \frac{e^2}{\varepsilon R}$$

$$\frac{R}{a_B^*} = \frac{\pi^2}{2} \approx 4.9$$

This transition has been observed at $R/a_B^* \approx 4$ in a CdS microcrystal.

If a charge is placed in a small medium, a surface polarization appears, which creates a Lorentz field in the medium. Consequently, the Coulomb force and the self-energy of the exciton in the small medium vary from that of the free exciton. The Hamiltonian of an electron–hole pair which includes the effect of the Lorentz field is shown in the effective-mass approximation as follows:

$$H = -\frac{\hbar^2\nabla_e^2}{2m_e^*} - \frac{\hbar^2\nabla_h^2}{2m_h^*} - \frac{e^2}{\varepsilon_1|r_e - r_h|} + V_e(r_e) + V_h(r_h) + \frac{e^2}{2R}\sum_{n=0}^{\infty}\alpha_n\left[\left(\frac{r_e}{R}\right)^{2n} + \left(\frac{r_h}{R}\right)^{2n}\right] - \frac{e^2}{R}\sum_{n=0}^{\infty}\alpha_n\left[\left(\frac{r_e r_h}{R^2}\right)^{n} P_n(\cos\theta_{eh})\right] \quad [2]$$

where

$$\alpha_n = \frac{(n+1)(\varepsilon-1)}{\varepsilon_1(n\varepsilon+n+1)}, \quad \varepsilon = \frac{\varepsilon_1}{\varepsilon_2}$$

ε_1 and ε_2 are the dielectric constants of the small particle and the surrounding material, respectively. r_e and r_h are the coordinates of the electron and the hole. $P_n(\cos\theta_{eh})$ is the Legendre polynomial, and θ_{eh} is the angle formed by the two lines connecting the center of the particle to the electron and to the hole. The fourth and fifth terms in eqn [2] are the confinement potentials for the electron and the hole, respectively. The sixth term is the Lorentz field correction, and the seventh term is the self-energy. The calculated result of the lowest energy of the confined exciton with the wave function, which is made by the product of the 1*s*-state electron and the 1*s*-state hole wave functions, is given as follows:

$$\Delta E = \frac{\hbar^2\pi^2}{2R^2}\left[\frac{1}{m_e^*} + \frac{1}{m_h^*}\right] - \frac{1.786e^2}{\varepsilon_1 R} + \frac{e^2}{R}\sum_{n=1}^{\infty}\alpha_n\left(\frac{S}{R}\right)^{2n} \quad [3]$$

The first term represents a change in the kinetic energy, the second term the energy due to the shielding Coulomb interaction, and the third term the polarization term. The ratio of the energy shift due to the polarization term to the total energy shift is ~ 0.07 for CdS. In addition, the value of the dielectric constant decreases with a decrease in the particle size, but this effect is less than 1% in general. Equation [3] can be used in the weak-confinement regime, if the total mass of the exciton is employed instead of the reduced mass.

Figures 1 and **2** show the size dependence of excitonic transition energies for CuCl and CdSe particles.

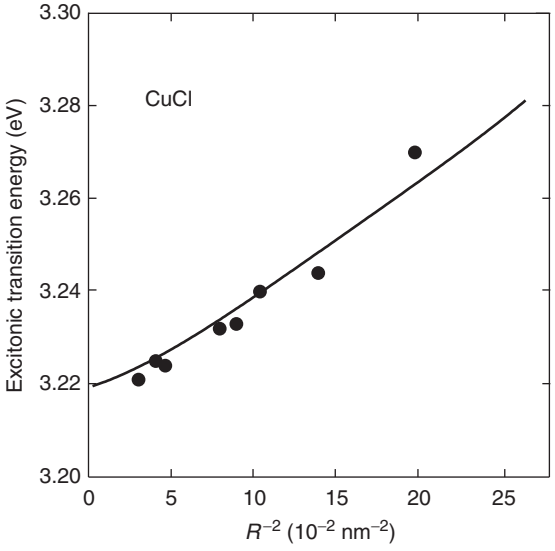

Figure 1 Size dependence of exciton energy for CuCl particles. The solid line denotes the result by the calculation assuming a dead zone with the thickness $a_B^*/2$ on the particle surface. The experimental data (solid circles) are from Itoh *et al.* (1988) *Physica Status Solidi* (b) 146:531.

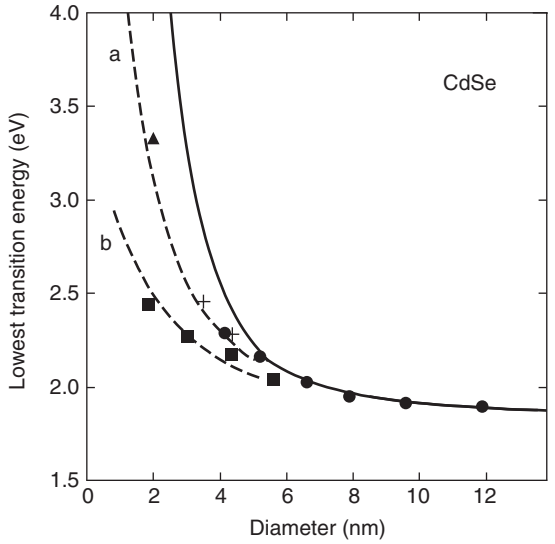

Figure 2 Size dependence of the lowest excitation energy (HOMO–LUMO transition energy) for CdSe particles. • from Arai T, *et al.* (1996) *Journal of Luminescence* 70:281; ■ from Nogami N, *et al.* (1991) *Journal of Non-Crystalline Solids* 135:182; + from Alivisatos AP, *et al.* (1988) *Journal of Chemical Physics* 89: 4001; ▲ from Chestnoy N, *et al.* (1986) *Journal of Chemical Physics* 85:2237. The solid line and the dashed lines denote the calculated results by an effective-mass approximation and by tight-binding approximations, respectively. The dashed line (a) is from Lippens PE, *et al.* (1990) *Physical Review B* 41: 6079 and (b) from Ramaniah LM, *et al.* (1993) *Physical Review B* 47: 7132.

The solid line in **Figure 1** shows the calculated result assuming a dead zone with thickness $a_B^*/2$ on the particle surface. The effective Bohr radius of the exciton in CuCl is 0.7 nm. Hence, the exciton confinement

regime is valid in the entire region of measurements. The radiation due to the dissociation of the biexciton (the exciton molecule) has been observed under intensive excitation. The binding energy of the biexciton, E_b, given by $2E_{ex} - E_{mol}$, also has size dependence, but its dependence is small compared to that of the exciton energy.

The exciton radius of CdSe is ~ 5.6 nm. The individual-confinement regime is valid in the size region, shown in **Figure 2**. The agreement between the experimental data and the effective-mass approximation calculation (solid line) is good in the region of diameters larger than ~ 6 nm. This implies that the disagreement in the small-size region is caused by the failure of the effective-mass approximation. In this region, the experimental data, however, agree with the tight-binding approximation calculations (dashed lines) (**Figure 2**).

In the above treatment, the potential well has a finite depth. Therefore, the wave function of the exciton tunnels out from the potential well. This effect becomes very important, when the small particles are arranged in a dense state.

Oscillator Strength

The coherent state of the exciton spreads over the entire region of a very small size particle; therefore, the oscillator strength increases with increasing size in the very small size region. This phenomenon is called the "giant oscillator strength" (GOS) effect. The oscillator strength of the exciton, f_{ex}, in the small particle with radius R is given by

$$f_{ex} = \frac{8}{\pi}\frac{R^3}{\nu} f_0 \propto R^3$$

where ν is the volume of the unit cell and f_0 is the oscillator strength in the bulk crystal and is given by

$$f_0 = \frac{2m^*\omega}{\hbar}|\mu_{eg}|^2 \frac{1}{\pi a_B^{*3}}$$

Here, μ_{eg} is the electric dipole moment in the transition process between e and g states.

The lifetime of an exciton is inversely proportional to the third power of the particle radius due to the GOS effect:

$$\tau = \frac{3m^*c^3}{16e^3 n\omega^2 f_0}\left(\frac{\nu}{R^3}\right) \propto \frac{1}{R^3}$$

The bandwidth of the photoluminescence spectrum, Γ_h, measured by a selective-excitation method is inversely proportional to the lifetime. Thus, Γ_h increases with an increase in the particle size. The quantum yield of photoluminescence increases with an increase in the size due to the GOS effect. For example, the quantum yield in the case of very small size for CuCl particles has been observed to be $\sim 0.1\%$. The photoluminescence spectrum shifts to the higher-energy side compared with that of the bulk. The Stokes shift has not been observed, except at very low temperatures. When the radius of the particle becomes larger than the coherent length of the exciton, the GOS effect saturates. The GOS effect is important, especially in nonlinear optical effects.

Size Effect of Phonon

The binding force between atoms is mainly a short-range force in general. Therefore, the quantum size effect on the phonon energy does not appear apparently. However, in optical transitions a relaxation of the selection rule on the wave vector (the momentum) occurs. This effect has been observed in Raman scattering and photoluminescence spectra.

The size dependence of Raman intensity $I(\omega)$ owing to optical phonon scattering is expressed essentially as follows:

$$I(\omega) \approx \int d^3q \frac{|C(0,\boldsymbol{q})|^2}{\{\omega - \omega(\boldsymbol{q})\}^2 + (\Gamma_0/2)^2}$$

Here $\omega(\boldsymbol{q})$ is the optical phonon dispersion, $C(0,\boldsymbol{q})$ the Fourier coefficient of the phonon confinement function, and Γ_0 the natural bandwidth of the Raman line. If the Gaussian function, $w(r,L) = \exp(-8\pi^2 r^2/L^2)$, is used as an attenuation function, the Fourier coefficient of the phonon confinement function is given as follows:

$$|C(0,\boldsymbol{q})|^2 = \exp\left(-\frac{|\boldsymbol{q}|^2 L^2}{16\pi^2}\right)$$

Here L is the diameter of the particle, that is $L = 2R$. The range of the contributing wave vector $\boldsymbol{q}$ to the optical excitation is inversely proportional approximately to R^2. The Raman shift decreases and the bandwidth of the spectrum becomes broader with a decrease in the size, for example, in CdS and CdSe particles. The Raman scattering owing to the spheroidal and torsional modes in a spherical particle is also expected. These modes have been observed in a very low frequency region.

Exciton–Phonon Interaction

The exciton–phonon interaction has been investigated extensively in CuCl particles. There are light- and heavy-hole bands in a CuCl crystal, and the Z_3 exciton state splits into light- and heavy-hole excitons. The coherence of both the excitons is broken by

the interband scattering between excitons through the absorption and emission of LA phonon at low temperatures, while they are broken by LO phonon scattering at high temperatures. The temperature dependence of the homogeneous bandwidth of the exciton spectrum in CuCl particles has been interpreted by the above mechanism with a consideration of the localization properties of LA and LO phonons.

Optical Nonlinearity

Under intensive laser irradiation, the imaginary part of the third-order dielectric constant, Im $\chi^{(3)}$, is proportional to the square of the oscillator strength, f, and inversely proportional to the square of the homogeneous bandwidth, Γ_h, of the absorption spectrum. The absorption intensity in the selective excitation is given by $\alpha\Gamma_h$. Here α is the absorption coefficient. $\alpha\Gamma_h$ is proportional to fN (N is the number density of particles). Therefore, the third-order electronic susceptibility, $|\chi^{(3)}|$, is given as follows:

$$|\chi^{(3)}| \propto \frac{f^2 N T_1}{\Gamma_h^2}$$

Here T_1 is the longitudinal relaxation time. In very small size particles, $|\chi^{(3)}|$ at the resonance energy for the lowest excitation state becomes larger with an increase in the size, up to a critical size. According to the theory of the GOS effect on the confined exciton, the oscillator strength of the exciton increases as R^3, up to the critical size. The oscillator strength saturates at the critical size. Then, the oscillator strength decreases with a further increase in the size. The critical size decreases with an increase in the temperature. The reasons are the following: the energy separation between the excitonic states decreases with increasing particle size. Therefore, the thermal population of the exciton in the higher excitonic states increases and the coherent length of the lowest excitonic state decreases due to an increase in the scattering between the excitonic states. Contributions from the higher excitonic states overcome the resonance increment of the oscillator strength in the lowest state. Some theories have also suggested that the enhancement of $|\chi^{(3)}|$ is larger in materials having a relatively smaller Bohr radius. The maximum values reported for $|\chi^{(3)}|$ are 2×10^{-7}, 3×10^{-8}, and 1×10^{-6} esu for CdTe-, CdS-, and CuCl-doped oxide glasses, respectively.

Taking into account the two-energy-level system, $|\chi^{(3)}|/\alpha T_1$ is proportional to f, and inversely proportional to Γ_h, as described previously. Therefore, the oscillator strength can be estimated from the measured values of $|\chi^{(3)}|/\alpha T_1$ and the homogeneous bandwidth. The estimated value of the oscillator strength is ~ 5.5 for the 4.5 nm-size CuCl particle at the wavelength where $|\chi^{(3)}|/\alpha T_1$ is maximum. Compared to the value of the oscillator strength in bulk, 5.85×10^{-3}, the enhancement factor is $\sim 10^3$.

Many other nonlinear optical phenomena, such as the superradiation, the formation of the molecular exciton (the electron–hole droplet), and the saturation of absorption (the hole burning), are enhanced strongly due to the GOS effect. For example, the hole burning in the inhomogeneous broad band has been observed easily in CuCl particles with an average size of ~ 3.6 nm at 77 K. Not only is the hole burning formed but also the absorption at the lower-energy side of the exciting energy decreases and the absorption at the higher-energy side of the exciting energy increases. These phenomena are caused by the multiselective excitations which occur due to the size distribution of particles and the production of bi- and tri-excitons.

Photoluminescence at an energy lower than that of the usual exciton luminescence has been observed in nanoparticles of some ionic crystals under irradiation of an intense laser with the resonance energy of the exciton. When this luminescence occurs, the absorption coefficient at the exciting energy is only about half of that obtained in the usual light irradiation. Therefore, this luminescence originates from the dissociation of the molecular exciton created by the two-photon absorption. The luminescence occurs in smaller excitation intensity compared to that in the bulk. It may be due to the enhancement of mutual interaction among excitons owing to the occupancy of the close position. According to the results of the research on the dynamical properties of the relaxation of a molecular exciton, the optical density, $I_S T_1$, is proportional to $1/R^3$, where I_S and T_1 are the saturation intensity of absorption and the longitudinal relaxation time of the molecular exciton, respectively.

In the highly excited Frenkel exciton system, in a small-size particle, a new elementary excitation (called an excitonic n-string) appears, and a superradiation from the n-string is expected. In the highly excited Wannier exciton system, the electron–hole droplet has been observed in Si and Ge, and the excitonic molecule has also been observed in III–V and III–VI compounds. However, the exchange interaction does not support the bound states of more than two Wannier excitons (exciton molecule). In contrast, a bound state of several Frenkel excitons (i.e., excitonic n-string) is possible in a linear chain of molecules, when the exciton accompanies the static dipole moment larger than the transition dipole moment along the chain.

The superradiation from a Wannier exciton in microcrystallites has been shown theoretically and

experimentally. New sharp superradiance with a strong peak intensity from the Frenkel exciton system is expected in intense excitation because of the high density of oscillators. According to the calculated results of the spectrum and pulse width in time, the peak intensity, I, from the n-string is given by

$$I = \tfrac{1}{2}N_s\left(\tfrac{1}{2}N_s + 1\right)\Gamma$$

where Γ is a spontaneous emission rate of a single exciton and N_s is the number of excitons in the n-string, that is, $N_s = n$. The pulse width is inversely proportional to N_s. The intensity I increases as $N_s^{1.5}$. This should be compared with the N_s^2 dependence for Diche's superradiation from atomic and/or molecular gas systems. This may be because the cooperation number is kept to the maximum for the two-level atoms, while it decreases in the emission process due to the effect of excitation transfer.

Crystals which have a zinc blende structure, such as CuCl and CuBr, have two types of excitons, Z_3 and Z_{12}, due to the splitting of the valence band. The Z_{12} exciton consists of the multicomponent exciton states due to light and heavy holes and a k-linear term in the Γ_8 valence band. The energies of both the excitons in a small particle are higher than that in the bulk crystal. In addition, the Z_{12} exciton level splits off into two levels due to a confinement effect because of the multicomponent exciton. Spectral analyses on the degenerated four-wave mixing signals have shown that the correlation curve between the luminescence signal and the delay time consists of an oscillatory structure superimposed onto the exponential decay. The oscillation period corresponds to the energy separation of the Z_{12} exciton levels in the nanoparticle. Thus, this oscillation has been interpreted as the quantum beat between the separated Z_{12} exciton levels.

Metal Particles

Absorption of Surface Plasmon

The so-called stained glass consists of glass-dispersed fine particles of metal. The optical properties of isolated fine particles in a transparent matrix were first treated by Mie. There are many different modes in the particle. Higher modes are localized on the surface, and the lowest mode, the so-called Frölich mode, polarizes uniformly in the particle. The Frölich mode is important in the small particle – it gives rise to surface plasmons which cause the colors present in a stained glass. The Frölich mode is treated in the following.

The dielectric constant of metal, ε_m, differs from that of the matrix, ε_d. Therefore, the local field in the metal particle, E_l, should differ from the field of incident radiation, E, and is given by

$$E_l = \frac{3\varepsilon_d}{\varepsilon_m + 2\varepsilon_d}E = f_l E$$

The constant f_l is termed as the factor of the local field. The averaged electric field in the material, E_{av}, and the averaged polarization of the material, P_{av}, can be defined as

$$E_{av} = (1-f)E + fE_l$$
$$P_{av} = [(1-f)(\varepsilon_d - 1)E + f(\varepsilon_m - 1)E_l]/4\pi$$

Here f is the volume fraction of the metal (i.e., the filling factor of the metal). The average dielectric constant of the material with dispersed metal particles, ε_{av}, calculated by the dipole–dipole interaction approximation is given as follows:

$$\varepsilon_{av}(\omega) = \varepsilon_d(\omega)\left\{1 + \frac{3f[\varepsilon_m(\omega) - \varepsilon_d(\omega)]}{\varepsilon_m(\omega)(1-f) + \varepsilon_d(\omega)(2+f)}\right\}$$

The absorption coefficient α is given by

$$\alpha(\omega) = \frac{\omega}{c}\frac{\mathrm{Im}\,\varepsilon_{av}(\omega)}{\mathrm{Re}\,\sqrt{\varepsilon_{av}(\omega)}}$$

The peak of absorption is given by the condition that $\mathrm{Re}\,\sqrt{\varepsilon_{av}(\omega)} = 0$. Thus, the peak of absorption is given by

$$\mathrm{Re}\,\varepsilon_m(\omega_s) = -\varepsilon_d(\omega_s)\frac{f+2}{1-f}$$

Here ω_s is the angular frequency of the surface plasmon. The above equation can be written as

$$\mathrm{Re}\,\varepsilon_m(\omega_s) = -2\varepsilon_d(\omega_s)$$

in the small-f region. The absorption spectrum in the small-f region is given as follows:

$$\alpha = \frac{18\pi f\varepsilon_d^{3/2}}{\lambda}\frac{\mathrm{Im}\,\varepsilon_m}{(\mathrm{Re}\,\varepsilon_m + 2\varepsilon_d)^2 + (\mathrm{Im}\,\varepsilon_m)^2}$$

Here λ is the wavelength of light. The results calculated by the above equation show that the absorption peak shifts to the shorter-wavelength side and the width of the absorption band becomes narrower with a decrease in the particle size. However, the experimental results do not coincide with the calculated results, because the mean free path length of the electron in a metal is generally several tens of nanometers and is limited by the particle size in small particles. If one calculates the dielectric constant including this effect, the peak value of the absorption band becomes smaller and the bandwidth of the absorption becomes wider with a decrease in the particle size.

Third-Order Electric Susceptibility

The third-order susceptibility, $\chi^{(3)}$, in the composite material which has dispersed metal nanoparticles in a transparent material is given by

$$\chi^{(3)} = f \cdot f_l^2 |f_l|^2 \chi_m^{(3)} \quad [4]$$

Here f and f_l are the volume fraction of the metal and the factor of the local field, respectively, as denoted previously. $\chi_m^{(3)}$ is the third-order electric susceptibility of the metal itself. As mentioned already, the factor of the local field increases at the surface plasma frequency. When the combination of the matrix and the particle satisfies the resonance condition, $\mathrm{Re}\,\varepsilon_m = -2\varepsilon_d$, the factor of the local field increases. As seen in eqn [4], $\chi^{(3)}$ increases as f_l^4. The susceptibility depends on the size of the metal particle. If one can choose the size that satisfies the resonance condition, $\chi^{(3)}$ increases. The enhancements of $\chi^{(3)}$ in Cu and Ag composite SiO_2 glasses are approximately 5 times and 10^4 times in the best condition, respectively.

The time dependence of a nonlinear response was measured by a pump–probe method under several $\mathrm{mJ\,cm^{-2}}$ energy density of irradiation. The bleaching of absorption at the pumping wavelength and the enhancement of absorption on either side of the pumping wavelength were observed. The shapes of the absorption bands before and after irradiating the pumping light were Lorentzian. However, the bandwidth was observed to be a few times wider on pumping. Therefore, the decay character of the absorption band gives information on the scattering mechanism of hot electrons. The decay curve is composed of fast and slow components. The decay times of these components are approximately a few picoseconds and a few hundreds of picoseconds, respectively. The fast component is due to the electron–phonon scattering and the slow component may be due to the electron–matrix scattering. The decay time of the fast component becomes shorter with a decrease in the energy density of irradiation. A similar decay character has also been observed under high-intensity radiation condition for particles of II–VI compounds such as CdS, CdSe, and CdTe.

Nomenclature

a^*_B	effective Bohr radius of exciton
c	speed of light
$C(0, q)$	Fourier coefficient of phonon confinement function
E	energy, electric field
E_{av}	averaged electric field
E_b	binding energy of biexciton
E_{ex}	energy of exciton
E_l	local field of metal particle
E_{mol}	energy of exciton molecule
f	oscillator strength, volume fraction of metal (filling factor)
f_0	oscillator strength in bulk crystal
f_{ex}	oscillator strength of exciton
f_l	factor of local field
$\hbar$	$h/2\pi$ (h: Planck constant)
I	intensity (Raman, emission)
I_s	saturated intensity of absorption
m^*_e	effective mass of electron
m^*_h	effective mass of hole
M	mass
n	refractive index
N	number density of particles
N_s	number of excitons in excitonic n-string
P	polarization of material
P_{av}	averaged polarization of material
$P_n(x)$	Legendre polynomial
q	wave vector
r_e	coordinate of electron
r_h	coordinate of hole
R	radius
T_1	longitudinal relaxation time
v	volume of unit cell
α	absorption coefficient
Γ	spontaneous emission rate
Γ_h	homogeneous line width
ε	dielectric constant
ε_d	dielectric constant of matrix
ε_m	dielectric constant of metal
θ_{eh}	angle formed by the two lines connecting the center of particle to electron and hole

τ	lifetime	$\chi^{(3)}$	third-order dielectric constant (electronic susceptibility)
λ	wavelength of light	$\chi_m^{(3)}$	third-order dielectric constant of metal
μ	reduced mass of exciton	ω	angular frequency
μ_{eg}	electric dipole moment in optical transition between e and g states	ω_s	angular frequency of surface plasmon
σ	ratio of m_h^* to m_e^*		

Solid-State NMR Structural Studies of Proteins

C E Hughes and M Baldus, Max-Planck-Institute for Biophysical Chemistry, Göttingen, Germany

Introduction

Unlike macroscopic scattering methods such as X-ray diffraction, electron microscopy, or neutron diffraction, nuclear magnetic resonance (NMR) delivers structural information indirectly by probing the local electronic and magnetic environment of a nuclear magnetic moment (spin) or by investigating spin–spin interactions, both in the presence of a static magnetic field. The choice of NMR methods to detect such interactions can be strongly related to the mobility of the molecule of interest. In fact, molecular motion, or more generally speaking, the overall molecular correlation time τ_c, can be used to classify the type of NMR techniques for studying structure at the atomic level. Solution-state NMR studies in proteins are usually applied to systems with an overall correlation time in the nanosecond regime, while solid-state NMR, the area of research discussed in this article, traditionally relates to long or infinite correlation times (**Figure 1**).

In general, an increase in molecular correlation time may result from large molecular size, interactions with an anisotropic environment or from a decrease in temperature. In the context of this article, such phenomena may be related to large proteins, proteins interacting with membranes, or protein aggregates that are indicated in a growing number of protein folding disease states. In all cases, the molecular correlation time becomes longer than the inverse of the magnetic resonance frequency and all possible molecular orientations in the magnetic field are sampled in the NMR frequency spectrum. Unlike in solution, the spectral resolution and the overall sensitivity of solid-state NMR are furthermore influenced by the size of the nuclear spin interactions. Recent progress in NMR instrumentation, in particular the combination of ultrahigh magnetic fields (i.e., above 14 T) with rapid sample rotation (discussed in more detail below) has considerably improved the use of solid-state NMR in biophysical applications.

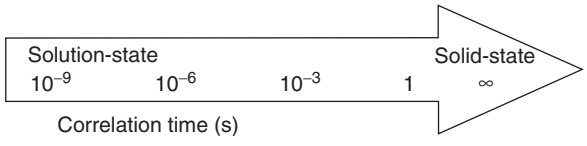

Figure 1 Typical ranges of molecular correlation times accessible to solution-state and solid-phase NMR.

So far, such conditions have not permitted a widespread application of high-resolution ^{1}H NMR spectroscopy, the most sensitive detection method in solution, but have greatly extended the possibilities for studying multiply or uniformly [^{13}C, ^{15}N]-isotope-labeled polypeptides with high sensitivity and adequate spectral resolution. In this article, an overview of the principal interactions that can be probed in NMR is provided, and a set of high-resolution solid-state NMR (HR-SSNMR) techniques that permit the detection of multiple structural parameters from a single protein sample or NMR data set, is introduced. In general, solid-state NMR spectra directly report on the conformational heterogeneity of the sample. Maximum spectral resolution is often obtained for proteins exhibiting a high degree of structural homogeneity. Hence, particular attention is placed on sample preparation and isotope labeling schemes. Finally, the possible range of applications of HR-SSNMR for the structural investigation of solid-phase (membrane) proteins is exemplified in three cases.

Interactions

The microscopic interactions that can be probed by NMR techniques are summarized in **Figure 2** and encompass the chemical shielding, the quadrupolar coupling, the dipolar coupling, and the scalar coupling. The chemical shielding describes the interaction between a nucleus and the applied magnetic field, as mediated by the environment of the nucleus. It is

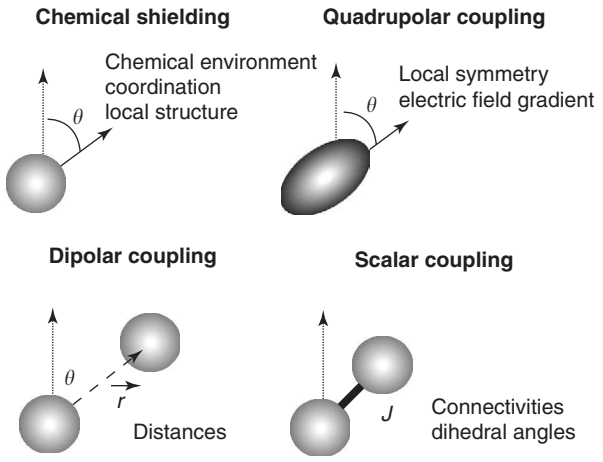

Figure 2 Summary of the four principal interactions probed by NMR. While chemical shielding and quadrupolar interactions involve only one-spin interactions, dipolar and scalar coupling refer to two-spin contacts.

observed as a shift in the resonant frequency, with isotropic and anisotropic contributions. In general, chemical shielding information can directly deliver information about the local electronic environment of a spin or the molecular coordination. In addition, for applications in polypeptides, the resulting resonance frequencies are not only diagnostic for each individual peptide residue but are also very sensitive to local backbone conformation.

The second interaction is the quadrupolar coupling, between the electric quadrupole moment of a nucleus and the electric field gradient at the nucleus. Only nuclei with a spin quantum number greater than 1/2 possess an electric quadrupole moment, making this interaction unimportant when dealing with spin-1/2 nuclei such as ^{1}H, ^{13}C, and ^{15}N. On the other hand, naturally abundant ^{14}N and deuteration with ^{2}H spins (both spin-1) may yield novel insights into the details of polypeptide structure and, in particular, dynamics. In addition to the interactions probing local chemical environments, two-spin interactions are invaluable tools for studying protein structure. For example, the dipolar coupling between pairs of nuclei, of either the same species (homonuclear) or different species (heteronuclear) directly reports on internuclear distances. This coupling is anisotropic in nature, having the same dependency upon spatial rotation as the anisotropic part of the chemical shielding. Finally, spin–spin interactions may be mediated by the through-bond coupling, also known as the scalar or *J*-coupling. This is an isotropic interaction between nuclei (homo- or heteronuclei) modulated by the bonding electrons. Both the dipolar and *J*-couplings can be exploited to transfer magnetization between nuclei, giving invaluable information about the proximity (dipolar) and bonding (*J*) of the nuclei.

In solutions, the rapid tumbling of molecules leads to an averaging out of the anisotropic interactions. In solids, these interactions remain and directly influence the detected NMR spectra. Because the dependence upon spatial rotation of both the chemical shift anisotropy (CSA) and the dipolar coupling is given by $3\cos^2\theta - 1$, where θ is the angle between the z principal axis of the interaction and the applied magnetic field, spinning a sample at an angle of 54.7° to the field axis results in a strong suppression of the anisotropic components of both interactions. The corresponding technique is known as magic-angle spinning (MAS). When MAS is combined with decoupling of the ^{1}H nuclei (whose dipolar couplings are larger and not generally removed by MAS) the line widths of many nuclei, including ^{13}C and ^{15}N, are narrowed toward values observed in solution-state NMR. By removing the dipolar and CSA interactions under ultrahigh magnetic fields (i.e., above 14 T), MAS makes the acquisition of high-resolution solid-state NMR spectra possible.

In addition, a variety of radio frequency (RF) NMR techniques have been developed to recover the structural information contained in the four interactions of **Figure 2** under MAS conditions. Some of these NMR schemes rely solely on particular settings of the MAS rate and are called rotor-driven recoupling techniques. Other techniques, known as radio-frequency-driven polarization transfer techniques, employ a series of RF pulses to overcome the effects of MAS or chemical shift perturbations and allow the detection of specific structural parameters in high resolution.

Sample Preparation

In general, for HR-SSNMR based studies on proteins, [^{13}C, ^{15}N]-isotope labeling is mandatory. Labeling patterns ranging from the incorporation of specifically [^{13}C, ^{15}N]-labeled amino acids to uniform [^{13}C, ^{15}N] substitution are often most economically generated during bacterial growth in minimal media. In addition, chemical synthesis, such as fluorenylmethoxycarbonyl (Fmoc) chemistry, or cell-free approaches can be employed to produce isotope-labeled polypeptides. In both cases, structural studies using solid-state NMR can be performed using a variety of macroscopic sample preparations. For globular proteins, NMR experiments can be conducted after lyophilization and subsequent rehydration, which often increases the structural homogeneity of the sample. For the same purpose, precipitants such as polymers (e.g., polyethylene glycol, PEG) or organic

solvents can be added that can lead to nano- or microcrystalline material. In the context of membrane proteins, structural studies have been conducted using frozen, detergent-solubilized specimens or liposomes in which the protein of interest has been reconstituted. Finally, fibrillized proteins have been extensively studied using solid-state NMR.

The highest sensitivity is usually achieved if the sample of interest is studied under MAS conditions using randomly oriented samples. In addition, macroscopically oriented samples, for example, mechanically oriented biopolymers or membrane-reconstituted peptides, aligned on thin polymer films, can be studied under fast MAS conditions. Furthermore, macroscopically oriented systems can also be investigated after orientation onto glass plates in static experiments or under MAS conditions.

Structural Analysis Using Solid-State NMR

Spectral Assignment

Of particular importance in the context of studying multiply or uniformly labeled proteins are polarization transfer methods employing scalar or dipolar two-spin interactions. Because of the isotropic character of the scalar coupling, polarization transfer mediated by through-bond interactions between two nuclei generally proceeds in an oscillatory manner, irrespective of the macroscopic orientation in the magnetic field (**Figure 3a**). In contrast, polarization transfer transmitted by through-space interactions under MAS conditions is dependent upon the orientation θ, of the dipolar vector in the static magnetic field. Integration over all possible molecular conformations can lead to a polarization transfer behavior, as depicted in **Figure 3b**, where positive and negative signal buildup corresponds to zero-quantum or double-quantum transfer, respectively.

An essential first step in NMR studies of multiply labeled proteins is the spectral assignment, based on the known amino acid sequence. Chemical shifts can be used to distinguish between general types of nuclei (e.g., ^{13}C nuclei in carbonyl (CO) and alpha (C_α) positions) but, for a full assignment, correlation experiments are necessary. These experiments generate two-dimensional (2D) spectra in which pairs of nuclei in close proximity are correlated. Two types of experiments exist, designed to establish intra- and inter-residue correlations. Different ^{13}C spin topologies of the amino acids give characteristic intra-residue correlation patterns, allowing the ^{13}C resonances to be assigned to the different residue types. Experiments

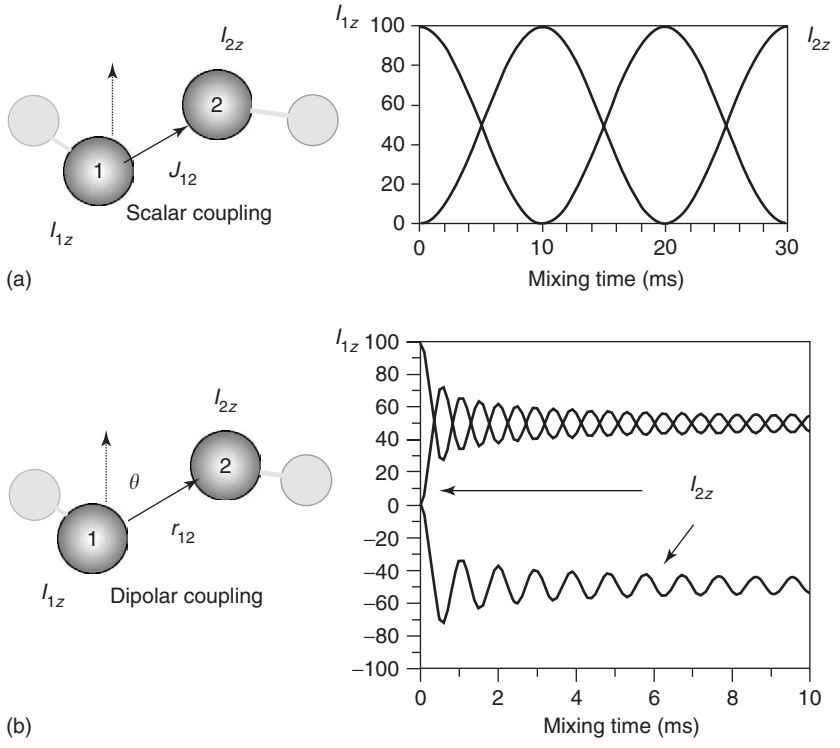

Figure 3 Analytical transfer functions for a two-spin system (denoted by the spin operators I_{1z} and I_{2z}) for the case of (a) the *J*-coupling and (b) the dipolar coupling. In both cases, the spin pair was initially prepared with magnetization only on spin 1. The transfer of polarization is subsequently monitored as a function of the mixing time (given in ms).

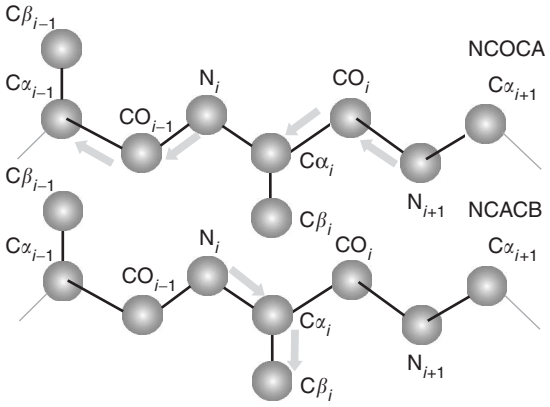

Figure 4 Graphical representation of NCOCA (upper row) and NCACB (lower row) correlation experiments that lead to spectral assignments in HR-SSNMR.

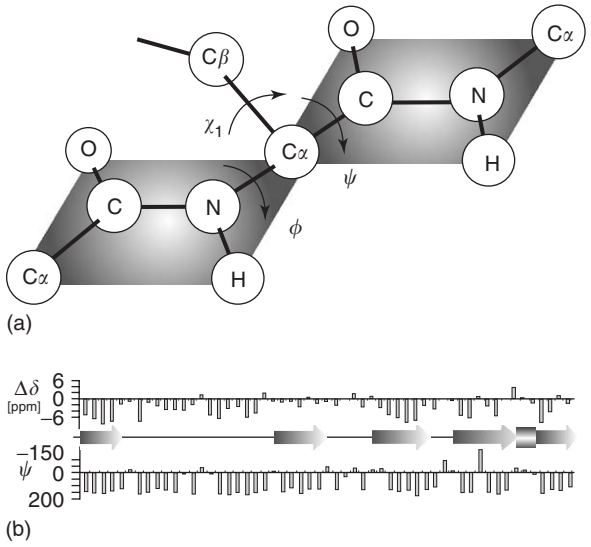

Figure 5 (a) The arrangement of atoms in the backbone of a protein. (b) The correlation between protein backbone structure, i.e., ψ, and secondary chemical shifts $\Delta\delta$ correlating C_α and C_β ^{13}C resonances obtained for the SH3 domain from α spectrin. $\Delta\delta$ is defined by the difference of observed (obs) and random coil (rc) C_α and C_β chemical shifts: $\Delta\delta = (\delta_{C\alpha}(\text{obs}) - \delta_{C\alpha}(\text{rc})) - (\delta_{C\beta}(\text{obs}) - \delta_{C\beta}(\text{rc}))$.

for acquiring these correlation spectra may use single-quantum or double-quantum signal in an indirect dimension to separate out different contributions to the simple one-dimensional spectrum.

To acquire inter-residue information, ^{13}C nuclei can be correlated with ^{15}N nuclei in the same residue and the adjacent residues. This requires selective transfer of polarization between ^{13}C and ^{15}N in order to generate the desired indirect dimension and to ensure good resolution in the direct dimension. A common method involves two experiments, carried out on uniformly ^{13}C and ^{15}N labeled samples. In the first, magnetization is transferred from the backbone ^{15}N nuclei to the adjacent carbonyl (CO) ^{13}C and then, in a subsequent step, on to the α ^{13}C nuclei. This links the ^{15}N in residue i to the ^{13}C nuclei in residue i–1 (**Figure 4**, upper row) and is, in general, referred to as an NCOCA correlation experiment. In the second experiment, magnetization is transferred from the peptide bond ^{15}N nuclei to the nearest neighbor $^{13}C_\alpha$ spin, linking the ^{15}N and ^{13}C nuclei within the same residue. A subsequent (^{13}C, ^{13}C) transfer step leads to C_β resonance of the same residue corresponding to an NCACB-type experiment (**Figure 4**, lower row). From these two experiments, all backbone ^{13}C and ^{15}N nuclei of the polypeptide can be investigated.

Secondary Structure

The secondary structure of a protein encompasses the arrangement of the backbone atoms, depicted in **Figure 5a**. As the bond lengths are invariant, the secondary structure is largely defined by the torsional angles CO($i-1$)–N(i)–C$_\alpha$(i)–CO(i) and N(i)–C$_\alpha$(i)–CO(i)–N($i+1$), known as the ϕ and ψ angles, respectively. These may be measured in a variety of ways. A strong correlation exists between the ^{13}C chemical shifts at the C_α and C_β positions and the values of ϕ and ψ. In particular, the two main backbone conformational types, the α-helix and the β-sheet, may be distinguished by comparing these ^{13}C chemical shifts to the average chemical shifts (so-called "random-coil" values) for each amino acid. An example of the strong correlation between, so-called, secondary chemical shifts $\Delta\delta$ and the torsion angle ψ is shown in **Figure 5b** for a U-[^{13}C, ^{15}N]-labeled sample of the SH3 domain from α spectrin.

Dihedral angle constraints may also be determined directly by experiments monitoring the relative orientation of the appropriate internuclear vectors. This encoding can be carried out by allowing the dipolar interactions to generate cross-peaks in a correlation spectrum characteristic of their relative orientation or by creating a multiple-quantum state that evolves under the influence of surrounding dipolar interactions. Distance measurements are also important for the determination of secondary structure. For example, the $H_\alpha(i)$–$H_N(i+1)$ distance is a sensitive measure of the ψ torsional angle and can be probed by indirect detection schemes in solid-state NMR. Specifically, ^{13}C and ^{15}N labeled samples can also be used to measure distances between residues, which are sensitive to the ϕ and/or ψ angles. In both cases, experiments are used which involve dipolar recoupling between the two nuclei of interest. The buildup of either magnetization transfer or double-quantum coherence depends upon the internuclear distance

and may be analyzed by appropriate theoretical or numerical models to give a measure of the distance. Of particular importance for structural characterization of side chains are HCCH and HNCH torsional angles, both of which can be measured using the methods outlined above.

Tertiary Structure

In order to establish the overall fold of a protein, distances must be measured between separate parts of the peptide chain. For a long time, the determination of these long-range contacts represented a major challenge for solid-state NMR due to an effect known as dipolar truncation, where the strong, short-range dipolar interactions dominate weaker, long-range interactions. As a result, relay effects over several short-range interactions may determine the spin system dynamics. These problems are most serious for uniformly [^{13}C, ^{15}N]-labeled proteins. Three approaches have been recently suggested to circumvent these difficulties. One is to dilute the isotope labeling of the protein by, for example, block labeling. A second approach involves the use of selective recoupling methods that establish polarization transfer for particular two-spin systems only. Finally, useful information may be obtained from an analysis of (^{1}H, ^{1}H) contacts, which is common practice in solution-state NMR. Because of the limited spectral resolution in solid-state ^{1}H NMR spectra, such interactions may be encoded indirectly in high-resolution ^{13}C and/or ^{15}N spectral dimensions. Correspondingly, the 2D NMR experiments have been denoted by CHHC and NHHC correlation methods, respectively.

Similar to the solution-state, NMR structure determination in the solid state subsequently involves the calculation of families of molecular conformations that are consistent with the experimentally derived distance or angle constraints. The number and precision of these parameters determine the accuracy of the resulting 3D structure.

Protein Orientations, Interactions, and Dynamics

In addition to revealing structural information about the protein in a near-biological environment, the orientation of the protein with respect to a macroscopic reference frame (for example, one defined by the membrane bilayer for membrane peptides and proteins) can be investigated. The application of such methods often involves the NMR study of macroscopically aligned polypeptides and has resulted in several high-resolution structures of membrane-embedded systems. Furthermore, interactions between different proteins, proteins–ligand interactions (e.g., involving drugs, hormones, etc.), or monomer–monomer interactions in oligomeric proteins (quaternary structure) can, in principle, be investigated by high-resolution solid-state NMR.

Applications

In the following, three examples for the range of structural problems in immobilized proteins that can be addressed by high-resolution solid-state NMR are given. In **Figure 6**, results of 2D CHHC correlation experiment conducted on a uniformly [^{13}C, ^{15}N]-labeled sample of the 2×10.4 kDa dimeric form of the regulatory protein Crh in microcrystalline form are shown. Each correlation reflects close proton–proton contacts encoded in ^{13}C resonance frequencies. Three sections are highlighted where short, inter-residue (^{1}H, ^{1}H) distances are observed. A combination of these results with NC correlation experiments discussed earlier leads to NMR assignments of the largest protein studied by HR-SSNMR thus far and provides the basis for investigating the Crh folding pathway from a monomeric, soluble protein to a domain-swapped dimer observed in the microcrystalline state. Domain-swapping is a process by which one protein molecule exchanges a domain with an identical partner, and has been discussed as a general means for creating protein complexes and as a mechanism for misfolding and aggregation.

Solid-state NMR not only can report on the complete structure of a membrane protein but can also probe dynamics in the protein of interest. Both aspects have recently been investigated in the context of a uniformly [^{13}C, ^{15}N]-labeled version of the LH2 light-harvesting complex, one of the largest membrane systems studied by solid-state NMR to date ($\sim$150 kDa). Here, the application of ultrahigh magnetic fields (up to 750 MHz) was crucial to establish high-resolution conditions in the solid state. Two-dimensional (^{15}N, ^{13}C) correlation experiments (such as shown in **Figure 7**) were conducted to assign backbone and side-chain resonances at different temperatures. At -10°C, a variety of spectral assignments within the transmembrane sections of the protein were possible. Additional correlations occur at lower temperatures consistent with the immobilization of flexible loop regions of the protein. A more detailed structural study in membrane proteins could include (^{13}C, ^{13}C) or indirect (^{1}H, ^{1}H) correlation experiments possibly in conjunction with advanced isotope-labeling approaches, to determine the complete 3D structure of a membrane protein in the solid state.

To date, no structural information of a high-affinity ligand bound to a G-protein-coupled receptor

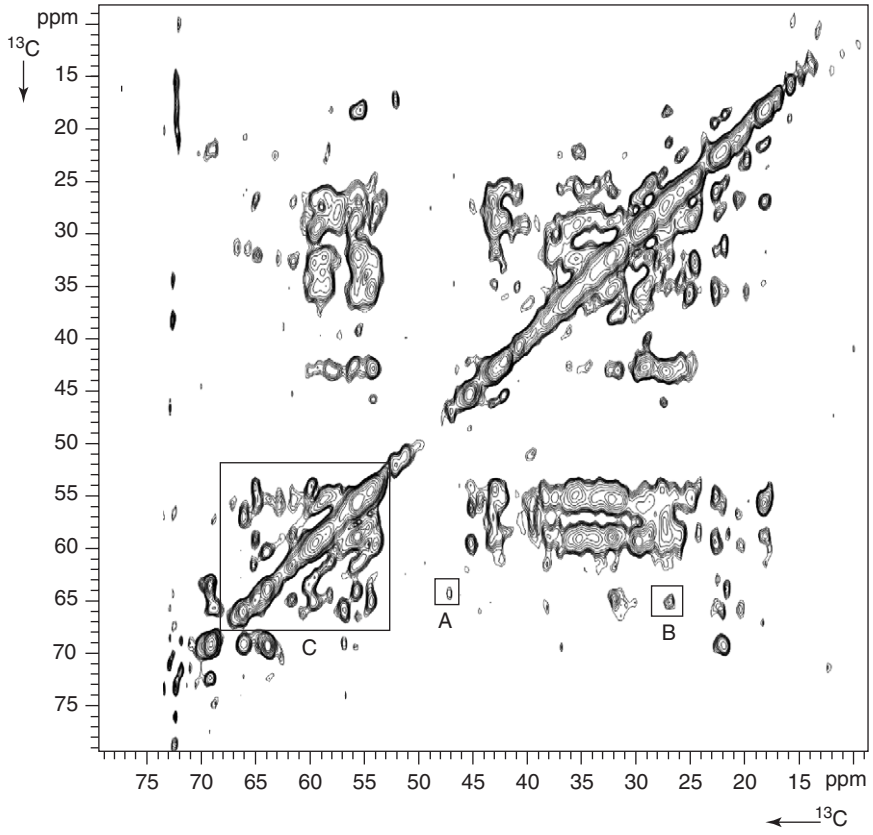

Figure 6 2D CHHC correlation experiment conducted on a uniformly [^{13}C, ^{15}N]-labeled sample of the 2 × 10.4 kDa dimeric form of the regulatory protein Crh. Each correlation reflects close proton–proton contacts encoded in ^{13}C resonance frequencies. Three sections are highlighted where short, inter-residue (^{1}H, ^{1}H) distances are observed: A – involving Gly49 and Ser46, B – Pro18 - Leu10, and C – a variety of C_α–C_α contacts.

(GPCR) is available. The recombinant expression of GPCRs in large quantities is usually difficult and must involve carefully optimized biochemical procedures. Restrictions regarding the availability of functional receptors also affect the quantities of ligand that can be studied. Moreover, the chemical environment including lipids and receptor protein can hamper the unambiguous spectral identification of a bound ligand in a solid-state NMR experiment. It has been recently shown how 2D solid-state NMR experiments can be used to detect microgram quantities of bound neurotensin, a 13-residue neuropeptide that binds in high affinity to the NTS-1 (101 kDa) receptor. For the 6-residue, biologically active, C-terminal sequence of neurotensin, a homonuclear (2Q, 1Q) correlation spectrum is sufficient to assign all C_α and C_β resonances of the uniformly [^{13}C, ^{15}N]-labeled ligand. These chemical shift assignments can be used to construct the backbone model of the ligand complexing with the receptor. Using the only high-resolution structure of a GPCR, rhodopsin, as a template, this information could be used to establish a molecular model for the binding pocket of NT(8-13) (**Figure 8**).

Conclusions and Outlook

In many research fields, NMR methods have made important contributions to the present understanding of molecular structure and function. In particular, NMR has become a standard method for the characterization of 3D structure and dynamics of proteins that undergo fast molecular reorientations in solution. Such macroscopic sample conditions are, however, difficult to establish for protein aggregates, which are associated with a growing number of protein folding diseases. Moreover, integral membrane proteins, which constitute about 30% of all proteins, are often difficult to solubilize or crystallize in functional form. In all these cases, NMR techniques particularly designed for the study of solid-phase systems ("solid-state NMR") offer unique possibilities to elucidate structural or dynamic parameters at atomic resolution.

In this article, a summary of high-resolution solid-state NMR methods that permit the detection of multiple structural parameters from a single protein sample or NMR data set is given. Recent applications in (membrane) proteins underline the growing

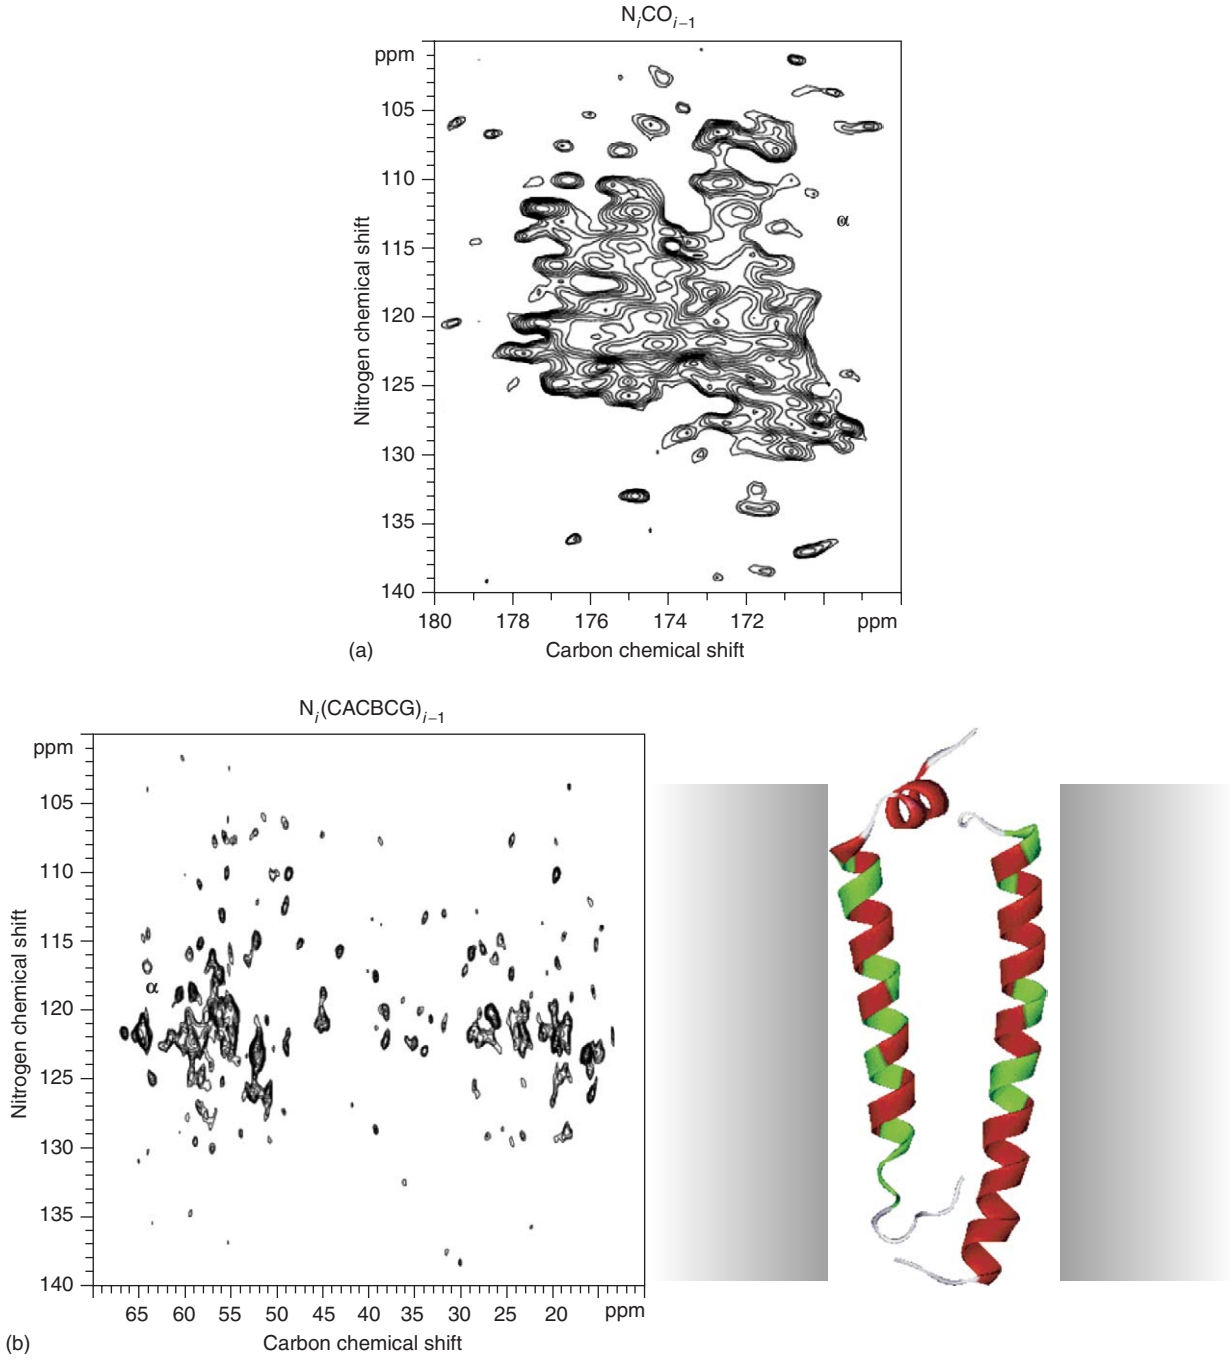

Figure 7 Combined NC-CC 2D transfer experiment on U-[^{13}C, ^{15}N]-labeled LH2 revealing a variety of N_iCO_{i-1} (a) and $N_i(CACBCG)_{i-1}$ (b) correlations. potential of HR-SSNMR to provide exclusive insight into the microscopic details of biological functioning. Advances regarding sample preparation (for example, including modular labeling, *in vitro* expression, and intein technology) and improvements in NMR hardware instrumentation could open up additional areas of solid-state NMR research, such as the investigation of large protein–protein complexes or the complete 3D characterization of larger membrane proteins. Solid-state NMR studies of multiply labeled biomolecules will furthermore profit from improved procedures for calculating 3D structures, in particular, in the presence of ambiguous or a limited number of structural constraints. In general, protein motion does not hinder the application of solid-state NMR methods, providing a very efficient

means of studying protein folding, flexibility, and function under biologically relevant conditions. Complementary to solution-state techniques and crystallographic methods, solid-state NMR can give detailed insight into protein structure and function.

Solidification: Models and Simulations

J A Dantzig, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Introduction

Solidification has been an important manufacturing process dating as far back as the bronze age. In more recent times, research has focused on controlling the microstructure – the internal segregation pattern which forms upon freezing – in order to control the properties of the product. This article describes how thermodynamics and heat and mass transfer interact to produce the complex patterns associated with solidification in crystalline materials. The discussion is restricted to binary alloys, which still leaves one with a rich spectrum of behavior. To begin with, the physical phenomena which occur during solidification are discussed, and then, some of the background material that supports the description is provided.

As a liquid alloy is cooled, crystallization begins at some temperature. In general, the composition of the solid is different from that of the liquid. Under the conditions normally found in conventional processes, thermodynamic equilibrium is established at the liquid–solid interface, and this provides a relationship between the interface temperature and the compositions of the phases. Microstructure formation represents the competition between heat transfer and mass transfer, mediated by thermodynamic equilibrium. The material properties which control the rates of the transport processes are the thermal diffusivities α_S and α_L, and the chemical diffusivities $\mathscr{D}_S$ and $\mathscr{D}_L$. Throughout this article, the subscripts S and L are used to indicate the solid and liquid phases,

respectively. For most materials, these quantities follow the relation that $\alpha_S \approx \alpha_L \gg D_L \gg D_S$. It is shown by scaling analysis that this hierarchy of values leads to a situation where the motion of the liquid–solid interface is controlled by heat flow, under the action of external boundary conditions, and the solute is unable to keep up with the heat transfer process. The resulting segregation pattern, called the microstructure, provides a frozen record of the results of the competition.

In the following sections, the thermodynamics of solutions is described first in order to establish the relationship between temperature and composition during solidification. Heat and mass transfer, and the unique mathematical and computational issues posed by the moving phase boundary are then taken up. Finally, some example calculations are given showing how these concepts can be used to compute microstructures.

Thermodynamics and Equilibrium Phase Diagrams

Thermodynamics tells about the equilibrium state of materials – the phases present, their compositions, and relative amounts at a given temperature – after an infinite time has passed. Although this is clearly never the case, the concepts of phase equilibria normally do apply locally, at the solidifying interface, and so an understanding of solidification begins with thermodynamics of solutions. The thermodynamic state of a mixture can be specified via the compositions of its constituents, and two of the three thermodynamic variables: temperature T, pressure p, and volume V. The third thermodynamic variable comes from an equation of state. For condensed phases, it is most convenient to choose T and p as the thermodynamic variables. It may also be noted that all but one of the compositions of the phases are independent, once the overall composition of the alloy is specified.

The free energy of the mixture can be computed from these thermodynamic quantities. Equilibrium is defined as the minimum in the free energy. Here, open systems are considered, for which the effect of pressure can be neglected, and a model which gives the free energy of the solution for any given temperature and composition is introduced. The regular solution model is a very powerful model which permits a wide range of experimentally observed behavior to be reproduced through the variation of just two parameters. Consider binary alloys, with components A and B. The composition of the alloy can be written as a mole fraction X, or as a mass fraction designated C. These measures are related through the molecular weights M_A and M_B, such that $C = M_B X/(M_A + (M_B - M_A)X)$. Solution models are more conveniently formulated in terms of X, while transport models are more compact when written in terms of C. In the regular solution model for binary alloys, the free energies of mixing G^{mix} in the solid and liquid states are given by

$$G_L^{mix}(X_L, T) = RT(X_L \ln X_L + (1 - X_L) \times \ln(1 - X_L)) + \Omega_L X_L (1 - X_L) \quad [1]$$

$$G_S^{mix}(X_S, T) = (1 - X_S)\Delta S_f^A (T - T_m^A) + X_S \Delta S_f^B (T - T_m^B) + RT\,(X_S \ln X_S + (1 - X_S)\ln(1 - X_S)) + \Omega_S X_S (1 - X_S) \quad [2]$$

where R is the ideal gas constant, ΔS_f^A and ΔS_f^B are the entropies of fusion of pure materials A and B, respectively, T_m^A and T_m^B are their melting points and Ω_S and Ω_L are the regular solution model parameters.

Three cases are considered, involving different values of Ω_S and Ω_L, and the relationship between the free energies and the equilibrium phase diagram is demonstrated. Free energy curves for the solid and liquid are shown at an interesting temperature for each case at the top of **Figure 1**. The intersection of the two free energy curves, called the T_0 point, indicates a temperature T_0 and composition X_0 which lies in a region of two-phase coexistence.

The compositions X_S and X_L of the solid and liquid phases in equilibrium are the same for any alloy in the two-phase region, including, of course, X_0. It follows from a simple mass balance that the fraction of each phase present is

$$f_S = \frac{X_L - X_0}{X_L - X_S}, \qquad f_L = \frac{X_0 - X_S}{X_L - X_S} \quad [3]$$

It follows that the total free energy G^{total} of the two-phase mixture is

$$G^{total}(x_0, T; [X_S, X_L]) = f_S G_S^{mix}(X_S, T) + f_L G_L^{mix}(X_L, T) \quad [4]$$

where the parametric dependence of G^{total} on the phase compositions X_S and X_L are explicitly indicated.

The equilibrium phase compositions are those which minimize the free energy. Thus, this may be posed as an optimization problem: find those values of X_S and X_L which minimize G^{total} in eqn [4]. The optimization problem has side constraints. For the example shown in **Figure 1a**, $0 \leqslant X_L < X_0$ and $X_0 < X_S \leqslant 1$. The equilibrium values for X_S and X_L are also the points on the two curves which share a common tangent, as indicated in the upper figure.

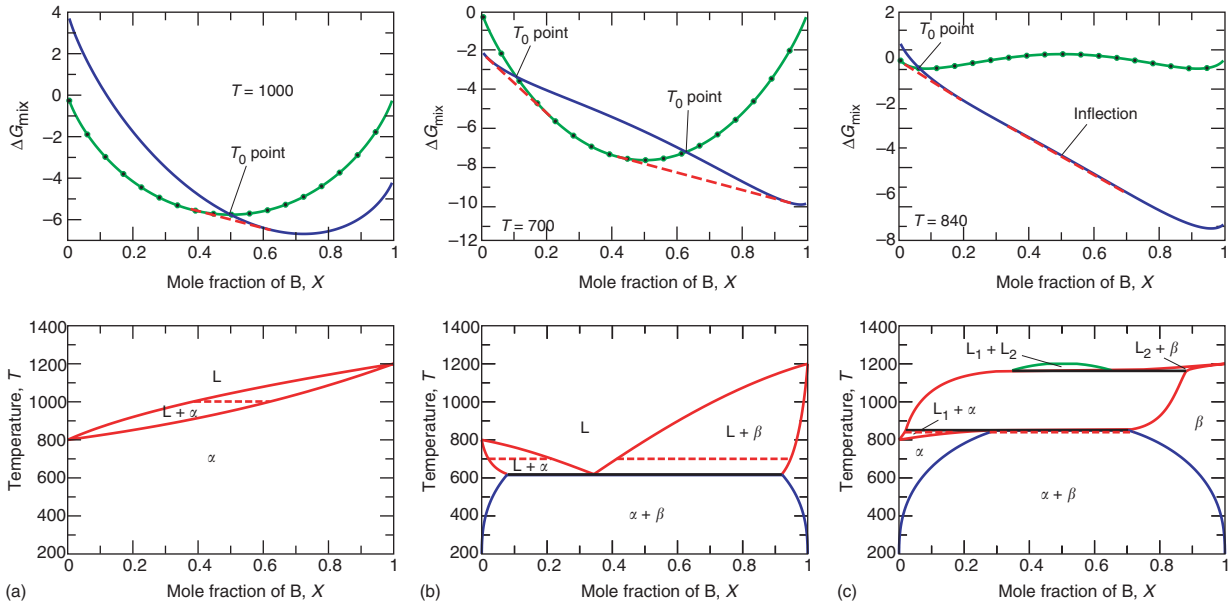

Figure 1 Correspondence between free energy and equilibrium phase diagrams for three different sets of parameters. For all three cases, $T_m^A = 800$, $T_m^B = 1200$, and $\Delta S_f^A = \Delta S_f^B = 20$. (a) An isomorphous system ($\Omega_S = \Omega_L = 0$), (b) a eutectic system ($\Omega_S = 15\,000$, $\Omega_L = -15\,000$), and (c) a system with a peritectic and a monotectic reaction ($\Omega_S = 15\,000$, $\Omega_L = 20\,000$) are shown. The dashed lines in the figures show how the common tangents in free energy correspond to two-phase equilibria. (●—●: liquid; ——: solid; and – – –: common tangent.)

The entire phase diagram can be constructed by performing a series of optimization problems over a range of temperatures, and plotting the results in the form shown in the lower part of **Figure 1**. The locus of all of the (X_L, T) pairs is called the "liquidus" curve, and the similar locus of all (X_S,T) curves is called the solidus. In the next section, these two curves are referred to as T_{liq} and T_{sol}, respectively.

The regular solution can produce a rich variety of phase diagrams, as shown in **Figure 1**. By varying only Ω_S and Ω_L, many different types of reactions can occur. For example, in **Figure 1b**, there are two points of common tangency between the liquid and solid free energy curves, and this leads to a eutectic reaction at lower temperature when the two liquid compositions coincide and there is a three-phase equilibrium. In **Figure 1c**, in addition to the liquid–solid equilibrium, a miscibility gap in the solid is seen. The solution parameters are normally found by fitting to experimental data, or from electronic structure models. While the principles are the same, the process of finding equilibrium compositions is more complicated when binary compounds A_aB_b can form, and when more than two components are used. The reader is referred to the "Further reading" section to find out more about these cases.

The thermodynamic data reveals the phases and compositions which should be in equilibrium for a given temperature and composition. However, it contains no information about either spatial distribution or the dynamics of the transformation. To address these issues, attention is drawn to heat and mass transfer.

Heat and Mass Transport

The discussion of microstructure evolution is given here in the context of the prototype experimental system called "directional solidification," illustrated in **Figure 2**. An alloy of interest is encapsulated between two microscope slides, and placed on a microscope stage with a fixed temperature gradient maintained by two temperature-controlled blocks. The alloy is frozen by translating the stage at a controlled velocity V. The experiment is normally performed in such a way that the liquid–solid interface is fixed in space, that is, the solidification velocity and the speed of traverse are the same. As suggested by the simulated microstructure shown in **Figure 2b**, a flat interface is unstable, leading to a complex pattern called the microstructure. This microstructure consists of tree-like forms called dendrites, which evolved from an initially flat interface. Primary arms are seen growing from left to right with a characteristic spacing that may be called λ_1. The goal here is to predict such structures from a knowledge of the alloy and process parameters.

To this end, the heat and mass transfer problem is taken up for the moving interface. The governing equations come from statements of the conservation

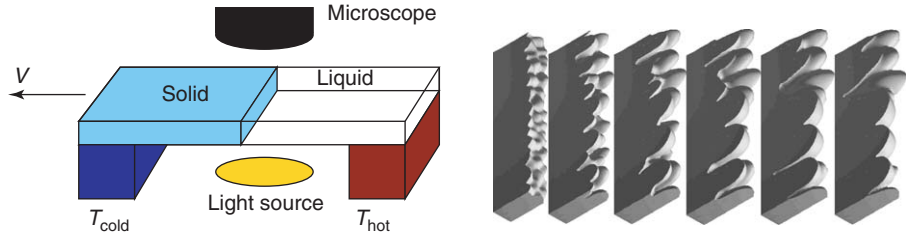

Figure 2 Schematic of (a) a directional solidification apparatus, and (b) a simulated microstructure showing the interface evolving over time. This simulation was done in three dimensions using adaptive finite elements, discussed later.

of energy and mass in the system, respectively. A linear relationship between the heat flux and temperature gradient (Fourier's law), and a similar relationship between solute flux and composition gradient (Fick's law) are assumed. It is more convenient to describe mass transport using the mass fraction C, as opposed to the mole fraction X used in the preceding section. The governing equations for heat and mass transport in the liquid and solid are

$$\rho_i c_p^i \frac{\mathrm{D}T_i}{\mathrm{D}t} = \nabla \cdot (k_i \nabla T) \qquad [5]$$

$$\rho_i \frac{\mathrm{D}C_i}{\mathrm{D}t} = \nabla \cdot (\rho_i \mathscr{D}_i \nabla C_i) \qquad [6]$$

where $i = \mathrm{S}, \mathrm{L}$ indicates the phase. The symbol $\mathrm{D}/\mathrm{D}t$ represents the material derivative $\partial/\partial t + v \cdot \nabla$ where t is time and is the mass-averaged velocity, ρ is the density, c_p is the specific heat at constant pressure, k is the thermal conductivity, C is the composition, measured in mass fraction, and $\mathscr{D}$ is the diffusion coefficient.

As the interface moves, it surrenders the latent heat of fusion L_f. The concentrations of the liquid and solid at the interface are different, given by the condition of thermodynamic equilibrium, as discussed previously. Denoting the normal velocity of the interface as V_n, energy and solute balances at the interface may be written as

$$k_\mathrm{S}\frac{\partial T_\mathrm{S}}{\partial n} - k_\mathrm{L}\frac{\partial T_\mathrm{L}}{\partial n} = \rho_\mathrm{S} L_\mathrm{f} V_\mathrm{n} \qquad [7]$$

$$\mathscr{D}_\mathrm{S}\frac{\partial C_\mathrm{S}}{\partial n} - \mathscr{D}_\mathrm{L}\frac{\partial C_\mathrm{L}}{\partial n} = (C_\mathrm{L} - C_\mathrm{S})V_\mathrm{n} \qquad [8]$$

where derivatives with respect to n represent the projection of the gradient normal to the interface. The necessary equations for solidification are completed using the assumption of thermodynamic equilibrium at the interface. This leads to a "coupling condition" between the temperature and composition, known as the Gibbs–Thomson equation:

$$T_\mathrm{S} = T_\mathrm{L} = T_\mathrm{liq}(C_\mathrm{L}) - \left(\frac{\gamma}{\Delta S_\mathrm{f}}\right)\kappa - \beta V_\mathrm{n} \qquad [9]$$

where γ is the surface tension, ΔS_f is the entropy of fusion, κ is the mean curvature, and β is a coefficient interface attachment kinetics. It is worth reiterating that $T_\mathrm{liq}(C_\mathrm{L})$ comes from thermodynamics and the equilibrium phase diagram.

In order to elucidate some important physics, consider the special case of directional solidification with a flat interface; there is no motion except for the translation of the stage at fixed velocity V in the x-direction. It is assumed that all material properties are constant, and that $\alpha_\mathrm{S} = \alpha_\mathrm{L}$. The latter assumption simplifies the presentation, and the temperature is simply written as T. The governing equations are now all one dimensional. If it is assumed that the process is steady with respect to a frame which is fixed at the interface, the governing equations reduce to

$$-V\frac{\partial T}{\partial x} = \alpha\frac{\partial^2 T}{\partial x^2}, \qquad -V\frac{\partial C_\mathrm{L}}{\partial x} = \mathscr{D}_\mathrm{L}\frac{\partial^2 C_\mathrm{L}}{\partial x^2}$$
$$-V\frac{\partial C_\mathrm{S}}{\partial x} = \mathscr{D}_\mathrm{S}\frac{\partial^2 C_\mathrm{S}}{\partial x^2} \qquad [10]$$

Even though the interface is considered to be flat (at the moment), **Figure 2b** shows clearly that there are characteristic length scales. The length is scaled on the primary dendrite spacing λ_1, defining $\xi = x/\lambda_1$. Each form in eqn [10] will then have a dimensionless ratio on the left-hand side called the Péclet number, representing the relative importance of advective to diffusive transport. The transparent organic system succinonitrile-acetone has been extensively studied experimentally, and if typical values from such experiments are taken to compute the dimensionless coefficients (see **Table 1**), one obtains

$$\frac{V\lambda_1}{\alpha} = 0.018, \qquad \frac{V\lambda_1}{D_\mathrm{L}} = 1.6$$
$$\frac{V\lambda_1}{D_\mathrm{S}} = 16\,000 \qquad [11]$$

Dropping terms that are small compared to the ones in eqn [10] leaves

$$0 \approx \frac{\partial^2 T}{\partial x^2}, \qquad -V\frac{\partial C_\mathrm{L}}{\partial x} = \frac{\partial^2 C_\mathrm{L}}{\partial x^2}, \qquad \frac{\partial C_\mathrm{S}}{\partial x} \approx 0 \qquad [12]$$

Table 1 Physical properties and experimental parameters for succinonitrile-acetone system used to evaluate dimensionless parameters

Quantity	*Value*	*Units*
α_S	1.125×10^{-7}	$m^2\,s^{-1}$
α_L	1.125×10^{-7}	$m^2\,s^{-1}$
$\mathscr{D}_L$	1.3×10^{-9}	$m^2\,s^{-1}$
$\mathscr{D}_S$	1.3×10^{-13}	$m^2\,s^{-1}$
V	3.4	$\mu m\,s^{-1}$
λ_1	610	μm

The first and third equations are easily integrated to find that the temperature profile is linear and "frozen" in space, and the composition of the solid is constant

$$T = T_{cold} + G(x - x_{cold}), \qquad C_S = \text{constant} \quad [13]$$

The composition in the liquid is obtained using eqn [8] as a boundary condition at the interface, and the far-field condition that $C_L(x \to \infty) = C_0$, the nominal composition of the alloy. As part of the solution process, one finds that $C_S = C_0$. Thermodynamic equilibrium at the interface implies that the temperature there is $T_{sol}(C_0)$, and correspondingly that $C_L(0) = C_{liq}(T_{sol})$, and so, $\Delta C_0 = C_{liq}(T_{sol}) - C_0$, and finally the solution for C_L is

$$C_L = C_0 + \Delta C_0 \exp\left(-\frac{Vx}{\mathscr{D}_L}\right) \quad [14]$$

The solution is shown schematically in **Figure 3**.

When the temperature gradient is relatively low, there is a region ahead of the interface where the local liquidus temperature is below the actual temperature, shown as a shaded region in the lower part of **Figure 3**. The existence of this region makes the interface unstable with respect to morphological disturbances. The interface will be stable when $G \leqslant m_L \partial C_L/\partial x$, where m_L is the slope of the liquidus curve on the equilibrium phase diagram at $T = T_{sol}$. This can be rewritten in terms of a dimensionless constant $\mathscr{M}$ called the morphological number:

$$\mathscr{M} = -\frac{m_L V \Delta C_0}{G \mathscr{D}_L} \leqslant 1 \quad [15]$$

To obtain information about the length scales which evolve from the unstable interface, one can perform a linear stability analysis, using the planar interface as a base state. Space does not permit reproduction of the analysis here, but there is an important piece of physics that comes out of it. When the interface is flat, the curvature term in eqn [9] plays no role. However, when the interface shape is perturbed, surface tension provides a restoring force. The strength of the surface tension is characterized

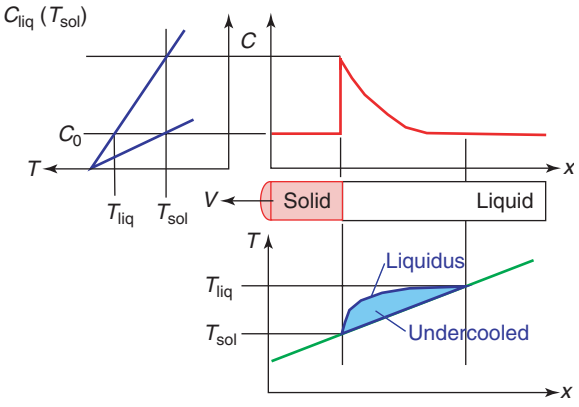

Figure 3 Pictorial view of the temperature and composition profiles during directional solidification with a flat interface. The solid and liquid compositions at the interface are given by the equilibrium phase diagram.

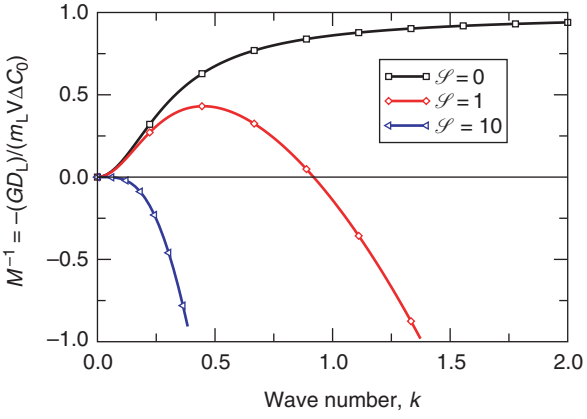

Figure 4 Neutral stability curves for plane front growth for different values of $\mathscr{S}$. Values of $1/\mathscr{M}$ above the neutral curve are stable, while values below are unstable. Negative values of $1/\mathscr{M}$ are physically unattainable.

through a second dimensionless parameter $\mathscr{S}$ given by

$$\mathscr{S} = -\frac{\gamma V}{\mathscr{D}_L m_L \Delta C_0} \quad [16]$$

Figure 4 shows the dispersion relation for various values of $\mathscr{S}$. It can be seen that for $\mathscr{S} = 1$, the presence of surface tension stabilizes small wavelength disturbances, and that only certain wave numbers are unstable. These are the ones that one expects to see in the directional solidification experiment. Note that for sufficiently high values of $\mathscr{S}$, such as $\mathscr{S} = 10$, all wavelengths are stable, a condition known as absolute stability. The linear stability analysis is useful for understanding the length scales of the initial disturbances. **Figure 2** shows, however, that a complex selection process continues after the initial instability, and this is beyond the scope of analytical treatment.

The critical question in directional solidification is to predict the microstructure which will evolve under a given set of processing conditions. The answer is understood in a semiquantitative way for a single isolated dendrite. If one imagines an isolated dendrite whose shape near the tip resembles a paraboloid of revolution, then the shape is characterized by a single parameter, the tip radius ρ_{tip}. A solution of the transport equations gives only the product $\rho_{\text{tip}}V$ as constant, leaving the exact shape undetermined. The stability analysis of the transport solution indicates that $\rho_{\text{tip}}^2 V = \sigma^\star$, a constant, and the two criteria combine to provide a unique solution or operating state. The value of the selection constant $\sigma^\star$ is determined by experiment. The theory for the isolated dendrite has been applied to directional solidification, with reasonable agreement with experiment. The dynamics of the selection process, and dependence on initial conditions must be addressed by numerical simulations, which is taken up in the next section.

Numerical Simulation of Microstructure

The numerical simulation of microstructure evolution poses some unique challenges. The governing equations of heat and mass transfer eqns [5] and [6] are to be solved, satisfying the boundary conditions given in eqns [7]–[9]. The two principal difficulties are the disparity in length and time scales in the heat and mass transfer processes, and the fact that the boundary conditions on the liquid–solid interface must be applied on a boundary whose position is unknown *a priori*.

While the length/time scale problem can be attacked by brute force, the free-boundary problem requires more care. There are two principal approaches to the problem: fixed-grid methods, which somehow spread the interface over a finite width, and recover its position from the solution; and interface-tracking methods, in which the mesh is adjusted locally to ensure that grid points coincide with the interface. In the fixed-grid methods, there is no longer a phase boundary, and the technique by which the interface is spread ensures that the boundary conditions are met. Interface-tracking methods specifically satisfy the boundary conditions. Most such methods follow a two-step procedure. First, the interface position is fixed, and the field equations are solved for temperature and composition using one of the boundary conditions, typically eqn [9]. Next, the interface is relocated using the remaining boundary conditions, typically the flux conditions. The grid is then adjusted, and the procedure begins anew. There are advantages and disadvantages to both methods, and to some extent, the choice is a matter of taste. To demonstrate this point, one example of a fixed-grid method, and another of an interface-tracking method are included.

One of the fixed-grid methods is called the phase-field method. In this approach, a continuous function ψ is introduced which has the property that $\psi = 1$ corresponds to the solid phase, $\psi = -1$ corresponds to the liquid phase, and intermediate values are associated with the interface. The phase-field function ψ satisfies an evolution equation of the form

$$\tau \frac{\partial \psi}{\partial t} = -\frac{\delta \mathscr{F}}{\delta \psi} \qquad [17]$$

where $\delta/\delta\psi$ indicates a variational derivative, and $\mathscr{F}$ is a function of the form

$$\mathscr{F} = \int_V \frac{1}{2}|w\nabla\psi|^2 + f(C, T, \psi)\, \mathrm{d}V \qquad [18]$$

where w is the interface width, and the function $f(C, T, \psi)$ is chosen such that it has a "double well" form, with minima at $\psi = \pm 1$, and contrived such that the functional dependence on C and T ensures that thermodynamic equilibrium is enforced. Flux conditions are satisfied by adding source terms proportional to $\partial\psi/\partial t$ to the field equations for T and C. There are many possible choices for f, but they should all lead to the same computational result when their parameters are chosen properly.

There are two major challenges in using the phase-field method. It is necessary to determine the relationship between the phase-field model parameters and the physical parameters, such as γ and β in eqn [9]. This usually requires an asymptotic analysis of the phase-field model, and may lead to very restrictive computational limits for some sets of parameters, most notably when the diffusion coefficients in the liquid and solid are quite different. This problem can be solved, but it always requires that computations be carried out such that the interface width w is small compared to the characteristic diffusion length, in this case $\mathscr{D}_{\text{L}}/V$. Further, the grid spacing Δ must be small compared to w in order to resolve the interface in the computations. The second difficulty comes from the need to resolve microstructural length scales as well, which implies that the computational domain characteristic length $\mathscr{L}$ must be large compared to $\mathscr{D}_{\text{L}}/V$.

Taking these two requirements together, the number of grid points in each direction in a uniform grid is $N = \mathscr{L}/\Delta = \mathscr{O}(10^3)$. This poses a severe limit on 2D computations, and makes 3D computations prohibitively expensive. One approach to deal with this restriction is to use an adaptive grid, fine near the

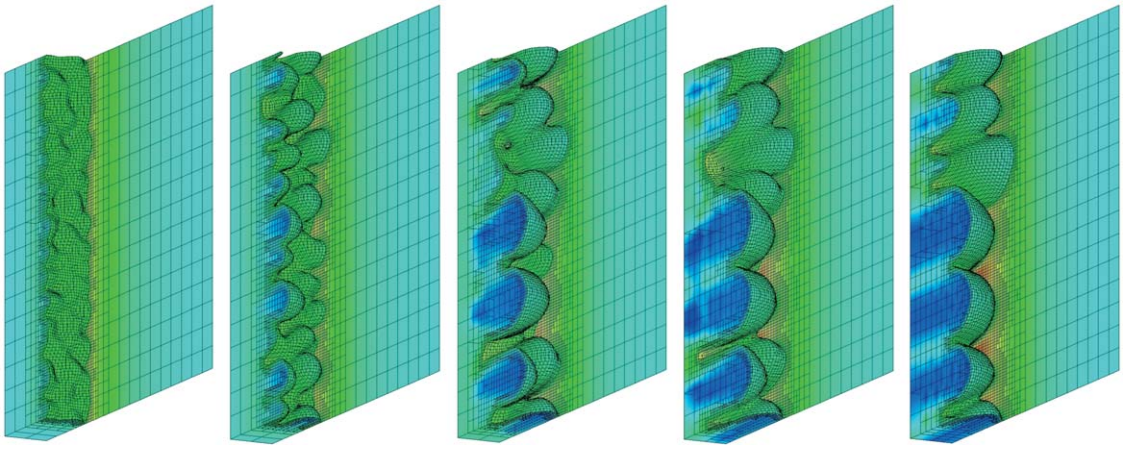

Figure 5 Time sequence of images simulating directional solidification using an adaptive finite element mesh. Color represents concentration. Note the evolution of length scales and segregation patterns during growth.

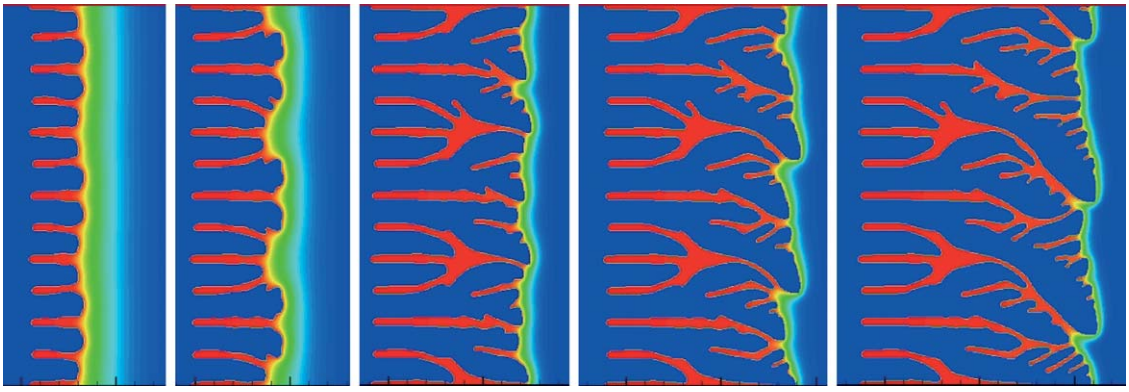

Figure 6 Sequence of images depicting the microstructure and concentration field during directional solidification, obtained using a level-set method. The crystallographic direction corresponding to the direction of fastest growth is oriented at 45° to the growth direction. Notice that the concentration field ahead of the interface is compressed as the growth velocity increases with time.

interface, and much coarser elsewhere. **Figure 5** shows an example of this technique for computing a directionally solidified microstructure. The simulation begins with a random disturbance on the interface, which evolves over time to form the pattern shown. The temperature gradient is assumed to remain constant (see eqn [13]) and the material moves through the domain at the pulling speed V. The figures have stripped most of the domain, showing the interface and concentration profiles in the solid on the front, and in the liquid on the rear of the domain. Periodic boundary conditions are applied on the narrow faces. Clearly, there are computational costs associated with the adaptive gridding procedure, but it enables these computations.

The level-set method uses front tracking to study microstructure evolution. In the level-set approach, there is an underlying fixed grid, and the interface is tracked as it moves through by defining a level-set function ϕ, contrived such that the interface corresponds to the level set $\phi = 0$, and $\phi(\boldsymbol{x})$ represents the normal distance from the interface. The field equations are first solved with the interface fixed, applying the Gibbs–Thomson condition. Determining an accurate representation for the curvature (for use in the Gibbs–Thomson equation) from the sequence of points, which define the interface, is one of the challenges of this method. In the second step, the interface is moved using a pure advection equation for ϕ:

$$\frac{\partial \phi}{\partial \mathrm{t}} + \boldsymbol{u} \cdot \nabla \phi = 0 \qquad [19]$$

The velocity $\boldsymbol{u}$ is chosen such that on the interface, $\boldsymbol{u} \cdot \boldsymbol{n} = V_{\mathrm{n}}$. Solution of eqn [19] requires great care to control oscillations and artificial diffusion due to truncation errors in the numerical schemes. Most analysts use a high-order WENO scheme to integrate eqn [19]. One of the main advantages of this method is that there is no asymptotic analysis required, and the typical condition that $\mathscr{D}_{\mathrm{S}} \ll \mathscr{D}_{\mathrm{L}}$ is readily incorporated. An example calculation of a 2D dendritic interface, obtained using level sets, is shown in **Figure 6**.

There are similar issues in the level-set method to those described for the phase-field method concerning the need for higher resolution near the interface than far away from it. However, the level-set method is less restrictive on this point, because it does not need to resolve a diffuse interface. Rather, the restriction on grid spacing comes from the need to resolve the local diffusion fields and the interface curvature. The combination of adaptive gridding with level sets for interface tracking provides a powerful combination for this type of problem.

Outlook

The modeling of microstructure development is becoming mature. The combination of more powerful computers and advanced modeling techniques has made the simulation of realistic systems accessible. However, the simulations are still limited to the size of the systems which can be modeled. Simulations in 2D are the rule, and simulations in 3D are still rather rare. Fluid flow is only occasionally included.

Extending these calculations to macroscopic-scale solidification processes requires a different approach. Consider, for example, a cast metal part which has dimensions $250 \times 25 \times 100\,\text{mm}$, and an average grain diameter of $100\,\mu\text{m}$. This object contains more than 10^8 grains. Clearly, it is neither practical nor sensible to model each one.

Instead, microstructure models, such as those presented earlier, should be used to develop scaling laws relating microstructure to process parameters, such as local thermal and flow conditions. Stochastic approaches used to predict nucleation events can be combined with the growth laws to determine the overall microstructure.

The value of such simulations is limited also by available data. Many material properties whose values are not well known appear in the simulations. In particular, the surface tension and attachment kinetics, along with their crystallographic anisotropy, are not well characterized. This topic is amenable to molecular dynamics simulations, which are now being used to address it. This is another example of the hierarchy of length scales in the problem, and how simulations at one length scale feed into those performed at larger ones.

Space Groups

T Janssen, University of Nijmegen, Nijmegen, The Netherlands

Introduction

For the description or the study of properties of physical systems, symmetry is of paramount importance. The symmetry groups of crystals are the so-called space groups. Other symmetry operations, such as time reversal, are sometimes also relevant, but the most important operations are the elements of the space groups. Space group symmetry is a generalization of the property that crystals are, usually, periodic in three dimensions. This article deals with the periodicity, the other symmetry operations of crystals, the classification of the space groups, and, what is of greater relevance for the physical properties, their representations.

Lattice Periodicity

Ideally, the most common crystals consist of a periodic array of identical building blocks repeated in all three directions. There are other types of crystals also, but a discussion of these will be taken up at the end of this section. Real crystals always have shortcomings in their periodic order; they are finite, which implies that there is a limit to the periodicity. Repetition means that one may go from one block into another by a translation. Such a translation is given by a vector $\boldsymbol{n}$. All vectors of the translations form a lattice. That means there are three fundamental translations, with vectors $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$, such that each lattice translation $\boldsymbol{n}$ is a linear combination of these three with integer coefficients, and each such combination transforms a building block into another:

$$\boldsymbol{n} = n_1\boldsymbol{a} + n_2\boldsymbol{b} + n_3\boldsymbol{c}, \quad \text{with integers } n_1, n_2, n_3 \qquad [1]$$

The building blocks do not have an overlap, and there are no gaps between them. Each building block consists of an arrangement of atoms or molecules. It is called a unit cell. The whole structure then remains the same if it is shifted by any of the translations of the lattice. Suppose that there are N atoms in the building block at positions $\boldsymbol{r}_1, \ldots, \boldsymbol{r}_N$. Then the position of an arbitrary atom of the crystal is given by the expression

$$\boldsymbol{r}_{n,j} = \boldsymbol{r}_j + n_1\boldsymbol{a} + n_2\boldsymbol{b} + n_3\boldsymbol{c} \qquad [2]$$

for specific values of j, n_1, n_2, and n_3. The vectors $\boldsymbol{r}_j$ may be chosen inside the unit cell. The vectors $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ are the basis vectors.

Because the building blocks are repeated in all directions, the three fundamental vectors are independent, which also means that every point in space can be reached from a fixed point by a linear combination, not necessarily with integer coefficients. In general, the coefficients are real numbers. In particular, the position of an arbitrary atom with respect to a chosen origin can be written as

$$\boldsymbol{r}_{n,j} = (n_1+\xi_1)\boldsymbol{a} + (n_2+\xi_2)\boldsymbol{b} + (n_3+\xi_3)\boldsymbol{c} \qquad [3]$$

Here $(n_1+\xi_1)$, etc., are real numbers. For example, for CsCl, the three basis vectors are in Cartesian coordinates $(a, 0, 0)$, $(0, a, 0)$, and $(0, 0, a)$. There is a Cs atom at $\boldsymbol{r}_1 = (0, 0, 0)$ and a Cl atom at $\boldsymbol{r}_2 = (a/2, a/2, a/2)$. With respect to the lattice basis, the Cl coordinates are $\xi_1 = \xi_2 = \xi_3 = 1/2$. The unit cell is a cube.

Distance-Preserving Transformations

Physical laws remain the same if positions are transformed into newer positions with the same distances. Therefore, such distance-preserving transformations are important for physics. Among them are translations, where all positions are shifted by the same translation vector. In addition, rotations around an arbitrary point and the full reflection of all points through an arbitrary point leave the distances invariant. Let O be an arbitrary point in space. Then the orthogonal group consists of all rotations leaving this point invariant and all products of such a rotation with the reflection through O. The group of three-dimensional orthogonal transformations is denoted by $O(3)_O$. Choosing O as origin and a basis of space consisting of three basis vectors $\boldsymbol{e}_1$, $\boldsymbol{e}_2$, $\boldsymbol{e}_3$, an orthogonal transformation R corresponds to a matrix via

$$R\boldsymbol{e}_i = \sum_{j=1}^{3} R_{ji}\boldsymbol{e}_j \quad (i = 1, 2, 3) \qquad [4]$$

For a special choice of the basis, namely, with three mutually perpendicular vectors of the same length, the matrices satisfy $\sum_j R_{ij}R_{kj} = \delta_{ik}$ or $RR^{\mathrm{T}} = E$, where T indicates the transpose, and E the unit matrix. Such matrices are called orthogonal. Their determinant is either $+1$ (for rotations) or -1. If one chooses another origin, the orthogonal group around that point gives the same group of matrices, which can then be indicated by $O(3)$.

All distance-preserving transformations can be obtained as a combination of a translation and an orthogonal transformation around an origin O. The effect on a point $\boldsymbol{r}$ of an orthogonal transformation R together with a translation $\boldsymbol{t}$ is

$$\{R|\boldsymbol{t}\}\boldsymbol{r} = R\boldsymbol{r} + \boldsymbol{t} \qquad [5]$$

All these transformations again form a group, the Euclidean group $E(3)$. Its elements are called Euclidean transformations. The product of two such transformations then is the subsequent execution of the two:

$$\begin{aligned}\{R_1|\boldsymbol{t}_1\}\{R_2|\boldsymbol{t}_2\}\boldsymbol{r} &= \{R_1|\boldsymbol{t}_1\}(R_2\boldsymbol{r} + \boldsymbol{t}_2) \\ &= R_1R_2\boldsymbol{r} + R_1\boldsymbol{t}_2 + \boldsymbol{t}_1 \end{aligned} \qquad [6]$$

from which it follows that

$$\{R_1|\boldsymbol{t}_1\}\{R_2|\boldsymbol{t}_2\} = \{R_1R_2|\boldsymbol{t}_1 + R_1\boldsymbol{t}_2\} \qquad [7]$$

In particular, $\{R|\boldsymbol{t}\} = \{E|\boldsymbol{t}\}\{R|\boldsymbol{0}\}$ and $\{R|\boldsymbol{t}\}^{-1} = \{R^{-1}|-R^{-1}\boldsymbol{t}\}$.

A rotation R from $O(3)_O$ leaves the point O invariant. A translation $\boldsymbol{u}$ transfers O to $O+\boldsymbol{u}$ and this point is left invariant by $\{E|\boldsymbol{u}\}\{R|\boldsymbol{0}\}\{E|-\boldsymbol{u}\}$. This means that, the product $\{R|\boldsymbol{u}-R\boldsymbol{u}\}$ belongs to the orthogonal group $O(3)_{O+\boldsymbol{u}}$. In other words, the translation part $\boldsymbol{t}$ of a space group element $\{R|\boldsymbol{t}\}$ may be changed by an origin shift $\boldsymbol{u}$ according to

$$\boldsymbol{t} = \boldsymbol{t} + (E-R)\boldsymbol{u} \qquad [8]$$

The combination of a translation and a rotation around O is then the same as a combination of another translation and a rotation around $O+\boldsymbol{u}$ (see **Figure 1**).

There is a simple matrix formulation for the action of a Euclidean transformation on a point $\boldsymbol{r}$ with coordinates x, y, and z:

$$\{R|\boldsymbol{t}\}\begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} = \begin{pmatrix} R_{11} & R_{12} & R_{13} & t_1 \\ R_{21} & R_{22} & R_{23} & t_2 \\ R_{31} & R_{32} & R_{33} & t_3 \\ 0 & 0 & 0 & 1 \end{pmatrix}\begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \qquad [9]$$

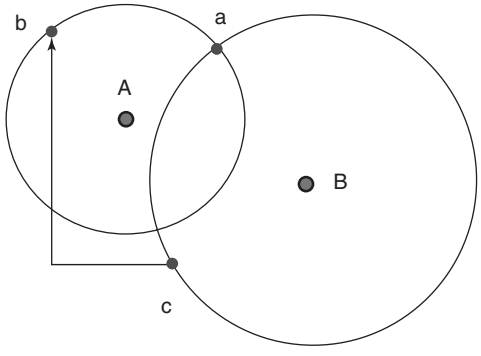

Figure 1 The 90° rotation around A brings a to b, a 90° rotation around B plus a translation brings a via c to b.

Space Groups, Plane Groups, Higher Dimensions

A collection of atoms which is invariant under the translations of a three-dimensional lattice is, in general, invariant under still more Euclidean transformations. A space group is a group of Euclidean transformations that has a translation subgroup as a lattice group, with three linearly independent basis vectors. If $\{E|\boldsymbol{a}\}$ is a translation from the translation subgroup, and $\{R|\boldsymbol{t}\}$ an arbitrary element of the space group, then the following relation holds:

$$\{R|\boldsymbol{t}\}\{E|\boldsymbol{a}\}\{R|\boldsymbol{t}\}^{-1} = \{E|R\boldsymbol{a}\} \qquad [10]$$

The first consequence is that the translation subgroup is an invariant subgroup. (A subgroup A of a group G is invariant if, for each element a of A and each g from G, the element gag^{-1} is an element of A.) Because $\{E|R\boldsymbol{a}\}$ is a translation, and therefore an element of the translation subgroup, $R\boldsymbol{a}$ belongs to the lattice. Consequently, the lattice is invariant under R, and because all R's form a subgroup of $O(3)$, this is a crystallographic point group, one of the 32 point groups. The Euclidean transformations leaving the CsCl structure invariant are the 48 elements of the cubic point group, combined with the lattice translations of the cubic lattice.

A plane group is a subgroup of the Euclidean group in two dimensions having as translation subgroup a two-dimensional lattice group. The elements R now form one of the 10 two-dimensional crystallographic point groups. The generalization to space groups in arbitrary dimensions then is straightforward. Such a group in arbitrary dimensions (including two) is also called a space group.

The Structure of a Space Group

The translation subgroup A of a space group G is invariant. (It is also called a normal subgroup.) The orthogonal transformations R appearing in the elements $\{R|\boldsymbol{t}\}$ form a three-dimensional crystallographic point group K. All the elements of K can now be numbered: $R_1 = E, R_2, \ldots, R_N$. All elements $\{R_i|\boldsymbol{t}\}$ in G form a set S_i for fixed i. One can multiply two such sets: the product S_iS_j is the set S_k if $R_iR_j = R_k$. In this

way, the sets S_i form a group, which is in fact identical to the group of all elements R_i, that is, the point group K. The group of sets S_i is called the factor group, and it is identical to (more precisely isomorphic to) the point group K. So, the space group G has an invariant subgroup A and the factor group G/A is isomorphic to the point group K.

From each set S_i, one may choose an element $\{R_i|\boldsymbol{t}_i\}$. Then, every other element from S_i may be written as the product of the representative $\{R_i|\boldsymbol{t}_i\}$ and a lattice translation $\{E|\boldsymbol{a}\}$. Of course, one could have chosen another representative element $\{R_i|\boldsymbol{t'}_i\}$. Then the two translations $\boldsymbol{t}_i$ and $\boldsymbol{t}_i'$ differ by a translation $\boldsymbol{a}$ from the lattice. The translations $\boldsymbol{t}_i$ are not necessarily lattice vectors, and they are determined by R_i only up to a lattice vector. If the representatives can be chosen such that their translation part is zero, that is, when all translations $\boldsymbol{t}_i$ are lattice vectors, the group has a simple structure: each element is a product of an element of the translation subgroup and an element of the point group. Then the space group is called symmorphic.

Consider as examples the plane groups of the two-dimensional structures for which the unit cell is given in **Figure 2**. The unit cells are rectangles, the lattices have bases vectors $(a, 0)$ and $(0, b)$. The example of **Figure 2a** has two different atoms in (0,0) and (1/2, 1/2). The point group symmetry of the lattice consists of the identity E, the two mirrors m_x and m_y, and the inversion $-E$. All four elements transform the position of an atom to a position that is related to the original position by a lattice vector. Thus, the plane group has a point group ($2mm$) with four elements. The example of **Figure 2b** has one molecule at the position $(0, 0)$. There are only two point group elements leaving the molecule invariant, and the point group is 2 with elements E and $-E$, although the lattice is the same. In example (c), there are molecules at $(0, 0)$ and $(1/2, 1/2)$. The subgroup leaving each molecule invariant has two elements: $\pm E$. The transformation m_x does not leave a molecule invariant, but the Euclidean transformation $\{m_x|(1/2,\ 1/2)\}$ does. The space group elements are the elements of the translation subgroup A and the cosets $\{-E|0\}A$, $\{m_x|(1/2,\ 1/2)\}A$, and $\{m_y|(1/2,\ 1/2)\}A$. The point group is again $2mm$.

Space Group Elements

Each element of a space group is a product of an orthogonal transformation (an element of the point group K) and a translation $\boldsymbol{t}$, the latter not always a lattice translation. The translations $\boldsymbol{t}_i$ form a vector system for the space group. The translations satisfy

$$\boldsymbol{t}_i + R_i\boldsymbol{t}_j = \boldsymbol{t}_k \quad \text{up to a lattice vector } \boldsymbol{a} \quad \text{if } R_iR_j = R_k \qquad [11]$$

The translations $\boldsymbol{t}_i$, however, depend on the choice of the origin. According to eqn [8] they change to $\boldsymbol{t}_i + (E - R_i)\boldsymbol{u}$, if the origin is shifted by a translation $\boldsymbol{u}$. This makes it necessary to review the concept of a symmorphic space group. A space group is called symmorphic if there is an origin such that all representatives $\{R_i|\boldsymbol{t}_i\}$ may be chosen with $\boldsymbol{t}_i = \boldsymbol{0}$. Then each element of G is the product of a point group element and a lattice translation. If the group is not symmorphic, then it is called nonsymmorphic.

A three-dimensional rotation has an axis and a rotation angle. If one chooses an orthonormal coordinate system and the rotation angle along the z-axis, then the rotation is given by a matrix

$$\begin{pmatrix} \cos\phi & -\sin\phi & 0 \\ \sin\phi & \cos\phi & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

When an orthogonal transformation has a determinant equal to -1, it has the same form but with an overall minus sign. Consider the case that the orthogonal transformation is combined with a translation $\boldsymbol{t}$ with coordinates a, b, and c in the same reference system. By a shift of origin over the vector $\boldsymbol{u}$ with components x, y, and z, the translation is transformed into the translation $\boldsymbol{t} + (1 - R)\boldsymbol{u}$, with components

$$a + x(1 - \cos\phi) + y\sin\phi,$$
$$b - x\sin\phi + y(1 - \cos\phi), \quad c$$

By a proper choice of $\boldsymbol{u}$, the first two components can be eliminated, but not the third. It is the case of a screw axis, a rotation combined with a translation along the rotation axis. If the rotation is over an

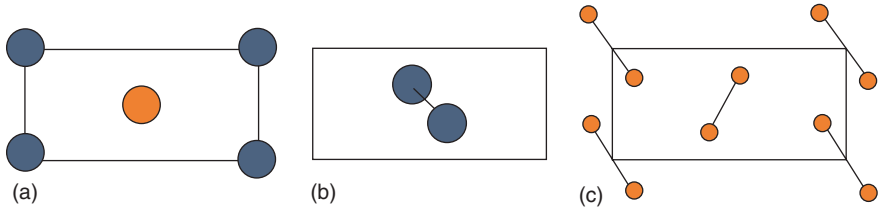

Figure 2 Three unit cells for the space groups (a) *pmm*, (b) *p2*, and (c) *pgg*.

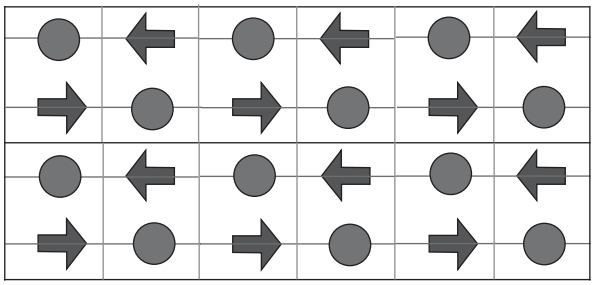

Figure 3 A two-dimensional pattern with *pgm* symmetry: rectangular lattice, horizontal mirrors, and vertical glides.

angle $\phi = 2\pi m/n$, with $n = 2,3,4$, or 6, the translation is always $1/n$ of a lattice vector. When the determinant is -1, the origin can always be shifted such that the translation vanishes, except for the case $n = 2$. Then the orthogonal transformation is

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}$$

and the first two components cannot be changed. It is a mirror operation with a translation in the mirror plane, and is called a glide operation. The plane of the mirror is the glide plane (**Figure 3**).

In two dimensions, the only plane group elements with intrinsic nonzero translation components are glide operations. For a rotation with a translation, the latter can always be eliminated by a shift of the origin.

Classification

Because the orientation and the lattice constants may vary continuously, the number of space groups is infinite. However, there is good reason to identify space groups under certain conditions, for example, if they are just different orientations of the same group in space. In principle, which groups may be identified depends on the physics of the problem one wants to study by symmetry. Space groups are subgroups of the inhomogeneous affine group as well, the group of pairs of nonsingular linear transformations and translations. If a group G_1 may be transformed into group G_2 by a change of origin (translation) and a linear transformation of the lattice (homogeneous affine transformation), the two may be identified, or in other words considered as equivalent, because the choice of origin and basis does not change the physics. This is a definition inspired by physics. In mathematical language, the two groups are conjugated subgroups of the inhomogeneous affine group. This means that the groups G_1 and G_2 are considered to be equivalent if there is a nonsingular linear transformation S and a translation $\{E|\boldsymbol{t}\}$ such that

$$G_1 = \{S|\boldsymbol{t}\}G_2\{S|\boldsymbol{t}\}^{-1} \qquad [12]$$

With this relation, there are 219 equivalence classes of three-dimensional space groups. If the handedness of the basis is relevant, for instance, in the case of helical structures, there is a finer definition, which calls the groups equivalent if the conjugation is by an element $\{S|\boldsymbol{t}\}$ such that $\det(S) > 0$. Then there are 230 equivalence classes of space groups in three dimensions. With both definitions, there are 17 different plane groups in two dimensions. A theorem by Bieberbach states that conjugation in the affine group is equivalent to isomorphism.

The space groups can also be grouped into larger classes. A coarser classification uses arithmetic equivalence. Choosing an origin and a lattice basis, the point group K of a space group corresponds to a group of integer matrices $D_1(K)$. After a basis transformation, corresponding to an integer nonsingular matrix S, the same group is represented by an integer matrix group $D_2(K) = SD_1(K)S^{-1}$. Two such groups are called arithmetically equivalent. Then a space group determines an arithmetic crystal class. If one drops the condition that the conjugation matrix S has integer entries and allows real matrices, two groups conjugated by S are said to be geometrically equivalent. Arithmetic equivalence implies geometric equivalence. Space groups may be grouped into affine equivalence classes, and further into arithmetic and geometric crystal classes. In three dimensions, there are 219 affine classes, 73 arithmetic classes, and 32 geometric classes. The latter two classifications can, of course, be used for point groups as well. For each arithmetic class there is exactly one symmorphic space group. Finally, there are seven systems (triclinic, monoclinic, orthorhombic, tetragonal, rhombohedral, hexagonal, and cubic) and six families (each three-dimensional system is a family, except the rhombohedral and hexagonal, which belong to the same family). The reader is referred to more specialized works on crystallography for a definition.

Notation

Because the full explanation of the notation and nomenclature for crystallographic groups requires much more space, only a brief discussion is presented here. There are two systems, the Hermann–Mauguin symbols, recommended by the International Union for Crystallography (IUCr), and the Schoenflies symbols. The latter are based on the symbols for the 32 point groups arranged in geometric classes. For each class there is a numbering of the corresponding space

groups. An example is C_2^2 with point group C_2 consisting of an identity and a two-fold rotation. It is the second group with this point group. The Hermann–Mauguin symbols tend to have more information. They are based on the IUCr symbols for point groups. A second ingredient are the lattices. Lattices are considered to be equivalent if the point groups that leave them invariant (which on a lattice basis may be given by groups of integer matrices) may be represented by a change of lattice basis by the same groups of matrices. These classes are the Bravais classes. In three dimensions, there are 14 Bravais classes (**Table 1**). For lattices with the same point group symmetry, there is a common conventional basis on which the point group elements are simple, but one needs additional lattice vectors. For example, there are three Bravais classes for which the symmetry is the symmetry group of the cube, with 48 elements. The lattices of one Bravais class have a basis with three mutually perpendicular basis vectors of the same lengths. For the other two, the face-centered cubic (f.c.c.) and body-centered cubic (b.c.c.), there is a sublattice of this kind, but not all lattice vectors belong to that. One needs additional vectors to obtain all the lattice translations: $(0, 1/2, 1/2)$, $(1/2, 0, 1/2)$, and $(1/2, 1/2, 0)$ for f.c.c. and $(1/2, 1/2, 1/2)$ for b.c.c (**Figure 4**). These additional vectors are given by capital letters in three dimensions, and lower case letters in two dimensions. The symbols of the symmetry groups of the three cubic lattices are $Pm\bar{3}m$, $Fm\bar{3}m$, and $Im\bar{3}m$. These are the Hermann–Mauguin symbols for the space groups of the primitive cubic, f.c.c., and b.c.c. lattices, respectively. For each of the 73 arithmetic crystal classes, and thus for all symmorphic space groups there is such a symbol, consisting of the symbol for the point group preceded by a letter indicating the additional lattice vectors (the centering).

Finally, for nonsymmorphic space groups, the nonlattice translations for the elements appearing in the symbol for the symmorphic space group are

Table 1 The 14 Bravais classes in three dimensions and their maximal symmorphic space groups

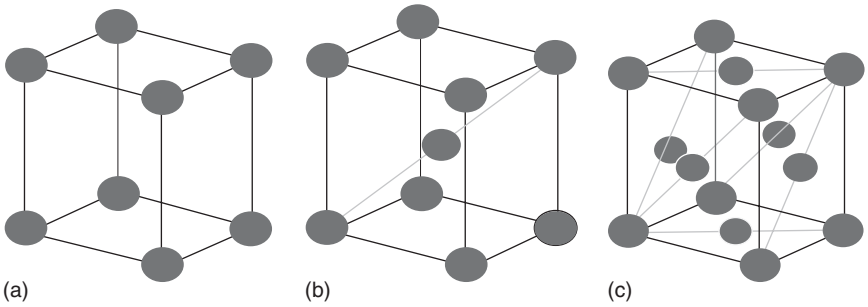

Figure 4 Unit cells for lattices from each of the three cubic Bravais classes. (a) Primitive, (b) b.c.c. with additional basis vector (1/2, 1/2, 1/2), and (c) f.c.c. with additional (0, 1/2, 1/2), (1/2, 0, 1/2), and (1/2, 1/2, 0).

indicated by either a change of the letter or by a subindex. The symbol for a symmorphic space group with point group m may be Pm. If the mirror m becomes a glide with nonlattice translation in the third direction, the symbol is Pc. The symbol $P2$ gives a symmorphic space group with point group 2, $P2_1$ indicates a nonsymmorphic group with a screw axis. All space groups, their symbols and their elements can be found in the *International Tables for Crystallography, vol. A*.

Reciprocal Lattice, Invariant Functions, Extinction Rules

A function that is invariant under translations has special properties for its Fourier transform. Suppose $\rho(\boldsymbol{r})$ is such a function (e.g., a density function of a crystal). It has the property that $\rho(\boldsymbol{r})$ and $\rho(\boldsymbol{r}+\boldsymbol{a})$ are equal for every translation $\boldsymbol{a}$ from the lattice. Writing down the Fourier decomposition yields

$$\begin{aligned}\rho(\boldsymbol{r}) &= \int \hat{\rho}(\boldsymbol{k})\, \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r})\mathrm{d}\boldsymbol{k} \\ \rho(\boldsymbol{r}+\boldsymbol{a}) &= \int \hat{\rho}(\boldsymbol{k})\, \exp(\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{r}+\boldsymbol{a}))\mathrm{d}\boldsymbol{k}\end{aligned} \quad [13]$$

from which it follows that $\boldsymbol{k}\cdot\boldsymbol{a} = 0 \pmod{2\pi}$ for each translation vector $\boldsymbol{a}$. Therefore, for each wave vector $\boldsymbol{k}$ occurring in the Fourier expansion, one has this relation. All vectors $\boldsymbol{k}$ satisfying this relation form a lattice, as is easily checked. This lattice is called the reciprocal lattice for the so-called direct lattice of the vectors $\boldsymbol{a}$.

If $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ span the direct lattice, a basis for the reciprocal lattice is givenby $\boldsymbol{a}^*, \boldsymbol{b}^*, \boldsymbol{c}^*$ defined by

$$\begin{aligned}&\boldsymbol{a}^* = 2\pi(\boldsymbol{b}\times\boldsymbol{c})/V, \quad \boldsymbol{b}^* = 2\pi(\boldsymbol{c}\times\boldsymbol{a})/V, \\ &\boldsymbol{c}^* = 2\pi(\boldsymbol{a}\times\boldsymbol{b})/V\end{aligned} \quad [14]$$

where $V = \boldsymbol{a}\cdot(\boldsymbol{b}\times\boldsymbol{c})$ is the volume of the unit cell. Then the Fourier decomposition is

$$\rho(\boldsymbol{r}) = \sum_{\boldsymbol{k}\in\Lambda^*} \hat{\rho}(\boldsymbol{k})\, \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}) \quad [15]$$

where Λ^* is the reciprocal lattice. Each vector of the reciprocal lattice can be expressed in terms of the basis of the lattice

$$\boldsymbol{k} = h\boldsymbol{a}^* + k\boldsymbol{b}^* + l\boldsymbol{c}^* \in \Lambda^* \quad [16]$$

The reciprocal lattice is left invariant by the point group K as well.

Apart from translations, a lattice periodic function is generally left invariant by other distance-preserving transformations as well. Suppose $g = \{R|\boldsymbol{t}\}$ is an element of the space group that leaves a function $\rho(\boldsymbol{r})$ invariant. This means that $\rho(\boldsymbol{r})$ and $\rho(g^{-1}\boldsymbol{r})$ are the same (the exponent -1 is just for convenience). Then one has the relation

$$\rho(\boldsymbol{r}) = \rho(\{R|\boldsymbol{t}\}^{-1}\boldsymbol{r}) \quad [17]$$

For the Fourier components $\hat{\rho}(\boldsymbol{k})$, this implies

$$\hat{\rho}(\boldsymbol{k}) = \hat{\rho}(R\boldsymbol{k})\, \exp(\mathrm{i}R\boldsymbol{k}\cdot\boldsymbol{t}) \quad [18]$$

This is a very interesting formula. It is known that the wave vectors occurring in the Fourier decomposition belong to the reciprocal lattice. Now, consider a reciprocal lattice vector $\boldsymbol{k}$ that is invariant under orthogonal transformation R. Then the expression becomes $\rho(\boldsymbol{k}) = \rho(\boldsymbol{k})\exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{t})$. This is only possible if $\rho(\boldsymbol{k}) = 0$ or if $\boldsymbol{k}\cdot\boldsymbol{t} = 0 \pmod{2\pi}$. If $\boldsymbol{t}$ is a translation from the lattice, this relation is trivially fulfilled. But if there is a $\boldsymbol{t}$ such that the second relation is not satisfied, this means that the corresponding Fourier component $\hat{\rho}(\boldsymbol{k})$ vanishes. This is an extinction rule.

An important example is the diffraction intensity. A crystal diffracts and the diffraction pattern consists of sharp Bragg peaks at the positions $\boldsymbol{k}$. The intensity of the peaks is given by the square of the absolute value of the static structure factor:

$$I(\boldsymbol{k}) = |F(\boldsymbol{k})|^2 = \left|\frac{1}{N}\sum_{j=1}^{N} \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_j)\right|^2 \quad [19]$$

Here j runs over the N particles in the unit cell. It is the Fourier transform of the autocorrelation function, which is invariant under space group elements. Hence, the positions of the Bragg peaks are on the reciprocal lattice, and the extinction rules apply: the intensity is zero at $\boldsymbol{k}$ if there is a space group element $\{R|\boldsymbol{t}\}$ with $R\boldsymbol{k} = \boldsymbol{k}$ and $\boldsymbol{k}\cdot\boldsymbol{t} \neq 0 \pmod{2\pi}$. Additionally, one has for arbitrary $\boldsymbol{k}$ that $I(R\boldsymbol{k}) = I(\boldsymbol{k})$. Consequently, the diffraction has the point group in its symmetry group.

Representations of Space Groups

Euclidean transformations act on positions in space. A quantum mechanical system in such a space has states on which the Euclidean transformations act as linear operators. For example, if the state is given by a wave function $\psi(\boldsymbol{r})$, the effect of a Euclidean transformation $\{R|\boldsymbol{t}\}$ gives a new wave function $\psi'(\boldsymbol{r}) = \psi(R^{-1}(\boldsymbol{r}-\boldsymbol{t}))$. This is the action of a linear operator T_g, with $g = \{R|\boldsymbol{t}\}$. Choosing a basis $\psi(\boldsymbol{r})$ in the space of states, such a linear operator corresponds to a matrix $D(g)$:

$$T_g\psi_i(\boldsymbol{r}) = \sum_{j=1}^{N} D(g)_{ji}\psi_j(\boldsymbol{r}) \quad [20]$$

(n is the dimension of the state space.) Now the matrices satisfy $D(g_1)D(g_2) = D(g_1g_2)$. This is called a (matrix) representation. If the dimension of the space is n, then the representation is said to be n-dimensional, and the matrices are $n \times n$. These representations are important for characterizing energy levels and other properties. Clearly, the space is mapped onto itself and, therefore, it is invariant under the group of transformations G. If there is no subspace (different from the origin or the whole space) that is invariant, the representation is said to be irreducible. In general, an energy level space carries an irreducible representation of the symmetry group, the dimension of the space is the level degeneracy, and there are orthogonality relations between states from the state space.

This gives a short argument why one should look at the irreducible representations of the space groups. The simplest space group is just a translation group, with three basis translations. Because the order in which translations are applied is not relevant, it is a commutative group, and according to the results of group theory the irreducible representations of commutative groups are one-dimensional, that is the matrices are just numbers. They satisfy $D(\{E|\boldsymbol{a}\})$ $D(\{E|\boldsymbol{b}\}) = D(\{E|\boldsymbol{a}+\boldsymbol{b}\})$. The solution is $D(\{E|\boldsymbol{a}\}) = \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{a})$ for some vector $\boldsymbol{k}$. Two vectors $\boldsymbol{k}$ and $\boldsymbol{k}'$ give the same representation if $\boldsymbol{k}-\boldsymbol{k}'$ belongs to the reciprocal lattice, because then $\boldsymbol{k}\cdot\boldsymbol{a} = \boldsymbol{k}'\cdot\boldsymbol{a} \pmod{2\pi}$ for all lattice vectors $\boldsymbol{a}$. Therefore, the irreducible representations are characterized by a vector from the unit cell of the reciprocal lattice. A special choice of this unit cell is the Brillouin zone. It is the unit cell of the reciprocal lattice consisting of all points in reciprocal space which are closer to the origin than to any other point of the reciprocal lattice. Of course, the unit cell of a lattice is not uniquely defined. However, the choice of the Brillouin zone is very convenient when studying electrons or elementary excitations in crystals.

A wave function $\psi(\boldsymbol{r})$ in a lattice periodic crystal which belongs to an irreducible representation of the lattice subgroup has a special form, the Bloch form, as follows from a group-theoretical argument. Under a translation $\boldsymbol{a}$, the function transforms to $\psi(\boldsymbol{r}-\boldsymbol{a})$ which should be equal to $\exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{a})\psi(\boldsymbol{r})$ for some $\boldsymbol{k}$. Then define $U(\boldsymbol{r}) = \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r})\psi(\boldsymbol{r})$. It follows that

$$\begin{aligned} U(\boldsymbol{r}+\boldsymbol{a}) &= \exp(\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{r}+\boldsymbol{a}))\psi(\boldsymbol{r}+\boldsymbol{a}) \\ &= \exp(\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{r}+\boldsymbol{a}))\exp(-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{a})\psi(\boldsymbol{r}) \\ &= U(\boldsymbol{r}) \end{aligned}$$

which proves that $\psi(\boldsymbol{r})$ is the product of a plane wave, $\exp(-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r})$ and a lattice periodic function $U(\boldsymbol{r})$. This constitutes the well-known Bloch's theorem.

Consider a state space that is invariant under a space group acting on the space by operators T_g for each element g of the space group G. Suppose, furthermore, that the representation is irreducible. The translation subgroup A is a subgroup of G. So, there is a basis formed by functions ψ_i for the space consisting of the eigenvectors of the commuting operators T_a. One has

$$T_a\psi_j = \exp(\mathrm{i}\boldsymbol{k}_j\cdot\boldsymbol{a})\psi_j \qquad [21]$$

A subspace of the space is that belonging to one particular wave vector $\boldsymbol{k}$. For each state, ψ from this space it holds that $T_a\psi = \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{a})\psi$. Applying T_g to any state from this space, ψ transforms to $T_g\psi$. How does this transform under the translations? Applying a translation $\{E|\boldsymbol{a}\}$ to the transformed vector:

$$\begin{aligned} T_aT_g\psi &= T_g(T_{g-1}T_aT_g)\psi = T_gT_b\psi \\ &= \exp(-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{b})T_g\psi \end{aligned}$$

Here $\boldsymbol{b} = R^{-1}\boldsymbol{a}$ if $g = \{R|\boldsymbol{t}\}$. The state $T_g\psi$, therefore, acquires a phase factor $\exp(\mathrm{i}R\boldsymbol{k}\cdot\boldsymbol{a})$ and belongs to the subspace of states transforming with a wave vector $R\boldsymbol{k}$. This means that, if there are states transforming under translations with a wave vector $\boldsymbol{k}$, then there are, in the irreducible space, states transforming with the wave vector $R\boldsymbol{k}$ for every point group element. One can write the whole space as a sum of spaces each belonging to a specific $R\boldsymbol{k}$. One of these spaces is that of states transforming with $\boldsymbol{k}$.

Now define the subgroup of G consisting of all elements $\{R|\boldsymbol{t}\}$ for which $R\boldsymbol{k} = \boldsymbol{k}$ (modulo the reciprocal lattice because $\boldsymbol{k}$ and $k+\boldsymbol{K}$ give the same representation if $\boldsymbol{K}$ belongs to the reciprocal lattice). This group is called the group of $\boldsymbol{k}$: $G_{\boldsymbol{k}}$. The subspace of states transforming with $\boldsymbol{k}$ under translations is invariant under the group of $\boldsymbol{k}$. Then for an element g from the group of $\boldsymbol{k}$:

$$T_g = \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{t})D_R \quad (g = \{R|\boldsymbol{t}\})$$

The operators form an irreducible representation of the group of $\boldsymbol{k}$. For a symmorphic group of $\boldsymbol{k}$ the elements g can be written as a product $\{E|\boldsymbol{t}\}\{R|0\}$ of a lattice translation and a point group element. In this case, the operators D_R form an irreducible representation of the point group of the group of $\boldsymbol{k}$, denoted by $K_{\boldsymbol{k}}$. These are known, and can be labeled by a label ν. Then a basis of the space of $G_{\boldsymbol{k}}$ transforms under g as

$$T_g\psi_j = \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{t})D_{kj}(R)\psi_k \qquad [22]$$

The basis carries an irreducible representation ν of the point group K (simply take $\boldsymbol{t}=0$ in the last formula). Here the matrices $D(R)$ are the irreducible representation ν of the point group $K_{\boldsymbol{k}}$. For nonsymmorphic groups, the procedure is somewhat

more complicated, because not only standard representations but projective representations also occur.

Finally, a basis for the full state space can be constructed as follows. The group of $\boldsymbol{k}$ is a subgroup of the space group G. G can be decomposed according to

$$G = G_{\boldsymbol{k}} + g_2 G_{\boldsymbol{k}} + \cdots + g_s G_{\boldsymbol{k}}$$

where the space group elements g_i have homogeneous parts R_i for which $R_i\boldsymbol{k} = \boldsymbol{k}_i$. Then the basis is defined as

$$\Psi_{ij} = T_{gi}\psi_j \qquad [23]$$

The dimension of the representation is sd, where s is the number of points $\boldsymbol{k}_i$, and d the dimension of the point group representation $D(K_{\boldsymbol{k}})$. The irreducible representation carried by the state space then is characterised by the so-called "star" of $\boldsymbol{k}$ (all vectors $\boldsymbol{k}_i$), and an irreducible representation of the point group $K_{\boldsymbol{k}}$. This means that electronic states and phonons can be characterized by $\boldsymbol{k}$, v. Their transformation properties under space group transformations follows from this characterization.

Aperiodic Crystals

Apart from crystals with three-dimensional lattice periodicity, there are materials with a diffraction pattern with sharp Bragg peaks on positions

$$\boldsymbol{k} = \sum_{i=1}^{n} h_i \boldsymbol{a}_i^* \quad (\text{integer } h_i) \qquad [24]$$

When $n = 3$, the structure is periodic. If $n > 3$, the structure is aperiodic, but it is still considered as crystal, because there is long-range order. Examples are modulated phases and quasicrystals. They may be described as intersections of physical space with a higher-dimensional lattice periodic structure. The symmetry of such structures is a space group in n dimensions, and in this case the theory of space groups in arbitrary dimensions can be used.

Nomenclature

$\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$	lattice basis vectors
$\boldsymbol{a}^*$, $\boldsymbol{b}^*$, $\boldsymbol{c}^*$	reciprocal lattice basis vectors
A	translation subgroup of a space group
$D(R)$	matrix representation
$\exp(-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r})U(\boldsymbol{r})$	Bloch form of a wave function
$E(3)$	Euclidean group
$F(\boldsymbol{k})$	structure factor
G	space group
K	point group
$\boldsymbol{n}$	lattice translation vector
$O(3)$	orthogonal group in three dimensions
$\boldsymbol{r}_j$	position of an atom in the unit cell
R	orthogonal transformation
$\{R\|\boldsymbol{t}\}$	space group element
T_g	linear operator for group element g:
$\hat{\rho}(\boldsymbol{k})$	Fourier component of $\rho(\boldsymbol{r})$
$\rho(\boldsymbol{r})$	density function
ψ_i	basis of a state space
$\psi(\boldsymbol{r})$	wave function

Specific Heat

N E Phillips and R A Fisher, University of California at Berkeley, Berkeley, CA, USA

Introduction

The specific heat of a substance is the amount of heat required to raise the temperature by one degree. When heat is introduced under certain specified conditions, it is a well-defined thermodynamic property that gives a measure of the increases in the entropy, the energy, and the enthalpy with increasing temperature. It is related to other thermodynamic properties, for example, the thermal expansion, which is a measure of the pressure dependence of the entropy. Specific-heat data make an important contribution to

the determination of the Gibbs and Helmholtz energies, the thermodynamic properties that govern the direction of spontaneous change and the equilibrium conditions for chemical reactions and phase transitions. When interpreted in terms of microscopic models and theories, they provide information on the forces and interactions at the atomic and molecular level that determine the macroscopic properties.

Thermodynamic Relations

The specific heat of a substance is the amount of heat required to increase the temperature by one degree:

$$C \equiv \frac{\delta q}{\mathrm{d}T}$$

where δq, an inexact differential, is the quantity of heat added and $\mathrm{d}T$ is the increase in temperature produced in the process. By the first law of thermodynamics, $\delta q = \mathrm{d}U - \delta w$, where U is the internal energy and δw is the work done in the process. Since U is a "thermodynamic property," a quantity that depends only on the thermodynamic state of the system, $\mathrm{d}U$ is an exact differential and depends only on the initial and final states. However, δw, and therefore both δq and C, depend on details of the way the process takes place as well as on the initial and final states. If the work is done by an external hydrostatic pressure, P, $\delta w = -P\ \mathrm{d}V$, where V is the volume. In that case,

$$C = \frac{\mathrm{d}U + P\ \mathrm{d}V}{\mathrm{d}T} = \frac{\mathrm{d}(U + PV) - V\ \mathrm{d}P}{\mathrm{d}T}$$

With the definition for the enthalpy, $H \equiv U + PV$, this leads to expressions for the constant volume and constant pressure specific heats,

$$C_V = \left(\frac{\partial U}{\partial T}\right)_V$$

and

$$C_P = \left(\frac{\partial H}{\partial T}\right)_P$$

thermodynamic properties, which can be expressed in, for example, units of $\mathrm{J\,K^{-1}\,mol^{-1}}$. If work is done by magnetic or electric forces, the relevant variables are the magnetic induction, $\boldsymbol{B}$, the magnetization, $\boldsymbol{M}$, the electric field, $\boldsymbol{E}$, and the dielectric displacement, $\boldsymbol{D}$. (In free space $\boldsymbol{B} = \mu_0 \boldsymbol{H}$, where μ_0 is the permeability of free space and $\boldsymbol{H}$ is the magnetic field.) The expressions for the work are $\delta w = \boldsymbol{H}\ \mathrm{d}\boldsymbol{M}$ and $\delta w = \boldsymbol{E}\ \mathrm{d}\boldsymbol{D}$, respectively. In other thermodynamic relations, $\boldsymbol{H}$ or $\boldsymbol{E}$ replaces the intensive variable P and $-\boldsymbol{M}$ or $-\boldsymbol{D}$ replaces the extensive variable V.

With other thermodynamic relations, based on both the first and second laws, it can be shown that

$$C_P - C_V = \frac{TV\alpha^2}{\kappa}$$

where $\alpha = V^{-1}(\partial V/\partial T)_P$ is the thermal expansion, and $\kappa = V^{-1}(\partial V/\partial P)_T$ is the isothermal compressibility. Thermodynamic stability requires that both C_V and κ be positive. Although α can be either positive or negative, it appears as the square, and $C_P - C_V$ is always positive: when the heat is absorbed at constant volume, $\delta w = 0$. In the constant-pressure process there is, generally, a change in V, $\delta w \neq 0$ and can be either positive or negative, but the increase in U ensures that the heat absorbed is always greater than in the constant-volume process. Evaluation of α and κ for an ideal gas, for which $PV = RT$, where R is the gas constant, gives $C_P - C_V = R$.

Microscopic Interpretation

Classical, High-Temperature Limit

In classical statistical mechanics, each term in the Hamiltonian for the total energy that is the square of either a momentum or a coordinate, contributes $(1/2)k_\mathrm{B}T$ to the thermal energy, where k_B is the Boltzmann constant. For a particle moving freely in space, the translational kinetic energy includes three terms in the square of a momentum, corresponding to the three dimensions in space: $U = (3/2)k_\mathrm{B}T$, and $C_V = (3/2)k_\mathrm{B}$. For Avagadro's number, N_A, of such particles, one mole of an "ideal gas," $C_V = N_A(3/2)k_\mathrm{B} = (3/2)R$. For a particle bound by harmonic forces to a lattice site in three dimensions, there are three terms in the square of a momentum in the kinetic energy and three in the square of a coordinate in the potential energy: $U = 3k_\mathrm{B}T$, and $C_V = 3k_\mathrm{B}$. At sufficiently high temperatures, quantum statistical mechanics gives the same results, the classical or high-temperature limit. At temperatures for which $k_\mathrm{B}T$ is of the order of, or smaller than, the spacing of the quantum mechanically allowed energy levels, the higher energy levels are not fully accessible, and U and C do not reach the classical limit. The energies of the allowed translational states of the particles of an ideal gas are proportional to $m^{-1/2}\,V^{2/3}$, where m is the mass of the particles and V is the volume of the container. For gases of atoms and molecules at ordinary densities, the energy levels are so closely spaced that the classical limit applies at all temperatures of interest, but for an electron gas at densities of the conduction electrons in a metal, that limit is reached only at temperatures $\sim 10^5\,\mathrm{K}$. The specific heat of a harmonic oscillator offers a typical

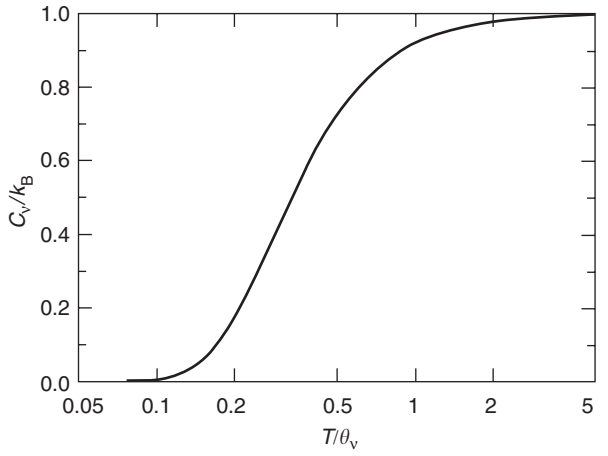

Figure 1 The contribution to the specific heat of a one-dimensional harmonic oscillator, C_v, displayed as C_v/k_B, vs. T/θ_v.

example of the effects of quantization: the energy levels are equally spaced, at intervals of $\hbar\omega \equiv k_B\theta_v$, where $\hbar$ is Planck's constant divided by 2π, T is the characteristic frequency, and θ_v is a defined characteristic temperature. As shown in **Figure 1**, the specific heat approaches k_B in the high-temperature limit and goes to zero, as $\exp(-\theta_v/T)$ at temperatures for which k_BT is less than the energy of the first excited level.

Gases

The heat capacities of gases are often treated in the ideal-gas, rigid-rotor, harmonic-oscillator approximation, in which C is the sum of contributions, C_t, C_r, and C_v, associated with translational, rotational, and vibrational motion, respectively. At sufficiently high temperatures, excited electronic states can also contribute to C_V. For a molecule with n atoms, $3n$ coordinates are required to specify the positions of the atoms: there are $3n$ "degrees of freedom." Three of these are associated with translation of the molecule as a whole; three are associated with rotation for nonlinear molecules, but only two for linear molecules (there is no rotation about the axis); the rest, $3n-6$ or $3n-5$, respectively, are associated with vibration. Each translational degree of freedom contributes one square term to the kinetic energy; each rotational degree of freedom contributes one square term, in an angular momentum, to the kinetic energy; each vibrational degree of freedom contributes one square term to the kinetic energy and one to the potential energy. In the high-temperature limit, and for one mole of gas, $C_v = 3nR$ for nonlinear molecules, but $(3n+1/2)R$ for linear molecules. The vibrational contributions decrease to zero at temperatures below the characteristic temperatures θ_v, as shown in **Figure 1**. The rotational contributions go to zero below characteristic temperatures θ_r that are defined by the allowed rotational energy levels, but there is no general expression for C_r in closed form. Some representative values of θ_v and θ_r are given in **Table 1**. **Figure 2** shows the temperature dependence of C_V for HD, an asymmetric, linear, diatomic molecule. The local maximum near 50 K is related to details of the spacing and degeneracy of the rotational levels. For symmetric molecules, certain combinations of rotational and nuclear spin states are not

The horizontal dashed lines mark the high-temperature limits of the different contributions. (The rotational contribution was obtained from tabulations in: Mayer JE and Mayer MG (1940) *Statistical Mechanics*, p. 450. New York: Wiley.)

allowed. The prototypical examples are o-H_2, with triplet spin and even rotational states, and p-H_2, with singlet spin and odd rotational states. Depending on conditions, transitions between the two spin states can be very slow; o-H_2 and p-H_2 can exist as separate molecules with very different specific heats.

Condensed Matter

Separability of contributions The specific heat of a condensed matter phase is usually taken to be the sum of contributions arising from different modes of excitation. For a nonmagnetic metal these are the lattice, C_l, and electron, C_e, contributions that are associated with, respectively, the vibrational states of the ions that form the lattice and the energy states of the conduction electrons. The vibrational states of the lattice and the energy states of the electrons are not independent, however: The frequencies of the normal modes of the lattice are affected by the presence of the conduction electrons, and the allowed energy states of the electrons are affected by the spatially periodic potential of positive ions of the lattice and also by interaction with the quanta of vibrational energy of the lattice, the phonons. Nevertheless, to an adequate degree of approximation for most purposes, the specific heat can be taken to be the sum of separable contributions from the lattice and the conduction electrons, with the understanding that the energy levels of each system are determined in part by interaction with the other. In experimental data, the two contributions are generally separated by assigning them different, theoretically expected temperature dependences. Similar considerations apply to magnetic contributions, C_m, associated with electronic magnetic moments, and hyperfine contributions, C_h, associated with nuclear moments.

Phonon contribution For one mole of a "monatomic" solid, which has one atom per primitive cell, there are $3N_A$ vibrational degrees of freedom. In the harmonic-lattice approximation, the phonon or lattice contribution to the specific heat, C_l, is the sum of $3N_A$ harmonic-oscillator contributions, one for each of the normal vibrational modes. In the high-temperature limit, also called the Dulong–Petit limit in this context, each contributes k_B to C_l, giving $C_l = 3R$. Anharmonic effects make a contribution to C_l that becomes more important at high temperatures, and can give values of C_l that exceed the Dulong–Petit limit.

In the Einstein model, the normal modes were approximated by $3N_A$ harmonic oscillators with the same frequency, ω_E, corresponding to the characteristic, Einstein temperature, $\Theta_E \equiv \hbar\omega_E/k_B$. The Einstein expression for the specific heat is

$$\frac{C_E}{3R} = \left(\frac{\Theta_E}{T}\right)^2 \frac{\exp(\Theta_E/T)}{[\exp(\Theta_E/T) - 1]^2}$$

This model is of historical importance because it was the first to account for the decrease of C_l at low temperature, but it gives $C_l \propto \exp(-\Theta_E/T)$ in the low-temperature limit, while the experimentally observed behavior is $C_l \propto T^3$.

In the Debye model, the frequencies of the normal modes were approximated by those of the acoustic modes in an elastic continuum. A cutoff frequency, ω_D, was introduced to limit the number of modes to $3N_A$. The cutoff frequency, and the Debye temperature, $\Theta_D \equiv \hbar\omega_D/k_B$, can be calculated from the elastic constants. The Debye specific heat, given by an integral over the phonon density of states,

$$\frac{C_D}{3R} = 3\left(\frac{T}{\Theta_D}\right)^3 \int_0^{\Theta_D/T} \frac{x^4 e^x}{(e^x - 1)^2}\,dx$$

is a function of T/Θ_D. In the low-temperature limit, $C_D = (12/5)\pi^4 R(T/\Theta_D)^3$, in agreement with experiment with respect to both the T^3 temperature dependence and the relation of Θ_D to the elastic constants. **Figure 3** is a comparison of the Debye model with the lattice specific heat of Cu. The best fit to the data for $10 \leqslant T \leqslant 300\,K$ is obtained with

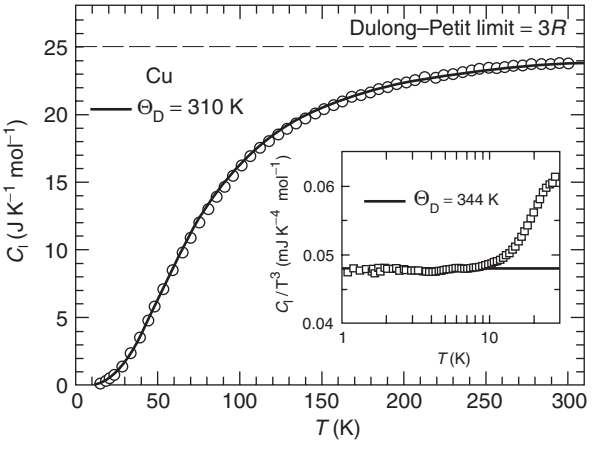

Figure 3 The lattice specific heat, C_l, of Cu: compared with the Debye model for $10 \leqslant T \leqslant 300$ K in the main panel; compared with the low-temperature, T^3 behavior predicted by the Debye model in the inset. The electron contribution to C_V has been subtracted to obtain C_l as plotted here. The data for the main panel are from: Giauque WF and Meads PF (1941) The heat capacities and entropies of aluminum and copper from 15 to 300 K. *Journal of the American Chemical Society* 63: 1897. The measurements were made at constant pressure, but corrected to C_V with the values of α and κ. (The low-temperature data in the inset are from measurements (unpublished) made in the authors' laboratory at the University of California, Berkeley, California 94720, USA.)

$\Theta_D = 310$ K, but the data in the low-temperature, T^3 region gives $\Theta_D = 344$ K, in agreement with the value calculated from the elastic constants. This comparison of data for a monatomic metal with the Debye model is fairly typical: at low temperatures, the Debye model gives the T^3 term, the contribution of the lowest-frequency acoustic phonons, correctly. Although the Debye model gives T^3 behavior for $T \leqslant \Theta_D/10$, and negative deviations from T^3 behavior at higher temperatures, experimental data typically show deviations that are positive and occur at lower temperatures. The negative deviations given by the model are a consequence of the sharp cutoff frequency; the positive deviations in a real solid are a consequence of phonon dispersion, which is neglected in the model. At higher temperatures, where the model is an approximation, experimental data cannot be fitted accurately with a single value of Θ_D. The value determined by the "best fit" in some interval of temperature is an average that reflects the structure in the phonon density of states for the real lattice at frequencies that contribute to C_l in that interval. The T^3 phonon contribution to the specific heat is also observed in liquids, as shown in an inset to **Figure 11** for ^{4}He.

Although the Debye model is a useful approximation to the lattice specific heat of many materials over a wide range of temperatures, experimental data can show substantial deviations, particularly at intermediate temperatures. For a discrete lattice with n atoms per primitive unit cell, the frequency distribution of the normal modes is that of three acoustic phonon branches and $3n - 3$ optical phonon branches. For the acoustic branches, phonon dispersion, the variation of the sound velocity with frequency, has an important effect on the phonon density of states that is not taken into account in the Debye model. The optical modes are omitted in this model. The harmonic-lattice approximation, which gives an expansion of C_l in odd powers of T that starts with the Debye T^3 term, is often used to fit experimental data at low temperatures. Sums of Einstein functions, which represent contributions from the optical modes or other peaks in the phonon density of states, and a Debye function are useful over a wide range of intermediate temperatures. **Figure 4** shows an unusual case, C_l for YbGaGe, which is well represented by a single Einstein frequency and a Debye function.

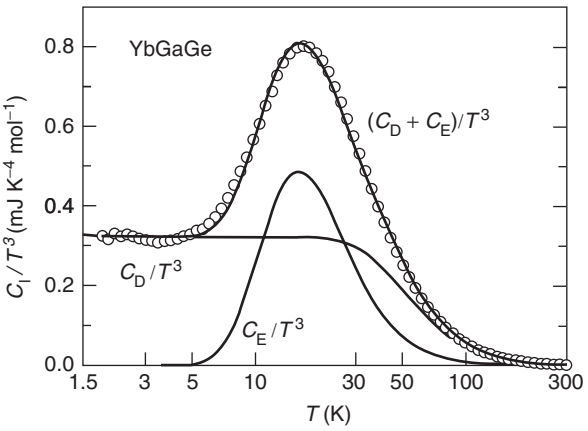

Figure 4 The lattice heat capacity of YbGaGe, as C_l/T^3 vs. log T, fitted with the sum of one Einstein function and one Debye function. The peak in C_l/T^3 centered near 20 K is an unusually prominent, but otherwise typical, signature of a "soft mode," a peak in the phonon density of states. (Specific-heat data are from measurements made at the Los Alamos National Laboratory, Los Alamos, New Mexico: Drymiotis FR, Lawes G, Migliori A, Ledbetter H, Betts JB, *et al.* (2004), unpublished. The electron contribution was subtracted from the data for this figure.)

Conduction electron contribution At ambient and low temperature, and at the densities at which they occur in metals, the conduction electrons must be treated with Fermi–Dirac statistics: there can be at most two electrons, with opposite spin, in any energy state. Their contribution to the specific heat is similar to that of the hypothetical "free electron gas," in which there are no interactions between the electrons or with the lattice. For free electrons, the allowed states have kinetic energies proportional to the sum of the squares of the wave vectors. At $T = 0$, the states are filled up to the Fermi energy,

$$E_F = \left(\frac{\hbar^2}{2m_e}\right)\left(\frac{\pi^2 z N_A}{V}\right)^{2/3}$$

where m_e is the electron mass, z is the "valence," and zN_A the number of electrons in the atomic volume, V. For values of the parameters appropriate to metals, the corresponding characteristic temperature, the Fermi temperature, $T_F \equiv E_F/k_B$, has values $\sim 10^4$–10^5 K. For $T \ll T_F$, most of the states at $E < E_F$ remain fully occupied. It is only electrons with energies within a range $k_B T$ in energy in the vicinity of E_F that can be thermally excited, and by an energy that is also of order $k_B T$. The simple argument that a fraction of the electrons, T/T_F, makes the classical contribution gives $C_e \sim RT/T_F$, which agrees both in temperature dependence and order of magnitude with experimental observations. An exact calculation gives

$$C_e = \left(\frac{\pi^2 z R}{2}\right)\left(\frac{T}{T_F}\right) = \left(\frac{\pi^2 k_B^2}{3}\right) N(E_F) T \equiv \gamma T$$

where $N(E_F)$ is the density of electron states at the Fermi level. The coefficient γ, as defined here for the free electron gas, is proportional to m_e.

The properties of the conduction electrons in a metal are modified by the interactions of the electrons with the periodic potential of the lattice, by electron–electron interactions, and by the electron–phonon interaction. However, according to Landau's Fermi-liquid theory, there is a one-to-one correspondence between excitations in the free electron gas and those in the gas with interactions; the coefficient γ is changed, with m_e replaced with an "effective mass," m^*, but the temperature dependence of C_e is unchanged. The periodic potential of the lattice modifies the relation between electron energy and wave vector. The effect on $N(E_F)$ is to replace m_e with m_{bs}, the "band-structure mass," in the expression for γ. The electron–phonon interaction, which is also responsible for the pairing of the electrons in the BCS theory of superconductivity, introduces an enhancement of γ by a factor $(1 + \lambda)$. In many cases m_{bs} can be calculated with good accuracy, and comparisons with experimental values of γ give the values of λ. For most metals, λ is in the range 0.2–1, with higher values occurring for strong-coupled superconductors such as Hg and Pb. (There is also a contribution to m^* from electron–electron interactions, but it is small, difficult to determine, and usually ignored.) The combined effect of the lattice potential and the electron–phonon interaction gives $m^* = (1 + \lambda)$ m_{bs}. Experimental values of m^*/m_e are ~ 1 for many metals, as high as 10 for some transition and lanthanide metals, and 10^2–10^3 for heavy-fermion compounds, mainly Ce and U intermetallic compounds, in which the large effective mass is associated with the Kondo effect.

Many metals undergo a transition to the superconducting state at a critical temperature, T_c. In most cases, the superconducting-state C_e is approximately exponential in temperature as predicted by the BCS theory, but T^2 and T^3 dependences are found in some "unconventional" superconductors, including heavy-fermion and cuprate superconductors. C_e for Al, a BCS superconductor with $T_c = 1.2$ K, is shown for both the superconducting and normal states in **Figure 5**. In this case the lattice contribution to the specific heat at T_c and below is relatively small, and C_e in the superconducting state is particularly well defined by the experimental data.

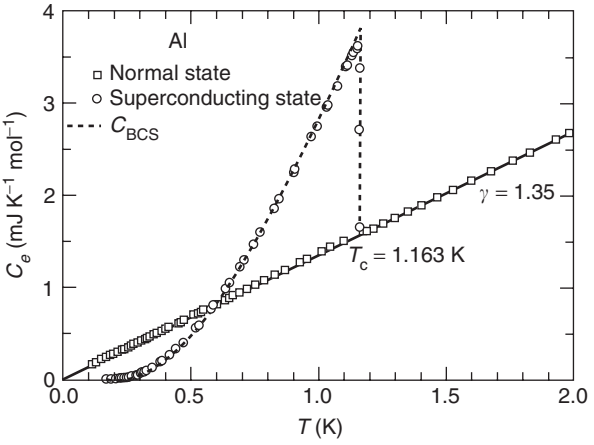

Figure 5 Conduction electron contribution to the specific heats of Al in the normal and superconducting states. The normal-state data below T_c were obtained in a magnetic field that quenched the superconductivity. The dashed curve is the theoretical specific heat of a BCS superconductor (Bardeen J, Cooper LN, and Schriffer JR (1957) Microscopic theory of superconductivity. *Physical Review* 106: 162), with numerical values from: Mühlschlegel B (1959) *Zeitschrift fur physik* 155: 313. Specific-heat data for aluminum are from: Phillips NE (1959) Heat capacity of aluminum between 0.1 and 4.0 K. *Physical Review* 114: 676.

Magnetic contribution Magnetic moments, of the order of magnitude of the Bohr magneton, μ_B, can be associated with the itinerant electrons in a metal and can appear as localized moments in both metals and insulating materials. At sufficiently high temperatures, in the paramagnetic phase, and in the absence of an applied magnetic field, they are randomly oriented and contribute $R \ln(2J + 1)$ to the entropy, S, where J is the resultant angular momentum. However, there is always some internal interaction that tends to produce an ordered structure at temperatures for which $k_B T$ is small relative to the energy of the interaction. In both metals and insulators, the possible interactions include dipole–dipole interactions and exchange interactions. In metals, the RKKY interaction that couples the localized moments via an intermediate polarization of the conduction electrons, and the Kondo effect, which leads to a compensation of the localized moments by conduction electron moments, are also important. In accordance with the third law of thermodynamics, the interactions produce a completely ordered, zero-entropy state at $T = 0$. (Possible exceptions are "frustrated" antiferromagnets, in which the exchange interactions cannot all be satisfied simultaneously.) In the temperature region in which the ordering and the associated reduction in entropy occur, there is a "specific-heat anomaly," a peak in the specific heat, which is related to the entropy by $C_P = (\partial S/\partial T)_P$. The temperature at which the ordering occurs can vary widely, reflecting differences in the energies of the interaction, for example, less than 1 mK for $Ce_2Mg_3(NO_3)_{12} \cdot 24H_2O$ and 1043 K for metallic iron.

When the ordering is driven by an external field, there are $2J + 1$ states with energies $g m_J \mu_B B$, where g is the spectroscopic splitting factor and m_J takes values from $-J$ to $+J$. The specific heat associated with

the magnetic ordering, C_m, takes the form

$$\frac{C_m}{R} = \left(\frac{g\mu_B \boldsymbol{B}}{2k_B T}\right)^2 \left\{ \operatorname{csch}^2\left(\frac{g\mu_B \boldsymbol{B}}{2k_B T}\right) - (2J+1)^2 \operatorname{csch}^2\left[(2J+1)\left(\frac{g\mu_B \boldsymbol{B}}{2k_B T}\right)\right] \right\}$$

This is an example of a Schottky anomaly, a term that is used more generally for any specific-heat anomaly associated with a finite number of energy levels. Electric fields of the crystal lattice acting on the orbital component of the angular momentum can also split the manifold of $2J+1$ states of the isolated ion to produce a Schottky anomaly, in that case called a crystal-field anomaly. For an external magnetic field and $J = 1/2$, an example of a "two-level system," the anomaly takes a particularly simple form,

$$\frac{C_m}{R} = \left(\frac{\Delta}{k_B T}\right)^2 \frac{\exp(\Delta/k_B T)}{[1+\exp(\Delta/k_B T)]^2}$$

where Δ is the energy difference between the two states, in this case $g\mu_B \boldsymbol{B}$. $CuK_2(SO_4)_2 \cdot 6H_2O$ in a field of 1.5 T provides an example of this behavior: the internal interactions, which produce an ordering near 0.05 K in the absence of an external field, can be neglected and the experimental data are in good agreement with the calculated two-level Schottky anomaly, as shown in **Figure 6**.

The internal interactions in α-$MnCl_2 \cdot 4H_2O$ produce antiferromagnetic ordering that results in a specific-heat anomaly near 1.5 K. **Figure 7** shows the zero-field anomaly, which has a shape typical of that associated with ordering by exchange interactions, and the evolution of the anomaly to a more Schottky-like form in an increasing external field. **Figure 8** shows the specific heat of $CeCu_6$, a heavy-fermion compound, in the low-temperature region where the Kondo effect produces a compensation of the Ce moments by an exchange interaction with the conduction electrons.

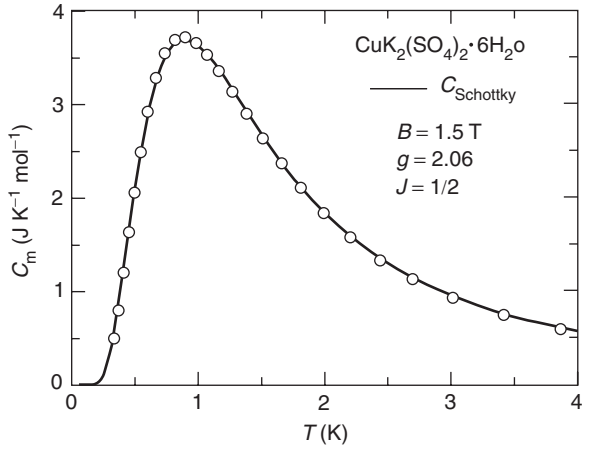

Figure 6 The magnetic specific heat, C_m, of $CuK_2(SO_4)_2 \cdot 6H_2O$ in a magnetic field of 1.5 T. At the temperatures of the measurements, the interactions between the magnetic Cu^{2+} ions have a negligible effect, and a "two-level" Schottky function for isolated ions provides an excellent fit to the data. (The data are from: Giauque WF, Brodale GE, Hornung EW, and Fisher RA (1971) Magnetothermodynamics of $CuK_2(SO_4)_2 \cdot 6H_2O$. II. Magnetic moment, heat capacity, entropy from 0.5 to 4.2 K with fields to 90 kG along the γ magnetic axis. *Journal of Chemical Physics* 54: 273.)

Nuclear moment contribution Contributions to the specific heat associated with nuclear moments, the "hyperfine" specific heat, C_h, are analogous to those associated with electronic moments. The differences arise from the small size of the nuclear magnetic moments, of the order of magnitude of the nuclear magneton, μ_N, three orders of magnitude smaller than μ_B, and the existence of nuclear electric quadrupole moments, Q, which interact with electric-field gradients in the lattice. The nuclear magnetic moments interact with external applied magnetic fields and with internal hyperfine fields produced by ordered electronic moments. They interact with each other through direct dipole–dipole interactions and, in the case of metals, through RKKY coupling. Except in the case of the internal hyperfine fields, which can be very large, it is generally only the high-temperature tail of a Schottky anomaly, associated with the interactions with magnetic fields or electric-field gradients, that is observed. For the case that the electric-field gradient and the magnetic field are in the same direction, the first two terms in the high-temperature expansion of the Schottky anomaly for C_h are D_2/T^2 and D_3/T^3, the coefficients of which have the forms

$$\frac{D_2}{R} = \left(\frac{1}{80}\right)\left[\frac{(I+1)(2I+3)}{I(2I-1)}\right]\left(\frac{e^2qQ}{k_B}\right)^2 + \left(\frac{1}{3}\right)\left(\frac{I+1}{I}\right)\left(\frac{\mu \boldsymbol{B}}{k_B}\right)^2$$

and

$$\frac{D_3}{R} = -\left(\frac{1}{1120}\right)\left[\frac{(2I-3)(I+1)(2I+3)(2I+5)}{2I^2(2I-1)^2}\right] \times \left(\frac{e^2qQ}{k_B}\right)^3 - \left(\frac{1}{10}\right)\left[\frac{(I+1)(2I+3)}{2I^2}\right] \times \left(\frac{e^2qQ}{k_B}\right)\left(\frac{\mu \boldsymbol{B}}{k_B}\right)^2$$

where I is the nuclear spin, μ is the nuclear moment in units of μ_N, e^2q is the electric field gradient, and Q is the nuclear quadrupole moment. These terms have

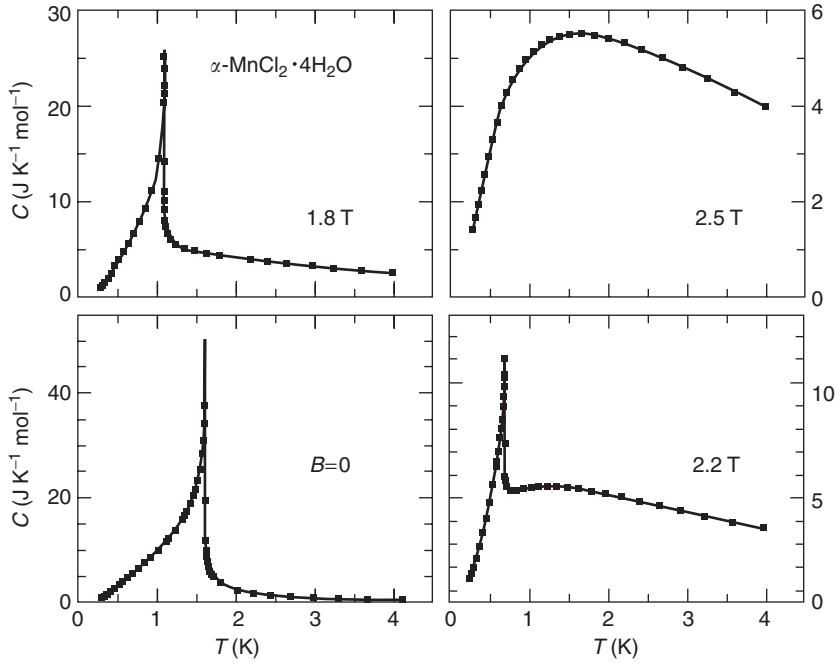

Figure 7 Specific heats for α-$MnCl_2 \cdot 4H_2O$ in various magnetic fields. For $\boldsymbol{B} = 0$, the Mn^{2+} ions order antiferromagnetically with a "lambda" anomaly at a Néel temperature of 1.6 K. As the magnetic field is increased, the antiferromagnetic ordering moves to lower temperatures and the anomaly is attenuated. For sufficiently large $\boldsymbol{B}$, the antiferromagnetic ordering is suppressed and the specific heat evolves into a more Schottky-like anomaly. (The data are from: Giauque WF, Fisher RA, Brodale GE, and Hornung EW (1970) Magnetothermodynamics of α-$MnCl_2 \cdot 4H_2O$. II. Heat capacity, entropy, magnetic moment from 0.4 to 4.2 K with fields to 90 kG along the *b* crystallographic axis. *Journal of Chemical Physics* 52: 2901.)

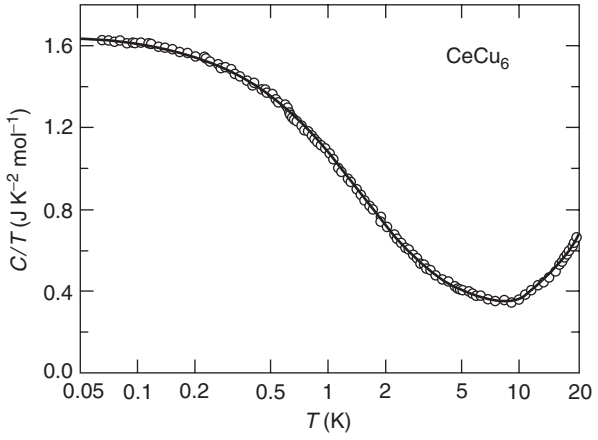

Figure 8 *C/T* vs. log *T* for the heavy-fermion compound $CeCu_6$. The high values of the heat capacity at temperatures below 5 K are a manifestation of the Kondo effect, in which the exchange interaction between the localized 4*f* moments of the Ce ions and the conduction electrons produces a compensation of the Ce moments by the conduction electrons. The associated specific heat is described by a temperature-dependent coefficient of the electron specific heat, $\gamma(T)$. At $T = 0.064$ K, $\gamma(T)$ has increased to 1.63 J K^{-2} mol^{-1}, corresponding to a conduction electron effective mass, m^*, that is three orders of magnitude greater than the free electron mass. (The data are from: Fisher RA, Lacy SE, Marcenat C, Olsen JA, Phillips NE, *et al.* (1987) Specific heat of heavy-fermion $CeCu_6$: effect of pressure and magnetic field. *Journal of Applied Physics* (*Japan*) 26: 1257.)

been identified in experimental data, usually in the vicinity of 0.1–1 K. The large internal hyperfine field, 930 T, in Ho, produces a Schottky anomaly with a maximum near 0.3 K. **Figure 9** is a comparison of the experimental data with the fitted Schottky anomaly, which includes a small quadrupole contribution. Examples of nuclear ordering at the other extreme of the temperature range in which the phenomenon is known are provided by Cu and Ag: in both cases the nuclei order antiferromagnetically, by a combination of dipole–dipole and RKKY interactions, and reductions in the nuclear entropy related to the associated specific-heat anomaly have been observed experimentally. The ordering occurs in the vicinity of 50 nK for Cu, and in the vicinity of 0.8 nK for Ag, which has a lower concentration of nuclear magnetic moments that are also smaller in magnitude.

Phase transitions Phase transitions take a variety of forms and display a corresponding variety in the associated specific-heat anomalies. Discontinuities in the entropy and the volume, the first derivatives of the Gibbs energy, *G*, are the defining characteristic of a thermodynamic first-order transition. They are related to the slope of the phase boundary in the *P*–*T* plane

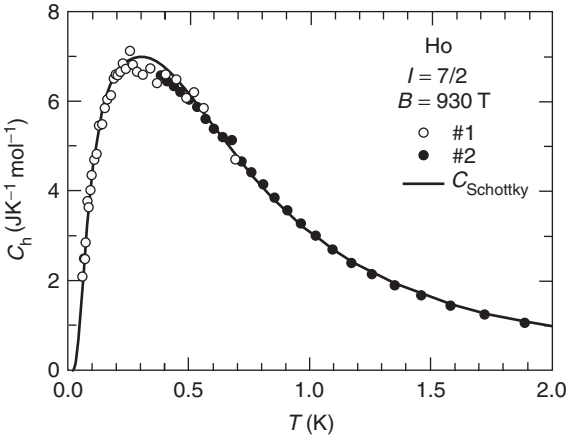

Figure 9 The hyperfine specific heat, C_h, for two samples of ferromagnetically ordered Ho metal. The splitting of the nuclear spin states arises mainly from the interaction of the nuclear magnetic moments with the effective hyperfine field created by the ordered 4*f* electron moments, but there is also a small effect of interaction of the electric quadrupole moment with an electric field gradient. The solid curve, a theoretical fit to the data, is a Schottky function calculated for the resulting, unevenly spaced levels. (The data for sample ♯1 are from: Van Kampen H, Miedema AR, and Huiskamp WJ (1964) Heat capacities of the metals terbium and holmium below 1 K. *Physica* 30: 229; for sample ♯2, from: Lounasmaa OV (1962) Specific heat of holmium metal between 0.38 and 4.2 K. *Physical Review* 128: 1136.)

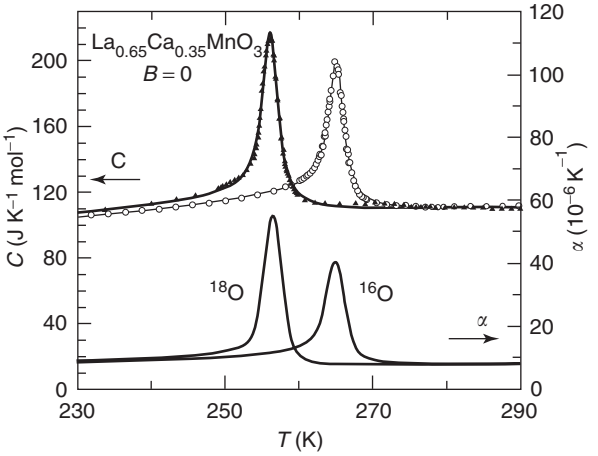

Figure 10 The specific heat, *C*, and thermal expansion, α, of $La_{0.65}Ca_{0.35}MnO_3$, a "colossal magnetoresistance" material that undergoes a first-order transition from a high-temperature, insulating, paramagnetic phase to a low-temperature, metallic, ferromagnetic phase. The transition, at the Curie temperature, shows a strong isotope effect. Data for both ^{16}O and ^{18}O samples are shown. (The data are from: Gordon JE, Marcenat C, Franck JP, Isaac I, Zhang G, *et al.* (2001) Specific heat and thermal expansion of $La_{0.65}Ca_{0.35}MnO_3$: magnetic-field dependence, isotopic effect, and evidence for a first-order phase transition. *Physical Review B* 65: 24441.)

by the Clapeyron equation, $dP/dT = \Delta S/\Delta V$. Ideally, there would be a δ function in C at the transition that would integrate to $T\Delta S$, but the transition is usually broadened by impurities, inhomogeneity, or other factors. **Figure 10** shows the specific heat at the first-order transition associated with the ferromagnetic ordering in $La_{0.65}Ca_{0.35}MnO_3$. In that case, the random mixture of La and Ca ions on their common sites accounts quantitatively for the breadth of the transition. The fitted curves correspond to broadened discontinuities in the entropy and the specific heat. The thermal-expansion data, included in the same figure, illustrate the similarity in the temperature dependence of the two properties, which is expected on the basis of simple thermodynamic models. They also give the value of ΔV, which, together with ΔS from the specific-heat data, satisfies the Clapeyron equation, confirming the first-order nature of the transition.

At an Ehrenfest second-order transition, the first derivatives of the Gibbs energy are continuous, but there are discontinuities in the second derivatives, the specific heat, the thermal expansion, and the compressibility. The Ehrenfest relations for the slope of the phase boundary are $dP/dT = \Delta\alpha/\Delta\kappa = \Delta C_P/\Delta VT\Delta\alpha$. The zero-field transition of a metal from the normal state to the superconducting state is an Ehrenfest second-order transition with a discontinuity between two finite values of the specific heat. The transition in Al, shown in **Figure 5**, is an example. For many second-order transitions, the specific heat diverges at the transition, as illustrated by the antiferromagnetic ordering in α-$MnCl_2 \cdot 4H_2O$ in **Figure 7**. They are frequently called λ transitions, as suggested by the shape of the specific-heat anomaly and the name given to the transition to the superfluid state in liquid ^{4}He at the "λ point." The λ transition in ^{4}He, for which the specific heat is shown in **Figure 11**, has been particularly intensively studied because an exceptionally high degree of sample purity and homogeneity can be attained. In the vicinity of the λ point, the specific heat varies as $\ln|T - T_\lambda|$.

Thermodynamics of Chemical Reactions

Currently, most measurements of specific heat are made for the interest in their microscopic interpretation, but historically a major motivation was to obtain data relevant to the third law of thermodynamics and to the thermodynamics of chemical reactions more generally. At constant pressure and temperature, the conditions for equilibrium between the products and reactants of a chemical reaction, and for equilibrium between two phases of the same substance, are determined by the change in Gibbs energy for the transformation. At constant volume and temperature, the change in the Helmholtz energy, *A*, takes that role. Specific-heat data contribute to the determination of

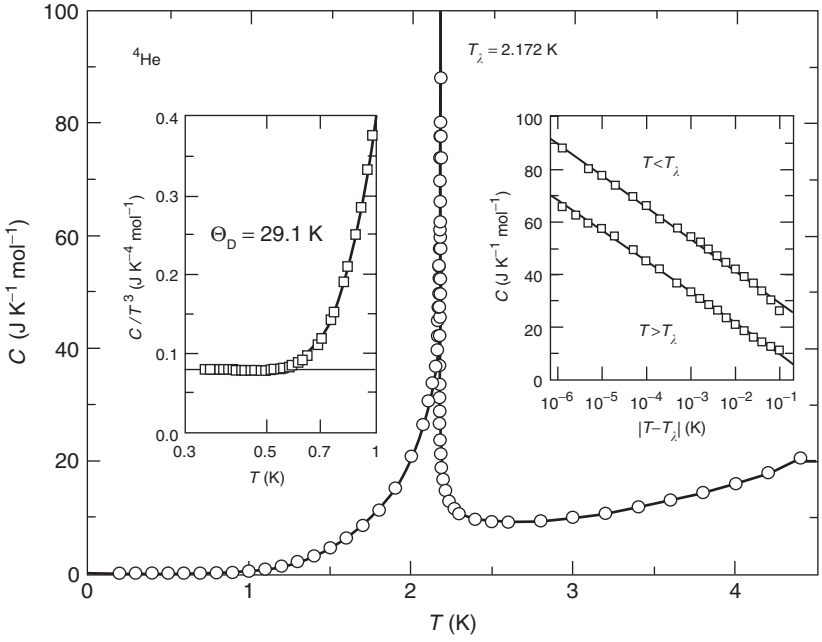

Figure 11 The specific heat of liquid ^{4}He. At T_λ, there is a transition from a low-temperature superfluid phase to a high-temperature, normal-liquid phase. The superfluid phase has properties that are analogous to those of a metal in the superconducting state. As shown in the inset on the left, $C \propto T^3$ for $T \leqslant 0.5$ K: The phonon contribution to the specific heat has the same form, and the same relation to elastic constants, as in solids. In this case, the initial deviation from the T^3 dependence includes a "roton" contribution. At T_λ, there is a logarithmetic divergence of the specific heat, as demonstrated in the inset on the right. (The data for the main panel and right inset are from: Buckingham MJ and Fairbanks WK (1961) The nature of the λ-transition in liquid helium. In: Gorter CJ (ed.) *Progress in Low Temperature Physics*, vol. 3. Amsterdam: North-Holland; for the left inset, from: Hoffer JK (1968) *PhD Thesis* (unpublished), Lawrence Berkeley National Laboratory, University of California, Berkeley, California 94720, USA.)

the Gibbs and Helmholtz energies through the thermodynamic relations $G \equiv H - TS$, $(\partial H/\partial T)_P = C_P$, $(\partial S/\partial T)_P = C_P/T$, $A \equiv U - TS$, $(\partial U/\partial T)_V = C_V$, and $(\partial S/\partial T)_V = C_V/T$. They determine the values of the entropy, and the temperature dependences of the enthalpy, energy, and Gibbs and Helmholtz energies.

As stated in one of the many formulations of the third law of thermodynamics, for any substance in a perfect crystalline state, the entropy is zero in the limit $T \to 0$. The importance for chemical thermodynamics is that values of the entropy can be obtained from specific-heat data alone: the "third-law entropy" is obtained by extrapolating specific-heat data to 0 K, integrating C_P/T to obtain $S(T)$–S_0, and assuming, as suggested by the third law, that S_0, the entropy at the 0 K state reached by the extrapolation, is zero. Typically, the data extend to a temperature between 1 and 15 K, the extrapolation is by a semiempirical fit to the lowest-temperature data that is based on appropriate theoretical expressions, and the entropies are tabulated for 298.15 K and the standard state (the thermodynamically stable form of the substance at a pressure of one bar).

The agreement obtained in comparisons of the values of ΔS for chemical reactions calculated with and without using third-law entropies, and in comparisons of the third-law entropies with values calculated from spectroscopic data played an important role in establishing the third law. In other cases, however, similar comparisons led to the identification of substances, for example, CO, NO, and H_2O, that do not attain a "perfect crystalline state" at 0 K, and for which $S_0 \neq 0$. The existence of such materials emphasizes the importance of caution in applying the third law to the determination of entropies from specific-heat data. The third law of thermodynamics, unlike the first and second laws, cannot be expressed by a simple mathematical relation that applies rigorously in all cases. Its application requires an understanding of its nature, which can be based on a statistical mechanical expression for the entropy, the Boltzmann formula, $S = k_B \ln \Omega$ (where Ω is the number of accessible quantum states, subject to the constraint of a fixed energy), together with the principle that there is a single state of lowest energy that is reached at $T = 0$ by systems that are in thermodynamic equilibrium. The case of CO, which is well understood, is a useful illustration of the factors that determine whether or not $S_0 = 0$: In the solid, the two orientations of a molecule that differ by an interchange of the C and O atoms are two distinguishable states, but, because the molecule is

relatively symmetric with respect to both shape and electric charge distribution, the difference in energy is small. The lowest energy configuration is one in which there is a perfectly ordered arrangement of the molecules with each in a definite orientation relative to the others, but the energy is not much lower than that of the higher-entropy, random distribution of orientations that is thermodynamically stable at high temperature. Below $\sim 5\,\mathrm{K}$ the lower-energy, ordered configuration does become thermodynamically stable, but there is a potential barrier to reorientation of the molecules that exceeds the thermal energy at that temperature, and the perfectly ordered state is not attained. For kinetic reasons, there is "frozen-in disorder" at 0 K and $S_0 \neq 0$. In the completely random configuration, there are two possible states for each molecule, $\Omega = 2^{N_A}$, $S = R \ln 2 = 5.76\,\mathrm{J\,K^{-1}\,mol^{-1}}$. The experimental value is $S_0 = 4.2\,\mathrm{J\,K^{-1}\,mol^{-1}}$, indicating that the molecules are partially ordered, at least in the particular measurement that gave this result. There are other cases, for example, NO, H_2O, and the H_2O in $Na_2SO_4 \cdot 10H_2O$, in which the disorder is complete. These examples afford an understanding of the treatment of nuclear contributions to the entropy: the random distribution over the lattice sites of different isotopes of the same element persists to 0 K, the disorder is frozen-in, and there is no contribution to experimental specific-heat data. The disorder associated with nuclear spin orientation is not frozen in, but at temperatures above 1 K it is normally complete, the associated entropy is constant, and there is no contribution to the specific heat. Both of these contributions to the entropy cancel in chemical reactions, and, although they could be calculated with the Boltzmann formula, they are omitted in tabulations of the entropies of chemical substances. There are also some paramagnetic salts in which the magnet moments of the unpaired electrons, as in the case of nuclear moments, order only below 1 K. Specific-heat measurements to 1 K would suggest $S_0 \neq 0$, but measurements to sufficiently low temperature would give $S_0 = 0$.

The enthalpy, energy, and Gibbs and Helmholtz energies cannot be determined from specific-heat data alone. Tabulations of thermodynamic data give the values of these quantities for compounds in their standard states, relative to the values for the elements in their standard states, for example, as values of the "heat of formation," ΔH, for the reaction in which the compound is formed from the elements. Specific-heat data do determine the temperature dependences of these quantities, but determination of absolute values requires, in addition, the evaluation of constants of integration. For the enthalpy and energy, one constant of integration is needed, for example, one value of a heat of formation for the enthalpy; for the Gibbs and Helmholtz energies, two are needed.

Nomenclature

A	Helmholtz energy ($\mathrm{J\,mol^{-1}}$)
B	magnetic induction (T) (tesla $\equiv$ weber $\mathrm{m^{-2}}$)
$\boldsymbol{B}_\mathrm{h}$	hyperfine magnetic induction (T)
C	specific heat ($\mathrm{J\,K^{-1}\,mol^{-1}}$)
C_e	electronic specific heat ($\mathrm{J\,K^{-1}\,mol^{-1}}$)
C_h	hyperfine specific heat ($\mathrm{J\,K^{-1}\,mol^{-1}}$)
C_l	lattice specific heat ($\mathrm{J\,K^{-1}\,mol^{-1}}$)

C_m	magnetic specific heat ($J K^{-1} mol^{-1}$)
C_P	specific heat at constant pressure ($J K^{-1} mol^{-1}$)
C_r	rotational specific heat ($J K^{-1} mol^{-1}$)
C_t	translational specific heat ($J K^{-1} mol^{-1}$)
C_v	vibrational specific heat ($J K^{-1} mol^{-1}$)
C_{BCS}	specific heat of a BCS superconductor ($J K^{-1} mol^{-1}$)
C_D	Debye specific heat ($J K^{-1} mol^{-1}$)
C_E	Einstein specific heat ($J K^{-1} mol^{-1}$)
C_V	specific heat at constant volume ($J K^{-1} mol^{-1}$)
D	electric displacement vector ($C m^{-1}$ (coulomb m^{-1}))
e	electron charge (C (coulomb))
e^2q	electric-field gradient at the nucleus ($V m^{-2}$ (volt m^{-2}))
E	electric field ($V m^{-1}$ (volt m^{-1}))
E_F	Fermi energy ($J mol^{-1}$)
g	spectroscopic splitting factor (dimensionless)
G	Gibbs energy ($J mol^{-1}$)
$\boldsymbol{H}$	magnetic field ($A m^{-1}$ (ampere m^{-1}))
H	enthalpy ($J mol^{-1}$)
I	nuclear spin quantum number (dimensionless)
J	electronic spin quantum number (dimensionless)
k_B	Boltzmann constant ($J K^{-1}$)
m	mass (kg)
m_e	free electron mass (kg)
m_J	quantum numbers labeling sublevels of J in a magnetic field (dimensionless)
m_{bs}	electron mass from band structure calculations (kg)
m^*	effective electron mass (kg)
$\boldsymbol{M}$	magnetic moment ($J T^{-1} mol^{-1}$)
n	number of atoms (dimensionless)
N_A	Avagadro's number (mol^{-1})
$N(E_F)$	density of states at the Fermi energy (states $J^{-1} mol^{-1}$)
P	pressure ($N m^{-2}$ (newton m^{-2} = pascal))
q	heat ($J mol^{-1}$)
Q	nuclear electric quadrupole moment (m^2)
R	gas constant ($J K^{-1} mol^{-1}$)
S	entropy ($J K^{-1} mol^{-1}$)
T	temperature (K)
T_c	superconducting critical temperature (K)
T_F	Fermi temperature (K)
T_λ	lambda temperature for ^{4}He superfluid transition (K)
U, E	energy ($J mol^{-1}$)
V	volume (m^3)
w	work ($J mol^{-1}$)
z	valence (dimensionless)
α	thermal expansion (K^{-1})
Δ	energy difference between two states (J)
γ	Sommerfeld constant ($J K^{-2} mol^{-1}$)
θ_r	characteristic rotation temperature (K)
θ_v	characteristic vibration temperature (K)
Θ_D	Debye temperature (K)
Θ_E	Einstein temperature (K)
κ	isothermal compressibility ($m^{-2} kg^{-1}$)
λ	electron–phonon interaction parameter (dimensionless)
μ	nuclear magnetic moment (in units of μ_N)
μ_0	permeability of free space (henry m^{-1})
μ_B	Bohr magneton ($J T^{-1}$)
μ_N	nuclear magneton ($J T^{-1}$)
ω	frequency (s^{-1})
ω_D	Debye cutoff frequency (s^{-1})
ω_E	characteristic Einstein frequency (s^{-1})
$\hbar$	Planck's constant h divided by 2π (J s)

Spin Density Waves and Magnons

N Harrison, Los Alamos National Laboratory, Los Alamos, NM, USA

Introduction

A review of semiconductors would be incomplete without the inclusion of those classes of extremely narrow gap semiconductors and semimetals that result from microscopic interactions between itinerant (or nearly free) electrons in a correlated metal. This article is devoted to spin-density waves, which are a consequence of Coulomb interactions between electrons causing a system to become antiferromagnetic, which would otherwise be metallic. Perhaps, the most extreme example is that where the Coulomb interactions between electrons exceed the total electronic bandwidth, leading to an insulator that can be very well described by the Hubbard model. Spin-density waves are subtle by comparison, being much more dependent on details of the Fermi surface topology. It is, therefore, more convenient to consider spin-density waves as perturbations of electronic bands of quasiparticles in a metal. The gaps are

significantly smaller, enabling quasiparticles to be easily excited across the spin-density wave gap, with tiny pockets of metallic carriers surviving in many cases.

The resulting antiferromagnetism can be mapped onto the simple case of a Heisenberg antiferromagnet. The moments are nevertheless smaller with comparatively long spatial periodicities of the spin modulation projected in preferred crystallographic directions that are predetermined by the details of the band structure. The existence of thermodynamic coupling between the spin-density wave and the charge degrees of freedom of the electronic bands causes these systems to be subject to phase excitations (or phasons) in a manner similar to the charge-density wave systems. Changes in the orientation of the spins, in contrast, take place via spin-wave excitations (or magnons), which are qualitatively similar to those that occur in Heisenberg antiferromagnets.

This article begins by considering the instability at the Fermi surface responsible for the spin-density wave formation, and then continues by discussing their static and dynamic properties. These include collective excitations involving both electronic (phason) and spin (magnon) degrees of freedom. Finally, the topic of field-induced spin-density waves, in which orbital contributions to the total free energy help stabilize such ground states in the presence of a strong magnetic field, is discussed. Transitions between different field-induced spin-density wave phases involving different levels of orbital quantization give rise to a novel manifestation of the bulk quantum Hall effect.

Fermi Surface Nesting and Spin-Density Wave Formation

The term "spin-density wave" refers to a simple one-dimensional (1D) antiferromagnetic modulation of the local spin density $\boldsymbol{S} = \boldsymbol{S}_0 \cos(\boldsymbol{r} \cdot \boldsymbol{Q}_0 + \phi_0)$ condensed from electrons that may subsequently become insulating. An essential precondition for spin-density wave formation to be energetically favorable is that a large fraction of the electron and hole quasiparticles share the same group velocity $\boldsymbol{v}_F$ at the Fermi energy ε_F. The residual Coulomb potential between quasiparticles U must also be significant, but smaller than the total electronic bandwidth W. These requirements tend to be met in systems where the calculated electronic bands (1) are very narrow and (2) are highly anisotropic or have large flat sections of Fermi surface that can efficiently nest. The term "nesting" refers to the process by which the translational symmetry breaking of the crystalline lattice at a characteristic wave vector $\boldsymbol{Q}_0$ eliminates major sections of the Fermi surface upon opening a gap 2Δ. In a spin-density wave system, this gap opens up wherever spin-up and spin-down electronic bands cross. **Figure 1** shows an example of the cross section of a Fermi surface amenable to nesting. The combined process of nesting and gap formation saves energy by greatly reducing the total electronic density of states at ε_F.

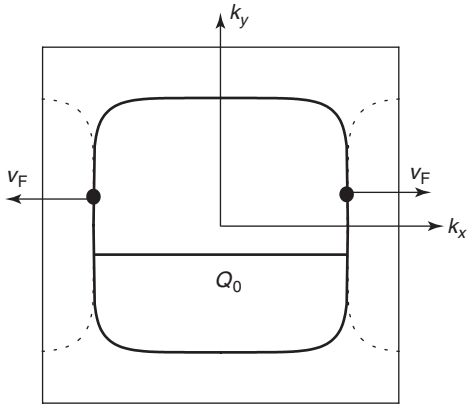

Figure 1 An example of a fictional Fermi surface susceptible to nesting. The Fermi velocity $\boldsymbol{v}_F$ is always perpendicular to the Fermi surface. Translation of the Fermi surface by the nesting vector $\boldsymbol{Q}_0$ enables sections of the Fermi surface with opposing Fermi velocities to meet each other tangentially. The nested sections become dielectric if the bands anticross upon opening of a gap. The dotted lines represent shadows of the translated Fermi surface.

Ground states of spin-density waves occur most commonly in molecular or organic metals, although classic examples occur in elemental chromium and its alloys. The antiferromagnetic ground states of heavy fermion systems, which have quasiparticle effective masses many times the free electron mass, can also sometimes be understood in terms of spin-density waves. While many of these materials have complicated electronic structures, the spin-density wave theory is most easily applied to systems with only a single electronic band,

$$\varepsilon_{k,\sigma} = \hbar^2 k_x^2/2m + \varepsilon_\perp(k_y, k_z) + \sigma_g \mu_B B \qquad [1]$$

crossing ε_F. The simplest case, by far, is that for a metal where the single electronic band has a significant dispersion only along chains parallel to $\boldsymbol{x}$, where k_x is the x-component of the momentum vector $\boldsymbol{k}$ and $\sigma = \pm 1/2$ represents spin-up and spin-down branches. A purely 1D dispersion is obtained by setting the limit $\varepsilon_\perp(k_y, k_z) \to 0$. Because spin-density wave formation only affects states that are close to ε_F, it is often convenient to consider a linear approximation of the form

$$\varepsilon_{k,\sigma} = \hbar v_F |k_x - k_F| + \sigma_g \mu_B B \qquad [2]$$

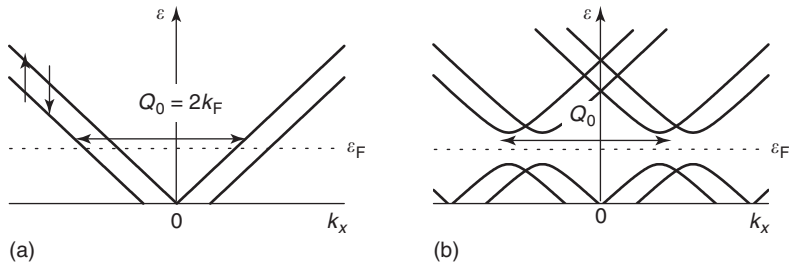

Figure 2 (a) The electronic dispersion according to eqn [2] with a finite magnetic B included to lift the spin degeneracy. The up and down arrows indicate the spin-up and spin-down branches respectively, while Q_0 denotes the nesting vector. (b) The same bands, according to eqn [3] after Fermi surface nesting and gap formation. The size of the gap at ε_F is 2Δ.

where $v_F = \hbar k_F/m$ at the 1D Fermi surface where $k = \pm k_F$. Theoretical models of spin-density waves regularly consider a dispersion of the form given by eqn [2] in conjunction with a lattice spacing along x equal to $a = 2k_F/\pi$. This situation then corresponds to a half-filled band containing one electron per unit cell. There are two reasons why theoreticians make such a choice. One is that stoichiometric metals always contain an integral number of electrons per unit cell, where 1 is then the simplest number. The other is that half-filled bands facilitate direct comparisons with the Hubbard model, which can also yield antiferromagnetic ground states. Here, eqn [2] is assumed to apply to more general band fillings. **Figure 2a** shows a sketch of this dispersion relation for which $\varepsilon_\perp(k_y, k_z) \approx 0$ and the degeneracy of the spin-up and spin-down states is lifted by a finite B in order to demonstrate the independence of $Q_0 = 2k_F$ on a magnetic field. **Figure 2b** shows this same dispersion relation after undergoing translational symmetry breaking with respect to the nesting vector and gap formation. The resulting multiple bands are obtained by solving

$$(2\varepsilon_\Delta - (\varepsilon_{k,\sigma} + \varepsilon_{nQ_0-k,-\sigma}))^2 - (\varepsilon_{k,\sigma} - \varepsilon_{nQ_0-k,-\sigma})^2 = 4\Delta^2 \quad [3]$$

for ε_Δ. The existence of a 1D Fermi surface enables perfect nesting in this case, giving rise to a fully gapped quasiparticle spectrum. Because spin-up and spin-down bands are mixed, spin is no longer a good quantum number for quasiparticle excitations across the gap.

Microscopic Theory

The opening of the gap 2Δ can be formally described in terms of the Bardeen–Cooper–Schrieffer (BCS) theory that applies to superconductivity, but with the pairing occurring at a finite momentum $Q = Q_0$ between electron and hole quasiparticles of opposite spin. The distinction between electrons and holes is purely a relative one, introduced to account for the fact that their group velocities oppose. In charge- and spin-density wave systems alike, the Fermi surface instability originates from a divergency in the Q-dependent charge and spin susceptibilities at $Q_0 = 2k_F$ which becomes logarithmic, $\chi_0(Q) \propto \ln|(Q + Q_0)/(Q - Q_0)|$, when the electronic dispersion is 1D as given by eqn [2]. Spin-density wave formation becomes increasingly favorable over the charge-density wave formation when the spin susceptibility is enhanced by a Stoner factor such that $\chi(Q) = \chi_0(Q)/(1 - U\chi_0(Q)/2\mu_0\mu_B^2)$. Because Q_0 is independent of the magnetic field, spin-density waves are particularly robust in magnetic fields, and in some cases can even be strengthened, as will be shown to be the case of the field-induced spin-density wave systems. For the dispersion relation given by eqn [2] and **Figure 2a**, the mean-field theory yields

$$\Delta_{T=0} = We^{-1/\lambda} \quad [4]$$

at zero temperature, where $\lambda = Un(\varepsilon_F)$ is the effective coupling constant, and $n(\varepsilon_F) \cong W^{-1}$ is the density of the electronic states (per unit cell) at ε_F. The effective electronic bandwidth is $W = \pi\hbar v_F/a$ for the dispersion relation given by eqn [2]. As is the case for superconductivity, the transition into a spin-density wave phase is expected to be of second order in the absence of an applied magnetic field and additional interactions, with the transition temperature T_{SDW} given by

$$2\Delta \cong 3.52k_B T_{SDW} \quad [5]$$

in the weak coupling limit. The single-particle electronic density of states becomes

$$n(\varepsilon) = W^{-1}\mathrm{Re}\left\{\frac{|\varepsilon - \varepsilon_F|}{\sqrt{(\varepsilon - \varepsilon_F)^2 - \Delta^2}}\right\} \quad [6]$$

upon opening a gap, which can be obtained by differentiating k_x in eqn [3] with respect to energy ε.

The spin-density wave condensation energy at zero temperature is given by

$$\Phi = -\tfrac{1}{2}\, n(\varepsilon_F)\Delta^2 \qquad [7]$$

which is again similar to that in superconductivity. Since the present model considers only the case of a 1D dispersion, the coherence length, $\xi_0 = \hbar v_F/\pi\Delta$, is strictly defined in one dimension.

Basic Static Properties

In high-quality samples at temperatures far below T_{SDW}, the correlation length over which the spin-density wave remains periodic greatly exceeds the coherence length. It often follows that the low-temperature, low electric field, and low-frequency conducting properties are those of a simple semiconductor or semimetal. In the case of the simple dispersion given by eqn [2], perfect nesting leads to a classic semiconductor-like behavior of the conductivity

$$\sigma_{xx} = \sigma_0 e^{-\Delta/k_B T} \qquad [8]$$

Ordinary quasiparticles must be thermally excited across the spin-density wave gap in order to contribute to the electrical conductivity, just as in a semiconductor. In metals with more complicated band structures, such as chromium, however, imperfect nesting leaves behind residual electron and hole pockets that continue to conduct in a conventional metallic fashion. In such a case, the electrical properties of the ground state are those of a semimetal, for which the conductivity contribution from quasiparticles excited across the spin-density wave gap is comparatively negligible. An important exception occurs in the case of magnetic field-induced spin-density waves, where the gap is augmented by a magnetic field as a consequence of Landau quantization.

The magnetic properties of spin-density waves are qualitatively similar to those of an antiferromagnet with a reduced moment

$$\mu = g\mu_B S = \frac{4\Delta}{U}\mu_B \qquad [9]$$

and with a long period

$$\Lambda = \frac{2\pi}{Q_0} \qquad [10]$$

that is matched to $2k_F$ rather than the crystalline lattice period a. The direction in which the spins preferentially align is determined by the effective coupling constants between them. The primary coupling constant for a simple 1D chain is given by

$$J = \frac{\hbar v_F (1-\lambda)^{1/2}}{\Lambda} \qquad [11]$$

in the weak coupling limit. If the spins order in a preferred direction orthogonal to the chains, the magnetic susceptibility $\chi_{||}$ along that preferred direction is zero at temperatures $T \ll T_{SDW}$, provided the applied magnetic field is lower than that required to flop the spin. In other directions, the spins are able to cant, giving rise to a finite spin susceptibility $\chi_\perp = Ng^2\mu_0\mu_B^2/2VJ$, where V is the volume per unit cell.

In a similar manner to charge-density waves, the commensurability of a spin-density wave is determined by the number of electrons per unit cell, $N = Q_0 a/\pi$ where $2\pi/a$ is the length of the 1D Brillouin zone prior to ordering. If N can be accurately reduced to a simple fraction of the form $N = A/B$, where A and B are integers, the superlattice period over which both the spin-density and atomic positions repeat is aB, in which case the spin-density wave is considered to be commensurate. The spin-density wave is incommensurate if N is an irrational number.

Collective Excitations: Phasons

The close correlation between the periodicity of spin-density waves and the electronic structure near the Fermi energy implies that they can undergo charge excitations like charge-density waves. These excitations then determine the electrodynamics of spin-density waves. It also serves as a useful approximation to simplify the treatment of the charge degrees of freedom by expanding the free energy in even powers of the order parameter and its spatial and temporal derivatives so as to obtain

$$\Phi = \alpha|\Delta|^2 + \beta\left(\frac{d\Delta}{dx}\right)^2 + \gamma\left(\frac{d\Delta}{dt}\right)^2 \qquad [12]$$

Compatibility with the mean-field theory is obtained by setting $\alpha = -n(\varepsilon_F)/2, \quad \beta = n(\varepsilon_F)(\hbar v_F/2\Delta)^2$, and $\gamma = n(\varepsilon_F)(\hbar/2\Delta)^2$. The order parameter itself can be expanded as

$$\Delta = (\Delta_0 + \delta)e^{i\phi} \qquad [13]$$

where δ respresents a small perturbation in its amplitude and $\phi = \boldsymbol{Q}\cdot\boldsymbol{r} = Qx$ accounts for the phase of the spin modulation described in the introduction. The dispersion relations for the excitation of the spin-density wave can then be obtained by assuming independent oscillatory variations $\delta = \delta_0 e^{i(\omega_A t - kx)}$ and $\phi = \phi_0 + \delta\phi e^{i(\omega_\phi t - kx)}$ of the amplitude and phase of the spin-density wave, respectively. Noting that the first two terms on the right-hand side of eqn [12] are potential energy terms while the third is a kinetic energy term, the application of Lagrangian mechanics yields

$$(\hbar\omega_A)^2 = 2\Delta^2 + (\hbar v_F k)^2 \qquad [14a]$$

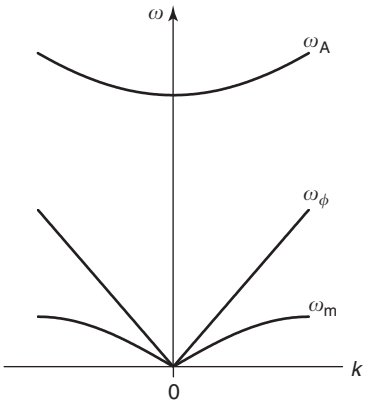

Figure 3 Approximate dispersion relations of excitations of a simple spin-density ground state at low temperatures, ignoring the effects of impurities and magnetic anisotropy. ω_A is the amplitude mode, which effectively corresponds to high-energy magnon excitations. ω_ϕ is the phason mode, corresponding to deformation and translational motion of the spin-density wave. ω_m is the magnon mode, corresponding to spin-waves involving purely rotational degrees of freedom of the spins.

and

$$\omega_\phi = v_F k \qquad [14b]$$

for the amplitude and phase modes, respectively, which are illustrated in **Figure 3**. The first mode occurs at energies comparable to the gap. Since $S \propto \Delta$, this mode is effectively a high-energy magnon mode. The second mode vanishes at $k = 0$, therefore corresponding to a collective sliding mode of the spin-density wave phase, which carries a dissipationless current analogous to the Fröhlich mode in charge-density wave systems. In practice, spin-density waves become strongly coupled to impurities and defects in the crystalline lattice, resulting in the opening of a small gap at $k = 0$. This inhibits dissipationless sliding, thereby restoring the familiar semiconducting properties of the spin-density wave state at low excitation energies.

The frequency-dependent conductivity can be estimated by considering an electric field, $E(t) = E_0 e^{i(\omega_\phi t - kx)}$ that then couples directly to the condensate charge. The equation of motion becomes

$$\frac{d^2\phi}{dt^2} + v_F^2 \frac{d^2\phi}{dx^2} = \frac{2k_F eE(\omega_\phi)}{m} \qquad [15]$$

where

$$\rho = \frac{e}{\pi}\frac{d\phi}{dx} \qquad [16]$$

is the accumulated electrical charge resulting from compression or tension of the spin-density wave and

$$j_{SDW} = \frac{e}{\pi}\frac{d\phi}{dt} \qquad [17]$$

is the electrical current resulting from its sliding motion. The solution of eqn [15] yields a frequency-dependent conductivity of the collective mode of the form

$$\sigma_{coll}(\omega_\phi) = \frac{ne^2}{m}\left(\frac{\pi}{2}\,\delta(\omega_\phi) + \frac{i}{\omega_\phi}\right) \qquad [18]$$

where n is the carrier density (becoming N/a in one dimension) and $\delta(\omega_\phi)$ is a Dirac delta singularity. Since it does not include pinning interactions with impurities, which occur in real systems, this result is somewhat academic. Such interactions have two effects: the first is to bind the spin-density wave to the lattice, causing the Dirac delta singularity to be shifted to finite frequencies, $\delta(\omega_\phi - \omega_0)$, and the second is to resist the sliding motion of the spin-density wave causing losses that broaden the collective mode. This broadening can be phenomenologically modeled by considering an effective relaxation time, τ. In spite of these complications, eqn [18] is a useful result because an integration $(2/\pi)\int \sigma_{coll}\, d\omega_\phi$ of the conductivity over the frequency yields the same total spectral weight ne^2/m as is obtained in the normal metallic state. The implication of this result is that the spin-density wave collective mode is able to account for all of the spectral weight. This contrasts with the case of a charge-density wave where coupling to the ionic lattice distortion causes the collective mode to acquire a heavy effective mass, reducing its share of the spectral weight.

A convenient means of modeling the effects of impurities on the frequency-dependent conductivity is to assume that the pinning forces dominate for small local perturbations of the spin-density wave position compared to the spin-density period $\Lambda = 2\pi/Q_0$, causing it to resonate about pinning sites at a characteristic frequency ω_0. This can be formally accomplished by inserting a pinning restoring force $\omega_0^2 x$ and a damping term $(1/\tau)d\phi/dt$ into eqn [15], and by assuming rigid motion of the spin-density wave, whereby $v_F^2(d^2\phi/dx^2) = 0$. Hence,

$$\frac{d^2\phi}{dt^2} + \frac{1}{\tau}\frac{d\phi}{dt} + \omega_0^2\phi = \frac{2k_F eE(\omega_\phi)}{m} \qquad [19]$$

which facilitates a particularly trivial solution of the form

$$\sigma_{coll}(\omega_\phi) = \frac{ne^2}{i\omega_\phi m}\left(\frac{\omega_\phi^2}{\omega_0^2 - \omega_\phi^2 - i\omega_\phi/\tau}\right) \qquad [20]$$

Owing to the simplifications made in eqn [19], eqn [20] can only be considered as an approximation. In addition to not taking into consideration deformations

of the phase, it also does not consider any details of the mechanism by which spin-density waves interact with impurities and defects. In the case of a charge-density wave, for example, the collective mode consists of a spatial modulation of the local charge, providing a direct means of coupling to charged impurities in the lattice. A spin-density wave must undergo relative phase shifts between its spin-up and spin-down components in order to realize a qualitatively similar type of coupling. In spite of these limitations, eqn [20] provides a surprisingly good account of the frequency-dependent conductivity observed in most spin-density wave systems. The conductivity at yet higher frequencies then includes an additional resonance corresponding to quasiparticle excitations across the gap 2Δ, which is typically two to three orders of magnitude larger than ω_0.

By taking appropriate limits, eqns [19] and [20] also provide one with a rough phenomenological understanding of the reaction of spin-density waves to a constant electric field. By setting $\omega_\phi = 0$ in eqn [20], for example, one can obtain zero conductivity, which is an appropriate value for small values of the electric field E_0 at $T = 0$. By seeking a time-independent solution to eqn [19], one can see that the spin-density wave will undergo a continuous sliding motion provided the electric field exceeds a threshold value $E_0 > m\omega_0^2\phi/2ek_F$, where the pinning force should eventually reverse and oscillate with x for $\phi > \pi/2$. This leads to a situation for large E_0 where the force of the electric field is balanced against the damping term, yielding a Drude-like conductivity.

Collective Excitations: Magnons

In eqn [14a], the amplitude of the spin modulation can be seen to undergo excitations, but with a rather large gap 2Δ equivalent to that for quasiparticle excitations at $T = 0$. Low-energy magnon modes are not obtained from the simple model of the free energy given by eqn [12], because it does not consider the rotational degrees of freedom of the spins that are necessary to produce spin waves. These can instead be obtained by mapping the spin degrees of freedom onto a simple 1D Heisenberg antiferromagnet Hamiltonian of the form

$$H = \left(\frac{\mu}{\mu_B}\right)^2 J \sum_p \boldsymbol{S}_{2p}\boldsymbol{S}_{2p+1} - g\mu_B \boldsymbol{B} \sum_p \boldsymbol{S}_{2p} + H_\perp \qquad [21]$$

Here, the prefactor accounts for the reduced moment, while the index p refers to a system with the periodicity Λ of the reconstructed Brillouin zone rather than the original lattice. The magnetization is expected to be isotropic for isolated chains, in which case $H_\perp = 0$, leading to a gapless spin wave behavior.

The equation of motion

$$\hbar\frac{d\boldsymbol{S}_{p+q}}{dt} = \boldsymbol{m} \times \boldsymbol{B}_{eff} \qquad [22]$$

for spin waves is obtained by equating the rate of change of the angular momentum against the torque imposed on spins rotated with respect to each other along the chain. Here, $\boldsymbol{m} = \mu g \boldsymbol{S}$ is the reduced moment expressed in vector form to account for its orientation. The total effective molecular field of an antiferromagnet,

$$\boldsymbol{B}_{eff} = (-1)^q \frac{J}{g\mu_B}(\boldsymbol{S}_{2p+q-1} + 2\boldsymbol{S}_{2p+q} + \boldsymbol{S}_{2p+q+1}) \qquad [23]$$

felt by each moment due to its two nearest neighbors alternates between odd and even q sites. The solution to eqn [22] is well known to have the form

$$\hbar\omega_m = 2JS\left|\sin\frac{\Lambda k}{2}\right| \qquad [24]$$

where, $\Lambda/2$ is the effective separation between spins along the chain. The dispersion relation given by eqn [24] is sketched in **Figure 3** along with the other modes, and can be seen to be approximately linear at low excitation energies.

In real spin-density wave systems, the crystal extends in three dimensions, leading to the possibility of additional couplings between the chains. Should the spins then have preferred axes of orientation, the antiferromagnet becomes anisotropic. The spins may no longer be free to rotate under such circumstances, causing the linear dispersion given by eqn [24] to become gapped. These effects are usually modeled by considering the anisotropy term $H_\perp$ in eqn [21] to include contributions that increase or reduce the energy D associated with the alignment of spins along certain directions. The size of the gap is typically of the order $2S\sqrt{JD}$.

Field-Induced Spin-Density Waves

Equation [3], as depicted in **Figure 2a**, yields a set of bands that change with the magnetic field, but where the gap in the density of electronic states at ε_F remains symmetric about ε_F. This occurs because the spin-density waves are the consequence of pairing between electron and hole quasiparticles of opposite spin, causing simple spin-density wave systems to be independent of a magnetic field. This situation changes, however, as soon as the nesting becomes imperfect. Imperfect nesting leaves behind small

pockets of the Fermi surface that then undergo orbital quantization in a magnetic field. Orbital quantization has a pronounced effect on the free energy of the total system at low temperatures, providing an additional term that can help make the spin-density wave ground states more stable in a magnetic field. Such effects should occur in all spin-density wave systems with imperfect nesting, including elemental chromium, but are more pronounced in systems where the transition temperature into the spin-density wave phase is low, or where the electronic bands are highly anisotropic. By far, the most striking behavior occurs in systems with an incipient spin-density wave, as has been shown to be the case in certain examples of the Bechgaard salts. "Incipient" here means that the Coulomb interactions are present to the extent that the metal is on the threshold of forming a spin-density wave phase, but where the efficiency of the nesting is insufficient to make a spin-density wave ground state stable at zero magnetic field. The system then has the potential to undergo transitions into spin-density wave phases in a magnetic field; hence, the term "field-induced spin-density waves." At zero magnetic field, the ground state can be a normal metal or a superconductor. The spin-density wave phase supersedes superconductivity in a magnetic field, because superconductivity is inhibited by magnetic fields.

One way to understand the origin of field-induced spin-density waves is through the process of one dimensionalization of the electron motion in a magnetic field. A simple model to consider is that where the k_y component of the electronic dispersion given by eqn [1] has the form

$$\varepsilon_\perp(k_y) = -2t_b \cos k_y b - 2t'_b \cos 2k_y b \qquad [25]$$

where $t_b < W/4$ and $t'_b < t_b$ are the nearest neighbor and second nearest neighbor electron transfer energies along the b-axis of a crystal. As shown in **Figure 4a**, the Fermi surface can no longer be nested by $\boldsymbol{Q}_0 = (2k_F, 0)$ or $\boldsymbol{Q}_0 = (2k_F, \pi/b)$ owing to the finite values of the transfer integrals along b. A magnetic field causes electrons on the 2D Fermi surface to follow a snake-like path similar to that in **Figure 4b**, where its real space width $4bt_b/\hbar\omega_b$ and period $\ell = 2\pi v_F/\omega_b$ decrease inversely proportionately with the frequency $\omega_b = eBv_F b/\hbar$, and hence the magnetic field B. One can make the qualitative argument that the motion becomes 1D as soon as $4t_b < \hbar\omega_b$, whereupon quasiparticles are mostly confined to single 1D chains.

From the quantum mechanical perspective, the one-dimensionalization can be understood by making a Landau–Peierls substitution, $\boldsymbol{k} \rightarrow i\nabla - e\boldsymbol{A}/\hbar$, into the

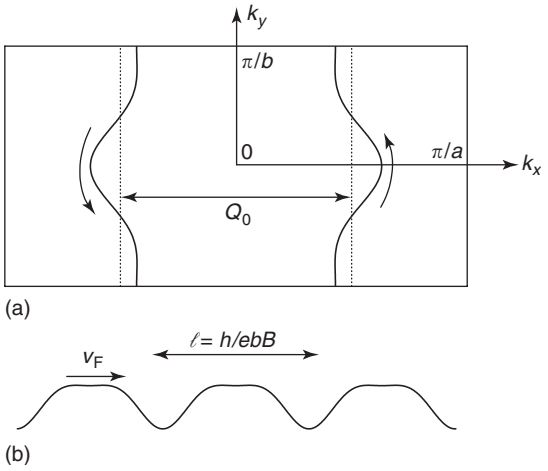

Figure 4 (a) A sketch of a Fermi surface similar to that seen in the Bechgaard salts, in which the nesting at vector $\boldsymbol{Q}_0$ is imperfect. The dotted lines show what the Fermi surface looks like when $\varepsilon_\perp(k_y) = 0$, whereupon perfect nesting is recovered. Arrows indicate the direction of motion of quasiparticles on the Fermi surface for a magnetic field pointing out of the page. (b) The trajectory of a quasiparticle in real space, obtained through the equation of motion, $\hbar\partial k/\partial t = e\boldsymbol{v}_F \times \boldsymbol{B}$, where $\boldsymbol{v}_F = \nabla_k \varepsilon$. The spatial dimensions of the real space trajectory are inversely proportional to the magnetic field strength. The product ℓb encloses a single flux quantum.

dispersion relation given by eqns [1] and [25], which yields a 1D Schrödinger equation

$$\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}\psi(x) - 2t_b \cos\left(k_y b - \frac{2\pi}{\ell}x\right) - 2t'_b \times \cos\left(2k_y b - \frac{4\pi}{\ell}x\right) = \varepsilon\psi(x) \qquad [26]$$

that is a function of only x where k_y then merely determines the shift in the coordinate of the center of the wave function.

The spin-density wave formation now involves the nesting of ε as determined by eqn [26]. In spite of the added complexity, the thermodynamics is shown to be surprisingly similar to that of a conventional spin-density wave ground state. Notably, eqns [4],[5], and [7] continue to be applicable but with the effective coupling constant having a modified form

$$\lambda = Un(\varepsilon_F)J_0^2\left(\frac{2t'_b}{\omega_b}\right) \qquad [27]$$

where J_0 is a zeroth-order Bessel function. The electronic density of states continues to be fully gapped, but with 2Δ also functioning as a Landau gap between Landau bands dispersed with respect to k_x, in which the orbital motion of quasiparticles is quantized. The orbital angular momentum of each quasiparticle in each Landau band is given by

$\hbar(l+1/2)$, where the quantum number has values $l=0,1,2,\ldots$, as for Landau levels in a simple 2D electron gas. The Landau bands are each separated in energy by an effective cyclotron energy $\hbar\omega_c$ that depends on the details of the nested band structure. By making an analogy with 2D electron gas systems, one can gain further insight into understanding as to why imperfectly nested spin-density waves are stabilized by a magnetic field. The free energy of a 2D electron gas experiences sharp minima as a function of B whenever ε_F is situated in a Landau gap (i.e., somewhere in the gap between two adjacent Landau levels, l and $l+1$). It is by utilizing such minima between Landau bands that field-induced spin-density waves become stable. This, therefore, exerts a constraint by which ε_F must always be situated within a Landau gap in a field-induced spin-density wave phase.

The above constraint has two important implications for field-induced spin-density wave systems. The first is that the Landau bands are always completely filled, giving rise to a type of integer quantum Hall effect where

$$\sigma_{xy} = \pm\frac{2ve^2}{h} \qquad [28]$$

per layer, v is the quantum number of the highest occupied Landau level and the sign depends on whether one or two closed pockets contain a net number of electrons or holes. The second implication is that the nesting vector is quantized, where

$$Q_0 = \left(2k_F \pm \frac{2\pi v}{\ell}, \frac{\pi}{b} + \delta k_y\right) \qquad [29]$$

in the simplest case, in order to sustain an integer filling factor v. This type of quantum Hall effect differs from that in conventional 2D electron gas systems in several ways. The first is the factor of 2 in the numerator of eqn [28], which results from the fact that up- and down-spin states are paired with no net spin quantum numbers, giving rise to completely spin-degenerate Landau bands. The second is that the net slope of the Hall resistivity $\rho_{xy} \approx 1/\sigma_{xy}$ throughout the field-induced spin-density wave phases, depicted in **Figure 5**, does not intersect $\rho_{xy} = B = 0$. Finally, the quantum Hall effect does not depend on the existence of localized states in the tails of Landau levels as it does in conventional 2D electron gas systems. The inability of ε_F to reside in a Landau band implies that a change in the value of the quantized Hall conductivity must be realized by means of a first-order phase transition between phases with different optimal values of v. An alternative possibility is that the normal metallic phase is restored between stable Hall plateaux. Orbital quantization within field-induced spin-density wave phases causes the off-diagonal components of the conductivity tensor to dominate over the diagonal ones, giving rise to a low resistivity state, $\rho_{xx} \sim \sigma_{xx}/\sigma_{xy}^2 \to 0$, as in the conventional quantum Hall effect. This contrasts with the semiconductor-like behavior seen in perfectly nested spin-density wave phases.

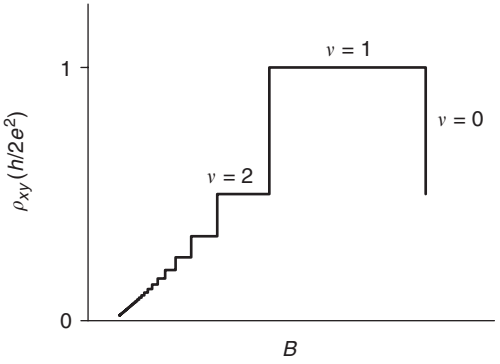

Figure 5 A plot of the Hall resistivity (per layer) of a field-induced spin-density wave system vs. magnetic field, exhibiting quantized Hall plateaux. Sharp changes are expected to occur between different states characterized by different values of v owing to the first-order nature of the transitions.

Nomenclature

a or b	lattice constant along $\boldsymbol{x}$ or $\boldsymbol{y}$ (m)
A or B	arbitrary integers (dimensionless)
$\boldsymbol{B}$ or B	magnetic flux density (magnetic field) (T)
$\boldsymbol{B}_{\text{eff}}$	Heisenberg molecular field (T)
D	anisotropy energy (J, eV)
e	electron charge (C)
E	electric field (Vm^{-1})
g	electronic g-factor (dimensionless)
h	Planck constant (J s)
$\hbar$	Planck constant divided by 2π(J s)
H	Heisenberg spin Hamiltonian (J, eV)
$H_{\perp}$	anisotropy Hamiltonian (J, eV)
i	square root of –1 (dimensionless)
j_{SDW}	current of collective mode (C s^{-1})
J	Heisenberg interaction (J, eV)
$\boldsymbol{k}$	electronic wave vector (m^{-1})
k_{F}	Fermi wave vector (m^{-1})
k_x, k_y, or k_z	electronic wave vector along $\boldsymbol{x}$, $\boldsymbol{y}$, or $\boldsymbol{z}$ (m^{-1})
l	Landau level index (dimensionless)
ℓ	one-dimensional Fermi surface traversal length (m)
m	quasiparticle effective mass (kg)
$\boldsymbol{m}$ or μ	moment of spin (Am^2 or units of μ_{B})
n	carrier density (3D) (m^{-3})
$n(\varepsilon)$	electronic density of states per unit cell (J^{-1}, eV^{-1})
N	number of electrons per unit cell (dimensionless)
p or q	indices of spin (dimensionless)
Q	quasiparticle excitation wave vector (m^{-1})
$\boldsymbol{Q}_0$ or Q_0	optimum nesting vector (m^{-1})
$\boldsymbol{S}$ or S	spin per unit cell (dimensionless)
t	time (s)
t_b	transfer integral along b (nearest neighbor, second nearest) (J, eV)
T	temperature (K)
U	Coulomb potential (J, eV)
$\boldsymbol{v}_{\text{F}}$ or v_{F}	quasiparticle group velocity at Fermi surface (m s^{-1})
W	electronic bandwidth (J, eV)
x	spatial dimension along $\boldsymbol{x}$ (m)
2Δ	gap energy (J, eV)
ε	electronic dispersion (J, eV)
ε_{F}	Fermi energy (J, eV)
$\varepsilon_{\perp}$	electronic dispersion orthogonal to $\boldsymbol{x}$ (J, eV)
Λ	period of spin modulation (m)
λ	effective coupling constant (dimensionless)
ρ	charge density per unit length (C m^{-1})
ν	Landau level filling factor (dimensionless)

ω_{ϕ}	phason frequency (s^{-1})

Statistical Mechanics: Classical

D Cassi, Università di Parma, Parma, Italy

Introduction

Statistical mechanics was created in the second half of the nineteenth century as a branch of theoretical physics with the purpose of deriving the laws of thermodynamic systems from the equations of motion of their elementary constituents, that is, atoms and molecules.

It is commonly recognized that statistical mechanics originated principally through the efforts of Rudolf Clausius (1822–1888), who first interpreted heat as the kinetic energy of molecules, James Clerk Maxwell (1831–1879), who derived the velocity distribution of the molecules in an ideal gas and, most importantly, Ludwig Boltzmann (1844–1906), who gave a statistical meaning to entropy.

Statistical mechanics was also the field where quantum physics first revealed itself: indeed, in 1900, Max Planck proposed the quantization hypothesis and gave a statistical interpretation of the black body radiation. Only two years later, Josiah Willard Gibbs

(1839–1903) introduced the statistical-ensembles approach, which is commonly used today and allows one to extend statistical methods to a great variety of physical systems.

In the 1920s, the application of statistical methods to quantum mechanical systems gave rise to a substantially new discipline which was called quantum statistical mechanics; the theory in use up to that time, and its further developments – not involving quantum mechanics (e.g., the theory of phase transitions and critical phenomena) – were accordingly called classical statistical mechanics.

Usually, statistical mechanics deals with equilibrium phenomena and it should be called, more precisely, equilibrium statistical mechanics. Nonequilibrium phenomena are typically more difficult to study, but several important statistical treatments of them exist, starting with the famous and seminal Boltzmann equation. These topics of nonequilibrium statistical mechanics are generally discussed as specific subjects directly related to their applications (e.g., transport phenomena, relaxation phenomena). In the following sections, the basics of classical equilibrium statistical mechanics are introduced.

Macroscopic and Microscopic Variables

The physical systems studied by statistical mechanics are composed of a very large (typically 10^{23}) number (N) of particles or degrees of freedom. In classical mechanics, the (microscopic) state of a system is univocally identified by giving the generalized positions q and momenta p of all the constituents.

For the sake of clarity the following will focus on a system composed of N pointlike particles. The $6N$-tuple of all momenta and positions are denoted by (p, q) (or, when it is convenient to explicitly specify the number of particles, by $(p^{(N)}, q^{(N)})$), defining

$$\begin{aligned}(p,q) &= (p^{(N)}, q^{(N)}) \\ &= (p_{1x}, p_{1y}, p_{1z}, \ldots, p_{Nx}, p_{Ny}, p_{Nz}, \\ &\qquad q_{1x}, q_{1y}, q_{1z}, \ldots, q_{Nx}, q_{Ny}, q_{Nz})\end{aligned}$$

The microstate (p, q) is, therefore, a point in the $6N$-dimensional phase space Ξ_N, which is the set of all possible physical states of the system.

According to classical dynamics, the time evolution of a system is determined by its Hamiltonian $H(p, q)$, and its coordinates $(p(t),q(t))$ satisfy the Hamilton equations

$$\frac{\mathrm{d}p_i}{\mathrm{d}t} = -\frac{\partial H}{\partial q_i}, \qquad \frac{\mathrm{d}q_i}{\mathrm{d}t} = \frac{\partial H}{\partial p_i}$$

On the other hand, the macroscopic state (macrostate) of a system, which is the object of thermodynamics, is described by a very small number of macroscopic variables (e.g., volume, pressure, temperature); therefore, it corresponds to many different microscopic states. The macroscopic variables appearing in thermodynamic laws can be divided into two different categories: the mechanical (or, in more general systems, the magnetic, the electric, etc.) and the statistical (or thermal) ones. The former can be calculated even for a single microstate from its coordinates (p, q), that is, they are functions, $f(p, q)$, of the points of the phase space (e.g., the internal energy). The latter cannot be determined for a single microstate, but all the microstates belonging to a given macrostate are needed in order to calculate them, that is, they are functions of subsets of the phase space (e.g., the entropy).

Time Averages

A fundamental assumption of classical statistical mechanics concerns the characteristic times of microscopic versus macroscopic dynamics. It is assumed that the microscopic dynamics is much faster than the macroscopic one, so that during a macroscopic measurement (the measurement of a macroscopic variable) the system assumes many different microstates (indeed, for continuous coordinates, infinite microstates). Therefore, the measured value of a mechanical macroscopic variable M is to be considered the time average $\bar{m}_t$ of the corresponding microscopic one m:

$$\bar{m}_t = \frac{1}{t}\int_0^t m(\tau)\,\mathrm{d}\tau \qquad [1]$$

t being the measurement duration. Considering that t is typically very large with respect to all characteristic times involved in microscopic dynamics, one takes the $t \to \infty$ limit, defining the macroscopic variable M as

$$M = \lim_{t\to\infty} \bar{m}_t \qquad [2]$$

Even with this simplifying assumption, the problem of determining M would require the solution of the equations of motion for the system, unless some further hypotheses are introduced. These are connected with the statistical equilibrium condition, that is, to the experimentally observed time independence of macroscopic variables: first, it must be supposed that the limit in [2] exists; then, M is required to be independent of the specific microstate (belonging to the given macrostate) assumed by the system at the instant $t = 0$ (formally the beginning of the measurement).

Phase-Space Averages

A crucial technical step in the development of classical statistical mechanics is the passage from time averages to phase-space averages. To introduce it, it is considered that in classical mechanics every mechanical variable m is a function, $m(p, q)$, of the phase-space coordinates p and q. Therefore, to calculate time averages one could simply consider the number of times the system has visited each point in phase space (or, more precisely, an infinitesimal volume $\mathrm{d}p\,\mathrm{d}q$ around that point); associating with every point (p, q) a weight $\rho(p, q)$ proportional to the number of visits, one can then obtain the time average of any variable m by computing its weighted average on the phase-space points. These heuristic considerations can be mathematically formalized as follows (assuming all the conditions for the interchange of the integrals and the limit hold)

$$\begin{aligned} M &= \lim_{t\to\infty} \frac{1}{t}\int_0^t m(p(\tau), q(\tau))\mathrm{d}\tau \\ &= \lim_{t\to\infty} \frac{1}{t}\int_0^t \left[\int m(p,q)\delta(p-p(\tau)) \right. \\ &\quad \left. \times\delta(q-q(\tau))\mathrm{d}p\ \mathrm{d}q\right]\mathrm{d}\tau \\ &= \int m(p,q)\left[\lim_{t\to\infty}\frac{1}{t}\int_0^t \delta(p-p(\tau))\right. \\ &\quad \left. \times\delta(q-q(\tau))\mathrm{d}\tau\right]\mathrm{d}p\ \mathrm{d}q \\ &\equiv \int m(p,q)\rho(p,q)\mathrm{d}p\ \mathrm{d}q \end{aligned} \qquad [3]$$

where

$$\rho(p,q) \equiv \lim_{t\to\infty}\frac{1}{t}\int_0^t \delta(p-p(\tau))\delta(q-q(\tau))\mathrm{d}\tau$$
$$\text{with } \mathrm{d}p \equiv \mathrm{d}p_{1x}\cdots\mathrm{d}p_{Nz} \text{ and } \mathrm{d}q \equiv \mathrm{d}q_{1x}\cdots\mathrm{d}q_{Nz} \qquad [4]$$

Notice that the introduction of $\rho(p, q)$ allows one to calculate the average values of any mechanical variable without knowing its dynamics: in other words, once $\rho(p, q)$ is known, the time can be completely neglected in all further calculations.

From the requirements introduced at the end of the last section, and from the generality of M, it follows that the function $\rho(p, q)$ only depends on, and completely determines, the macrostate it corresponds to. Therefore, it must parametrically depend only on the restricted number of macroscopic variables defining that macrostate. The same requirements would imply that, for any starting point (p, q) belonging to the macrostate, the system visits all the microstates belonging to it and that the frequency of visits is $\rho(p, q)$. This property cannot be proved for a generic dynamical system, and it has to be considered as one of the fundamental assumptions of classical statistical mechanics.

The Statistical Ensembles

The calculation of $\rho(p, q)$ from its definition would imply the complete solution of the equations of motion with any initial condition. This is in practice impossible even for simple systems, due to the large number of degrees of freedom. In fact, $\rho(p, q)$ was determined in a general form once and for all by Gibbs for the most significant cases, on the basis of physical considerations and assumptions.

Gibbs followed an alternative approach. Instead of just one system, he considered a large set of physically identical systems at once, all having the same Hamiltonian but being in different microstates at a given time t, and he assumed that the representative points (p, q) in phase space were distributed with a density $\rho(p, q)$. He called such a set a statistical ensemble and $\rho(p, q)$ its distribution. In other words, each system in the ensemble is, at time t, in a microscopic state (p, q) corresponding to the macroscopic state described by $\rho(p, q)$, with a probability given by $\rho(p, q)$ itself. Then he imposed the statistical equilibrium condition by requiring that the density of the points representing the systems in the phase space was left invariant during their time evolution. Finally, he proved that this condition is fulfilled if and only if

$$\rho(p,q) = f(H(p,q)) \qquad [5]$$

that is, if and only if $\rho(p, q)$ depends on the phase-space coordinates p and q only through the Hamiltonian of the system.

Now, considering the typical macroscopic constraints characterizing a thermodynamic system, he identified three main general kinds of ensembles and, using [5] and some specific hypotheses, he calculated their distributions. Gibbs called these ensembles microcanonical, canonical, and grand canonical, and these names have been used ever since.

The Microcanonical Ensemble

Even though Gibbs first considered the canonical ensemble and then derived the microcanonical one from it, the following formal development of statistical mechanics suggested inverting the order, to have a stronger connection with the microscopic dynamical equations.

The microcanonical ensemble describes a closed isolated system, that is, a system which cannot exchange particles and energy with the external world, confined in a fixed volume. Therefore, the macroscopic variables characterizing it are the number of particles N, the volume V, and the total energy E. Notice that all of them are mechanical variables: indeed, the microcanonical ensemble is the statistical

ensemble which is most directly connected with a classical dynamical system. The variables N, V, and E are also all extensive, that is, they are asymptotically proportional to the number of degrees of freedom (usually $3N$) for large N. Many physical properties of thermodynamic systems turn out to be simpler by taking the thermodynamic limit $N \to \infty$; in that case, it shall be required that the ratios of V and E to N (called the specific volume and the specific energy, respectively) are constant in this limit:

$$\lim_{N\to\infty} \frac{V}{N} = v, \qquad \lim_{N\to\infty} \frac{E}{N} = \varepsilon \qquad [6]$$

Due to its defining conditions, the energy of each system belonging to the microcanonical ensemble is constant during time evolution; in other words, its trajectory in phase space entirely lies on the hypersurface $H(p, q) = E$. The microcanonical distribution is obtained assuming that $\rho(p, q)$ is constant on this hypersurface and zero elsewhere:

$$\rho^{\mu C}_{N,V,E}(p,q) = \frac{\varepsilon_0 \delta(E - H(p,q))}{\Gamma(N,V,E)} \qquad [7]$$

where

$$\Gamma(N,V,E) = \varepsilon_0 \int \delta(E - H(p,q)) \mathrm{d}p \; \mathrm{d}q \qquad [8]$$

is the measure of the region of the phase space accessible to the system, that is, it measures how large the set of microstates corresponding to the given macrostate identified by N, V, and E is, and ε_0 is an arbitrary but fixed constant with the dimension of an energy, which is convenient to introduce to give Γ the dimension of a volume in phase space (without loss of generality, it can be set equal to 1).

The assumption leading to [7] means that the system, in its motion, explores "in a uniform way" the whole constant-energy hypersurface. Many attempts have been made during the last century to mathematically prove this hypothesis to be a consequence of general properties of Hamiltonian dynamical systems. However, this problem, known as the ergodic problem, has not been solved but for a very restricted class of systems (typically hard-spheres gases), and the ergodic hypothesis will be considered to be a reasonable assumption leading to experimentally verifiable results.

Knowing the microcanonical distribution $\rho^{\mu C}_{N,V,E}(p,q)$, it is possible to calculate the average of any mechanical variable according to [3]. However, there is no rule to calculate the fundamental thermal variables, such as the entropy S and the temperature T. In order to connect the microcanonical distribution with the thermodynamics, the most important postulate of all statistical mechanics has to be introduced, namely, the Boltzmann relation, which derives the entropy from Γ:

$$S(N,V,E) = k_B \ln \frac{\Gamma(N,V,E)}{\Gamma_0} \qquad [9]$$

where $k_B = 1.3807 \times 10^{-23} \mathrm{J K^{-1}}$ is the Boltzmann constant and Γ_0 is a fixed but arbitrary number with the same dimensions as Γ. It represents a unit of measure for volumes in phase space and it is necessary to make the argument of the logarithm adimensional. It is to be noted that it does not make the definition [9] ambiguous, since the entropy, like every thermodynamic potential, is always defined up to an arbitrary additive constant. As is well known, this arbitrariness can be eliminated by introducing the so-called third principle of thermodynamics, or the Nernst postulate, according to which the entropy must vanish for $T \to 0$: this requirement univocally fixes the value of Γ_0. Moreover, in order to have a coherent definition of Γ_0 for different values of N when taking the thermodynamic limit, it is customary to choose once for all the unit of measure γ for the smallest phase space, corresponding to only one particle in one dimension, and then define $\Gamma_0(N)$ for a system of N particles (in three dimensions) as

$$\Gamma_0(N) = \gamma^{3N} \qquad [10]$$

Considerations based on the semiclassical limit of quantum mechanics suggest then to choose $\gamma = h$, where h is the Planck constant, but this is outside the proper domain of classical statistical mechanics.

The Boltzmann relation cannot be mathematically proved and one has to consider it as a postulate. All that can be done is proving that, under some restrictive hypotheses, the statistical entropy defined by [9] has the same mathematical properties as the thermodynamic entropy defined by the differential relation $\mathrm{d}S = \mathrm{d}Q/T$. The fundamental of these hypotheses concerns the interactions between the particles in the system: they must decay rather fast with increasing distance. More precisely, suppose the interactions are isotropic, for the sake of simplicity, the interaction potentials $V(r)$ must decay faster than r^{-2} as $r \to \infty$. This means that equilibrium statistical mechanics cannot be applied to systems with (non-negligible) gravitational interactions, as well as to systems containing electrically charged particles and having nonzero total charge.

An important modification to [9] has to be introduced if the particles of the system are indistinguishable. Indeed, many years before the quantum concept of identical particles was introduced, Gibbs proved that Γ needs to be divided by $N!$ in order to preserve the asymptotic additivity of the entropy (his argument

is commonly know as the Gibbs paradox):

$$S(N, V, E) = k_B \ln \frac{\Gamma(N, V, E)}{\Gamma_0 N!} \quad [11]$$

In the most general case, not all the particles are indistinguishable, but one can have N_1 indistinguishable particles of one kind, N_2 of a different kind, and so on. If the system is composed of m different kinds of indistinguishable particles, with $\sum_{i=1}^{m} N_i = N$ (allowing even $N_i = 1$ for the sake of generality), the most general expression of the entropy is given by

$$S(N_1, \ldots, N_m, V, E) = k_B \ln \frac{\Gamma(N_1, \ldots, N_m, V, E)}{\Gamma_0 N_1! \cdots N_m!} \quad [12]$$

A slightly different definition of the microcanonical ensemble can be found in literature, according to which the systems belonging to the ensemble have energy between E and $E + \Delta E$ instead of exactly E. Assuming a constant distribution in the entire phase-space region satisfying that constraint, and defining Γ to be the volume of this region, one can again define S using [12]. It can be shown that in the thermodynamic limit, the two definitions of the entropy are asymptotically equivalent and the corresponding distributions give the same thermodynamic behavior.

Equation [12] is the starting point for deriving all the thermodynamics of the microcanonical ensemble. Applying basic thermodynamic relations, one obtains

$$\frac{1}{T} = \left.\frac{\partial S}{\partial E}\right|_{V, N_1, \ldots, N_m} \quad [13]$$

$$\frac{P}{T} = \left.\frac{\partial S}{\partial V}\right|_{E, N_1, \ldots, N_m} \quad [14]$$

$$\frac{\mu_i}{T} = -\left.\frac{\partial S}{\partial N_i}\right|_{V, E} \quad [15]$$

giving the temperature, the pressure, and the chemical potentials, respectively.

The Canonical Ensemble

The most typical system studied in statistical mechanics is confined in a fixed volume and is closed, but it is not isolated and it can exchange energy with a thermal bath (or a reservoir) at a fixed temperature. It is described by the canonical ensemble, and the macroscopic variables characterizing it are the number of particles N, the volume V, and the temperature T.

It can be considered as a small but macroscopic subsystem of a closed isolated system, the remaining part of which acts as a reservoir. Therefore, the canonical distribution from the microcanonical one can be obtained, calculating the distribution of a closed subsystem whose volume and number of particles in the thermodynamic limit satisfy

$$\lim_{N\to\infty} \frac{V}{N} = v,$$
$$\lim_{N\to\infty} \frac{N}{N_{TOT}} = \lim_{N\to\infty} \frac{V}{V_{TOT}} = 0 \quad [16]$$

N_{TOT} and V_{TOT} being the number of particles and the volume of the whole closed isolated system. Introducing, as usual, some suitable hypotheses (e.g., the ratio between the external surface of the subsystem and its volume must vanish in the thermodynamic limit) after some calculations, one gets

$$\rho^{C}_{N,V,T}(p, q) = \frac{e^{-H(p,q)/k_B T}}{Z(N, V, T)} \quad [17]$$

where

$$Z(N, V, T) = \int e^{-H(p,q)/k_B T} dp\, dq \quad [18]$$

is called the canonical partition function.

For the canonical ensemble, Z plays a role analogous to Γ for the microcanonical one: it is a sort of normalization factor which is not directly measurable, but it is the starting point for deriving all the thermodynamic quantities. The basic relation connecting it to a thermodynamic potential is

$$F(N, V, T) = -k_B T \ln \frac{Z(N, V, T)}{Z_0} \quad [19]$$

F being the Helmholtz free energy and Z_0 an arbitrary constant with the same dimensions as Z, playing the same role of Γ_0 in [9]; indeed, F too is defined up to an additive constant like S and the arbitrariness can be eliminated in the same way by assuming the third principle of thermodynamics to hold. Moreover, the same considerations introduced for Γ_0, concerning the normalization in the thermodynamic limit and the presence of indistinguishable particles, apply. Accordingly, the general form of [19] becomes

$$F(N_1, \ldots, N_m, V, T) = -k_B T \ln \frac{Z(N_1, \ldots, N_m, V, T)}{Z_0(N) N_1! \cdots N_m!} \quad [20]$$

with

$$Z_0(N) = \gamma^{3N} \quad [21]$$

After determining F by [20], all the thermodynamics of the canonical ensemble can be easily deduced. The

main thermodynamic equations needed are

$$S = -\left.\frac{\partial F}{\partial T}\right|_{V,\, N_1,\ldots,\, N_m} \quad [22]$$

$$P = -\left.\frac{\partial F}{\partial V}\right|_{T,\, N_1,\ldots,\, N_m} \quad [23]$$

$$\mu_i = \left.\frac{\partial F}{\partial N_i}\right|_{V,\, T} \quad [24]$$

$$E = F + TS \quad [25]$$

where E denotes the internal energy and coincides with the average value of the Hamiltonian.

The Grand Canonical Ensemble

The case of a system occupying a fixed volume but exchanging particles and energy with the external world, at fixed temperature and chemical potentials, is described by the grand canonical ensemble. In the simplest situation, all the particles are of the same kind and a macrostate is as usual defined by three macroscopic variables, the volume V, the temperature T, and the chemical potential μ (representing the energy increment due to the addition of a particle). However, a microstate is no longer represented by a point in a usual phase space. Indeed, the dimension of the phase space depends on the number of particles N, and here N is variable.

To consider this problem, one has to introduce an extended space Ξ given by the union of the phase spaces Ξ_N corresponding to all possible N:

$$\Xi = \bigcup_{N=0}^{\infty} \Xi_N \quad [26]$$

A point in this space is given by the $(6N+1)$-tuple $(N, p^{(N)}, q^{(N)})$, that is, by the number of particles N and a point in the corresponding phase space Ξ_N (note that one has to include the case $N=0$, corresponding to an empty system). For any N, one has also to consider a specific Hamiltonian $H_N(p^{(N)}, q^{(N)})$ and, to have a coherent definition of volumes in phase spaces of different dimensions, the volume unit $Z_0(N) = \gamma^{3N}$ is chosen according to [21].

To obtain the grand canonical distribution, a procedure similar to the one used to derive the canonical distribution from the microcanonical one can be followed.

A small but macroscopic subsystem of a closed isolated system is considered, the remaining part of which acts as a reservoir of energy and particles. The subsystem is open (it can exchange particles and energy with the external world), but it occupies a fixed volume V in space. It is assumed that, taking the thermodynamic limit,

$$\lim_{V \to \infty} \frac{V}{V_{\mathrm{TOT}}} = 0 \quad [27]$$

where V_{TOT} is the volume of the whole closed isolated system, and that the ratio between the external surface of the subsystem and its volume also vanishes in the thermodynamic limit. After some algebra, one obtains

$$\rho^{\mathrm{GC}}_{\mu,V,T}(N, p^{(N)}, q^{(N)}) = \frac{\mathrm{e}^{(\mu N - H_N(p^{(N)}, q^{(N)}))/k_{\mathrm{B}}T}}{\gamma^{3N} N! Z^{\mathrm{GC}}(\mu, V, T)} \quad [28]$$

where

$$Z^{\mathrm{GC}}(\mu, V, T) = \sum_{N=0}^{\infty} \frac{\mathrm{e}^{\mu N/k_{\mathrm{B}}T}}{\gamma^{3N} N!} \times \int \mathrm{e}^{-(H_N(p^{(N)}, q^{(N)})/k_{\mathrm{B}}T)} \mathrm{d}p^{(N)}\, \mathrm{d}q^{(N)} \quad [29]$$

is the grand canonical partition function or grand partition function. The last expression can also be written as

$$Z^{\mathrm{GC}}(\mu, V, T) = \sum_{N=0}^{\infty} \frac{z^N Z(N, V, T)}{\gamma^{3N} N!} \quad [30]$$

in terms of the canonical partition functions $Z(N, V, T)$ and of the activity z, defined by

$$z = \mathrm{e}^{\mu/k_{\mathrm{B}}T} \quad [31]$$

In the most general case of a system composed of m different kinds of indistinguishable particles, a different chemical potential for each kind of particle has to be introduced; therefore, the macroscopic variables characterizing a macrostate are T, V, and the m chemical potentials $\mu_1, \ldots, \mu_m$.

As for the microstates, the number N_i of particles of each kind $i = 1, \ldots, m$ has to be specified, and the corresponding phase space $\Xi_{N_1,\ldots,N_m}$ has to be introduced with coordinates $(p^{(N_1,\ldots,N_m)}, q^{(N_1,\ldots,N_m)})$. Accordingly, the extended space Ξ of [26] becomes

$$\Xi = \bigcup_{N_1=0}^{\infty} \cdots \bigcup_{N_m=0}^{\infty} \Xi_{N_1,\ldots,N_m} \quad [32]$$

and a point of Ξ is specified by the coordinates $(N_1, \ldots, N_m, p^{(N_1,\ldots,N_m)}, q^{(N_1,\ldots,N_m)})$, while the Hamiltonian acting on it is $H_{N_1,\ldots,N_m}$ $(p^{(N_1,\ldots,N_m)}, q^{(N_1,\ldots,N_m)})$. Using this notation, the grand canonical

partition function is given by

$$\rho^{\mathrm{GC}}_{\mu_1,\ldots,\mu_m,V,T}(N_1,\ldots,N_m,\ p^{(N_1,\ldots,N_m)},q^{(N_1,\ldots,N_m)}) = \frac{\mathrm{e}^{\left(\sum_{i=1}^{m}\mu_i N_i - H_{N_1,\ldots,N_m}(p^{(N_1,\ldots,N_m)},q^{(N_1,\ldots,N_m)})\right)/k_{\mathrm{B}}T}}{\gamma^{3\sum_{i=1}^{m}N_i}N_1!\cdots N_m!Z^{\mathrm{GC}}(\mu_1,\ldots,\mu_m,V,T)} \quad [33]$$

with

$$Z^{\mathrm{GC}}(\mu_1,\ldots,\mu_m,V,T) = \sum_{N_1=0}^{\infty}\cdots\sum_{N_m=0}^{\infty}\prod_{i=1}^{m}\frac{z_i^{N_i}}{\gamma^{3N_i}N_i!} \times\int \mathrm{e}^{-(H_{N_1,\ldots,N_m}(p^{(N_1,\ldots,N_m)},q^{(N_1,\ldots,N_m)}))/k_{\mathrm{B}}T} \times \mathrm{d}p^{(N_1,\ldots,N_m)}\ \mathrm{d}q^{(N_1,\ldots,N_m)} \quad [34]$$

and

$$z_i = \mathrm{e}^{\mu_i/k_{\mathrm{B}}T} \quad [35]$$

The thermodynamics of the grand canonical ensemble can be derived from the basic equation

$$\Omega(\mu_1,\ldots,\mu_m,V,T) = -k_{\mathrm{B}}T\ \ln\ Z^{\mathrm{GC}}(\mu_1,\ldots,\mu_m,V,T) \quad [36]$$

where the thermodynamic potential Ω is defined by

$$\Omega = -PV \quad [37]$$

The other thermodynamic quantities are obtained from Ω applying the relations

$$S = -\left.\frac{\partial\Omega}{\partial T}\right|_{V,\mu_1,\ldots,\mu_m} \quad [38]$$

$$N_i = -\left.\frac{\partial\Omega}{\partial\mu_i}\right|_{V,T} \quad [39]$$

$$E = \Omega + TS + \sum_{i=1}^{m}\mu_i N_i \quad [40]$$

where N_i denotes the average number of particles of kind i.

The Perfect Gas

The simplest and best-known application of classical statistical mechanics concerns the so-called perfect gas, that is, a system of noninteracting particles. This is obviously an ideal case, since a complete absence of interaction would prevent a system from reaching the equilibrium, but it can be considered a good approximation for rarefied real gases, where the potential energy is negligible with respect to the kinetic energy. It also represents the natural starting point for the study of more complicated systems by perturbative techniques.

Choosing, for the sake of simplicity, a monatomic gas composed of indistinguishable pointlike particles of only one kind, the perfect gas Hamiltonian is

$$H_N(p^{(N)},q^{(N)}) = \sum_{i=1}^{N}\frac{\boldsymbol{p}_i^2}{2m} \quad [41]$$

with $\boldsymbol{p}_i = (p_{ix}, p_{iy}, p_{iz})$ and m being the mass of each particle.

Microcanonical Ensemble

The case of a closed isolated system is studied first and described by the microcanonical ensemble. It is supposed that the gas is confined in a fixed space volume V, with a fixed energy E, and number of particles N.

To calculate the thermodynamic properties of such a system, first its entropy is to be determined according to [11], and to do that, the measure $\Gamma(N, V, E)$ of the region of the phase space accessible to the system is needed:

$$\Gamma(N,V,E) = \varepsilon_0\int\delta(E-H(p,q))\mathrm{d}p\ \mathrm{d}q = \varepsilon_0 V^N\int\delta\left(E-\sum_{i=1}^{N}\frac{\boldsymbol{p}_i^2}{2m}\right)\mathrm{d}\boldsymbol{p}_1\cdots\mathrm{d}\boldsymbol{p}_N \quad [42]$$

After some straightforward steps, one obtains

$$\Gamma(N,V,E) = \frac{\varepsilon_0 V^N(E)^{3N/2-1}(2m\pi)^{3N/2}}{\Gamma_{\mathrm{Eul}}(3N/2)} \quad [43]$$

and, substituting in [11] and using [10],

$$S(N,V,E) = k_{\mathrm{B}}\ \ln\frac{\varepsilon_0 V^N(E)^{3N/2-1}(2m\pi)^{3N/2}}{\Gamma_{\mathrm{Eul}}(3N/2)\gamma^{3N}N!} \quad [44]$$

which, for $N\to\infty$ and using the definitions [6], gives the asymptotic expression

$$S(N,V,E)\approx k_{\mathrm{B}}N\left(5/2+\ln\frac{(4m\varepsilon\pi/3)^{3/2}v}{\gamma^3}\right) \quad [45]$$

It is to be noted that the entropy [45] is extensive as expected, due to the Gibbs factor $N!$ introduced in [11]. Finally, applying [13]–[15], the usual thermodynamic equations for the perfect monatomic gas are

obtained:

$$\frac{1}{T} = \frac{3}{2}\frac{k_B}{\varepsilon} \quad [46]$$

$$\frac{P}{T} = \frac{k_B}{v} \quad [47]$$

$$\frac{\mu}{T} = -k_B \ln \frac{(4m\varepsilon\pi/3)^{3/2} v}{\gamma^3} \quad [48]$$

It can be noted that, due to the presence of the arbitrary normalization constant γ, the chemical potential is not univocally defined unless one introduces the third principle of thermodynamics or quantum mechanical arguments (see the comments to eqns [9] and [10]).

Canonical Ensemble

Consider the perfect monatomic gas composed of N particles in a fixed volume V, in thermal equilibrium with a reservoir at temperature T. This system is described by the canonical ensemble, and to calculate its thermodynamics the partition function Z defined in [18] is needed. Calculating Z for the Hamiltonian [41] one obtains

$$\begin{aligned} Z(N,V,T) &= \int e^{-H(p,q)/k_B T} dp\, dq \\ &= V^N \int e^{-\sum_{i=1}^{N} (p_i^2/2mk_B T)} dp_1 \cdots dp_N \\ &= V^N (2\pi m k_B T)^{3N/2} \end{aligned} \quad [49]$$

and, applying [20] for $m = 1$ and $N \to \infty$,

$$\begin{aligned} F(N,V,T) &= -k_B T \ln \frac{Z(N,V,T)}{N!\gamma^{3N}} \\ &\approx -k_B T N \ln(ev(2\pi m k_B T \gamma^{-2})^{3/2}) \end{aligned} \quad [50]$$

Again, the Helmholtz free energy is extensive due to the Gibbs factor $N!$

The main thermodynamic equations are then given by eqns [22]–[25]:

$$S = Nk_B \ln(e^{5/2} v(2\pi m k_B T \gamma^{-2})^{3/2}) \quad [51]$$

$$P = \frac{k_B T}{v} \quad [52]$$

$$\mu = -k_B T \ln(v(2\pi m k_B T \gamma^{-2})^{3/2}) \quad [53]$$

$$E = \tfrac{3}{2} N k_B T \quad [54]$$

Grand Canonical Ensemble

Finally, consider the case of a perfect monatomic gas in a fixed volume V, exchanging energy and particles with a reservoir at fixed T and μ. Using expression [30] for the grand canonical partition function, with $Z(N, V, T)$ given by [49], one obtains

$$\begin{aligned} Z^{GC}(\mu,V,T) &= \sum_{N=0}^{\infty} \frac{z^N Z(N,V,T)}{\gamma^{3N} N!} \\ &= \sum_{N=0}^{\infty} \frac{z^N V^N (2\pi m k_B T)^{3N/2}}{\gamma^{3N} N!} \\ &= e^{zV(2\pi m k_B T \gamma^{-2})^{3/2}} \end{aligned} \quad [55]$$

and, from [36] and [37],

$$\Omega = -PV = -k_B z V T^{5/2} (2\pi m k_B \gamma^{-2})^{3/2} \quad [56]$$

while the thermodynamic relations given by eqns [38]–[40] are

$$S = \left(\frac{5}{2} - \frac{\mu}{k_B T}\right) k_B z V (2\pi m k_B T \gamma^{-2})^{3/2} \quad [57]$$

$$N = zV(2\pi m k_B T \gamma^{-2})^{3/2} \quad [58]$$

$$E = \tfrac{3}{2} k_B T z V (2\pi m k_B T \gamma^{-2})^{3/2} \quad [59]$$

The thermodynamic equations derived for the three ensembles have obviously different meanings, since they refer to different physical situations. Indeed, quantities which are fixed in one of the ensembles can be fluctuating in a different ensemble (e.g., E is fixed in the microcanonical and fluctuating in the other ensembles). However, if the average values of the fluctuating quantities are considered, all these equations become equivalent from a mathematical point of view, allowing a unified thermodynamic description. From a physical point of view, this makes sense as far as the fluctuations around the average values are negligible with respect to the average values themselves or, in other words, as far as the relative fluctuations vanish.

This can be shown to happen usually in the thermodynamic limit, with the important exception of systems near critical point, where even the relative fluctuations typically diverge.

One of the fundamental results in classical statistical mechanics is the Boltzmann distribution function. Given a system formed by a large number of identical particles and in contact with a thermal reservoir, it gives the probability for the system to have a given energy E. The Boltzmann distribution can be derived by counting the number of possible microscopic configurations which lead to the same energy and assuming that they occur with the same probability. Another crucial assumption, which seems perfectly justified in the classical world, is that the particles, albeit identical, are supposed to be distinguishable. This last hypothesis does not hold in the quantum world, as one of the postulates of quantum mechanics states that identical particles should be considered as indistinguishable. The wave function of a system of identical particles should be unchanged, up to a phase factor, under a permutation of two of them. The standard argument to derive the statistics is to apply a permutation between two particles twice, that is, restoring the initial configuration. It immediately follows (the 2D case is not considered) that under a permutation, the wave function can remain unchanged (symmetric) or change sign (antisymmetric). These two cases define two different classes of particles named bosons and fermions, respectively. Bosons are particles with an integer spin, while for fermions, the spin assumes half-integer values. In both cases, the presence of a particle in a given state influences the probability of the other particles to be in that state; this is not the case in the hypothesis which leads to the Boltzmann distribution. (Indistinguishability of identical particles and then quantum mechanical effects are intimately related to the fact that the wave functions of two particles have appreciable overlap. Decreasing the temperature T or increasing the density, ρ, of an identical particle system will lead to a wave packet overlap when the thermal de Broglie wavelength $\lambda_{dB}(T) = \sqrt{2\pi\hbar^2/mk_BT}$ becomes of the order or greater than the average distance between particles, $\lambda_{dB}(T) \geqslant d \approx 1/\rho^{1/3}$.) If P_1 is the probability of adding a classical particle to a state with n particles, from the symmetry properties of the wave functions, it is easy to show that in the case of fermions or bosons, this probability is respectively suppressed by a factor $(1 - n)$, or enhanced by a factor $(1 + n)$. The probability for two bosons to be in the same quantum state is enhanced; on the contrary, fermions obey the Pauli principle which forbids two fermionic particles to have the same quantum numbers.

In order to obtain the distribution function for fermions and bosons one can proceed as follows. Consider two energy states E_1 and E_2; the principle of detailed balance states that in equilibrium the ratio of transition rates between the two states is equal to the ratio of the populations of particles in the two states or, equivalently, to the ratio of the Boltzmann factors: $\Gamma_{2\to1}/\Gamma_{1\to2} = n_1/n_2 = e^{-\beta E_1}/e^{-\beta E_2}$. The probability of having n fermions/bosons in a given state can be expressed in terms of the Boltzmann distribution if the rates are properly modified so as to account for the suppression/enhancement factor due to the occupancy of the final state. The detailed balance condition can then be rewritten as

$n_1(1 \pm n_1)/[n_2(1 \pm n_2)] = e^{-\beta(E_1 - E_2)}$ where $\beta = 1/k_B T$, T is the temperature and k_B is the Boltzmann constant. From the previous equation it follows that the distribution functions for quantum particles are

$$n_{FD}(E) = \frac{1}{e^{\beta(E-\mu)} + 1} \quad \text{for fermions} \qquad [1]$$

$$n_{BE}(E) = \frac{1}{e^{\beta(E-\mu)} - 1} \quad \text{for bosons} \qquad [2]$$

In the previous equations the chemical potential μ fixes the average total number of particles. The functions $n(E)$ are named after the scientists who formulated them, as Bose–Einstein and Fermi–Dirac distribution functions. Equations [1] and [2] are represented in **Figure 1** for different values of the temperatures. At energies E much larger than $1/\beta$, the quantum statistics approaches the Boltzmann distribution; in the limit of high temperatures, the average occupation of each energy state is much smaller than one and the quantum effects can be ignored. Indeed for $n \ll 1$, the suppression/enhancement factor related to the quantum statistics can be ignored and thus the classical distribution function is recovered. In the low temperature limit, the quantum effects become dominant. Bose–Einstein statistics lies always above the Boltzmann distribution. The Fermi–Dirac distribution function is always less than one (due to the Pauli principle), and at zero temperature, drops abruptly from one to zero at the (so-called) Fermi energy E_F (coincident in this case with the chemical potential).

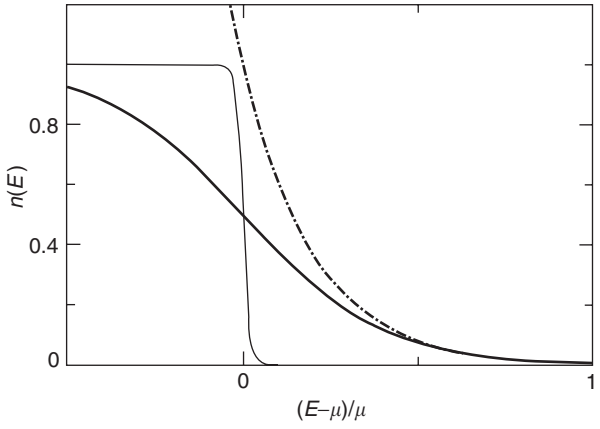

Figure 1 The Fermi–Dirac distribution function (thin solid curve) is compared to the Boltzmann distribution (dashed-dotted curve) for a temperature of $T = 0.2\,\mu/k_B$. The agreement with the classical distribution is good only for energies far above the Fermi energy. At low energies the Pauli principle prevents the double occupancy of the same state as it would follow from the classical analysis. For completeness, the Fermi–Dirac distribution is plotted also at lower temperature $T = 0.01\,\mu/k_B$; it can be noted that it approaches a step function at zero temperature.

The differences in the distribution functions will reflect in the properties of Fermi and Bose systems at low temperatures. Although it is impossible to briefly review this huge field of investigation, it is nevertheless useful to recall a few brief important examples where quantum statistics plays a dominant role. In order to keep the presentation as simple as possible, perfect gases are considered, that is, the only contribution to the energy is due to the kinetic term while interaction between particles are disregarded. The fact that a direct interaction term is not present does not mean that the particles do not feel each other. As discussed already, indistinguishability implies that the probability for a particle to occupy a given state influences the probability of the other particles being in the same state. Let fermions be considered first. At zero temperature, from the Pauli principle, it follows that all states below a certain energy are occupied while all the states above it are empty. The energy of the highest occupied level is defined as the Fermi energy. A Fermi gas is said to be degenerate when its temperature is small compared to E_F/k_B; in the opposite limit of a non-degenerate gas, the properties are those of a classical gas and therefore, they are not discussed here. For a gas of N fermions contained in a volume V, the Fermi energy is given by

$$E_F = \frac{\hbar^2}{2m}\left(\frac{3\pi^2 N}{V}\right)^{2/3} \qquad [3]$$

where $\hbar$ is the Planck constant divided by 2π, and m is the fermion mass. Another useful quantity to characterize the system is the density of states $N(\varepsilon)$, defined as the number of states which are present in an energy shell between E and $E + dE$. For a Fermi gas, counting the states in the given shell results in a density of states

$$N(E) = \frac{V}{2\pi^2}\left(\frac{2m}{\hbar^2}\right)^{3/2} E^{1/2} \qquad [4]$$

The chemical potential μ coincides with the Fermi energy at zero temperatures; on increasing T, it decreases and becomes negative (a 3D system is considered) at temperatures of the order of the Fermi temperature $T_F = E_F/k_B$. Typical values of the Fermi energy for metals are such that at room temperature the ratio T/T_F is of the order of 10^{-2}. In this case, which is the most frequently encountered situation, the density of states can be assumed to be constant in an interval of the order of T centered in T_F. A good example to see deviations in the thermodynamic quantities due to quantum effects is to consider the heat capacity of a Fermi gas, such as electrons in a metal. One can recall the equipartition theorem which states that, for a monoatomic gas the heat

capacity is constant and is 3/2. That is what is expected for a Fermi gas at temperatures higher than the Fermi temperature. In the low temperature limit, the only states which contribute to the heat capacity are those in a strip of width $k_B T$ around the Fermi energy, that is, those in the energy region where the Fermi function is smeared. All the other electrons are effectively frozen due to the Pauli principle. The number of electrons thus contributing to the temperature dependence of the internal energy are of the order of NT/T_F, each of them having an energy of the order of $k_B T$. A detailed calculation leads to the result $C_e = (\pi^2/2)Nk_B T/T_F$; it goes to zero linearly with temperature. It is possible to measure the electronic contribution to the heat capacity in metals at low temperature (typically of the order of kelvin) when the lattice contribution (which depends on T^3) can be disregarded. Another interesting example of the consequence of the Pauli principle in the thermodynamic quantities is the Pauli spin susceptibility, which measures the spin response of the electron system to an applied magnetic field. Using the same line of reasoning as before, it is evident that at low-temperature spin susceptibility, $\chi = N(E_F)$. Indeed the argument goes as follows: the number of spins which can be flipped by an applied magnetic field is a fraction of T/T_F around the Fermi energy because, due to the Pauli exclusion principle, the other spins cannot be flipped since the corresponding (spin-flipped) state is occupied. The susceptibility per spin is given by the Curie law $\sim 1/T$. From here it therefore follows that the Pauli result of a spin susceptibility is independent of temperature and proportional to the density of states at the Fermi energy. In the presence of electron–electron interaction and/or external potential, instead of the particles, one can describe the properties of the Fermi liquid by means of the long-lived quasiparticle excitations close to the Fermi energy. The leading temperature dependence of the various observables is not modified (for example the heat capacity remains linear in the temperature dependence); however, the effect of the interaction enters in the renormalization of the parameters characterizing the Fermi liquid. Degenerate Fermi systems are observed in a variety of very different physical situations ranging from electrons in metals to electrons in white dwarfs. It is worth stressing at this point that the effect of interaction between electrons, or interaction of the electrons with the ions of the lattice does not always result in the renormalization of the parameters (such as effective mass).

A completely different behavior is observed in a gas of bosons at low temperatures. Here there is no Pauli blocking; on the other hand, for bosons, the probability of being in the same quantum state is enhanced as compared to the classical value. A very interesting phenomenon observed in the Bose system is that of the Bose–Einstein condensation. Below a given critical temperature, there is a macroscopic fraction of the particles which condense into the state with the lowest energy. In order to grasp the process of Bose–Einstein condensation, it is useful to understand the behavior of the chemical potential close to the transition temperature. (If the total number of bosons is not conserved, as for photons, the chemical potential is zero and the Bose–Einstein distribution coincides with the Planck distribution for the blackbody radiation.) As in the case of fermions, an ideal boson gas with a macroscopic fixed number N of particles of spin zero is considered. The density of states $N(E)$ of this system is given by eqn [4]. The factor $1/2$ is due to the fact that the density of states per spin species is being considered. In order to avoid that some occupation number could be negative, the value of chemical potential must always be less than the ground-state energy which, for simple reasons is assumed to be equal to zero, $\mu < 0$ (see eqn [2]). The chemical potential depends on the number of particles and on the temperature. At zero temperature all the N particles are in the ground state; from this fact it is easy to show that for $T \to 0$, the chemical potential tends to the ground-state energy as $\mu = -k_B T/N$. The particles are distributed among the ground state and all the excited states as

$$\begin{aligned} N &= \sum_i \frac{1}{e^{(E_{i_i}-\mu)/k_B T} - 1} = N_0(T) \\ &\quad + \int_0^\infty N(E) \frac{1}{e^{(E-\mu)/k_B T} - 1} \, dE \\ &= N_0(T) + N_{ex}(T) \end{aligned} \qquad [5]$$

The integral in eqn [5] can be calculated and the result is

$$N = N_0(T) + \frac{V}{\lambda_{dB}^3(T)} g_{3/2}(e^{\mu/k_B T}) \qquad [6]$$

where $g_\eta(z) = \sum_{t=1}^\infty z^t/t^\eta$.

At "high" temperature the value $N_{ex}(T)$ is of the same order of magnitude of N, and the population is distributed over all the states, each state being weakly occupied. Below a critical temperature $T_c \propto \rho^{2/3}$, where ρ is the particle density, the ground state becomes macroscopically occupied and the fraction of particle in the ground state is

$$\frac{N_0(T)}{N} = 1 - \left(\frac{T}{T_c}\right)^{3/2} \qquad [7]$$

The temperature T_c is the Einstein condensation temperature and satisfies the relation $N_{ex}(T_c) = N$; it

is important to note that the critical temperature is usually several orders of magnitude higher than the level spacing between the ground state and the first excited state. The occurrence of a single quantum state macroscopically occupied is the key to the Bose–Einstein condensation. The experimental observation of Bose–Einstein has been recently realized with dilute alkali gases.

Quantum statistical mechanics embraces a large class of situations where quantum effects do not necessarily stem from the quantum statistics of the constituent particles. There are a large number of situations where, though the particles are localized (therefore, the indistinguishability is not important), quantum mechanics plays a crucial role. Probably, among the most popular situations, the studies on localized spins interacting through an exchange coupling are mentioned. In this case, quantum effects emerge due to the quantum nature of the spin degree of freedom. The fact that different components of the spin do not commute reflects in a kind of quantum frustration. The impact of spin models in quantum statistical mechanics is not confined only to the theory of magnetism. More generally, pseudo-spin models should be considered as they cover a wider range of materials, for example, glasses and superconductors. They can be described in terms of fictitious spins located in a given network, in certain limits.

As it is already hinted in the previous paragraph, interaction between the particles is responsible for a huge variety of phenomena which will appear in many articles in this encyclopedia. In the brief description made of the properties of Fermi systems, it is mentioned that electron–electron interaction can be incorporated by means of renormalization of the physical parameters characterizing the fermion liquid. However, this is not always the case. Among the others, interaction between particles often leads to instabilities and consequently a phase transition to a condensed phase occurs. Examples of phase transitions are ferromagnetism, superconductivity, and charge/spin density waves, just to mention a few important cases. Phase transitions can be driven both by thermal fluctuations and by quantum fluctuations. In the former case, below a certain temperature the system orders spontaneously even in the absence of any applied field. The prototype example is the ferromagnetic transition; below the Curie temperature, the system will present a spontaneous magnetization even in the absence of any external magnetic field. A quantum phase transition instead takes place at zero temperature, and it is driven by the changing of some parameter, for example, a coupling constant or an external field, of the system. In this case the thermodynamical properties, for example, the magnetization, are deeply connected to the dynamical ones since both derive from the quantum dynamics of the many-body system. Probably, the simplest example of a quantum phase transition can be described in a model of spin interacting via an (ferromagnetic) exchange coupling (with strong anisotropy in the x-direction) J_x, and subjected to an external magnetic field B (say along the z-direction). This model Hamiltonian, known as Ising model in a transverse field, appropriate for this model is

$$H = -\frac{J_x}{2}\sum_{\langle ij\rangle}\sigma_i^x\sigma_j^x - B\sum_i \sigma_i^z \qquad [8]$$

where σ^a are the Pauli matrices ($a = x, y, z$). The interaction, in order to give an example, is chosen to be between nearest neighbors. In the limit of a large external field the spin will align along the z-direction. However, because of the quantum nature of the spin degree of freedom, the alignment along the direction of the external field prevents any kind of ordering along the x-direction due to the exchange interaction. By increasing the ratio between J_x/B, at a given critical value the spin will prefer to order along the x-direction, and the system will develop a nonzero magnetization along the x-direction. The transition to the ordered state can be induced at zero temperature solely by the variation of the parameter J_x/B and, as has already been said, is intimately related to the quantum properties of the spin. All the signals for the emergence of a phase transition are contained in the dynamical properties of the interacting spins. If the spins of the Ising model are arranged in a chain, this is one of the few exactly solvable models in quantum statistical mechanics. Here the case of a 3D lattice is considered and the quantum phase transition by means of the mean field approximation is discussed. It consists in replacing the interaction among the neighboring spins by an effective field which acts on each spin, that is, it consists in replacing $\sigma_i^x = \langle\sigma_i^x\rangle + (\sigma_i^x - \langle\sigma_i^x\rangle)$, where the angular brackets $\langle .. \rangle$ mean the quantum statistical average, disregarding the quadratic fluctuations around the average internal field. The value of $\langle\sigma^x\rangle$ is determined self-consistently by imposing that the average value of the magnetization calculated with the approximated form of the Hamiltonian, which reads $H_{\mathrm{MF}} = -(J_x z\langle\sigma^x\rangle/2)\ \sum_i\ \sigma_i^x - B\sum_i \sigma_i^z$, coincides with the mean field. In the previous equation, z is the number of nearest neighbors. This condition leads to the self-consistent equation

$$\langle\sigma^x\rangle = \langle\psi_{\mathrm{MF}}|\sigma^x|\psi_{\mathrm{MF}}\rangle \qquad [9]$$

where the $|\psi_{\mathrm{MF}}\rangle$ is the ground-state wave function of the mean field Hamiltonian (only the case of zero temperature is considered). A numerical solution of eqn [9] sketched in **Figure 2**, shows the behavior that is

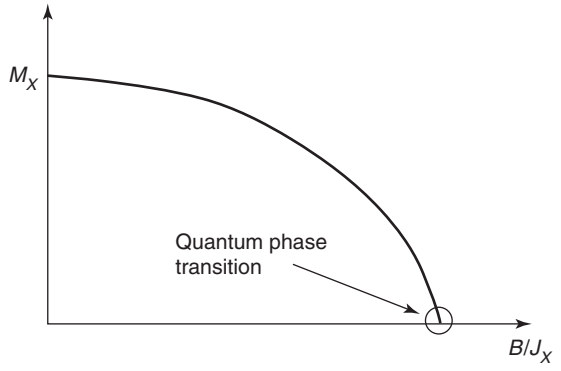

Figure 2 A sketch of the magnetization, at zero temperature, along the *x*-axis is plotted against the ratio B/J_x. The spontaneous magnetization is different from zero only at sufficiently low fields. Close to the critical point the magnetization goes as $|\lambda - \lambda_\chi|^\beta$. In the mean field analysis discussed in the text $\beta = 1/2$.

briefly outlined. As it is beautifully described by Nielsen and Chuang in 2000, thanks to universality, most of the properties of a system close to a phase transition do not depend on the microscopic details of the model. For the example discussed, while the value of the critical field is indeed dependent on the exchange coupling, the behavior of the magnetization is only related to the dimensionality of the system and to the symmetry which is spontaneously broken.

As it should emerge from these remarks, quantum mechanics plays a different role in classical and quantum phase transitions. Let superconductivity as an example be taken in order to elucidate this point. A transition to the superconducting state is induced by the condensation of a pair of electrons (the Cooper pairs). The effective electron–electron attractive interaction (which in conventional superconductors is mediated by the phonons) is responsible for the formation of the pairs. The formation of a bound state of two electrons is a Fermi surface effect, which relies on quantum mechanics. Although quantum mechanical effects are responsible for the instability to the superconducting state, the properties of the transition itself can be described by classical statistical mechanics. In a quantum phase transition, instead, the quantum fluctuations are primarily responsible for the transition itself, which is now related to a modification of the ground-state wave function.

This last paragraph represents a return to the theme in the introduction and a slight deviation from the traditional quantum statistical mechanics. The question of indistinguishability viewed from a different perspective, has stimulated a number of works in the newly born field of quantum information. The (anti-)symmetrized form of the wave function for a system composed by N (fermions) bosons implies that the many-body state cannot be written, even in the absence of any interaction, as a product of wave functions related to each single particle. The many-body wave function is said to be entangled. Entanglement is the property of quantum states to exhibit correlation which cannot be accounted for by classical physics. It arises as a consequence of the principle of superposition in the presence of a Hilbert space with a tensor product structure. Entanglement denotes the nonlocal correlations that exist, even in the absence of direct interaction, between two (spatially separated) parts of a given quantum system. Since the early days of quantum mechanics, understanding the phenomenon of entanglement has been central to the understanding of the foundations of quantum theory. Besides its fundamental importance, a great deal of interest has been brought forth by its role in quantum information. Entanglement is believed to be the main ingredient of computational speed-up in quantum information protocols. In the case being discussed here, entanglement is of statistical origin. With the development of information theory, a great deal of attention has been devoted to the characterization and quantification of entanglement contained in a given quantum state. Although the progress has been impressive, a full characterization is still far from being completed. Parallel to understanding entanglement in systems of two-level systems (qubits) used for quantum information, research has touched the question on how to characterize entanglement in "traditional" condensed matter systems with the aim of finding a bridge between information science and condensed matter. In order to understand more deeply the role of quantum mechanics in the collective properties of quantum many-body systems, probably conventional approaches in quantum statistical mechanics can be conveniently supplemented by the use of a variety of techniques developed in quantum information theory. As a final example, the attention devoted recently to the study of quantum phase transitions from a "quantum information" point of view is mentioned. Both classical and quantum phase transitions can indeed be formulated in the framework of Ginzburg–Landau approach. A crucial point that determines all the properties close to the transition is the fact that the systems behave cooperatively. Classical correlations between particles do not, however, imply that quantum correlations (entanglement) do follow the same behavior. As entanglement is one of the major resources in quantum computation, it is certainly important to be able to understand the properties and the amount of entanglement possessed by a large number of particles close to a quantum phase transition. The link between statistical mechanics and quantum information theory has been carried ahead in refining established methods

for examining many-body interacting systems. An QJ;example is the entanglement preserving Density Matrix Renormalization Group, where a deep understanding of the entanglement properties of the many-body systems has helped in reformulating and generalizing this method. A final mention is made of the attention which is being devoted to the possibility of using quantum spin networks, a traditional arena for quantum statistical mechanics, as quantum channels for transporting and/or manipulating quantum information.

Stochastic Processes in Physics and Chemistry

C Cercignani, Politecnico di Milano, Milan, Italy

Introduction

The adjective "stochastic" goes back to the Greek word $\sigma\tau o\chi o\varsigma$, meaning "target" and is more or less equivalent to "random." Thus, a stochastic process is governed by a probabilistic rather than a deterministic law.

The typical example of a stochastic process is the Brownian motion, called after the English botanist Robert Brown, who noticed (in 1827) that pollen grains suspended in water jiggle about, following a zigzag path. Several scientists of the nineteenth century remarked that an explanation of this movement is provided by the molecular theory of matter. A suspended particle is constantly and randomly bombarded from all sides by the molecules of the liquid. If the particle is very small, the hits it takes do not balance (as is the case for a sizable object) and cause it to jump. These small random jumps are what make up the Brownian motion. The first detailed theory of this phenomenon was developed by Einstein in 1905.

Stochastic processes are involved in physics because there are many phenomena which depend on time in an extremely complicated way, far beyond any possibility of calculation, but which have some average features that obey simple laws. For example, the instantaneous value of the force exerted by the N molecules of a gas on the walls of a container varies rapidly in an unpredictable way, but when averaging over a small time interval, it becomes a simple function of the density and the average kinetic energy of a molecule. Thus, probability considerations in physics are due to the ignorance of the precise values of microscopic variables and the remarkable fact that it is still possible to detect regularities in the behavior of a few quantities that describe the macroscopic behavior in a satisfactory way.

The microscopic state (or microstate, in short) of a gas is determined by $6N$ variables, the coordinates, and the components of momentum of the N molecules. If one assigns the values of these variables at time $t = 0$, then their values at any other time instant are determined by the equations of motion, provided the forces are known as functions of position and velocity. In other words, the initial microstate x determines the microstate $y(x, t)$ at any time t.

If one considers the set of initial microstates with a probability distribution, one has a stochastic variable X, which determines the subsequent microstates, described by another stochastic variable Y; in other words, $Y = Y(X, t)$ describes a stochastic process. To find $Y(X, t)$ is as hard as finding the original motion.

From a purely Newtonian standpoint, one should not talk of a stochastic process, but rather of a stochastic model of a process. As a matter of fact, the

complex trajectory of a tossed coin, or a die, are all phenomena ruled by deterministic laws, and thus, not random at all. The stochastic description is useful due to the fact that one can obtain simplified evolution equations by averaging over the irrelevant variables. In the case of a dilute gas, this leads to the famous Boltzmann equation, which may even become exact, in a probabilistic sense, when the number of particles N tends to infinity.

Quantum mechanics brings in an additional unpredictability due to the basic theory and not the complicated nature of the system. The classical averaging over microscopic states in a region of phase space is equivalent, in quantum mechanics, to the averaging over all unit vectors in a linear subspace of the Hilbert space of the system. This is the conventional interpretation of quantum mechanics; a description of quantum processes as genuine stochastic processes has been provided by E Nelson, which is discussed at the end of this article.

Stochastic Variables

First the concept of the stochastic (or random) variable: it is a variable X which can have a value in a certain set Ω, usually called "range," "set of states," "sample space," or "phase space," with a certain probability distribution. When a particular fixed value of the same variable is considered, the small letter x is used.

The set may be discrete; the simplest example is heads or tails, where the probability distribution is 1/2 for each outcome (if one assumes an unloaded coin). More commonly, the set is continuous: for example, the kinetic energy of a particle undergoing a Brownian motion may take any real non-negative value x. The set of states may be multidimensional, in which case, X is conveniently written as a vector X. For example, X might be the velocity of a particle undergoing a Brownian motion; in this case, the set of states is a three-dimensional space and X may take any vector value x.

When the variable is continuous, the probability distribution $P(X) \geqslant 0$ is a non-negative function normalized to unity in the sense that

$$\int_{\Omega} P(x)\, \mathrm{d}x = 1 \qquad [1]$$

where the integral extends to the whole range. When not stated otherwise, the stochastic variables are assumed to be continuous. More generally, the probability can be a measure μ of the subsets of the set Ω ($\mu(\Omega) = 1$); the measure can be defined for a family F of "elementary sets" and then extended to other subsets of Ω, via the basic properties of μ (positivity, additivity for disjoint subsets).

The average or expectation value of any function $f(X)$ of the stochastic variable X is given by

$$\langle f(X) \rangle = \int_{\Omega} f(x) P(x)\, \mathrm{d}x \qquad [2]$$

In particular, $\mu_n = \langle X^n \rangle$ is called the nth moment of X, and μ_1 the average or mean of X. Also,

$$\begin{aligned} \sigma^2 &= \langle (X - \langle X \rangle)^2 \rangle = \mu_2 - \mu_1^2 \\ &= \langle X^2 \rangle - \langle X \rangle^2 \end{aligned} \qquad [3]$$

is called the variance or dispersion and is the square of the standard deviation σ.

If X is a stochastic variable having r components $X_1, X_2, ..., X_r$, its probability density $P(x) = P_r(x_1, x_2, ..., x_r)$ is also called the joint probability distribution of the r variables $X_1, X_2, ..., X_r$. If one takes a subset of $s < r$ variables $X_1, X_2, ..., X_s$, their probability distribution, regardless of the values of the remaining variables $X_{s+1}, ..., X_r$, is

$$\begin{aligned} P_s(x_1, x_2, ..., x_s) = \int_{\Omega_{r-s}} & P_r(x_1, x_2, \ldots, x_s, x_{s+1}, \ldots, x_r) \\ & \times \mathrm{d}x_{s+1}, \ldots, \mathrm{d}x_r \end{aligned} \qquad [4]$$

and is called the marginal distribution of the given subset of variables.

One can also attribute fixed values to $X_{s+1}, ..., X_r$ and consider the joint probability distribution of the s variables $X_1, X_2, ..., X_s$. This is called the conditional probability of distribution of $X_1, X_2, ..., X_s$ when $X_{s+1}, ..., X_r$ have the prescribed values $x_{s+1}, ..., x_r$. It is usually denoted by $P_{s|r-s}(x_1, x_2, ..., x_s | x_{s+1}, ..., x_r)$. This probability is related to the previous one by the Bayes rule

$$\begin{aligned} & P_{s|r-s}(x_1, x_2, ..., x_s | x_{s+1}, ..., x_r) \\ & \quad = \frac{P_r(x_1, x_2, ..., x_r)}{P_{r-s}(x_{s+1}, x_2, ..., x_r)} \end{aligned} \qquad [5]$$

Stochastic Processes

Once a stochastic variable has been defined, an infinite number of other variables can be derived from it, that is, all the quantities Y which are functions of X, $Y = f(X)$. If a family of functions indexed by a variable t is taken $Y_t = f(X, t)$, a stochastic process is obtained. Mathematically, the functions are assumed to be measurable, that is, belong to a suitable measure space.

In most applications t is the time variable, as suggested by the notation and the name process, but this is not a part of the definition. t might belong to a set T. For example in the so-called Bernoulli scheme

(or the heads and tails process), Ω is the set $[+1, -1]$, where $+1$ represents heads and -1 tails. In this case, T is the set (N) of natural numbers; and the process is the set of sequences $y = (a^1, a^2, \ldots)$ with $a^i = +1$ or -1, each with probability 1/2. If T is manifold (such as space or space–time), a stochastic process is usually called a stochastic field.

For a stochastic process, one can define joint probability densities referring to different values of t (or different instants of time), $P_n(y_1, t_1; y_2, t_2, \ldots, y_n, t_n)$. This hierarchy of functions obeys four consistency conditions:

1. $P_n \geqslant 0$,
2. P_n does not change when interchanging two pairs $(y_i, t_i$ and $y_k, t_k)$,
3. $\int P_n(y_1, t_1; \ldots, y_{n-1}, t_{n-1}, y_n, t_n)\, dy_n = P_{n-1}(y_1, t_1; \ldots, y_{n-1}, t_{n-1})$, and
4. $\int P_1(y_1, t_1)\, dy_1 = 1$.

Kolmogorov has shown that any set of functions satisfying these four conditions determines a stochastic process. One can similarly discuss the conditional probabilities.

A stochastic process is called stationary if all the joint probability densities depend on the time differences alone. A necessary, but not sufficient, condition is that $P_1(y_1)$ is independent of time.

Markov Processes

A Markov process is a stochastic process with the property that the state at a certain time t_0 determines the states for $t > t_0$ and not the states $t < t_0$. In other words,

$$P_{1|n-1}(y_n, t_n | y_1, t_1, \ldots; y_{n-1} t_{n-1}) = P_{1|1}(y_n, t_n | y_{n-1}, t_{n-1}) \quad \text{for } t_1 < t_2 \cdots < t_n \quad [6]$$

A Markov process is fully determined by the two functions $P_1(y_1, t_1)$ and $P_{1|1}(y_2, t_2 | y_1, t_1)$. Thus, for example,

$$P_3(y_1, t_1; y_2, t_2; y_3, t_3) = P_1(y_1, t_1) P_{1|1}(y_2, t_2 | y_1, t_1) \times P_{1|1}(y_3, t_3 | y_2, t_2) \quad \text{for } t_1 < t_2 < t \quad [7]$$

Integrating this identity with respect to y_2, one obtains

$$P_2(y_1, t_1; y_3, t_3) = P_1(y_1, t_1) \int_\Omega P_{1|1}(y_2, t_2 | y_1, t_1) \times P_{1|1}(y_3, t_3 | y_2, t_2)\, dy_2 \quad (t_1 < t_2 < t_3) \quad [8]$$

or

$$P_{1|1}(y_3, t_3 | y_1, t_1) = \int_\Omega P_{1|1}(y_2, t_2 | y_1, t_1) P_{1|1} \times (y_3, t_3 | y_2, t_2)\, dy_2 \quad (t_1 < t_2 < t_3) \quad [9]$$

This is called the Chapman–Kolmogorov equation. This equation and the obvious equation

$$P_1(y_2, t_2) = \int_\Omega P_{1|1}(y_2, t_2 | y_1, t_1) P_1(y_1, t_1)\, dy_1 \quad [10]$$

are both necessary and sufficient for two non-negative functions $P_1(y_1, t_1)$ and $P_{1|1}(y_2, t_2 | y_1, t_1)$ to uniquely define a Markov process.

There are two examples of the Markov process which are worth discussing in some detail. The first is the so-called Wiener process defined by

$$P_{1|1}(y_2, t_2 | y_1, t_1) = \frac{1}{\sqrt{2\pi(t_2 - t_1)}} \exp\left[-\frac{(y_2 - y_1)^2}{2(t_2 - t_1)}\right] \quad (t_1 < t_2) \quad [11]$$

which can be checked to satisfy the Chapman–Kolmogorov equation with $P_1(y_1, 0) = \delta(y_1)$. It describes the stochastic behavior of the position of a Brownian particle (for simplicity, the diffusion coefficient v is taken to be unity; to reinstate it, one must replace time t by vt and, as a consequence, multiply $P_{1|1}$ by v). The probability density for $t > 0$, according to eqn [10], is

$$P_1(y, t) = \frac{1}{\sqrt{2\pi t}} \exp\left[-\frac{y^2}{2t}\right] \quad [12]$$

It is easy to check that

$$\lim_{\tau \to 0+} \frac{\langle [Y(t+\tau) - Y(t)]^2 \rangle}{\tau} = \lim_{\tau \to 0+} \frac{1}{\sqrt{2\pi\tau^3}} \int_{-\infty}^{\infty} y^2 \exp\left[-\frac{y^2}{2\tau}\right] dy = 1 \quad [13]$$

In the second example, $Y(t)$ takes on non-negative integer values n and $t \geqslant 0$. A Markov process is defined by

$$P_{1|1}(n_2, t_2 | n_1, t_1) = \frac{(t_2 - t_1)^{n_2 - n_1}}{(n_2 - n_1)!} e^{-(t_2 - t_1)} \quad (t_1 \leqslant t_2)$$
$$P_1(n, 0) = \delta_{n,0} \quad [14]$$

This is called a Poisson process.

When a Markov process is stationary, then $P_{1|1}$ depends on just the time difference $\tau = t_2 - t_1$ and the Chapman–Kolmogorov equation simply states that the integral operator T_τ with kernel $P_{1|1}(y_2, y_1; \tau)$ has the semigroup property $T_{\tau+\tau'} = T_\tau T_{\tau'}$.

The best known example of a stationary Markov process, after the Wiener process, is the Ornstein–Uhlenbeck process, for which

$$P_{1|1}(y_2|y_1;\tau) = \frac{1}{\sqrt{2\pi(1-e^{-2\tau})}} \exp\left[-\frac{(y_2 - y_1 e^{-\tau})^2}{2(1-e^{-2\tau})}\right]$$
$$P_1(y) = \frac{1}{\sqrt{2\pi}} e^{-y^2/2} \quad [15]$$

In the case of a stationary Markov process, eqn [7] becomes

$$P_3(y_1,t_1;y_2,t_2;y_3,t_3) = P_1(y_1,t_1) \times P_{1|1}(y_2|y_1,t_2-t_1)P_{1|1}(y_3|y_2,t_3-t_2) \quad [16]$$

and, of course, it can be trivially extended from P_3 to P_n. Thus, the probability that a particle starting from $x=0$ will be found between α_1 and β_1 at time t_1, between α_2 and β_2 at time t_2, etc., and between α_n and β_n at time t_n, is given by the formula

$$\int_{\alpha_1}^{\beta_1} \dots \int_{\alpha_n}^{\beta_n} P_1(y_1,t_1)P_{1|1}(y_2|y_1;t_2-t_1)\dots P_{1|1} \times (y_n|y_{n-1};t_n-t_{n-1}) \quad [17]$$

If the Wiener process for which $P_1(y_1,0)=\delta(y_1)$ is considered, eqn [10] with $t_1=0$ becomes

$$P_1(y_2,t_2) = P_{1|1}(y_2|0;t_2) \quad [18]$$

and eqn [17] becomes

$$\int_{\alpha_1}^{\beta_1} \dots \int_{\alpha_n}^{\beta_n} P_{1|1}(y_1|0;t_1)P_{1|1}(y_2|y_1;t_2-t_1) \dots P_{1|1}(y_n|y_{n-1};t_n-t_{n-1}) \quad [19]$$

This result was first derived by Einstein and Smoluchowski for a free Brownian particle.

Time Evolution Equations for the Probability Density

A stationary Markov process can be characterized by the transition probability per unit time $W(y_3|y_1)$ of going from state y_1 to y_3. Then, the Chapman–Kolmogorov equation may be replaced by the so-called master equation

$$\frac{\partial}{\partial\tau} P_{1|1}(y_3|y_1;\tau) = \int_\Omega \{W(y_3|y_2)P_{1|1}(y_2|y_1;\tau) - W(y_2|y_3)P_{1|1}(y_3|y_1;\tau)\}dy_2 \quad [20]$$

which is sometimes written as

$$\frac{\partial}{\partial t} P(x,t) = \int_\Omega \{W(x|x')P(x',t) - W(x'|x)P(x,t)\}dx' \quad [21]$$

when it is not necessary to mention the argument y_1 of the previous equation.

If the range of Y is a discrete set of states with labels n, the master equation for the probability p_n of a state reads as follows:

$$\frac{\partial}{\partial t} p_n(t) = \sum_{n'} \{W_{nn'}p_{n'}(t) - W_{n'n}p_n(t)\} \quad [22]$$

This equation can be applied to a chemical reaction which changes the number of molecules n of a given species.

One can easily show that if the coefficients $W_{nn'}$ are non-negative, then $p_n(t)$is non-negative for $t>0$, if it is for $t=0$. In most situations of interest, there is an equilibrium solution p_n^e such that

$$\sum_{n'} \{W_{nn'}p_{n'}^e - W_{n'n}p_n^e\} = 0 \quad [23]$$

If this is the case, introduce a function $H(t)$ by

$$H(t) = \sum_n p_n^e f\left(\frac{p_n}{p_n^e}\right) = \sum_n p_n^e f(x_n) \quad [24]$$

where $x_n = p_n/p_n^e$ for convenience, and $f(x)$ is a non-negative differentiable convex function:

$$f \geqslant 0, \quad (x-y)f'(x) \geqslant f(y) - f(x) \quad (0 \leqslant x < \infty) \quad [25]$$

where the equality sign applies if and only if $y=x$. If $f(x)$ is twice differentiable, this implies (and is implied by) $f''(x) \geqslant 0$. Then

$$\frac{dH(t)}{dt} = \sum_{n,n'} W_{nn'}p_{n'}^e\{x_{n'}f'(x_n) - x_{n'}f'(x_{n'})\} \quad [26]$$

It is also remarked that for any set of numbers c_n, eqn [23] implies

$$\sum_{n'} W_{nn'}p_{n'}^e(c_n - c_{n'}) = 0 \quad [27]$$

Thus, if one chooses $c_n = f(x_n) - x_n f'(x_n)$ and adds the result to eqn [26], one obtains

$$\frac{dH(t)}{dt} = \sum_{n,n'} W_{nn'}p_{n'}^e\{(x_{n'} - x_n) + f(x_n) - f(x_{n'})\} \leqslant 0 \quad [28]$$

where [25] has been used. Thus, H decreases in time unless $x_n = 1$ or $p_n = p_n^e$. Since H cannot become negative, it must tend to zero when $t \to \infty$; if the number of states is finite, this immediately implies that p_n also tends to a limit and this limit is p_n^e. To show that this is true under more general conditions requires a more detailed argument.

Any convex function such as, $f(x) = x^{\alpha}(\alpha > 1)$ could do, but one usually chooses

$$f(x) = x \log x, \quad H = \sum_n p_n \log \frac{p_n}{p_n^e} \qquad [29]$$

for at least two reasons. One is that this choice also works for the nonlinear Boltzmann equation and the other is that this choice of H produces a function which has all the properties of entropy (except for the sign).

Similar arguments work in the continuous case as well, which is taken up again. Sometimes, it is convenient to write $W(x|x') = W(x'; r)$, where $r = x - x'$. If one assumes that $W(x; r)$ is a peaked function of r about $r = 0$ and P varies slowly with x, then a Taylor expansion to the second order in r leads to the so-called Fokker–Planck equation (also called the "Smoluchowski equation," "second Kolmogorov equation," or "generalized diffusion equation")

$$\frac{\partial}{\partial t} P(x,t) = \frac{\partial}{\partial x}[a_1(x)P] + \frac{1}{2}\frac{\partial^2}{\partial x^2}[a_2(x)P] \qquad [30]$$

where

$$a_v(x) = \int_{\Omega} r^v W(x; r)\, \mathrm{d}r \qquad [31]$$

If $a_1 = 0$ and a_2 is independent of x, the Fokker–Planck equation becomes the standard diffusion equation describing the Brownian motion. In more than one dimension, the coefficients a_1 and a_2 become a vector and a tensor, respectively.

The Wiener Measure and the Feynman–Kaç Integral

Wiener introduced a probability measure for the trajectories of the Brownian motion. For the sample space Ω, the set of all real-valued functions $x(t)$ $(0 < t < \infty)$, normalized by the condition $x(0) = 0$, is first taken. As a family of "elementary sets," one takes sets of functions defined by conditions of the form

$$\{\alpha_1 < x(t_1) < \beta_1, \alpha_2 < x(t_2) < \beta_2, \ldots, \alpha_n < x(t_n) < \beta_n\}$$
$$0 < t_1 < t_2 \cdots < t_n \qquad [32]$$

The measure (Wiener measure) assigned to the set eqn [32] is given by the Einstein–Smoluchowski formula (eqn [19]) with $P_{1|1}(x|y;\ t_2 - t_1)$ as given by eqn [11]. It is now easily verified that this particular assignment of measures to the elementary sets satisfies the usual consistency conditions. In fact, it is seen that consistency conditions are implied by the Chapman–Kolmogorov equation [10]. Once consistency is established, one can construct (by a general theorem of Kolmogorov) a completely additive measure in the space of all real-valued functions $x(t)$ $(x(0) = 0)$. So constructed, this measure is nearly useless because many sets of direct relevance and interest are nonmeasurable. For instance, the set C of continuous functions turns out to be nonmeasurable. It has been shown by Doob that if one restricts to continuous functions and maintains the measures [19] for the sets in [32] (but now only continuous functions are allowed in these sets), then a completely additive measure μ^w with $\mu^w(C) = 1$ can be constructed. The set of differentiable functions turns out to have a vanishing measure; this means that the instantaneous velocity of the Brownian motion as described by the Wiener process is meaningless.

Having a completely additive measure in C, one can define an integral (Wiener integral) which has all the basic properties of the Lebesgue integral. For any continuous function $V(x)$ defined in $(-\infty, \infty)$ with $V(x) > 0$, Kaç considered the Wiener integral

$$I = \int_{a<x(t)<b} \exp\left[-\int_0^t V(x(\tau))\mathrm{d}\tau\right] \mathrm{d}\mu_t^{\mathrm{W}} \qquad [33]$$

which is easily shown to exist and to be equal to the ordinary integral

$$I = \int_a^b \psi(x,t)\, \mathrm{d}x \qquad [34]$$

where $\psi(x,t)$ is given by

$$\psi(x,t) = \sum_{k=0}^{\infty} (-1)^k \psi_k(x,t) \qquad [35]$$

where

$$\psi_0(x,t) = (2\pi t)^{-1/2} \exp\left(-\frac{x^2}{2t}\right)$$
$$\psi_{n+1}(x,t) = \int_0^t \int_{-\infty}^{\infty} [2\pi(t-\tau)]^{-1/2} \times \exp\left[-\frac{(x-y)^2}{2(t-\tau)}\right] V(y)\psi_n(y,\tau)\, \mathrm{d}y\, \mathrm{d}\tau \qquad [36]$$

As a consequence, $\psi(x,t)$ satisfies

$$\psi(x,t) = \psi_0(x,t) - \int_0^t \int_{-\infty}^{\infty} [2\pi(t-\tau)]^{-1/2} \times \exp\left[-\frac{(x-y)^2}{2(t-\tau)}\right] V(y)\psi(y,\tau)\, \mathrm{d}y\, \mathrm{d}\tau \qquad [37]$$

and hence, the partial differential equation

$$\frac{\partial \psi}{\partial t} = \frac{1}{2}\frac{\partial^2 \psi}{\partial x^2} - V(x)\psi \qquad [38]$$

that is, there is a relation between the solutions of this equation and the functional integral [33].

In his research, Kaç was inspired by the famous Feynman path integral. If the connection is considered, the integral I can be seen as the limit

$$\lim_{n\to\infty}(2\pi t n^{-1})^{-n/2}\int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty}\exp\left[-tn^{-1}\left\{\sum_{k=1}^{n}V(x_k)+\frac{1}{2}\sum_{k=1}^{n}\left(\frac{x_k-x_{k-1}}{tn^{-1}}\right)^2\right\}\right] \quad [39]$$

which makes it obvious that the exponent is simply a discretization of

$$-\int_0^t\left\{\frac{1}{2}\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2+V(x(\tau))\right\}\mathrm{d}\tau \quad [40]$$

In this form, the symbolism is physically appealing, since the expression in braces is the Hamiltonian of a particle under the action of a potential $V(x)$. Following Feynman's notation, the functional integral [33] may be written as

$$\int\exp\left[-\int_0^t\left\{\frac{1}{2}\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2+V(x(\tau))\right\}\mathrm{d}\tau\right]\mathrm{d}(\text{path}) \quad [41]$$

Actually Feynman, in his approach to nonrelativistic quantum mechanics, was led to considering

$$\int\exp\left[\mathrm{i}\hbar^{-1}\int_0^t\left\{\frac{1}{2}\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2-V(x(\tau))\right\}\mathrm{d}\tau\right]\mathrm{d}(\text{path}) \quad [42]$$

where $\hbar = h/2\pi$ (h = Planck's constant). The functional

$$A=\int_0^t\left\{\frac{1}{2}\left(\frac{\mathrm{d}x}{\mathrm{d}t}\right)^2-V(x(\tau))\right\}\mathrm{d}\tau \quad [43]$$

is the classical action along the path $x(t)$. Because of the factor i ($=\sqrt{-1}$) in the exponent, Feynman's theory is not easily made rigorous. One way is to replace $\hbar^{-1}$ by $\hbar^{-1}+\mathrm{i}\varepsilon$; this gives an integral which can be treated as Kaç's integral, and then one can pass to the limit when $\varepsilon\to 0+$. Of course, the partial differential equation [38] then becomes the Schrödinger equation:

$$\mathrm{i}\hbar\frac{\partial\psi}{\partial t}=-\frac{\hbar^2}{2}\frac{\partial^2\psi}{\partial x^2}+V(x)\psi \quad [44]$$

When $\hbar$ tends to zero, the trajectories become very irregular and their contributions to the Feynman integral tend to cancel by interference, except for the contribution of the classical trajectory.

Stochastic Differential Equations and Stochastic Mechanics

In many cases, the coefficients a_1 and a_2 appearing in eqn [30] permit one to reconstruct the corresponding diffusion process (i.e., to find $P(y, t)$). Another way of constructing a diffusion process from these coefficients is based on the theory of the stochastic differential equations. It can be said that the stochastic process X is a solution of the stochastic differential equation

$$\mathrm{d}X=\sigma(t,X)\,\mathrm{d}W_t+b(t,X)\,\mathrm{d}t \quad [45]$$

with initial condition $X = X_0$, if

$$X=X_0+\int_0^t\sigma(t,X)\,\mathrm{d}W_t+\int_0^t b(t,X)\,\mathrm{d}t \quad [46]$$

where $b(t, x)$ is uniformly Lipschitzian in t, $W_t = W(t)$ is the Wiener process, and the first integral makes sense as a stochastic integral; in the simplest case, σ is a constant and the integral equals $\sigma(W(t) - W(0))$. The notation [45] is a purely symbolic notation in place of the rigorous one in [46] because, generally speaking, the trajectories of the processes $W(t)$ and $X(t)$ are continuous but almost nowhere differentiable, and hence, $\mathrm{d}X/\mathrm{d}t$ does not exist with probability 1. There are very general theorems which state the existence of solutions to eqn [46]. The relation between the two methods occurs through an important formula due to Itô. Frequently, the stochastic equation for a diffusion process is called the Langevin equation in physical literature.

It is clear that

$$\begin{aligned}\lim_{\tau\to 0+}\frac{\langle[X(t+\tau)-X(t)]^2\rangle}{\tau}&=[\sigma(t)]^2\\ \lim_{\tau\to 0+}\frac{\langle[W(t+\tau)-W(t)]^2\rangle}{\tau}&=[\sigma(t)]^2\end{aligned} \quad [47]$$

Thus, the coefficient $\sigma(t)$ is related to $a_2(t)$, used before, by $a_2(t) = [\sigma(t)]^2$.

Nelson has proposed a stochastic kinematics for Markov processes. He defines a forward velocity DX (the limit of the expected value of $(X(t+\tau)-X(t))/\tau$ conditioned by the past history of the process when $\tau\to 0+$) and a backward velocity D_*X (the analogous limit of the expected value of $(X(t)-X(t-\tau))/\tau$ conditioned by the future history of the process). They both coincide with $\dot{x}$ when the particular history $x(t)$ is differentiable. $v=(DX+D_*X)/2$ is called the mean velocity and $u=(Dx-D_*X)/2$ the osmotic velocity. For the acceleration, one can consider DDX, D_*D_*X, D_*DX, DD_*X, and even more choices are available for the mean acceleration a ($(DDX+D_*D_*X)/2$, $(DD_*X+D_*DX)/2$, $(DDX+D_*\,D_*X+$

$DD_*X + D_*DX)/4$). By giving examples, Nelson shows that the only choice which makes sense is $a = (DD_*X + D_*DX)/2$.

Assuming a process with forward velocity $b = b(x,t)$, backward velocity $b_* = b_*(x,t)$, and constant diffusion coefficient $\nu = \sigma^2/2$, it is easy to show that the expected value for the derivative of any function $f(X,t)$ is, by [47],

$$\langle Df \rangle = \lim_{\tau \to 0+} \left[\frac{\partial f}{\partial t} + \frac{\langle [X(t+\tau) - X(t)] \rangle}{\tau} \frac{\partial f}{\partial x} + \frac{\langle [X(t+\tau) - X(t)]^2 \rangle}{2\tau} \frac{\partial^2 f}{\partial x^2} \right] = \frac{\partial f}{\partial t} + b \frac{\partial f}{\partial x} + \nu \frac{\partial^2 f}{\partial x^2} \quad [48]$$

and, similarly

$$\langle D_* f \rangle = \frac{\partial f}{\partial t} + b_* \frac{\partial f}{\partial x} - \nu \frac{\partial^2 f}{\partial x^2} \quad [49]$$

In a similar way, one can obtain the Fokker–Planck equations satisfied by the backward and forward processes

$$\frac{\partial P}{\partial t} = -\frac{\partial (bP)}{\partial x} + \nu \frac{\partial^2 P}{\partial x^2} \quad [50]$$

$$\frac{\partial P}{\partial t} = -\frac{\partial (b_* P)}{\partial x} - \nu_* \frac{\partial^2 P}{\partial x^2} \quad [51]$$

In principle, the probability density in the second equation should be $P_* \neq P$, but Nelson says that at the basic level, there should be time symmetry and, more or less explicitly, assumes $P = P_*$, $\nu = \nu_*$. This implies

$$u = \frac{b - b_*}{2} = \nu \frac{1}{P} \frac{\partial P}{\partial x} \quad [52]$$

Since $v = (b + b_*)/2$, one also has

$$\frac{\partial P}{\partial t} + \frac{\partial (Pv)}{\partial x} = 0 \quad [53]$$

The mean acceleration a can be easily shown to be (by [48] and [49])

$$a = \frac{\partial v}{\partial t} + v \frac{\partial v}{\partial x} - u \frac{\partial u}{\partial x} - \nu \frac{\partial^2 u}{\partial x^2} \quad [54]$$

If $a = F/m$, where F is the force, one obtains the dynamics of the stochastic motion, described by [53] and [54], provided u is given by eqn [52]. It is an extremely remarkable fact that, by a change of unknowns ($\psi = \sqrt{P} \exp(\mathrm{i} \int_0^x v(x')\, \mathrm{d}x'/(2\nu))$), this system becomes the Schrödinger equation (eqn [44]), provided $\nu = \hbar/2m$. In more than one dimension, this holds if and only if the force is a gradient plus (possibly) a Lorentz force.

Equations [53] and [54] (with $a = F/m$) constitute the stochastic version of quantum mechanics proposed by Nelson.

Strengthening Mechanisms in Metals *See* Mechanical Properties: Strengthening Mechanisms in Metals.

Strongly Correlated Electron Systems

H v Löhneysen, Universität Karlsruhe, Karlsruhe, Germany

Introduction

Atomic magnetic moments arise from the presence of partly filled orbitals classified by their main quantum number n and angular momentum $l \leqslant n-1$ in the atomic configuration of the elements. In addition, the electron spin also contributes to the magnetic moment. In the solid state, the electrons occupying these orbitals are subject to the electrostatic potential not only of their "own" ion core but also of the potential generated by the surrounding ions and electrons. This effect depends on the spatial extent of the

wave function of the partly filled shells. Electrons in strongly localized orbitals behave like localized moments retaining their atomic quantum numbers, with the ground-state multiplet given by Hund's rules. Hence the magnetic susceptibility χ increases with decreasing temperature T, often in a Curie–Weiss behavior $\chi \sim (T-\theta)^{-1}$, where θ is a measure of the interaction between moments. The ground-state multiplet is split by the weak crystalline electric field of the neighboring ions. On the other hand, electrons in spatially extended orbitals such as s or p electrons, in general, delocalize, resulting in a weak Pauli susceptibility independent of T. An interaction between magnetic moments leads to various types of magnetic order.

In nature, magnetic properties of solids often fall between these two extremes – localized versus delocalized moments – where the electron correlations are particularly strong and lead to a wealth of novel effects. One can order the metallic elements in a new fashion, not with increasing atomic number as in the periodic table of the elements, but with increasing spatial extent of the partly filled orbitals. The approximate sequence, $4f-5f-3d-4d-5d$, maps the increasing degree of delocalization. In intermetallic $4f$ systems, due to the strong localization of the $4f$ electrons, charges of the surrounding ligands disturb the spherically symmetric atomic potential only weakly, providing a splitting of the Hund's rule ground-state multiplet, commonly referred to as crystalline electric field (CEF) splitting. The ground state Hund's rule multiplet is determined by (1) maximizing the total spin S, (2) maximizing the total angular momentum L compatible with (1), and (3) taking account of the spin–orbit (SO) interaction with $J = |L \mp S|$ where $-(+)$ applies when the shell is less (more) than half-filled. In $3d$ systems, on the other hand, the SO coupling, depending strongly on the atomic number ($\sim Z^4$), is rather weak. Here the d-electron wave functions are rather extended, so that the ligands strongly affect the wave functions and the orbital moment ceases to be a good quantum number ("quenching" of orbital momentum). This often leads to a "spin only" magnetic moment in insulating $3d$ systems. This article focuses on intermetallic compounds and alloys where interactions between electrons lead to a wealth of new phenomena. Of particular interest are systems where the electrons in partly filled orbitals behave "between" being localized and delocalized.

Fermi Liquids

In a metal, the conduction electrons interact with each other due to their Coulomb repulsion. At the same time, there is a strong correlation by virtue of the Pauli principle, which states that two electrons (or, more generally, two indistinguishable fermions, i.e., particles with half-integer spin) cannot be in the same quantum state. The physics of a noninteracting electron gas is well known. For $kT \ll E_F$, the specific heat of a noninteracting electron system is given by $C = \gamma_0 T$ with $\gamma_0 = (\pi^2 k^2/3) N(E_F)$, where $N(E_F)$ is the density of levels at the Fermi energy E_F, and k the Boltzmann constant. For free electrons, $N(E_F) = m_0 k_F/(\hbar^2 \pi^2) = (3/2) N_A/E_F$ where m_0 is the free-electron mass, k_F the Fermi wave number, and N_A the Avogadro number. The Pauli spin susceptibility is independent of T, $\chi_0 = \mu_0 \mu_B^2 N(E_F)$ where $\mu_0 = 4\pi \times 10^{-7}\,\mathrm{V\,s\,A^{-1}\,m^{-1}}$ and μ_B is the Bohr magneton. The contribution to the electrical resistivity due to electron–electron (e–e) scattering is given by $\rho_{e-e} = c(kT/E_F)^2$ where c is a microscopic scattering cross section. Because of the large E_F in simple metals, ρ_{e-e} is difficult to observe.

Assuming a one-to-one correspondence between the excitations of an interacting electron system, termed "quasiparticles," and of the noninteracting electron gas, Landau postulated that the low-T properties for the interacting system obey the same laws as for the Fermi gas, with a renormalized effective mass m^* (with respect to the free-electron mass m_0) and a few additional parameters taking account of the residual interactions among the quasiparticles. This special case of an interacting electron system which can be obtained from the noninteracting Fermi gas by adiabatically turning on the interaction is called a (Landau) Fermi liquid. In such a Fermi liquid (FL), the specific heat is given by $C = \gamma T = (m^*/m_0)\ \gamma_0 T$, the spin susceptibility by $\chi = \chi_0 (m^*/m_0)(1 + F_0^a)$ where F_0^a is an additional Landau parameter, and the resistivity by ρ_{e-e}, which is again proportional to $(kT/E_F)^2$ where E_F may be modified due to the interactions.

Heavy-Fermion Systems

Heavy-fermion systems (HFS) are perhaps the most remarkable manifestation of strongly correlated electron systems. These are compounds with a (often) regular sublattice of $4f$ or $5f$ atoms, notably Ce, Yb, or U. They are close to a magnetic instability giving way to long-range magnetic order arising from the interactions between the $4f$ or $5f$ magnetic moments via the conduction electrons. It is instructive to consider first the case of an isolated magnetic impurity in a nonmagnetic metallic host. The hybridization between conduction electrons and f electrons, together with a large on-site Coulomb repulsion U between f electrons, may lead to a complete screening of the magnetic moment, resulting in a singlet ground state. (Historically, this interaction was first considered

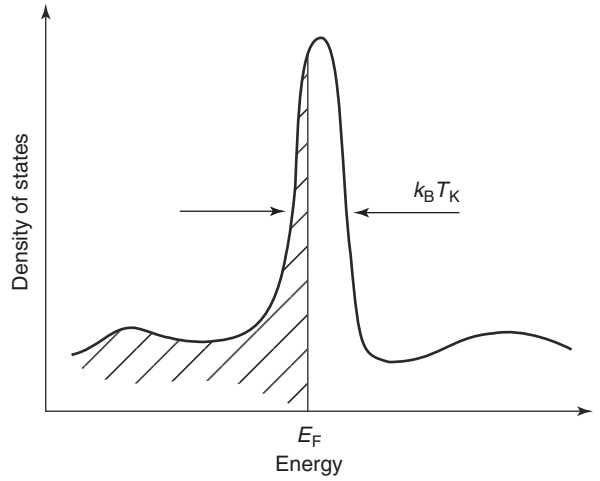

Figure 1 Local Kondo resonance at the Fermi level in the electronic density of states of a metal with a magnetic impurity. The width of the resonance is given by the Kondo temperature T_K and its height by $1/T_K$. In a simple picture, the density of states of a heavy-fermion compound may be viewed as a lattice-coherent superposition of local Kondo resonances.

between conduction electrons and localized d electrons, hence often termed as "s–d exchange" in older literature.) The interaction between conduction electrons and f electrons can be described in terms of the Kondo Hamiltonian $\mathscr{H} = -JS \cdot s$, where S is the impurity spin and s the conduction-electron spin, with an effective antiferromagnetic (AF) exchange interaction J. This screening is dynamic and can be visualized as being due to virtual transitions between the localized f level and the conduction-electron states at E_F, leading to a resonance at E_F, the so-called Kondo or Abrikosov–Suhl resonance (**Figure 1**). The "binding energy" of this singlet state is of the order kT_K. At sufficiently low T well below the characteristic Kondo temperature T_K, a local FL is formed around the magnetic impurity, exhibiting a huge specific heat $C \sim kT/T_K$. By comparison with the free-electron expression for γ_0, T_K plays the role of an effective Fermi temperature, $T_F = E_F/k$.

In a grossly simplified picture, HFS can be considered as lattice-coherent superpositions of these local FLs. Hence at low T, most HFS can be described within the framework of the FL theory with, however, a very large effective mass m^* derived from the huge linear specific heat coefficient $\gamma = C/T$ – hence the term heavy fermions – and a correspondingly large Pauli susceptibility χ, both being only weakly dependent on T. m^* exceeds m_0 by a factor of several hundreds in some cases. The contribution $\rho_{e-e} \sim (T/T_K)^2$ to the resistivity is readily observable in HFS, because the characteristic temperature scale $T_K \sim 10$ K is much smaller than T_F in typical metals.

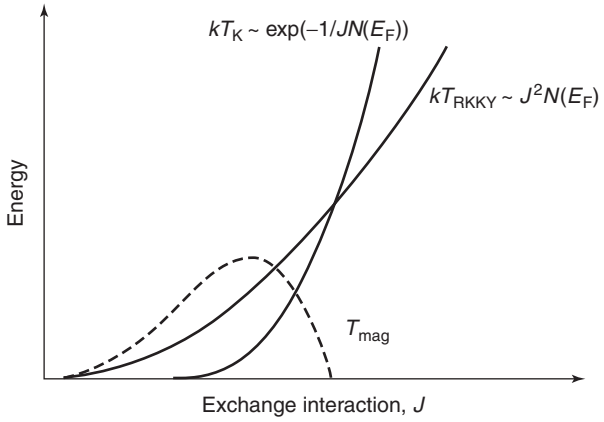

Figure 2 Competition between the on-site Kondo energy kT_K favoring singlet formation and the amplitude of the oscillating intersite RKKY interaction kT_{RKKY} as a function of conduction electron–4f electron exchange J, leading to magnetic order T_{mag} at intermediate values of J (dashed line).

The competition between the on-site Kondo interaction just discussed (quenching the 4f or 5f localized magnetic moments) and the spatially oscillating intersite Ruderman–Kittel–Kasuya–Yosida (RKKY) interaction between these moments mediated by the conduction electrons via the exchange interaction J allows for nonmagnetic or magnetically ordered ground states in HFS. This competition is, in principle, governed by a single parameter, namely the effective exchange constant J which enters the characteristic energy scales $kT_K \sim \exp(-1/N(E_F)J)$ and $kT_{RKKY} \sim J^2N(E_F)$ for Kondo and RKKY interactions, respectively. **Figure 2** illustrates the competition between T_K and T_{RKKY}, first pointed out by Doniach. The magnitude of J is usually tuned by composition or pressure. Because of the exponential dependence of T_K on J which in turn depends on the hybridization, volume changes are often the dominant effect in producing a magnetic–nonmagnetic transition. The hybridization can, of course, be strongly affected when alloying with nonisoelectronic ligands.

Magnetic Phase Transitions in Strongly Correlated Electron Systems

Magnetic phase transitions are usually observed by varying the temperature T and monitoring changes in thermodynamic quantities such as the magnetic susceptibility or the specific heat. Second-order transitions, where the first derivatives of the free energy, that is, the magnetization or entropy, vary continuously, are strongly influenced by thermal fluctuations. These fluctuations determine how at the critical temperature T_c, the system goes from a disordered state

at $T > T_c$ to a magnetically ordered state at $T < T_c$. The fluctuations diverge spatially as T_c is approached, as characterized by the correlation length $\xi \sim |T - T_c|^{-\nu}$ with a critical exponent ν, and have a typical lifetime given by $\tau \sim \xi^z$, where z is called the dynamical critical exponent. The renormalization group theory predicts that the static properties near a phase transition (PT) depend on a few parameters only, namely the spatial dimension of the system d, the symmetry of the order parameter (OP), and the range of the interaction leading to magnetic order. These parameters determine the universality class of the system. For magnetic systems, the OP is usually the spontaneous magnetization (for antiferromagnets and incommensurate magnets, the staggered magnetization), which is zero above T_c and acquires a finite value below T_c. In HFS, an AF or incommensurate order is found much more often than a ferromagnetic (FM) order.

In many cases, for example, when the magnetic moments are spatially localized, the symmetry of the OP is described completely by the number n of its components, that is, $n = 1$ (Ising model), $n = 2$ (XY model), or $n = 3$ (Heisenberg model). While the critical behavior of static properties such as the specific heat or magnetization for these examples is entirely determined by the universality classes, the dynamic behavior within a given class may differ, depending on z. Fluctuations can actually suppress a PT altogether, the more so, the easier it is to generate fluctuations, that is, the larger n is. A PT to a long-range order is only possible above a lower critical dimension d_L. $d_L = 2$ for $n = 3$, $d_L = 2$ for $n = 2$, and $d_L = 1$ for $n = 1$. (For $n = 2$ and $d = 2$, a special type of PT, the Kosterlitz–Thouless transition, exists.) On the other hand, there is an upper critical dimension d_U above which fluctuations in local-moment systems are deemed unimportant because they effectively average out, with $d_U = 4$ for a wide range of models. In general, for $d > d_U$ a mean-field theory (MFT) accurately describes the PT.

Of particular interest is the possibility that T_c may be driven to zero by some external parameter δ. This can indeed occur in HFS, where δ can be pressure or composition, thus tuning J. The picture of a "classical" phase transition (CPT) has to be modified when T_c vanishes at a critical value δ_c. For such a quantum phase transition (QPT), the relevant length scales and timescales of the critical fluctuations are coupled via the uncertainty principle. At finite temperatures, the quantum energy of fluctuations $\hbar/\tau$ becomes relevant when $\hbar/\tau > kT$, leading to the time entering as additional z dimensions. For any finite T_c, the quantum energy becomes irrelevant because $\tau \to \infty$ for $T \to T_c$ (critical slowing down). Formally, the inverse temperature corresponds to an imaginary time, hence the system acquires its full effective dimensionality $d_{eff} = d + z$ only at $T = 0$. The added time dimensions drive the system toward a mean-field behavior, where above $d_{eff} = 4$ only Gaussian fluctuations are observed and genuine critical behavior is absent. In all cases of a QPT, however, the static properties are influenced by z. This leads to a behavior even at finite T close to δ_c, which distinctly differs from that at a CPT.

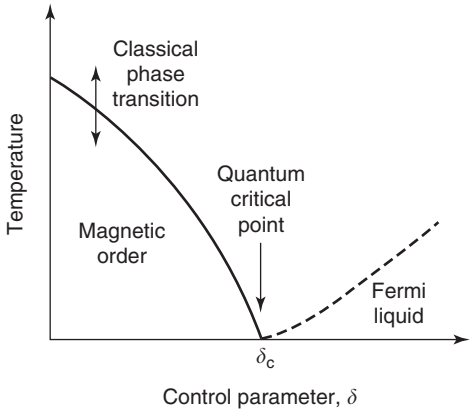

Figure 3 Schematic phase diagram of a metal with an instability towards magnetic order driven by a control parameter δ which may be pressure or composition.

A QPT scenario relevant to HFS is sketched in **Figure 3**, where an itinerant electron system is driven toward (or away from) the magnetic order by δ. While far away from δ_c, the low-T properties of the system can be described in the framework of an FL; unusual "non-Fermi liquid" (NFL) behavior is observed at finite T around δ_c. This picture assumes that the heavy quasiparticles generated by virtue of the Kondo effect retain their identity when passing through the quantum critical point (QCP), while part of the electron system goes into a spin–density wave (SDW) state. This model is in accordance with the simple Doniach picture (**Figure 2**). An alternative view, based on experimental inelastic neutron scattering (INS) data on $CeCu_{6-x}Au_x$ (see next section), suggests that the Kondo effect itself becomes inoperative at the QCP, leading to the appearance of nearly independent local moments. NFL signatures close to a QPT have been observed in weakly magnetic transition-metal compounds and in rare-earth based HFS. On the other hand, NFL behavior in metals does not necessarily arise from the proximity to a magnetic instability. Single-ion effects such as the multichannel Kondo effect or a distribution of Kondo temperatures may also lead to NFL-like properties.

When magnetic order is driven towards an instability by a control parameter, the relevant interactions also become weak or cancel each other. Hence

new low-energy scales may appear which are otherwise masked by the magnetic order. This may lead to an inherent instability of a QPT itself, in the sense that residual interactions drive the system toward a first-order transition where the coherence length and time of the critical fluctuations remain finite, or altogether new phases may appear. A prominent example of the latter is the occurrence of superconductivity (SC) near a QCP in a number of HFS (see below).

A recently discovered very interesting example of a possible novel phase is the partial order in MnSi. This compound exhibits a long-wavelength ($\lambda = 175$ Å) helical magnetic order below $T_c = 29.5$ K. Upon application of hydrostatic pressure p, T_c is reduced, with $T_c = 0$ for $p_c = 14.6$ kbar. In the vicinity of and extending considerably even above p_c, the helical order persists partially: while the λ remains practically constant, the orientation of the helix pointing toward the $\langle 1\,1\,1 \rangle$ directions at $p = 0$, is largely lost. This resembles the structure of certain liquid-crystal phases. An open question at present is how this partial order, here observed for the first time in a magnetic system, is related to the NFL resistivity $\Delta\rho \sim T^{1.5}$ found over a large T and p range.

Magnetic Instability in Heavy-Fermion Systems: $CeCu_{6-x}Au_x$, A Case Study

A large number of investigations have been carried out on HFS close to the magnetic instability. NFL behavior, that is, deviations from the FL predictions in the low-T thermodynamic and transport properties has been reported for systems too numerous to be mentioned here. The main observations are a specific heat coefficient γ exhibiting a logarithmic T dependence, saturating toward low T in a number of cases, and a T^m dependence of the electrical resistivity ρ with $m < 2$. There are only relatively few magnetization studies. The most decisive probe for magnetic fluctuations near a QPT, INS, has been employed only for a few systems so far.

Since many of the HFS are driven through the QPT by changing the composition, introducing disorder, its effect on the critical behavior is an important issue. One has to distinguish between disorder by dilution of the 4*f* or 5*f* site as, for example, in $Ce_{1-x}La_xRu_2Si_2$, or by altering the ligand configuration as, for example, in $CeCu_{6-x}Au_x$. In the first case, a "Kondo hole" introduced by dilution might lead to a substantial quasiparticle scattering and an ultimate loss of coherence. In the second case, the Ce atoms experience different local environments and this may lead to different local Kondo temperatures. In $CeCu_{6-x}Au_x$, the QPT was tuned both by composition and pressure, with no difference in the functional $C(T)$ and $\rho(T)$ dependencies. Disorder may, however, play an important role in other systems.

Table 1 Predictions of the SDW model for the temperature dependence of the linear specific heat coefficient C/T and the electrical resistivity ρ at the quantum critical point. d is the dimensionality of the system and z the dynamic critical exponent for an FM and an AF

	$d = 3$		$d = 2$	
	$z = 3$ (FM)	$z = 2$ (AF)	$z = 3$ (FM)	$z = 2$ (AF)
C/T	$\sim -\ln(T/T_0)$	$\sim \gamma_0 - \beta\sqrt{T}$	$\sim T^{-1/3}$	$\sim -\ln(T/T_0)$
ρ	$\sim T^{5/3}$	$\sim T^{3/2}$	$\sim T^{4/3}$	$\sim T$

Practically, all HFS investigated so far are close to an AF instability (as opposed to an FM instability). A number of systems, notably $Ce_{1-x}La_xRu_2Si_2$, have been compared in detail with the SDW model (see **Table 1**). A long-range AF is introduced into $CeRu_2Si_2$ by a moderate La doping because of the concomitant lattice expansion. The behavior near the QPT, occurring for $x_c \sim 0.075$, is broadly consistent with the expectations, although some differences between INS-derived and specific-heat-derived parameters remain.

In $CeCu_{6-x}Au_x$ which has been studied most extensively, the QPT can be tuned by the Au concentration x, again by virtue of a weakening of J upon expansion of the $CeCu_6$ lattice by Au doping. At the critical concentration $x_c \sim 0.1$, an NFL behavior occurs with $\gamma = a\ln(T_0/T)$ observed as temperature T changes by two orders of magnitude (see **Figure 4**), and $\rho \approx \rho_0 + AT$, between 0.02 and 0.5 K. These T dependences can be understood in terms of the SDW model when two-dimensional critical fluctuations are assumed (hence $d = 2$), which are coupled to quasiparticles with three-dimensional dynamics. Indeed, INS experiments for $x = 0.1$ reveal quasi-one-dimensional features in the dynamical structure factor $S(q; E = \text{const})$ which correspond to quasi-two-dimensional "rods" in real space. Here, the neutron energy transfer was $E = 0.15$ meV. For strictly two-dimensional fluctuations, the system would be at the upper critical dimension $d_{\text{eff}} = d + z = 4$.

The energy dependence of the critical fluctuations measured at $\mathbf{Q} = (0.8\,0\,0)$, that is, at a $\boldsymbol{q}$ point on the "rods" where $S(\boldsymbol{q}, E = \text{const})$ is maximal, has revealed an anomalous scaling with E and T of the imaginary part of the dynamical susceptibility $\chi''(\boldsymbol{q}, E, T) = S(\boldsymbol{q}, E, T) \times (1 - \exp(-E/kT))$, that is, $\chi''(E, T) = T^{-\alpha} g(E/kT)$ with $\alpha = 0.74$ (**Figure 5**). The scaling is incompatible with the SDW scenario, and the scaling function g is consistent with a simple

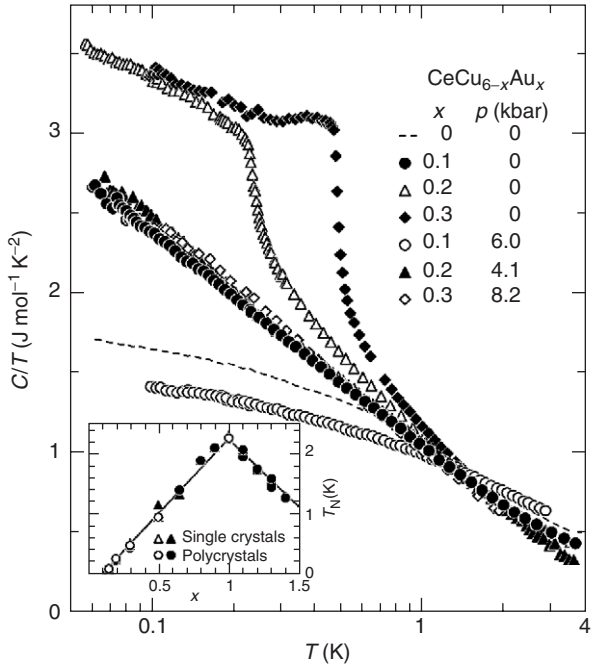

Figure 4 Specific heat C of $CeCu_{6-x}Au_x$ plotted as C/T vs. log T for different hydrostatic pressures p. Note that when $T_N = 0$, (i.e., for $x = 0.3$ at 8.2 kbar and for $x = 0.2$ at 4.1 kbar) the C/T curve falls on the same "universal curve" as for $x = 0.1$ where $T_N = 0$ at ambient pressure. Here a pressure of 6.0 kbar leads to a FL behavior $C/T \approx$ const. Dashed line indicates C/T for $CeCu_6$. Inset shows the Néel temperature T_N vs. x at $p = 0$. (Adapted from von Löhneysen H (1999) Fermi-liquid instability at magnetic-nonmagnetic phase transitions. *Journal of Magnetism and Magnetic Materials* 200: 532–551.)

form of the dynamical susceptibility

$$\chi(\boldsymbol{q}, E, T) = c(f(\boldsymbol{q}) + (-\mathrm{i}E + bT)^{\alpha})^{-1} \qquad [1]$$

where c and b are constants. The anomalous T dependence of the uniform static magnetic susceptibility can be modeled up to 7 K by $\chi = c'(\chi_0^{-1} + b''T^{\alpha})^{-1}$ with $\alpha = 0.8$. The fact that α as obtained from INS for $\boldsymbol{Q} = (0.8\,0\,0)$ is equal to α $(q = 0, E = 0)$ may imply that: (1) the nonlocal physics is contained in $f(\boldsymbol{q})$ which vanishes as $\boldsymbol{q} \to \boldsymbol{Q}$ where $\boldsymbol{Q}$ is a critical vector, that is, belongs to the quasi-one-dimensional features of $S(\boldsymbol{q}, E = \text{const})$, and (2) the anomalous scaling exponent is a local property since it appears to be independent of $\boldsymbol{q}$. This "local" behavior is, however, different from a simple local Lorentzian fluctuation spectrum that would be described by $\alpha = 1$. **Figure 5** also shows that the uniform magnetization obeys a field-temperature scaling with the same anomalous exponent α.

The QPT in $CeCu_{6-x}Au_x$ has not only been tuned by x but also by pressure. **Figure 4** shows that magnetically ordered samples with $x > x_c$ can be driven to the QPT, that is, $T_N = 0$ by appropriate hydrostatic pressure p. This proves that lattice expansion by Au is indeed the dominant effect leading to a long-range magnetic order. Near the QPT, C/T is identical for all samples indicating the equivalence of pressure and concentration tuning in this system. Likewise, the sample with $x = 0.1$ can be driven by p away from the QPT toward an FL behavior $C/T \sim$ const approximately followed by pure $CeCu_6$. The linear $T_N(p)$ and $T_N(x)$ dependencies are in agreement with the scenario of two-dimensional fluctuations. The detailed mechanism of how local moments and long-range fluctuations work together to produce the unique quantum-critical behavior of $CeCu_{6-x}Au_x$ has yet to be disentangled.

The QPT in the related system $CeCu_{6-x}Ag_x$ and also in $CeCu_{6-x}Au_x$ has been tuned by a magnetic field. The T dependencies of C/T and ρ are compatible with the SDW scenario with $d = 3$ and $z = 2$ (**Table 1**), although this scenario does not include a magnetic field.

Thorough studies of $YbRu_2Si_2$, which is close to quantum criticality at ambient pressure (AF order occurs at $T_N \sim 70$ mK), have shown not only similarities to $CeCu_{6-x}Au_x$ in that $\Delta\rho \sim T$ over an even larger T range, but also differences in the specific heat which exhibits a low-T deviation in excess of the $\gamma \sim \ln(T_0/T)$ behavior. Replacement of Si by Ge (doping of nominally 5 at. % Ge leads to $T_N = 20$ mK) amplifies these differences. The data have been suggested to support the local-criticality model introduced to account for the behavior of $CeCu_{6-x}Au_x$. Furthermore, the disparity between thermodynamic and transport data — the resistivity does not show deviations from $\Delta\rho \sim T$ — has been emphasized for $YbRh_2Si_2$. Unfortunately, neutron scattering data are not yet available for this interesting system.

Superconductivity in the Vicinity of Magnetic Order

Superconductivity (SC) was long believed to be incompatible with a long-range magnetic order. This belief was based on two facts: (1) a magnetic field drives the superconducting transition to lower temperatures, and (2) minute amounts of magnetic impurities often suppress SC. However, as **Figure 6** shows, there are a number of examples where SC exists in the proximity of a magnetic order. The common theme of all these materials is that they exhibit strong electronic correlations. These materials exhibit "unconventional" SC, in the sense that either the symmetry of the Cooper-pair wave function differs from the "conventional" s-wave pairing found for

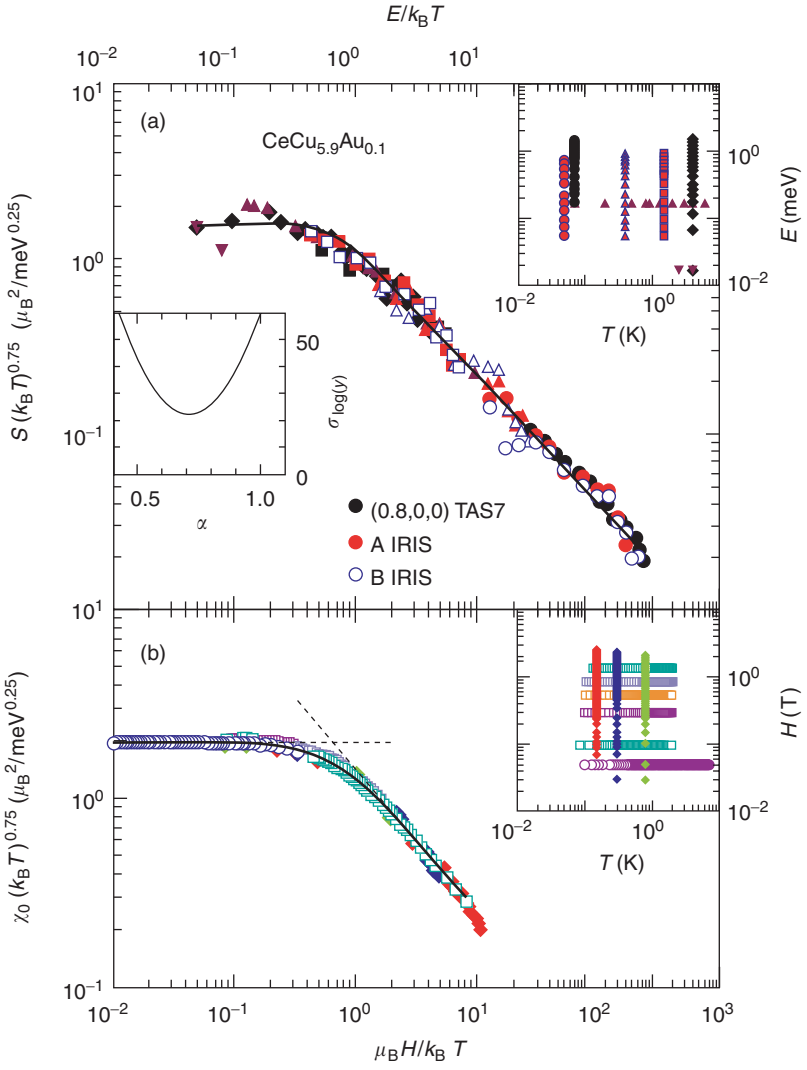

Figure 5 Scaling properties of $CeCu_{5.9}Au_{0.1}$ at quantum criticality (a) Inelastic neutron-scattering function $S(\boldsymbol{q}, E, T)$ multiplied with $T^{0.75}$ vs. E/kT. Different symbols correspond to measurements at different points in $\boldsymbol{q}$ space. The solid line presents a scaling function to eqn [1]. Upper right-hand inset shows the range in neutron energy transfer E and temperature T covered. Left inset shows the "scatter" of the scaling plot as a function of the exponent α, being minimal for $\boldsymbol{Q} = 0.72 \pm 0.05$. (b) Field-temperature scaling of the local contribution to the uniform magnetization $M(T, H)$, with $1/\chi_0 = (dM/dH)^{-1} - (4.1\mu_B^2\ \text{meV})^{-1}$. Solid line corresponds to a scaling function $f(H, T) = (1 + (g\mu_BH/kT)^2)^{-\alpha/2}$ with $\alpha = 0.75$ and $g\mu_B = 1.5\mu_B$. Inset shows range of magnetic field H and temperature T covered. (Adapted from Schröder A, Aeppli G, Coldea R, *et al.* (2000) Onset of antiferromagnetism in heavy-fermion metals. *Nature* 407: 351–355.)

elemental and many alloy superconductors, or the mechanism for an attractive interaction between electrons leading to the formation of Cooper pairs differs from the conventional electron–phonon interactions. Of course, these two aspects are related, as the $\boldsymbol{k}$ dependence of the attractive interaction determines the Cooper-pair wave function. The first "strongly correlated" superconductor, $CeCu_2Si_2$, was discovered in 1979, followed by several other systems. UPt_3 presents a particularly interesting case with several superconducting phases that differ by the spatial dependence of the superconductive order parameter. The high-temperature cuprate superconductors discovered in 1986, that is, $La_{2-x}Sr_xCuO_4$ or $YBa_2Cu_3O_{7-\delta}$, are derived from parent compounds ($x = 0$ or $\delta = 1$, respectively) that are AF insulators because of strong on-site electronic correlations. The CuO_2 planes that are the constituting feature in these materials become metallic and even superconducting upon doping with charge carriers. The interplay between SC and magnetic correlations is not completely understood at present. A particularly interesting case is $CePd_2Si_2$, which in a small p range where T_N is suppressed to zero, exhibits SC below a large T range of NFL behavior. An analogous behavior was found for $CeIn_3$ ($T_N = 10$ K at ambient pressure) and a number of

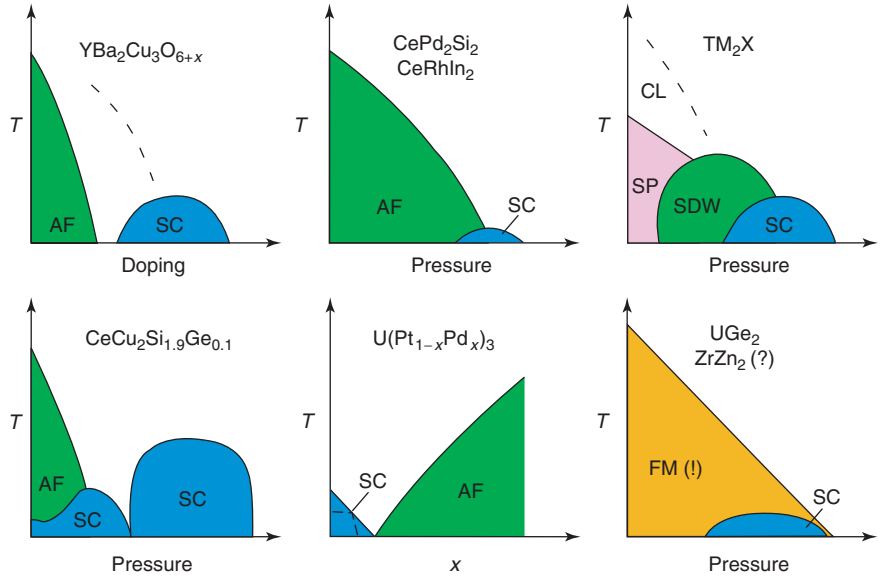

Figure 6 Qualitative picture of the proximity of SC to magnetic order in different types of strongly correlated electron systems. Upper left presents the qualitative phase diagram of cuprate high-temperature superconductors, upper right presents that of quasi-two-dimensional organic conductors. AF = antiferromagnetic order, FM = ferromagnetic order, SC = superconductivity, SP = spin-Peierls phase, SDW = spin-density wave order, CL = charge-localized phase. TM_2X is a quasi-one-dimensional organic conductor, where TM stands for TMTTF ($(CH_3)_4C_6S_4$) or TMTSF ($(CH_3)_4C_6Se_4$), and X for PF_6 or AsF_6 (so-called Bechgaard salts).

other Ce systems. This is suggestive of a spin-fluctuation-mediated SC. A very interesting new material class, based on $CeIn_3$, was recently introduced. This is $CeMIn_5$ where M = Co, Rh, Ir, that is, isoelectronic $3d$, $4d$, and $5d$ elements. While $CeRhIn_5$ is AF ($T_N = 3.8$ K), $CeIrIn_5$ ($T_c = 0.4$ K) and $CeCoIn_5$ ($T_c = 2.3$ K) are superconducting. A pressure of 16 kbar drives $CeRhIn_s$ superconducting with a maximum T_c of 2.1 K. The wealth of new phenomena in these materials is presently exploited by using pressure and composition as tuning parameters, and employing a large number of experimental techniques. However, the detailed interplay between SC and AF order in these materials is not known yet. Low-dimensional organic conductors, also shown by example in **Figure 6**, present an equally rich phase diagram of SC and magnetic order. At first sight, even more surprising, coexistence of SC with ferromagnetism, recently reported for UGe_2, URhGe and $ZrZn_2$ – theoretically anticipated more than 20 years ago – is possible if the spins of the two electrons forming a Cooper pair line up parallel, instead of antiparallel in "classical" superconductors and also in high-T_c cuprates.

Non-Fermi Liquid Behavior Due to Single-Ion Effects

Multichannel Kondo Effect

A perfect screening of the magnetic moment via the Kondo effect, leads to a local FL around a magnetic impurity in a metal as discussed above. In general, however, several conduction-electron channels N may be present and the Kondo Hamiltonian reads $\mathscr{H} = \sum_{\alpha=1}^{N} J_\alpha \boldsymbol{S}\boldsymbol{s}^\alpha$, where α is the channel index. For $N < 2S$, the screening is not complete, whereas $N = 2S$ leads to a perfect screening for $T \to 0$. In the case of degenerate channels, $J_\alpha = J$ for all α, the impurity spin will be overscreened if $N > 2S$. For the special case $S = 1/2$ and $N = 2$, an NFL behavior is predicted with $C/T \sim \chi \sim -\ln(T/T_K)$ and $\rho \sim 1 - (T/T_K)^{1/2}$ for $T \to 0$. Up to now, the experimental evidence for an NFL behavior by overscreening of the magnetic moment of an impurity has been scarce.

In a more general sense, the Kondo effect may also pertain to orbital degrees of freedom of an impurity acting as a pseudospin instead of the spin. This has been discussed for the interaction of conduction electrons with tunneling states, first in amorphous metals and more recently in metallic nanoconstrictions. In these cases, the two channels are provided by the spectator spin of the conduction electrons. For certain rare-earth and actinide metals, a quadrupolar Kondo effect (QKE) has been considered where the pseudospin of the impurity is the quadrupolar moment arising from the aspherical charge distribution of the $4f$ or $5f$ electrons. Again, the two channels are provided by the spin degeneracy of the conduction electrons. Indeed, the NFL anomalies as first reported for $U_{0.2}Y_{0.8}Pd_3$ were suggested to arise from the QKE. Here, NFL anomalies persist to rather dilute U alloys thus favoring

the single-ion QKE model. On the other hand, the NFL behavior might be due to an AF instability, supported by long-range AF order in $U_{0.4}Y_{0.6}Pd_3$. In addition, a divergence of the quadrupolar susceptibility for $T \to 0$ as predicted for the QKE scenario was not found. Hence the situation for $U_xY_{1-x}Pd_3$ is not clear at this point.

The clearest signature of a QKE is found in $U_{1-x}Th_xBe_{13}$. In $U_{1-x}Th_xPd_2Al_3$ single-ion scaling of the NFL properties compatible with the QKE is observed, while $U_{1-x}Y_xPd_2Al_3$ exhibits signatures of a magnetic instability around $x_c = 0.7$ whence the NFL properties might be due to a QPT.

Distribution of Kondo Temperatures

Features of an NFL behavior may arise from quite a different single-ion scenario, that is, a distribution of Kondo temperatures $P(T_K)$ in disordered systems. Fluctuations in J or the local $N(E_F)$ near a disorder-induced metal–insulator transition may lead to a wide distribution of $P(T_K)$. In the case of heavy-fermion solid solutions, the statistical distribution of atoms may lead to a distribution of T_K, as first put forward for the case of $UCu_{5-x}Pd_x$ ($x = 1$ and 1.5) on the basis of NMR measurements which directly showed a distribution of Knight shifts, and hence Kondo temperatures. Even for a rather narrow distribution of J and/or $N(E_F)$, a broad $P(T_K)$ with a finite value for $T_K \to 0$ may occur because of the exponential dependence of T_K on J and $N(E_F)$. A model combining the proximity to a magnetic instability and disorder, the so-called Griffiths phase model, invokes tunneling of ordered regions between different magnetic configurations.

Structure Types and Classifications

J Plévert and T J White, Nanyang Technological University, Singapore, Singapore

Introduction

The classification of structure types is an invaluable process for revealing and systematizing relationships between different compounds and for understanding basic principles governing chemical stability and physical properties. Moreover, the *ab initio* computation of atomic arrangements in solids of given stoichiometry remains a key problem in materials science, and although a general predictive method remains elusive, structural classification schemes provide guidance in constraining such calculations.

While more than 150 000 entries can be found in the two main databases of inorganic solids and alloys (ICSD and CRYSTMET, respectively), there is a striking contrast between the simplicity of some compounds such as NaCl, which is readily described by

simple hard sphere packing, and the apparently overwhelming diversity of more complex structures. It should also be added that intricate atomic patterns do not necessarily predicate involved chemistries. For example, boron offers a rich diversity of complex polymorphs.

It is well appreciated that structural diversity originates from manifold atomic interactions – ionic, covalent, van der Waals, and so on – that define bonding characteristics. Even subtle changes in atomic interactions, perhaps as a function of temperature, pressure, or chemistry, can lead to variations in the atomic arrangement that create hurdles for structural cataloging and make the development of systematic taxonomies a challenging task. Nevertheless, the goal of all classification schemes is to establish mutually exclusive categories, while at the same time, striving to be as comprehensive as possible. Practically, all sorting regimes will be complicated, and to some extent limited by intrinsic disturbances such as nonstoichiometry, solid solution series, structural or compositional modulations, polytypism, and so on.

Structure Types

Although the need for categorization was evident from the earliest days of crystallography, the "structure type" concept remains ambiguous; its meaning nuanced according to scientific discipline and the family of solids under consideration. However, the definition of structure type must be resolved as it underpins, and indeed dictates, the lexicon of any classification scheme. To address this issue the International Union of Crystallography has proposed a set of definitions to create a hierarchy-of-resemblance between structures in which:

1. isopointal structures correspond to structures possessing the same space group and Wyckoff sequence;
2. configurational isotypic structures are isopointal structures with each corresponding Wyckoff position showing a similar geometrical environment; and
3. crystal-chemically isotypic structures are configurational isotypic structures with similar physical/chemical characteristics.

It is noted that only isopointal structures are the same and allow a precise assignment of crystallographic equivalence. The next levels classify structures as similar because of the "inherent difficulty in defining *a priori* limits on the similarity," or in other words, the problem of defining mutually exclusive structure types cannot be resolved uniquely.

In the special case of strictly cubic configurational isotypic structures, the similarity ambiguity is removed as all atoms are located in fixed crystallographic positions (the coordination of corresponding atoms is identical), however there is no restriction placed on physical/chemical properties. So, for instance, NaCl (rocksalt) and PbS (galena) are strict configurational isotypes, but not crystal-chemical isotypes (**Figure 1**). Their bonding properties are different – ionic versus covalent character – leading to bandgap energies of about 0.4 eV (PbS) and 8.5 eV (NaCl) and numerous other differentiating characteristics.

Despite such obvious limitations the hierarchy-of-resemblance provides useful guidance for classification, and in-line with its principles, four main styles of representation can be selected for infinitely periodic structures (**Figure 2**). The chemical mode describes the compound as a formula, based on the stoichiometric composition only. The geometric view emphasizes the local environment of individual atoms, particularly the shape of nearest-neighbor coordination polyhedra (normally, but not exclusively cation-centered) that define the coordination number. The structural approach highlights the symmetry of the structure, including the space group, Wyckoff positions, and lattice complexes. The topological description represents structures as a net, where the atoms are vertices and bonds are the edges. These four genres are employed in various forms to systematize mineral, oxide, and alloy structural families. Although many structural classification schemes have been proposed, some are rarely used or applicable to

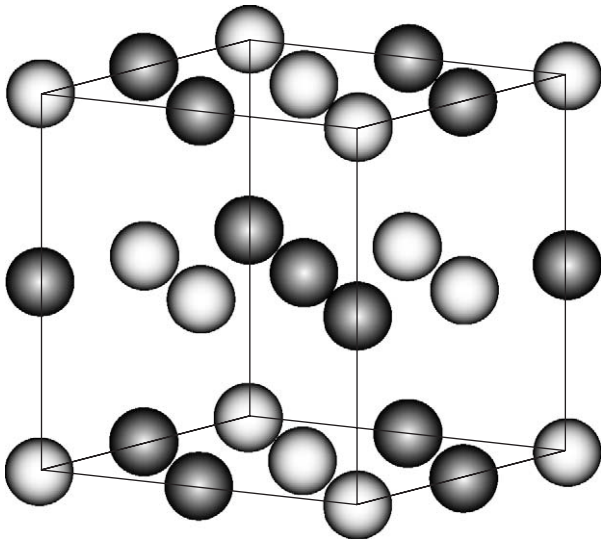

Figure 1 The atomic arrangement in the isopointal structures NaCl (rocksalt) and PbS (galena) are precisely the same although their physical and chemical characteristics are different. The crystallographic or unit cell repeat is outlined.

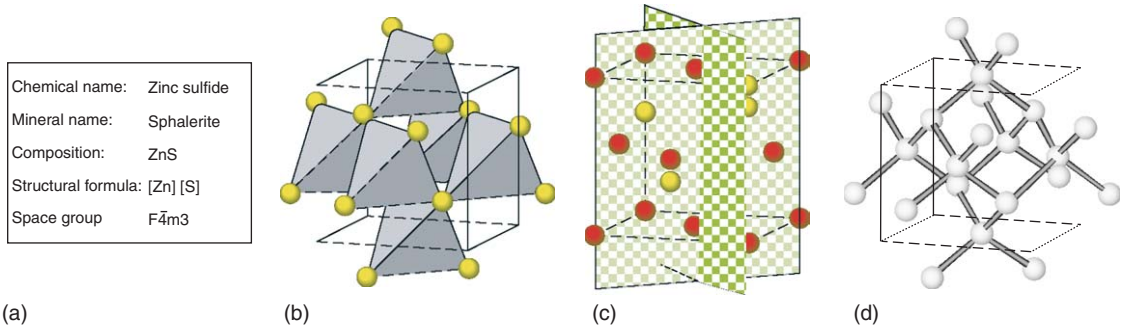

Figure 2 The cubic sphalerite form of ZnS is represented in: (a) the chemical mode where the crystallographically distinct sites are emphasized in square brackets; (b) the geometric mode where the ZnS_4 tetrahedra is shown to form a continuous motif; (c) the structural mode where set of equivalent positions occupied by the atoms Zn and S and symmetry are highlighted, in this case two orthogonal mirror planes are inserted; and (d) the topological mode where a net is constructed with Zn or S at the nodes and connections drawn between these.

a limited subset of materials. Only the better-known sorting methods are considered here.

Strukturbericht Symbols

The antecedent for grouping similar structures was developed by P P Ewald and C Hermann for arranging early crystallographic determinations collated in the journal Strukturberichte (1913–1939). This simple nomenclature was based on chemical composition (**Table 1**), with stoichiometry specified by an upper case letter: A for an element, B for binary, and C for AB_2 compounds. The letter D represents the A_mB_n family that is subdivided according to the A:B ratio such that $D0 \equiv AB_3$, $D1 \equiv AB_4$, $D5 \equiv A_2B_3$, and so on. The letters L and S represent the family of alloys and silicates respectively. A number, or sometimes a letter, follows the composition code, which reflects an entry number.

The type of crystal structure adopted by the elements depends on their position in the periodic table. Most metals are known to crystallize as a close packing of atoms because of the nondirectional character of the metallic bond. The elements in the copper group possess face-centered cubic (f.c.c.) structures, which are assigned the Strukturbericht type *A*1. The alkali metals are found in general as body-centered cubic (b.c.c.) with Strukturbericht type *A*2. Some alkaline earth metals or their polymorphic modifications, as well as zinc and cadmium, adopt the hexagonal close packing (h.c.p.), Strukturbericht symbol *A*3. The diamond type *A*4 is found in the carbon group where covalent bonding is prevalent, and graphite is assigned the Strukturbericht *A*9.

Tetragonal distortions of the f.c.c. (*A*1) may be face-centered tetragonal (f.c.t.) *A*6 or body-centered tetragonal (b.c.t.) A_a, depending on the *c*/*a* ratio of the unit-cell parameters. In this scheme, some configurational isotypes are regrouped with different Strukturbericht symbols, as in the case of $CaCl_2$ (*C*35) and marcasite FeS_2 (*C*18), the orthorhombic form of pyrite. A further complexity is that revised structures can be found with new entries as in the case of boron nitride, *B*12, and B_k.

Table 1 Strukturbericht symbols

Strukturbericht types	*Compounds*
A	Elements
B	AB
C	AB_2
D	A_mB_n
D0, D1, D5…	AB_3, AB_4, A_2B_3…
E, F, G, H, K	$A_mB_nC_o$…
L	Alloys
O	Organic solids
S	Silicates

While the Strukturbericht classification can in principle accommodate any kind of alloy (Cu_3Au, $L1_2$), mineral (olivine, $S1_2$), or molecular (NH_3, *D*1) structure, there is inherent limitations. In particular, although the designations are convenient for simple phases, they become increasingly confusing and arbitrary as structures become more complex. For this reason, the Strukturbericht designation was not maintained in editions published after 1940 (then known as Structure Reports) and to a large extent this nomenclature has fallen into disuse except for common structures.

Pearson Symbols

Fourteen different three-dimensional lattices, the Bravais lattices, are possible: *aP*, *mP*, *mS*, *oP*, *oS*, *oI*, *oF*, *tP*, *tI*, *hP*, *hR*, *cP*, *cI*, *cF*. In this nomenclature, the first lower case letter indicates the crystal family *a*, *m*, *o*, *t*, *h*, *c* (anorthic, monoclinic, orthorhombic,

Table 2 Comparison of nomenclatures for some common materials

Compound	*Strukturbericht*	*Pearson*	*Lattice complex*
NaCl (halite)	B1	cF8	$F+\frac{1}{2}\frac{1}{2}\frac{1}{2}F$
PbS (galena)	B1	cF8	$F+\frac{1}{2}\frac{1}{2}\frac{1}{2}F$
C (diamond)	A4	cF8	D
ZnS (sphalerite)	B3	cF8	$F+\frac{1}{4}\frac{1}{4}\frac{1}{4}F$
$SrTiO_3$ (perovskite)	$E2_1$	cP5	$P+\frac{1}{2}\frac{1}{2}\frac{1}{2}P+J$
$MgAl_2O_4$ (spinel)	$H1_1$	cF56	$D+\frac{1}{2}\frac{1}{2}\frac{1}{2}T+\frac{3}{4}\frac{3}{4}\frac{3}{4}F_{222}xxx$

tetragonal, hexagonal, and cubic) while the second upper case letter gives the Bravais lattice *P*, *S*, *I*, *F*, *R*. The assignments m*S* and o*S* stand for any setting of a face-centered Bravais lattice in the monoclinic and orthorhombic families respectively, independent of the unit-cell setting adopted. So, to avoid confusion, the symbol *S* designating the "side-face centered" type is used rather than *C*.

Pearson symbols unite crystal lattice symmetry with the total number of atoms in the unit-cell by combining the two-letter code of the Bravais lattice and the total number of atoms in the cell. Thus, NaCl crystallizes in a face-centered cubic unit-cell *cF* with four Na cations and four Cl anions per cell, yielding its Pearson symbol *cF*8. The Pearson classification is concerned with Bravais translations but not with symmetry operations that can be applied on the unit-cell content. For example, non-isopointal structures may possess the same Pearson symbol, as observed in the case of diamond (*A*4), NaCl (*B*1) and zinc blende ZnS (*B*3) (**Table 2**). To address such limitations, ASTM proposed a nomenclature based on the Bravais centering and the number of atoms in the unit-cell, but added a lower case letter to distinguish between different structure types: diamond – 8*aF*, NaCl – 8*bF*, ZnS – 8*cF*. A suggestion from IUPAC was to add the name of a prototype to the Pearson symbol (e.g., *cF*8, NaCl).

Pearson symbols are widely used by scientists studying intermetallic alloys and are recorded in comprehensive treatises such as "Pearson's Handbook of Crystallographic Data for Intermetallic Phases" or the "Gmelin Handbook of Inorganic and Organometallic Chemistry." Perhaps more practically, Pearson symbols are used as search codes in structure databases.

Lattice Complex Notation (Bauverband)

A lattice complex is defined as a set of all point configurations that may be generated within one type of Wyckoff sets. The same lattice complex may belong to different space groups and are designated by the symbol of the space group of the highest symmetry, followed by a Wyckoff letter. In the simplest cases, invariant lattice complexes are formed from Wyckoff sets containing fixed crystallographic positions and are represented by an upper case letter named after the Bravais lattice (*P*, *C*, *I*, *F*), or representative of the lattice of common structural types. For example, the structure of diamond corresponds to the invariant lattice complex *D* with characteristic Wyckoff position Fd-3m a, which defined the eight symmetrically equivalent points generated by the position 000 (8a) in space group Fd-3m. It follows that lattice complexes can be used for the systematic enumeration of structural elements in different crystal systems. Indeed, the combination of all 16 invariant cubic lattice complexes allows all possible invariant structures to be defined.

A nomenclature has been derived from this approach in which a structure type is represented by listing the lattice complex and the relative shifts between different lattice complexes, expressed by a vector in fractional coordinates. For example, NaCl can be represented by the combination of two lattice complexes F, shifted along the diagonal of the unit cell, as $F+\frac{1}{2}\frac{1}{2}\frac{1}{2}F$, while ZnS is described as $F+\frac{1}{4}\frac{1}{4}\frac{1}{4}F$. The lattice complex F appears in second order, as F_{222}, when the complex F can be found in a subcell with volume an eighth of the basic unit-cell.

Although precise, the description becomes cumbersome if the geometrical configuration of lattice complexes is variable in ways that lead to different coordination numbers and geometry of coordination polyhedra. In these cases, the distances between nodes of a complex depend on fractional parameters *x*,*y*,*z* and the relative values of the cell parameters a:b:c and α:β:γ for crystal systems with less than cubic symmetry. Consequently, two structures with the same combination of lattice complexes may not necessarily be configurationally isotypic. Those lattice complexes with degrees of freedom are described by adding to the invariant complex symbol the splitting number of the fixed crystallographic position and the coordinate triplet of the characteristic Wyckoff positions. For example, the univariant lattice complex P8xxx splits the invariant complex P (where x = 0) into eightfold position xxx along the diagonals of a cube.

To address the examination of more intricate structures, Bauverband terminology extends lattice

complex notation with symbolism representing the nature of coordination polyhedra around atoms, the type of linkedness (corner, edge, face sharing) and their mutual orientation by selected symmetry operations, such that configurational isotypes might be more easily recognized. In particular, different Bauverband symbols can be assigned to the same structure.

Topological Descriptions

A consideration of topology (in this instance referring to descriptions of connectedness) offers a different perspective on structure types and their classification. In this case, structures are represented by nets (infinite graphs), where each vertex corresponds to an atom and each edge corresponds to a representative bond. Individual atoms can be advantageously replaced by groups of atoms as vertices, to yield simplified descriptions. Thus, structures composed of corner-connected polyhedra are usually described as nets where the central atoms are the vertices, and the edges connect the vertices corresponding to the same coordination spheres. This approach can be extended to larger groups of atoms and is well suited for streamlining the description of complex structures as illustrated in the case of faujasite, an alumino-silicate framework $T_{192}O_{384}$ (T = Si or Al), that can be described as a diamond net of sodalite cages composed of 24 T atoms (**Figure 3**).

Topological isotypism can be recognized irrespective of differences in chemical composition or symmetry, so diamond (Struckturbericht A4, lattice complex D) is topologically isotypic to ZnS (Struckturbericht B3, lattice complex $F + \frac{1}{4}\frac{1}{4}\frac{1}{4}F$).

Often, nets are named after simple structures, such as diamond net, or the well-known Kagome net. Unnamed nets can be designated using their Schlafli symbol N^n that specifies the number n of N-gons around each vertex (e.g., diamond 6^6). However, there is no systematic nomenclature for solids, except for the family of zeolites and other microporous solids, which are identified by a three-letter code.

Prototype Assignments

Amongst mineralogists and solid-state chemists, crystal structures are often referred to by the name, or the chemical composition, of a representative solid known as the prototype or aristotype, a structural representative in the space group of highest symmetry. For example, NaCl (rocksalt, halite) is the prototype of a very common structure type, representative of more than 20 distinct chemical compositions. This approach, while embracing the concept of crystal-chemical isotypism, is broadened by excluding the requirement for similar physiochemical properties. Given this latitude, it is perhaps surprising that a small number of common prototypes of similar topology, account for several thousand common, and technologically significant structures. Although prototypes are generally simple structures of high symmetry and the more common are shown in **Table 3**, heterotypes derived from these may be chemically diverse and often have lower symmetry.

A well-known example is the perovskite-type in which the prototype is $SrTiO_3$. This cubic structure consists of corner-connected TiO_6 octahedra that create cavities containing strontium. Crucially, it is the capacity of these octahedra to twist and distort that allows perovskites to accommodate a wide range of compositions – in excess of 800 distinct

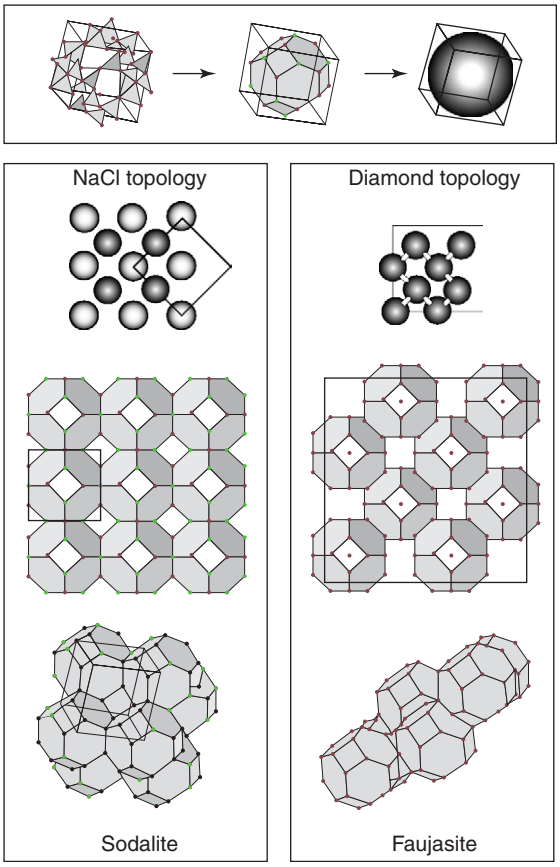

Figure 3 In complex structures, such as zeolites, relationships can be simplified by highlighting particular topologies, in which the nodes are not single atoms, as in the case of ZnS (see **Figure 2**) but groups of atoms. Uppermost is shown the progressive simplification of an atomic cluster in sodalite. Far left the AlO_4 and SiO_4 tetrahedra are highlighted in a representation that is difficult to visualize. This can be clarified by converting each tetrahedron to a single node. It is then evident that the arrangement is that of a truncated octahedron. Finally, this entire polyhedron can be regarded as a packing "sphere." In this way, it then becomes obvious that these units are packed together in NaCl topology in the case of sodalite, or in diamond topology in the zeolite faujasite.

Table 3 Frequently occurring structural prototypes

Prototype		*Approximate number of distinct species*
Name	*Compound*	
Perovskite	$SrTiO_3$	>800
Spinel	Mg_2AlO_4	>800
Apatite	$Ca_5(PO_4)_3(OH)$	>150
Olivine	Mg_2SiO_4	>400
Rocksalt	NaCl	>20

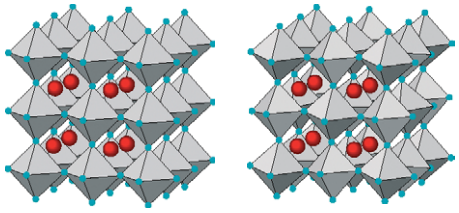

Figure 4 The *Pm-3m* perovskite prototype (or aristotype) is shown left with the TiO_6 octahedra shaded and Sr inserted large cuboctahedral cavities. $SrTiO_3$ adopts the prototype structure precisely, but many compounds belong to the perovskite family. The capacity to accommodate a wide range of chemistries arises because the octahedra are connected through their vertices in a manner that allows tilting and distortion to accommodate atoms of different sizes. The mineral perovskite $CaTiO_3$ has tilted octahedra and adopts *Pnma* symmetry.

species are known – that can display properties ranging from ion conductivity to superconductivity to semiconductor characteristics amongst others (**Figure 4**). It is interesting to note that the structure of the mineral perovskite $CaTiO_3$ is an orthorhombic derivative of the prototype.

Another useful feature of prototype classification is that an even greater variety of structures may be described as intergrowths of two prototypes. For example, the olivine-type Mg_2SiO_4 is important in geochemistry and as a refractory material. However, a different structural family – the humite family – is created by intergrowth of slabs of olivine with the prototype brucite $Mg(OH)_2$ (**Figure 5**). Thus, in addition to relating different structures, this approach may also be extended to describe, and in some cases predict, the existence of new compounds.

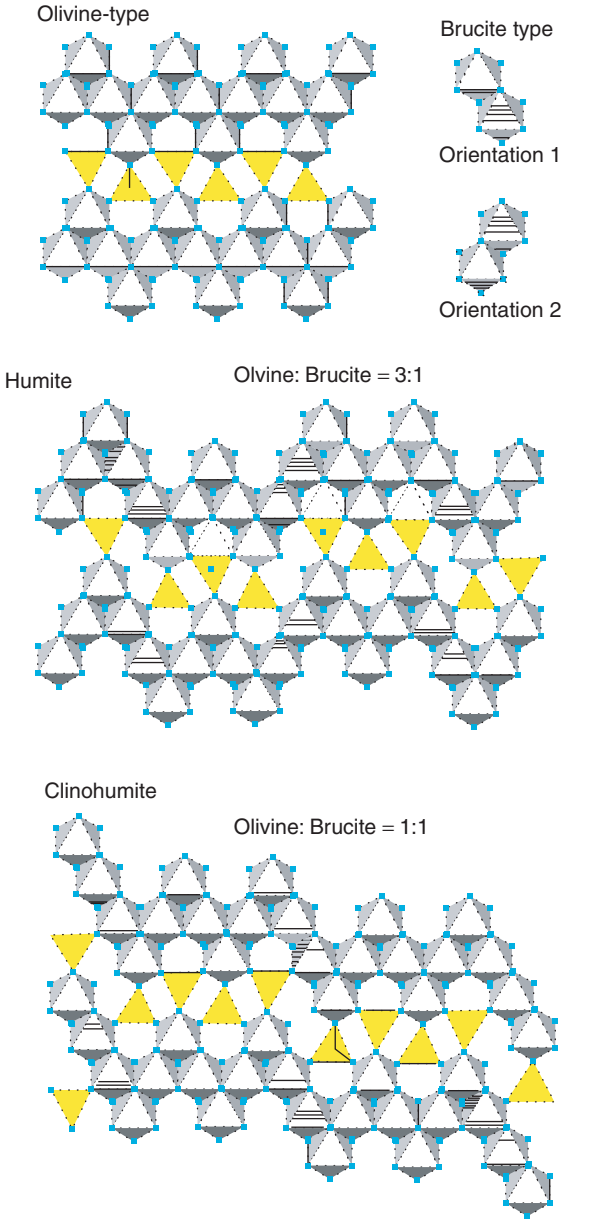

Figure 5 Structure types can be "intergrown" to build new and more complex structures. The humite structural series is derived from the olivine (Mg_2SiO_4) and brucite ($Mg(OH)_2$) prototypes through variation of the olivine:brucite ratio. In nature, four members of this structural family are known – norbergite (olivine : brucite = 1 : 1), chondrodite (2 : 1), humite (3 : 1), and clinohumite (4 : 1) – but many complex intergrowths have been observed in synthetic analogs.

Applying Structural Classification

Several different ways to describe crystallographic structures have been summarized here, but many others are known – Laves notation, Povarennykh's mineral systematization and so on. While each differs in its precision and breadth of coverage, no classification scheme is more or less correct, rather it is a question of appropriateness for a particular application, and the insights that may be drawn from their use. It is not surprising that schemes devised for comparing simple ionic solids are inadequate for complex covalent compounds, or conversely that the simplifications made for complicated systems fail to satisfy the need for exactitude in austere structures.

Sum Rules and Kramers–Kronig Relations in Nonlinear Optics

F Bassani, Scuola Normale Superiore, Pisa, Italy

General Description of Nonlinear Optical Functions

Nonlinear optics includes a number of phenomena, which are of great interest and have come to be of very common use with the availability of intense laser radiation. Among them are multiple-frequency generation, dynamic Stark effect, two-photon absorption, stimulated Raman absorption, and electromagnetically induced transparency. All these phenomena must obey the causality principle and consequently the Kramers–Kronig (KK) relations, and optical sum rules may be obtained for nonlinear optical phenomena in a way totally analogous to those used in linear optics.

One may start with the definition of the nth order polarization of a medium, expressed in terms of the external electric fields as

$$P^{(n)}(t) = \int_{-\infty}^{+\infty} \mathrm{d}t_1 \cdots \mathrm{d}t_n G^{(n)}(t_1, \ldots, t_n) \times E_1(t - t_1) \cdots E_n(t - t_n) \quad [1]$$

where the response function is symmetric under an exchange of variables, and satisfies the time causality condition

$$G^{(n)}(t_1, t_2, \ldots, t_n) = 0 \quad \text{if any } t_i < 0 \quad [2]$$

The electric fields are taken to be sinusoidal, with given frequencies, of the form

$$\boldsymbol{E}_n(\tau) = E_n(\omega_n)\exp[-\mathrm{i}\omega_n\tau] + E_n^*(\omega_n)\exp[\mathrm{i}\omega_n\tau] \quad [3]$$

where, by convention, the first term gives contributions to the susceptibility of argument ω_n and the second of argument $-\omega_n$.

Taking the Fourier transform of the polarization, the expression for the frequency component of the polarizability at any order is obtained as

$$P^{(n)}(\omega) = \chi^{(n)}(\omega_1, \ldots, \omega_n) E_1(\omega_1) \cdots E_n(\omega_n) \times \delta[\omega - (\omega_1 + \cdots + \omega_n)] \quad [4]$$

where $\chi^{(n)}(\omega_1, \ldots, \omega_n)$ is defined as the Fourier transform of $G^{(n)}(t_1, \ldots, t_n)$

$$\chi^{(n)}(\omega_1, \ldots, \omega_n) = \int_0^{\infty} \mathrm{d}t_1 \cdots \int_0^{\infty} \mathrm{d}t_n \exp[\mathrm{i}(\omega_1 t_1 + \cdots + \omega_n t_n)] \times G^{(n)}(t_1, \ldots, t_n) \quad [5]$$

and the symmetry in time implies that it is symmetric for the exchange of frequencies. The reality of $G_n^{(n)}(t_1, \ldots t_n)$, also implies

$$\chi^{(n)}(-\omega_1, \ldots, -\omega_n) = \chi^{(n)*}(\omega_1, \ldots, \omega_n) \quad [6]$$

If the fields are not sinusoidal, one can expand them in their Fourier components of type [3] and the sum over the frequencies $\omega_1, \ldots, \omega_n$ must be considered, with the appropriate field amplitudes.

One may observe that in the nonlinear case, the polarization is obtained by multiplying the nth order susceptibility by all the field amplitudes, so that its dimensionality depends on the order considered. The susceptibilities $\chi^{(n)}(\omega_1, \ldots, \omega_n)$ contain all the optical properties of the system to all orders, in the presence of a number of radiation beams.

The various terms of the susceptibilities to any order correspond to particular phenomena, and specific

expressions can be obtained in each case, but, since one is interested in the general properties, only the asymptotic behavior for $\omega \to \infty$ or $t \to 0^+$ is of interest. A simple way to obtain it in the classical model is to extend the Lorentz oscillator scheme described in the linear case by adding to the harmonic contribution a potential with all the anharmonic terms, and solving the resulting equations of motion by iteration. A more precise quantum-mechanical expression can be used, which is an extension of the expression given for the linear case

$$G^{(n)}(t_1, \ldots, t_n) = \frac{1}{n!(\mathrm{i}\hbar)^n} \sum T(1, \ldots, n) \times \{\mathrm{Tr}[P(-t_1), \ldots, [P(-t_n), \varrho_0]]P\} \quad [7]$$

where the sum is from 1 to n and T denotes the time ordering operator, and P is the dipole moment operator whose time dependence is expressed in the interaction representation in terms of the Hamiltonian H_0.

Since dissipation is proportional to the time average

$$-\left\langle \frac{\mathrm{d}P(t)}{\mathrm{d}t} E(t) \right\rangle \quad [8]$$

it vanishes when the fields and the polarization oscillate at different frequencies.

At different orders, one has different effects by considering all possible frequencies of the external electromagnetic fields. It is convenient to indicate the frequency of $P(\omega)$ and those of the external fields explicitly in the susceptibilities.

In the second order, an intense beam results in the second-harmonic generation from $\chi^{(2)}(2\omega_1; \omega_1, \omega_1)$ and optical rectification from $\chi^{(2)}(0; \omega_1, -\omega_1)$; at higher orders one has higher harmonic generation $\chi^{(n)}(n\omega_1; \omega_1, \ldots, \omega_1)$. With different beams, in the second order one has the sum and difference frequency generation $\chi^{(2)}(\omega_1 + \omega_2; \omega_1, \omega_2)$ and $\chi^{(2)}(\omega_1 - \omega_2, \omega_1, -\omega_2)$, and at higher order, all possible sums and differences. These do not give any absorption because the polarization frequency and the field frequency are different; the real and imaginary parts define in this case the phases of the susceptibility amplitudes.

In the third order and at higher odd orders, an important contribution to the susceptibility corresponds to the so-called pump and probe experiments, where one detects the dispersion and the absorption of a weak probe beam of frequency ω, in the presence of an intense beam of frequency ω_2. The nonlinear susceptibility $\chi^{(2n+1)}$ is proportional to the intensity of the pump beam at the nth power. The susceptibility $\chi^{(3)}(\omega; \omega, \omega_2, -\omega_2)$ and more generally $\chi^{(2n+1)}(\omega; \omega, \omega_2, -\omega_2, \ldots)$ contains a dynamical Stark effect when ω is close to a first-order resonance, a two-photon absorption when $\omega + \omega_2$ is close to a possible transition frequency, the stimulated Raman effect when $\omega - \omega_2$ is close to a transition frequency. In the pump and probe case, with a three-level system, one also obtains, under particular conditions, a coherent interference effect which produces an electromagnetically induced transparency (EIT) inside the first-order absorption line.

To consider the general properties related to pump and probe nonlinear dispersive–dissipative effects, the dielectric function which is the sum of the linear contribution and all odd nonlinear contributions with final frequency ω of the probe field may be studied

$$\varepsilon_{\mathrm{tot}}(\omega; \omega_2, E_2(\omega_2)) = \varepsilon^{\mathrm{L}}(\omega) + \varepsilon^{\mathrm{NL}}(\omega; \omega_2, E(\omega_2)) = 1 + 4\pi \sum_{n \text{ odd}} a_n \chi^{(n)} \times (\omega; \omega, \omega_2, -\omega_2, \ldots, \omega_2, -\omega_2) E^{n-1}(\omega_2) \quad [9]$$

where

$$a_n = \frac{1}{2^{n-1}} \frac{(n-1)!}{((n-1)/2)!((n-1)/2)!} \quad [10]$$

The nonlinear contribution $\varepsilon^{\mathrm{NL}}$ is given by the sum of the terms with $n > 1$, and the numerical factor is given by the invariance of the susceptibility for permutation of the frequencies. The most important nonlinear term is clearly $\chi^{(3)}(\omega; \omega, \omega_2, -\omega_2)$.

Kramers–Kronig Relations and Sum Rules

The analytic properties of the nonlinear optical susceptibilities can be examined in increasing order, and a number of sum rules can be obtained easily, when KK relations hold, by extending the procedure given for the linear case.

A first property follows immediately from causality due to the Titchmarsh theorem: the susceptibility is holomorphic in the upper half of the complex plane associated with one of the frequency variables when all the others are kept fixed. A second more general theorem due to time causality was derived by Scandolo: the nonlinear susceptibility is holomorphic in the upper half-plane of any straight line with a positive slope in the frequency space of all the ω_i. This also holds by taking the line with zero slope along a given axis, provided the other values can be kept fixed.

From the above results, it can be seen immediately that KK relations can be established in most cases

previously described, in second and higher harmonic generation along ω_1, as well as in pump and probe experiment along ω, keeping ω_2 fixed. They do not apply in optical rectification, because any straight line in the space $\omega, \omega_2 = -\omega$ cannot have positive slope; they do not apply also for $\chi^{(3)}(\omega_1; \omega_1, -\omega_1, \omega_1)$, when only one beam is present. The asymptotic behavior of the nonlinear susceptibilities is in general much faster than in the linear case, so that one may consider all integrable products of the type $\omega^k \chi^{(n)}(\omega)$, along the line of positive slope which is considered, and thus obtain a number of KK relations. From them, (using the superconvergence theorem as shown in the linear case) the asymptotic behaviors of the real and the imaginary part of the susceptibility can be obtained in terms of their moments (integrals of powers of the frequency times the susceptibility), up to a given value, above which the integral does not converge. A comparison of such asymptotic behaviors of the susceptibility with the behavior obtained from specific calculations gives a number of new sum rules for the nonlinear susceptibilities considered.

Harmonic Generation

As a first example, consider the second-harmonic generation. The asymptotic behavior of $\chi^{(2)}(2\omega, \omega, \omega)$ as $\omega \to \infty$ can be obtained easily from the anharmonic oscillator model or equivalently from the quantum theory. They give similar results, provided the appropriate third-order derivative $\partial^3 V(x)/\partial x^3$ for x-polarized radiation is substituted in the quantum theory by its expectation value on the ground-state wave function. The following second-harmonic asymptotic behavior obtains

$$\underset{\omega \to \infty}{\chi^{(2)}}(2\omega; \omega, \omega) = +\frac{1}{2!}\frac{e^3}{m^2}\varrho\left[\frac{\partial^3 V(x)}{\partial x^3}\right]_0 \times \frac{1}{4}\frac{1}{\omega^6} + o(\omega^{-6}) \qquad [11]$$

where ρ is the electron density and the potential term is given by the anharmonic coefficient in the extended Lorentz model, and by its expectation value on the ground state in the quantum-mechanical approach. In the presence of the polarized beams of the same frequency, the derivatives can refer to the polarization directions of the fields and to the polarization directions of $\boldsymbol{P}$, so that a third-order tensor component is defined. As a consequence of the asymptotic behavior [11], three independent KK relations are obtained, one for $\chi^{(2)}(2\omega; \omega, \omega)$, one for $\omega^2\chi^{(2)}$, and another one for $\omega^4\chi^{(2)}$. They can be summarized as follows in terms of their real and imaginary part χ_1 and χ_2:

$$\omega^{2\alpha}\chi_1^{(2)}(2\omega; \omega, \omega) = \frac{2}{\pi}\fint_0^\infty \frac{\omega'^{2\alpha+1}\chi_2^{(2)}(2\omega'; \omega', \omega')}{\omega'^2 - \omega^2}\,\mathrm{d}\omega'$$

$$\omega^{2\alpha-1}\chi_2^{(2)}(2\omega; \omega, \omega) = -\frac{2}{\pi}\fint_0^\infty \frac{\omega'^{2\alpha}\chi_1^{(2)}(2\omega'; \omega', \omega')}{\omega'^2 - \omega^2}\,\mathrm{d}\omega' \qquad [12]$$

with $0 \leqslant \alpha \leqslant 2$ where the line on the integral denotes that the principal part has to be considered. By comparing the asymptotic behaviors obtained from the above KK relations, via the superconvergence theorem, which amounts to neglecting ω'^2 in the denominator of [12], with the requested one given above [11] six sum rules are obtained, which can be summarized as follows:

$$\int_0^\infty \omega^{2\alpha}\chi_1^{(2)}(2\omega; \omega, \omega)\mathrm{d}\omega = 0, \text{ for } \alpha = 0, 1, 2$$

$$\int_0^\infty \omega^{2\alpha+1}\chi_2^{(2)}(2\omega; \omega, \omega)\mathrm{d}\omega = 0, \text{ for } \alpha = 0, 1 \qquad [13]$$

$$\int_0^\infty \omega^5\chi_2^{(2)}(2\omega; \omega, \omega)\mathrm{d}\omega = -\frac{\pi}{2}\cdot\frac{e^3}{8}m^{-2}\varrho\left[\frac{\partial^3 V}{\partial x^3}\right]_0$$

The procedure given has been extended to higher harmonics and gives a large number of sum rules. All integrals of even moments of the real part of the susceptibility vanish up to the $2n$ moment, and all odd moments of the imaginary part of the susceptibility vanish, with the exception of the $2n+1$ moment which gives a result depending on the dynamics of the system.

Pump and Probe

Now, consider the pump and probe experiments, where the response to a beam of frequency ω is studied in the presence of an intense beam of frequency ω_2. The nonlinear contributions due to the probe beam alone are neglected, and the nonlinear susceptibility $\chi^{(3)}(\omega; \omega, \omega_2, -\omega_2)$, or more generally $\chi^{(2l+1)}(\omega; \omega, \omega_2, -\omega_2, \ldots, -\omega_2)$ for a very intense pump beam is considered. The asymptotic behavior can also be obtained in this case from the anharmonic oscillator model, or from the quantum-mechanical approach by using the Fourier transform [5] of the response function [7] for $t_1 \to 0^+$. One can show that the asymptotic behavior of the nonlinear susceptibility is

$$\tilde{\chi}^{\mathrm{NL}} = -\frac{C}{\omega^4} + o(\omega^{-4}) \qquad [14]$$

with

$$C = -\sum_{n\ \mathrm{odd}>1} \frac{a_n e^2}{n!(-\mathrm{i}\hbar)^{n-1} m^2} E_2^{n-1}(\omega_2) \int \mathrm{d}t_2 \cdots \int \mathrm{d}t_n \times \exp[-\mathrm{i}(\omega_2 t_2 - \omega_2 t_n)] \times \mathrm{Tr}\left\{ \frac{\partial^2 V}{\partial x^2} \sum_P T(2, \ldots, n)[P(-t_2) \cdot [\ldots P(-t_n), \varrho_0]] \right\} \quad [15]$$

and

$$a_n = \frac{1}{2^{n-1}} \frac{(n-1)!}{((n-1)/2)!((n-1)/2)!} \quad [16]$$

From this, it can be seen that two KK relations are obtained. One is the same as the linear KK relations and applies to $\chi^{\mathrm{NL}}(\omega; \omega_2,\ E_2)$. The other, typical of a nonlinear contribution for the probe–pump situation, applies to $\omega^2\ \chi^{\mathrm{NL}}(\omega; \omega_2,\ E_2)$. It is

$$\omega^2 \chi_1^{\mathrm{NL}}(\omega; \omega_2,\ E_2) = \frac{2}{\pi} \fint_0^\infty \mathrm{d}\omega' \frac{\omega'^3 \chi_2^{\mathrm{NL}}(\omega'; \omega_2, E_2)}{\omega'^2 - \omega^2}$$
$$\omega^2 \chi_2^{\mathrm{NL}}(\omega; \omega_2,\ E_2) = -\frac{2\omega}{\pi} \fint_0^\infty \mathrm{d}\omega' \frac{\omega'^2 \chi_1^{\mathrm{NL}}(\omega'; \omega_2, E_2)}{\omega'^2 - \omega^2} \quad [17]$$

These relations, appropriate to the nonlinear contribution, can be used to relate dispersive to dissipative nonlinear phenomena, as well as the original KK relation in the linear approximation.

By comparing the asymptotic expansion [14] and asymptotic expansions of the two KK relations obtained, one can derive four sum rules for the nonlinear susceptibility by following the usual procedure of imposing that their asymptotic behaviors coincide. They are the following:

$$\int_0^\infty \chi_1^{\mathrm{NL}}(\omega; \omega_2, E(\omega_2))\mathrm{d}\omega = 0$$
$$\int_0^\infty \omega \chi_2^{\mathrm{NL}}(\omega; \omega_2, E(\omega_2))\mathrm{d}\omega = 0$$
$$\int_0^\infty \omega^2 \chi_1^{\mathrm{NL}}(\omega; \omega_2, E(\omega_2))\mathrm{d}\omega = 0$$
$$\int_0^\infty \omega^3 \chi_2^{\mathrm{NL}}(\omega; \omega_2, E(\omega_2))\mathrm{d}\omega = C\frac{\pi}{2} \quad [18]$$

where C is given by [16]. The first two are analogous to the linear sum rules whose validity is thus extended to the optical response to all orders in the presence of a pump beam. The last two are typical of the nonlinear susceptibility. The last one, in particular, gives a measure of the strength of the nonlinear response through the value of the constant C.

Another simple sum rule gives immediately the nonlinear contribution of the pump field to the static susceptibility (limit $\omega \to 0$ in the KK dispersion relations)

$$\chi^{\mathrm{NL}}(0; \omega_2, E(\omega_2)) = \frac{2}{\pi} \int_0^\infty \mathrm{d}\omega' \frac{\chi_2^{\mathrm{NL}}(\omega'; \omega_2, E(\omega_2))}{\omega'} \quad [19]$$

Analogous sum rules can be obtained for all the nonlinear optical functions related to the susceptibility, as in the linear case.

It has been shown by Zimmermann that the sum rules given here are also valid when the expansion [1] in terms of the electric field does not converge, and the polarizability must be obtained in a non perturbative way, because the presence of the external field does not affect the short-time inertial character of the response function.

Examples and Applications

The Anharmonic Oscillator

One can display the relevance of the above-described sum rules by considering the simple, but physically significant anharmonic-oscillator case.

By solving the equation of motion with the probe frequency ω and the pump ω_2, the anharmonic contribution $\chi^{(3)}(\omega; \omega, \omega_2, -\omega_2)$ is obtained in the third order. The result is displayed in **Figure 1** as a function of the frequency of the probe beam, ω.

One can observe the modification of the absorption near the resonance ω_0 which is a dynamic Stark effect with a positive and a negative contribution; also a peak is present in correspondence to a two-photon absorption at $\omega_0 - \omega_2$ and another peak due to stimulated Raman absorption at $\omega = \omega_0 + \omega_2$.

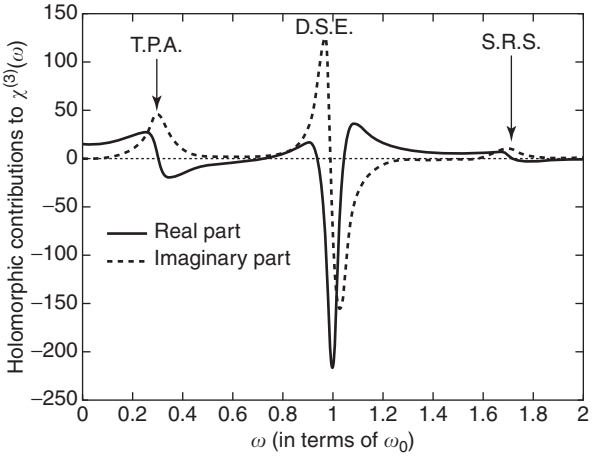

Figure 1 Nonlinear susceptibility of the anharmonic oscillator ($\omega_2 = 0.75\omega_0$.).

The sum rules [18] are all verified, but include contributions from all these effects and cannot be referred to a particular phenomenon on its own.

Analogous results are obtained from a quantum mechanical study of the oscillator, where however differences are found from the classical model in the nonlinear optical functions.

Three-Level System

The sum rules can be useful in the study of a system consisting of three levels, denoted with E_0, E_1, E_2, when the pump beam is nearly resonant with the transition between E_1 and E_2.

The two possible configurations in the three-level system are shown in **Figure 2**, and are called, respectively, the ladder and the lambda configurations. In both cases, the sum rules must be obeyed if no other levels are considered, and coherence effects must be included in studying the time dependence of the dipole moment of the system in terms of the density matrix ϱ_{ij}.

Using the Heisenberg equation for the time evolution of the density matrix and accounting for all the lifetime decay processes, one obtains in the lowest order

$$\chi^{(3)}(\omega,\omega_2,E_2) \simeq \varrho\left\{\frac{|\langle 1|ex|0\rangle|^2}{E_{10}-\hbar\omega-i\Gamma_1-\alpha_2^2/(E_{20}\pm\hbar\omega_2-\hbar\omega-i\Gamma_2)} + \frac{|\langle 1|ex|0\rangle|^2}{E_{10}+\hbar\omega+i\Gamma_1-\alpha_2^2/(E_{20}\pm\hbar\omega_2-\hbar\omega+i\Gamma_2)}\right\} \quad [20]$$

where the sign $+(-)$ refers to the ladder (lambda) configuration and $\alpha_2 = \langle 2|ex|1\rangle E_2/2$ is the Rabi frequency of the pump beam in energy units. The sum rules [18] can be immediately verified in both cases by observing that the asymptotic behavior of [20] is of order ω^{-4} as expected, and the constant C can be directly estimated.

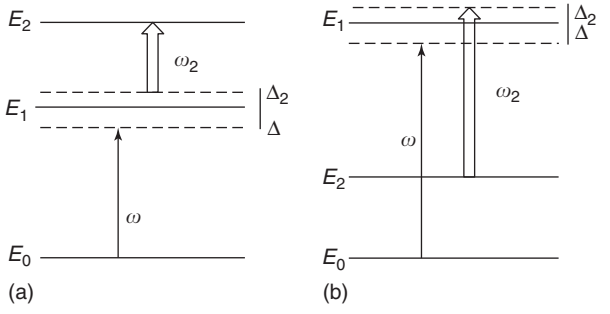

Figure 2 Three-level systems (a) in the ladder configuration or (b) lambda configuration, probe and pump beams are indicated by single and double arrows, respectively.

In the case of resonant ω_2, the typical results are given in **Figures 3** and **4** for large and small values of Γ_2, respectively. The nonlinear contributions become negative at resonance, and nearly cancel the absorption. Total transparency is obtained, when the lifetime $(\tau = (h/\Gamma))$ of level 2 is much longer than that of level 1, in particular when E_2 is a metastable state $(\Gamma_1 \gg \Gamma_2)$ and α_2 is sufficiently large. This phenomenon has been called coherent electromagnetically induced transparency (CEIT) (first observed by Alzetta *et al.* in 1976). It is of great interest because of its important applications. The CEIT effect has been so far observed in hot and cold atomic systems, but is now being studied also in solid-state materials. For

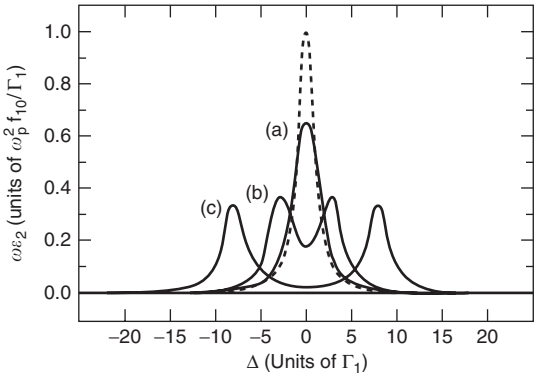

Figure 3 Probe absorption coefficient as a function of probe detuning for a resonant pump beam of increasing intensities: (a) $\alpha_2 = \Gamma_1$; (b) $\alpha_2 = 3\Gamma_1$; (c) $\alpha_2 = 8\Gamma_1$. Here, $\Gamma_2 = 2\Gamma_1$. The dotted line is the linear absorption. (From Scandolo S and Bassani F (1992) Nonlinear sum rules: the three level and the anharmonic oscillator models. *Physical Review B* 45: 5838.)

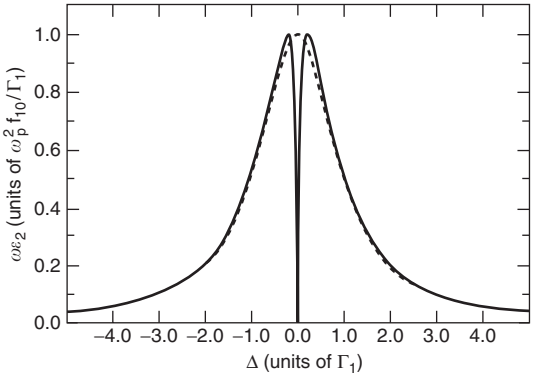

Figure 4 Probe absorption coefficient as a function of probe detuning for a resonant pump beam of moderate intensity $(\alpha_2 = 0.2\Gamma_1)$; here, $\Gamma_2 = 10^{-3}\Gamma_1$. The dotted line is the linear absorption. (From Scandolo S and Bassani F (1992) Nonlinear sum rules: the three level and the anharmonic oscillator models. *Physical Review B* 45: 5838.)

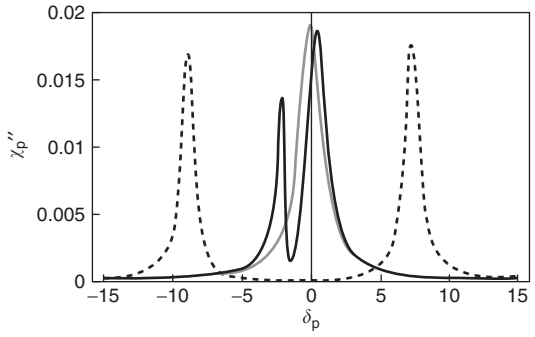

Figure 5 Imaginary part of the probe susceptibility as a function of probe detuning for slightly detuned pump beam of different intensities: $\alpha_2 = \Gamma_1$ (black solid line), $\alpha_2 = 8\Gamma_1$ (dashed line). Here, $\Gamma_2 = 0.1\Gamma_1$. The gray line is the linear absorption. (From Artoni M, Larocca GC and Bassani F (2000) Electromagnetic-induced transparency of Wannier–Mott excitons. *Europhysics Letters* (49): 445.)

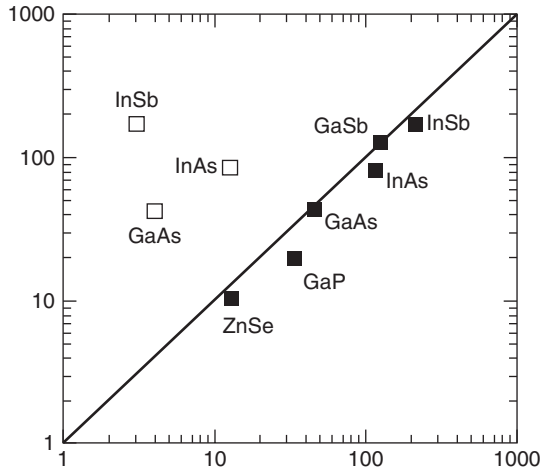

Figure 6 Second-order static susceptibility for some semiconductors. Abscissae: theoretical calculations in units 10^{-8} esu; ordinate; experimental data squares in units of 10^{-8} esu. (From Scandolo S and Bassani F (1995). Miller's rules and the static limit for second harmonic generation. *Physical Review B* 51: 6928.)

instance, **Figure 5** shows the computed absorption of a three-level system consisting of the ground state, the 1*s* metastable exciton, and 2*p* exciton in Cu_2O. These results can be seen as effects forced by the sum rules, which also have the effect of increasing the absorption away from the induced transparency in a way appropriate to verify them.

The EIT has important consequences in all phenomena related to propagation of light in dispersive media, because it produces hyperanomalous dispersion with a very large value of $dn/d\omega$. The most important effect observed is the reduction of the group velocity of light to extremely small values down to a few meters per second (slow light).

Second-Harmonic Generation

A further example of how the sum rules can be used to verify detailed theories, and to implement useful simplified models can be seen as an application to second-harmonic generation.

The quantum-mechanical calculation of $\chi^{(2)}(2\omega;\omega,\omega)$ is very complicated, because a knowledge of all excited states and a double summation involving all dipole matrix elements between them is required. A simple model is set up by considering an expansion about the main poles at ω_0 and $\omega_0/2$, ω_0 being the average frequency of the direct interband transitions in the semiconductors, which is also responsible for the static linear dielectric constant. Thus:

$$\chi^{(2)}(2\omega;\omega,\omega) = \frac{f_1}{\omega-\omega_0+i\varepsilon^+} + \frac{f_2}{(2\omega-\omega_0)+i\varepsilon^+} + \frac{f_3}{(\omega-\omega_0+i\varepsilon^+)^2} + \text{c.c}(\omega\rightarrow-\omega) \quad [21]$$

where ε^+ is a positive infinitesimal which can be set to zero. The coefficients f_i give the strength of the poles and substitute the detailed double sum of the dipole matrix elements. Imposing the sum rules, one can obtain expressions for all the coefficient f_i, in terms of the quantity C which appears in the 5th moment sum rule (see eqn [18]).

Taking the limit $\varepsilon^+ \rightarrow 0$, and expressing the first-order susceptibility in terms of the average transition frequency to the conduction band as

$$\chi = \frac{\varrho e_1^2}{m(\omega_0^2-\omega^2)} \quad [22]$$

one obtains Miller's empirical rule

$$\chi^{(2)}_{ijk}(2\omega;\omega,\omega) = \Delta_{ijk}\chi^{(1)}_{ii}(2\omega)\chi^{(1)}_{jj}(\omega)\chi^{(1)}_{kk}(\omega) \quad [23]$$

where Miller's empirical constant Δ is given by

$$\Delta_{ijk} = -\frac{1}{2e^3\varrho^2}\left\langle\frac{\partial^3 V}{\partial r_i \partial r_j \partial r_k}\right\rangle_0 \quad [24]$$

This can be easily computed for crystals from the pseudopotential theory, by means of the values of the pseudopotential parameters used in the energy band calculations. One can thus compute the static limit in a number of semiconductors and obtain values of $\chi^{(2)}(0,0)$ in good agreement with experiment, as shown in **Figure 6**.

A similar result can be obtained for third- and higher-order harmonic generation processes.

Data Analysis

The above described sum rules and KK relations can be also used to complete the experimental data available by imposing that they verify such general properties. This is particularly useful in nonlinear optics, where results on a limited frequency range are experimentally available, and only at a few fixed frequencies, both real and imaginary nonlinear susceptibilities are measured. For details on this, refer to the "Further reading" section.

Conclusions

It has been shown that the principle of time causality implies a number of KK relations between the real and the imaginary part of the nonlinear susceptibility and of all nonlinear optical constants. From them, a variety of sum rules can be obtained for the frequency moments of the real and the imaginary parts of the nonlinear susceptibilities. All frequency moments of the susceptibility vanish up to the highest integrable odd moment of the imaginary part of the susceptibility, which gives a value related to the density and to the expectation value of appropriate derivatives of the potential on the ground state.

The dispersion relations and the sum rules are shown to be useful to interpret experimental data and to verify the accuracy of the calculation models.

Superconductivity: Applications

D J Bishop, Bell Labs, Lucent Technologies, Murray Hill, NJ, USA

Introduction

In this section, what superconductivity is, why it is interesting from a scientific point of view, and why it has attracted the significant attention it has for applications will be discussed. This section shall lay the groundwork for the later detailed discussions of the applications of superconductivity.

The twentieth century was truly the century of the electron. At the beginning of the century, mankind had harnessed to a remarkable degree the power and benefits of machines of a great many kinds ranging from trains and cars to printing presses and steam engines. However, the electron was only beginning to be understood and used widely. However, by the end of the century we had computers, airplanes, cars, radios, TVs, EKG machines, and the Internet. None of these would have been possible without a century of extraordinary achievements in harnessing the use of the electron. However, in a century of remarkable discoveries, none is perhaps as revolutionary as the discovery of the effect called superconductivity.

One way to parametrize the nearly infinitely wide range of solid matter is by how well a given sample can carry electrical currents. At one end of the spectrum are metals such as copper, aluminum, gold, and silver that can carry electrical currents very well. These materials are conductors whose electrical resistivity is low. At the other end of the spectrum are materials that do not carry currents at all, called insulators. Examples of such insulating materials are glass, plastic, cloth, and paper. Typical electrical circuits of the kind found in homes for lighting consist of conductors – the wires (typically copper) and insulators (typically plastics) to keep the wires from making accidental connections. Despite the fact that many materials are good conductors, they all suffer from the disadvantage that the resistance is always nonzero. The resistance can be small but it is always finite for normal conductors. For example, when a house gets wired, the builder uses a large diameter wire to keep the losses small, but they are always

finite. In a house, these nonzero losses can be kept acceptably small. However, in an electric power station, these losses can be as much as 10% of the total power through the plant and represent a significant economic cost.

Before the discovery of the phenomenon of superconductivity, these losses found in normal conductors appeared to be inevitable. However, the discovery by Kamerlingh Ohnes in 1904 that below $\sim 4\,\mathrm{K}$ the resistivity of mercury drops to zero changed forever our view of electrical conduction in metals. This was one of the greatest scientific discoveries of the twentieth century, a century with many great discoveries. The discovery was the first and perhaps the finest example of condensed matter physics – the study of systems with many degrees of freedom.

The early superconductors, while scientifically very important, were impractical for use in any applied context. That is because they were what are now known as type I superconductors and these materials cannot carry any appreciable electrical currents or tolerate any sizable magnetic fields. At low temperatures type I superconductors exhibit what is known as the Meissner effect. In this remarkable effect, the magnetic field is completely expelled from the interior of the sample (not trapped, but completely expelled). However, this only works for relatively low fields (or small currents which is, in essence, the same thing) (see **Figure 1**). Typical fields that type I materials can tolerate are usually much less than 1000 G. This means type I materials are limited to use at low temperatures, low fields, and low currents which provide limited scope for applications.

The first type II superconductors were discovered by Shubnikov and co-workers in 1937. In these materials, there is also a Meissner state at low fields but there is also a new superconducting regime, a mixed state at higher fields. In this mixed state, the applied magnetic field enters the sample in the form of quantized lines of magnetic flux, magnetic vortices. This mixed state can survive to very high magnetic fields (and/or support large currents) and are the only practical superconductors. The discovery of the type II superconductors started the real search for applications for the phenomenon.

Figure 1 Magnetic levitation of a magnet about a YBCO sample.

Since the original discovery of superconductivity in mercury at 4 K, there have been literally thousands of other materials discovered with a wide range of transition temperatures (the temperature below which superconductivity occurs). However, the field of superconductivity was thrown into high gear in 1987 when a new class of materials was discovered by Bednorz and Muller, the so-called "High T_c Superconductors." These materials opened the way to the use of much less expensive cooling technologies such as liquid nitrogen ($\sim 77\,\mathrm{K}$) and closed-cycle refrigerators for cooling the materials. Much of the real work in finding applications for superconductivity was driven by the explosive growth in interest stimulated by the discovery of the high-T_c materials.

The basic phenomenology of superconductivity lends itself to application for three distinct reasons. The first is the characteristic that gives it its name, zero resistance or superconductivity. This allows conductors to be built that can carry very high current densities with, in principle, zero resistive losses and zero heating. The second phenomenon is that the materials superconduct because they are in a macroscopic quantum state that can be measured and exploited with such devices as a SQUID (described later). The third effect is that the transition into the superconducting state is what is called a phase transition or a change of state with a well-defined transition temperature such as the melting point of ice or the boiling point of water. This effect allows for applications in which the superconductor can be a very sensitive thermometer. All the applications of superconductivity discussed use one or more of these attributes to good advantage and none of these attributes can be found in conventional conductors such as copper or silver.

The final part of this introduction talks about a number of useful materials. While many thousands of superconductors have been discovered, only a few are used in practical applications. Useful materials not only need to have the characteristic of being superconductors, they also need many others as well. Additional needed characteristics include good metallic properties such as ductility, chemical stability, low thermal expansion, mechanical strength, low cost, ease of fabrication, nontoxicity, ease of joining, and others. When this long list of necessary characteristics is used to filter the many thousands of candidates, only a few are found to be practically useful. One of

the easiest and most useful materials is pure niobium. Thin films can be deposited and devices like SQUIDS and high-Q microwave cavities can be built. As a pure element, niobium is still very useful in a wide variety of applications. For wires, two alloys of niobium are widely used today. The first is NbTi and the second is Nb_3Sn. These materials are widely available commercially and still dominate the market despite 15 years of hard work on the high-T_c materials.

Among the newer, high-T_c materials, YBCO ($Y_1Ba_2Cu_3O_7$) and BSCCO ($(Bi,Pb)_2Sr_2Ca_2Cu_3O_x$ (Bi-2223)) are the materials of choice. They combine a reasonable combination of workable physical properties, extremely high critical magnetic fields (the maximum field at which they are still superconductors), and high critical currents (the maximum currents they can carry and still be superconducting). In general, the critical field is measured at very low currents and critical currents at very low applied fields and there is a tradeoff between the two quantities where finite fields lower the useful range of currents and finite currents lower the useful range of fields.

In the following sections, some of the nearly unlimited range of applications for these and other materials are discussed.

Power Generation/Transmission/Storage Applications

In this section, one of the most important application areas for superconductivity – electrical power generation and transmission – is discussed. The electrical power industry is one of the largest and most important industries in the US today. Indeed, without this industry, none of the others could exist. Currently, electrical power worth tens of billions of dollars is generated, stored, transmitted, and turned into useful work every day. The current system is the result of many years of work and is quite efficient, given the limitations of the real materials the engineers have at their disposal. The current system is roughly 90% efficient, a modern marvel. However, it is that last 10% which represents a vast economic payoff for superconducting technology.

Most power in the world is produced by large generators that are either hydroelectric (driven by the force of moving water) or steam (produced by geothermal, oil, coal, natural gas, or nuclear sources of heat). Generators consist of a rotor and a stator. Both have coils of wires. The stator is used to create a magnetic field that the rotor moves in. The rotor wires, when moved in the stator's field, have currents induced in them which is the current produced by the generator. Superconducting wires, because of their low losses in carrying electrical currents, can allow the generator to be smaller, lighter, and more electrically efficient than generators made using conventional conductors. Many such superconducting generators have been built and are nearing commercial deployment.

After generation, the electrical power must be transmitted to where it will be used. Most electrical power is sent around via the electrical power grid. This grid allows the power to be used a long way from where it is generated. In addition, the grid allows a more efficient process of supply and demand as peak demand periods move from east to west with the time zones. Also, the grid acts as a kind of buffer in case of scheduled or unscheduled outages in a particular generating station. The challenge of operating a power plant is that while the plant needs to be sized to handle peak loads and its cost is related to that peak capacity, the return to the investors is proportional to the average use of the plant. Therefore, a plant whose peak demands are much higher than the average demand is uneconomical to operate. The grid allows a much more efficient use of the country's generating capacity because power can flow to where it is needed, when it is needed, and average out the peak demands. Despite its evident value, sending electrical power long distances is neither cheap nor easy. The current way this is done is with high-voltage transmission lines that reduce the I^2R losses by increasing the voltage and reducing the currents that need to flow to send a given amount of power through the line. The current state of the art is million volt transmission lines. This is an important opportunity for superconductivity.

By building transmission lines using superconductors with very low losses instead of conventional conductors with a finite amount of loss, the efficiency of electrical transmission could be enhanced significantly. This has been an area of significant effort in the area of superconducting research for decades. Many trials have been done and with the advent of the high-T_c materials, the technology appears close to being ready for commercial deployment.

Another application for superconducting technology is in large crossbar switches used to protect and route the large currents generated and transmitted in the power grid. Superconducting switches, with their intrinsically low losses, offer a very cost-effective way to do this. In addition to using superconductivity to generate, switch, and transmit power, it can also be used for storage. The issue discussed above about the need to average out demand peaks also argues for the value of an efficient way to store large amounts of power. Power could then be generated during off-peak periods for use when the demand peaks and by doing this, the size

(and cost) of the plant could be reduced. As shown by Ohnes in his pioneering work on superconductivity, currents induced in superconducting loops can flow for very long times (almost infinitely long). Thus, large coils could store electrical power for long periods of time. Such large storage facilities are increasingly being envisioned for times in the not too distant future when the costs of fossil fuels rise as shortages appear.

Two final applications of superconductivity in the power plant in the longer term are the use of magneto-hydro-dynamics (MHD) and in fusion reactors. MHD generates power by having ions flow past low loss conductors inducing large electric fields and hence currents. Low losses associated with superconductivity make MHD technology feasible to install and use. Also, as will be discussed later, there is much basic research in building fusion reactors where atoms such as hydrogen are joined as opposed to fission where heavy atoms such as uranium or plutonium are split apart. The fusion reaction is expected to allow an unlimited amount of clean, cheap power. Such plants are quite likely to use strong superconducting magnets to contain the reactions in much the same way they are used today for the research experiments.

To sum up, there are many places in the generation, transmission, switching, and storage of electrical power where the low electrical losses allowed by using superconducting technology will drive many applications. Early field trials and tests have been completed for many of these devices and full-scale deployment is not too far off.

Medical- and Health-Related Applications

Another massive industry in the US is health and medical. Close to a trillion dollars a year is being spent in the pursuit of long and healthy lives for all the planet's inhabitants. One of the most important tools used in hospitals today for diagnostic imaging is MRI or magnetic resonance imaging. This technique uses the fact that many atoms have a magnetic spin that can be resonantly excited with RF coils in a magnetic field. By applying both a uniform field and a field gradient, density maps of the various atoms can be made in a living organism. These can be used to see with remarkable clarity bones, blood vessels, organs, and other structures within a living human body. The physics of the technique is such that the higher the field the better the signal-to-noise of the image and the better the spatial resolution. This is a perfect application for superconducting wires which enable very high field magnets to be made.

Figure 2 An MRI machine in operation. (Siemens press picture. Reproduced from Siemens AG, Munich/Berlin.)

A typical magnet may generate fields 20 000 times the earth's field in a magnet the size of a small car. The patient is usually placed on a belt that moves them into and out of the field while the image is being taken (**Figure 2**). Another place where superconductors are often used in such systems is in the RF coils used to excite the relevant magnetic atoms. The lower electrical losses of such coils give better signal-to-noise in a typical MRI system. Today MRI is being used for everything from routine hospital diagnostics to the study of how the human brain functions – not so much what you are thinking but where you are thinking.

In MRI systems superconductors are being used to generate very large magnetic fields. A completely different and new application is to use them to sense very small magnetic fields. The device is called a SQUID or superconducting quantum interference device. A SQUID uses the unique properties of the superconducting state itself – it is a macroscopic quantum state that can be "phase shifted" by the application of a small magnetic field. A typical SQUID is a ring structure with a weak link and induced currents that flow in the ring are periodic with the applied field. Such devices can sense fields in the picogauss range. The medical application for such devices is to sense the magnetic fields associated with flowing blood, magneto-cardiography, and magnetic fields associated with flowing currents in the brain, magneto-encephalography. In both cases it is possible to image defects that other techniques cannot, providing useful diagnostic information. In the brain imaging case, it is possible to find the source of localized defects that can cause tremors and, when localized, excise them noninvasively using a gamma knife. Such systems are being used in field trials today and will soon be deployed widely.

Clearly the use of superconductivity in medicine is already a large and growing industry and given the graying of the US population, shows no signs of slowing down.

Military and Homeland Security Applications

The military applications of superconductivity are as varied and important as the commercial possibilities. These application areas range from large devices such as motors and generators to microscopic ones such as would be found in a sensor network. Clearly, the military applications are well appreciated and much DOD funding has gone into superconductivity research.

For ships and submarines there are many applications for large motors and generators. Aboard ships and especially submarines, size and weight are important considerations. The same features that make superconducting motors appealing in a commercial power station make them useful on a ship or sub. The fact that superconducting wire allows for higher current densities over conventional conductors makes it possible to build smaller, lighter, and higher performance motors and generators even when the cooling plant needed for superconducting motors is taken into account.

Another area attracting attention in the military world are superconducting rail guns. A rail gun uses very high currents in an applied magnetic field to impart large velocities to projectiles, usually much greater than could be obtained with conventional explosives. In fact, rail guns are envisioned as being able to put small objects into orbit, something that cannot presently be done with a conventional, single-stage explosive shell.

The ability to use superconductivity to store large amounts of power in a compact way may be applied to military laser systems. For many applications such as missile defense, very high-power lasers are needed. Generally, these are pulsed systems which require large amounts of power for short periods of time. For the same reasons as in a commercial power plant, superconductivity may be the technology of choice for this application.

A final application area discussed here are SQUID sensor networks. Described earlier, a SQUID can be configured to allow very small magnetic fields to be sensed. Devices and networks of such devices are currently being used to sense everything from submarines in the deep ocean to perimeter defense in a tactical situation.

High current densities and sensitive magnetic field detection are but two of the characteristics that make superconductivity an appealing technology that will be applied in military and homeland security areas.

Electronic Applications for Superconductivity

The world as we know it has been changed beyond all recognition by the relentless progress in electronics. Everything from computers to air travel would be impossible without microelectronics and silicon VLSI. This progress in electronics has been well described by Moore's law, the observation that transistors get a factor-of-two smaller, cheaper, and faster every 18 months. However, it is clear that this trend cannot go on for much more than another decade or so. The race is on for what can replace conventional silicon VLSI. For high-end computing applications where the cooling will not be a problem, superconducting electronics is being actively pursued.

In conventional electronics one of the things that makes it difficult to scale transistors into the deep submicron regime is the heat they generate as they switch at high speeds. As wires, gates, sources, and drains all get smaller, the current densities they must work at get larger and this heat limits both performance and lifetime. Superconducting electronics allows one to use both switches and interconnects that dissipate much less power than their conventional counterparts. They then allow a much faster, higher-performance operation for the chip. A number of high-end superconducting processing systems have been built and made commercially available and more can be expected in the next decade or so.

Another aspect of superconductivity and computing that go naturally together is the concept of quantum computing. In quantum computing, the q-bits (the analog to the classical bit) obey the rules of quantum mechanics, not classical mechanics. For certain classes of problems such as factoring large numbers, quantum computers are expected to be much faster than conventional ones. While the theory of such computers is progressing well, the experimental work has proceeded much more slowly. One of the experimental challenges is to find systems where the quantum coherence occurs over large enough distances and for long enough times for real circuits to be built and tested. One of the best candidates for such systems are networks of Josephson Junctions built from superconducting materials. While work in this area is at an early stage, it appears likely that if a practical quantum computer is ever built, it will use superconductors for its practical implementation.

In the area of microwave electronics, superconductors have found a number of unique application areas. For microwave systems filters play a crucial role allowing the entire available electromagnetic spectrum in a given band to be used. Filters using superconducting films have properties superior to conventional filters and are beginning to be deployed in both military and commercial RF systems. Superconductors are also being used as both microwave detectors/mixers and microwave sources. As detectors and mixers, they are currently state-of-the-art in terms of sensitivity and noise and are widely used in microwave astronomy applications. As sources, they are being used as frequency standards in high-precision applications.

The economic value of high-end electronic computing is large and it is clear that as we get to the end of the Moore's law curve, superconductivity will play an ever-increasing role.

Applications of Superconductivity in Transportation

Transportation is one of the major needs any civilized society has to provide for its citizens. However, it is clear that the current arrangement of personal cars powered by fossil fuels is destined to be replaced by more efficient mass transportation. One of the leading candidates for efficient, fast, and convenient mass transportation is magnetically levitated trains or MAGLEV trains. Such trains use superconducting magnets to create large magnetic fields to levitate the train so that wheel friction is absent making the trains faster, lighter, and much more power efficient. They literally glide on a layer of magnetic field like the suspended magnet shown in **Figure 1**. Such trains are being actively developed with a number of large-scale field trials having been completed. Work in this area in Japan is particularly advanced. It is clear that in the next decade or so superconducting MAGLEV trains will enter commercial service.

Other application areas for superconductivity in transportation include large motors and generators for ships, subs, and trains and storage devices for use in clean vehicles. In particular, when a train or car stops, it turns all of the kinetic energy generated by the motor into heat. An efficient storage device such as a superconducting storage ring would allow one to convert that kinetic energy into energy usable to start the car or train moving again. Significant fuel efficiencies would result from such a system.

Superconductivity will play an important role in providing safe, inexpensive, and fast transportation in the coming decades.

Scientific Applications of Superconductivity

The business of science is a place where superconducting technology is already being widely applied. In many places, state-of-the-art measurements are being done in ways that are only possible with superconducting devices. This is then the cutting edge of applying superconducting technology.

One of the largest-scale deployments of superconducting technology is for high-energy particle accelerators. These machines apply large magnetic fields at just the right time to accelerate charged particles to nearly the speed of light. Superconductors allow for much higher fields, lower costs, smaller sizes, and better performance than anything a conventional conductor could achieve. Devices such as the TEVATRON at Fermi Lab and RICK at Brookhaven could not have been built without superconductivity.

Another key area of scientific research is in MRI imaging. For example, in functional brain imaging, the large magnetic fields that can only be attained using superconductors allow brain scientists to gain fundamental insights into how the brain works. MRI is both a key research tool as well as a key diagnostic tool used in most hospitals in the US today. NMR of complex molecules is another important scientific field which would be impossible without superconductivity.

Another area of scientific research is the use of large research magnets built using superconducting wires. Fields as high as 45 T can be obtained allowing everything from work on the quantum Hall effect to superconductivity itself to be studied.

As mentioned earlier, fusion research uses high-field superconducting magnets to generate the magnetic fields needed to contain the hot plasmas created during the fusion process. At the other end of the field spectrum, devices such as SQUIDS are being used to do precision measurements on things ranging from the magnetization of new materials to gravity wave detectors. Superconducting devices are also being used to create a new class of particle detectors that work as sensitive bolometers where the particle, when absorbed by the detector, heats up the detector and this change in temperature is sensed by an edge detector which is a superconducting film biased to be just at the transition to normal conduction; Mose resistance, therefore, is very sensitive to small changes in temperature.

The art of scientific measurement relies heavily on superconducting technology and this provides a kind of testing ground for later, large-scale commercial applications of the technology. The extensive use of such technology in science makes it clear that large-scale commercial applications are on their way.

Miscellaneous Applications of Superconductivity

The numerous applications already discussed by no means exhausts the list of active areas of superconducting development. Superconducting technology is being used to create very sensitive gravity detectors for use in prospecting for oil and gas.

Magnetic separation is another area of considerable commercial importance. These devices allow the separation of materials with differing responses to a magnetic field such as aluminum and iron alloys. In practice, a stream of particles is shot through the magnet and their trajectory is determined by their response to the applied magnetic field. The potential commercial value of such devices is very large as we increasingly focus on recycling materials as opposed to creating new ones in our manufacturing processes.

Conclusions and the Future

It should be clear that the range of potential applications for superconducting technology is truly vast. This article, being limited in scope, has only begun to scratch the surface of what is being done and what will be done in terms of applications. In almost every area of human commercial activity, superconductivity will play an important role. Power generation and transmission, transportation, electronics, military systems, scientific research, and health and medicine are some important examples but by no means exhaust the list. While superconductivity was discovered in the twentieth century, the twenty-first century will see an amazing range of applications for the technology developed and deployed. It will be an exciting time for both scientists and engineers working in the field.

Superconductivity: BCS Theory

K H Bennemann, Freie Universität Berlin, Berlin, Germany

Introduction

For many years superconductivity has remained one of the most interesting phenomena in physics. After its discovery by Kamerlingh–Onnes in 1911, many superconductors have been found, see **Figure 1**. The recent discovery of MgB_2 as a superconductor with a transition temperature $T_c = 39\,K$ suggests that further surprises can be expected in the future. The basic interdependence of superconductivity and lattice structure still needs to be understood. **Figure 2** shows the transition temperature of some interesting metals.

Some of the cornerstones in the history of superconductivity were the observation of (1) a vanishing electrical DC resistivity $\rho(T)$ at T_c, (2) the magnetic behavior exhibiting type-I superconductors expelling magnetic flux (Meissner–Ochsenfeld), and type-II superconductors where quantized magnetic flux can penetrate in filaments, (3) the isotope effect, $T_c \propto M^{-\alpha}$, for example, $\alpha \approx 0.5$ for Hg, suggesting that the electron–phonon coupling might be responsible for superconductivity, and (4) Josephson tunneling with an electronic current $j = j_0 + j_1 \sin(\Delta\varphi - (2e/\hbar)\, V_{21} t)$, where $\Delta\varphi$ is the phase difference and V_{21} the voltage between two superconductors 1 and 2. There are many additional interesting observations including the occurrence of a gap in the electronic density of states (DOS), gapless superconductors and the interdependence of atomic structure and T_c, seen in particular in layered structures, granular superconductors, etc.

Most important theories developed for a physical understanding of the superconductivity phenomena were: (1) the London theory in 1935 explaining the Meissner–Ochsenfeld effect by using for the superconducting current driven by the vector potential $\boldsymbol{A}$ the expression $\boldsymbol{j}_s = -(c/4\pi\lambda_L^2)\boldsymbol{A}$, with the penetration

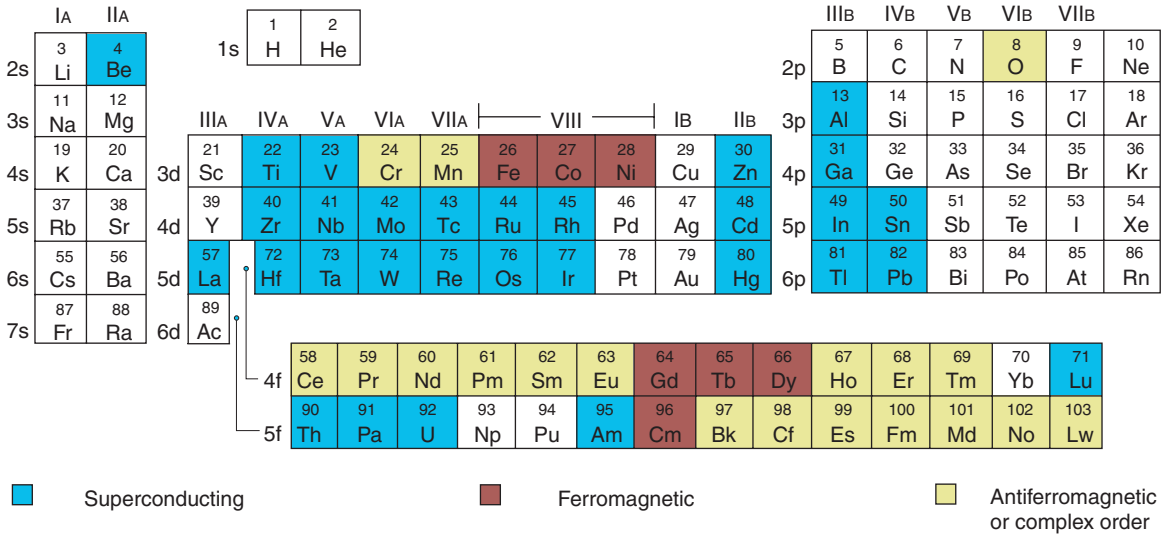

Figure 1 The occurrence of superconductivity in the periodic table is illustrated. As the history of superconductivity shows, alloys and compounds of the elements play an important role.

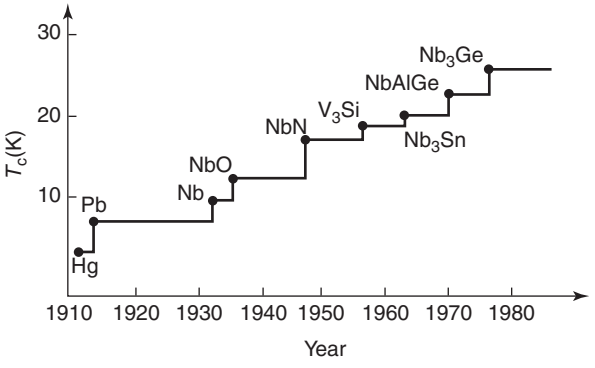

Figure 2 History of the transition temperature T_c for the first 70 years following the discovery of superconductivity in 1911. The A-15 compounds were of particular interest in the search for higher T_c superconductors.

depth $\lambda_L = (mc^2/4\pi e^2 n_s)^{1/2}$, where n_s is the superfluid density. (2) the Ginzburg–Landau (GL) theory in 1950, which extended the London theory by writing the free energy in terms of an order parameter $\psi(\boldsymbol{r}, t) = |\psi| e^{i\varphi(r)}$ as

$$F = F_0 + \int d^3r \left\{ a|\psi|^2 + \frac{1}{2} b|\psi|^4 + \frac{\hbar}{2m^*} \left| \left(\nabla - \frac{ie^*}{\hbar c} \boldsymbol{A} \right) \psi \right|^2 + \frac{h^2}{8\pi} \right\} \quad [1]$$

yielding the current via minimization with respect to ψ (or ψ^*):

$$\boldsymbol{j}(\boldsymbol{r}) = -\frac{ie^*}{2m^*} \left\{ (\psi^* \nabla \psi - \psi \nabla \psi^*) - \frac{e^{*2}}{m^* c} |\psi|^2 \boldsymbol{A}(\boldsymbol{r}) \right\} \quad [2]$$

(3) In 1956, the Bardeen–Cooper–Schriefer theory (BCS) deriving superconductivity from an electronic Hamiltonian $H = H_0 + H_{eph}$, where H_{eph} describes the electron–phonon interaction. It is to be noted that eqn [2] immediately yields the Meissner effect, by assuming that the superconducting wave function is rigid and is not affected by an electromagnetic field (thus, the first term in eqn [2] is zero), and for $\psi = |\psi| e^{i\varphi(r)}$ ($\psi\psi^* \sim n_s$ and φ are conjugate variables). The Josephson tunnel current between two superconductors 1,2 (with phase and voltage difference $\Delta\varphi$, ΔV) is given by

$$j_J = j_0 \sin\left(\Delta\varphi - \frac{e^*}{\hbar} \Delta V t \right) \quad [3]$$

Here,

$$\Delta\phi = \varphi_2 - \varphi_1 + \frac{2\pi}{\phi_0} \int_1^2 \boldsymbol{A} \cdot d\boldsymbol{l}$$

$$j_0 = \frac{e^* \hbar}{m^* d} |\psi|^2 \quad (m^* = 2m,\ e^* = 2e)$$

and d is a parameter referring to the tunnel junction, $\phi_0 = \hbar c/2e$. Assuming the single-valuedness of ψ, one obtains the quantization of flux trapped (in a filament) in a superconductor (see gauge transformation ψ):

$$\phi = \phi_0 \left(n + \tfrac{1}{2} \right), \quad n = 0, \pm 1, \ldots \quad [4]$$

These are remarkable general results which hold for different possible mechanisms causing condensation of a Fermi liquid into a superconducting state.

The BCS theory is one of the most elegant theories in physics and effectively explains superconductivity resulting from Cooper-pairs ($\boldsymbol{k}\uparrow$, $-\boldsymbol{k}\downarrow$) for electrons

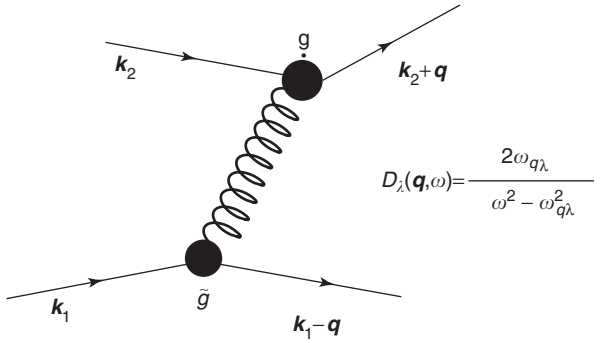

Figure 3 Illustration of the interaction between electrons with k_1 and k_2 via exchange of a phonon with polarization λ, wave vector q and energy $\omega_{q\lambda}; \omega \simeq \varepsilon_{k_1-q} - \varepsilon_{k_1}$; then an attractive effective electron–electron interaction $g^2 D < 0$ results, if $\omega < \omega_{q\lambda}$. $\tilde{g} = g\Gamma$, where Γ denotes many-body corrections to the electron–phonon coupling g ($\tilde{g} \simeq g$; see Migdal theorem).

with opposite spin and momentum k at the Fermi surface. As illustrated in **Figure 3**, the exchange of virtual phonons yields an attractive interaction and thus, a singlet Cooper pairing. This pairing causes a gap in the single-electron DOS, reflecting the binding energy of the Cooper pairs, $\Delta = \Delta(T, h, \ldots)$. The theory correctly predicts the behavior $\Delta(T = 0) \propto T_c$ and some other thermodynamical and electrodynamical quantities.

Following the BCS theory, the quantum field theory using the Green's function method, in particular by Gor'kov *et al.*, gave the theory of superconductivity a very elegant form. In general, for phase transitions (ferromagnetism, etc.), the superconducting state cannot be obtained from the normal state by using the perturbation theory. That the electron–phonon interaction described in second-quantization notation by

$$H_{\text{eph}} = \sum_{k,k',\lambda} g_{kk'\lambda} c_{k'}^{+} c_k + \cdots \qquad [5]$$

is responsible for superconductivity was suggested early by Fröhlich and others and explains, for example, the isotope effect. The electron–phonon coupling constant is given by

$$g_{kk'\lambda} = \sum_{i,\alpha} \left(\frac{\hbar N_\alpha}{2\omega_{q\lambda} M_\alpha} \right) \langle k' | \nabla_i U_{i\alpha} | k \rangle \times \mathscr{E}_{q\lambda}(\alpha) e^{iq\cdot\rho_\alpha^0} \qquad [6]$$

where $U_{i\alpha}$ is the potential of the ion i, α and $\mathscr{E}_{q\lambda}$ are the lattice polarization vectors. Since, as illustrated in **Figure 3**, emission and absorption of phonons by electrons at the Fermi surface can lead to an effective attractive interaction, it seemed possible that Cooper pairing ($k\uparrow$, $-k\downarrow$) occurs for electrons within an energy shell of $2\omega_D$, where ω_D is the Debye frequency. On general grounds, one expects, for an attractive potential with a range of the order of the interatomic distance ($a \sim p_F^{-1}$), due to the Pauli principle, singlet pairing and pairing of k and $-k$ electrons to avoid kinetic energy of the Cooper pairs and thus to obtain maximal condensation energy. To avoid the destructive repulsive electron–electron interaction, the pairing results from a retarded potential. The electron $k\uparrow$ polarizes the lattice for a time of the order of $t \sim \omega_D^{-1}$, which is slower than the electron motion, and then the other electron $-k\downarrow$, arriving at the polarized lattice within that time might feel an effective attractive electron–electron interaction due to over-screening. The resultant binding energy 2Δ causes a correlation and coherence length of the order of $\xi \sim v_F/2\Delta$. It is to be noted that Coulomb fields are screened at a distance of the order of the interatomic distance. This analysis and the study by Cooper, showing that for electrons at the Fermi surface the pair wave function $\psi = \sum_{k \sim k_F} a_k e^{ik\cdot\rho}$, $\rho = r_1 - r_2$, lowers the energy ($(H_0 + V)\psi = E\psi$ and $V < 0$), gave a more definite clue that the Cooper pairing of the electrons within an energy shell of the order of $2\hbar\omega_D$ causes superconductivity.

Cooper pairing is the essence of the electronic BCS theory, which gives the microscopic justification of the phenomenological Ginzburg–Landau theory. Its formulation was achieved with the help of quantum field theoretical methods.

BCS Theory

The BCS theory begins by using the Hamiltonian

$$H = \sum_{k,\sigma} \xi_k n_{k\sigma} + \sum_{k,k'} V_{kk'} a_{k\uparrow}^{+} a_{-k\downarrow}^{+} a_{-k'\downarrow} a_{k'\uparrow} + \cdots \qquad [7]$$

with excitation energies $\xi_k = \varepsilon_k - \mu$ for electrons near the Fermi energy (μ is the chemical potential) and the effective interaction $V_{kk'}$ between electrons with wave vector k and $-k$ and spin $\uparrow$ and $\downarrow$. Note that the remaining interactions between the electrons are assumed to be included in the energies $\xi_k . a_{k\sigma}^{+}$ and $a_{k\sigma}$ are the usual creation and annihilation operators for fermions with k and spin σ, and $n_{k\sigma}$ is the occupation operator. The BCS theory uses the wave function

$$|\psi\rangle = \prod_k (u_k + v_k a_{k\uparrow}^{+} a_{-k\downarrow}^{+}) |\psi_0\rangle, \quad |u_k|^2 + |v_k|^2 = 1 \qquad [8]$$

to calculate the free energy. The ground state is $|\psi_0\rangle$. $|v_k|^2$ gives the probability of a pair ($k\uparrow$, $-k\downarrow$). The diagonalization of H is most elegantly achieved by the

Bogoliubov and Valatin canonical transformations

$$b^+_{-k+} = u_k a_{-k\downarrow} + v_k a^+_{k\uparrow}, \quad b_{k-} = u_k a_{k\uparrow} - v_k a^+_{-k\downarrow}, \quad u_k^2 + v_k^2 = 1 \qquad [9]$$

which introduce new fermion operators $b_{k\sigma}$, $b^+_{k\sigma}$. Due to isotropy, the coefficients u_k, v_k depend only on k and can be chosen to be real and such that, for a given entropy the electronic energy E is minimal. Then one gets straightforwardly (with $V_{kk'} = -g/V$)

$$E = 2\sum_k \xi_k v_k^2 + \sum_k \xi_k (u_k^2 - v_k^2)(n_{k\uparrow} + n_{k\downarrow}) - \frac{g}{V}\left(\sum_k u_k v_k (1 - n_{k\uparrow} - n_{k\downarrow})\right)^2 \qquad [10]$$

and, from $\partial E/\partial u_k = 0$, the result

$$2\xi_k u_k v_k = \Delta_k (u_k^2 - v_k^2) \qquad [11]$$

Here, using $v_k^2 + u_k^2 = 1$ and eqn [9], the order parameter ($\Delta_k \propto \langle a_{k\uparrow} a_{k\downarrow} \rangle$)

$$\Delta_k = \frac{g}{V}\sum_k u_k v_k (1 - n_{k\uparrow} - n_{k\downarrow}) \qquad [12]$$

has been introduced. The order parameter can be expressed as

$$\Delta_k = \frac{g}{V}\sum_{k'} \frac{\Delta_{k'}}{2\mathscr{E}_{k'}} \tanh(\mathscr{E}_{k'}/2k_B T), \quad \mathscr{E}_k = \sqrt{\xi_k^2 + \Delta_k^2} \qquad [13]$$

It is of interest to note that eqn [13] has solutions not only for attractive interaction (with $g > 0$), but possibly also for repulsive ones with $g < 0$. Then the k dependence of Δ_k is important.

The new quasiparticle energies are $\mathscr{E}_k = (\mathrm{d}E/\mathrm{d}n_k)_{u_k, v_k} = \sqrt{\xi_k^2 + \Delta_k^2}$. Their distribution function is $n_k = (\mathrm{e}^{\mathscr{E}_k/kT} + 1)^{-1}$. These quasiparticles contribute to the energy the term $\sum_k \varepsilon_k n_{k\sigma}$. It is to be noted that $2\Delta_k$ is the binding energy of the correlated electrons $k\uparrow$, $-k\downarrow$. Thus, the coherence length $\xi = \hbar v_F/2\Delta$ gives the correlation distance, for most conventional superconductors, a much larger value than the interatomic distance ($\hbar/p_F$).

Note that for an isotopic gap $\Delta_k = \Delta$ one gets

$$1 = \frac{g}{V}\sum_k \frac{1}{2\sqrt{\xi_k^2 + \Delta^2}} \tanh\left(\frac{\mathscr{E}_k}{2k_B T}\right) \qquad [14]$$

and from this, for $\Delta(T)$, the expression

$$\Delta(T) = 3.2 k_B T_c \left(1 - \frac{T}{T_c}\right)^{1/2} \qquad [15]$$

The superconducting transition temperature T_c follows from $\Delta(T_c) = 0$. Thus, ($\sum_k \to \int_{-\omega_D}^{\omega_D} \mathrm{d}\varepsilon$, $\omega_D \propto M^{-1/2}$)

$$T_c \simeq 1.14\hbar\omega_D \mathrm{e}^{-1/(N(0)g)} \propto M^{-1/2}, \quad 2\Delta(T=0)/k_B T_c = 3.52 \qquad [16]$$

As shown by McMillan, Garland, Bennemann and others, eqn [16] needs to be improved to calculate realistic T_c values for simple metals, transition metals, A-15 compounds, alloys, etc., and to understand the interdependence of superconductivity and atomic structure better. Taking into account more details of the electron–phonon coupling, the phonon spectrum, the retardation of the pairing potential, and the remaining repulsive electron–electron interaction ($\propto \mu^*$, pseudo-Coulomb potential), one gets the McMillan equation:

$$T_c \simeq \frac{\omega_D}{1.45} \exp\left(-\frac{1.04(1+\lambda)}{\lambda - \mu^*(1 + 0.62\lambda)}\right), \quad \lambda = 2\int_0^\infty \mathrm{d}\omega \frac{\alpha^2(\omega) F(\omega)}{\omega} \qquad [17]$$

Here, the effective coupling constant λ depends on the DOS, $N(0)$. First $\lambda \propto N(0)$, then λ saturates and decreases again as $N(0)$ increases such as in transition metals. Note that $\lambda = (m^*/m) - 1$. Typically $\mu^* \approx 0.1$, but μ^* may also change strongly near magnetic instabilities.

The DOS for the quasiparticles is given by

$$N_s(\varepsilon) = N_n(0) \frac{\varepsilon}{\sqrt{\varepsilon^2 - \Delta^2}} \qquad [18]$$

This follows from the one-to-one correspondence of old and new quasiparticles, $N_s(\varepsilon)\mathrm{d}\varepsilon = N_n(\xi)\mathrm{d}\xi$. For the thermodynamic potential Ω, which is the appropriate function for a system with given μ, all thermodynamic properties can be calculated using the formulas

$$\left.\frac{\partial \Omega}{\partial g}\right|_{T,V,\mu} = -V\frac{\Delta^2}{g^2}, \quad \Omega_s - \Omega_n = \int_0^\Delta \mathrm{d}\Delta\, \Delta^2 \frac{\mathrm{d}(1/g)}{\mathrm{d}\Delta} \qquad [19]$$

This gives, in particular at T_c, the specific heat (**Figure 4**)

$$c_s - c_n \simeq \frac{4 m p_F}{7\xi(3)\hbar^3} T_c, \quad c_s(T) \propto \mathrm{e}^{-\Delta_0/T} \qquad [20]$$

where $\xi(x)$ is the Riemann–Zeta function, $V = 1$. To obtain the behavior in electromagnetic fields, one uses the recipe $\boldsymbol{p} \to \boldsymbol{p} - e\boldsymbol{A}/c$, $\boldsymbol{p} \to -\mathrm{i}\hbar\nabla$, where $\boldsymbol{A}$ denotes the vector potential ($\boldsymbol{A} = \sum_q \boldsymbol{a}_q \mathrm{e}^{\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}}$). This

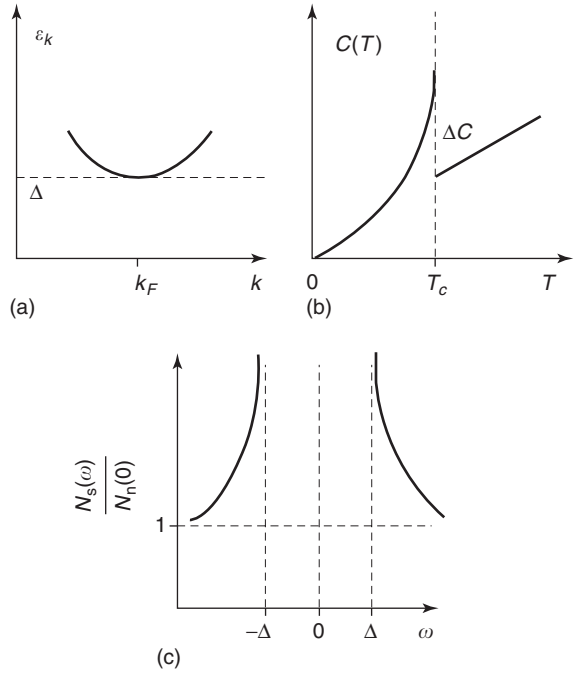

Figure 4 Illustration of (a) the gap Δ in the elementary excitation spectrum, (b) the jump $(C_S/C_n)_{T_c} = 2.43$ in the specific heat, and (c) the electronic DOS.

yields the coupling

$$H_{\text{int}} = \frac{ie\hbar}{2mc}\sum_k (\boldsymbol{v}_k \cdot \boldsymbol{A} + \boldsymbol{A} \cdot \boldsymbol{v}_k)$$
$$= -\frac{e\hbar}{mc}\sum_{k,q} \boldsymbol{k} \cdot \boldsymbol{a}_q c^+_{k+q\sigma} c_{k\sigma} \qquad [21]$$

Here, the spin is unchanged, since $\boldsymbol{A}$ couples dominantly to the orbital motion of pairing electrons. (Note that $\boldsymbol{q} \cdot \boldsymbol{a} = 0$ for tranversal fields.) Thus, one obtains, as in the GL theory for the electric current due to $\boldsymbol{A}$ ($\boldsymbol{j} = en\boldsymbol{v}$) for Cooper pairs ($m \to 2m$, $e \to 2e$):

$$\boldsymbol{j} = -\frac{ne^2}{me}\boldsymbol{A} + \boldsymbol{j}_2 \qquad [22]$$

where the paramagnetic current is $\boldsymbol{j}_2 = e\hbar/m \sum_{k,q} \boldsymbol{k} a^+_{k-q} a_k$, which would vanish if the superconducting wave function ψ is rigid, that is, not affected by $\boldsymbol{A}$.

It is to be noted that, since n_s is the density of Cooper pairs, the first term gives the famous London equation:

$$\boldsymbol{j}_L = -\frac{n_s e^2}{mc}\boldsymbol{A} = -\frac{c}{4\pi\lambda^2}\boldsymbol{A},$$
$$\lambda^2 = \frac{mc^2}{4\pi e^2 n_s} \qquad [23]$$

Hence, by determining the penetration depth λ of an external magnetic field $\boldsymbol{h}$ into a superconductor, one may calculate the superfluid density n_s, an important quantity reflecting whether all electrons at the Fermi surface pair. Evidently, if $\xi > \lambda$, eqn [22] gives the Meissner effect. Using the response theory,

$$\boldsymbol{j}_q = -\frac{c}{4\pi} K_q \boldsymbol{a}_q \qquad [24]$$

where $K_q = \lambda^{-2}(1 + \lambda^2 K'_q)$ and K'_q is calculated within the BCS theory.

The two characteristic length scales ξ and λ suggest that there exist two types of superconductors characterized by $K = \lambda/\xi$. As shown by Abrikosov, they correspond to types I ($\kappa < 1/\sqrt{2}$) and II ($\kappa > 1/\sqrt{2}$). Superconductors of type I repel an external magnetic field, which however may penetrate via an array of quantized flux filaments into type-II ones. For these, one expects vortex lines with $\Delta \simeq 0$ around them. The superconductor compromises both effects in order to profit from the Cooper-pair condensation energy and the magnetic field energy. It is to be noted that the formation of a vortex costs an energy of the order $(\xi h^2/8\pi)$ due to a variation of $\Delta(\boldsymbol{r})$ or the wave function ψ, and reduces the (diamagnetic) field energy by about $(\lambda h^2/8\pi)$. **Figure 5** characterizes the behavior of superconductors in an external magnetic field. From the general formula for the free energy,

$$F_s = F_n - \frac{h^2}{8\pi} \qquad [25]$$

assuming no field penetration into the superconductor, one gets a critical magnetic field H_{c1} below which a pure Meissner superconductor is present. Above H_{c1}, the magnetic flux ϕ (around vortices) may penetrate until $H_{c2} = \phi/\pi\xi^2$ (ϕ = flux of area $(\pi\xi^2)$). As already noted, the flux ϕ is quantized due to the macroscopic phase of the superconductor as a whole. Note that for fields h such that $H_{c1} < h < H_{c2}$ one gets a mixed state, with $H_{c2} = \sqrt{2}KH_{c1}$. Surfaces may favor Cooper-pair condensation. Then there exists another critical field h_{c3} above which superconductivity at the surface is destroyed ($H_{c3} \simeq 1.7H_{c2}$).

Obviously, strong magnetic fields may also affect Cooper pairing by destroying the singlet state. This is of relevance for the interdependence of superconductivity and magnetism in antiferromagnets or ferromagnets. As a result of internal molecular fields acting on the electron spins, one may get a spatially inhomogeneous superconducting state, $\Delta = \Delta(\boldsymbol{k}, \boldsymbol{r})$, and then again a compromise to profit from both Cooper pairing energy and magnetic energy.

The spin–orbit coupling and scattering by local spins (paramagnetic impurities) also affect the singlet pairing. Scattering by paramagnetic impurities with spins via exchange coupling (J), $H_{ex} = -\sum_i J\boldsymbol{S}_i \cdot \sigma$, will, of course, weaken the singlet Cooper pairing. The

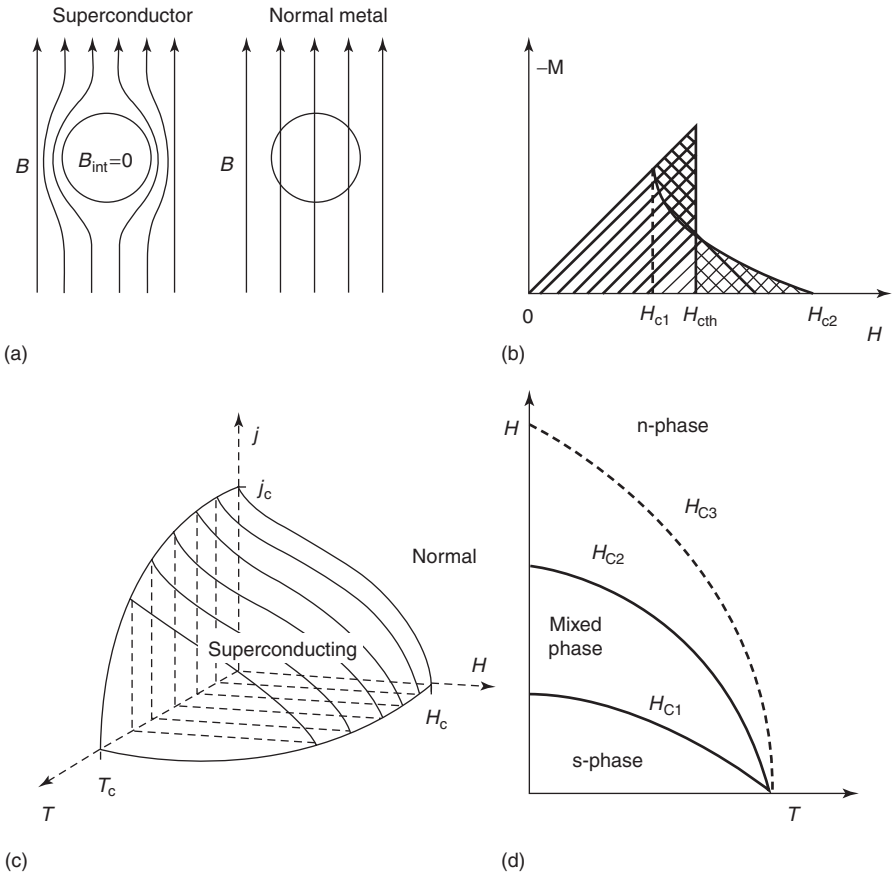

Figure 5 (a) Meissner-effect for type-I superconductors where, below the superconducting transition temperature T_c, the magnetic flux B is abruptly expelled; (b) Typical behavior of type-II superconductors, where, below B_{c2}, the flux penetrates, and perfect Meissner-effect behavior occurs below B_{c1}; (c) dependence of type-I superconductor on B and j and (d) temperature dependence of critical magnetic fields. At H_{c3} surface superconductivity disappears, $B = H + 4\pi M$.

interesting analysis by Abrikosov and Gorkov yields

$$\ln\frac{T_c}{T_{co}} = \psi\left(\frac{1}{2}\right) - \psi\left(\frac{1}{2} + \frac{\hbar}{4\pi\tau}\frac{1}{T_c}\right) \qquad [26]$$

where τ is spin scattering time and $\psi(x) = \Gamma'(x)/\Gamma(x)$ is the digamma function. The discovery of gapless elementary excitations was unexpected. The effects on the singlet superconducting state due to spin-mixing via spin–orbit coupling and spin-flip scattering via exchange interaction are observed through the temperature dependence of the Knight shift $K(T)$, for example, and cause $K > 0$ for $T \to 0$. Clearly, the spin splitting of the Fermi surface for spin $\uparrow$ and $\downarrow$ electrons also weakens pairing of k and $-k$ electrons.

For a better understanding of the phonon and electron dynamics due to H_{eph}, one can use the Hamiltonian $H = H_0 + H_{eph} + H_{el}$, where H_0 refers to phonons and electrons in the absence of H_{eph}, and H_{el} to the electron–electron interactions. The dynamic field operators ψ, ψ^+, and φ are treated on the same level. This yields renormalizations of both phonon and electron excitations. The physical situation is illustrated in **Figure 6**. Then one obtains a frequency-dependent complex superconducting order parameter $\Delta(\omega)$ and, for the DOS (see **Figure 7**),

$$N_S(\omega) \sim \mathrm{Re}\frac{\omega}{\sqrt{\omega^2 - \Delta^2(\omega)}} \qquad [27]$$

Using matrix Green's functions, the Nambu notation $\psi_k^+ = (c_{k\uparrow}^+ c_{-k\downarrow})$, and Matsubara frequencies, one gets for $\mathscr{G} = -\langle T_\tau \psi_k(\tau)\psi_k^+(0)\rangle$, and similarly for $\mathscr{D}(q,\tau)$, the Dyson equations shown in **Figure 6** where

$$\mathscr{G} = \begin{pmatrix} G & F \\ F^+ & \tilde{G} \end{pmatrix}, \quad \mathscr{G}_0 = \begin{pmatrix} G_0 & 0 \\ 0 & \tilde{G}_0 \end{pmatrix}, \quad \mathscr{D} = \begin{pmatrix} D & 0 \\ 0 & \tilde{D} \end{pmatrix}$$

One gets (for $D \equiv (\mathrm{i}\omega_n Z)^2 - (\varepsilon_k + \xi)^2 - \phi^2$, $\omega_n = (2n+1)\pi T$)

$$G(\boldsymbol{k}, \mathrm{i}\omega_n) = \frac{(\mathrm{i}\omega_n Z + \varepsilon_k + \xi)}{D}, \qquad F = \frac{\phi(\boldsymbol{k}, \mathrm{i}\omega_n)}{D} \qquad [28]$$

for the electron (G) and Cooper pair Green's function (F), respectively. Note that $D = 0$ yields the elementary excitations and $\Delta = \phi/Z$ the order parameter

$Z \simeq 1$. After continuation to the real axis, one obtains

$$\Delta(\omega) = \frac{N(0)}{Z(\omega)} \int_{\Delta_0}^{\omega_c} d\omega' \, \mathrm{Re} \frac{\Delta(\omega')}{\sqrt{\omega'^2 - \Delta^2}} \times (K_{ph} - U_c), \quad (T \to 0) \qquad [29]$$

with $U_c = V_c/(1/N(0)V_c \ln(\omega_m/\omega_0))$ due to electron–electron interactions, ($\omega_m \sim \varepsilon_F$, ω_0 – cutoff parameter) and (from phonon spectrum $B_\alpha(q, z)$)

$$K_{ph} = \sum_\alpha \int_0^{2k_F} \frac{dg\, q}{2k_F^2} \int_0^\infty dz \, B_\alpha(q,z) |g_{q\alpha}|^2 \times \left(\frac{1}{\omega' + \omega + z - i\delta} + \frac{1}{\omega' - \omega + z - i\delta} \right) \qquad [30]$$

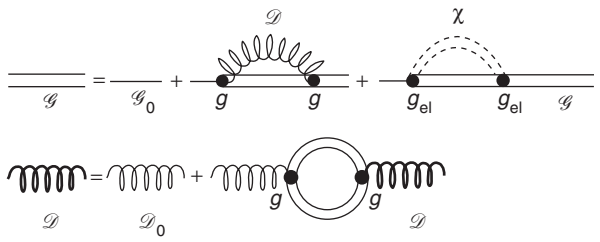

Figure 6 Illustration of the dynamics of the coupled electron and phonon systems using Feynman diagrams and thermodynamic matrix Green's functions $\mathscr{G}$, $\mathscr{D}$ (Eliashberg, McMillan type theory). The graph(= = =)refers to an additional electron–electron interaction and also to spin excitations (and impurity scattering) (g = eph., g_{el} = el−el.).

These equations are the essence of the Eliashberg-type theory (McMillan) and produce, for a simplified phonon spectrum, the results obtained by Scalapino, Schrieffer, and Wilkins (SSW) shown in **Figure 7**. This analysis is of utmost significance, since it shows definitely that for BCS-type superconductors the electron–phonon coupling causes Cooper pairing. Note that phase-coherent Cooper pairs occur at T_c. The phonon frequencies are

$$\omega_q^2 \simeq (\omega_q^0)^2 + 2\omega_q^0 \frac{|g_g|^2}{V_c(q)} \left(\frac{1}{\mathscr{E}(q,\omega)} - 1 \right) \qquad [31]$$

where $\mathscr{E}(q,\omega)$ is the dielectric function. Presumably, the Dyson equation illustrated in **Figure 6** also applies if $\mathscr{D}$ is replaced by the Green's function of spin excitations, the dynamical spin susceptibility $\chi(q, i\omega_n)$, or of other modes that possibly cause Cooper pairing. **Figure 6** describes not only singlet, but also triplet Cooper pairing such as in He^3, and also suppression of Cooper pairing due to magnetic interactions; see "Further reading" section. Superconductivity in different materials, for example, isotropic lattices, layered lattice structures, nanostructures, and amorphous metals can be described adequately by taking into account details of the coupling constant $g_{kk'\lambda}$ and its renormalization due to vertex corrections (Ward identities) (**Table 1**).

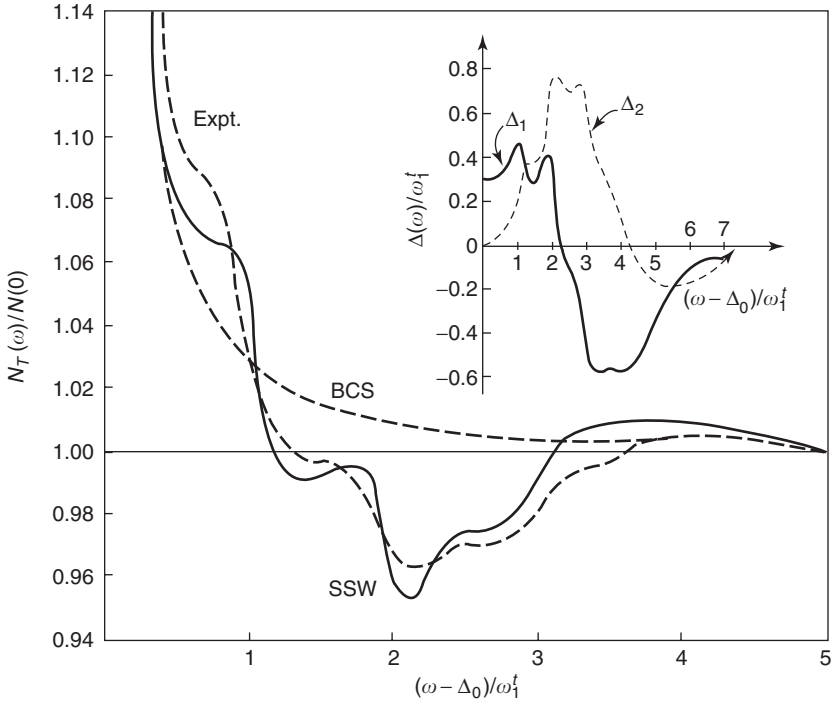

Figure 7 Tunneling DOS with structure due to electron–phonon interaction. Also $\Delta(\omega) = \Delta_1 + i\Delta_2$ is given (ω^t: phonon frequency).

Summary and Outlook

Both BCS theory and its extension including dynamical effects yielding the Abrikosov–Gorkov and Eliashberg theory explain superconductivity resulting from electron–phonon coupling. It still remains a challenge to calculate T_c from first principles and its dependence on atomic structure, lattice instabilities, and magnetic activity.

Changes in the atomic structure affect the phonon spectrum and the coupling constant $g_{q\lambda}$ and T_c, Δ, etc., as observed for disordered and amorphous metals. In transition metals and alloys thereof with large $N(0)$, one may attempt to relate T_c to the cohesive energy, since $g \sim \langle \nabla t_{ij} \rangle \sim t$, where t_{ij} is the hopping integral for electrons. Similarly, for transition metal alloys A_xB_{1-x}, the different bonds (AA, AB, and BB) may play a role in determining $\Delta(x)$ and $T_c(x)$. For this, the BCS theory has been extended by Bennemann and co-workers, using the coherent-potential approximation. In case of strong anisotropy of the lattice structure as in layered structures, one may expect approximately two coupling constants g_i ($g_i \sim \nabla t_i \cdot e$), different critical fields H_{c2}^{a-b}, H_{c2}^{c} and two gaps ($i \simeq \pi, \sigma$, $a-b$ in plane, $c \perp a-b$)

$$\Delta_i Z_i \simeq \pi T \sum_{l,m} \frac{\lambda_{il} - \mu_{il}^*}{\sqrt{\omega_m^2 + \Delta_l^2(m)}} \Delta_l(m) \qquad [32]$$

Figure 8, shows the results for MgB_2. Note that hybridization of π, σ electrons gives a common T_c.

The interplay of magnetism and superconductivity suggested already by the occurrence of superconductivity in the periodic table is, for several reasons, of utmost interest. This has, for example, been studied for (film) structures $N_1|N_2|N_3$. Results are given in **Figure 9**.

Organic superconductors display, in particular, interesting dimensional structural effects and those due to charge-wave and magnetic instabilities. Also, astonishingly, superconductivity may be induced by strong magnetic fields. In **Figure 10** the interesting phase diagram of κ-(BEDT-TTF)$_2$-Cu[N(CN)$_2$]Br, a typical composition of a charge-transfer salt, is

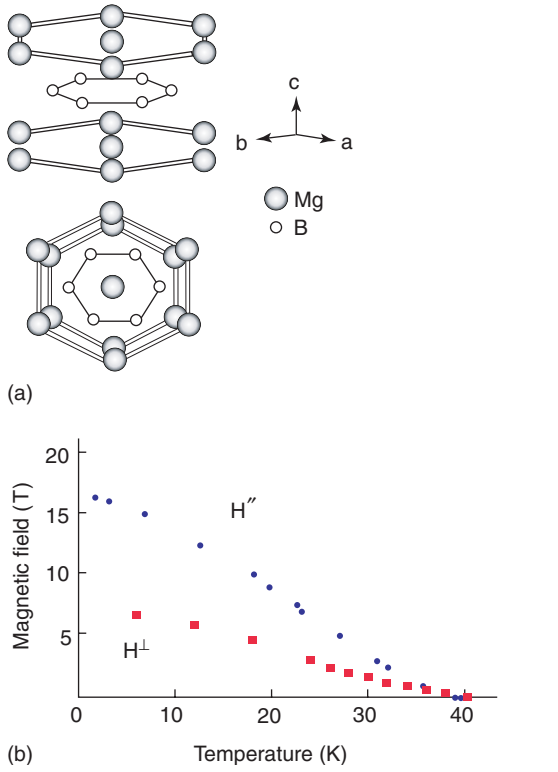

Figure 8 (a) Structure of MgB_2 (AlB_2, etc.). The boron planes seem to play an important role regarding superconductivity and Cooper pairing. The Mg–B bonds are softer than the B–B ones. (b) Critical upper magnetic fields $H''_{c2}(T)$ and $H^{\perp}_{c2}(T)$ referring to the B-planes and direction perpendicular to it, respectively. The anisotropic behavior of $H_{c2}(T)$ suggests two-gap behavior.

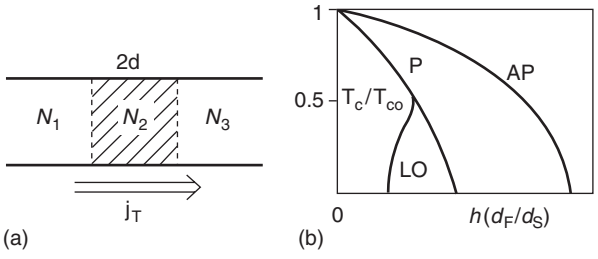

Figure 9 (a) Illustration of a tunnel junction $N_1/N_2/N_3$, where N_i may refer to singlet and triplet superconductors and to normal-state metals, including ferromagnets. The tunnel current j_T may refer to single electrons or Cooper pairs and transport of charge and spin. Depending on the thickness, $2d$, of the tunnel medium proximity effect and Andreev reflection at S/N interfaces plays a role. (b) Phase diagram of a (F_1/S/F_3) sandwich. S refers to a singlet superconductor and F_1,F_3 to ferromagnets with parallel (P) or antiparallel (AP) orientation of their magnetization. LO is the Larkin–Ovchinnikov phase, h the exchange field and T_c and T_{co}, the superconducting transition temperature in the presence and absence, respectively, of the exchange field. d_F and d_S refer to the thickness of the ferromagnetic and superconducting film, respectively.

shown. Such molecules are stacked into layers. Planes of Cu[N(CN)$_2$]Br anions separate these layers. Within these layers, the molecules form dimers and electrons or holes can then hop easily from one

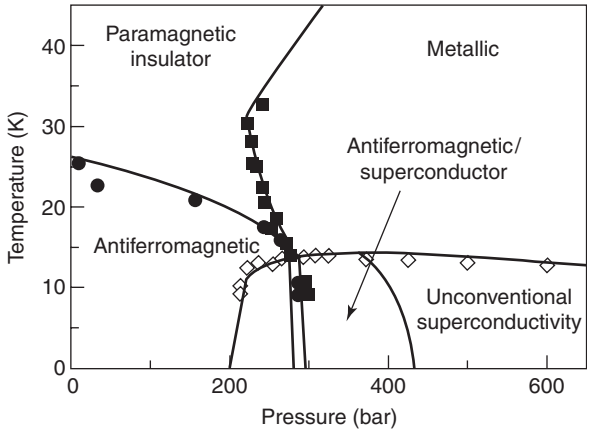

Figure 10 Phase diagram of κ-(BEDT-TTF)$_2$ Cu[N(CN)$_2$]Br, an organic superconductor, from AC-susceptibility and nuclear magnetic resonance.

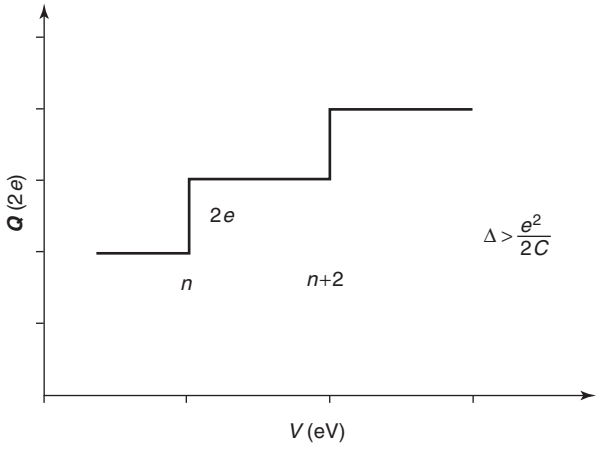

Figure 11 Charging-up behavior of a small superconductor with capacitance C and charge $Q = en$, n even, in a potential V ($\Delta > e^2/2C$). This behavior follows from $E_n = E_{n+2}$ and reflects Cooper pair formation. One also has $E_n = E_{n+1} + \Delta$, where E_{n+1} refers to a state with one unpaired electron. Then Q changes by e at $\Delta V \propto (2n+1)$.

molecule to the next one, but not perpendicular to the layers. The salts consist of conducting layers separated by a nonconducting enviroment (anions). Clearly, bond-length changes, also due to pressure, will sensitively change the electrical properties. Also, a magnetic field perpendicular to the layers (along the *c*-axis) affects the system due to the formation of Landau levels, which will pass the Fermi energy as the external magnetic field varies (cf. de Haas–van Alphen oscillations). In stronger magnetic fields quantum mechanical interband tunneling also occurs. Note that superconductivity occurs at relatively low temperatures, usually upon applying pressure. Experiments indicate unconventional Cooper pairing ($2\Delta_0 \sim 7k_B T_c$, non-*s*-symmetry of $\Delta_{\boldsymbol{k}}$). Whether phonons are involved in Cooper pairing must be clarified by further analysis.

In an external magnetic field, interesting behavior, such as Landau-level formation and spin-split bands, may result due to the layered structure. Possibly, Cooper pairs ($\boldsymbol{k}\uparrow$, $-\boldsymbol{k}+\boldsymbol{q}\downarrow$) may form. A Larkin–Ovchinnikov (LO) state with $\Delta_{\boldsymbol{k}} \sim \cos(\boldsymbol{kr})$ may occur. In general, the response to an external magnetic field is highly anisotropic. Furthermore, it is interesting that superconductivity may be induced in λ-(BETS)$_2$FeCl$_4$ by a magnetic field h, which destroys long-range magnetic order of the Fe^{3+}. Field-induced superconductivity may also occur in α-(BEDT-TTF)$_2$KHg(SCN)$_4$ by affecting the charge density-wave (CDW) with the external magnetic field h. Further experiments are needed; however, rich behavior may be expected in general, since CDW and SDW excitations, Landau levels, and 2D properties are present.

Superconductivity in small particles (radius R) due to electronic level discretisation ($\delta_2 \approx \mathscr{E}_F/n \approx (\hbar v_F/R)(k_F R)^{-2}$, $\xi \sim (R\delta/kT_c)(Rk_F)^2$), and charge fluctuations, $Q = en \leftrightarrow Q \pm e$, as a result of single electron and Cooper pair hopping, exhibit interesting behavior.

The charging of small particles is controlled by electrostatic energy. The change of the charge $Q = en \rightarrow Q \pm 1$ causes an energy change $e^2/2C$, where C is the capacitance of the small particle, leading to a Coulomb blockade (in tunneling, for example). At temperatures $T \simeq 0$, due to the electrostatic energy, it is ($\Delta Q = e\Delta n$)

$$E_n = \frac{Q^2}{2C} - \frac{Q}{C} C' V \qquad [33]$$

(C, C' are capacitances of a system including voltage contact and V is the external potential), and the blockade is periodically lifted as a function of n and V ($E_{n+1} = E_n$). In the superconducting state, one has for $T \simeq 0$ that $\Delta > e^2/2C$. The situation is illustrated in **Figure 11**. From $E_{n+1} + \Delta = E_n$ and $E_{n+2} = E_n$, n even and large sea of Cooper pairs, a period doubling results, with respect to the normal state. Note that the equation $E_{n+2} = E_n$ might not hold for smaller density of Cooper pairs. In view of the strong quantum-mechanical behavior of small particles, structures consisting of a larger number of small particles seem very interesting (mesoscopic systems).

An ensemble of grains for illustration may exhibit transitions to superconductivity at T_{c1}, where the single grains get superconducting, and at T_{c2}, where the whole ensemble becomes superconducting ($T_{c2} \leqslant T_{c1}$) globally and phase coherently; see **Figure 12**. Generally, an ensemble of grains may resemble an alloy-like array of S/S and S/N junctions (S = superconducting, N = normal state grains). The behavior of an ensemble of grains depends, of course,

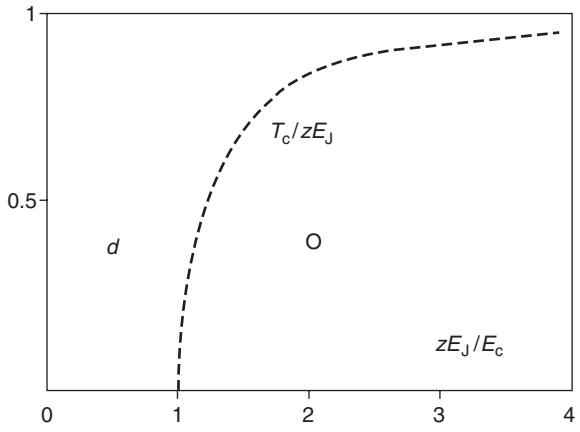

Figure 12 Transitions in an ensemble of superconducting quantum dots controlled by the Josephson-energy E_J and the Coulomb-energy $E_c = e^2/2C$. T_c refers to the global superconducting transition temperature of the ensemble. Phase O refers to a globally ordered superconducting state of the ensemble and phase *d* to superconducting grains with no global Cooper pair phase coherence, z is the coordination number.

on the coupling and electron hopping between the grains. Also the structural order of the grains plays a role. A regular lattice-like arrangement of the grains (one-dimensional or two-dimensional topology) is of particular interest. For small distances between the cluster particles, electron tunneling and inelastic Cooper pair tunneling (Josephson coupling) occur. Hence, charge fluctuations are present in such granular superconductors. The resultant interesting Josephson effect can be described by

$$H = H_T - \sum_{i,j} E_g(i,j)\cos\Phi_{ij} + \frac{2e^2}{C}\sum_{i,j}(N_i - N_j)^2 + \cdots \qquad [34]$$

The first term refers to normal electron hopping between the grains, the second term to Cooper-pairs tunneling between neighboring superconducting grains (Josephson effect), and the last term is the electrostatic energy due to different charges of neighboring grains i, j. For simplicity, the same capacitance C and E_J (Josephson energy) are used. The phase difference $\Phi_{ij} = \Phi_i - \Phi_j$ refers to the phases Φ_i of the superconducting order parameter $\Delta_i = |\Delta_i|e^{i\Phi_i}$ of grain i. It is important to note that $[\Phi, N] = i$, where N is the Cooper-pair number operator.

In conclusion, BCS superconductivity has been discussed. While the basis of the BCS theory is well developed, details of the physics may have interesting consequences that have not been understood yet. New important discoveries can be expected. The relationship of phase-coherent and, in particular, phase-incoherent Cooper-pairing with the Bose–Einstein condensation (BEC) is of fundamental interest. One expects, in particular, for more local pairing, perfect boson behavior of the two paired electrons and thus an intimate relationship between Cooper pairing and BEC. Meissner-type superconductivity and BEC should result only for phase-coherent Cooper pairing.

Superconductivity: Critical Currents

A Gurevich, University of Wisconsin, Madison, WI, USA

Introduction

The superconducting state exists at temperature T below the critical temperature T_c and magnetic fields below the upper critical field $H_{c2}(T)$. A superconductor can carry any weakly dissipative current of density J smaller than the critical current density $J_c(H,T)$, in the region of the H–T–J phase diagram as shown in **Figure 1**. Both the critical current density $J_c(H,T)$ and the irreversibility field $H^*(T) < H_{c2}(T)$ at which $J_c(H)$ vanishes are essential parameters invaluable for applications of superconductors in power transmission lines, magnets for medical magnetic resonance imaging systems, etc. This article gives a background to the basic mechanisms of critical currents, which are determined not only by the physics of vortices in superconductors but also by complex multiscale defect structures of superconducting materials.

There are two types of superconductors, which exhibit very different mechanisms of current transport. In the type-I, superconductors represented mostly by pure metals, such as Al, Pb, and Sn current can only flow in a narrow surface layer, due to the magnetic flux expansion and the ideal diamagnetism of the superconducting state (Meissner effect). Once the magnetic field generated by the transport current I on the sample surface exceeds the "thermodynamic critical field" H_c, a type-I superconductor switches into a resistive state at the critical current $I_c = 2\pi R H_c$ (for a round wire of radius R). However, many superconducting alloys, intermetallic and cuprate high-T_c layered compounds are type-II superconductors, which can carry bulk nondissipative currents in a wide magnetic field range above the "lower critical field" H_{c1}, but below the "upper critical field" H_{c2}. Critical currents of type-II superconductors in the mixed state at $H_{c1} < H < H_{c2}$ are determined by the pinning of vortices by various defects of the crystalline structure. Because the upper critical fields H_{c2} of many compounds can reach very high values $\sim 20 - 100$ T, it is the high-field type-II superconductors, which are of interest in power and magnet applications. The current-carrying capability of type-II superconductors is determined by multiple mechanisms on very different length scales: from the nanometer scales set by the size of vortex cores to the micrometer and larger scales, which define the scales of current flow in polycrystals. An optimum defect structure can, in principle, be produced by appropriate treatment of the material.

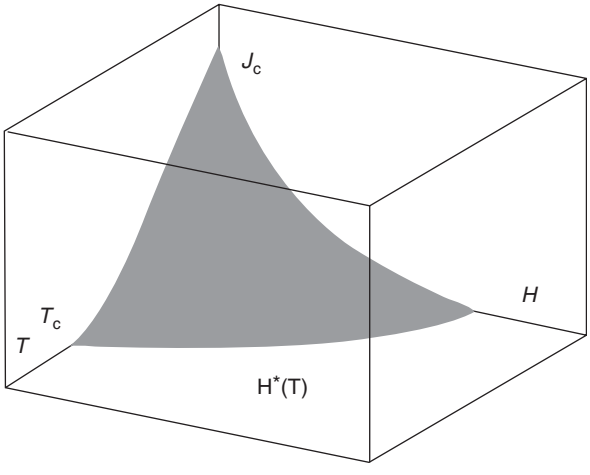

Figure 1 Typical $J_c(T,B)$ surface which defines the region $J < J_c$ on the H–T diagram where a superconductor can carry weakly dissipative currents.

Elementary Pinning Mechanisms

Under equilibrium conditions, magnetic flux penetrates into the bulk of a type-II superconductor above the lower critical field $H_{c1}(0) \sim 10-20$ mT for many high-field materials. At $H > H_{c1}$, this magnetic flux exists in the form of a hexagonal lattice of quantized vortex lines. Each vortex is a tube of radius of the London magnetic penetration depth $\lambda(T)$, in which screening currents circulate around a small nonsuperconducting core of radius $\xi(T)$, where the coherence length $\xi(T)$ at $T = 0$ quantifies the size of the Cooper pairs. Bulk vortices exist if the Ginzburg–Landau parameter $\kappa = \lambda/\xi$ exceeds $2^{-1/2}$, as characteristic of many superconducting compounds, especially such extreme type-II superconductors as Nb_3Sn or layered high-T_c cuprates with $\kappa = 20-100$. The flux produced by screening currents in a vortex equals the flux quantum $\phi_0 = 2.07 \times 10^{-15}$ Wb, so the vortex density $n = B/\phi_0$ is proportional to the magnetic induction B. Bulk superconductivity is destroyed when the normal cores overlap at the upper critical field, $H_{c2}(T) = \phi_0/2\pi\mu_0\xi^2(T)$. In isotropic superconductors such as Nb–Ti and Nb_3Sn, vortex lines are continuous, but in anisotropic layered high-T_c compounds, such as $Bi_2Sr_2Ca_2Cu_3O_x$ and $Bi_2Sr_2CaCu_2O_x$, vortex lines consist of stacks of weakly coupled "pancake" vortices whose circulating

currents are mostly confined within the superconducting CuO_2 planes.

Superconductors can carry bulk currents if there is a macroscopic vortex density gradient (or bending of vortices in thin films) defined by the Maxwell equation $\nabla \times \boldsymbol{B} = \mu_0 \boldsymbol{J}$. This gradient can only be sustained by pinning the vortices (flux pinning) at microstructural defects. Flux pinning is determined by spatial perturbations of the free energy of the vortex lines due to local interactions of their normal cores and screening currents with these microstructural imperfections. In addition, the vortex structure is subjected to the Lorentz force $\boldsymbol{F}_L = \boldsymbol{J} \times \boldsymbol{B}$ of the macroscopic current density $\boldsymbol{J}$. The critical current density $J_c(T, B)$ is then defined by the balance of the pinning and Lorentz force $J_c(T, B)B = F_p(T, B)$, where F_p is the volume pinning force produced by pinning defects in the strongly interacting array of flux lines. Ideally, a type-II superconductor can carry any nondissipative current density J smaller than J_c. If J exceeds J_c, a superconductor switches into a dissipative vortex flow state driven by the Lorentz force. Flux pinning sets the upper limit to J_c, which itself cannot exceed the depairing current density J_d, the maximum current density circulating near the vortex cores:

$$J_c = \frac{\phi_0}{3\sqrt{3}\pi\mu_0\lambda^2\xi} \qquad [1]$$

Pinning defects can be classified by their spatial extent and/or by mechanisms of the elementary pinning forces f_p between vortices and defects. These defects can be either randomly distributed point pinning centers, such as nanoscale nonsuperconducting precipitates and oxygen vacancies in high-T_c superconductors, or defects extended along vortex lines (grain boundaries, dislocations or columnar radiation tracks). In turn, elementary pinning interactions can be either due to a short-range interaction of the vortex cores with point defects, or due to a more long-range magnetic interaction with extended planar defects. The core pinning results from the gain in the superconducting condensation energy as the core crosses a defect, the strongest pinning force corresponding to defect sizes $\sim\xi$ (see **Figure 2**). Magnetic pinning results from the deformation of vortex screening currents near a planar defect on the scale $\sim\lambda$, as shown in **Figure 3**. The magnetic pinning force $f(x) = \phi_0^2/4\pi\mu_0\lambda^2 x$ can be rather strong if the distance x between the vortex and the defect is smaller than the interaction length $l = \phi_0/2\pi\mu_0\lambda^2 J_b$. Here, $l < \lambda$ is the distance from the vortex core at which the circulating current density $J(x)$ equals the maximum current density J_b which can pass through the defect.

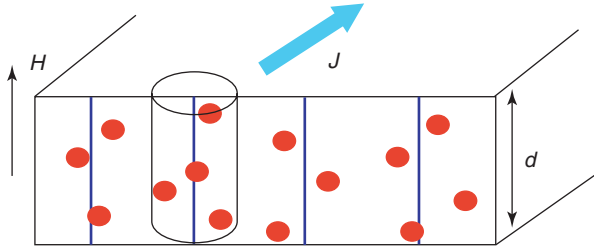

Figure 2 Pinning of vortex cores (vertical lines) by uncorrelated defects (dots) in a film of thickness d in a magnetic field H. The cylindrical region around the vortex cores depicts the region of circulating screening currents.

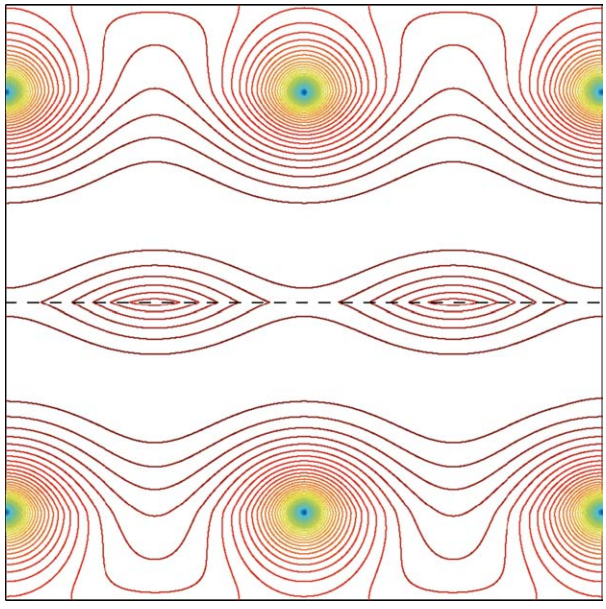

Figure 3 Deformation of vortex current streamlines near a planar defect. If the distance between normal cores of bulk vortices and the defect is smaller than the magnetic interaction length $l = \phi_0/2\pi\mu_0\lambda^2 J_b$, vortices are attracted strongly by the defect. Vortices localized on the defect have no normal cores, which turn into extended regions of length l along the defect in which the superconducting gap is not suppressed by circulating vortex currents. These elongated vortices on the defect have a highly anisotropic pinning force, which is maximum for J parallel to the defect and minimum for J perpendicular to the defect.

Identification of the most effective pinning defects in a particular superconductor is a difficult problem. The best information about the limits to flux pinning in practical superconductors is obtained from extensive studies of Nb–47%Ti, in which strong pinning by a dense ~20–25 vol.% lamellar structure of nonsuperconducting α-Ti ribbons ~1 nm (0.2ξ) thick can produce a J_c that approaches 5–10% of J_d at zero field and 4.2 K. The flux pinning mechanism is also known for Nb_3Sn, in which J_c is determined by the magnetic interaction of vortices with grain boundaries. These materials have zero-field J_c values, which can exceed 1 MA cm^{-2} at 4.2 K. Details of flux pinning

Table 1 Parameters of some type-II superconductors

Material	T_c (K)	$\lambda(0)$ (nm)	$\xi(0)$ (nm)	H_{c2} (T)	H^* (T)	J_d (4.2 K) (MA cm^{-2})	J_c (MA cm^{-2})
Nb–Ti	9	240	4	12 (4.2 K)	10.5 (4.2 K)	36	~0.4 (5 T, 4.2 K)

interactions in high-T_c superconductors are largely unknown, partly because ξ is so small that practically any atomic-size defects such as oxygen vacancies can pin vortices. The critical temperature of high-T_c superconductors is extremely sensitive to the carrier (hole) density, which is in turn determined by local oxygen nonstoichiometries, so that even a weak hole-depletion at crystalline defects can locally drive a high-T_c superconductor into an antiferromagnetic insulator. The proximity of the high-T_c superconducting state to the metal–insulator transition, the *d*-wave pairing symmetry, the very short in-plane coherence length $\xi(0) = 1.5-2$ nm and the much longer Debye screening length $l_D \sim \xi(0)$, all combine to produce significant suppression of superconductivity near crystal defects, such as impurities, dislocations, and grain boundaries, thus making them effective pinning centers. Characteristic parameters of some superconductors are summarized in **Table 1**.

Single-Vortex and Collective Pinning by Point Defects

Calculation of J_c requires a summation of elementary pinning forces acting on flexible, strongly interacting vortex lines. This is a very difficult theoretical problem, which has not been completely resolved so far. Here, the basic physics of the pinning force summation is discussed, by first evaluating J_c at low B for a single straight vortex interacting with randomly distributed precipitates in a film of thickness d (**Figure 2**). If d is much greater than the mean spacing l_i between the precipitates, a vortex interacts with $N \sim r_p^2 d n_p$ pinning centers, adjusting its position so that the net force vanishes. Here, r_p is the pinning interaction radius, and $n_p = l_i^{-3}$ is the density of precipitates. The transport current displaces the vortex from a local minimum of the pinning potential, so that random elementary pinning forces do not compensate each other. The balance of the total pinning force from uncorrelated defects in the volume dr_p^2 against the total Lorentz force, $f_p N^{1/2} = d\phi_0 J_c$ yields

$$J_c = \frac{1}{\phi_0}\sqrt{\frac{\gamma}{d}} \qquad [2]$$

where $\gamma = f_p^2 r_p^2 n_p$ is the pinning strength parameter. The critical current density $J_c(d)$ decreases as the film thickness increases. For $d \to \infty$, eqn [2] gives $J_c = 0$ because the net pinning force per unit length of an infinite straight vortex in a random potential averages to zero.

Calculation of bulk J_c must, therefore, take into account local bending of vortices near pinning defects, using the following approach of a collective pinning theory. Now introduce a correlation length L_c along the vortex line defined by the relation $\langle u(L_c)u(0)\rangle = r_p^2$, where $\langle u(z)u(0)\rangle$ is a correlation function of pinning-induced transverse vortex displacements. The relative displacement of the ends of a vortex segment of length L_c exceeds the pinning interaction radius r_p, so a vortex may be regarded as an array of straight segments of length L_c pinned independently. Therefore, J_c can be evaluated from eqn [2] with d replaced by L_c. In turn, L_c is evaluated from the balance of a characteristic pinning energy $\phi_0 J_c r_p$ and an elastic bending energy $\varepsilon(r_p/L_c)^2$, where $\varepsilon = (\phi_0^2/4\pi\mu_0\lambda^2)\ln\kappa$ is the vortex line tension. Hence, the condition $\phi_0 J_c r_p = \varepsilon(r_p/L_c)^2$ along with eqn [2] at $d = L_c$ yields

$$J_c = \frac{\gamma^{2/3}}{\phi_0 \varepsilon^{1/3} r_p^{1/3}}, \qquad L_c = \frac{\varepsilon^{2/3} r_p^{2/3}}{\gamma^{1/3}} \qquad [3]$$

Due to the collective interaction of a vortex with many defects, J_c increases as the line energy ε decreases, because a more flexible vortex can bend more easily to accommodate pinning centers, as depicted in **Figure 4**. Meanwhile, the correlation length L_c increases as the pinning parameter γ decreases, resulting in a "dimensional crossover" in films, from the two-dimensional pinning of rigid straight vortices at $d < L_c$ to the three-dimensional pinning of flexible vortices for $d > L_c$.

A theory of weak collective pinning in strong fields $H \gg H_{c1}$ involves two characteristic spatial scales: the correlation length along the vortex lines $L_c(T, B)$ and the correlation length $R_c(T, B)$ perpendicular to the vortex lines. These lengths define the correlation volume $V_c = R_c^2 L_c$ – a mesoscopic region in which pinned vortices still maintain the positional hexagonal short-range order characteristic of the ideal flux

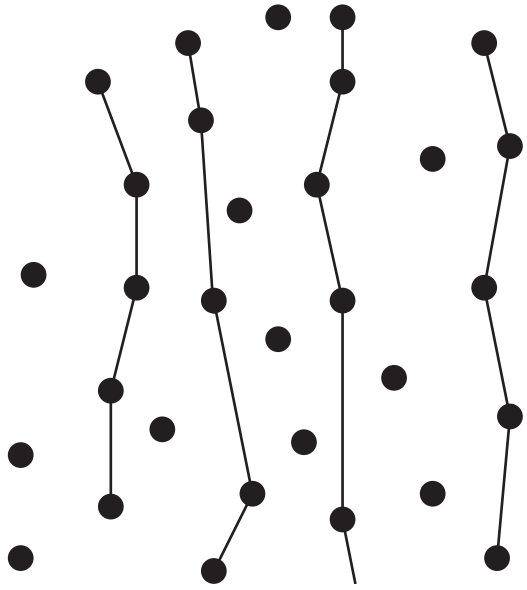

Figure 4 Vortex lines pinned by randomly distributed precipitates.

line lattice. The positional long-range order of vortices is destroyed by pinning on scales larger than the correlation lengths L_c and R_c. The critical current density is then defined by the balance of the Lorentz force applied to the correlation volume, BV_cJ_c against the pinning force from spatially uncorrelated defects, $f_pN_c^{1/2}$, where $N_c = n_pV_c$. This yields

$$J_c = \frac{f_p}{BR_c}\sqrt{\frac{n_p}{L_c}} \qquad [4]$$

where both $L_c(T,B,\gamma)$ and $R_c(T,B,\gamma)$ depend not only on T and B, but also on the pinning parameter γ. The lengths $L_c(T,B,\gamma)$ and $R_c(T,B,\gamma)$ are determined self-consistently from the conditions $\langle u(R_c,0)u(0,0)\rangle = r_p^2$ and $\langle u(0,L_c)u(0,0)\rangle = r_p^2$, where the correlation function of vortex displacements $\langle u(\boldsymbol{r})u(0)\rangle$ is calculated using a continuum elasticity theory for the vortex lattice perturbed by a weak random pinning potential. Depending on the relations between the pinning correlation lengths and the London penetration depth λ and the vortex spacing $a = (\phi_0/B)^{1/2}$, the collective pinning theory predicts a variety of behaviors of $L_c(T,B,\gamma)$ and $R_c(T,B,\gamma)$, which manifest themselves in different dependencies of J_c on T and B. For instance, a crossover from a weak collective pinning to a strong single-vortex pinning regime typically occurs at lower B for which $R_c(T,B,\gamma)$ becomes smaller than the vortex spacing. In this case, pinning-induced correlations of neighboring vortex displacements disappear and vortices become pinned independently. The collective pinning theory for layered high-T_c superconductors is more complicated because it has to take into account a highly anisotropic elastic response of the vortex lattice to pinning forces.

Pinning by Extended Defects

Pinning by extended defects, such as grain boundaries or columnar radiation defects, can be different from pinning by uncorrelated disorder, because a single extended defect parallel to B can pin a vortex segment greater than the correlation length $L_c = \xi(J_d/J_c)^{1/2}$ of the collective pinning theory. Pinning by extended defects can be rather effective and result in high J_c values. Indeed, a single vortex trapped by a cylindrical cavity of radius $\cong\xi$, has the pinning energy U_p of the order of the condensation energy of the vortex core $\phi_0^2/4\pi\mu_0\lambda^2$, yielding a very high $J_c \cong U_p/\xi\phi_0$ of the order of the depairing current density [1]. This model has been used to describe experiments on irradiation of high-T_c superconductors with 1–10 GeV heavy ions (Pb, Au, Xe, etc), which can produce 10–100 μm columnar tracks of about 5–10 nm in diameter comparable to ξ. The density of the columnar defects n_i is normally expressed in terms of the matching field $B_m = \phi_0 n_i$ which typically ranges from 0.1 to 10 T for different irradiation conditions. For $B < B_m$, each vortex is trapped by a columnar defect, resulting in enhancement of J_c and H^* in high-T_c superconducting films, as has been shown by many experimental groups.

Pinning by extended planar defects such as grain boundaries in Nb_3Sn, or by thin α-Ti ribbons in Nb–Ti can also result in high J_c values, $\sim$1–10 MA cm^{-2} at 4.2 K and $H = 0$ (see **Table 1**). Chemical nonstoichiometry, lattice disorder, strain, and charging effects associated with grain boundaries cause local suppression of superconductivity. This can result in the so-called weak link behavior of grain boundaries, which is especially pronounced in high-T_c cuprates because the critical current density through grain boundaries J_b decreases exponentially as a function of the misorientation angle θ between neighboring grains if $\theta > \theta_0 \cong 4-5°$. As a result, J_b through grain boundaries or thin α-Ti ribbons in Nb–Ti, is usually much smaller than the depairing current density [1] in the bulk. It is the suppression of J_b as compared to J_d, which causes a strong magnetic and core interaction between a vortex and a planar defect, in particular, the radical change in the structure of the vortex core as it moves closer to the defect shown in **Figure 3**. Therefore, there are two different types of vortices in polycrystals: vortices in the grains pinned by a long-range magnetic interaction with grain boundaries and elongated vortices on grain boundaries. The critical current density J_c can be evaluated by balancing the

total Lorentz force BJ_cD^3 in the grain of size $\cong D$ against the total pinning force proportional to the surface area of the grain D^2. This yields the inverse dependence of $J_c \propto D^{-1}$ on the grain size, as has been observed on Nb_3Sn.

In polycrystals, grain boundaries not only pin vortices, they can also block macroscopic current flow. Indeed, current loops can form in the grains if the critical current density J_g, due to pinning of vortices in the grains, is higher than the current density J_b, which can flow through grain boundaries. This effect of magnetic granularity can limit global critical current density J_c of superconducting polycrystals. In turn, it indicates that there is an optimum value of J_b, which maximizes J_c, because J_c vanishes in the two limiting cases of $J_b = J_d$ (no pinning, since grain boundaries do not disturb currents circulating around vortices) and $J_b = 0$ (current cannot pass through grain boundaries). Calculation of the optimum J_b, in addition to the summation of all vortex interactions, also requires the account of the grain geometry and microscopic mechanisms of current transport through the grain boundary.

Current transport through grain boundaries is very important for high-T_c polycrystals, for which the weak link behavior of high-angle grain boundaries is one of the most serious current-limiting mechanisms. This behavior is due to rapid decrease of $J_b(\theta) = J_0 \exp(-\theta/\theta_0)$ with the misorientation angle θ and the resulting increase of the vortex core size, from ξ to $l(\theta) = \xi J_d/J_b(\theta)$ for $l(\theta) < \lambda$ or to the so-called Josephson length $l(\theta) = [\xi\lambda J_d/J_b(\theta)]^{1/2}$ for $l(\theta) > \lambda$. The extended core of the grain boundary vortices leads to their weaker pinning force parallel to the boundary against the Lorentz force of the transport current flowing perpendicular to the boundary. As a result, the global J_c of polycrystals may be limited by depinning of a small fraction of vortices, which can move more easily along a network of grain boundaries. This percolative motion of grain boundary vortices is impeded by structural defects along grain boundaries (such as facets, nanoprecipitates) and by magnetic pinning shear stress as the grain boundary vortices move past more strongly pinned vortices in the grain (see **Figure 3**). The significant reduction of J_b of grain boundaries in high-T_c superconductors is due to extreme sensitivity of their critical temperature to a rather weak hole depletion, which can drive the high-T_c superconducting state into an antiferromagnetic insulator. The local hole depletion near grain boundaries can be due to local oxygen nonstoichiometry, charging and strain effects produced by the crystalline dislocations which form the grain boundary, or more macroscopic strain fields due to faceting. The values of J_b in $YBa_2Cu_3O_7$ can be improved by local overdoping with appropriate impurities (such as Ca) near grain boundaries. The current-carrying capability of $YBa_2Cu_3O_7$ polycrystals can also be improved by depositing $YBa_2Cu_3O_7$ films onto "biaxially textured" metallic substrates to eliminate the weakest high-angle grain boundaries.

Global Critical Currents of Superconductors

Multiple pinning mechanisms in superconducting materials manifest themselves in different dependencies of the critical current density on T and B. For low-T_c superconductors, the field dependence of J_c can often be described as follows:

$$J_c(h) = J_{c0}(T)h^{-p}(1-h)^q \qquad [5]$$

where $h = H/H^*(T)$ is a reduced field, $H^*(T)$ is the irreversibility field, and J_{c0}, p and q depend on a particular material. For instance, eqn [5] with $p = 0$ and $q = 1$ describes well the $J_c(B)$ for Nb–Ti alloys, while Nb_3Sn is better described by eqn [5] with $p = 1/2$ and $q = 2$, consistent with strong pinning by grain boundaries. In high-T_c superconductors, $J_c(T, H)$, at elevated temperatures $T > 20-30$ K, often exhibits an exponential field dependence, $J_c(H) = J_{c0} \exp(-H/H_0)$, where $H_0(T)$ can be much smaller than $H_{c2}(T)$, especially in layered $Bi_2Sr_2CaCu_2O_x$.

In high-T_c superconductors, the irreversibility field $H^*(T)$ can be much smaller than $H_{c2}(T)$, whereas in low-T_c superconductors, such as Nb–Ti and Nb_3Sn, or even "intermediate-T_c" compound MgB_2 with $T_c = 39$ K, the field $H_{c2}(T)$ is rather close to $H^*(T) \approx 0.8-0.9H_{c2}(T)$ as shown in **Figure 5** (see also **Table 1**). This fact has important consequences for superconductivity applications at the liquid nitrogen temperature of 77 K, because high-T_c cuprates, despite their very high H_{c2} values, can carry weakly dissipative currents only in a small part of their H–T diagram. The reason for this behavior is due to strong magnetic "flux creep," caused by thermally activated hopping of vortices between neighboring pinning positions even if the current density J is below J_c. Vortex creep velocity $\boldsymbol{v}$ is parallel to the driving Lorentz force $[\boldsymbol{J} \times \boldsymbol{B}]$, causing the electric field $\boldsymbol{E} = [\boldsymbol{v} \times \boldsymbol{B}]$ directed along J (in isotropic materials). The E–J characteristic of a superconductor for $J < J_c$ has the form

$$\boldsymbol{E} = E_c \exp\left[-\frac{U(J,T,B)}{k_BT}\right]\frac{\boldsymbol{J}}{J} \qquad [6]$$

where the Boltzmann factor $\exp(-U/k_BT)$ accounts for the fact that only a small fraction of all vortices is

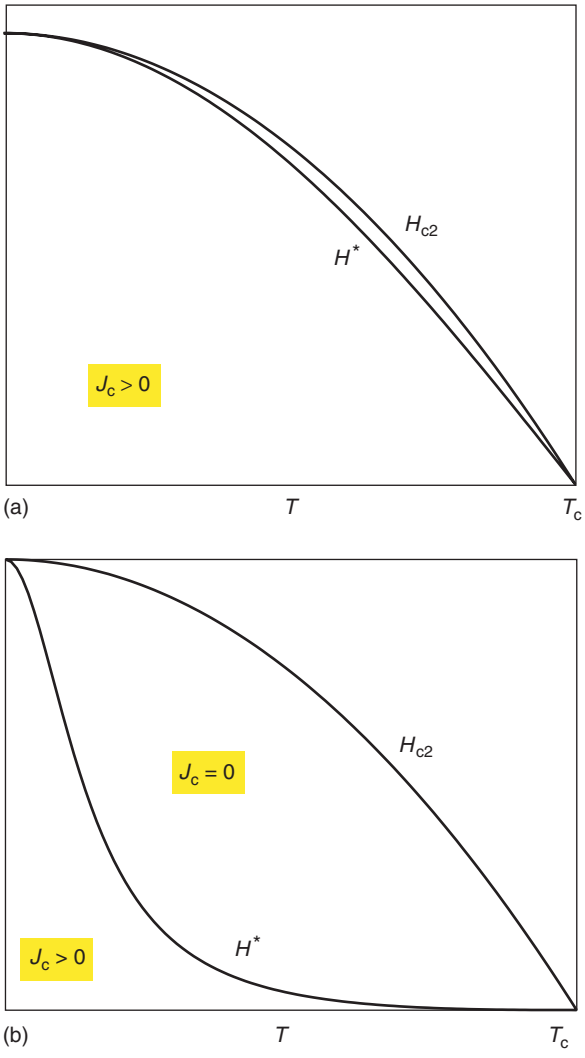

Figure 5 (a) Magnetic phase diagram of low-T_c superconductors, for which $H^*(T) \approx H_{c2}(T)$. (b) Typical magnetic phase diagram of high-T_c superconductors which cannot carry critical currents in a wide field range $H^*(T) < H < H_{c2}(T)$. Both cases (a) and (b) correspond to extreme type-II superconductors ($\kappa \gg 1$) for which the lower critical field $H_{c1} \ll H_{c2}$ is not shown.

thermally activated and thus contribute to the global flux motion. The flux creep activation energy U depends on J, which makes the E–J curve highly nonlinear at $J < J_c$. It is convenient to define U in such a way that $U(J)$ vanishes at $J = J_c$, using the following expressions for U: (1) $U = U_0(1 - J/J_c)$, (2) $U = U_0 \ln(J_c/J)$, (3) $U = U_0[(J_c/J)^{\mu} - 1]$, where $U_0(T, B)$ is a characteristic energy barrier for thermally activated hopping of a correlated group of vortices. These models give the same exponential dependence of E on J at $J \approx J_c$, but rather different behaviors of $E(J)$ at $J \ll J_c$. Typical energy barriers in low-T_c superconductors with strong pinning are $\sim$500–1000 K, whereas in high-T_c superconductors they can be considerably smaller, $U_0 \sim$ 100–400 K, because pancake vortices on neighboring *ab* planes are weakly coupled due to highly anisotropic structures of these materials.

Since current flow causes dissipation at $J < J_c$, critical currents depend on the electric field E_c at which J_c is measured. Generally, J_c is defined as a crossover current density at which a resistive transition from an exponentially small $E(J)$ to a linear flux flow portion of the E–J curve occurs (a conventional criterion of $E_c = 1\ \mu\text{V cm}^{-1}$ is often used). The relation between the critical current densities J_c and J_c' defined at different electric fields E_c and E_c' can be obtained from eqn [6] by linearizing the activation energy $U(J) \approx U_0(1 - J/J_c)$ near J_c:

$$J_c' = \left(1 + \frac{k_B T}{U_0} \ln \frac{E_c'}{E_c}\right) J_c \qquad [7]$$

For low-T_c superconductors ($k_B T_c/U_0 \sim 10^{-2}$), J_c is well defined in a practically accessible electric field window of $1\ \text{nV cm}^{-1} < E < 1\ \text{mV cm}^{-1}$, where $J_c(E_c)$ varies only by a few percent. By contrast, high-T_c superconductors with $k_B T_c/U_0 \sim 0.1$ exhibit a broader resistive transition at $J \approx J_c$ and a larger difference between J_c and J_c'. The parameter $k_B T/U_0$ also defines the rate at which magnetization currents in superconductors, $J(t) = J_c[1 - (k_B T/U_0) \ln(t/t_0)]$, decay due to thermally activated flux creep. The condition $U_0(H^*, T) \approx k_B T$ then determines the irreversibility field H^* at which a highly nonlinear $E(J)$ curve turns into a nearly linear $E(J)$ curve as shown in **Figure 6**. In high-T_c superconductors, such as $Bi_2Sr_2Ca_2Cu_3O_x$, the activation energy of weakly interacting pancake vortices on different *ab* planes is only a few times greater than $k_B T_c$. The resulting strong thermal activation of vortices yields $H^* \ll H_{c2}$, so pinning becomes ineffective in a significant part of the H–T diagram where J_c vanishes (**Figure 5b**). By contrast, in low-T_c superconductors, the reversible region $H^* < H < H_{c2}$ shown in **Figure 5a** is rather narrow as discussed above (see also **Table 1**).

In addition to multiscale pinning mechanisms, global critical current densities $J_c = I_c/A_{\text{eff}}$ of superconductors for a given critical current I_c are often limited by macroscopic scales of current flow defined by an effective current-carrying cross section A_{eff}. Here, A_{eff} is determined by current percolation through arrays of large second-phase precipitates, colonies of high-angle grain boundaries, microcracks, and other inhomogeneities much greater than the pinning correlation lengths L_c and R_c. This results in rather nonuniform current distributions in superconductors, which have been revealed by different experimental techniques, such as magneto-optical

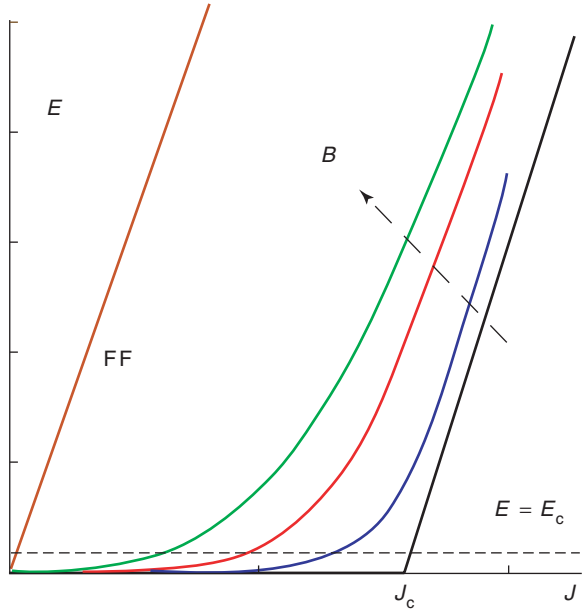

Figure 6 Broadening of the E–J characteristics as B increases. Here the green curve corresponds to B close to but below the irreversibility field B^*, while the FF line shows the Ohmic flux flow E–J characteristic for $B > B^*$. The dashed line shows the electric field criterion E_c at which J_c is defined in transport measurements.

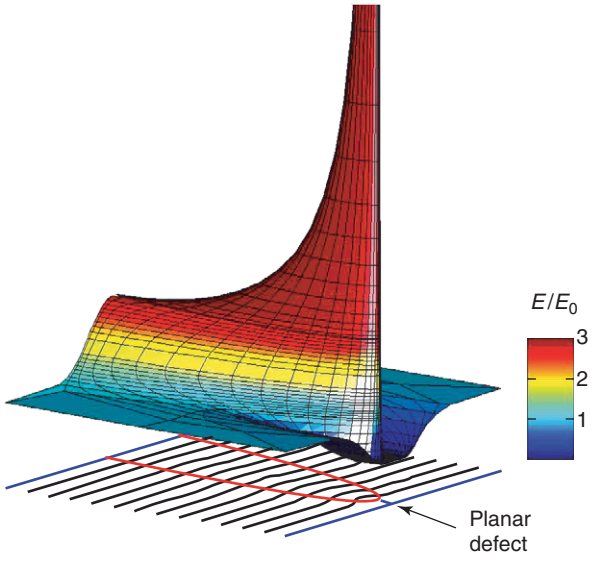

Figure 7 Spatial distribution of the electric field magnitude in a hot spot near a planar defect of length $b = 0.05w$ in a film of width w, calculated for the power-law E–J characteristic $E = E_0(J/J_0)^n$ for $n = 30$. Here, E_0 is the uniform field far away from the defect, and $J_0 = J_c(E_0)$. Below the $E(x, y)$ surface are the corresponding current streamlines in the film.

imaging or micro Hall probe arrays. Current flow in superconductors is described by a highly nonlinear Maxwell equation $\mathrm{div}\, \boldsymbol{J}(\nabla\varphi) = 0$ for the electric potential φ, where $E(J)$ is determined by eqn [6]. The nonlinearity of $E(J)$ results in extended electric field hot spots near defects on scales much greater than the defect size $\sim b$. For instance, for $E = E_c(J/J_c)^n$ characteristic of low-T_c superconductors, the electric field hot spot shown in **Figure 7** has the length $L_\perp \sim nb$ perpendicular to current flow and $L_\parallel \sim n^{1/2}b$ parallel to current flow. For $n \sim 30-50$, planar defects blocking only a few percent of the sample cross section can cause a noticeable voltage drop on the whole conductor. These effects have important consequences for current-carrying capability of superconductors.

Superconductivity: Flux Quantization

J R Kirtley and C C Tsuei, T J Watson Research Center, Yorktown Heights, NY, USA

Introduction

According to the Bardeen–Cooper–Schrieffer (BCS) theory of superconductivity, the normal-to-superconducting phase transition temperature (T_c) of a superconductor marks the inception of a macroscopic phase-coherent condensate of Cooper pairs. An energy gap (2Δ), centered at the Fermi energy (E_F) in the density of states of the electronic excitation spectrum, opens up at T_c. This gap grows as the temperature decreases and more pairs are condensed. The current-carrying superelectrons represent a short-circuit to those normal electrons which have not yet condensed.

In conventional low-T_c superconductors, such as Al, Pb, or Sn, the size of the Cooper pairs, as measured by the zero temperature coherence length ξ_0, is $\sim$of 10^3 Å. At temperatures $T \ll T_c$, there are as many as 10^6 pairs coexisting in the so-called coherence volume, $\sim \xi_0^3$. As a consequence of the many-body interactions among these overlapping paired electrons, the Cooper pairs acquire some of the attributes of Bose particles. In particular, in the superconducting state, the Cooper pairs form a superfluid condensate in which all paired electrons occupy the lowest-energy quantum state (ground state) and long-range phase coherence is established. Thus, the whole ensemble of the Cooper pairs in the condensate can be described by a single complex wave function:

$$\Psi = |\Psi| e^{i\varphi} \qquad [1]$$

The amplitude $|\Psi|$ determines quantities like T_c and Δ, which are measures of the pairing strength. It is related to the superfluid pair density n_s by $|\Psi|^2 = n_s$. The quantity n_s can be determined by measurements of the magnetic penetration depth λ or the muon spin relaxation rate. The macroscopic phase φ contains information about static and dynamic charge transport. The well-known hallmarks of superconductivity, such as zero resistance and perfect diamagnetism, all require the establishment of long-range phase coherence among all the Cooper pairs in the condensate. Under the influence of an increasing electric current or a magnetic field, a phase gradient $\nabla\varphi$ develops and grows until the critical field (B_c) or current density (J_c) is reached. At these points the global phase coherence is lost and the system reverts to the normal state.

The stability of the superconducting state can be evaluated from the energy E_{coh} needed to convert a coherence volume of the superconductor into the normal state.

$$E_{coh} = \frac{B_c^2(0)}{8\pi}\xi_0^3 = \frac{1}{2}N(E_F)\Delta_0^2\xi_0^3 \qquad [2]$$

where $B_c^2(0)/8\pi$ is the condensation energy per unit volume, and $N(E_F)$ is the density of states of the charge carriers at the Fermi energy.

For a typical low-T_c superconductor such as Al or Sn, E_{coh} is $\sim$1 eV, which corresponds to a thermal energy of 1.16×10^4 K. On the other hand, the energy cost of removing a Cooper pair from the BCS ground state ($2\Delta_0$) for Al, for example, is only 0.36 meV, or equivalently a thermal energy of $\sim$4 K. Such a large disparity between these two energy scales emphatically underscores the collective nature of the BCS pairing state. The rigidity of the BCS macroscopic wave function can also be attested to by the extremely small effect of thermal fluctuations near T_c. Based on the Ginzburg–Landau formalism, the temperature range δT over which the statistical average of the standard deviation of the wave function is of the same size as the pair wave function itself (i.e., $\langle \Psi^2 \rangle^{\frac{1}{2}} \approx \langle |\Psi| \rangle$) can be estimated by

$$\frac{\delta T}{T_c} \propto \left(\frac{k_B T_c}{8E_{coh}}\right)^2 \text{ for } T \approx T_c \qquad [3]$$

For typical low-T_c superconductors, the values of $\delta T_c/T_c$ are in the range 10^{-8} to 10^{-10}. Indeed, in conventional superconductors, Cooper pairing and phase coherence occur simultaneously.

The anomalous superconducting and normal-state properties of high-temperature superconductors (HTS) present an entirely different scenario. The superconducting cuprates belong to a family of correlated electron systems consisting of superconducting CuO_2 layers (the *ab*-planes) Josephson coupled via the charge reservoir layers in the *c*-axis direction. These quasi-two-dimensional layered superconductors are characterized by a low charge carrier (hole or electron) density, strong anisotropy, and (at least in the underdoped regime) nanometer-scale charge inhomogeneity. In particular, the extremely short and highly anisotropic coherence lengths ($\xi_0^{ab} \approx 20$ Å, $\xi_0^c \leqslant 1$ Å), combined with low charge density ($\sim 5 \times 10^{21}/\text{cm}^{-3}$), make the coherence volume in HTS so small that only a few pairs reside there, instead of 10^6 pairs for conventional superconductors. If the BCS formalism is assumed to be valid, the condensation energy per coherence volume $(\xi_0^{ab})^2\xi_c$ in HTS (see eqn [2]) would be

at least three orders of magnitude smaller than that of the low-T_c counterparts. Furthermore, due to the low superfluid density in the underdoped HTS regime, it has been suggested that phase fluctuations of the complex order parameter (eqn [1]) play an important role in determining various properties near T_c and into the superconducting state. As a consequence, the long-range phase coherence vanishes at T_c, but pairing can persist until another temperature T^* is reached. In between T_c and T^*, there is a suppression in the density of states of the electronic spectrum which is referred to as the "pseudogap". The value of T^* is of the order of 10^3 K near the Mott metal–insulator transition in the highly underdoped region of the cuprate phase diagram. T^* decreases monotonically with increasing doping (and T_c), and is roughly equal to T_c around the optimal doping, beyond which more conventional normal and superconducting states are observed. The idea of pairing without the establishment of macroscopic phase coherence provides a natural explanation for the pseudogap and related phenomena observed in underdoped HTS. However, another school of thought, instead of emphasizing the importance of phase fluctuations, suggests that the pseudogap may stem from some nonsuperconducting mechanisms such as spin, charge, or d-density waves, which represent orders competing with the BCS pair state. Another intriguing alternative possibility is that local pairing above T_c may be derived from the nanometer charge inhomogeneity which promotes pair formation locally and dynamically.

To assess the different unconventional theoretical approaches mentioned above, it is crucial to find out to what extent standard paradigms such as the Fermi liquid formalism and BCS theory can be used for understanding the origin of high-temperature superconductivity. To achieve this goal, it is important to first probe the nature of pairing and phase coherence in HTS.

Flux quantization is one of the most striking manifestations of macroscopic phase coherence in superconductors. Flux quantization based experiments have been employed for studying fundamental aspects of the superconducting state in HTS as well as conventional low-T_c superconductors. Some examples of such studies will be presented in the following sections.

Flux Quantization

The phenomenon of flux quantization is a direct consequence of the requirement that the pair wave function Ψ for describing the superconducting state has to be single-valued at any point in a superconductor. It is a quantum mechanical effect that manifests itself on a macroscopic scale.

When a superconducting sample is placed in a magnetic field, supercurrents are generated to screen the fields from penetrating into the bulk of the sample. This is the "Meissner effect." The length over which the shielding current and magnetic fields vary is the penetration depth λ. A Abrikosov showed in 1957 that if, as in conventional superconductors (type I), the penetration depth is shorter than the coherence length ξ, then it is energetically unfavorable for the sample to break up into magnetic domains with normal regions penetrating into the bulk of the superconductor. However, for superconductors with $\xi < \lambda$ (type II) such as the high critical temperature cuprate superconductors, the opposite is true. The crossover between the two types of behavior occurs at a Ginzburg–London parameter $k = \lambda/\xi = 1/\sqrt{2}$.

Consider a hole or normal region through a type I superconductor which is cooled below T_c in the presence of a magnetic field that is less than H_c. Due to the Meissner effect, the magnetic flux Φ trapped in the hole can penetrate into the superconductor only over a distance of the London penetration depth λ at the inner surface of the hole. There is a supercurrent (with vector current density $\boldsymbol{J}_s$) induced in this layer to support the flux threading through the hole. The flow of supercurrent can be described in terms of the spatial and temporal variations of the single macroscopic pair wave function $\Psi(\boldsymbol{r}, t)$ throughout the entire superfluid condensate. This leads to the quantum mechanical expression for $\boldsymbol{J}_s$:

$$\boldsymbol{J}_s = \frac{q^*}{m^*} n_s(\boldsymbol{r}, t)(\hbar \boldsymbol{\nabla} \varphi(\boldsymbol{r}, t) - q^* \boldsymbol{A}(\boldsymbol{r}, t)) \qquad [4]$$

where $n_s(\boldsymbol{r}, t) = |\Psi(\boldsymbol{r}, t)|^2$ is the local pair density, $\varphi(\boldsymbol{r}, t)$ is the local phase, $(\boldsymbol{A}(\boldsymbol{r}, t)$ is the magnetic vector potential, and q^* and m^* are the charge and mass of the charge carriers, respectively.

Although the absolute phase φ of the wave function is not gauge-invariant, the phase change along a path in space is well-defined. The phase difference $\delta\varphi$ can be obtained by integrating $\boldsymbol{J}_s$ around a closed contour such as C or C' in **Figure 1**:

$$\begin{aligned} \delta\varphi &= \oint \delta\varphi(\boldsymbol{r}, t) \cdot \mathrm{d}\boldsymbol{l} \\ &= \frac{m^*}{\hbar n_s q^*} \oint \boldsymbol{J}_s \cdot \mathrm{d}\boldsymbol{l} + \frac{q^*}{\hbar} \int_s \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{S} \end{aligned} \qquad [5]$$

where $\boldsymbol{B} = \boldsymbol{\nabla} \times \boldsymbol{A}$ is the magnetic flux density, and S is the area enclosed by the contour. As a consequence of

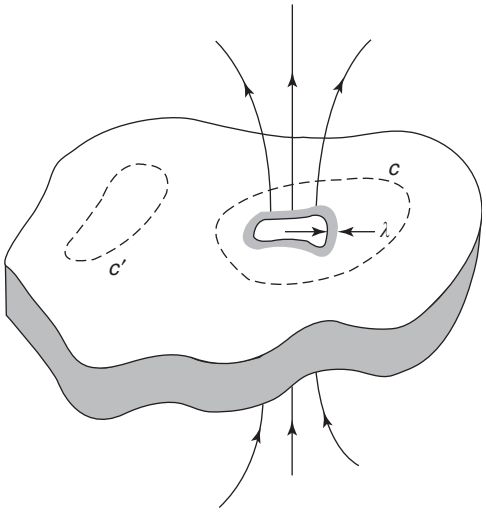

Figure 1 Schematic of magnetic flux threading through the interior of a superconductor.

the single-valuedness of the pair wave function $\Psi(\boldsymbol{r}, t)$ the phase $\varphi(\boldsymbol{r}, t)$ around a closed loop can vary only by a multiple of 2π (i.e., $\delta\varphi = 2n\pi$, $n = 0, 1, 2, \ldots$). One can rewrite the above equation as follows:

$$\Phi' = \frac{4m^*}{n_s q^{*2}} \oint \boldsymbol{J}_s \cdot \mathrm{d}\boldsymbol{l} + \int_S \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{S} = n\left(\frac{h}{q^*}\right) \qquad [6]$$

The quantity Φ' is called the fluxoid, first introduced by F London. The second term in the equation is the magnetic flux threading the hole (or normal region) and the penetration layer around it. Strictly speaking, it is the fluxoid contained in a loop so as C in **Figure 1** that is quantized in integral units of (h/q^*). However, if the dimensions of the superconductor are such that an integration contour such as C can be chosen such that $\boldsymbol{J}_s$ is always zero, then there is no difference between fluxoid and flux (i.e., $\Phi' = \Phi$). On the other hand, $\boldsymbol{J}_s$ is always zero along an integration path in a simply connected region (such as C' in **Figure 1**) and it encloses no flux. This leads to $n = 0$, a restatement of the Meissner effect.

Flux quantization was demonstrated independently by B S Deaver and W M Fairbank, and R Doll and M Näbauer in 1961. In these experiments, the flux trapped in superconducting hollow cylinders (with wall thickness much larger than the London penetration depth) was found to be quantized only in multiples of the flux quantum $\Phi_0 = h/2e = 2.07 \times 10^{-15}$ Wb $= 20.7$ G μm^2 (see **Figure 2a**). This pioneering work has provided compelling evidence for electron pairing in superconductors. Moreover, the concept of quantum phase coherence is validated eloquently through some simple classical magnetization measurements. Flux quantization in a ring made of a polycrystalline sample of the cuprate superconductor $YBa_2Cu_3O_{7-\delta}$ (YBCO) was demonstrated in 1987, shortly after the discovery of high-temperature superconductivity by Bednorz and Mueller. The magnetic flux state of the ring was monitored by using a superconducting quantum interference device (SQUID). As shown in **Figure 2b**, flux jumps, induced by a local source of electromagnetic noise, were found to occur only in integral multiples of the flux quantum Φ_0, thus providing strong evidence for Cooper pairing of charge $2e$ in HTS, as in conventional superconductors. This establishes the existence of macroscopic phase coherence in this very short coherence length ($\xi_0 \sim 1$ nm) superconductor, since the observed flux quantization is supported by a supercurrent flowing through the weak links between thousands of individual crystals around the ring. Since then, flux quantization has been observed many times in various cuprate systems.

Vortex State in Type II Superconductors

In Type II ($\kappa = \lambda/\xi > 1/\sqrt{2}$) superconductors it is energetically favorable for fields to enter in the form of flux lines when the applied field exceeds a critical value H_{c1}. Each of such flux lines, with screening currents circulating around it, is called a "vortex." One can apply the flux quantization condition previously described to show that each vortex carries exactly one flux quantum Φ_0. At the center of the

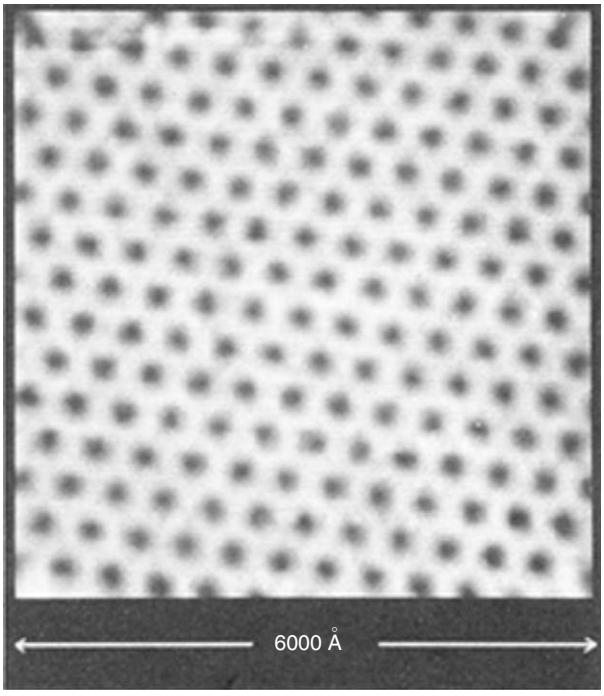

Figure 3 Scanning tunneling microscope image of a triangular lattice of vortices in $NbSe_2$. (Reproduced from Hess HF *et al.* (1989) *Physical Review Letters* 62: 214–216.)

vortex is the "vortex core," which is a region in which the superconductivity is suppressed of radius $\sim\xi$. Extending from the vortex center a distance of $\sim\lambda$ are supercurrents that circulate perpendicular to the vortex line, producing magnetic fields parallel to this line. As the applied magnetic fields increase, the vortices interact with each other more strongly. In a type II bulk superconductor, this interaction is repulsive. A Abrikosov showed in 1957 that this leads to a regular lattice of vortices. The different forms this lattice takes can vary: for conventional superconductors it is triangular. The existence of such flux line lattices have been observed and studied by a variety of techniques, including Bitter ferromagnetic powder decoration, small-angle neutron scattering (SANS), and scanning tunneling microscope (STM). As an example, an STM image of the triangular vortex lattice in $NbSe_2$ is shown in **Figure 3**.

The HTS superconductors have a large Ginzburg–London parameter $\kappa\approx 100$ and are therefore extreme type-II superconductors. The vortex state in HTS is significantly different from that of the conventional superconductors, both in their magnetic and electronic structures within the vortex core itself, and in the interaction between vortices. This leads to different vortex lattice structures and vortex dynamics. There is a vast literature on the study of the vortex state in conventional and high-temperature superconductors (see "Further reading" section). There has been a special emphasis on the study of vortex dynamics since dissipation in type II superconductors results from the motion of vortices. Recent progress in this area of research has been important for technological development, or electronic and large-scale applications of superconductivity.

Mesoscopic Effects

In type II ($\kappa=\lambda/\xi>1/\sqrt{2}$) superconductors, the magnetic fields and supercurrents of vortices spread upon reaching the surface, with a characteristic length given by the penetration depth λ. Vortices trapped in superconductors with a thickness $d\ll\lambda$ are called "Pearl vortices," after J Pearl, who first described them theoretically in 1966. These vortices have magnetic fields at short distances that diverge as r^{-1}, as opposed to $ln(r)$ for bulk vortices. They also have different vortex–vortex interactions. Vortices in highly anisotropic layered superconductors, such as the cuprates, can be described as strings of "pancake vortices," each pancake localized in a plane and interacting only weakly with its neighbors above and below in the vortex string. Vortices trapped in an interface between superconductors coupled by Josephson tunneling of Cooper pairs are called Josephson vortices. Josephson vortices can be highly anisotropic, with very strong screening and short penetration depths perpendicular to the interface, but weak screening and long penetration depths parallel to the interface.

Vortices do not normally occur in type I ($\kappa\equiv\lambda/\xi<1/\sqrt{2}$) superconductors. However, they can occur in very thin films of type I superconductors. "Giant" vortices with integer multiples of the fluxoid number can occur in superconductors with dimensions smaller as compared to the coherence length ξ. In addition, the fluxoids trapped in such samples can arrange in regular patterns to minimize their free energy. These patterns have been imaged using scanning Hall bar microscopy, and are in good agreement with predictions using the Ginzburg–Landau equations.

Spontaneous Vortex Generation

It has been proposed that phase transitions in condensed matter systems can be studied to provide clues to analogous phase transitions in the early development of the universe. One such phase transition is the normal-superconducting transition. Vortices can be generated in superconducting samples during the superconducting normal-phase transition, even in the absence of an applied magnetic field, if the cooling rate is sufficiently fast. Studies have been made of this spontaneous vortex generation in bulk

superconductors, and in rings of superconductors with and without Josephson weak links. This vortex generation is believed to result from a "freeze-out" of fluctuations in phase of the order parameter. This freeze-out can be the result of a slowing down of the communication between different sections of the superconductor or from the raising of the barrier to vortex formation as the temperature is lowered.

Half-Integer Flux Quantum Effect

The phenomena of integer flux quantization described so far are based on the requirement that the phase of a BCS pair wave function can change only by multiples of 2π when going around a closed superconducting circuit. However, a phase shift of π can be incorporated in a superconducting loop containing one or more Josephson junctions between unconventional superconductors. In a conventional (*s*-wave) superconductor, the pair wave function, which is proportional to the energy gap, always maintains the same sign, and has the full symmetry of the underlying crystal lattice. In sharp contrast, in unconventional superconductors, the wave-vector-dependent gap parameter $\Delta(\boldsymbol{k})$ is highly direction-dependent, with a symmetry lower than that of its *s*-wave counterpart. For example, it is believed that the cuprate superconductors have two-dimensional *d*-wave pair wave function which varies as $k_x^2 - k_y^2$. This wave function changes its sign across the node lines $\boldsymbol{k}_x = \pm \boldsymbol{k}_y$, where the amplitude of the pair wave function vanishes (see the four-leaf clover schematic representation in **Figure 4a**).

Consider a superconducting ring of inductance L interrupted by Josephson junctions between superconductors i and j with a critical current I_c^{ij}. The supercurrent circulating in the ring is governed by the Josephson equation for pair tunneling across the junction ij:

$$I_s = I_c^{ij} \sin(\delta\varphi_{ij}) \qquad [7]$$

where φ_{ij} is the phase difference between the macroscopic wave functions of the junction electrodes i and j. Since the critical current I_c^{ij} is proportional to the product of the energy gaps, or equivalently the pair wave functions, projected onto the normal to the junction interface, a negative critical current $I_c^{ij} < 0$ is therefore possible for a properly configured junction made of at least one unconventional (e.g., *d*-wave) superconductor which has nodes ($\Delta(\boldsymbol{k}) = 0$) in the gap function. A junction with $I_c < 0$ contributes a phase-shift of π to the phase-shift sum around the ring. If, for example, $I_c^{12} = -|I_c^{12}|$, then $I_s = -|I_c^{12}| \sin(\delta\varphi_{12} + \pi)$. The integer flux quantization of the ring requires that the total of the phase differences around the rings sums to an integral multiple of 2π:

$$2\pi\left(\frac{\Phi_a}{\Phi_0} + \frac{I_s L}{\Phi_0}\right) + \sum_{ij} \delta\varphi_{ij} + \alpha = n \times 2\pi \qquad [8]$$

where Φ_a is the flux applied by an external field, $I_s L$ corresponds to the flux generated by the pair tunneling current circulating in the ring, and $\alpha = \pi$ for a ring with an odd number of sign changes in I_s (termed a π-ring); $\alpha = 0$ for a ring with an even number of sign changes (0-ring). The combined constraints imposed by eqns [7] and [8] lead to the conclusion that the ground state ($\Phi_a = 0$, $n = 0$) of a π-ring is characterized by a spontaneous magnetization of a half-flux quantum $\Phi = I_s L \approx (1/2)\Phi_0$, provided that $I_c^{ij} \gg \Phi_0$. A free energy consideration of the π-ring has reached the same conclusion.

The magnetic flux threading through a superconducting loop with an intrinsic π-phase shift (called a π-loop) is quantized in half-integral multiples of the

flux quantum Φ_0:

$$\Phi = \pm\left(n + \frac{1}{2}\right)\Phi_0, \quad n = 0, 1, 2, \ldots \qquad [9]$$

where the $\pm$signs correspond to the screening supercurrents flowing respectively in the clockwise and counterclockwise directions. This half-integer flux quantum effect has been the basis for a new class of phase-sensitive tests for pairing symmetry in HTS. In particular, a series of tricrystal experiments have been used to establish the *d*-wave pairing symmetry in HTS. The basic design of the tricrystal experiments is shown in **Figure 4a**. The samples are made by depositing and patterning *c*-axis-oriented thin film rings of cuprate superconductors such as YBCO. The crystal orientations of the tricrystal substrates were chosen such that the three grain-boundary weak links in the ring encircling the tricrystal meeting point give rise to a net phase-shift of π, if the cuprate under test is a *d*-wave superconductor. **Figure 4b** shows a scanning SQUID microscope image, taken at 4.2 K and nominal zero field, of four YBCO rings on a tricrystal $SrTiO_3$ substrate with the configuration shown in **Figure 4a**. The fact that spontaneous magnetization of $\Phi_0/2$ is only observed in the 3-junction ring, but not in the 2- and 0-junction rings, represents strong evidence for *d*-wave pairing in YBCO. Additional tricrystal experiments have provided support for a *d*-wave pair state in various other HTS, including the electron-doped cuprates. Conventional techniques (e.g., angle-resolved photoemission spectroscopy, nuclear magnetic resonance, penetration depth measurement) have also produced important supporting evidence for *d*-wave pairing symmetry in HTS.

The establishment of *d*-wave pairing symmetry in HTS does not pin down a specific high-T_c mechanism. It does impose a well-defined constraint on possible models for high-temperature superconductivity. Recent research on the low-energy quasiparticle excitations near the nodes of the *d*-wave energy gap has led to the prediction and confirmation of new effects in low-temperature properties such as specific heat and thermal conductivity. These studies have produced strong evidence in support of *d*-wave pairing symmetry. Furthermore, they suggest that, in the context of the Fermi liquid formalism, BCS theory represents a valid description of the superconducting state in an unconventional superconductor.

Practical applications of *d*-wave superconductivity in areas such as π-SQUIDS and quantum computation, are still under active development. A recent work (see **Figure 5**) demonstrating fabrication of 25 000 π-loops on a single chip, and showing the presence of magnetic coupling between the individual π-loops in the array, represents an important step toward such potential applications.

Superconductivity: General Aspects

A I Larkin, University of Minnesota, Minneapolis, MN, USA

Introduction

Superconductivity is a very exciting and unusual macroscopic quantum phenomenon. Different superconducting devices are continuing to find more and more applications around the world. There is no doubt that in the future, these applications will become even more widespread. In order to understand how these devices work, one should know the general aspects of superconductivity. A lot of detailed information on the subject can be found in the corresponding specialized articles of this encyclopedia. This article deals with only the main results of the Bardeen–Cooper–Schrieffer (BCS) theory and the Ginzburg–Landau theory as well as those aspects of superconductivity which are not mentioned in the other articles such as unconventional superconductivity, inhomogeneous states (also known as Larkin–Ovchinnikov–Fulde–Ferrell (LOFF) states), superconducting fluctuations, pinning of vortices. A special chapter is devoted to the manifestation of superconductivity in various nonmetallic systems.

Conventional Superconductors

A major success of low-temperature physics was achieved with the introduction of the notion of quasiparticles by Landau. According to the Landau Fermi-liquid theory, the properties of a many-body interacting system at low temperatures are determined by the spectrum of some low-energy, long-living excitations (called quasiparticles). Another milestone of the many-body theory is the mean field approximation (MFA). The BCS theory of superconductivity is a good example of the use of both the quasiparticle description and MFA. In 1956, L Cooper found that even a weak attraction between particles in a degenerated Fermi liquid led to the formation of bound states, now called Cooper pairs. Soon after this discovery Bardeen, Cooper, and Schrieffer proposed a microscopic theory of superconductivity as a theory describing Bose condensation of Cooper pairs. N N Bogolyubov succeeded in solving the problem of superconductivity by the method of approximate second quantization and L P Gor'kov proposed a solution of the problem in the framework of the Green functions formalism. This method permitted the use of the well known Feynman diagram technique from the quantum field theory in the theory of superconductivity. Using these methods, Gor'kov demonstrated that the phenomenological Ginzburg–Landau equations followed from the BCS theory in the limit $T \to T_c$ (i.e., in the vicinity of the transition). According to the BCS theory, the excitation spectrum $E(p)$ in a superconductor has a gap proportional to the amplitude of the Bose-condensate of Cooper pairs:

$$E(p) = \sqrt{[\varepsilon(p) - \mu]^2 + \Delta^2(p)}$$

where $\varepsilon(p)$ is the excitation spectrum in the normal state, $\Delta(p)$ is the superconducting gap, and μ is the chemical potential. In conventional superconductors, the gap has the same symmetry as the one of the lattices and in some systems does not depend on the momentum. In the latter case, both the gap and the transition temperature do not depend upon the density of nonmagnetic impurities (this statement is known as the Anderson theorem).

Unconventional Superconductors

In some systems, the effective electron–electron interaction is strongly repulsive at short distances but becomes attractive at large distances. In this case, an unconventional pairing can take place, with the gap having a symmetry group smaller than the one of the lattices: For example, in a tetragonal high-T_c superconductor, the angular dependence of the gap has the form

$$\Delta_d(p) \propto p_x^2 - p_y^2$$

In the isotropic case, the such a dependence corresponds to the orbital momentum $l = 2$ (d-wave superconductivity). In the anisotropic case, the momentum is not a good quantum number anymore.

The corresponding label just indicates the number of zeros of the function $\Delta(p)$. For example, the d-wave gap function has four zeros corresponding to the momenta $p_x = \pm p_y$. Nonmagnetic impurities destroy unconventional superconductivity if $k_B T_{c0} \cdot \tau_{tr} > \hbar$, where τ_{tr} is the transport scattering time and T_{c0} is the transition temperature in the pure system.

Inhomogeneous State

In the usual BCS state, electrons forming a Cooper pair have opposite momenta and the total momentum of a pair is zero. In ferromagnetic superconductors or layered superconductors in a strong magnetic field, the densities and Fermi-momenta of electrons with opposite spins are different. In such conditions, it is more favorable for each electron to stay close to its Fermi surface and for Cooper pairs to have nonzero total momenta, unlike in the usual BCS state. In such systems, the condensate wave function varies in space and the ground state is inhomogeneous, which may lead to the formation of a crystalline structure (LOFF state). The LOFF state is believed to exist in heavy fermion systems such as $CeCoIn_5$, $CeRu_2$, UPd_2Al_3, and in some organic compounds. The LOFF state also appears in superconductor–ferromagnet–superconductor junctions. In these systems, the wave function of a Cooper pair oscillates inside the ferromagnet and, for a certain thickness of the layer, may have opposite signs on different sides of the ferromagnetic layer. As a result, the Josephson energy of the contact changes sign and has two minima, corresponding to the phase difference $\pm\pi$. Such a device, called π-junction, has two degenerate states and can be used as a qubit for quantum computation.

Fluctuations (Paraconductivity)

Phenomena that cannot be described within the quasiparticle method or the MFA are called fluctuations. In bulk samples of traditional superconductors, the critical temperature T_c sharply divides the superconducting and normal phases. Such a behavior of the physical characteristics of superconductors is in perfect agreement with both the Ginzburg–Landau phenomenological theory and the BCS microscopic theory of superconductivity. Both of these theories can be derived in the framework of the mean field approximation. In the BCS theory, only the Cooper pairs in the Bose-condensate are considered. The fluctuation theory deals with Cooper pairs out of the condensate. Fluctuation phenomena manifest themselves much stronger in disordered low-dimensional systems. This is because the fluctuation region in disordered superconducting films, which is determined by the resistance per unit square, is typically much wider than in bulk samples. What is even more important is that fluctuation effects exist beyond the critical region and affect not only thermodynamic quantities but also the kinetic ones. The phenomenon, which is now known as paraconductivity, is the decrease of the resistance of a superconducting sample above the transition temperature (i.e., in the normal phase) due to the appearance of fluctuating Cooper pairs. The fluctuation conductance g of a superconducting film reads:

$$g - g_n = \frac{e^2}{16\hbar} \frac{T_c}{T - T_c}$$

Note that in high-temperature, organic, amorphous, and low-dimensional superconducting systems being studied presently, the fluctuation effects strongly differ from those in traditional superconductors. The transition turns out to be much more smeared out. The appearance of superconducting fluctuations above the critical temperature leads to precursor effects of the superconducting phase occurring in the normal phase, sometimes far from the transition. The conductivity, heat capacity, diamagnetic susceptibility, sound attenuation, and other properties may change considerably in the vicinity of the transition. A strong dependence of superconducting fluctuations on the temperature and magnetic field permits one to definitely separate the fluctuation effects from other contributions and to use them as a source of information about the microscopic parameters of a material. The account for fluctuations has become a necessary part in the design of superconducting devices.

Pinning of Vortices

The greatest success of the Ginzburg–Landau theory was the explanation of Shubnikov's phase by A A Abrikosov in 1957. In this phase, superconductivity and a magnetic field can peacefully coexist. Abrikosov suggested that the magnetic field can penetrate a superconductor along vortex lines, which can form a perfect lattice structure. In homogeneous superconductors, an applied current causes a drift of the vortex lattice and dissipation. When a transport current j_{tr} flows through a superconductor, the Lorentz force $F_L = (\Phi_0/c) j_{tr}$ exerted on each vortex line appears immediately ($\Phi_0 = hc/2e$ is the flux quantum). In homogeneous superconductors, the vortices start moving due to this force. The corresponding flow of the magnetic flux induces the electric field $E = (v/c) \cdot B$ and energy dissipation. In order to preserve

superconductivity, one should prevent the motion of vortices by introducing a dry friction force. This can be done by creating local inhomogeneous regions (pinning centers), which would pin the vortex lattice. Such centers may appear due to structural inhomogeneities of the initial crystalline lattice (dislocations, accumulations of impurities, etc.). In the theory of collective pinning, even small structural fluctuations can qualitatively change the properties of the vortex structure. A single weak center causes only a weak elastic deformation, but the collective effect of a large number of weak centers destroys the lattice. The long-range lattice order disappears, while the short-range order survives only at distances smaller than a correlation length L_c. Each region of size L_c finds its equilibrium in a local minimum of the random pinning potential. A force is needed in order to move the pinned regions from the energetically favorable positions. The appearance of the frictional force leads to a finite critical current and hysteresis.

Superconductivity in Nonmetallic Systems

Organic superconductors

W A Little has proposed the possibility of a nonphonon pairing mechanism in some organic superconductors. Little's work has stimulated a lot of further theoretical activity in the field of one-dimensional systems. All real organic superconductors are not truly one-dimensional but consist of long chains strongly coupled to each other, which make the system effectively two-dimensional and strongly anisotropic. This may result in an unconventional superconducting pairing and in the appearance of inhomogeneous LOFF states in such systems. High upper critical fields in some organic materials (e.g., $(TMTSF)_2ClO_4$ or $(TMTSF)_2PF_6$) support the scenario of the unconventional triplet pairing. An experimental evidence of the LOFF state has been found in the organic compounds $k-(BEDT-TTF)_2-Cu(NCS)_2$ and $\lambda-(BETS)_2FeCl_4$.

Ceramic Superconductors

Most of the high-T_c superconductors are ceramic superconductors.

Superfluidity of helium Superfluidity in He_4 is a result of Bose condensation of He_4 atoms themselves. In He_3, the atoms are spin-1/2 particles and the normal state of He_3 is thought to be a Fermi-liquid. Superfluidity in He_3 is the result of Cooper pairing in the fermion system. Cooper pairs in He_3 have a total spin $S=1$ and orbital moment $l=1$, which corresponds to the p-wave unconventional superconducting pairing.

Superfluid model of atomic nuclei Strong interactions between nucleons in heavy nuclei may yield the formation of Cooper pairs. This leads to the gap in the spectrum of excitations in the nuclei, which typically is of the order of $\Delta \sim 2\,\text{MeV}$, which is much larger than the level spacing. The appearance of the nucleon Bose-condensate leads to parity effects in atomic nuclei. The energy and mass of a nucleus containing an even number of nucleons are smaller than the ones of an odd nucleus:

$$2M_{2N+1} - M_{2N} - M_{2N+2} = 2\Delta$$

A rotating nucleus creates supercurrents, which produce an effect similar to the anomalous diamagnetism in conventional superconductors. As a result, the moment of inertia of a nucleus is smaller than the one of a solid or liquid object with the same mass and geometry.

Superconductivity in neutron stars In neutron stars (pulsars), the density of neutrons may be of the order of their density in heavy atomic nuclei. As a result, Cooper pairs are created and superconductivity can arise. Since pulsars are spinning, the neutron superfluid is threaded with a regular array of rotational vortices. The rotation frequency of the superfluid is proportional to the density of the vortices. As a pulsar's spin rate gradually decreases due to the emission of electromagnetic radiation, the vortices gradually move outwards.

Color superconductivity In the core of a neutron star, the density is so high that quark matter can appear. Strongly interacting quarks may form Cooper pairs (it is predicted that the red up-quarks are paired with the green down-ones) yielding the so-called color superconductivity. Since the quarks forming pairs have different charges and slightly different densities, the Fermi surface splits into two and an inhomogeneous crystalline state similar to the LOFF state appears in a shell, where the quark densities satisfy the appropriate conditions. The rotational vortices may be pinned by the LOFF structure leading to the pinning effects. Within this picture, the so-called glitch phenomena (sudden increases of rotation frequencies of a pulsar) are explained as the hopping of vortex bundles from one metastable minimum to another.

Superconductivity and masses of elementary particles Papers of Nambu and Jona-Lasinio and Vaks

and Larkin have introduced the mechanism of elementary particle mass generation via the dynamical symmetry breaking. This spontaneous symmetry breaking is formally very similar to the one occurring in superconductors, with the superconducting gap corresponding to the masses of the elementary particles. In superconductors and in the models considered by Nambu and Jona-Losinio and by Vaks and Larkin, the transition occurs due to the appearance of the Bose-condensate of Cooper pairs, while in the standard model the symmetry breaking is due to the Bose-condensate of the scalar Higgs bosons. Furthermore, the Meissner effect, which is characterized by a penetration length, is the origin, in the elementary particle physics language, of the masses of the gauge vector bosons. The masses correspond to the inverse of the penetration length in the conventional theory of superconductivity.

Superconductivity: Ginzburg–Landau Theory and Vortex Lattice

E H Brandt, Max-Planck-Institut für Metallforschung, Stuttgart, Germany

Introduction

After the discovery of superconductivity in 1912 by Heike Kamerlingh-Onnes in Leiden, it took almost 50 years until this fascinating phenomenon was understood microscopically, when in 1957 Bardeen, Cooper, and Schrieffer established their BCS theory. But long before this electron-pairing theory, there were powerful phenomenological theories which were able to explain most electromagnetic and thermodynamic observations on superconductors, and which are very useful today also. The London theory, conceived by Fritz and Heinz London in 1935, is particularly useful for the description of the high-T_c superconductors, which were discovered in 1987 by Bednorz and Müller in Zürich. Perhaps the most useful and elegant phenomenological theory of superconductors was established by Vitalii Ginzburg and Lew Landau in 1951. The Ginzburg–Landau (GL) theory generalizes Landau's theory of second-order phase transitions to spatially varying charged systems in a magnetic field and should thus be applicable near the superconducting transition temperature T_c, but in many cases it yields a qualitatively correct behavior also at lower temperatures. The GL theory can be derived from the microscopic BCS theory, and it reduces to the London theory in situations when the GL function (the superconducting order parameter) has nearly constant magnitude.

The GL theory has high predictive power. It predicts that superconductors can be of type-I (with positive energy of the wall between normal conducting and superconducting domains) or of type-II (with negative wall energy, pointing to an instability) and that superconductivity can be suppressed by a high magnetic field and by a high current density, namely,

by the depairing current which breaks the Cooper pairs. Its most spectacular success was the prediction of spontaneous nucleation and penetration of magnetic vortices in type-II superconductors by Alexei Abrikosov in 1957. The properties of these Abrikosov vortices (or fluxons, flux lines, carrying one quantum of magnetic flux $\Phi_0 = h/2e = 2.07 \times 10^{-15}$ T m^2) and their motion and pinning by material inhomogeneities, are important topics both in research and in the practical application of superconductors. Most applications require type-II superconductors with high critical magnetic fields and currents, but high loss-free supercurrents require that the vortices are pinned so that they cannot move under the action of this current and dissipate energy.

Ginzburg–Landau Theory

The GL theory introduces a complex, spatially varying order parameter $\psi(\boldsymbol{r})$ in addition to the magnetic field $\boldsymbol{B}(\boldsymbol{r}) = \nabla \times \boldsymbol{A}(\boldsymbol{r})$ or vector potential $\boldsymbol{A}$. The GL function $\psi(\boldsymbol{r})$ later turned out to be proportional to the BCS energy-gap function $\Delta(\boldsymbol{r})$, and its square $|\psi(\boldsymbol{r})|^2$ to the density of Cooper pairs. It defines two characteristic lengths: the superconducting coherence length ξ sets the scale over which $\psi(\boldsymbol{r})$ can vary, while λ governs the variation of the magnetic field as in the London theory. Both λ and ξ diverge at the superconducting transition temperature T_c according to $\lambda \propto \xi \propto (T_c - T)^{-1/2}$, but their ratio, the GL parameter $\kappa = \lambda/\xi$, is nearly independent of the temperature T. The GL theory reduces to the London theory (which is valid down to $T = 0$) in the limit $\xi \ll \lambda$, which means constant magnitude $|\psi(\boldsymbol{r})| =$ const (except in the vortex cores, where ψ vanishes, see below). The GL equations are obtained by minimizing a free-energy functional $F\{\psi, \boldsymbol{A}\}$ with respect to the GL function $\psi(\boldsymbol{r})$ and the vector potential $\boldsymbol{A}(\boldsymbol{r})$. With the length unit λ and magnetic field unit $\sqrt{2}B_c (B_c = \Phi_0/(\sqrt{8}\pi\lambda\xi)$ is the thermodynamic critical field), the GL functional reads

$$F\{\psi, \boldsymbol{A}\} = \frac{B_c^2}{\mu_0} \int_V \left[-|\psi|^2 + \frac{1}{2}|\psi|^4 + \left| \left(-\frac{i\nabla}{\kappa} - \boldsymbol{A} \right) \psi \right|^2 + (\nabla \times \boldsymbol{A})^2 \right] \mathrm{d}^3 r \quad [1]$$

Here the integral is over the volume V of the superconductor. The first two terms are the superconducting condensation energy, which is minimum when $|\psi|^2 = 1$. The second term is the energy cost of the spatial variation of ψ; this gauge-invariant gradient also introduces $\boldsymbol{A}$ and thus the magnetic field. The last term is the magnetic energy density $B^2/2\mu_0$.

The GL functional and the resulting GL equations may be expressed in terms of the real-valued function $|\psi|$ and the gauge-invariant supervelocity $\nabla\varphi/\kappa - \boldsymbol{A}$, where $\varphi(\boldsymbol{r})$ is the phase of $\psi = |\psi|\exp(i\varphi)$. From the variation $\delta F/\delta\psi = 0$ follows the first GL equation determining the amplitude and phase of ψ. From the variation $\delta F/\delta\boldsymbol{A} = 0$ follows the supercurrent density $\boldsymbol{J} = \mu_0^{-1}\lambda^2[(\Phi_0/2\pi)\nabla\varphi - \boldsymbol{A}]|\psi|^2$, which has to be supplemented by the Maxwell equation $\boldsymbol{J} = \mu_0^{-1}$ curl curl $\boldsymbol{A}$ to obtain an equation for $\boldsymbol{A}$ or $\boldsymbol{J}$ alone. The minimization of F yields not only the functions $\psi(\boldsymbol{r})$ and $\boldsymbol{A}(\boldsymbol{r})$, but also the boundary condition that the current density and supervelocity do not have a component perpendicular to the free surface of the superconductor.

In an external field H_a, one has to minimize not the free energy F but the Gibbs free energy $G = F - \bar{B}H_a$, where $\bar{B}$ is the spatial average of the magnetic induction B in the superconductor. The condition $\partial G/\partial\bar{B} = 0$ yields the equilibrium field $H_a = \partial F/\partial\bar{B}$. In sufficiently low H_a, the superconductor expels the applied magnetic field completely, that is, one has $B = 0$ inside the superconductor (Meissner state). More precisely, the parallel applied field penetrates into a thin surface layer of thickness λ. In a superconductor filling the half space $x \geq 0$, one has $B(x) = \mu_0 H_a \exp(-x/\lambda)$. This screening of H_a is caused by a surface current of density $j(x) = (H_a/\lambda) \exp(-x/\lambda)$ flowing perpendicular to H_a. Such an exponential screening, strictly spoken, occurs only for London superconductors with large GL-parameter $\kappa \gg 1$, while for smaller κ values both $|\psi|$ and B vary near the surface and have to be obtained by solving the GL equations. Moreover, for superconductors of realistic shape, such as short cylinders or rectangular plates, the penetration of a magnetic field into the surface layer has to be calculated numerically; only for spheres and long cylinders with $\kappa \gg 1$, analytical solutions were obtained by London.

Critical Fields

In type-I superconductors (defined by $\kappa < 1/\sqrt{2}$), complete screening occurs when the applied magnetic field H_a is less than the thermodynamic critical field $H_c = \mu_0^{-1}B_c$; in larger fields $H_a \geq H_c$, these superconductors are normal conducting. For type-II superconductors (defined by $\kappa \geq 1/\sqrt{2}$), full screening occurs up to the lower critical field $H_{c1} = \mu_0^{-1}B_{c1}$ where penetration of Abrikosov vortices begins. With a further increasing of H_a, more vortices penetrate in the form of a more or less regular flux-line lattice (**Figure 1**), which has an average induction $\bar{B} = n\Phi_0$, where n is the area-density of vortices and $\Phi_0 = 2.07 \times 10^{-15}$ T m^2 is the quantum of magnetic

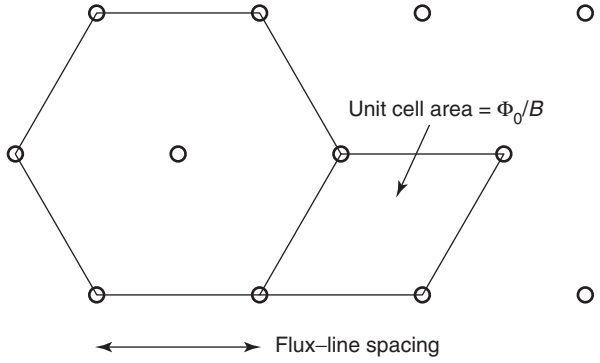

Figure 1 The triangular vortex lattice. The dots mark the positions of the vortex cores.

flux. When H_a reaches the upper critical field $H_{c2} = \mu_0^{-1} B_{c2}$, the vortex cores overlap so strongly that the superconductor turns normal and one has $\bar{B} = \mu_0 H_a \geqslant B_{c2}$. The GL theory yields

$$B_{c1} = \frac{\Phi_0(\ln\kappa + \alpha)}{4\pi\lambda^2}, \quad B_c = \frac{\Phi_0}{\sqrt{8}\pi\lambda\xi}, \quad B_{c2} = \frac{\Phi_0}{2\pi\xi^2} \quad [2]$$

with $\alpha(\kappa) \approx 0.5 + (1 + \ln 2)/(2\kappa - \sqrt{2} + 2)$. At $\kappa = 1/\sqrt{2}$, one has exactly $B_{c1} = B_c = B_{c2}$, and for type-II superconductors $B_{c1} \leqslant B_c \leqslant B_{c2}$. In both types of superconductors, B_c determines the area under the magnetization curve $\mu_0 M(H_a)$; this area equals the superconducting condensation energy B_c^2/μ_0. For ideal pin-free superconductors, the magnetization is $M = \mu_0^{-1}\bar{B} - H_a \leqslant 0$, see **Figure 2**. For type-II superconductors with an ideal planar surface, H_c is also the field up to which the so-called Bean–Livingston surface barrier may prevent a vortex penetration ("overheating"). Interestingly, as discovered theoretically by DeGennes in 1963, even above B_{c2}, a thin surface sheath of thickness ξ remains superconducting up to a third critical field, $B_{c3} = 1.695 B_{c2}$.

The above scenario applies to long superconductors in the parallel magnetic field H_a. In realistic samples like spheres, platelets, or films, demagnetization effects lead to flux penetration at lower fields. In ideal ellipsoids, the penetration fields, H_c or H_{c1}, are reduced by a factor $(1 - N)$, where N is the demagnetization factor. For spheres, one has $N = 1/3$, and for long cylinders, $N = 0$ in a parallel field and $N = 1/2$ in a perpendicular field, while for thin plates in a perpendicular field, one has $1 - N \ll 1$, and thus very small fields will force flux penetration from the edges.

In type-I superconductors with $N > 0$, demagnetization effects lead to partial penetration of flux in the form of planar domains or more complicated structures, while in type-II superconductors they just shear the magnetization curve, but the vortex lattice

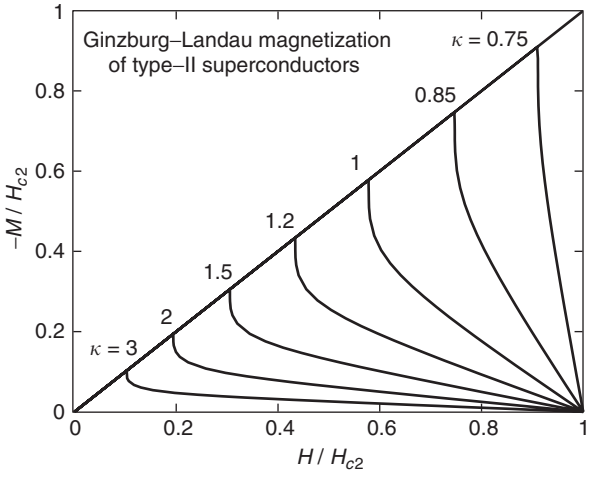

Figure 2 Magnetization curves $M(H)$ of long type-II superconductors in parallel magnetic field $H = H_a$ (demagnetization factor $N = 0$) calculated from the Ginzburg–Landau theory for various Ginzburg–Landau parameters $\kappa = 0.75 \ldots 3$. For $\kappa = 1/\sqrt{2}$, $-M$ jumps vertically from $-M = H$ to $M = 0$ at $H = H_{c1} = H_{c2}$.

remains uniform if the specimen is an ellipsoid. For other shapes such as platelets, strips, or disks with constant thickness, the demagnetization effects are more complicated and lead to a geometric barrier for flux penetration, with a penetration field which is approximately H_{c1} times the square root of the aspect ratio thickness/width. For specimens much larger than λ, this result can be derived by the continuum theory without considering individual vortex lines. But for small mesoscopic superconductors with size comparable to or smaller than λ, the full GL theory has to be solved numerically to see the detailed pattern of penetrated flux lines and the shape of the magnetization curve $M(H_a)$ that may exhibit jumps at certain values of H_a.

Vortex Lattice

In 1957 A A Abrikosov found a solution of the GL theory that exhibits a two-dimensional (2D) regular lattice of zeros in the order parameter $\psi(x,y)$ and a periodic magnetic field $B(x,y)$. This solution describes a lattice of parallel vortex lines along z. The ideal lattice is triangular, that is, each vortex has six nearest neighbors, see **Figure 1**. The vortices start penetrating at $H_a = H_{c1}$. The profiles $|\psi(r)|^2$ and $B(r)$ of one isolated vortex line are shown in **Figure 3** (r is the radial coordinate). As H_a is increased, more vortices penetrate and form a vortex lattice as shown in **Figure 4**. First, the magnetic fields of the flux lines overlap, such that the amplitude of the periodic $B(x,y)$ decreases. Then, the cores also overlap, such that the amplitude of the order parameter $|\psi|^2$ decreases until it vanishes at $H_a = H_{c2}$. For $b = \bar{B}/B_{c2} > 0.5$, good

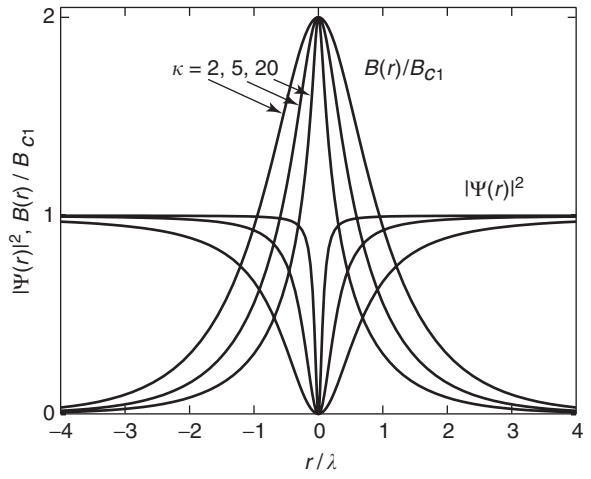

Figure 3 Magnetic field $B(r)$ and order parameter $|\psi(r)|^2$ of an isolated flux line calculated from the Ginzburg–Landau theory for Ginzburg–Landau parameters $\kappa = 2$, 5, and 20.

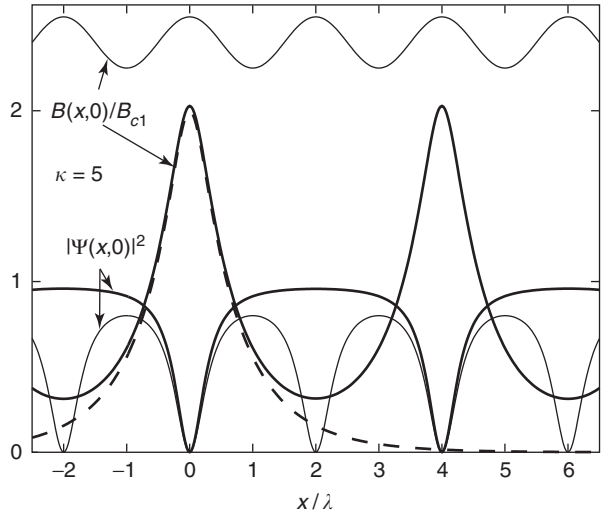

Figure 4 Two profiles of the magnetic field $B(x, y)$ and order parameter $|\Psi(x, y)|^2$ along the x-axis (a nearest-neighbor direction) for flux-line lattices with lattice spacings $a = 4\lambda$ (bold lines) and $a = 2\lambda$ (thin lines). The dashed line shows the magnetic field of an isolated flux line from **Figure 3**. Calculations from the Ginzburg–Landau theory for $\kappa = 5$.

approximations are

$$|\psi(\boldsymbol{r})|^2 = \frac{1 - \bar{B}/B_{c2}}{[1 - 1/(2\kappa^2)]\beta_A + 1} \sum_K a_K \cos \boldsymbol{K}\boldsymbol{r} \quad [3]$$

$$B(\boldsymbol{r}) = \mu_0 H_a - (\phi_0/4\pi\lambda^2)|\psi(\boldsymbol{r})|^2 \quad [4]$$

Here $\boldsymbol{r} = (x, y)$ and the sum is over all reciprocal lattice vectors $K_{mn} = (2\pi/x_1y_2)(my_2; -mx_2 + nx_1)$ of the periodic FLL with flux-line positions $R_{mn} = (mx_1 + nx_2; ny_2)$ $(m, n = \text{integer})$. The unit-cell area x_1y_2 yields the mean induction $\bar{B} = \phi_0/(x_1y_2)$. The first Brillouin zone has the area πk_{BZ}^2 with $k_{BZ}^2 = 4\pi\bar{B}/\phi_0$. For general lattice symmetry, the Fourier coefficients a_K and the Abrikosov parameter β_A are:

$$a_K = (-1)^{m+mn+n} \exp(-K_{mn}^2 x_1 y_2/8\pi) \quad [5]$$

$$\beta_A = \frac{\langle |\psi|^4 \rangle}{\langle |\psi|^2 \rangle^2} = \sum_K a_K^2 \quad [6]$$

From $\psi(\boldsymbol{r} = 0) = 0$ follows $\sum_K a_K = 0$, or with $a_{K=0} = 1$, $\sum_{K \neq 0} a_K = -1$. In particular, for the triangular vortex lattice with spacing $a = (2\phi_0/\sqrt{3}\bar{B})^{1/2}$, one has $x_1 = a$, $x_2 = a/2$, $y_2 = \sqrt{3}a/2$, $\bar{B} = 2\phi_0/(\sqrt{3}a^2)$, $a_K = (-1)^p \exp(-\pi p/\sqrt{3})$ with $p = m^2 + mn + n^2 = R_{mn}^2/R_{10}^2 = K_{mn}^2/K_{10}^2$. This yields $\beta_A = 1.15960$ (the reciprocal-lattice sum converges very rapidly) and the useful relationships $K_{10} = 2\pi/y_2$, $K_{10}^2 = 16\pi^2/3a^2 = 8\pi^2\bar{B}/\sqrt{3}\phi_0$. For the square vortex lattice, one has $x_1 = y_2 = a$, $x_2 = 0$, $\bar{B} = \Phi_0/a^2$, and $\beta_A = 1.18034$. This means the energy of the square vortex lattice is only slightly larger than that of the triangular lattice, by 2% at most. A vortex lattice with square symmetry has been observed experimentally, for example, when the underlying square symmetry of the atomic lattice couples to the vortex lattice such that the square vortex lattice has lower energy, but also other effects may stabilize the square lattice, for example, an anisotropic Fermi surface or a deviation from the GL theory.

The free energy $F(\bar{B})$ per unit volume and the negative magnetization $M = \mu_0^{-1}H_a - \bar{B} \geqslant 0$ with $H_a = \partial F/\partial \bar{B}$ are (still for $\bar{B}/B_{c2} > 0.5$ and from the GL theory):

$$F(\bar{B}) = \frac{\bar{B}^2}{2\mu_0} - \frac{(B_{c2} - \bar{B})^2/2\mu_0}{(2\kappa^2 - 1)\beta_A + 1} \quad [7]$$

$$-\mu_0 M(\bar{B}) = \frac{B_{c2} - \bar{B}}{(2\kappa^2 - 1)\beta_A + 1} = \frac{\phi_0}{4\pi\lambda^2}\langle |\psi|^2 \rangle \quad [8]$$

For the periodic field $B(\boldsymbol{r}) = \sum_K B_K \cos \boldsymbol{K}\boldsymbol{r}$, the Fourier coefficients are $B_{K \neq 0} = Ma_K$, $B_{K=0} = \bar{B}$, and $\langle |\psi|^2 \rangle = (4\pi\lambda^2/\phi_0)|M|$.

At lower induction $\bar{B}/B_{c2} < 0.5$, the vortex lattice and its magnetization curve have to be computed from the GL theory numerically, see **Figures 2–4**. However, when $\kappa \gg 1$, one may also use the London theory, which is a good approximation for small inductions $\bar{B}/B_{c2} < 0.2$.

London Theory

The London theory follows from the GL theory by putting $|\psi| = 1$, but it may also be obtained by minimizing the sum F of the energy of the magnetic

field $B(\boldsymbol{r})$ and the kinetic energy of the supercurrent density $J(\boldsymbol{r}) = \mu_0^{-1}\nabla \times B(\boldsymbol{r})$. This yields the London energy functional

$$F = \frac{1}{2\mu_0}\int_V [B^2 + \lambda^2(\nabla \times B)^2]\mathrm{d}^3 r \qquad [9]$$

Minimizing this with respect to $B = \nabla \times \boldsymbol{A}$, one obtains the homogeneous London equation $B - \lambda^2\nabla^2 B = 0$ or $J = -\mu_0^{-1}\lambda^{-2}\boldsymbol{A}$, where the Maxwell equations $\nabla \cdot B = 0$ and $\nabla \times B = \mu_0 J$ were used and the vector potential $\boldsymbol{A}$ was chosen in the "London gauge," which requires that $\nabla \times \boldsymbol{A} = 0$ and $\boldsymbol{A}$ is parallel to the surface everywhere. In the presence of vortices, one has to add singularities that describe the vortex core, which may be straight or curved.

For straight parallel vortex lines along the unit vector $\hat{\boldsymbol{z}}$, one gets the modified London equation

$$B(\boldsymbol{r}) - \lambda^2\nabla^2 B(\boldsymbol{r}) = \hat{\boldsymbol{z}}\Phi_0 \sum_v \delta_2(\boldsymbol{r} - \boldsymbol{r}_v) \qquad [10]$$

Here $\boldsymbol{r}_v = (x_v, y_v)$ are the 2D vortex positions, which now do not have to form a periodic lattice, and $\delta_2(\boldsymbol{r}) = \delta(x)\delta(y)$ is the 2D delta function. This linear equation may be solved by Fourier transform using the relations $\int \exp(\mathrm{i}\boldsymbol{k}\boldsymbol{r})\mathrm{d}^2 k = 4\pi^2\delta_2(\boldsymbol{r})$ and $\int \exp(\mathrm{i}\boldsymbol{k}\boldsymbol{r})(k^2 + \lambda^{-2})^{-1}\mathrm{d}^2 k = 2\pi K_0(|\boldsymbol{r}|/\lambda)$. Here, $K_0(x)$ is a modified Bessel function with the limits $K_0(x) \approx \ln(1.123/x)$ for $x \ll 1$ and $K_0(x) \approx (\pi/2x)^{1/2}\exp(-x)$ for $x \gg 1$. The resulting magnetic field of any arrangement of parallel vortices is the sum of individual London vortex fields centered at the positions $\boldsymbol{r}_\mathrm{v}$,

$$B(\boldsymbol{r}) = \hat{\boldsymbol{z}}\frac{\Phi_0}{2\pi\lambda^2}\sum_v K_0\left(\frac{|\boldsymbol{r} - \boldsymbol{r}_v|}{\lambda}\right) \qquad [11]$$

The energy $F_{2\mathrm{D}}$ of this 2D arrangement of vortex lines with length L (the specimen height) is obtained by inserting eqn [10] into [9]. Integrating over the delta function, one finds that the London energy is determined by the magnetic field values at the vortex positions,

$$\begin{aligned} F_{2\mathrm{D}} &= L\frac{\Phi_0}{2\mu_0}\sum_\mu B(\boldsymbol{r}_\mu) \\ &= L\frac{\Phi_0^2}{4\pi\mu_0\lambda^2}\sum_\mu\sum_v K_0\left(\frac{|\boldsymbol{r}_\mu - \boldsymbol{r}_v|}{\lambda}\right) \end{aligned} \qquad [12]$$

This expression shows that the energy is composed of the pairwise interaction energy (terms $\mu \neq v$) and the self-energy of the vortices (terms $\mu = v$). To avoid the divergence of the self-energy, one has to cut off the logarithmic infinity of B at the vortex centers $\boldsymbol{r}_v$ by introducing a finite radius of the vortex core of order ξ, the coherence length of the GL theory. This cutoff may be achieved by replacing, in eqns [11] and [12], the distance $r_{\mu v} = |\boldsymbol{r}_\mu - \boldsymbol{r}_v|$ by $\tilde{r}_{\mu v} = (r_{\mu v}^2 + 2\xi^2)^{1/2}$, and multiplying B by a normalization factor ≈ 1 to conserve the flux Φ_0 of the vortex. This analytical expression suggested by John Clem for a single vortex and later generalized to the vortex lattice, is an excellent approximation, as was shown numerically by solving the GL equation for the periodic FLL in the entire ranges of $\bar{B}$ and κ for $0 \leqslant \bar{B} \leqslant B_{\mathrm{c}2}$ and $\kappa \geqslant 1/\sqrt{2}$.

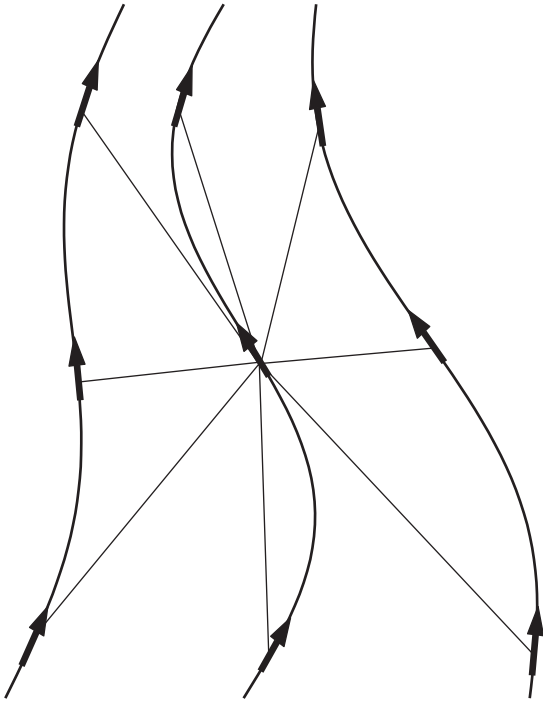
For curved vortices at arbitrary positions $\boldsymbol{r}_v(z) = [x_v(z), y_v(z), z]$, the 3D modified London equation reads

$$B(\boldsymbol{r}) - \lambda^2\nabla^2 B(\boldsymbol{r}) = \Phi_0 \sum_v \int \mathrm{d}\boldsymbol{r}_v\, \delta_3(\boldsymbol{r} - \boldsymbol{r}_v) \qquad [13]$$

Here, the integral is along the vortex lines and $\delta_3(\boldsymbol{r}) = \delta(x)\delta(y)\delta(z)$. The resulting magnetic field and energy are, with $\tilde{r}_{\mu v} = [|\boldsymbol{r}_\mu(z) - \boldsymbol{r}_v(z)|^2 + 2\xi^2]^{1/2}$,

$$B(\boldsymbol{r}) = \frac{\Phi_0}{4\pi\lambda^2}\sum_v \int \mathrm{d}\boldsymbol{r}_v \frac{\exp[-\tilde{r}_{\mu v}(\boldsymbol{r}_\mu = \boldsymbol{r})/\lambda]}{\tilde{r}_{\mu v}(\boldsymbol{r}_\mu = \boldsymbol{r})} \qquad [14]$$

$$\begin{aligned} F_{3\mathrm{D}} &= \frac{\Phi_0}{2\mu_0}\sum_\mu \int \mathrm{d}\boldsymbol{r}_\mu B(\boldsymbol{r}_\mu) \\ &= \frac{\Phi_0^2}{8\pi\mu_0\lambda^2}\sum_\mu\sum_v \int \mathrm{d}\boldsymbol{r}_\mu \int \mathrm{d}\boldsymbol{r}_v \frac{\exp(-\tilde{r}_{\mu v}/\lambda)}{\tilde{r}_{\mu v}} \end{aligned}$$



Interaction between curved flux lines

Figure 5 Pairwise interaction between all line elements (arrows) of curved flux lines within the London theory (schematic).

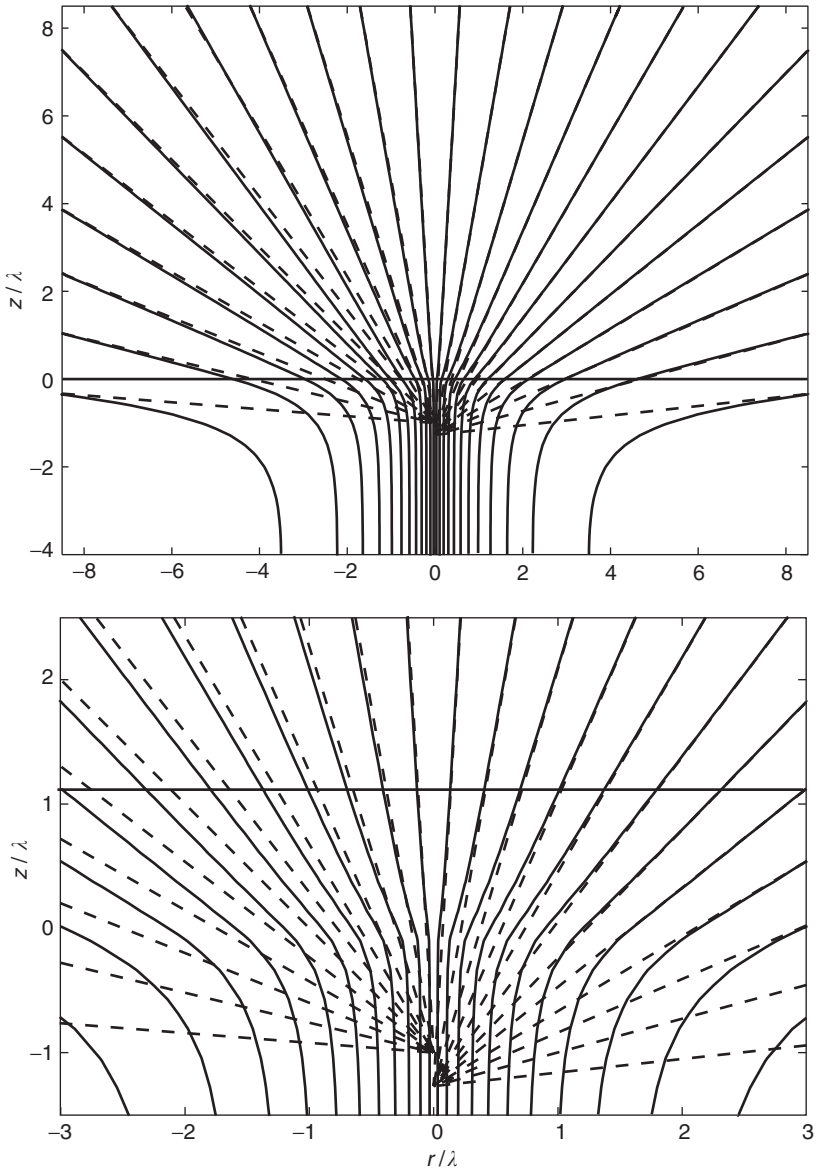


Figure 6 Magnetic field lines of a straight vortex in and near a superconducting half space. From the London theory, for $\kappa = 20$. The dashed lines give the radial field lines of a magnetic charge of size $2\Phi_0$ positioned on the vortex axis at a depth $-z_0 = \lambda$ (left half, the far field) and $-z_0 = 1.27\lambda$ (right half), which gives a better fit to the near field. The lower plot enlarges the center of the upper plot.

This means all the vortex segments interact with each other similar to magnetic dipoles or tiny current loops, but the magnetic long-range interaction $\propto 1/r$ is screened by a factor $\exp(-\tilde{r}_{\mu\nu}/\lambda)$. The 3D interaction between curved vortices is visualized in **Figure 5**.

Vortices Near Surfaces and in Films

The above London solutions apply to vortices in the bulk. Near the surface of the superconductor, these expressions have to be modified. In simple geometries, for example, for superconductors with one or two planar surfaces surrounded by vacuum, the magnetic field and energy of a given vortex arrangement is obtained by adding the field of appropriate images (in order to satisfy the boundary condition that no current crosses the surface) and a magnetic stray field which is caused by a fictitious surface layer of magnetic monopoles. This stray field makes the total magnetic field $B(\boldsymbol{r})$ continuous across the surface. **Figure 6** shows an example for this.

The magnetic field and interaction of straight vortices oriented perpendicular to a superconducting film of arbitrary thickness was calculated by Carneiro and Brandt from the London theory and by Brandt from the GL theory. In films of thickness $d \ll \lambda$ in a perpendicular magnetic field, the short vortices interact mainly via their magnetic stray field outside the

superconductor over an effective penetration depth $\Lambda = 2\lambda^2/d$. At short distances $r \ll \Lambda$, this interaction is logarithmic as in the bulk case, and at large $r \gg \Lambda$, it decreases as $\exp(-r/\Lambda)$. With decreasing thickness d, the Fourier transform of the 2D vortex interaction $V(r) = \int (\mathrm{d}^2k/4\pi^2)\tilde{V}(k)\exp(\mathrm{i}\boldsymbol{k}\boldsymbol{r})$ changes from $\tilde{V}(k) = E_0\ (k^2 + \lambda^{-2})^{-1}$ for $d \gg \lambda$ to $\tilde{V}(k) = E_0(k^2 + k\Lambda^{-1})^{-1}$ for $d \ll \lambda$, where $E_0 = d\Phi_0^2/(\mu_0\lambda^2)$.

As shown by Chem, a similar (but 3D) magnetic interaction exists between the 2D "pancake vortices" in the superconducting Cu–O layers of high-T_c superconductors, $\tilde{V}(\boldsymbol{k}) = E_0 d k_3^2 k_2^{-2}(\lambda^{-2} + k_3^2)^{-1}$, where now d is the distance between the layers, $k_2^2 = k_x^2 + k_y^2, k_3^2 = k_2^2 + k_z^2$, and $\lambda = \lambda_{ab}$ is the penetration depth for the supercurrents flowing in these layers.

Elasticity of the Vortex Lattice

Small flux-line displacements caused by pinning forces or by thermal fluctuations may be calculated using the linear elasticity theory of the vortex lattice. **Figure 7** visualizes the three basic distortions of the triangular vortex lattice: shear γ, uniaxial compression ε, and tilt α, defining the three elastic moduli c_{66}, c_{11}, and c_{44} and the naive (local) elastic energy

$$F_{\mathrm{elast}} = \frac{V}{2}[c_{11}\varepsilon^2 + c_{66}\gamma^2 + c_{44}\alpha^2] \qquad [15]$$

The linear elastic energy F_{elast} of the vortex lattice is obtained by expanding its free energy F with respect to small displacements $\boldsymbol{u}_v(z) = \boldsymbol{r}_v(z) - \boldsymbol{R}_v = (u_{vx}, u_{vy})$ of the vortices from their ideal parallel lattice positions $\boldsymbol{R}_v$ and keeping only the quadratic terms. This yields

$$F_{\mathrm{elast}} = \frac{1}{2}\int_{\mathrm{BZ}} \frac{\mathrm{d}^3k}{8\pi^3} u_\alpha(\boldsymbol{k})\Phi_{\alpha\beta}(\boldsymbol{k})u_\beta^*(\boldsymbol{k}) \qquad [16]$$

where $\boldsymbol{u}(\boldsymbol{k})$ is the Fourier transform of the displacement field $\boldsymbol{u}_v(z)$, $(\alpha, \beta) = (x, y)$, and $\boldsymbol{k} = (k_x, k_y, k_z)$. The k-integral in eqn [16] is over the first Brillouin zone (BZ) of the FLL since the "elastic matrix" $\Phi_{\alpha\beta}(\boldsymbol{k})$ is periodic in the k_x, k_y plane; the finite vortex core radius restricts the k_z integration to $|k_z| \leqslant \xi^{-1}$. For an elastic medium with uniaxial symmetry, the elastic matrix reads

$$\Phi_{\alpha\beta}(\boldsymbol{k}) = (c_{11} - c_{66})k_\alpha k_\beta + \delta_{\alpha\beta}[(k_x^2 + k_y^2)c_{66} + k_z^2 c_{44}] \qquad [17]$$

Here the coefficients c_{11}, c_{66}, and c_{44} are the elastic moduli of uniaxial compression, shear, and tilt, respectively. For the vortex lattice, $\Phi_{\alpha\beta}(\boldsymbol{k})$ was calculated from the GL and London theories. The result, a sum over reciprocal lattice vectors, should coincide with expression [17] in the continuum limit, that is, for small $|\boldsymbol{k}| \ll k_{\mathrm{BZ}}$, where $k_{\mathrm{BZ}} = (4\pi\bar{B}/\Phi_0)^{1/2}$ is the radius of the circularized (actually hexagonal) Brillouin

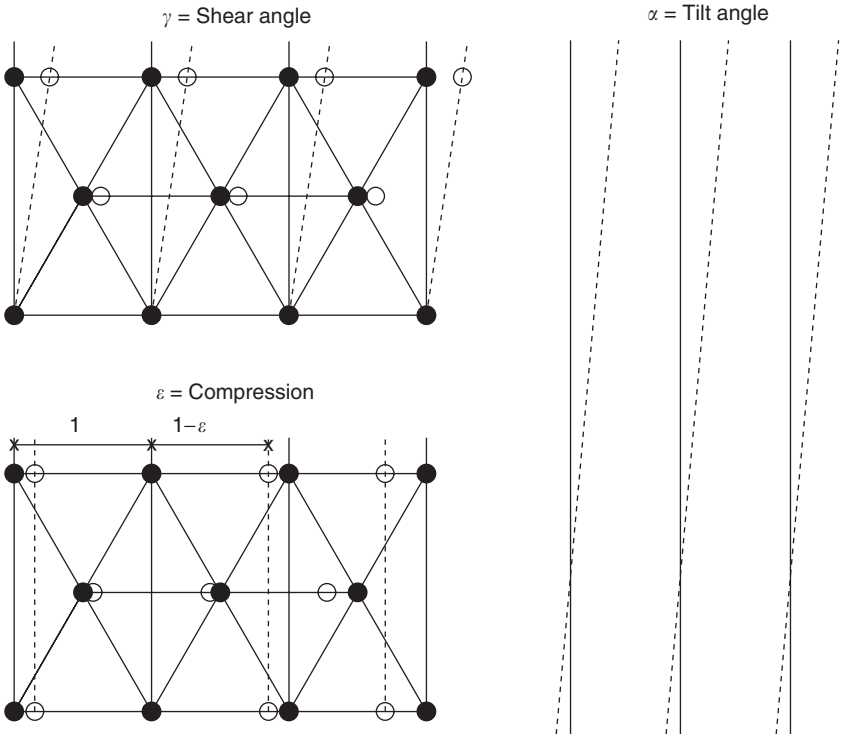

Figure 7 The three basic homogeneous elastic distortions of the triangular vortex lattice. The full dots and solid lines mark the ideal lattice, and the hollow dots and dashed lines the distorted lattice.

zone of the triangular vortex lattice with area πk_{BZ}^2. In the London limit, one finds for isotropic superconductors, the elastic moduli

$$c_{11}(k) \approx \frac{\bar{B}^2/\mu_0}{1+k^2\lambda^2}, \quad c_{66} \approx \frac{\bar{B}\Phi_0/\mu_0}{16\pi\lambda^2},$$
$$c_{44}(\boldsymbol{k}) \approx \frac{\bar{B}^2/\mu_0}{1+k^2\lambda^2} + \frac{\bar{B}\Phi_0/\mu_0}{8\pi\lambda^2} \ln \frac{\kappa^2}{1+k_z^2\lambda^2} \quad [18]$$

The GL theory yields an additional factor $(1-\bar{B}/B_{c2})^2$ in c_{66}, that is, $c_{66} \propto \bar{B}(\bar{B}-B_{c2})^2$, and replaces λ in c_{11} and c_{44} (first term) by $\lambda' = \lambda/(1-\bar{B}/B_{c2})^{1/2}$.

The $\boldsymbol{k}$ dependence (dispersion) of the compression and tilt moduli $c_{11}(k)$ and $c_{44}(\boldsymbol{k})$ means that the elasticity of the vortex lattice is nonlocal, that is, strains with short wavelengths, $2\pi/k \ll 2\pi\lambda$, have a much lower elastic energy than a homogeneous compression or tilt (corresponding to $\boldsymbol{k} \to 0$) with the same amplitude. This elastic nonlocality comes from the fact that the magnetic interaction between the flux lines typically has a range λ much longer than the flux-line spacing a_0; therefore, each flux line interacts with many other flux lines. Note that a large λ causes a small shear stiffness since $c_{66} \propto \lambda^{-2}$, and a smaller $c_{11}(k < \lambda^{-1})$ at short wavelengths, but the uniform compressibility $c_{11}(k=0)$ is independent of λ.

As a consequence of nonlocal elasticity, the vortex displacements $\boldsymbol{u}_v(z)$ caused by local pinning forces, and also the space- and time-averaged thermal fluctuations of the vortex positions, $\langle \boldsymbol{u}_v(z)^2 \rangle$, are much larger than they would be if $c_{44}(\boldsymbol{k})$ had no dispersion, that is, if it were replaced by $c_{44}(0) = \bar{B}H_a \approx \bar{B}^2/\mu_0$. The maximum vortex displacement $u(0) \propto f$ caused at $\boldsymbol{r}=0$ by a point force of density $f\delta_3(\boldsymbol{r})$, and the thermal fluctuations $\langle u^2 \rangle \propto k_B T$, are given by similar expressions,

$$\frac{2u(0)}{f} \approx \frac{\langle u^2 \rangle}{k_B T} \approx \int_{BZ} \frac{d^3k}{8\pi^3} \frac{1}{(k_x^2+k_y^2)c_{66} + k_z^2 c_{44}(\boldsymbol{k})} \approx \frac{k_{BZ}^2 \lambda}{8\pi[c_{66}c_{44}(0)]^{1/2}} \quad [19]$$

In this result, a large factor $[c_{44}(0)/c_{44}(k_{BZ})]^{1/2} \approx k_{BZ}\lambda \approx \pi\lambda/a \gg 1$ originates from the elastic nonlocality. In anisotropic superconductors with $B \| c$ (the crystalline c axis), the thermal fluctuations, eqn [19], are enhanced by an additional factor $\Gamma = \lambda_c/\lambda_{ab} \gg 1$, where λ_{ab} and λ_c are the two penetration depths of uniaxially anisotropic superconductors.

Superconductivity: Tunneling

A N Cleland, University of California, Santa Barbara, CA, USA

Introduction

The quantum mechanical tunneling of electrons and other charge carriers through an insulating or a vacuum barrier is at the heart of many electronic devices. In superconductors, the controlled tunneling of Cooper-paired electrons forms the basis for the Josephson junction and the DC and RF super-conducting quantum interference devices (RF and DC SQUIDs), as well as a number of other related devices.

The tunneling of a single particle through an energy barrier, such as an electron through an insulator or through vacuum, can be understood using a

one-dimensional quantum mechanical model. This single-particle picture can be extended to the tunneling of large numbers of electrons through a barrier separating two normal metals, a structure known as a tunnel junction, by convolving the one-particle tunneling result with the electronic distribution of states in the two metals; this can be done because the correlations between the electrons in a metal are sufficiently weak that they can be ignored. If the metals are in the superconducting state, both quasiparticles (the electron-like excitations in a superconductor) and Cooper pairs can tunnel through the barrier. The quasiparticles can be treated as independent, uncorrelated charge carriers, allowing the use of the single-particle picture. Cooper-pair tunneling involves the interference of the coherent superconducting wave functions on either side of the barrier, and, therefore, must be treated in a different fashion. This coherent process gives rise to the Josephson supercurrent. The DC Josephson effect describes the magnitude of the superconducting pair current, which is obtained for zero applied voltage and is determined by the difference in the quantum mechanical phases of the superconducting states on either side of the tunnel barrier. If a voltage V is applied between the two superconductors, this phase difference evolves in time, modulating the superconducting current; this is called the AC Josephson effect.

The article begins with the simple one-particle picture of tunneling between normal metals (NN tunneling), the discussion is then extended to include a superconductor on one side of the barrier, with a normal metal on the other (SN tunneling), and finally treats the case of superconducting metals on both sides of the barrier (SS tunneling). The article ends with a brief discussion of the effect of the electromagnetic environment on both normal and superconducting tunneling, an effect which is significant for tunnel junctions with very small geometric capacitance, where single charge effects, such as the Coulomb blockade, are relevant.

Normal Metal–Normal Metal Tunneling

Transmission through a Potential Barrier

An introductory problem in quantum mechanics is finding the transmission probability for a particle of mass m to pass through a one-dimensional potential barrier of height U and thickness d, with the barrier height greater than the particle energy E, as shown in **Figure 1a**. The particle is classically forbidden from entering the barrier region, but quantum mechanics allows a nonzero transmission probability. A solution of the one-dimensional Schrödinger equation

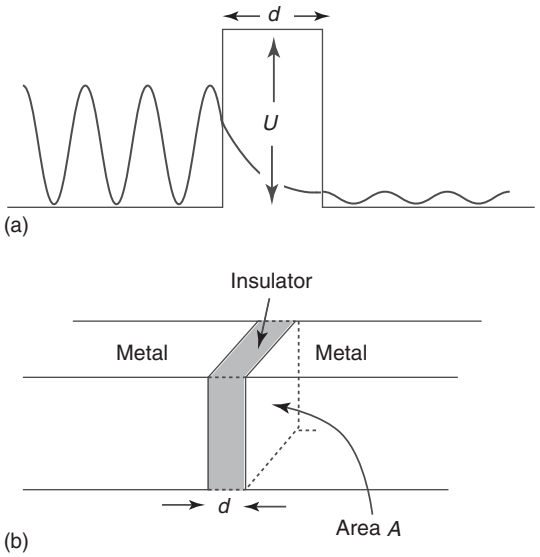

Figure 1 (a) Schematic of a one-dimensional potential barrier, with particle of energy E incident from the left and partially transmitted to the right. The barrier has height U and thickness d. (b) Schematic of metal–insulator–metal tunnel junction, of thickness d and cross-sectional area A.

yields a transmission coefficient that scales as $\exp[-2\kappa d]$, where

$$\kappa = \sqrt{\frac{2m(U-E)}{\hbar^2}} \qquad [1]$$

is the decay coefficient in the barrier region. The transmission is exponentially suppressed by increases in the barrier height and thickness. The tunneling transmission in the opposite direction, from right to left, is the same.

This simple model can be adapted to the tunneling of an electron in a metal through an insulating (or vacuum) barrier into another metal, as sketched in **Figure 1b**. The energy difference $\Delta E = U - E$ that determines the decay coefficient κ is taken to be $\Delta E \approx e(\Phi - \chi)$, the difference in the work function Φ of the metal and the insulator electron affinity χ. For a vacuum barrier, $\chi = 0$. For a characteristic energy difference $e(\Phi - \chi)$ of about 4 eV, the decay coefficient is $\kappa \approx 1 \times 10^{10}\ \mathrm{m}^{-1}$, so the transmission coefficient is reduced by a factor $1/e \approx 0.368$ for every 0.05 nm increase in the barrier thickness d. Reasonable transmission coefficients, yielding measurable rates of electron tunneling through such a tunnel barrier, require barrier thicknesses of the order $d \sim 1$ nm.

Current–Voltage Characteristic

In a real metal–insulator–metal interface, there are, of course, large numbers of electrons in each metal

electrode that can approach and interact with the tunnel barrier. The model described above is a single-particle picture, but can still be applied quite accurately to a metal as long as the Fermi exclusion principle is obeyed: there can be at most one electron in each distinct quantum mechanical state. This principle is included by allowing an electron to tunnel through the barrier only if the final state on the other side of the barrier has some probability of being empty; it is noted that, to first order, the initial and final energies of the tunneling electron must be equal.

At zero temperature, all the electron states in a metal with energy E less than the Fermi energy E_F are filled with probability unity, while all states above E_F are empty. For electrons at a nonzero temperature T, the probability that a state at energy E is occupied is given by the Fermi–Dirac distribution $f(E)$, which, for energies measured from the electrochemical potential μ_F, is given by

$$f(E) = \frac{1}{\exp(E/k_B T) + 1} \qquad [2]$$

The electrochemical potential μ_F is equal to the Fermi energy E_F at zero temperature; at a nonzero temperature, μ_F is the energy where the occupation probability is 1/2, and is very nearly equal to E_F if $k_B T \ll E_F$.

Consider applying a voltage V between the two metal electrodes, as shown in **Figure 2a**. This raises the electrochemical potential μ_L on the left electrode by an amount eV with respect to the electrochemical potential μ_R on the right, $\mu_L = \mu_R + eV$. An electron with energy E in the left electrode, measured from μ_L, will then tunnel into a state $E + eV$ in the right electrode, measured from μ_R. Using a transmission probability $|\mathscr{T}|^2$ per unit area, assumed independent of energy E, the rate at which electrons with energies in the range E to $E + dE$ will tunnel from the left to the right electrode is given by a Fermi's golden rule expression

$$\Gamma_{L\to R}(E)\,dE = \frac{2\pi A}{\hbar}|\mathscr{T}|^2 f(E)[1 - f(E + eV)]\,dE \qquad [3]$$

This includes the probability $f(E)$ of having an occupied state in the left electrode, and the probability $1 - f(E + eV)$ of a vacant state in the right electrode. There is a similar expression for electrons with energy between $E + eV$ and $E + eV + dE$ in the right electrode tunneling to the left

$$\Gamma_{R\to L}(E + eV)\,dE = \frac{2\pi A}{\hbar}|\mathscr{T}|^2 f(E + eV) \times [1 - f(E)]\,dE \qquad [4]$$

The net electrical current that flows due to these two opposing fluxes is the difference of these rates, summed over all initial energies, multiplied by the electron charge $-e$. Writing the sum over energy as an integral that includes the appropriate density of states $\mathscr{D}_{L,R}(E)$ in the left and right electrodes, the net electrical current (from right to left) is

$$\begin{aligned} I_{NN}(T) &= -e\Sigma_E(\Gamma_{R\to L}(E + eV) - \Gamma_{L\to R}(E)) \\ &= \frac{2\pi eA}{\hbar}|\mathscr{T}|^2 \int_{-\infty}^{\infty} dE\, \mathscr{D}_L(E)\mathscr{D}_R(E + eV) \\ &\quad \times \{f(E)[1 - f(E + eV)] \\ &\quad - f(E + eV)[1 - f(E)]\} \end{aligned} \qquad [5]$$

The range of integration is extended to $\pm\infty$, as the thermal occupations will limit the integrand to a range $k_B T \ll E_F$, so the increased range does not change the result. Then, the density of states is approximated on the left and right electrodes by their values at the Fermi level, $\mathscr{D}_{L,R}(E) \approx \mathscr{D}_{L,R}(0)$, and so

$$\begin{aligned} I_{NN}(T) &= \frac{2\pi eA}{\hbar}|\mathscr{T}|^2 \mathscr{D}_L(0)\mathscr{D}_R(0) \\ &\quad \times \int_{-\infty}^{\infty} dE\,(f(E) - f(E + eV)) \\ &= G_{NN} V \end{aligned} \qquad [6]$$

One thus finds a linear current–voltage relationship for a normal–insulator–normal metal tunnel junction, with a voltage- and temperature-independent electrical conductance G_{NN} given by

$$G_{NN} = \frac{2\pi e^2 A}{\hbar}|\mathscr{T}|^2 \mathscr{D}_L(0)\mathscr{D}_R(0) \qquad [7]$$

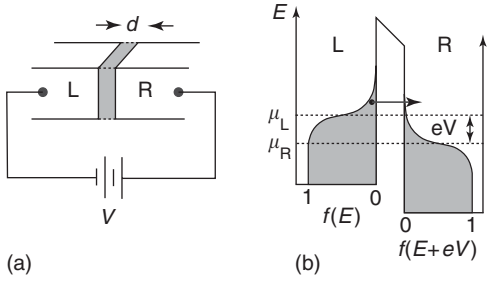

Figure 2 (a) Voltage V applied between metal electrodes on the left (L) and right (R). (b) Energy diagram for the electrons in the two electrodes with bias voltage V, showing the Fermi distributions on either electrode, with the zero of energy shifted by eV. The electrochemical potentials μ_L and μ_R are the points where the respective Fermi distributions are equal to 1/2, and are taken as the zero energy for each electrode.

Superconductor–Normal Metal Tunneling

If one of the normal metal electrodes is replaced with a superconductor, the rate of tunneling, and the form of the current–voltage characteristic, are modified

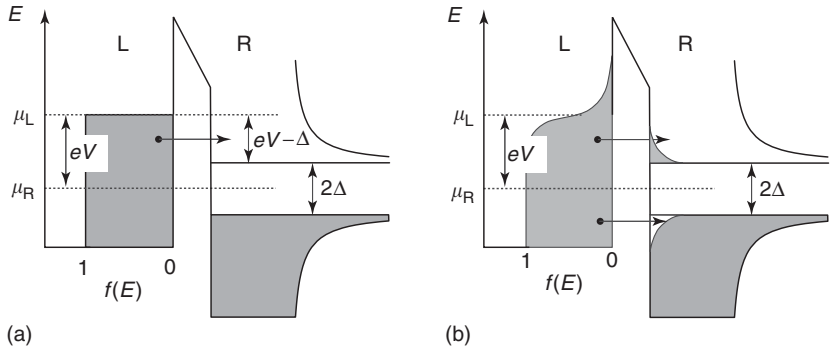

Figure 3 (a) Energy diagram at $T = 0$ for a normal metal (left) and superconductor (right) on either side of a tunnel barrier, the superconductor biased a voltage V above the normal metal. (b) Same as for (a), but at nonzero temperature, showing the distribution of occupied states in the normal metal and superconductor. Two possible tunneling processes, above and below the gap, are shown.

due to the change in the density of states in the superconducting electrode. At first, it appears that in addition, a change will occur due to the coherent quantum mechanical mixing of the electron and hole states above and below the Fermi level in the superconductor, involving the coherence factors that control this mixing. However, an electron can tunnel into either the hole-like or the electron-like excitation states, and the probabilities for these two processes add to 1. Therefore, the tunnel rate is affected only by the change in the density of states for the superconducting electrode. Choosing the right electrode as the superconductor, replace the normal metal density of states $\mathscr{D}_R(E)$ in eqn [5] with that for the superconductor,

$$\mathscr{D}_S(E) = \begin{cases} \mathscr{D}_R(0)\dfrac{|E|}{\sqrt{E^2 - \Delta^2}} & (|E| > \Delta) \\ 0 & (|E| < \Delta) \end{cases} \qquad [8]$$

where $\mathscr{D}_R(0)$ is the normal density of states at the Fermi level, and Δ is the superconducting energy gap, which depends on temperature. Energy E is measured from the electrochemical potential μ_R, which is the energy of the Cooper pairs.

At zero temperature, the quasiparticle states in the superconducting electrode are all unoccupied, as the quasiparticles are all condensed into Cooper pairs. The electron states in the left (normal metal) electrode are occupied with probability unity below the Fermi level E_F, and empty above. Applying a bias voltage V to the superconducting electrode with respect to the normal metal electrode, only electrons in the normal metal with energy E in the range $\Delta - eV < E < 0$ are able to tunnel into the superconductor (see **Figure 3a**). The current at zero temperature is given by

$$I_{SN}(0) = \frac{2\pi eA}{\hbar}|\mathscr{T}|^2 \int_{\Delta - eV}^{0} \mathscr{D}_L(E)\mathscr{D}_S(E + eV)\,dE \qquad [9]$$

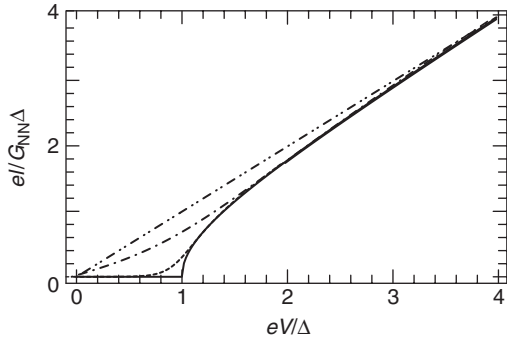

Figure 4 Current–voltage characteristic for a superconductor–normal metal tunnel junction, showing the calculated current for temperatures $k_B T = 0$, $\Delta/10$, $\Delta/2$, and for a normal–normal tunnel junction.

Inserting the density of states, eqn [8], for the superconductor, replacing the density of states for the normal metal, $\mathscr{D}_L(E)$, by the value at the Fermi level, $\mathscr{D}_L(0)$, and changing the variable of integration to $E' = E + eV$, this is

$$I_{SN}(0) = \frac{2\pi eA}{\hbar}|\mathscr{T}|^2 \mathscr{D}_L(0)\mathscr{D}_R(0) \times \int_{\Delta}^{eV} \frac{E'}{\sqrt{E'^2 - \Delta^2}}\,dE' \qquad [10]$$

$$I_{SN}(0) = \begin{cases} \dfrac{G_{NN}}{e}\sqrt{(eV)^2 - \Delta^2}, & |eV| \geq \Delta \\ 0, & |eV| < \Delta \end{cases} \qquad [11]$$

in terms of the normal–normal conductance G_{NN}, eqn [7]. The form of the zero-temperature conductance is plotted in **Figure 4**.

At nonzero temperatures, the occupation probabilities for the normal metal and superconducting quasiparticle states must be included. These are both described by the Fermi–Dirac distribution $f(E)$ given by eqn [2], measured from the local electrochemical potential; the corresponding distribution of occupied

states is shown in **Figure 3b**. The current at temperature T is the given by

$$I_{SN}(T) = \frac{G_{NN}}{e}\left(\int_{-\infty}^{-\Delta} + \int_{\Delta}^{\infty}\right)\frac{E'}{\sqrt{E'^2 - \Delta^2}} \times [f(E' - eV) - f(E')]\,dE' \qquad [12]$$

where the limits have been extended to $\pm\infty$ to include all the thermally excited states. This integral can be evaluated numerically. The current–voltage characteristics at a few temperatures are shown in **Figure 4**.

Andreev Reflection

The expressions derived for superconductor–normal metal tunneling are correct to first order in the tunneling probability $|\mathscr{T}|^2$. These predict zero current for voltages below the superconducting gap, $|V| < \Delta/e$, when at zero temperature. To second order in $|\mathscr{T}|^2$ (i.e., of order $|\mathscr{T}|^4$), however, an additional process becomes important. In this process, two electrons in the normal metal, symmetrically positioned about the electrochemical potential in the superconductor with wave vectors $\boldsymbol{k}$ and $-\boldsymbol{k}$, can tunnel simultaneously into the superconductor and form a Cooper pair. Another way to describe this process is that an electron with wave vector $\boldsymbol{k}$ tunnels into a Cooper pair, and the unfilled (hole) state in the pair tunnels simultaneously back into the normal metal, emerging with a wave vector $-\boldsymbol{k}$. The incident electron is then said to have been reflected from the superconductor as a hole, a process known as Andreev reflection. This process yields a nonzero conductance for a superconductor–normal tunnel barrier below the gap voltage.

Superconductor–Superconductor Tunneling

When both metals contacting a tunnel barrier are superconductors, there are two important effects that change the situation in comparison to the superconductor–normal metal tunnel junction: one is the appearance of the superconducting density of states on both sides of the tunnel barrier, changing the nature of the quasiparticle current–voltage characteristic. The other very significant change is the appearance of coherent Cooper-pair tunneling, present to first order in the tunneling probability $|\mathscr{T}|^2$. The theory for this process was first derived by B D Josephson, a prediction for which he was awarded the Nobel prize in 1973.

Quasiparticle Tunneling

The incoherent process of quasiparticle tunneling is first discussed, similar to that in the superconductor–normal metal tunnel junction. The rate of quasiparticle tunneling is controlled by the superconducting density of states appearing on both sides of the barrier, as well as the thermal occupation probability of these states. A sketch of the energy diagram is shown in **Figure 5**.

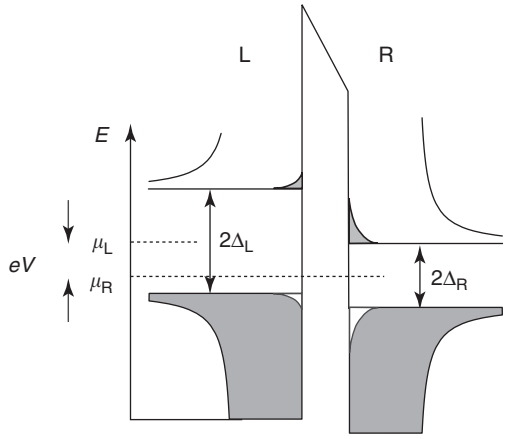

Figure 5 Quasiparticle energy diagram for two superconductors with different gaps Δ_L and Δ_R, biased with voltage V at a nonzero temperature.

The expression for the quasiparticle current $I_{SS}(T)$ at temperature T, for the right electrode biased by voltage V above the left electrode, is given by

$$I_{SS}(T) = \frac{G_{NN}}{e}\int_{-\infty}^{\infty}\frac{|E' - eV|}{\sqrt{(E' - eV)^2 - \Delta_L^2}}\frac{|E'|}{\sqrt{E'^2 - \Delta_R^2}} \times [f(E' - eV) - f(E')]\,dE' \qquad [13]$$

with energy E' measured from the electrochemical potential μ_R in the right electrode. Different superconducting gaps Δ_L and Δ_R are allowed, and it is understood that the density of states goes to zero in the gap regions on either side of the barrier, so that for energies E' in the ranges $|E'| < \Delta_R$ and $|E' - eV| < \Delta_L$, the integrand is zero. This is sketched in **Figure 5**.

At zero temperature, there is no current for voltages $|V| < (\Delta_R + \Delta_L)/e$ (for identical superconductors, this translates to $|V| < 2\Delta/e$). At the gap voltage $|V| = (\Delta_R + \Delta_L)/e$, there is a discontinuity in the current, which goes from zero to $(\pi G_{NN}/2e)(\Delta_R\Delta_L)^{1/2}$. For $T \neq 0$, an additional feature appears for voltages near the difference of the gap energies, $|V| \approx |\Delta_L - \Delta_R|/e$, due to the overlap of the discontinuity in the density of states of the larger-gap superconductor with the nonzero occupation number of the quasiparticle states in the smaller-gap superconductor. The form of the temperature-dependent current–voltage characteristic is shown schematically in **Figure 6**. For identical superconductors, with

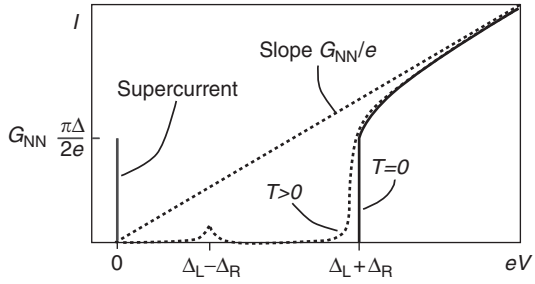

Figure 6 Sketch of a superconductor–superconductor current–voltage characteristic, showing the quasiparticle current for $T = 0$ and $T \neq 0$, for superconductors with different gaps. Also shown is the supercurrent branch at $V = 0$; the zero-temperature supercurrent amplitude I_0 and the discontinuity in the quasiparticle current at $eV = \Delta_L + \Delta_R$ are equal.

$\Delta_R = \Delta_L$, at very low temperatures $T \ll \Delta/e$, and voltages below the gap $|V| < 2\Delta/e$, an approximate analytic form for the current–voltage characteristic is given by Van Duzer and Turner

$$I_{SS}(V,T) = \frac{2G_{NN}}{e}\exp\left(-\frac{\Delta}{k_B T}\right)\sqrt{\frac{2\Delta}{eV+2\Delta}}(eV+\Delta) \times \sinh\left(\frac{eV}{2k_B T}\right)K_0\left(\frac{eV}{2k_B T}\right) \quad [14]$$

where K_0 is the zeroth-order modified Bessel function.

Josephson Effects

In addition to the incoherent tunneling of quasiparticles between two superconducting electrodes, there exist the very important and rich effects predicted by Josephson and first observed by Anderson and Rowell. A simple model for the Josephson effect is described by Feynman, and his model is reproduced here.

The superconducting state, being a macroscopic quantum condensate, can be described by a single macroscopic wave function Ψ, such that

$$\Psi(\boldsymbol{r}) = A(\boldsymbol{r})\exp[i\theta(\boldsymbol{r})] \quad [15]$$

where the real amplitude $A(\boldsymbol{r})$ is related to the Cooper-pair number density, $A(\boldsymbol{r})^2 = n(\boldsymbol{r})$, and $\theta(\boldsymbol{r})$ is the macroscopic phase of the superconducting wave function. In the simplest description, the equation of motion for the wave function of an isolated superconductor is

$$i\hbar\frac{\partial\Psi}{\partial t} = E\Psi \quad [16]$$

where E is the ground-state energy of the superconductor.

With two superconducting wave functions, Ψ_L and Ψ_R, on the left and right sides of a tunnel barrier, the tunnel barrier is assumed to give a weak coupling between the two wave functions, parametrized by the coupling constant K. The coupled equations of motion can be written as

$$i\hbar\frac{\partial\Psi_L}{\partial t} = E_L\Psi_L + K\Psi_R$$
$$i\hbar\frac{\partial\Psi_R}{\partial t} = E_R\Psi_R + K\Psi_L \quad [17]$$

The energies of the ground states E_R and E_L differ by the applied bias voltage V: $E_L - E_R = 2eV$, the factor of 2 accounting for the charge of a Cooper pair. Taking the zero of energy at the midpoint between the 2 superconductors, and separating the equations for the pair number density, $A_R = \sqrt{n_R}$ and $A_L = \sqrt{n_L}$, from that for the phases θ_R and θ_L,

$$\frac{\partial n_L}{\partial t} = +\frac{2}{\hbar}K\sqrt{n_R n_L}\sin\delta$$
$$\frac{\partial n_R}{\partial t} = -\frac{2}{\hbar}K\sqrt{n_R n_L}\sin\delta$$
$$\frac{\partial\theta_L}{\partial t} = -\frac{eV}{\hbar} - \frac{K}{\hbar}\sqrt{\frac{n_R}{n_L}}\cos\delta$$
$$\frac{\partial\theta_R}{\partial t} = +\frac{eV}{\hbar} - \frac{K}{\hbar}\sqrt{\frac{n_L}{n_R}}\cos\delta \quad [18]$$

where the phase difference $\delta = \theta_R - \theta_L$.

From these equations, it is seen that $\dot{n}_R = -\dot{n}_L$, so that the rate of increase of the pair density on the right is exactly the rate of decrease of pair density on the left; this is due to a current density $J = -2e\dot{n}_R$ flowing from right to left. In actuality, the pair density does not change. The depletion of charge in the vicinity of the barrier is replenished by a flow of current through the external circuit. To equilibrate the electrochemical potentials at zero voltage, take $n_L = n_R$.

It is thus found that at zero voltage, there is a supercurrent density $J = (2K/\hbar)\sqrt{n_R n_L}\sin\delta$. The critical current density of the barrier can be defined, $J_0 = (2K/\hbar)\sqrt{n_R n_L}$, so that $J = J_0\sin\delta$. Assuming uniform current density across the area A of the junction, the total current is $I = AJ$, and the critical current is defined as $I_0 = AJ_0$. Thus, the DC Josephson relation:

$$I = I_0\sin\delta \quad [19]$$

This shows that the current depends on the difference in the quantum mechanical phases of the superconducting states on either side of the tunnel barrier.

An equation can also be found for the evolution of the phase difference, by taking the difference of the fourth and third relations in eqn [18]. This is the AC

Josephson relation:

$$\frac{\mathrm{d}\delta}{\mathrm{d}t} = \frac{2eV}{\hbar} \quad [20]$$

(note the assumption $n_L = n_R$ has been used).

At zero voltage, the AC Josephson relation, eqn [20], shows that the phase difference δ remains fixed, and there is then a constant supercurrent $I = I_0 \sin\delta$. The phase difference can be manipulated through an external circuit, for instance, by closing a superconducting loop and applying an external magnetic field. This is the basis of the superconducting quantum interference devices, the DC and RF SQUID.

At a nonzero, fixed voltage V_{DC}, the phase evolves linearly in time

$$\delta = \delta_0 + \frac{2eV_{DC}t}{\hbar} \quad [21]$$

where δ_0 is the value at $t = 0$. Equation [19] then yields a sinusoidally oscillating current

$$I = I_0 \sin(2eV_{DC}t/\hbar + \delta_0) = I_0 \sin(\omega_J t + \delta_0) \quad [22]$$

The oscillation frequency

$$f_J = \frac{\omega_J}{2\pi} = \frac{2eV_{DC}}{h} \quad [23]$$

is called the Josephson frequency.

If one applies a voltage comprising a constant plus a sinusoidally oscillating term,

$$V = V_{DC} + v\cos\omega t \quad [24]$$

the phase evolves according to

$$\delta(t) = \delta_0 + 2eV_{DC}t/\hbar + (2ev/\hbar\omega)\sin\omega t \quad [25]$$

The Josephson supercurrent is then, for small $v \ll V_{DC}$,

$$I = I_0\left[\sin(\delta_0 + \omega_J t) + \frac{2ev}{\hbar\omega}\sin\omega t\cos(\delta_0 + \omega_J t)\right] \quad [26]$$

where $\omega_J = 2eV_{DC}/\hbar$. Averaging over times much larger than the inverse of the frequencies ω and ω_J, the first term vanishes, but the second term is nonzero for the frequencies $\omega_n = n\omega_J$, where n is an integer. This "phase-locking" of the Josephson current to an external signal gives rise to Shapiro steps, a structure in the current–voltage characteristic appearing when $V_{DC} = \hbar\omega/2ne$.

The critical current I_0 has a characteristic temperature dependence, and is related to the normal-state tunnel conductance G_{NN}, as can be worked out in the microscopic theory. The relation is

$$I_0(T) = G_{NN}\frac{\pi\Delta(T)}{2e}\tanh\left(\frac{\Delta(T)}{2k_BT}\right) \quad [27]$$

Effect of the Electromagnetic Environment

With the advent of technology capable of fabricating very small area tunnel junctions, with correspondingly small geometric capacitances, single charge effects became relevant in tunneling through both NN and SS tunnel barriers. These effects occur when the energy to charge the tunnel junction capacitance C becomes larger than the available thermal energy k_BT, creating what is called the Coulomb blockade. The simple theory described above only works well in the limit where the voltage across the tunnel barrier is fixed, that is, when the electromagnetic environment presents a very low impedance at all frequencies.

A more general treatment must be used when the voltage is not fixed, applicable to both NN and SS tunneling. For NN tunneling, the expression given by eqn [5] is modified to read

$$\begin{aligned} I_{NN}(T) = \frac{G_{NN}}{e}\int_{-\infty}^{\infty}\mathrm{d}E\int_{-\infty}^{\infty}\mathrm{d}E'\,\{f(E) \\ \times[1-f(E')]P(E+eV-E') \\ -[1-f(E)]f(E')P(E'-E-eV)\} \end{aligned} \quad [28]$$

The new term here is the appearance of the function $P(E)$, which allows the emission and absorption of energy between the tunneling electron and the electromagnetic environment during the tunneling process. This function is defined by

$$P(E) = \frac{1}{2\pi\hbar}\int_{-\infty}^{\infty}\mathrm{d}t\exp\left[J(t) + \frac{\mathrm{i}}{\hbar}Et\right] \quad [29]$$

using what is known as the equilibrium phase correlation function

$$J(t) = \langle[\phi(t) - \phi(0)]\phi(0)\rangle \quad [30]$$

In this expression, the phase $\phi(t)$ is the phase across the junction, related to the superconducting phase described above:

$$\phi(t) = \frac{e}{\hbar}\int_{-\infty}^{t}\mathrm{d}t'\,V(t') \quad [31]$$

When the electrical environment can be represented by a linear impedance $Z(\omega)$, the phase correlation function may be written as

$$\begin{aligned} J(t) = \int_0^{\infty}\frac{\mathrm{d}\omega}{\omega}\frac{\mathrm{Re}Z(\omega)}{R_Q}\left\{\coth\left(\frac{\hbar\omega}{2k_BT}\right)\right. \\ \left.\times[\cos(\omega t) - 1] - \mathrm{i}\sin\omega t\right\} \end{aligned} \quad [32]$$

where R_Q is the resistance quantum, $R_Q = h/2e^2$.

In the limit of a voltage-biased junction with a low electrical impedance, $Z(\omega) \ll R_Q$, the function $P(E)$

reduces to a delta function, $P(E) = \delta(E)$, and the results found above are obtained. More generally, however, the fluctuations presented by the real part of the environmental impedance significantly modify the current–voltage characteristic, most particularly in the limits where the tunnel barrier has a small capacitance.

The results above may be carried over to the discussion of quasiparticle tunneling in SS junctions. For the coherent Josephson processes, the effect of the electrical environment is different, but quite simple: one finds that one can get a supercurrent at nonzero voltages, and the current–voltage characteristic is given by

$$I_{SS}(V) = \frac{\pi\hbar I_0^2}{4e}[P(2eV) - P(-2eV)] \qquad [33]$$

Superconductors, High T_c

M J Qin and S X Dou, University of Wollongong, Wollongong, NSW, Australia

Introduction

In 1911, Onnes discovered superconductivity in mercury with a transition temperature T_c of 4.2 K, at which the DC resistance of mercury dropped to zero. The second characteristic of a superconductor was its perfect diamagnetism, discovered by Meissner and Ochsenfeld in 1933. A theoretical understanding of superconductivity is based on the BCS microscopic theory, proposed by Bardeen, Cooper, and Schrieffer in 1957. Before 1986, the highest T_c in the now so-called low-temperature superconductors (LTSC) was found in Nb_3Ge (23 K).

In 1986, Bednorz and Muller reported superconductivity in $(LaBa)_2CuO_4$ with a T_c of 35 K, in contrast to the previous record of 23 K in LTSC. Their discovery opened up the era of high-temperature superconductivity. Shortly after that, $YBa_2Cu_3O_7$ ($T_c = 90$ K), $Bi_2Sr_2Ca_2Cu_3O_{10}$ ($T_c = 110$ K), and $Tl_2Ba_2Ca_2Cu_3O_{10}$ ($T_c = 125$ K) were discovered. Since then, high-temperature superconductivity has been the subject of intensive study. This article reviews some of the fundamental properties of high-temperature superconductor (HTSC).

Crystal Structures

Crystal structures of most HTSCs can be obtained by stacking perovskite, rock salt and/or fluorite structure along the *c*-axis. As an example, **Figure 1** shows the orthorhombic $YBa_2Cu_3O_{7-\delta}$ unit cell. Other families of HTSCs can be constructed in a similar way. The CuO chains are unique to $YBa_2Cu_3O_{7-\delta}$; however, the most important features of the crystal structures of HTSCs are the two-dimensional copper oxide CuO_2 conduction planes, which are critical for high-temperature superconductivity. Carriers are doped into the CuO_2 conduction planes by transfer of charges resulting from the introduction of foreign ions, interstitial defects, and vacancies in structural blocks between two CuO_2 planes. These blocks are called charge reservoirs.

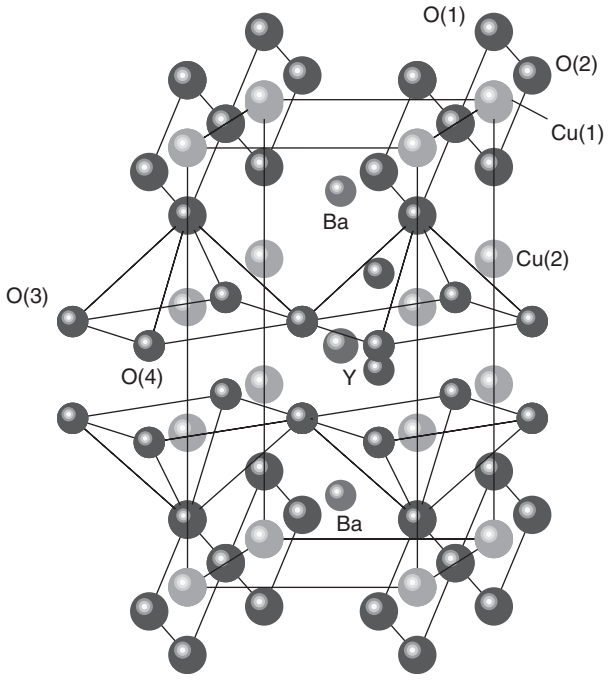

Figure 1 Crystal structure of orthorhombic $YBa_2Cu_3O_{7-\delta}$.

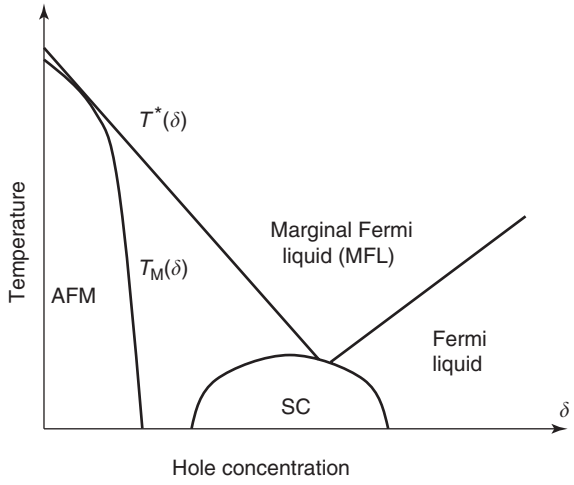

Figure 2 Generic temperature (T) vs. doping level (δ) phase diagrams of cuprates in zero magnetic field. (AFM: antiferromagnetic phase; SC: superconducting phase; T_N, and T^* are the Néel and pseudogap transition temperatures, respectively).

Phase Diagram

Depending on the temperature and the doping level, HTSCs demonstrate a wide variety of behaviors (see the phase diagram for hole-doped HTSCs in **Figure 2**). Undoped HTSCs are antiferromagnetic Mott insulators with nearest-neighbor Cu^{2+}–Cu^{2+} antiferromagnetic exchange interaction in the CuO_2 planes. The Néel temperature T_N for the antiferromagnetic-to-paramagnetic transition decreases with increasing doping level. At a certain doping level, the antiferromagnetism vanishes and one enters the pseudogap or underdoped region. The normal-state properties in this region are significantly different from those of a Fermi liquid. Some of the most interesting behaviors of HTSCs are observed in this region. Superconductivity arises upon further doping. The transition temperature T_c first increases with increasing doping level, reaching a maximum T_c at an optimal doping level, then decreases and finally vanishes with further increases in doping (overdoped regime). The non-Fermi liquid region above the superconducting region is well described by the so-called marginal Fermi liquid (MFL) hypothesis.

Superconducting Properties

The most unusual fundamental properties of HTSCs, compared to LTSCs, are high-transition temperature, short coherence length, and high anisotropy. The high anisotropy results from the layered structure shown in **Figure 1**. A phenomenological description can be achieved by means of the anisotropic Ginzburg–Landau equation.

Critical Temperature T_c

The critical temperature (i.e., transition temperature from normal state to superconducting state) is one of the most important parameters characterizing superconductors. The optimum T_c values for some of the HTSCs are listed in **Table 1**. T_c values above the liquid nitrogen temperature (77 K) open the way for many applications. However, higher operating temperatures also introduce large thermal fluctuations in HTSCs. Based on the two principal properties of superconductors (zero-resistance and perfect diamagnetism), the usual methods to obtain T_c are to measure the resistance versus temperature curve $R(T)$ or the AC susceptibility versus temperature $\chi(T)$ curve. Other methods such as measurement of DC magnetization versus temperature $M(T)$ and heat capacity versus temperature $C(T)$ are also applied to measure T_c.

Coherence Length ξ

It determines the distance over which the Cooper pairs are correlated. The short coherence lengths observed in HTSCs give rise to several unusual properties. Because the coherence length is much shorter than the penetration length, high-temperature cuprates are all type-II superconductors (see below). The short coherence length makes it very difficult to fabricate homogeneous high-temperature superconducting

samples. Also associated with the short coherence length is the weak pinning of flux lines in HTSCs, compared with the pinning in LTSCs. To measure the coherence length, one usually needs to measure the upper critical fields $H_{c2}^{ab}(0)$ and $H_{c2}^{c}(0)$, then the coherence lengths can be derived according to the equations based on the anisotropic Gingzburg–Landau equation

$$\mu_0 H_{c2}^{c}(0) = \Phi_0/2\pi\xi_{ab}^2(0)$$

$$\mu_0 H_{c2}^{ab}(0) = \Phi_0/2\pi\xi_{ab}(0)\xi_c(0)$$

Here, $H_{c2}^{ab}(0)$ and $H_{c2}^{c}(0)$ indicate the upper critical fields at $T = 0\,\mathrm{K}$ for fields applied parallel to the *ab*-plane and the *c*-axis, respectively. Typical values for the coherence lengths are $\xi_{ab}(0) = 1.2$–$1.6\,\mathrm{nm}$, $\xi_c(0) = 0.15$–$0.3\,\mathrm{nm}$, for $YBa_2Cu_3O_{7-\delta}$, $\xi_{ab}(0) = 2.7$–$3.9\,\mathrm{nm}$, $\xi_c(0) = 0.045$–$1.6\,\mathrm{nm}$ for $Bi_2Sr_2CaCu_2O_{8+\delta}$, and $\xi_{ab}(0) = 2.1\,\mathrm{nm}$, $\xi_c(0) = 0.03\,\mathrm{nm}$ for $Tl_2Ba_2CaCu_2O_{8+\delta}$.

Penetration Depth λ

It determines the distance that the applied DC magnetic field can penetrate exponentially into the superconductor. There are several methods to measure the penetration depth, such as muon spin resonance (μSR), electron paramagnetic resonance (EPR), and the polarized neutron reflection techniques. The penetration depth can also be derived from measurements of susceptibility or magnetization on samples with dimensions similar to the penetration depth. Typical values for the penetration depths are $\lambda_{ab}(0) = 130$–$180\,\mathrm{nm}$, $\lambda_c(0) = 500$–$800\,\mathrm{nm}$ for $YBa_2Cu_3O_{7-\delta}$, and $\lambda_c(0) = 270$–$300\,\mathrm{nm}$, $\lambda_c(0) \geqslant 3700\,\mathrm{nm}$ for $Bi_2Sr_2Ca_2Cu_2O_{8+\delta}$. **Figure 3** shows schematically the length scales (λ and ξ) of a vortex when the applied field is parallel to the *ab*-plane.

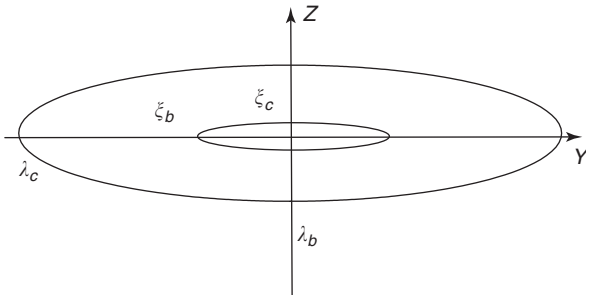

Figure 3 Schematic diagram of a single vortex when $H \| ab$, showing the anisotropic penetration depth and coherence length.

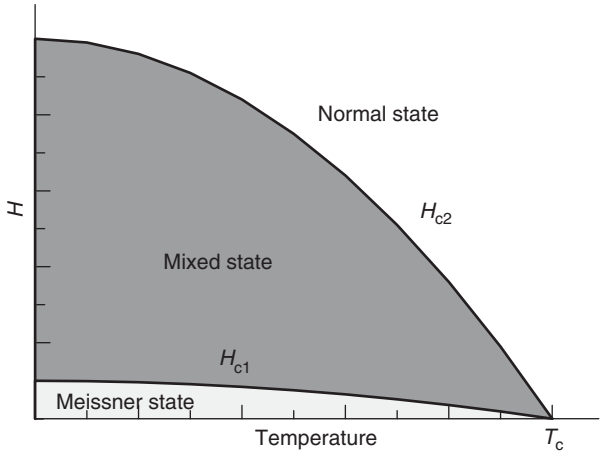

Figure 4 Phase diagram for a type-II superconductor.

Critical Fields

High-temperature cuprates are all type-II superconductors with three characteristic critical fields: the lower critical field H_{c1}, the upper critical field H_{c2}, and the thermodynamic critical field H_c (see **Figure 4**). $\mu_0 H_c^2/2$ is the free-energy difference between the superconducting and normal states. When the applied field is lower than H_{c1}, the superconductor shows perfect diamagnetism (called the Meissner state); when

the applied field is larger than H_{c1} but lower than H_{c2}, the applied field penetrates into the superconductor in the form of vortices (the so-called mixed state); when the applied field is larger than H_{c2}, the superconductor is forced into the normal state (see **Figure 4**). As the upper critical fields at low temperatures are experimentally inaccessible, one is normally interested in H_{c2} close to T_c; then using the dirty limit equation

$$H_{c2}(0) = -0.693 \times \left(\frac{dH_{c2}}{dT}\right)_{T_c} T_c$$

to obtain $H_{c2}(0)$. Typical values for $YBa_2Cu_3O_{7-\delta}$ are $\mu_0 H_{c2}^{ab}(0) = 200\,\mathrm{T}$ and $\mu_0 H_{c2}^{c}(0) = 40\,\mathrm{T}$. The lower critical field H_{c1} can be obtained from the virgin magnetization curves; typical values for $YBa_2Cu_3O_{7-\delta}$ at 4.2 K are $\mu_0 H_{c1}^{c} = 90\,\mathrm{mT}$, and $\mu_0 H_{c1}^{ab} = 20\,\mathrm{mT}$.

Pairing Symmetry

The pairing symmetry is very important for the discovery of the pairing mechanism. After the discovery of HTSCs, experiments such as those involving the observation of magnetic flux states of a polycrystalline $YBa_2Cu_3O_{7-\delta}$ ring, Andreev reflection, the Shapiro step of a Josephson junction, the high-resolution Bitter pattern technique, and Little–Parks oscillations have been performed to test whether Cooper pairing operates as in conventional superconductors. The results have confirmed electronic pairing in cuprate superconductors. In conventional superconductors, the phonon mediated electron–electron interaction gives rise to spin-singlet pairing with *s*-wave symmetry. However, the pairing symmetry in cuprate superconductors has been a controversial topic. Phase sensitive techniques (superconducting quantum interference device (SQUID) interferometry, single Josephson junction modulation, thin film magnetometry, etc.), combined with the refinement of several other symmetry-sensitive techniques (penetration depth, specific heat, thermal conductivity, angle-resolved photoemission, Raman scattering, nuclear magnetic resonance, nonlinear Meissner effect), have provided evidence in favor of *d*-wave symmetry pairing in cuprate superconductors. The energy gap, quasiparticle state, vortex state, and the surface and interfaces of *d*-wave superconductors are distinctly different from the *s*-wave case. Detailed discussions can be found in the "Further reading" section.

Energy Gap

The energy gap indicates the minimum energy required to excite a quasiparticle from a phase-coherent Cooper-pair condensate. The BCS theory predicts a universal ratio between the energy gap and the thermal energy $2\Delta(0)/k_B T_c = 3.53$, here $\Delta(0)$ is the energy gap at $T = 0\,\mathrm{K}$. For HTSCs, the energy gap can be determined from experiments such as single-electron tunneling, Andreev reflection, Raman scattering, photoemission spectra. Typical values for $YBa_2Cu_3O_{7-\delta}$ are $2\Delta_{ab}(0)/k_B T_c = 6$–$8$, $2\Delta_c(0)/k_B T_c = 3$–3.5; and for $Bi_2Sr_2CaCu_2O_{8+\delta}$ are $2\Delta_{ab}(0)/k_B T_c = 8$–$11$, $2\Delta_c(0)/k_B T_c = 5$–7. For conventional superconductors, the Cooper pairs have an isotropic *s*-wave symmetry, which means that the energy gap is 2Δ everywhere in *k*-space (see **Figure 5**). However, for a

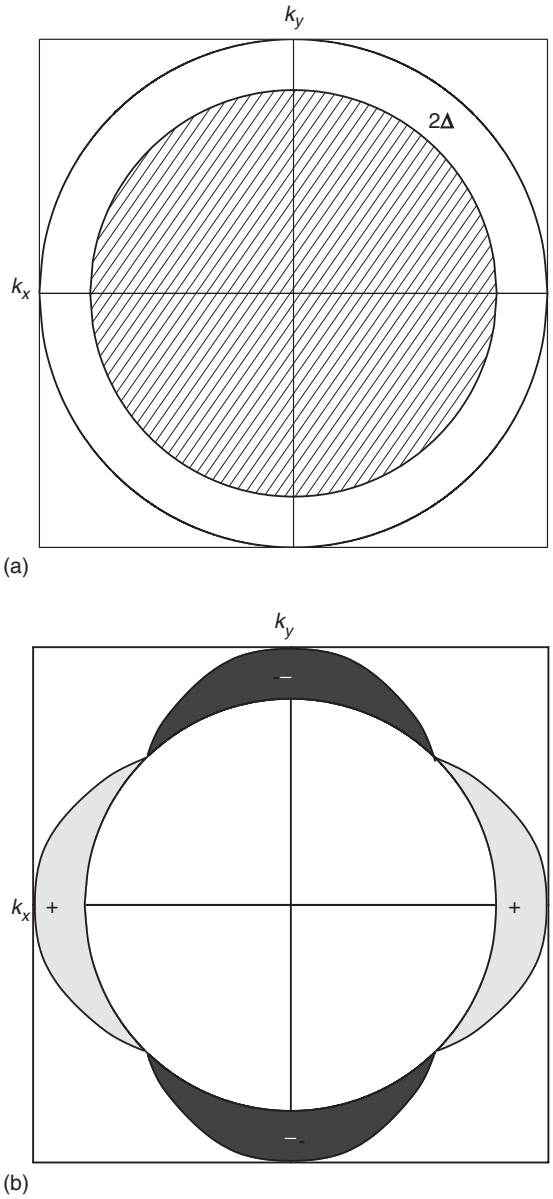

Figure 5 The energy gap for *s*-wave superconductors (upper panel) and *d*-wave superconductors (lower panel). The *s*-wave symmetry has an isotropic value of 2Δ, while for a *d*-wave symmetry the gap vanishes and changes sign at $k_x = k_y$.

d-wave symmetry superconductor, in momentum space when $k_x = \pm k_y$, the energy gap is zero, which implies that it would change sign at $k_x = \pm k_y$ (see **Figure 5**). Both properties will have important implications from both fundamental and applied points of view.

Type-II Superconductivity

HTSCs have very short coherence lengths ξ and large penetration depths, so the Ginzburg–Landau parameter $\kappa = \lambda/\xi \gg 1$, and HTSCs are typical type-II superconductors. In this section, some of the properties in the mixed state are discussed.

Vortex Structure

Due to the high anisotropy of cuprate superconductors, the vortex structures are different from those in conventional superconductors. When the applied field is along the *ab*-plane, the screening current flows both along the *ab*-plane and along the *c*-axis. There exist insulating layers alternating with conduction layers along the *c*-axis, the current is the Josephson current in the insulating layers (see **Figure 6**). When the applied field is parallel to the *c*-axis or at an angle to the *c*-axis, the vortices can be regarded as pancake vortices stacked along the *c*-axis (see **Figure 7**). Each pancake vortex is located in one of the conduction planes. The pancake vortices in the neighboring layers are coupled by means of a Josephson current, which forms a Josephson vortex. The forces between pancake vortices in the conduction plane are repulsive, while the forces between pancake vortices in the neighboring layers are attractive. Depending on the temperature and the magnetic field, the vortex system can go through a 3D to 2D transition. The magnetic properties of 2D superconductors can be described by the Lawrence–Doniach (LD) model.

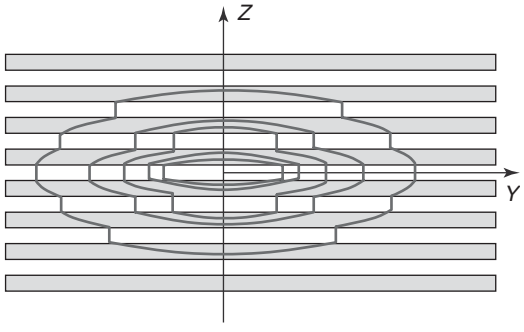

Figure 6 Schematic diagram of a single vortex when the applied magnetic field is parallel to the *a*-axis (*x*-direction). Gray areas indicate the superconducting layers.

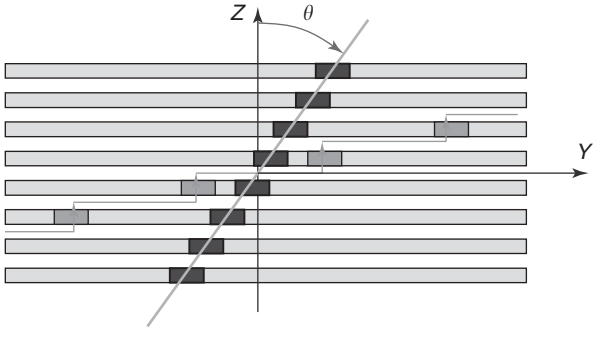

Figure 7 Schematic diagram for pancake vortices when the applied magnetic field is at an angle to the *c*-axis (*z*-direction). Gray areas indicate the superconducting layers.

Irreversibility Field

After the discovery of cuprate superconductors, it was soon reported that zero-field-cooled (ZFC) and field-cooled (FC) magnetization of La–Ba–Cu–O versus temperature at a fixed applied magnetic field can be separated into two regions. Below T_{irr}, ZFC and FC magnetization are different and irreversible, above T_{irr}, ZFC and FC magnetization are the same and reversible. T_{irr} is dependent on the magnetic field. $T_{irr}(H)$ or $H_{irr}(T)$ is called the irreversibility line. $H_{irr}(T)$ is lower than H_{c2} but larger than H_{c1} and separates the mixed state into two regions, a vortex liquid above $H_{irr}(T)$ and a vortex solid below $H_{irr}(T)$. The irreversibility line can also be obtained by hysteresis loop measurements and *I*–*V* characteristics measurements. Generally, the irreversibility line follows $1 - T_{irr}/T_{c0} = CH_{irr}^{q}$, with T_{c0} the zero-field transition temperature, and $1/2 < q < 3/4$, depending on different materials. The vortex system depends on three energy scales: the pinning potential E_{pin}, the thermal energy E_{th} and the vortex–vortex interaction energy E_{vv}. When the $E_{th} \approx E_{pin}$, the system reaches the reversible region.

Critical Currents and Flux Pinning

Due to short coherence lengths and high anisotropy in cuprate superconductors, critical currents are much more complicated than in conventional superconductors. For an anisotropic superconductor, three critical currents are defined depending on the direction of the applied magnetic field (see **Figure 8**). Critical currents result from the interaction between vortices and crystal defects (pinning effect). Twin boundaries and screw dislocations in single crystal $YBa_2Cu_3O_{7-\delta}$ and Y_2BaCuO_5 phase, as well as stacking faults and dislocations in melt-textured-growth (MTG) $YBa_2Cu_3O_{7-\delta}$, have all been reported to act as pinning centers. Heavy ion and particle irradiation have also been used to enhance the critical current density in cuprate superconductors. Due

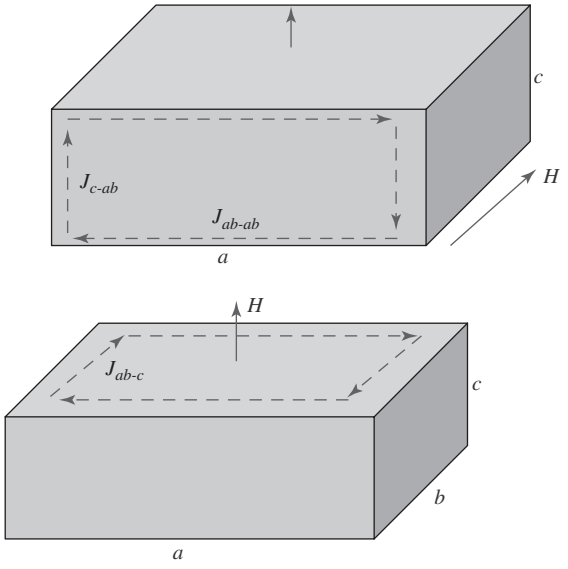

Figure 8 Schematic diagram showing the anisotropic cirtical current density in cuprate superconductors, when $H \| ab$ (upper panel) and $H \| c$ (lower panel).

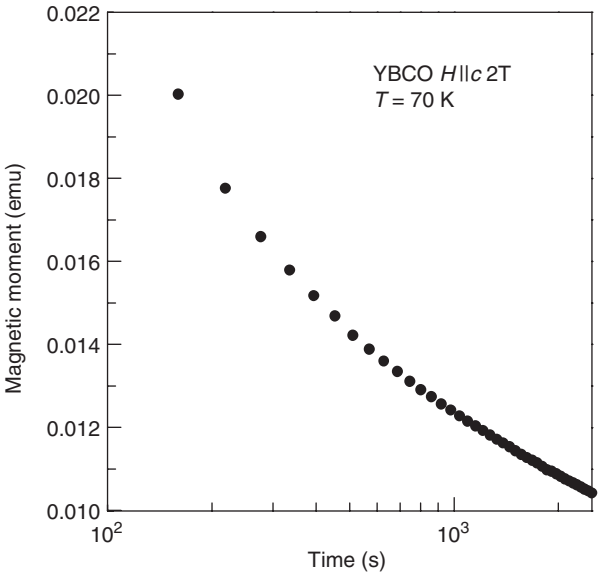

Figure 9 Magnetic relaxation of a melt-texture-growth (MTG) YBCO sample at $H \| c = 2\,\mathrm{T}$ and 70 K, showing nonlogarithmic relaxation.

to the short coherence length, point defects such as vacancies and substitution atoms may play an important role in cuprate superconductors.

Critical current can be directly obtained from transport I–V measurements. From hysteresis loop measurements, the critical state model is used to derive the current density from the measured hysteresis loop,

$$J_{ab,c} = \frac{20\Delta M}{a(1 - a/3b)} \quad (H \| c)$$

Because a larger electric field criterion is used in transport measurement, it usually provides a larger critical current density than magnetic measurements.

In polycrystalline samples, the current density across grains, called the intergrain critical current density, is very small, and shows the properties of a Josephson current. This is due to large angle grain boundaries in polycrystalline samples, and therefore these grain boundaries are called weak links. In order to have high critical current density, weak links should be avoided, by using, for example, MTG for $YBa_2Cu_3O_{7-\delta}$ bulk materials. Intragrain critical current densities up to $10^6\,\mathrm{A\,cm^{-2}}$ at 77 K and 0 T has been reported for $YBa_2Cu_3O_{7-\delta}$ thin films.

Flux Creep

In conventional superconductors, the current density was observed to decrease logarithmically with time at fixed temperature and field, an effect called magnetic relaxation. This effect was explained by vortices thermally activated out of the pinning potential (flux creep) with the hopping frequency

$$v = v_0 \exp\left[\frac{-U(j)}{k_B T}\right]$$

where v_0 is the attempt frequency and $U(j)$ the effective activation energy depending linearly on the current density,

$$U(j) = U_0\left(\frac{1 - j}{j_{c0}}\right)$$

The current density decreases logarithmically with time as

$$j(t) = j_{c0}\left[1 - \left(\frac{k_B T}{U_0}\right)\ln\left(\frac{t}{t_0}\right)\right]$$

In cuprate superconductors, strong and nonlogarithmic relaxation has been observed (see **Figure 9**). Due to high-operating temperatures and reduced pinning compared to conventional superconductors, relaxation in HTSCs is very large. Nonlogarithmic relaxation in HTSCs results from a nonlinear $U(j)$ relationship. A logarithmic $U(j)$ relationship has been proposed to account for the experimental results:

$$U(j) = U_0 \log\left(\frac{j_c}{j}\right)$$

On the other hand, according to the vortex glass theory, the $U(j)$ relationship is

$$U(j) = \left(\frac{U_0}{\mu}\right)\left[\left(\frac{j_c}{j}\right)^{\mu} - 1\right]$$

Here, the exponent μ depends on the dimensionality of the vortex system.

Magnetic relaxation measurements have been extensively performed on HTSCs to study the flux dynamics. The purpose is to determine the effective pinning potential $U(j)$ and compare it with theoretical predictions. Several methods such as the Maley method, the generalized inversion scheme, and dynamic relaxation and the AC susceptibility technique have been developed for this purpose. However, because too many parameters are used in theoretical predictions, it is impossible to unambiguously determine the effective activation energy from experiments. Most results in this area are not conclusive.

Melting of the Vortex Lattice

Thermal fluctuations in HTSCs are much more important than in conventional superconductors. According to the Lindemann melting criterion, as the displacement away from the ideal configuration by thermal fluctuation reaches 10–30% of the average flux-line separation, melting transition from vortex solid-to-vortex liquid (shear modulus equal to zero) might take place. The curve $T_m(H)$ in the H–T phase diagram at which the flux lattice melts is called the melting line. It has been suggested that in clean samples with negligible pinning the vortex solid-to-vortex liquid transition is expected to be of the first order, while static disorders drive the transition to the second order as in the vortex glass theory. Evidence for a first-order melting transition comes from a jump in the reversible magnetization, changes in latent heat, a frequency-independent peak in the AC susceptibility and a sharp, hysteretic, resistive transition. However, the effect of static disorders and their dimensionality on the order of transition is unclear as yet.

Mixed-State Phase Diagram

For a type-II superconductor, by varying the external field H, at the lower critical field H_{c1}, a phase transition from the Meissner phase to the Abrikosov phase (or mixed phase) takes place. The basic unit of the mixed state is the vortex, which contains a flux quantum given by $\Phi_0 = ch/2e = 2.07 \times 10^{-7}\,\mathrm{G\,cm^2}$, penetrating the system and forming a perfect triangular crystal (the Abrikosov lattice). At the upper critical field H_{c2}, the system is forced to undergo a second phase transition to the normal state. The simple phase diagram shown in **Figure 4** neglects disorders and thermal fluctuations, which is very serious in cuprate superconductors due to higher operating temperatures. When thermal fluctuations are taken into account, the first modification applied to the phase diagram ought to be the inclusion of the

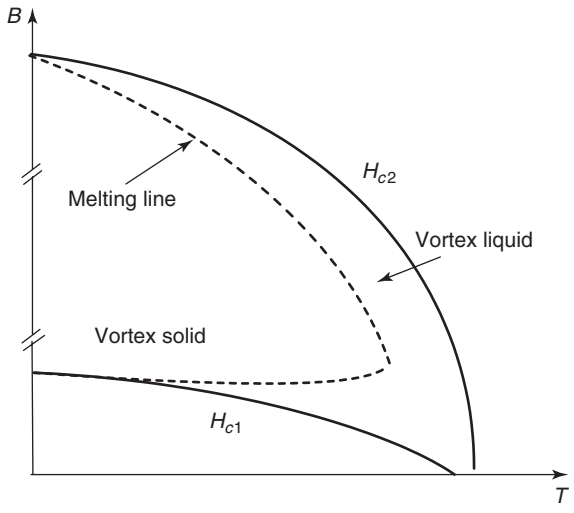

Figure 10 Schematic vortex phase diagram for high-temperature superconductors without disorders.

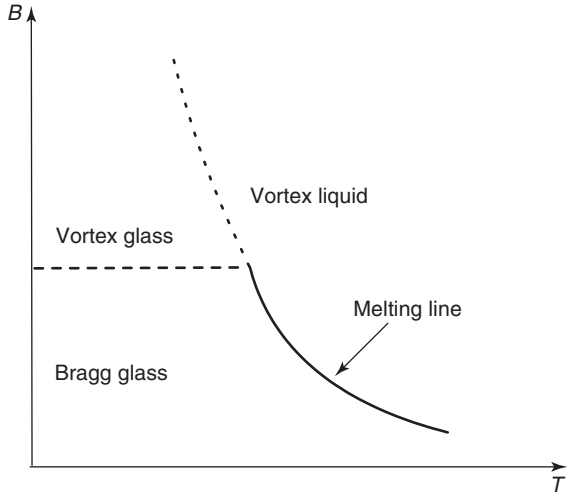

Figure 11 Schematic vortex phase diagram for high-temperature superconductors with disorders.

"water-like" melting phenomenon discussed above. In clean systems, the melting curve stretches from H_{c1} up to H_{c2} (see **Figure 10**). In case of disordered systems, the melting line terminates at much lower fields (characterized by the first-order transition). In practice, one is often far from the critical fields, leading to the unified phase diagram in **Figure 11**. Then, one has to discriminate between a sharp first-order phase transition at lower fields separating Bragg glass and vortex liquid and a more continuous second-order-like transition at higher fields separating vortex glass and vortex liquid.

Normal-State Properties

Properties in the normal state of cuprate superconductors have been found to be very useful for the

understanding of the mechanism of high-temperature superconductivity. These properties include resistivity, Hall coefficient, thermopower, magnetism, thermal conductivity, and optical properties. Although superconducting properties of cuprate superconductors are quite similar to those of conventional superconductors, the normal-state properties are unique. As an example, some general features for normal-state resistivity are listed: (1) the resistivity is anisotropic with the *c*-axis resistivity ρ_c two orders of magnitude larger than the in-plane resistivity ρ_{ab}, (2) ρ_{ab} shows metallic behavior, but ρ_c mostly shows semiconductor behavior. (3) ρ_{ab} is close to linear in T, which is the most striking normal-state property of cuprate superconductors. Theoretical explanations for these behaviors and other unique behaviors observed in optical and thermal properties remain controversial.

Mechanism of High-T_c Superconductivity

Superconductivity happens when charge carriers overcome their mutual electrostatic repulsion, bind together into Cooper pairs, and condense into a single quantum state below a certain temperature. In conventional superconductors, interactions between charge carriers and phonons (quantum vibrations of the crystal lattice) are responsible for the pairing. In HTSCs, however, the mechanism for the pairing has been controversial since the discovery of high-temperature superconductivity. The challenges are not only to find a mechanism to explain the high transition temperature in cuprate superconductors, but also to be able to account for the complex phase diagram exhibited by cuprate superconductors (see **Figure 2**). The phonon-based pairing mechanism in LTSCs is based on the so-called Landau–Fermi theory, in which the properties of single electrons are renormalized by interactions with other electrons to form quasiparticles. However, recent experimental results have provided evidence that phonons are not the principal cause of high-temperature superconductivity. There have been numerous theories proposed to understand high-temperature superconductivity. One proposal, which has attracted much attention, is based on the idea of a doped resonant valence bond (RVB) state. Other competing theories include those based on fluctuating stripes, those based on the polaron mechanism, and those based on spin fluctuations. However, a comprehensive theory, which could account for all the experimental observations, is yet to be achieved. The challenges for a successful theory are that it should predict the high transition temperature, describe the full complex phase diagram, and that it should reveal the special conditions in the cuprates that lead to this very special behavior. From this should follow some suggestions for other materials that would show similar behavior.

Material Processing

Material processing depends on the requirements of applications. Thin films, bulk materials, tapes and wires, and coated conductors have received much attention due to their applications in large- or small-scale applications.

Thin Films

$YBa_2Cu_3O_{7-x}$(YBCO) thin films are the most studied high-temperature superconducting thin films. Critical current densities up to $10^6\,A\,cm^{-2}$ have been achieved in high-quality YBCO thin films, making them very attractive for applications. There are, in general, two main methods for fabricating high-temperature superconducting thin films: *in situ* or *ex situ* film growth. *In situ* films are oxygen-treated before they are removed from the growth chamber, and therefore are superconducting after growth. *Ex situ* thin films must be annealed in an oxygen-rich environment after growth to be superconducting. Nearly every growth technique has been tried on high-temperature superconducting thin films, including evaporation, pulsed laser deposition (PLD), metal organic chemical vapor deposition (MOCVD), and on-axis and off-axis sputtering. Every technique has its merits and drawbacks, details of which can be found in the references. The search for substrate materials is an active research area. High-quality YBCO thin films have been deposited on $LaAlO_3$, $SrTiO_3$, MgO, YSZ, etc. BiSrCaCuO and TlBaCaCuO thin films have also been extensively studied. However, it is very difficult to obtain single-phase BiSrCaCuO thin films, while Tl is very toxic, creating problems in fabricating TlBaCaCuO thin films. The main application of superconducting thin films is in the area of superconducting electronics.

Bulk Materials

Many large-scale applications such as flywheel energy-storage systems need HTSCs in bulk form. Sintered YBCO polycrystalline samples used to have very low critical current densities ($100–1000\,A\,cm^{-2}$), which was attributed to weak links at grain boundaries, such as structural disorder at grain boundaries, chemical or structural variations at grain boundaries and non-superconducting materials along grain boundaries, as well as microcracking. Texture processing has been developed as a means to avoid or minimize the effects of weak links in polycrystalline YBCO. The initial success with bulks was due to the MTG process, which enhanced the critical current density two to

three orders of magnitude over that of sintered materials. Several modified MTG methods were developed later in order to further enhance the critical current density. These include the quench-and-melt-growth (QMG) process, the melt-powder-melt-growth (MPMG) process, the power-melting process (PMP), the floating-zone-melt (FZM) process, the platinum-doped melt-growth (PDMG) process, and the horizontal Bridgman method.

Tapes and Wires

The majority of the work on superconducting tapes and wires focuses on the $Bi_2Sr_2Ca_2Cu_3O_{10-x}$(BSCCO) system. The reasons are that the BSCCO system has a higher critical current at high magnetic fields, and that the BSCCO system does not suffer from the weak link problems of YBCO. The fabrication of BSCCO tapes and wires is usually carried out by means of the so-called oxide power-in-tube (OPIT) method. The powder is packed in a tube (typically Ag), then the Ag tube is drawn to a small diameter and rolled into a flat tape. The tape is then annealed, re-rolled and re-annealed again to obtain the best superconducting properties. Critical current densities up to $7000\,A\,cm^{-2}$ for a 650 m long and 19-filament-rolled tape have been achieved. Tapes and wires are widely used in applications such as motors and generators, magnet, transformers, and transmission lines.

Coated Conductors

Coated conductors are YBCO thin films deposited onto polycrystalline substrates. The films are biaxially textured, thus overcoming the phenomenon of weak links. This has been achieved by preparing a biaxially textured buffer layer, upon which the YBCO film is subsequently grown epitaxially. The two most advanced techniques are the ion beam-assisted deposition (IBAD) process, and the rolling-assisted biaxially textured substrate (RABiTS) process. In addition, inclined substrate deposition (ISD) has also emerged as a promising method for the fabrication of YBCO conductors. The coated conductors potentially have a performance superior to the first generation bismuth-based HTS compounds (BSCCO), such as high current carrying capacities, strong mechanical properties, and extraordinary magnetic field tolerances. Recently, it has been demonstrated that current densities up to $10^6\,A\,cm^{-2}$ have been achieved in conductors prepared by coating thick films of YBCO onto flexible metallic substrates. One of the biggest hurdles to widespread application of YBCO-coated conductor tape is developing a manufacturing process that will produce it in long lengths and at prices competitive to copper for applications such as motors, generators, transmission cables, and other power systems.

Introduction and Discussion of the Scope of This Article

Superconductivity is one of the most interesting macroscopic physical manifestations of the microscopic quantum mechanical world. In this remarkable phenomenon, the resistance of a material drops to zero at a finite temperature above absolute zero. The resistance drops to not just a small value but to a number which has been measured to be zero to many significant figures. Accompanying this drop in resistance are other extraordinary phenomena such as the Meissner effect whereby all magnetic fields are expelled from the interior of the sample, flux quantization and vortex lattices, the Josephson effect, and macroscopic quantum coherence. The richness and complexity of the phenomenon of superconductivity is unparalleled in solid-state physics.

In addition to its intrinsic scientific interest, the phenomenon gives rise to a very wide range of applications ranging from generating large magnetic fields to detecting tiny ones. Logic circuits to replace Si-CMOS, superconducting power lines, large motors and generators, magnetic resonance imaging, sensitive RF detectors, and much more, are all made possible by superconductivity.

In this article, the metallic superconductors are reviewed. Although a vast and wide range of superconducting materials and systems have been discovered over the last 100 years, the metallic superconductors still reign supreme in terms of economic importance and impact. Also, these materials are the best understood. In general, much of what is really known about the theory of superconductors applies to these materials. Most of the newer, more exotic, nonmetallic systems are still largely a scientific mystery. Clearly, in terms of applications, the metallic systems NbTi and Nb_3Sn dwarf all others in terms of tons used, money created, and impact on lives made. It is these materials that have allowed many Nobel prizes to be won by generating large magnetic fields for high-energy particle accelerators and solid-state experiments probing exotic states of matter at low temperatures and high magnetic fields. Magnetic resonance imaging of the type that has saved countless lives in modern hospitals is still only possible because of the metallic superconductors. Clearly, they are the workhorse materials of the field and will remain so for many years to come. This is because they are materials that are metals with all the good things that this implies. These materials are ductile, have good mechanical and thermal properties, are relatively inexpensive, can be joined by soldering and welding, are stable and nontoxic, and can be fabricated by reasonable, low-cost industrial processes. Although a number of newer materials such as the ceramic, high-T_c superconductors hold a lot of promise, to date this potential has yet to be realized on any commercial scale and given the large number of difficult manufacturing problems that still remain with these materials, it is not clear that they will ever replace the metallic materials for widespread application.

In this article, the focus is on the metallic superconductors to the exclusion of many other types of superconducting systems. Not considered here are such exotica as organic superconductors (those containing carbon), fullerenes and carbon nanotubes, molecular salts, borocarbides, polymers, perovskites and other ceramics, ruthenates, fluoro-argentates, diamond, and the ultraconductors. Briefly considered in the section "Exotic metallic superconducting systems" are such strange metallic systems as the heavy fermions, magnetic superconductors, and MgB_2. The basic goal here is to provide a broad overview of the metallic superconductors, their properties, materials, theory, and application. Clearly, it is a vast field that has filled libraries with information. What is presented here is just the barest introduction to the subject. Some references for further study are provided in the "Further reading" section.

Properties of the Metallic Superconductors

The most fundamental property of all superconductors, the one which gives rise to their name, is the zero resistance state. **Figure 1** (the first observation of superconductivity made by Kamerlingh Onnes in 1911) shows his measurement of the resistance of the liquid metal mercury as a function of temperature. At roughly 4.2 K, the resistance drops to a value indistinguishable from zero. This zero-resistance state is the property that many of the applications seek to exploit. In systems such as superconducting power lines, electric motors and generators, and large magnets, this zero-resistance state allows large currents to flow without the normal joule heating that would occur in a conventional metal with a finite resistance.

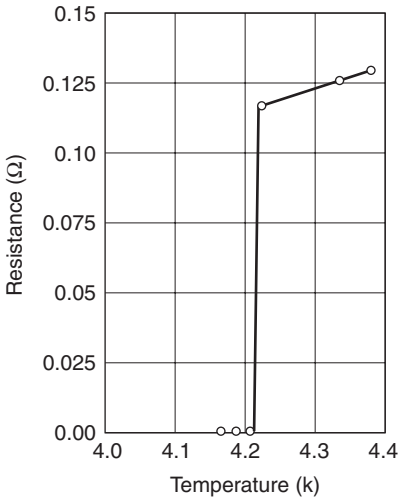

Figure 1 Data from Onnes, which is the first observation of superconductivity. It is a plot of the temperature dependence of the resistance of mercury. At 4.2 K the abrupt drop is the onset of the superconducting state.

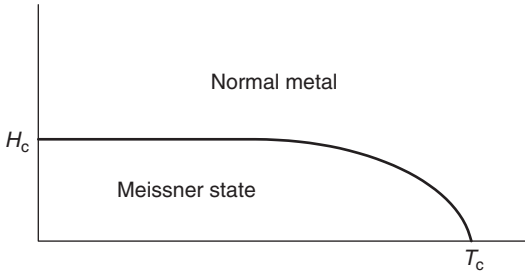

Figure 2 Phase diagram for a type I superconductor. Below T_c and H_c is the Meissner phase. For temperatures or fields above these, one regains normal metallic behavior.

All superconductors, including the metallic ones, fall into one of two broad categories. The first of these categories of superconductors are type I superconductors. Most elemental superconductors are of this type including mercury as shown in **Figure 1**. The phase diagram for these types of superconductors is given schematically in **Figure 2**. The figure shows an H–T phase diagram indicating the range of temperatures and fields for which superconductivity can occur. There are two key points on the graph, T_c and H_c. T_c is the temperature where, in zero applied magnetic field (and low measuring currents), superconductivity occurs. In general, for type I superconductors, T_c is relatively low with lead at 7.2 K being the highest known value (at ambient pressure). The other key point on the graph is H_c which is the field where, at zero (or very low) temperatures, an applied magnetic field destroys the superconductivity. For type I superconductors H_c also tends to be low, typically below 1000 G. These low critical temperatures

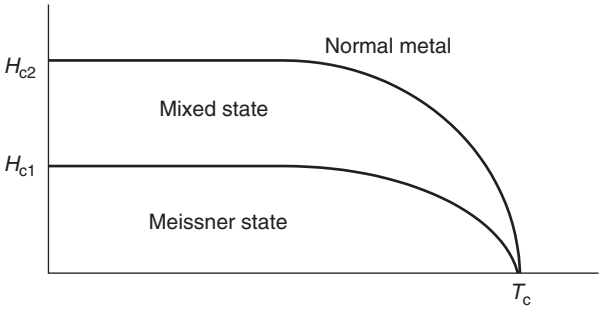

Figure 3 Phase diagram for a type II superconductor. There are two superconducting phases, the Meissner phase and the mixed state.

and low critical fields conspire to make type I superconductors not very interesting from an applications point of view.

One of the most interesting phenomena associated with type I superconductors is the Meissner effect. This effect arises because magnetic fields tend to destroy the superconducting state. This can be seen qualitatively by looking at **Figure 2** and noting that the higher the applied magnetic field, the lower the transition temperature for a type I superconductor. There are two types of superconductors, depending on how they behave under applied magnetic fields. In the first method, the system maximizes the total free energy associated with the superconducting state by totally expelling the magnetic field from the interior of the type I sample. This state of total diamagnetism was first discovered by Meissner and Ochsenfeld in 1933 and is now called the Meissner effect. The effect is large and easy to measure with relatively simple devices and is a common way to demonstrate that one has a bulk superconductor, not merely a system whose resistance has dropped to a small value which may or may not indicate superconductivity.

The other broad category of superconductors are type II superconductors. Most known superconductors, including most metallic superconductors, are of this type. Most of these superconductors are either metallic alloys or compounds. The elements vanadium, technetium, and niobium are the only known elemental type II superconducting materials (under ambient pressure). The phase diagram for type II superconductors is shown schematically in **Figure 3** and is more complicated and interesting than that found for type I superconductors. Below T_c and for fields less than a critical field called H_{c1}, there is a Meissner phase similar to that found for type I materials. However, for fields between H_{c1} and H_{c2} there is a new phase of matter called the mixed state. This arises because of the previously mentioned antipathy that the superconducting state has for applied magnetic fields. Whereas for small fields the type II material can

expel the magnetic field completely from the interior of the sample, for large fields this is no longer possible. But rather than allowing magnetic fields to enter the sample completely and uniformly as it would for a piece of copper, for example, the type II superconductor finds it energetically favorable to allow the field to penetrate in single magnetic flux lines called magnetic vortices. These lines of magnetic flux are exactly quantized to a precise value – all lines are identically the same. These lines can form a regular lattice, most typically hexagonal in symmetry although many other symmetries have been observed.

Type II superconductivity appears to be quite a robust state with observed T_c values as high as 138 K for an oxide superconductor. H_{c2}, the maximum magnetic field at which the sample is still superconducting, can also be very high with observed values in excess of a megagauss for some of the oxide superconductors. Among metallic superconducting materials such as NbTi ($T_c = 9.8$ K) and Nb_3Sn ($T_c = 18.1$ K), the critical fields are still very high allowing for a robust range of application.

Another characteristic property of superconductors that is very important is the critical current, J_c. J_c is the maximum current a sample can carry and still remain superconducting. This property is a measure of the current-carrying capacity of the superconductor. Typical values for a good system may reach one to ten million amps per square centimeter. In general, J_c tends to be not so much an intrinsic property of the material but an extrinsic one that depends on many things such as processing, thermal history, doping with impurities, and mechanical history. The larger the J_c, the more current can be carried by the system and the more useful the material is for applications such as magnets and motors. Only type II superconductors have usefully large J_cs. The physics of J_c is related to the magnetic vortex lattice mentioned above. Applied currents exert a Lorentz force on the flux lines. If they are pinned, no energy is dissipated and the superconducting state persists. However, if the lines can move, energy is dissipated as they move, heating the sample and destroying the superconducting state. The tricks used to pin the flux lines are many and complex and tend to be developed empirically. The techniques are similar to those developed to pin dislocation lines in metals to make them less ductile. For example, alloying is a common approach to both problems. Critical currents for type I superconductors tend to be very low because of the low value of H_c.

Theories of Metallic Superconductors

In general, the theoretical understanding of conventional metallic superconductors is quite good. This is to be contrasted with the rather poor state of understanding of theory for other types of superconductors such as the high-T_c cuprates. Most of the metallic superconductors (with the exotic ones discussed in the section "Exotic metallic superconducting systems" being the exceptions) are well described by the BCS theory developed by Bardeen, Cooper, and Schrieffer in 1957 and its extensions to type II materials developed by Abrikosov. All four were awarded the Nobel prize for their contributions to the understanding of these materials.

Superconductivity theory will be discussed elsewhere in this encyclopedia and so only a brief introduction is given on the most crucial concepts here. The key and basic idea behind the BCS theory is that of electron pairing. It had been understood by the London brothers in the 1930s that paired electrons could produce a gap at the Fermi surface and thereby produce superconductivity. A key intellectual challenge for the later theorists was to figure out how to get the normally repulsive electrons to pair. The BCS theory did this and showed how electrons of opposite momentum and spin could pair together giving rise to the zero-resistance state. The trick was to consider the underlying crystal lattice. In their theory, pairing of the electrons occurred because of the interaction of the electrons with the ionic crystal lattice of the material, thus creating an effective attractive interaction overcoming the normally repulsive Coulombic forces between electrons. A simple and naïve way to think about it is to imagine two bowling balls rolling around on a mattress producing an effective "attraction" between the balls. While wrong in all the details, this image is still an instructive way to understand in an intuitive way how a medium can effectively produce an attractive interaction between objects when nothing exists between them in the absence of the medium. A more correct way to think about the problem is to imagine that as the first electron moves through the lattice, its interactions with the positively charged ions produce a distortion in the crystal lattice that attracts the second electron, thereby creating an effective attractive force between the electrons. Within a few years of the publication of the BCS theory, many properties predicted and explained had been experimentally observed. Properties such as the energy gap, ultrasonic attenuation, isotope effect, the flux quantum, and Josephson tunneling (predicted by Josephson in 1962) were resounding confirmation of the theory. The isotope effect is a particularly striking example of BCS theory providing a predictive understanding. The theory predicted that changing the mass of an ion in the underlying lattice but not its electronic properties by using an isotope of the atom would change T_c in a

predictable and well-explained way. In general, these isotope effect predictions work well in the metallic superconductors, especially the simple metals, and confirm the BCS theory as the correct answer.

The work of the London brothers, Ginsburg and Landau, BCS, Abrikosov, and many others have led to the current theoretical understanding of conventional (e.g., metallic) type II superconductors. The basic idea that one needs to master to be able to understand many of the applications, which will be discussed later, is that the microscopic theory yields two important length scales in a superconductor. The first of these is called the coherence length, typically denoted by ξ. In the BCS theory, this is something like the size of the superconducting pair of electrons. Within the Ginsburg–Landau theory, it can be qualitatively understood as the spatial distance over which the superconducting order parameter can change. The second important length scale is called the penetration depth typically denoted by λ. This is defined in a number of different ways by the various theories, but in essence it is the distance over which magnetic fields can vary in a superconductor. In general, these lengths diverge (grow) with increasing temperature. For this discussion, zero-temperature values have been used. In this picture, type I and type II superconductors can be seen as the two limits of these fundamental microscopic lengths. In the limit where $\lambda > \xi/\sqrt{2}$ type II superconductivity is observed, and in the limit where $\lambda < \xi/\sqrt{2}$ type I superconductivity is observed.

An important advance was made by Josephson in 1962. He considered the situation in which one has two superconducting samples connected by a weak link through which electrons cannot normally travel. He considered the case of tunneling of the paired electrons through the junction and showed how this would produce a phase shift between the order parameters on each side of the junction. This phenomenon is the basis of an object called a superconducting quantum interference device (SQUID), the most sensitive magnetic field detector known. This effect is also the heart of the attempt to use superconducting devices to replace Si-CMOS as logic devices. The use of superconductivity in electronics generally employs some variation of the Josephson effect. This should be contrasted with large-current applications such as magnets and power lines.

This general theoretical framework outlined here very well describes the conventional metallic superconductors. In summary, the pairing mechanism is well known to be phonons (vibrations in the underlying crystal lattice), the two microscopic lengths can be related by theory to fundamental properties of the material, the various effects such as crystal structure and doping with impurities are well understood, and the microscopic understanding of the phenomena allows for a rational and predictive engineering of the materials for things like enhanced critical currents. The conventional metallic superconductors are therefore a solved theoretical problem. Understanding their properties and providing a detailed microscopic theory for their behavior has been arguably one of the greatest theoretical triumphs of physics in the twentieth century. Unfortunately, for nonmetallic superconductors such as the cuprates, this cannot also be said to be true.

Metallic Superconducting Materials

Type I Materials

Although there are over a thousand known metallic superconductors, metallic type I superconductors are only a few, several dozen under ambient pressure, with another couple of dozens that will superconduct only under high applied pressures. Essentially all the known type I superconductors are metallic elements and dilute alloys of these elements. In general, when heavily alloyed, these materials will tend to become type II superconductors. There are 27 type I superconducting elements under ambient pressure ranging from lead with a T_c of 7.2 K to rhodium with a T_c of 0.3 mK. **Table 1** lists these elements and their T_c values.

Under pressure, many more elements will superconduct. The highest known T_c for any type I material is phosphorus with a $T_c \sim 15$ K but it superconducts only under pressures of several mega-bars. While type I materials tend to be good metals, somewhat surprisingly, three of the best metals – copper, gold, and silver – do not appear to superconduct at all. This is due to the fact that their f.c.c. lattice structure is less susceptible to the kind of lattice distortion that gives rise to the BCS pairing mechanism responsible for superconductivity.

Because these type I superconductors tend to be good metals, their resistance with temperature follows the behavior shown in **Figure 1**. As the temperature is reduced, in the normal state the resistance drops due to a reduction in the thermally induced fluctuations in the ionic lattice that scatter the electrons. In the absence of superconductivity, their resistance would saturate at a nonzero value determined by the density of defects in the lattice as a result of impurities, and structural defects. However, for the materials that undergo a transition to superconductivity, this reduction of the resistance with decreasing temperature is interrupted by a sharp, precipitous drop to the zero-resistance state. Because

Table 1 List of known type I metallic superconductors (ambient pressure)

Element	*Symbol*	*Transition temperature* (K)
Aluminum	Al	1.2
Americium	Am	0.60
Beryllium	Be	0.02
Cadmium	Cd	0.52
Gallium	Ga	1.08
Hafnium	Hf	0.13

these materials tend to be clean metals, the superconducting transition is usually quite sharp with temperature. In fact, this very sharp, abrupt transition with temperature can be used as a very sensitive thermometer in devices such as bolometers to sense radiation. In a bolometer, the particle to be detected is absorbed in a small volume of material, the energy of the absorbed particle raises the temperature of this volume, and a small change in temperature causes a large change in resistance of the type I superconductor. Electrical circuits measure this change in resistance and "detect" the particle.

Type II Materials

The metallic type II superconductors are a much more diverse group of materials than the type I metals. Some of the simplest type II metallic materials are vanadium, technetium, and niobium. With the exception of these elements, all other metallic type II superconductors are either alloys or compounds (under ambient pressure). The earliest studied type II superconductors were lead–bismuth and lead–thallium alloys. In the early days, it was not clear that these alloys were a separate class of superconductors, the type II materials. It was thought that they were dirty type I materials that had a smeared out T_c and H_c. It was the work of Shubnikov (experimental) and Abrikosov (theory) that paved the way to the current understanding of type II materials as a separate and distinct class of materials with well-defined phase transitions into a Meissner state and a higher-field mixed state.

Table 2 List of some representative type II metallic superconductors

Superconductor	*Transition temperature* (K)
Pure elements	
Nb	9.25
Tc	7.80

Table 2 contains some typical metallic type II superconductors. The number of known type II materials is too large to make it practical to compose a comprehensive list, and with new discoveries everyday such a list would be obsolete almost immediately. Before the discovery of the high-T_c materials in 1986, the record transition temperature was held by the compound Nb_3Ge with a T_c of 23 K.

The two most technologically important materials today, even years after the discovery of the high-T_c materials, are Nb_3Sn with a T_c of 18 K and NbTi with a T_c of 10 K. This is basically due to their metallic properties. While the high-T_c materials are ceramics that are quite difficult to work with, the Nb compounds are relatively simple metals. The oxide superconductors are brittle, contain many elements, and are sensitive to small changes in composition, tend to require careful oxygenization, are unstable chemically, can be chemically poisonous, and are expensive to manufacture. Since the niobium compounds are metals, they have none of the above flaws. They are strong, tough, ductile metals that contain

only two elements and are not particularly sensitive to the composition, are reasonably chemically stable, are not particularly poisonous, and are relatively cheap to manufacture. These materials can be readily engineered to have high critical currents. While their T_c and H_{c2} are not as high as the high-T_c materials, their advantages far outweigh their drawbacks for most of today's applications.

Applications of the Metallic Superconductors

Because of the many advantages of the metallic superconductors discussed above, the vast majority of the applications to date have used these materials. Wires of NbTi and Nb_3Sn are widely used in many places ranging from magnets for magnetic resonance imaging (MRI) to levitating trains. Some of these applications are discussed here.

Easily the most important application of superconductivity to date is for MRI. It is currently responsible for $\sim$75% of the worldwide market for superconductivity and this application is likely to continue to dominate the market for at least the next decade. In this technique, the spins in the object to be imaged are excited by an applied RF field in the presence of a large static uniform DC magnetic field and a magnetic field gradient. The decay of the spins in time can be sensitively detected and their presence or absence measured. Using this technique one can create a 3D map of specific elements. In hospitals, it allows images to be made with unprecedented clarity, and precision without using any harmful or invasive radiation (e.g., X-rays). By using tricks associated with the field gradients, one can image "slices" of the body to be observed. Clearly, this has become a very important technology and no modern hospital today is without an MRI machine.

Another very important application of conventional metallic superconductors is for scientific research. Research magnets of every size and shape have been built for solid-state research and numerous important, Nobel prize-winning discoveries have been made as a result. In addition to solid-state physics, conventional metallic superconductors have been used for the bending magnets in numerous particle accelerators and fusion machines around the world.

Other applications for conventional metallic superconductors include magnetic levitation (maglev) trains, superconducting power lines, motors and generators, fault limiters and transformers, superconducting computers and other circuits using Josephson junctions, SQUID low magnetic field sensors, X-ray and light detectors, energy storage systems, and systems for the magnetic separation of materials. The current market for superconductors is estimated to be $\sim$\$3 billion/year in 2003, growing to be $\sim$\$5 billion in 2010 and then to be $\sim$\$40 billion in 2020. Of this total, the current fraction of this market owned by conventional, metallic superconductors is well over 95%. Even in the year 2010, 24 years after their discovery, high-temperature superconductors will still represent less than a third of the total market. Conventional metallic superconductors will still be used in more than two-thirds of the applications and will continue to dominate the market well into the twenty-first century.

To date large-scale systems and devices such as MRI magnets and magnets for R&D have dominated the market. In the future, smaller-scale electronic applications will emerge. These include magnetic field sensors, high-speed specialized electronic circuits, magnetocardiography and magnetoencephalography. The heart of many of these devices is the Josephson junction. As for the large current applications, these new markets will also be dominated by metallic superconductors such as Niobium and NbN. It is likely to be many years before a reliable high-T_c technology evolves that will allow a large number of Josephson junctions to be used in a single device. Thus, even this new developing application for superconductivity is likely to still be dominated by the conventional metallic superconductors.

Exotic Metallic Superconducting Systems

Up until now, conventional metallic superconductors whose properties are well understood and well explained by current theories, specifically BCS, were discussed. In this section, a number of newer superconducting systems are discussed which, while certainly metallic, remain far from being understood and represent some of the interesting current frontiers of research in superconductivity. This list is by no means complete – it is an attempt to show some examples of interesting current research topics.

Heavy-Fermion Superconductivity

Heavy-fermion superconductors are metals made out of various rare earth or actinide elements. They are an extremely strange group of metals that have normal state properties that are as bizarre as their superconducting properties. First seen by Bucher in 1973, there are now roughly ten known heavy-fermion compounds. The most interesting thing about them is that in the normal state, the effective masses of the conduction electrons can be hundreds of times the

electronic mass. Thus, they have "heavy" fermions. In the superconducting state, they have been shown to be unconventional in that the pairing state is not *s*-wave, as for conventional metals. In a conventional superconductor, the superconducting gap opens up uniformly over the Fermi surface. In these materials it is known that the gap is strongly anisotropic, that is, large in some directions, small or zero in others. These materials are ones where superconductivity and magnetism, both ferromagnetic and antiferromagnetic, seem to live in an uneasy proximity. The general antipathy that the superconducting order parameter has for magnetism creates a wide range of subtle responses, and heavy-fermion superconductivity appears to be one of them. Despite more than 30 years of study, heavy-fermion superconductivity is far from being a well-understood phenomenon, either theoretically or experimentally. While few things are well understood in these systems, perhaps the best known fact is that the BCS theory does not work here as an explanation.

Magnetic Superconductors

The issues discussed in the previous section about the coexistence of magnetism and superconductivity apply here as well. There exist a variety of phases which include rare-earth elements where the materials go from normal metals to superconductors to magnets as the temperature is reduced. There are roughly half a dozen of these compounds known where, depending on the temperature and magnetic field, one of the three known ground states for metals – normal metal, superconductor, or magnet (either ferromagnet or antiferromagnet) – can be reached. Thus, the study of these materials is one of seeing the interplay of a variety of states that compete with each other giving rise to novel and unexpected phenomena. Clearly, superconductivity in these materials is unconventional in that a predictive understanding of the behavior is not there. The study of the interplay of magnetism in all its forms and superconductivity will continue to be a major theme of research in solid-state physics for decades to come.

MgB_2

Superconductivity in MgB_2 was discovered by J Akimitsu in 2001. This is an extremely interesting compound in that at first glance it would appear to be a relatively simple material. Much of the interesting physics in superconductivity arises in compounds containing rare earth, lanthanide, or actinide ions. MgB_2 contains none of those exotic ions that produce such complex magnetic behavior. Both magnesium and boron are relatively low atomic number elements that have pretty simple and well-understood properties as pure materials. However, when combined, they form a fairly high-T_c superconductor with a transition temperature of 39 K. This material is interesting for a number of reasons. It has been found to be a material with two gaps. The theory suggests that there are two separate Fermi sheets with a different gap for each of them – the first such observation in solid-state physics. Second, the superconducting mechanism appears to be BCS in origin, but with an unusual set of properties that conspire to give a very high T_c for a phonon-mediated mechanism. Finally, and perhaps most importantly, this is a relatively high-T_c material that has good metallic properties, unlike materials such as the cuprates or the fullerene superconductors that also have high T_c values but bring along a lot of baggage in terms of their mechanical and physical properties that make their application quite difficult. MgB_2 might be a material that has a high enough transition temperature to make the use of closed-cycle refrigerators feasible but also has material properties that are sufficiently forgiving to make it practical to use them for a wide range of applications. It may be the best compromise between the conventional low-T_c niobium-based materials and the high-T_c cuprates. A final and not irrelevant consideration is that both magnesium and boron are abundant and cheap and so this material should be very inexpensive to manufacture. Clearly, it will be at least a decade before all this plays out and the true impact of this material is known but it will be an interesting story to follow.

Conclusions and the Future

In this article, the metallic superconductors have been briefly reviewed. In general, these are the well-known and well-understood workhorses of the field of superconductivity. Most of the physics that is actually understood in the field of superconductivity applies to these materials. The BCS theory, the extensions to type II behavior, flux line lattices, Josephson junctions, and all the rest work very well for these materials. In terms of applications, the conventional metallic materials still own the lion's share of the market and will do so for decades to come. As an example, the fact that the cuprate superconductors are materials with anisotropic superconducting properties with short coherence lengths makes them very hard to engineer for applications – grain boundaries represent a serious impediment to the flow of critical currents. The standard materials such as NbTi and Nb_3Sn do not suffer from such problems and will always be easier to apply both for high-current applications as well as for electronic applications.

In terms of interesting new physics, the metallic superconductors remain an interesting area. New materials are being discovered at a steady rate and the field shows no signs of slowing down. Clearly, this will be an exciting and interesting field for decades to come.

Superfluidity

E V Thuneberg, University of Oulu, Oulu, Finland

Introduction

Fluids (gases and liquids) are distinguished from solids by the property that they can flow. In almost all cases, there is viscosity associated with the flow. Due to viscosity, the flow energy is gradually dissipated into heat. Contrary to this common situation, there is a special class of fluids, which can flow without viscosity. These are called superfluids and the phenomenon is called superfluidity. As a concrete example, consider a ring-shaped container filled with a superfluid, see **Figure 1**. Once the fluid is put into circular motion, it will continue to circulate and no energy is dissipated. The flow can continue as long as the conditions for superfluidity are satisfied.

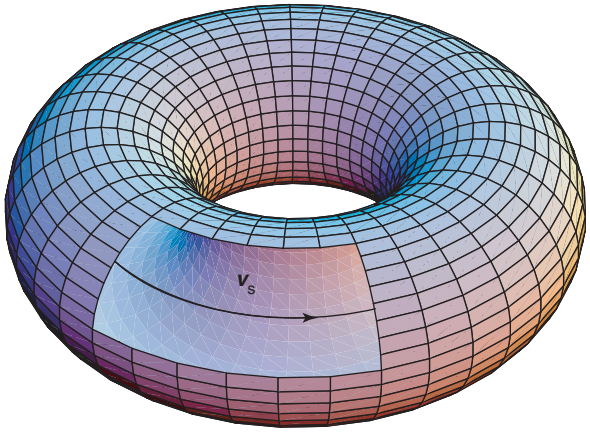

Figure 1 Once generated, the circulation of a superfluid (with velocity v_s) persists as long as the experiment can be continued.

Superfluids show many spectacular phenomena, which are discussed in sections "Hydrodynamics," "Quantization of circulation," "Rotating superfluid," and "Phase slip." Before going into these, the systems where superfluidity occurs (section "Occurrence") and the microscopic basis of superfluidity (section "Microscopic origin") are discussed. While section "Microscopic origin" gives deeper insight, it is not absolutely necessary for understanding the phenomena in the following sections.

Occurrence

Superfluidity occurs only in certain substances under special conditions. As a first case, liquid helium is discussed. Under standard pressure and temperature, helium is a gas. It liquifies at temperatures $\sim 4\,\mathrm{K}$. Cooling further down, it enters the superfluid phase at temperatures $\sim 2\,\mathrm{K}$, depending on pressure. The phase diagram of natural helium at low temperatures is shown in **Figure 2**. Natural helium consists essentially of isotope ^{4}He.

Helium has another stable isotope, ^{3}He. At temperatures below a few kelvin, its behavior is radically different from the isotope ^{4}He. It also becomes superfluid, but at temperatures that are a factor of 1000 smaller than for ^{4}He. The phase diagram of ^{3}He at low temperatures is shown in **Figure 3**. ^{3}He has three different superfluid phases, A, A_1, and B. The A_1 phase appears only in a magnetic field, and therefore is not visible in **Figure 3**.

Superfluidity is closely related to superconductivity. Superconductivity means that electric current can flow without resistance. This phenomenon appears at low temperatures in many metals like Al, Sn, and Nb. It arises from resistanceless motion of

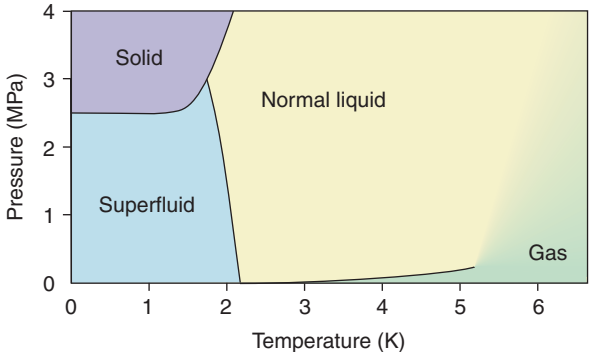

Figure 2 Phase diagram of ^{4}He at low temperatures. ^{4}He remains liquid at zero temperature if the pressure is below 2.5 MPa (~25 atm). The liquid has a phase transition to a superfluid phase, also known as He-II, at the temperature of 2.17 K (at vapor pressure).

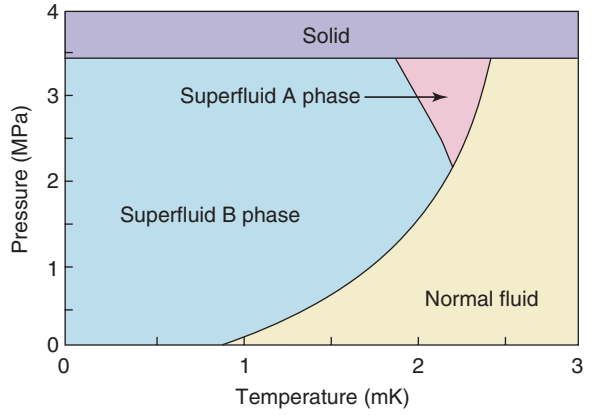

Figure 3 The phase diagram of ^{3}He at low temperatures. Note that the temperature is in units of millikelvin. Two superfluid phases of ^{3}He, A and B, are shown. (Figure based on data by DS Greywall.)

the conduction electrons in a metal. Therefore, superconductivity can be understood as superfluidity of the conduction electrons. Part of the discussion in this article applies also to superconductivity, but there are differences caused mainly by two reasons: (a) electrons have electric charge and therefore their motion is essentially coupled with magnetic fields; (b) the crystal lattice of the ions constitutes a preferred frame of reference, which does not exist for helium liquids.

With laser cooling, it is possible to cool certain atomic gases such as ^{87}Rb, ^{7}Li, ^{23}Na, and ^{1}H to very low temperatures. At low temperatures, Bose–Einstein condensation takes place in the gas. This state has many properties that are similar to superfluidity, although it is not a thermodynamically stable state, and therefore the flow cannot last for ever. Most of the discussion in this article applies also to condensed gases. An important difference is that instead of container walls for helium liquids, one has to consider the confining potential of the gas, which can be generated either magnetically (by field gradients) or optically (by laser beams).

Superfluidity is expected to occur also in astrophysical objects. The neutron liquid in a neutron star is believed to be in a superfluid state. This has been suggested as an explanation for the observed sudden changes in the rotation velocity of pulsars.

Microscopic Origin

In short, superfluidity can be explained as a quantum mechanical effect that shows up on a macroscopic scale.

Quantum mechanics is crucial in understanding the microscopic world. It explains that electrons in atoms have only discrete energies. There is no friction on the atomic scale, and the electrons can revolve around the nucleus without losing energy.

It is known that quantum mechanics rarely shows up on a macroscopic scale. Instead of quantum mechanics, macroscopic objects obey the rules of classical physics. The reason is that a macroscopic sample consists of large number of particles and, instead of individual particles, one can only observe their average behavior. Usually the particles are in different quantum states, and an average over them obeys the classical laws of physics. Examples of these laws are the Navier–Stokes equations for fluids and Ohm's law for electrical conduction.

Superfluidity is an exception to this general rule. In superfluids, a macroscopic number of particles is in the same quantum state. It follows that summing over particles does not lead to averaging, but produces a "macroscopic wave function."

Further analysis depends essentially whether the particles are bosons or fermions. ^{4}He and the gas atoms listed above are bosons, whereas ^{3}He atoms, electrons, and neutrons are fermions.

Consider a particle with mass m and momentum $\boldsymbol{p}$. Its energy is $E = \boldsymbol{p}^2/2m$. Its state is represented by the single-particle wave function

$$\psi(\boldsymbol{r}) = \frac{1}{\sqrt{V}} \exp\left(\frac{\mathrm{i}}{\hbar}\, \boldsymbol{p} \cdot \boldsymbol{r}\right) \qquad [1]$$

where V is the volume of the system and $h = 2\pi\hbar$ the Planck constant. The wave function of a many-body system $\Psi(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots)$ is more general and depends on the coordinates $\boldsymbol{r}_i$ of all particles.

Assume that the particles are bosons. This means that the total wave function must be symmetric when exchanging any pair of particles. In the case of two

particles, this means $\Psi(\boldsymbol{r}_1, \boldsymbol{r}_2) = \Psi(\boldsymbol{r}_2, \boldsymbol{r}_1)$. Further, assume that there is no interaction between the bosons. It can be shown that the occupation of the lowest-energy state becomes macroscopic, if the temperature T is less than

$$T_{\mathrm{BE}} = \frac{h^2}{2\pi m k_{\mathrm{B}}} \left(\frac{N}{2.612V} \right)^{2/3} \qquad [2]$$

where N is the number of particles and k_{B} the Boltzmann constant. This is known as Bose–Einstein condensation. The wave function [1] of the lowest-energy state ($\boldsymbol{p} = 0$) becomes macroscopic. At zero temperature, all particles are in this state.

While the ideal gas model explains Bose–Einstein condensation, it is quite insufficient in other respects. The interactions between particles are essential for the system to show superfluidity. In an interacting system, the macroscopically occupied state $\psi(\boldsymbol{r})$ need not be the lowest-energy state, and thus the macroscopic wave function can be nontrivial. In Bose gases (^{87}Rb, etc.) the interactions are weak, and a quantitative description can be achieved by the relatively simple Gross–Pitaevskii equation. In ^{4}He the interactions are much stronger, and a quantitative theory is not easily achieved.

Next, consider the fermions. Fermions have spin, which has to be described by an additional index s. Here, one needs to consider only spin-half particles, where s takes two values, $s = \pm\frac{1}{2}$. The wave function of a fermion system is $\Psi(\boldsymbol{r}_1, s_1, \boldsymbol{r}_2, s_2, \ldots)$, and it has to be antisymmetric in the exchange of any pair of particles. For a two-particle state, this means

$$\Psi(\boldsymbol{r}_1, s_1, \boldsymbol{r}_2, s_2) = -\Psi(\boldsymbol{r}_2, s_2, \boldsymbol{r}_1, s_1) \qquad [3]$$

This implies that the occupation of any single-particle state can only be zero or one. This is known as the "Pauli exclusion principle." Thus, macroscopic occupation of a single-particle state [1] is not possible.

Superfluidity in a fermion system can appear as a result of an attractive interaction between particles. Such an interaction can cause formation of pairs. Each pair has to satisfy the antisymmetry condition [3]. However, a pair is a unit that behaves like a boson. In particular, it is not excluded that several pairs are in the same pair state. Superfluidity in fermion systems can be understood as a macroscopic occupation of a single-pair state.

The spin part of the pair wave function has four different possibilities. These can be classified as a singlet state

$$\uparrow\downarrow - \downarrow\uparrow \qquad [4]$$

(which is a compact notation for $\delta_{s_1,1/2}\delta_{s_2,-1/2} - \delta_{s_1,-1/2}\delta_{s_2,1/2}$) and three triplet states, which can be chosen as

$$-\uparrow\uparrow + \downarrow\downarrow,\ i(\uparrow\uparrow + \downarrow\downarrow),\ \uparrow\downarrow + \downarrow\uparrow \qquad [5]$$

Consider the case of spin singlet [4]. The pair wave function in this case is assumed to be of the form

$$\Psi(\boldsymbol{r}_1, s_1, \boldsymbol{r}_2, s_2) = \psi\left(\frac{\boldsymbol{r}_1 + \boldsymbol{r}_2}{2}\right)\chi(\boldsymbol{r}_1 - \boldsymbol{r}_2)(\uparrow\downarrow - \downarrow\uparrow) \qquad [6]$$

where the orbital wave function has been separated into a center of mass part ψ and a relative part χ. The singlet spin state [4] is antisymmetric in the exchange of the two spins. In order to satisfy pair antisymmetry [3], the corresponding orbital part $\chi(\boldsymbol{r}_1 - \boldsymbol{r}_2)$ has to be symmetric. In most superconductors, the pair wave function is of the form [6]. In majority of them (Al, Sn, Nb, …), χ is approximately independent of the direction of $\boldsymbol{r}_1 - \boldsymbol{r}_2$. This is called s-wave pairing in analogy with s, p, d, etc. atomic orbitals. In high-T_{c} superconductors, there is strong evidence of d-wave symmetry of χ.

Another alternative is that the spin state of a pair is triplet [5]. This case is realized in ^{3}He (and possibly in some superconductors). In ^{3}He, the orbital wave function is of p-type. There are three degenerate p-wave states p_x, p_y, and p_z. The pair wave function can be written as

$$\Psi(\boldsymbol{r}_1, s_1, \boldsymbol{r}_2, s_2) = \sum_{j=1}^{3}\sum_{\mu=1}^{3} \psi_{\mu j}\left(\frac{\boldsymbol{r}_1 + \boldsymbol{r}_2}{2}\right) p_j(\boldsymbol{r}_1 - \boldsymbol{r}_2) i\sigma_\mu\sigma_2 \qquad [7]$$

Here $i\sigma_\mu\sigma_2$ denotes the same three spin states as in eqn [5], but expressed using Pauli spin matrices σ_i.

The macroscopic wave function of bosons is called "order parameter," since it describes ordering of the particles and it vanishes in the normal fluid phase. For fermions, the same role is played by the center of mass part of the pair function. This is the soft degree of freedom, which can change as a function of time and location, whereas the other parts in the pair wave function [6]–[7] are fixed. One can see that the order parameter in ^{4}He, and in most superconductors is a complex-valued scalar ψ, but in ^{3}He, it is a 3×3 matrix $\psi_{\mu j}$.

The quantitative theory of fermion superfluids is based on the Bardeen–Cooper–Schrieffer theory of superconductivity. Many properties can also be described by the simpler Ginzburg–Landau theory.

Hydrodynamics

Many properties of superfluids can be understood in terms of the "two-fluid model." The basic assumption

is that the liquid consists of two parts. These are called the superfluid and normal components. The current density $\boldsymbol{j}$ can be represented as a sum

$$\boldsymbol{j} = \rho_s \boldsymbol{v}_s + \rho_n \boldsymbol{v}_n \quad [8]$$

where ρ_s and $\boldsymbol{v}_s$ are the density and velocity of the superfluid component and ρ_n and $\boldsymbol{v}_n$ are the corresponding quantities for the normal part. The liquid density is the sum of the two densities, $\rho = \rho_s + \rho_n$. The superfluid component can flow without viscosity and it carries no heat or entropy. Moreover, it is curl free,

$$\nabla \times \boldsymbol{v}_s = 0 \quad [9]$$

(This is valid only in uncharged superfluids.) The normal component behaves more like a usual viscous fluid.

The two-fluid model can be justified from the microscopic theory discussed in the section "Microscopic origin." The superfluid component corresponds to particles in the macroscopic wave function, and the normal component to particles in other single-particle states. The densities of the two components depend on temperature. With increasing temperature, $\rho_s(T)$ drops continuously from $\rho_s(0) = \rho$ and vanishes at the superfluid transition temperature T_c.

The two-fluid model can explain many properties of superfluids. In particular, the existence of frictional forces depends on the type of experiment. On one hand, the flow in a ring-shaped container persists because it is only the superfluid component that flows (**Figure 1**). On the other hand, nonvanishing viscosity is measured with a rotational viscometer, where the superfluid is placed between two coaxial cylinders that rotate at different angular velocities. Here, the normal component is driven into motion and causes dissipation.

Superfluids show peculiar mixing of thermal and mechanical properties. Consider a superfluid in a channel which is heated at one end, see **Figure 4**. The superfluid component is attracted to the hot region because the chemical potential is lower there. As a consequence, a pressure difference appears. This drives the normal component in the direction of decreasing temperature and convects the heat away from the source. Assuming the geometry does not allow net mass transfer, the mass transported by the normal and superfluid components in opposite directions are equal in magnitude.

In addition to usual sound wave, superfluids have another propagating mode. This second sound is an oscillation where normal and superfluid components move in opposite directions. This leads to an oscillation of temperature whereas the density remains nearly constant. The second sound can be generated by heating the superfluid periodically, and standing waves of temperature have been demonstrated experimentally.

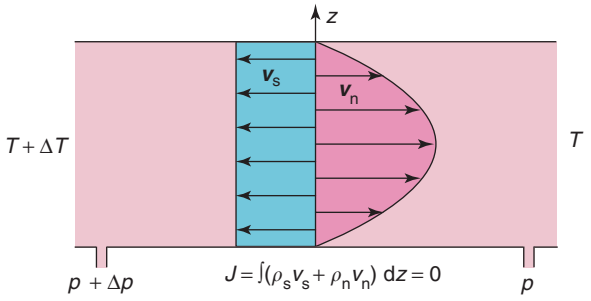

Figure 4 A difference in temperature generates flow of normal and superfluid components in opposite directions, and a pressure difference appears. The viscosity of the normal component causes $\boldsymbol{v}_n$ to vanish at walls. The superfluid velocity $\boldsymbol{v}_s(z)$ has to be constant in order to be curl free [9].

In addition to the mass current $\boldsymbol{j}$, there can be persistent spin currents. This is possible in superfluids whose order parameter is more complicated than scalar (^{3}He). The spin current is described by a tensor $j^{\text{spin}}_{\mu j}$. The index $\mu = x, y, z$ indicates the direction of the spin angular momentum that is flowing, and $j = x, y, z$ indicates the direction of the flow. Even in equilibrium, the order parameter of ^{3}He has a nontrivial spatial variation called "texture." This is associated with persistent spin currents and, in case of ^{3}He-A, also with persistent mass currents.

Quantization of Circulation

Consider a superfluid with order parameter ψ. (Assume an uncharged superfluid, ψ can be either scalar or matrix.) The superfluid velocity $\boldsymbol{v}_s$ can be expressed as a function of the order parameter as

$$\boldsymbol{v}_s = \frac{\hbar}{M} \nabla \phi \quad [10]$$

where $\phi(\boldsymbol{r})$ is the phase of the order parameter, $\psi(\boldsymbol{r}) = A e^{i\phi(r)}$, and the amplitude A is assumed to be constant. M is the boson mass, that is, the mass of a particle in a boson superfluid and the mass of a pair in a fermion superfluid. Equation [10] can be justified starting from the expression of current in quantum mechanics.

An alternative form of eqn [10] is obtained by taking the line integral along a closed path,

$$\oint \boldsymbol{v}_s \cdot d\boldsymbol{l} = N \frac{h}{M} \quad [11]$$

Here the property that ϕ is defined modulo 2π, and N is an integer, is used. Equation [11] is known as

"quantization of circulation." The curl-free condition [9] is a direct consequence of eqn [10] or [11].

Consider again a superfluid in a ring-shaped container (**Figure 1**). By applying eqn [11] to a path in the ring, one can see that, in addition to being persistent, the superfluid velocity can only have discrete values. A similar phenomenon in superconductors is flux quantization.

Rotating Superfluid

Consider a superfluid in a container that is rotated with angular velocity $\boldsymbol{\Omega}$. The normal component will follow this motion because of its viscosity. In equilibrium, it rotates uniformly with the container, $\boldsymbol{v}_n = \boldsymbol{\Omega} \times \boldsymbol{r}$. This is not possible for the superfluid component because it has to be curl free [9]. (Equation [9] should be compared to $\boldsymbol{\nabla} \times \boldsymbol{v}_n = 2\boldsymbol{\Omega}$.)

The rotating state of a superfluid is most commonly realized by "vortex lines." On a path around the vortex line, the phase ϕ changes by 2π (or an integral multiple of it). This is illustrated in **Figure 5**. Equivalently, the circulation of superfluid velocity [11] around the vortex line is h/M. Assuming cylindrical symmetry, the phase ϕ is the same as the azimuthal angle in the cylindrical coordinate system (r, ϕ, z). The velocity field can be calculated from eqn [10]:

$$\boldsymbol{v}_s = \frac{\hbar}{Mr}\,\hat{\boldsymbol{\phi}} \qquad [12]$$

where $\hat{\boldsymbol{\phi}}$ is a unit vector in the azimuthal direction.

The structure of the rotating state is determined by minimum of free energy. The rotation of the container is taken into account by minimizing $F = F_0 - \boldsymbol{L} \cdot \boldsymbol{\Omega}$, where F_0 is the free-energy functional in the stationary case and $\boldsymbol{L}$ the angular momentum. In the two-fluid model, this reduces to

$$F = \int \mathrm{d}^3 r\, \frac{1}{2}\, \rho_s (\boldsymbol{v}_s - \boldsymbol{v}_n)^2 + \text{constant} \qquad [13]$$

Thus, the optimal solution corresponds to $\boldsymbol{v}_s$ as equal as possible to $\boldsymbol{v}_n = \boldsymbol{\Omega} \times \boldsymbol{r}$, but subject to condition [10]. This is achieved by a regular array of vortex lines. The number of vortex lines n per unit area is determined by the condition that the circulations of normal and superfluid velocities are the same over an area containing many vortex lines. This yields

$$n = \frac{2M\Omega}{h} \qquad [14]$$

There are $\sim$1000 vortex lines in a circular container of radius 1 cm that is rotating 1 round per minute.

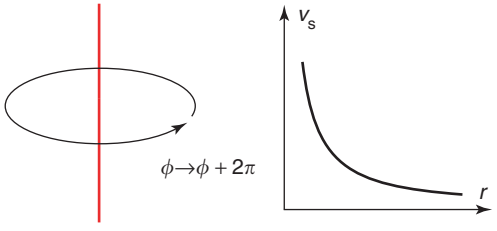

Figure 5 The vortex line and the magnitude of the velocity field [12] around it.

Vortex lines in an uncharged superfluid are analogous to flux lines, which occur in type II superconductors. Flux lines of superconductors appear in a magnetic field, which is analogous to the rotation of an uncharged superfluid.

The velocity field [12] of a vortex diverges at the vortex line. Thus, there must be a vortex core, where the two-fluid description is insufficient. A finite energy in the vortex core is achieved if the amplitude of the order parameter vanishes at the vortex line. This is the case for a scalar order parameter. For a matrix order parameter, it is not necessary that all components of the matrix vanish at the line. Such vortex lines are realized in superfluid ^{3}He-B.

The quantization of the superfluid velocity [11] is not always true for uncharged superfluids. This happens when there is an additional contribution to the superfluid velocity [10] coming from the matrix form of the order parameter. Such a case is realized in superfluid ^{3}He-A, and a careful reanalysis of the rotating state is needed. It turns out that, in addition to one-dimensional vortex lines, the vorticity may be arranged as two-dimensional vortex sheets and three-dimensional textures. All these have been confirmed experimentally. In any case, a homogeneous rotation of the superfluid is excluded.

Phase Slip

Consider superflow in a channel under thermal equilibrium ($\boldsymbol{v}_n = 0$). The maximum supercurrent is determined by a process called phase slip. Consider that a short piece of vortex line is nucleated at a surface on one side of the channel. This vortex expands, goes through the whole cross section of the channel, and finally disappears on the other side. As a result of this process, the phase difference $\Delta\phi$ between the ends of the channel has changed by 2π. Part of the superfluid kinetic energy is dissipated in the motion of the vortex. This means that the flow ceases to be dissipationless above a critical velocity for phase slips. Phase slips take first place in constrictions of the flow channel, where the superfluid velocity has its maximum value.

A special type of phase slip takes place in very short constrictions, where eqn [10] ceases to be valid. An ideally short constriction shows the Josephson

effect, where the supercurrent J_s depends on the phase difference $\Delta\phi$ as

$$J = J_c \sin(\Delta\phi) \quad [15]$$

and J_c is a constant. Moreover, the time derivative of $\Delta\phi$ is proportional to the difference of the chemical potential $\Delta\mu$ on the two sides of the constriction,

$$\frac{d\Delta\phi}{dt} = -\frac{2\Delta\mu}{\hbar} \quad [16]$$

Combining the two equations, one sees that a constant $\Delta\mu$ generates an oscillating current at the frequency $2\Delta\mu/h$.

The Josephson effect takes place in all superfluids, and has extensively been studied in superconductors. In helium superfluids, it is more difficult to fabricate constrictions that are small enough, but this has been achieved recently.

Surfaces and Interfaces, Electronic Structure of

G Chiarotti and C Goletti, Università di Roma "Tor Vergata," Rome, Italy

Introduction

The presence of the surface modifies significantly the atomic and electronic structure of the first few layers of the solid. Since some of the properties of the solid are to some extent properties of its surface (e.g., the work function, the photoelectric threshold, chemisorption and physisorption, conductivity in the surface channel(s), optical reflectance, and the scattering of electrons, ions, and atoms by the solid), a detailed knowledge of the surface is important for solid-state physics and chemistry as well as for materials science and technical applications.

In this article, the discussion is limited to the so-called "clean surfaces," or surfaces that are atomically clean (i.e., with a controlled chemical composition) and crystallographically well defined. "Real surfaces" (i.e., surfaces with unspecified chemical impurities, crystallographic defects, macroscopic faults, etc.) are considered only occasionally.

Clean surfaces are obtained in ultrahigh vacuum (UHV) conditions (10^{-10} torr or better) by cleavage, ion bombardment and annealing (IBA), high-temperature annealing, molecular beam epitaxy (MBE), etc. Conversely, real surfaces are obtained and handled at ordinary pressures, mechanically ground, chemically etched, etc., and their properties often depend upon the way of preparation.

This article discusses the surface reconstruction and relaxation, electronic surface states, examples of reconstruction of relevant semiconductor surfaces and interfaces.

Surface Reconstruction and Relaxation

The structure of an "ideal surface" is that of a half crystal obtained by dividing the crystal in two halves with a lattice plane as a boundary, removing all atoms on one side and leaving the other atoms in their original positions. An ideal surface is then characterized by the Miller indices of the boundary plane.

It should be considered, however, that the atoms in the ideal surface plane experience a force different from that of their partners in the bulk. Moreover, they have a larger freedom of movement so that

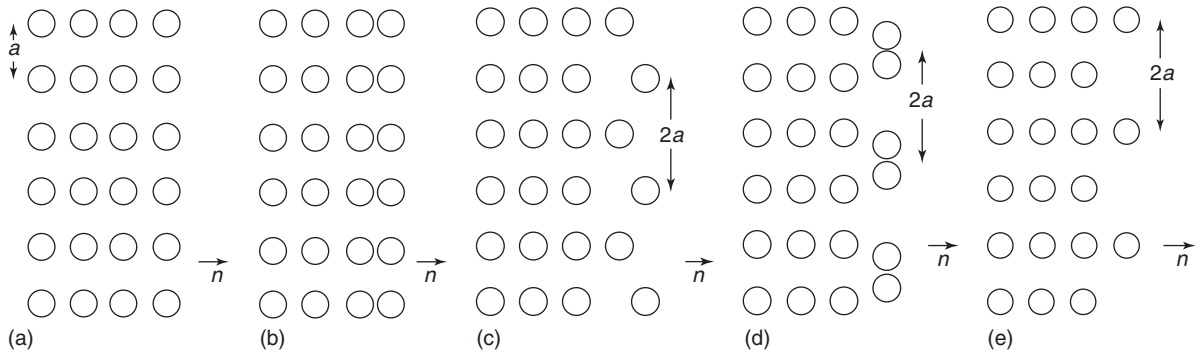

Figure 1 Schematic representation of a surface: (a) ideal surface; (b) relaxed surface; (c), (d), and (e) reconstructed surfaces (simplified examples of buckling, dimerization, and missing row models).

some rearrangement takes place due to the reduction of the free energy of the surface. Two deviations from the ideal surface are possible: relaxation and reconstruction.

Relaxation consists of a rigid displacement of all the atoms of the surface plane (in general, perpendicularly to it) that leaves unaltered the translational symmetry of the surface. On the contrary, reconstruction is a displacement of individual atoms that changes the translational symmetry in the surface plane.

The two situations are schematically shown in **Figure 1** (where it is assumed that the planes are stacked on top of each other in order to obtain the three-dimensional (3D) crystal). It is seen that in case (b), which represents relaxation, the surface unit cell is still a square of side a, while in cases (c), (d) and (e), which represent reconstruction, the surface unit cell is a rectangle of sides a and $2a$. In Wood's notations, these last reconstructions are called 2×1. It is seen that Wood notations do not univocally characterize the surface: they only give the symmetry of the reconstruction. As such, they are directly obtained from the LEED patterns.

The experimental determination of the actual coordinates of the atoms of the first few layers (that would completely characterize the reconstructed surface) is a very complex problem that may require the use of various techniques and the comparison with theoretical models. Among the most common techniques used for this purpose are: dynamical LEED, STM (scanning tunneling microscopy), ARUPS (angle-resolved ultraviolet photoemission), inverse photoemission, optical reflectance with polarized light, high-energy electron diffraction, elastic and inelastic scattering of atoms, ions, and electrons, etc.

Energies associated with reconstruction are $\sim 10^{-2}$ eVatom^{-1} for metals and $\sim 10^{-1}$ eVatom^{-1} for semiconductors. Metals are then seldom reconstructed, while semiconductors are very often so. In metals, in fact, electrons are delocalized so that the free energy does not depend much on the position of the single atoms. The opposite is true in semiconductors where directional bonding is significant.

Tables 1 and **2** list a few examples of reconstruction of metals and semiconductors. It is seen that, for a given surface, various reconstructions are possible, depending upon the method by which the surface is obtained (shown in the last column). In a few instances, reversible transformations between two phases of reconstruction have been observed as a function of temperature. On the other hand, impurities and defects may stabilize some phases.

The tables show clearly that reconstruction is a problem of extreme variety and complexity, as well as of the greatest interest. Up to now, a theory that explains the occurrence of the various types of reconstruction is not available from first principles.

Guidelines and heuristic models are discussed in the section "Examples of reconstruction of relevant semiconductor surfaces."

Electronic Surface States

The structural variations associated with reconstruction have important consequences on the electronic properties of the surface. Regardless of this, however, the reduction of the translational invariance caused by the surface is enough to introduce additional levels in the electronic structure of the solid. This was shown, for a Kronig–Penney potential, by I Tamm in 1932 and extended to a more realistic case by W Shockley in 1939.

A 1D potential with a surface at $z = 0$ is shown schematically in **Figure 2a**. Inside the solid ($z < 0$) the wave function is given, according to the Bloch theorem, by

$$\Psi(z,t) = u_k(z)\exp[\mathrm{i}(kz - \omega t)] \qquad [1]$$

Table 1 Surface structure of (some) metals

Metal	*Face*	*Reconstruction*	*Model*	*Preparation and remarks*
Ag	(1 0 0)	1×1	Relaxation	Epitaxial film on MgO. 1×1 stable for $T < 773$ K
	(1 1 0)	1×1	Relaxation (7–10%)	Roughening transition at $T \cong 700$ K
	(1 1 1)	1×1	Relaxation	$30 < T < 140$ K

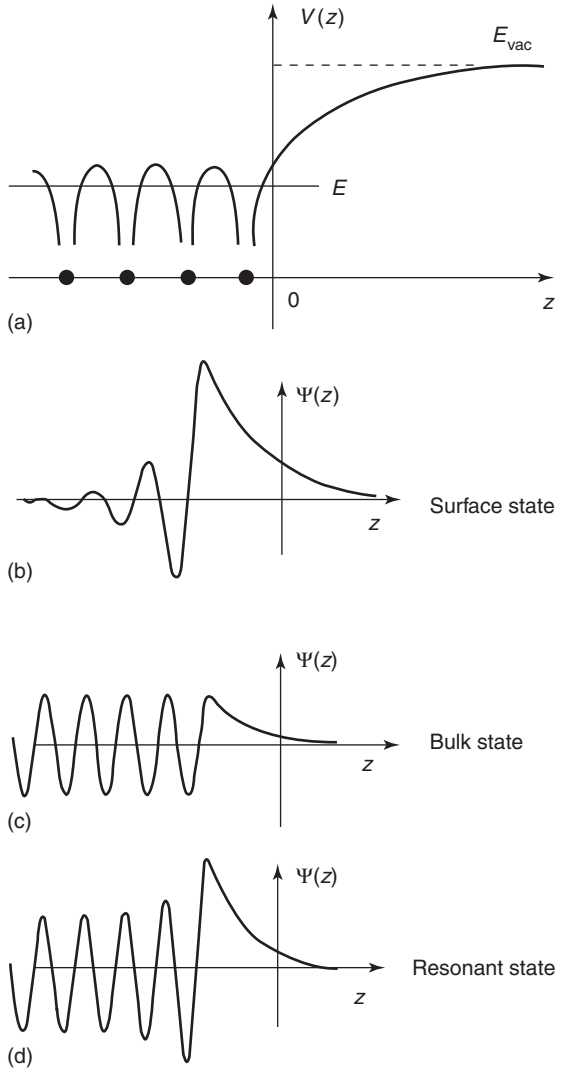

Figure 2 Schematic representation of a surface in a 1D model: (a) potential energy of an electron; (b) wave function for a surface state with energy in the gap; (c) bulk electron scattered at the surface; and (d) surface resonant state.

where $u_k(z)$ is a function with the same periodicity of the lattice, $k = 2\pi/\lambda$ is the wave number, and $E = \hbar\omega$ is the energy of the electron.

For an unbound lattice $(-\infty < z < \infty)$, k must be a real number so that eqn [1] represents a wave propagating along z. Imaginary values of k are discarded because the wave function cannot be normalized. Since the energy is a function of k, real (imaginary) values of k correspond to allowed (forbidden) bands.

In the presence of a surface, however, imaginary values of k cannot be discarded since now, the wave function can be normalized and states localized at the surface, with energies in the forbidden gaps, become possible. If it is assumed that $k = i\mu$ (with μ real), the spatial part of the wave function can be written (for $z < 0$) as

$$\psi_\mu(z) = u_\mu(z)e^{-\mu z} \qquad [2]$$

When $\mu < 0$, the wave function can be matched, at the surface, to that appropriate for $z > 0$ (a decaying exponential if the potential is given by a step function). This is shown in **Figure 2b** that represents schematically a state localized at the surface with energy in the forbidden gap. Such a state is called a "surface state." The matching, however, can also be done when k is real, giving rise to the state shown in **Figure 2c** that represents a bulk electron scattered at the surface.

In three dimensions, the translational symmetry is preserved on the surface plane so that the surface state is now represented by a Bloch wave propagating along the surface with wave vector $\boldsymbol{k}_{||}$, damped on both sides of the surface as in the 1D example. In this case, however, the energy of the surface state does not necessarily fall into the forbidden gaps because of the energy (kinetic and potential) associated to the motion along the surface.

When the degeneracy of the surface state with the bulk bands is not limited to energy but extends to $\boldsymbol{k}$-values, the state is called a "resonant state." A 1D example is shown schematically in **Figure 2d**. In a naïve picture, such a resonant state corresponds to a bulk electron that is scattered at the surface, though dwelling there for some time.

In order to present the correlation between surface and bulk states, it is customary to project the bulk bands on the surface Brillouin zone and plot the surface bands there. This is done for un-reconstructed Si(1 1 1) in **Figure 3**. Surface states are represented by dotted lines, surface resonances by full lines, while projected bulk bands are shown as hatched regions.

When the surface is reconstructed, the calculation of the bands is more difficult and can be done only on the basis of a model.

A common procedure is to pile up a number of crystallographic planes where atoms are displaced from their ideal positions according to a given model of reconstruction. The slab should be large enough (10–20 layers) so that in the interior, the structure of the bulk is resumed. Each slab exposes two surfaces. The slabs are then arranged periodically with spacing (between each two) large enough to avoid a sizable perturbation. This fictitious periodic structure allows the use of the theorems of the 3D band theory.

The results are usually presented in terms of the so-called "local density of states." As it is known, the "total density of states" $\rho^{\text{tot}}(E)$ gives the number of

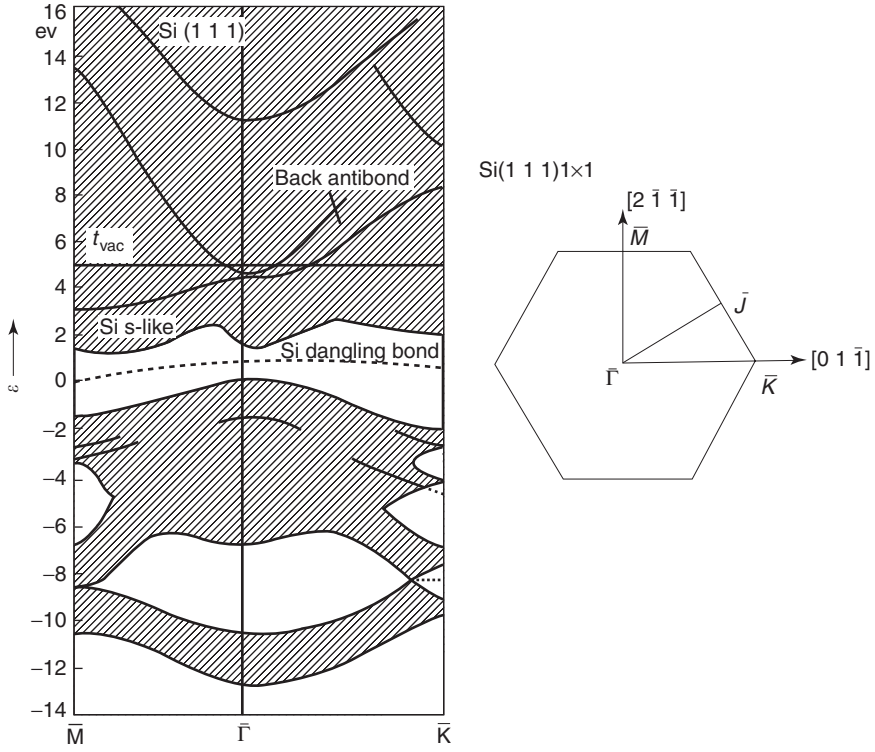

Figure 3 Bulk bands projected into the surface Brillouin zone for the ideal (un-reconstructed) surface of Si(1 1 1). Bulk bands are hatched; surface states are shown with dotted lines; surface resonances with full lines. The surface Brillouin zone is shown on the right. (After Schlüter M and Cohen ML (1978) *Physical Reviews B* 17: 716.)

states present in a unit energy range around E:

$$\rho^{\text{tot}}(E) = \sum_i \delta(E - E_i) \qquad [3]$$

where δ is the Dirac function and the sum runs over the energy states E_i.

In turn, the local density of states is defined as:

$$\rho^{\text{local}}(x, y, z; E) = \sum_i |\Psi_i(x, y, z)|^2 \delta(E - E_i) \qquad [4]$$

that is, each state is weighed with the probability of finding an electron at x, y, z.

Figure 4 shows the local density of states for the ideal surface Si(1 1 1)1 × 1. The figure clearly shows the presence of unsaturated bonds (dangling bonds, DB) on atoms of the first layer.

An important development for calculating the structural and electronic properties of a surface came from the application of the so-called Car–Parrinello method that consists of simulating the dynamical evolution of a reduced set of atoms ($\sim$100), starting from an initial configuration that can as well be the ideal surface. For each configuration, the electronic energy is calculated and,

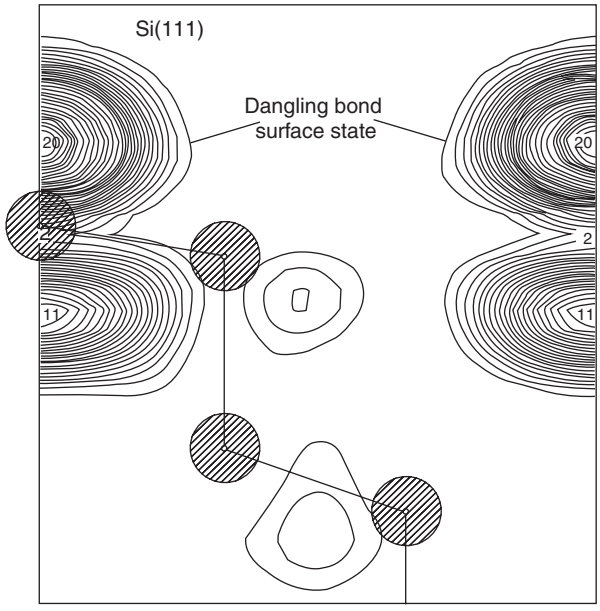

Figure 4 Charge density contours in the (1 1 0) plane (perpendicular to the (1 1 1) surface) for the un-reconstructed (ideal) surface of Si(1 1 1). The dangling bonds protruding into vacuum are clearly visible on the atoms of the surface layer. (After Schlüter M, Chelikowsky JR, Louie GS, and Cohen ML (1975) *Physical Review B* 12: 4200.)

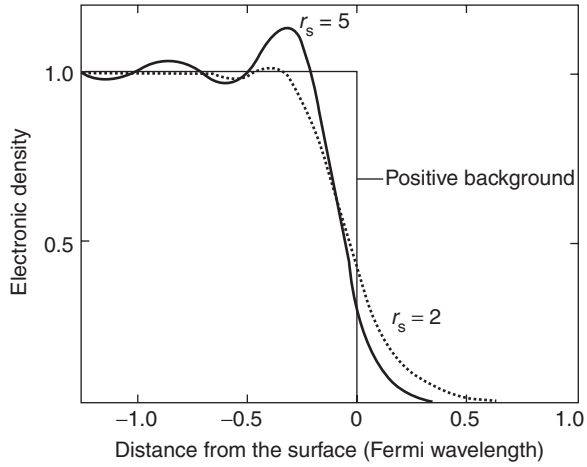

Figure 5 Surface charge density for the jellium model of a metal, plotted for two values of the electron densities. The radius r_s (in atomic units) is that of the sphere that contains one electron. $r_s = 2$, 5 correspond approximately to the cases of Al and Cs, respectively. (After Lang ND and Khon W (1970) *Physical Review B* 1: 4555.)

through the Hellman–Feynman theorem of quantum mechanics, the force on the single atoms is determined and so is the dynamical evolution of the system. Eventually, a stable configuration is reached that corresponds to the reconstructed surface. This "*ab initio*" calculation requires, however, a high computational power and some "educated guesses," especially if the reconstruction is not that of thermodynamical equilibrium.

In metals, one-electron theories are generally inadequate and calculations must be done on the basis of the many-body theory. A model that has given reliable results for the work function of several metals is the so-called "jellium," which assumes that the electrons form a gas of negatively charged particles neutralized by a continuous distribution of fixed positive charge that goes abruptly to zero at the surface. **Figure 5** shows the electron density distribution near the surface for two cases representative of Al (dashed line) and of K (continuous line). Electrons protrude from the surface giving rise to an electric dipole directed inwards, which reduces the work function. Characteristic oscillations of the electron density (Friedel oscillations) should be noticed.

A further peculiarity of metals is that the major contribution to the surface barrier comes from the image force of electrostatics. The potential energy is then, at a large distance from the surface, Coulomb-like. If the electron energy corresponds to a gap, the electron cannot penetrate the solid and remains confined in a sort of a well that extends from $z = 0$ to the Coulomb barrier. In such a well, quantized levels called "image states" exist. Each state is characterized by an integer quantum number, $n \geqslant 1$. In this scheme, the Shockley (or Tamm) states are those with $n = 0$.

The states discussed so far are called "intrinsic surface states" and can be observed only on clean surfaces. On real surfaces, electronic states associated with mesoscopic defects such as steps, kinks, islands, terraces, and pits, or with surface impurities are also present. Such states are called "extrinsic surface states" and may modify the properties of technical surfaces.

In semiconductors, the presence of surface states (both intrinsic and extrinsic), especially when localized in the gap, modifies many of the properties of the sample significantly. The accumulation of charge into surface states creates a macroscopic potential that alters the position of the Fermi level at the surface and introduces a "band bending" that extends for a length of the order of the Debye length defined as

$$L_D = \sqrt{\frac{\varepsilon_b \varepsilon_0 kT}{e^2(n_b + p_b)}} \qquad [5]$$

where $\varepsilon_b\varepsilon_0$ is the dielectric constant and n_b, p_b the densities of negative and positive carriers in the bulk. L_D spans from a fraction of an Å at metal densities to a fraction of a mm in large gap semiconductors.

Such a band bending bears a great importance on many functions of the metal oxide semiconductor (MOS), Schottky barrier, and heterostructure devices.

Examples of Reconstruction of Relevant Semiconductor Surfaces

A few examples of reconstruction of relevant surfaces of semiconductors and some of their associated electronic properties are given below. An outline of the basic experimental evidence is also presented for each surface.

Covalent or partially ionic semiconductors such as C (diamond), Si, Ge, GaAs, and InSb, crystallize in the diamond, zinc blende (or wurtzite) structures in which each atom is tetrahedrally coordinated with four neighbors. The chemical bond is essentially of the directional sp^3 type. The presence of the surface introduces a number of unsaturated bonds called dangling bonds (DBs) that play a great role in reconstruction. Since the energy associated with sp^3 bonds is rather high, the atoms on the surface tend to rearrange in order to reduce the number of DBs. This can be done in a number of ways: dimerization, formation of adatoms (i.e., atoms that have left their ordinary position to sit in the interstice on top of three atoms), π-bonding, etc.

It should be observed in this respect that the sp^3 bond is easily deformable, in the sense that little

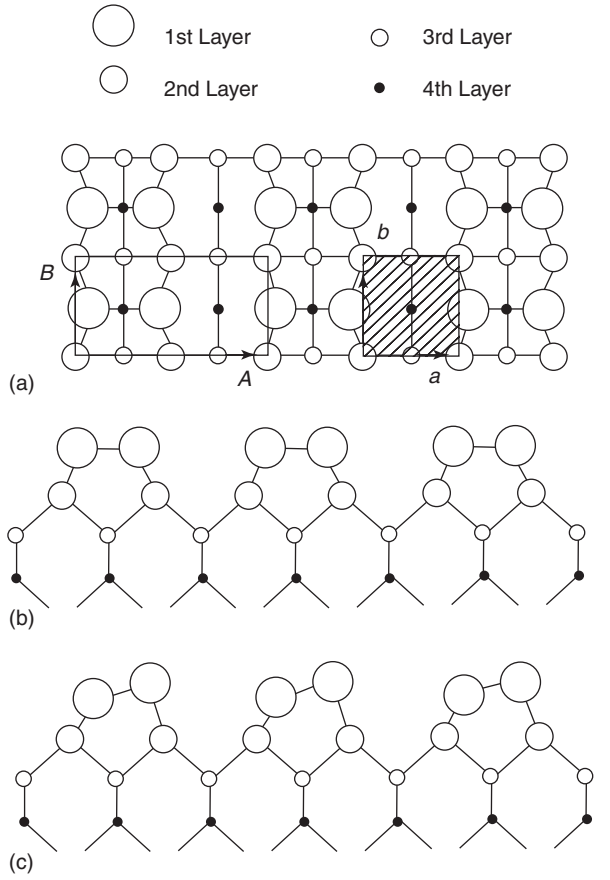

Figure 6 Stick and ball model of the surface of Si(1 0 0) reconstructed 2×1 through dimerization: (a) top view. The 1×1 unit cell (hatched, basis vectors *a*, *b*) and the 2×1 cell (basis vectors *A*, *B*) are shown; (b) side view; (c) side view with buckled dimers.

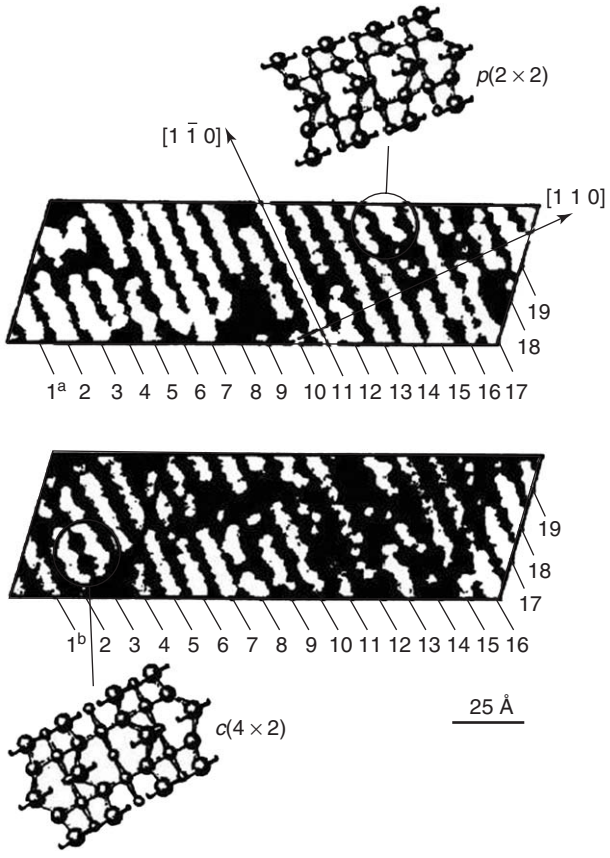

Figure 7 STM pictures of the Si(1 0 0)2×1 surface. The photographs show locally $p(2 \times 2)$ reconstruction (rows 14, 15 in the upper picture) and $c(4 \times 2)$ reconstruction (rows 2, 3 in the lower picture). (From Tromp RM, Hamers RJ, and Demuth JE (1985) *Physical Review Letters* 55: 1303.)

energy is required to change the angles among the bonds. Reconstruction takes advantage of this flexibility, allowing a number of different structures to be present even on the same surface.

Si(1 0 0)2 × 1

The ideal (1 0 0) face exposes two DBs per surface atom and is then highly unstable. Dimerization is a process that produces the 2×1 reconstruction usually observed. The 2×1 reconstructed surface is shown schematically in **Figure 6**: (a) in top view and (b), (c) in side view. The dimers are symmetric in (b) and asymmetric (buckled) in (c). A small buckling is believed to stabilize the surface.

The saturation of the DB cannot be complete so that other types of reconstruction are observed, namely $p(2 \times 2)$ and $c(4 \times 2)$ that occur on $\approx 5\%$ of the surface. Two STM pictures that show the three types of reconstruction on the same surface are presented in **Figure 7**: in the upper picture dimers are seen most distinctly in rows 7, 1, 13 while the $p(2 \times 2)$ reconstruction is seen in rows 14–15. On the other hand, the $c(4 \times 2)$ reconstruction is seen in rows 2–3 of the lower picture.

Si(1 1 1)2 × 1

The (1 1 1) face is the cleavage plane of Si and exposes one DB per surface atom. The 2×1 reconstruction is observed after cleavage at $T < 550\,\mathrm{K}$ at which temperature it transforms irreversibly into the more stable 7×7 structure. The electronic structure consists of two bands (one full and one empty) separated by a gap of $\sim 0.5\,\mathrm{eV}$, from which optical transitions are observed. The opening of the gap is probably the process that stabilizes the surface.

Several models have been proposed for this surface. The only one that satisfies the various experimental findings is that proposed in 1981 by K C Pandey, which consists of π-bonded chains along [1 1 0] directions. The model is shown in **Figure 8** in top and side views. It is seen that in order to create the chains some bonds should be broken. This, however, can be

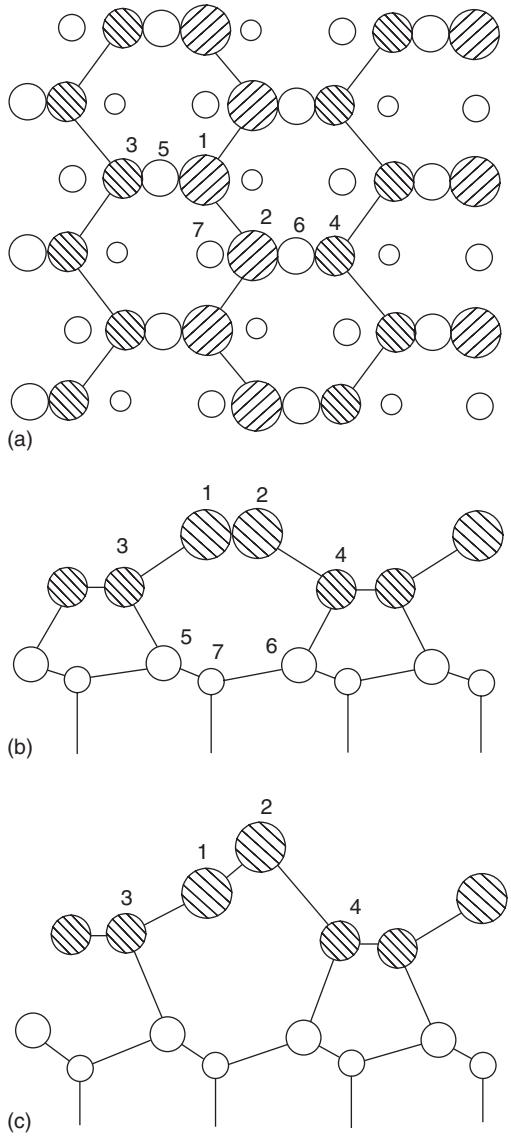

Figure 8 Stick and ball model of the Si(1 1 1)2 × 1 surface, according to the π-bonded chain reconstruction: (a) top view; (b) side view; and (c) side view for a buckled chain.

done almost adiabatically (with negligible activation energy) as can be seen from **Figure 9**, where the local density of states is plotted for various configurations starting from a slightly buckled (almost ideal) surface.

The chain model explains, among others, the following experimental results: (1) the great anisotropy of optical transitions that occur only if the electric vector lies on one of the [1 1 0] directions and (2) the strong dispersion of the occupied states observed in photoemission. The model has been subsequently verified directly by STM. A small buckling along the chain (**Figure 8c**) is necessary to explain the relatively large optical gap.

Si(1 1 1)7 × 7

As already mentioned, this is the equilibrium reconstruction of the (1 1 1) face. The elementary cell contains 49 atoms in the uppermost plane. It has then a complex structure that resisted, for at least two decades, all attempts at theoretical explanation.

By combining accurate electron diffraction at high energies (to avoid multiple scattering), STM pictures, and theoretical considerations, K Takayanagi and Coll proposed in 1985 the reconstruction model shown in **Figure 10**. The elementary cell is a rhomb with two nonequivalent halves and four vacancies at the corners. Dimers can be seen along the sides and the shorter diagonal. 12 adatoms and 6 so-called "rest atoms" (i.e., atoms that have maintained their original positions) are also visible. A stacking fault is present in the left half of the elementary cell. The model is then called DAS (dimers–adatom-stacking fault) and is universally accepted. The number of DB (which were 49 in the unreconstructed cell) has now been reduced to 19 (12 on the adatoms, 6 on the rest atoms, 1 in the vacancy). A similar 5×5 structure (with 6 adatoms, 2 rest atoms, and 4 corner vacancies) is seen in surfaces prepared by MBE and is often associated with the more common 7×7.

From the electronic point of view, the 7×7 structure has a metallic character as shown by photoemission and by the absence of optical transitions in the gap.

Interfaces

The interface is the region that connects two different physical systems, for example, a metal and a semiconductor (Schottky barrier), two different semiconductors (heterojunction) and, in an extended sense, the surface itself, which defines the boundary between the solid and the vacuum.

When the interface forms and thermal equilibrium is reached, the Fermi levels of the two sides line up. This alignment produces a charge redistribution to preserve the overall neutrality of the system, changing the electrical properties of the contact zone.

If two metals come into contact, the difference between the respective work functions results in a flow of electrons from the metal with lower work function Φ_1 into the metal with higher work function Φ_2. A contact potential difference $\Delta = (\Phi_2 - \Phi_1)/e$ develops between the metals (Volta effect), and a dipole layer appears at the interface. Due to the high charge density in metals, the thickness of the interface region is only a fraction of an angstrom.

If the junction connects a metal and a semiconductor, the Fermi level alignment in both materials results in the band scheme of **Figure 11** where the

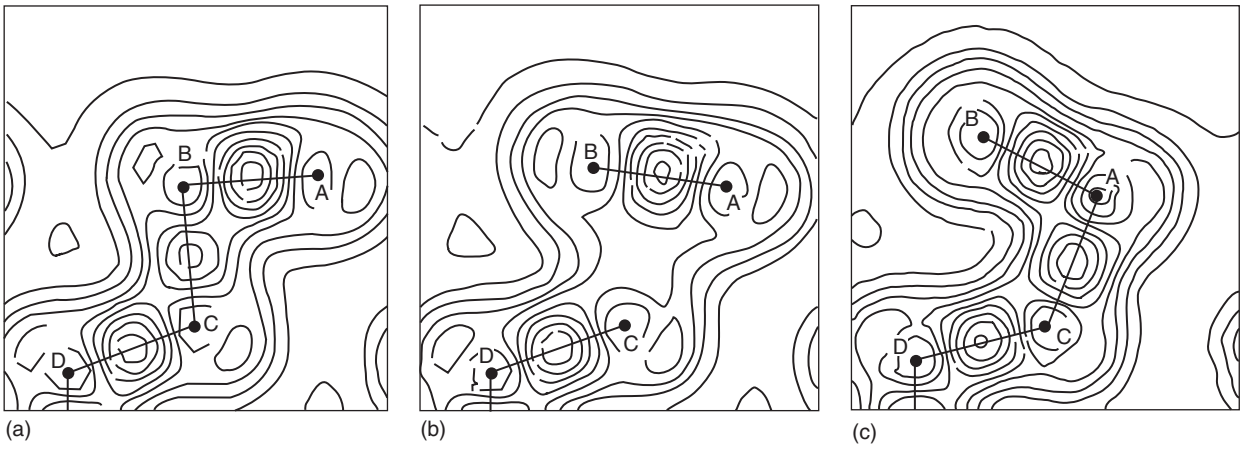

Figure 9 Theoretical contour plots of charge density in the (1 1 0) plane of Si(1 1 1)2 × 1: (a) for a slightly buckled (nearly ideal) surface; (b) for an intermediate geometry; and (c) for the chain model of **Figure 8**. (After Northrup JE and Cohen ML (1982) *Physical Review Letters* 49: 1349.)

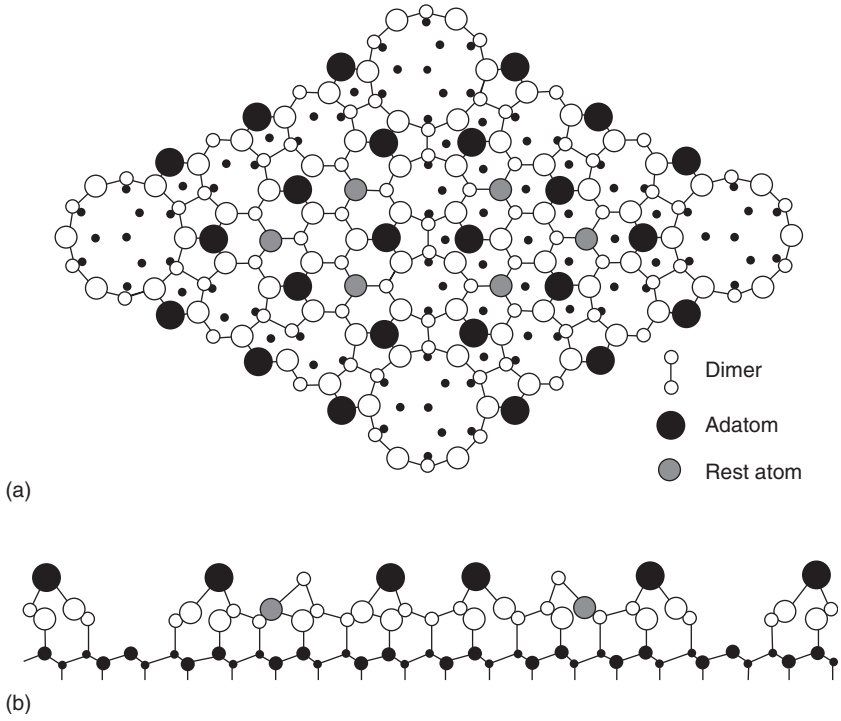

Figure 10 Structure of the Si(1 1 1)7 × 7 surface according to the DAS model: (a) top view; (b) side view. Notice the different positions of the lower neighbors of the rest atoms in the left and right half of the elementary cell, caused by the presence of the stacking fault.

band structures are shown in equilibrium: (a) before and (b) after the contact. An electron moving from the metal to the semiconductor (or vice versa) experiences a barrier (Schottky barrier, Φ_{SB}) given by

$$\Phi_{SB} = \Phi - \chi \qquad [6]$$

where χ is the electron affinity of the semiconductor. The space charge layer in the semiconductor has a much larger width than in the metal because of the difference of carrier densities and screening lengths (for the definition of Debye screening length see the section "Examples of reconstruction of relevant semiconductor surfaces", eqn [5]).

In **Figure 12**, the experimental values of the Schottky barrier for different metals deposited onto the Si(1 1 1)2 × 1 surface are shown. Though the general trend of eqn [6] is maintained, it is apparent

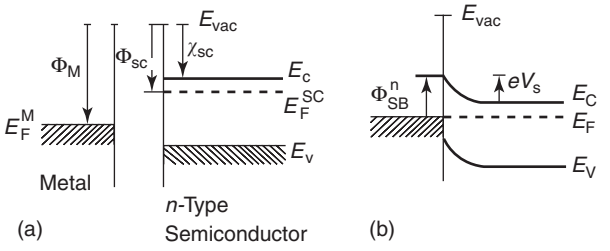

Figure 11 Band scheme of a metal–semiconductor (*n*-type) system: (a) before the contact is established; (b) in equilibrium after the contact. Φ_M (Φ_{SC}) are the work functions of the metal (semiconductor), χ_{SC} the electron affinity of the semiconductor, Φ_{SB} the Schottky barrier height, and eV_S the band bending at the surface.

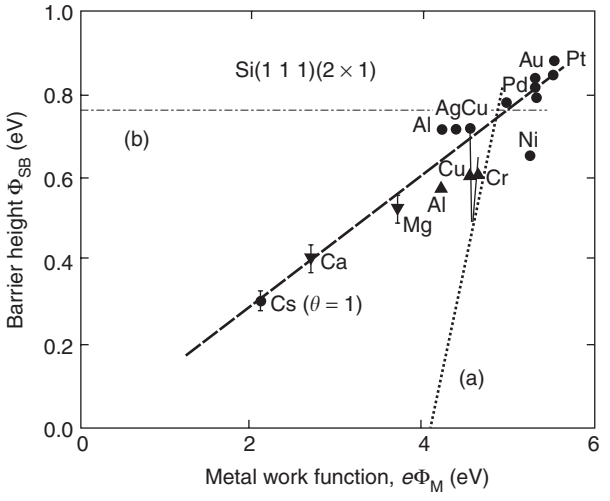

Figure 12 Experimental values of Schottky barriers for several metals on top of Si(1 1 1)2 × 1. The lines represent (a) the Schottky behavior given by eqn [6] (dotted) and (b) the case of complete pinning of Fermi level at the surface (Bardeen behavior, dash-dotted). (After W. Mönch (1986) Festkörperprobleme Vol 26.)

that the simple theory outlined above (dotted line) is inadequate to fit the experiments. The qualitative explanation is that in deriving eqn [6], the presence of electronic surface states at the interface (interface states) has been neglected. If their density is sufficiently large, they pin the Fermi level at the surface of the semiconductor, making the Schottky barrier independent of the work function of the metal (dash-dotted line in **Figure 12**). The experimental situation is intermediate between the two hypotheses (i.e., absence of interface states and complete pinning of the Fermi level).

The nature of the interface states has been the subject of extended research. An important advancement came from the introduction of the so-called metal-induced gap states (MIGS). Consider again **Figure 2c** of the section "Electronic surface states," where the scattering of a bulk electron at the surface is outlined. If the electron at the metal side of the junction has an energy corresponding to the semiconductor gap, it cannot propagate for $z > 0$. A situation similar to that of **Figure 2c** is then a reasonable approximation for the interface wave function: the electronic charge spills into the semiconductor giving rise to a density of states localized at the interface in the semiconductor side (MIGS).

On the other hand, extrinsic states due to defects, mismatching, impurities, and structural changes induced by interface chemical reactions have the same general effect as MIGS. A comprehensive theory of the electronic structure of interfaces is at present not available.

If the interface is created between two different semiconductors, it is called a heterojunction. The alignment of the Fermi levels on both sides determines the band scheme shown in **Figure 13**. The difference between the forbidden gaps of the two semiconductors is distributed between the valence-band discontinuity (ΔE_v) and the conduction-band discontinuity (ΔE_c). Moreover, band bending (eV_1 and eV_2) occurs at the two sides of the interface. Given their great influence on carrier transport, they are the important parameters determining the performance of the interface, and play a central role in the behavior of real heterojunction devices (diodes, solar cells, photodetectors, lasers, quantum devices, etc.).

The presence of electronic states at the interface modifies the distribution of charge producing the situation schematically presented in **Figure 13d**. Such states originate, in analogy to MIGS, from the tailing of the semiconductor wave function in the forbidden gaps.

In the ideal heterojunction, the two materials have the same (or slightly different) lattice parameters so that there is little strain at the interface, and the materials maintain their original properties up to the abrupt junction. If the lattice parameters are different, strain results at the junction, with the formation of dislocations, defects, and disorder. Sizable interdiffusion and chemical reactions may also occur. Such defects give rise to extrinsic electron states.

Three significant examples are given below:

1. The interface resulting after growth of GaAs (lattice parameter $a = 5.6531$ Å) onto AlAs ($a = 5.662\,2$ Å) is a representative example of a nearly ideal heterojunction between materials with a very small lattice mismatch ($\Delta a/a = 0.5\%$). The resulting interface is atomically abrupt, with a very low number of defect states.

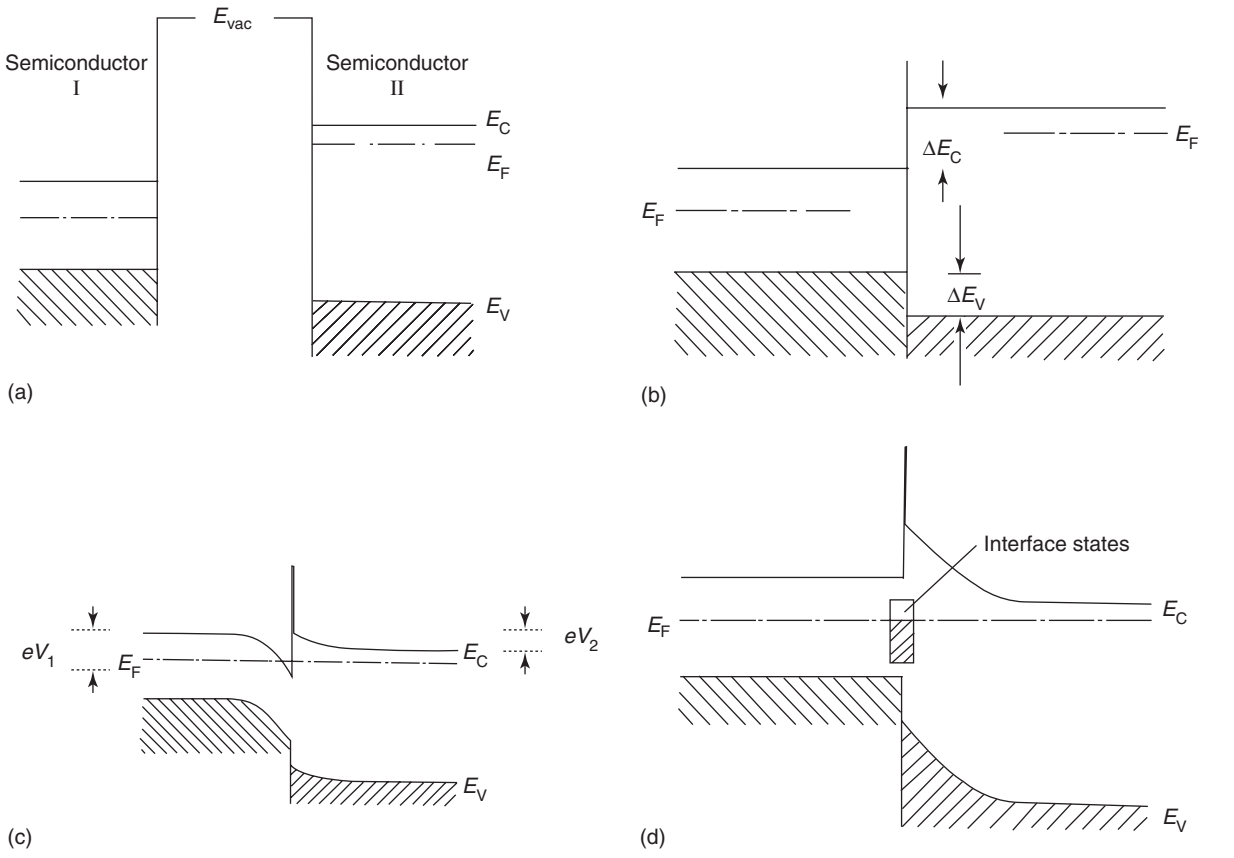

Figure 13 Band scheme of a heterojunction: (a) when the materials are not in contact; (b) after the contact is established, but before equilibrium (Fermi levels not aligned); (c) in equilibrium; (d) in equilibrium, when interface states are present.

2. The interface between Ge ($a = 5.6578$ Å) and Si ($a = 5.4307$ Å) presents a lattice mismatch of 4%, too large to be simply accommodated by a strained layer. The interface is then characterized by intermixing, with the formation of a Ge–Si alloy.
3. In the junction between Ge ($a = 5.6578$ Å) and GaAs ($a = 5.6531$ Å), the mismatch is extremely favorable (about 8×10^{-4}). Nevertheless, the chemistry of materials, that is, the high chemical affinity of Ge, Ga, and As produces a great complexity of the interface composition, with possible effects on doping. Ge acts as a donor or an acceptor in bulk GaAs, while Ga and As are, respectively, an acceptor or a donor when the Ge atom is substituted.

Heterojunctions and heterostructures (i.e., the sequence of a high number of heterojunctions, as in a superlattice) are usually grown by MBE or metal-organic chemical vapor deposition (MOCVD). These epitaxial techniques allow the production of graded junctions that are important in many semiconductor devices.

Introduction

In this article, an overview of the application of linear optical spectroscopies in surface science is given. From a historical point of view, optical methods were important in the very first development of surface-state spectroscopy of clean semiconductor surfaces at the end of the 1960s, when progress in both vacuum technology and surface diagnostics made it possible to reproducibly obtain well-characterized clean surfaces. In fact, optical transitions between filled and empty surface states of intrinsic type were discovered at that time in Ge(1 1 1)2×1 and Si(1 1 1)2×1 by differential reflectance with multiple internal reflections. These results demonstrated the existence of intrinsic (electronic) surface states for the first time in a direct way rather than indirectly from electrical measurements. In the subsequent years, many other surface-sensitive spectroscopies were successfully applied to investigate surface states at the cleavage faces of semiconductors as well as at other clean surfaces.

Generally speaking, in order to study surface optical properties, one has to extract the optical signal originating from the surface from the overwhelming bulk term. For example, in the surface differential reflectivity (SDR), this is accomplished by measuring a change of reflected-light intensity induced by either contamination (usually oxidation or hydrogenation) or chemisorption of foreign atoms. Instead, in reflectance anisotropy spectroscopy (RAS), which is also named reflectance difference spectroscopy (RDS), one measures the reflectance difference for light linearly polarized along two (orthogonal) axes of symmetry at the surface of cubic semiconductors. Since, in general, the surface has a lower symmetry than the bulk, an anisotropy signal originating from the surface is often measured.

When performed with polarized light, SDR yields information on all surface optical transitions (both isotropic and anisotropic) but requires a reference surface, which is obtained by modifying the sample in an irreversible way. On the other hand, RAS does not require any reference surface but is obviously limited to detection of anisotropic transitions only.

The interpretation of the optical experiments is, in general, not straightforward. Hence, the full potentiality of surface optical spectroscopy can be exploited only by a strong interplay of experimental and theoretical work.

At the beginning of the twentieth century, the so-called three-layer model (ambient–surface layer–substrate) was introduced by Drude to describe the surface optical properties from a phenomenological point of view. However, the first steps of the modern theory of surface optical spectroscopy started in 1971, when McIntyre and Aspnes expanded the reflectivity formula for the three-layer model to first order in the surface-layer thickness, obtaining a simple result, suitable for a clear physical interpretation. Realistic and *ab initio* calculations of surface optical properties have later been carried out, even including (in recent years) the electron–hole interaction. At present, the theory is fully developed, but its application to complex surfaces is hampered by the limitations of computational capabilities.

In the following, some relevant results obtained with surface optical spectroscopies, mainly SDR, RAS, and ellipsometry, are briefly described, together with their theoretical interpretations.

Results Obtained with SDR

One of the best-known semiconductor surfaces is the cleavage face of silicon, namely Si(1 1 1)2 × 1, whose reconstruction is described by the chain model developed in 1981 by Pandey. The optical properties of this surface have been extensively investigated over the years, in particular with reflectance techniques. **Figure 1** shows the so-called absorption constant in the near infrared due to transitions between filled and empty surface states possessing a dangling-bond character, at Si(1 1 1)2 × 1. These pioneering results (1971) were obtained by applying the method of multiple internal reflections to cleaved samples in order to amplify the small surface effect. They proved the semiconducting character of the surface, in spite of the fact that the ideal (1 1 1) face should be metallic, with an energy gap of ∼0.45 eV. Similar results were obtained in 1968 for Ge(1 1 1)2 × 1.

The results of **Figure 1** were compatible with Haneman's model, in which the lack of equivalency of surface atoms was explained by a charge transfer associated with a partial dehybridization, due to their up and down displacement with respect to the surface plane. These results were indeed interpreted in the framework of that model. However, when the chain model appeared many years later, its pronounced one-dimensional character suggested a strong anisotropy of the optical properties, at variance with what was predicted by Haneman's model. Indeed, this prediction was confirmed by another experiment with linearly polarized light. **Figure 2** shows the surface reflectance peak (analogous to the absorption peak of **Figure 1**) for light polarized parallel and perpendicular to the chains of surface atoms at single domain Si(1 1 1)2 × 1. The results, recently confirmed by RAS, point out that this peak is totally anisotropic, thus providing a convincing evidence for the chain model.

In 1999, Rohlfing and Louie carried out a calculation of the optical properties of this surface, according to the method of the Bethe–Salpeter equation to account for the electron–hole interaction. The result (see **Figure 3**) has suggested that the experimental peak in **Figure 2** is due to a bound exciton, with

the electron and hole in two surface-state bands with a binding energy of 0.27 eV.

Results Obtained with RAS

RAS was developed as a modulation technique distinct from SDR (in USA) by Aspnes and in Russia by Safarov, independently, in the mid-1980s.

In the beginning, Aspnes mainly studied optical anisotropies of real surfaces of elemental semiconductors, in particular, Si substrates for technological applications. These anisotropies, ∼1%, are not related to intrinsic surface states. They are, instead, associated to a lower symmetry of the subsurface region with respect to the (cubic) bulk, which perturbs the bulk-state wave functions, a situation often described as "bulk states modified by the surface." **Figure 4** shows an example of these surprising anisotropies in the case of oxidized Si(1 1 0).

It is seen in **Figure 4** that the line shape of the surface anisotropy clearly mimics the imaginary part of the bulk dielectric function of Si. While oxidized Si(1 1 0) now has become a standard for calibration of RAS apparatuses, the interpretation of spectra, such as those of **Figure 4**, is still an intriguing matter. After some controversies on the origin of the spectrum in **Figure 4**, the last calculations carried out, including the electron–hole interaction by Bechstedt and coworkers, have finally shown that it can be explained in terms of surface effects on the bulk resonant exciton underlying the E1 peak, close to 3.4 eV.

Since optical techniques can be performed in metal organic chemical vapor deposition (MOCVD) environments as well in vacuum, RA spectra during

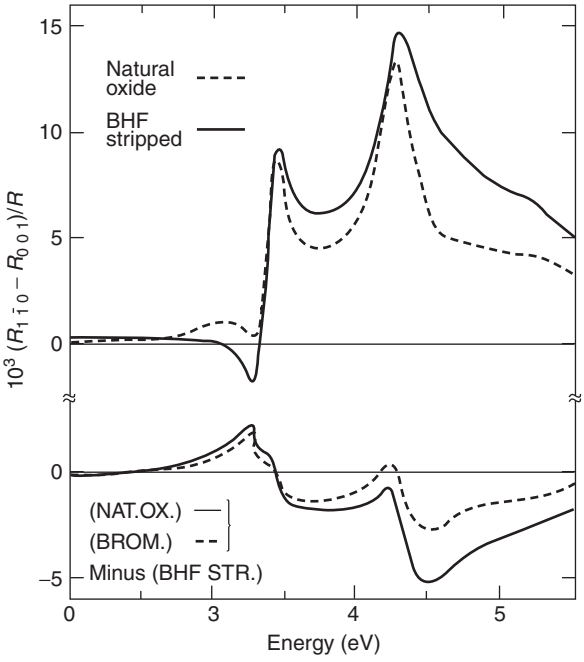

Figure 4 Top: Reflectance anisotropy spectra for a naturally oxidized Si(1 1 0) surface before and after stripping with buffered HF acid. growths of GaAs(0 0 1) by both molecular beam epitaxy and MOCVD have been compared. As a result, a striking correspondence has been found between RAS signals characteristic of surface reconstructions in vacuum and those obtained in an MOCVD reactor at atmospheric pressure of hydrogen in suitable conditions. **Figure 5** shows this correspondence, demonstrating that local ordering is the same in the two cases.

Calculations have been carried out for various reconstructions of GaAs(0 0 1), using both semi-empirical and *ab initio* methods, in order to understand the origin of the observed structures. A good explanation of the RAS of the As-rich reconstructions has been obtained. Most of the RAS structures arise from transitions across surface-perturbed bulk states. However, on the (2 × 4) reconstruction, a combined energy loss and RAS experimental work have recently revealed true surface-state transitions at ∼2.5 eV, well below the first bulk critical point. The optical properties of the Ga-rich (0 0 1) surface, instead, are not yet completely understood. In recent years, interesting RAS investigations have been performed on other semiconductor surfaces, both clean and covered with monolayers of alkali atoms, by the groups of Richter and Paget. Also, organic molecules deposited on different substrates have been studied

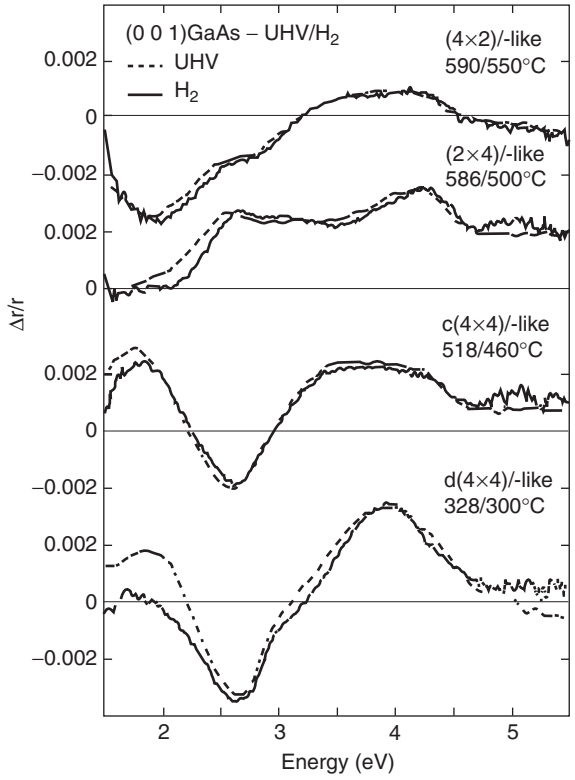

Figure 5 Reflectance anisotropy spectra of the primary reconstructions of GaAs(1 0 0) in UHV and atmospheric pressure of hydrogen, at the indicated temperatures. by RAS, especially by Weightman and Chiaradia-Goletti. Moreover, RAS shows promise to yield valuable information on low-dimensional systems (quantum wires and dots) and nanostructures (carbon nanotubes, polymers, etc.).

Results Obtained with Ellipsometry

Ellipsometry measures changes in the polarization parameters of light upon reflection from a surface. These parameters are: the relative phase Δ and the relative amplitude ratio arctan Ψ of the two components of linearly polarized light, parallel and perpendicular to the plane of incidence,

$$r^{p}/r^{s} = \tan \Psi \exp(i\Delta) \qquad [1]$$

From the spectral dependence of Δ and Ψ, the optical constants n and k are obtained by making use of the Fresnel formulas for the reflection coefficients r^{p} and r^{s}.

When surface properties are studied by ellipsometry, a differential method has to be used, as in the case of SDR. Thus, the changes $\delta\Delta$ and $\delta\Psi$ of the

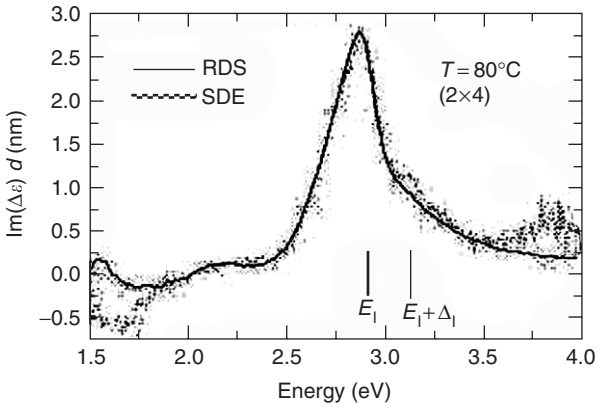

Figure 6 Dielectric anisotropy of GaAs(1 0 0) 2×4, as obtained from reflectance difference spectroscopy (RDS) and from surface differential ellipsometry (SDE). (Reproduced with permission from Wassermeier M, Behrend J, Ploog KH, Zettler JT, Stahrenberg K, and Richter W (1996) *Physical Review B* 53: 13542.)

ellipsometric parameters are recorded upon adsorption of a gas. Under simplifying hypotheses, in the framework of the usual three-layer model, the optical constants of the surface are eventually obtained.

Starting from the pioneering work of Mayer in the 1970s, ellipsometry has been applied to derive the surface optical constants of a number of clean semiconductor surfaces. Especially, various crystallographic faces of Si and Ge, as well as the cleavage faces of GaP, GaAs, and ZnO, and also a number of metallic surfaces have been investigated by this technique.

In spite of the seemingly greater complexity in the data reduction, the results obtained by ellipsometry are practically coincident with those obtained by reflection-based methods, as demonstrated, for instance, by the spectra of **Figure 6**, reporting the dielectric anisotropy obtained from both RAS and ellipsometry data for GaAs(0 0 1) 2×4.

Other Experimental Techniques

Many other optical techniques have contributed in the past to the development of surface physics. Although some of them have fallen into disuse, they deserve to be mentioned here: surface photoconductivity, surface photovoltage, photothermal displacement spectroscopy, and surface photoluminescence. A review of the main results obtained by means of these techniques, especially in the field of clean semiconductor surfaces, can be found in the literature.

Theory

Theoretical work is needed in order to fully exploit the potentiality of surface optical spectroscopy. Three

steps are involved in the theory: (1) the determination of one-electron wave functions; (2) the calculation of the dielectric susceptibility, possibly including many-body interactions; and (3) the solution of light-propagation equations. The last problem was solved in a quite simple way at the end of the 1970s. The surface contribution to reflectivity (i.e., the reflectance difference with and without the surface layer) can be calculated according to the formula:

$$\Delta R/R = 4\left(\frac{\omega}{c}\right)\cos\theta\,\mathrm{Im}\left\{\frac{\Delta\varepsilon_{yy}}{(\varepsilon_b - 1)}\right\} \qquad [2]$$

for *s*-light incident from vacuum in the *xz*-plane and polarized in the *y* direction.

Here, θ is the angle of incidence, and

$$\Delta\varepsilon_{yy} = \int_{-\infty}^{\infty} \mathrm{d}z \int_{-\infty}^{\infty} \mathrm{d}z' [\varepsilon_{yy}(z,z') - \delta(z-z')\varepsilon_0(z)] \qquad [3]$$

$\varepsilon_0(z) = \theta(-z) + \varepsilon_\mathrm{b}\theta(z)$ is the zeroth-order dielectric constant yielding Fresnel formulas, and $\varepsilon_{yy}(z,z')$ is the relevant component of the nonlocal dielectric tensor of the solid–vacuum interface.

For a microscopic evaluation of surface optical properties, one has to calculate eqn [3]. If excitonic and local-field effects are neglected, $\varepsilon_{yy}(z,z')$ can be computed from one-electron wave functions. It is usually evaluated mimicking the semi-infinite crystal by a slab of several (from 10 to 30) atomic layers. In this case, the right-hand side of eqn [3] is related to the slab dielectric function. Within the single-particle scheme, its imaginary part is simply related to the transition probability induced by the radiation between slab states:

$$\varepsilon_{yy}^{(2)}(\omega) = (8\pi^2 e^2/m^2\omega^2 A) \sum_{\boldsymbol{k}} \sum_{\mathrm{v,c}} |p_{\mathrm{v,c}}^{y}(\boldsymbol{k})|^2 \times \delta(E_c(\boldsymbol{k}) - E_v(\boldsymbol{k}) - \hbar\omega) \qquad [4]$$

where $p_{\mathrm{vc}}^{y}(\boldsymbol{k})$ is the matrix element of the *y*-component of the momentum operator between initial (v) and final (c) slab states at the point $\boldsymbol{k}$ in the two-dimensional Brillouin zone (BZ), and A is the sample area. The real part is computed via the Kramers–Kronig relation.

One more ingredient entering eqn [2] is the bulk dielectric function, whose imaginary part is analogous to eqn [4], where, now, eigenstates and eigenvalues of the infinite crystal, together with three-dimensional $\boldsymbol{k}$ vectors, are involved. The study of the optical response of surfaces within the single-particle picture amounts then to calculating (1) the single-particle spectrum and (2) the transition probability between occupied and unoccupied states, both for the perfect crystal and for the crystal with a surface.

If the dielectric susceptibility $\varepsilon_{yy}(z,z')$ is assumed to be local, and a three-step model is hypothesized for its z dependence, the formula of McIntyre and Aspnes mentioned in the section "Introduction" is recovered.

The one-electron states appearing in eqn [4] should be obtained, strictly speaking, within the theory of Green's functions, by solving the quasiparticle Schrödinger-like equation. In this framework, electrons move in a potential which is the sum of the ion potential, the Hartree potential due to the electronic charge density, and of a nonlocal energy-dependent self-energy, which accounts for exchange-correlation (XC) effects due to the interaction with the other electrons. The so-called *GW* approximation to the self-energy, developed by Hedin in 1965, completes the recipe for a rigorous calculation of band energies in solids. Calculations carried out starting in the 1980s have yielded band energies in agreement within 0.1 eV with experimental values for semiconductors.

GW calculations of the electronic structure of solids are computationally very demanding. Hence, as in the past, before the advent of vector computers, even now for complex systems, simpler – yet less accurate – methods are being used. Semi-empirical methods include the tight-binding and pseudopotential methods, where the matrix elements of the Hamiltonian (in the former case) or of the total potential (in the latter case) between basis functions (local orbitals in the former case, plane waves in the latter) are fitted to reproduce bandgaps at some high-symmetry points of the BZ, obtained from experiments. An *ab initio* method often used to determine the band structure of solids is the density-functional theory (DFT), where the XC self-energy is substituted by a local energy-independent XC potential, which is a functional of the electron density. Optical spectra calculated for bulk semiconductors within the one-electron approximation yield only qualitative agreement with experimental spectra, no matter which method – semi-empirical or *ab initio*, *GW*, or DFT – is used. This is because the excitonic and local-field effects are neglected. When these are considered, the discrepancies disappear, as it was shown first by Hanke and Sham in 1980 with a tight-binding calculation. *Ab initio* calculations of the optical properties of bulk solids including the electron–hole interaction and local-field effects yield quantitative agreement with experiments.

The most used methods to calculate surface optical properties are those relying on the single-particle approximation, ranging from the simplest (less accurate) ones (such as semi-empirical tight binding) to the rigorous quasiparticle *GW* method. Anyway, if the

electron–hole interaction is not included, one can expect only a qualitative description of the spectra. The inclusion of the electron–hole interaction in the calculation of excited spectra leads one to consider a two-particle problem (the Bethe–Salpeter equation) rather than a single-particle problem (the Schrödinger-like equation for quasiparticles). Hence, the computational cost increases dramatically and makes the method usable, at present, only for simple surfaces.

The semi-empirical tight-binding method, for its computational speed, has been the first method used for calculating surface optical properties in 1986, when it was successfully applied to Si(1 1 1)2 × 1 and explained the strong optical anisotropy shown in **Figure 1**. In spite of its limitations, this method has yielded, in many cases, results in qualitative agreement with experiments and has helped in clarifying the atomic and electronic structure of a number of surfaces.

Ab initio methods have been developed in the last decade within DFT local-density approximation (DFT-LDA), by expanding the wave functions in plane waves and using nonlocal norm-conserving pseudopotentials. Finally, a rigorous one-electron calculation of surface optical properties should rely on the Green's function approach, with the electron self-energy calculated according to the *GW* approximation. These approaches are much more demanding than semi-empirical tight binding from the computational point of view, since a great number of plane waves are needed to represent slab wave functions.

As an example, the case of GaAs(1 1 0) is discussed. First-principles calculations including self-energy corrections according to the *GW* approximation have been carried out for this surface and are shown in **Figure 7**. They are compared to room temperature (RT) experiments carried out by Esser and co-workers. Calculations show that the experimental peak at 2.7 eV has a substantial (∼50%) contribution arising from transitions across surface states, while all other structures are due to transitions across surface-perturbed bulk states. The reflectance anisotropy calculated in this way has the main structures in very good agreement with experimental ones as far as energy positions are concerned, while the DFT-LDA calculation, also shown in **Figure 7**, is considerably red-shifted, as a consequence of the DFT "gap problem." Differences in line shapes are still present, which are expected to be fixed by introducing excitonic and local-field effects in the calculations.

Finally, the inclusion of the electron–hole interaction can be performed by solving the Bethe–Salpeter equation at surfaces. The first calculation of this kind, carried out by Rohlfing and Louie for Si(1 1 1)2 × 1 in 1999, is shown in **Figure 3**. As it was mentioned

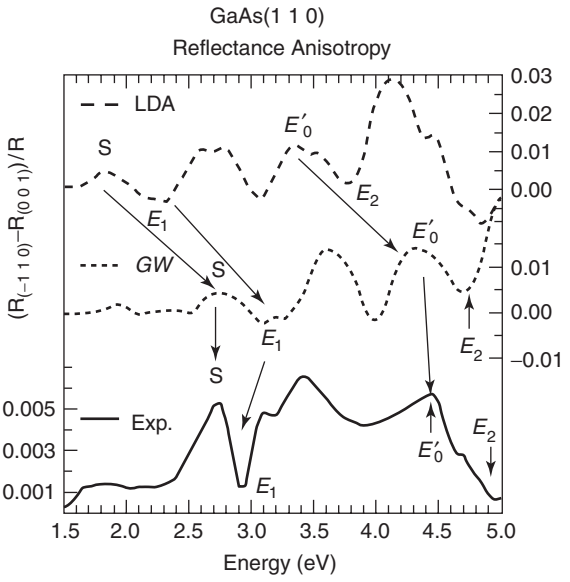

Figure 7 Reflectance anisotropy of GaAs(1 1 0). Upper curve: DFT-LDA calculation. Middle curve: *GW* calculation. Lower curve: RT experiment. (After Del Sole R, Palummo M, and Pulci O (2004) In: Cricenti A (ed.) *Epioptics*-7, p. 1. World Scientific.)

before, the SDR peak at 0.45 eV is ascribed to a surface-state bound exciton, which takes over most of the oscillator strength of the transitions across the dangling-bond (DB)-like surface states. As a consequence, these transitions become very weak and are hardly visible in the experimental spectra. Another application of this technique has been done by Bechstedt and co-workers in 2002 for Si(1 0 0):H, which explained the line shape of the RAS spectrum of **Figure 4** as due to a polarization-dependent quenching of bulk excitonic effects close to 3.4 eV.

Conclusions

Optical spectroscopy has become, in the last decades, an important tool for surface analysis, of great sensitivity to structural changes and versatility. The theoretical understanding of the results is becoming more and more satisfactory, thanks to the application of advanced many-body techniques to the simulation of surface optical properties. Nevertheless, some problems are still open: the most obvious is the extension of these techniques to complex surfaces (those with higher-order reconstructions), which is hampered by the current computational limitations. Less obvious problems are those related to the electron–phonon interaction, which affects surface optical line shapes in a drastic way, and to the complex morphological structure of surfaces, arising from steps, multiple domains, and defects, whose study is now at an initial stage.

Synchrotron Radiation

G Margaritondo, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Electron accelerators such as synchrotrons and storage rings are the best sources of X-rays and ultraviolet photons for research applications. The physical mechanisms for all sources in this class use relativistic effects to increase the emitted photon energies, and therefore require an electron (or positron) beam moving at relativistic speed. The specific implementation of this strategy is reviewed for different types of synchrotron or synchrotron-related sources: bending magnets, wigglers, undulators, helical wigglers, linear accelerator (LINAC) based sources, and free-electron lasers (FELs).

Introduction: X-Ray Sources

X-rays and ultraviolet photons are very extensively used in research. They are the basic ingredients of a wide variety of experimental techniques ranging from microscopy and spectroscopy to imaging and structural analysis. The reason for their usefulness is quite fundamental: they possess photon energies and wavelengths that match basic magnitudes such as the binding energy of valence or core electrons and the length of chemical bonds.

As a consequence, the development of powerful X-ray and ultraviolet sources has been for many decades a high priority for research in many different disciplines. Progress in this field, however, has been rather slow until the advent of the sources in the class broadly labeled as "synchrotrons" in the late 1960s.

A conventional, nonsynchrotron source emits X-rays or ultraviolet photons by bringing electrons to an excited state and then exploiting their radiative decay. Considering the photon energies to be emitted, the process must involve core electrons. Its effectiveness is limited: for example, pumping core electrons to an excited state requires putting a high power in the system (e.g., by bombarding it with electrons) – but the power is limited by the thermal stability of the medium.

Furthermore, the photon emission occurs over a broad angular range. This limits the collimation of the source and its usefulness in experiments that require not only a high photon flux but also a high intensity.

The best parameter to characterize the source quality is the so-called "brightness" or "brilliance," b. Roughly speaking (**Figure 1**), this parameter is proportional to the flux F and inversely proportional to the source area A and to the angular range of emission Ω:

$$b \propto \frac{F}{A\Omega} \qquad [1]$$

(more precisely, F is the number of photons per second emitted in a given bandwidth of 0.1%; A is the product of the horizontal and vertical source sizes; Ω is the product of the horizontal and vertical angular spreads of the emitted photon beam, and $b = F/(4\pi^2 A\Omega)$).

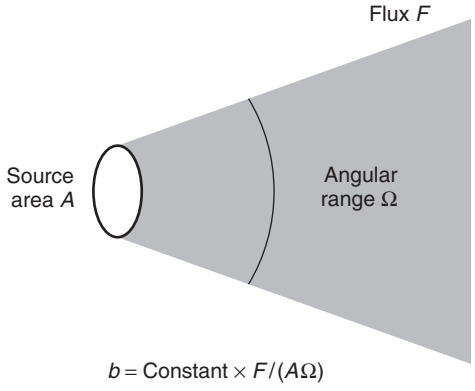

Figure 1 The brightness b is the parameter which is most often used to characterize the quality of photon sources, including synchrotron sources.

A limited flux and a large angular range result in a small brightness. Limited brightness was in fact a major problem in the experimental use of X-rays and ultraviolet photons until the advent of synchrotrons. For example, a crystallographic procedure that today is implemented with a synchrotron source in a few minutes would have required days or months – or would have been impossible.

For visible light, high brightness can be obtained from lasers. This is not easy for X-rays and ultraviolet photons. As discussed later, the effectiveness of the lasing mechanisms decreases, and the fabrication of optical cavities become problematic. Only recently have high-peak-brightness short-wavelength X-ray lasers started to appear technically feasible.

The sources in the "synchrotron" class solve the problem of increasing the flux and the brightness with an altogether different strategy with respect to classical sources. This strategy is based on a clever use of relativistic effects and therefore requires electrons or positrons moving at a speed close to the speed of light, c.

The Relativistic Basis of Synchrotron Sources

Consider (**Figure 2**) a very simple emitter of electromagnetic waves: an electron moving along a circular orbit under the action of a constant magnetic B-field (cyclotron motion). The emitted photon energy $h\nu$ is determined by the cyclotron frequency which, according to classical physics is given by $\nu = eB/(2\pi m_0)$ – where e and m_0 are the charge and the rest mass of the electron. This result derives, as it is well known, from the balance between the Lorentz force and the mass times the centripetal acceleration. The typical emitted photons have rather low energies with respect to X-rays.

Imagine, however, the same phenomenon when the speed of the circulating electron becomes close to the speed of light. In an inertial reference frame moving with the same velocity and speed (v) as the electron at a given time, the transverse Lorentz force vB of the B-field becomes a transverse electrostatic force of magnitude γvB, where the relativistic γ-factor (the energy of the moving electron divided by m_0c^2) is given by

$$\gamma = \frac{1}{\sqrt{1 - (v^2/c^2)}} \qquad [2]$$

As a consequence, relativistic dynamics predicts a cyclotron frequency $\gamma eB/2\pi m_0$, which is γ times larger than the classical result. The emitted photon energy is also multiplied by this factor in the reference frame of the electron, shifting toward the ultraviolet and X-ray spectral domains.

This shift toward shorter wavelengths and larger photon energies is further enhanced if one observes the emission in the reference frame of the laboratory. Imagine, for example, that the emitted photon energy is measured in the laboratory frame along the direction of the electron velocity. Since the source (the electron) is in motion, the photon energy is affected by the Doppler effect, which for electromagnetic waves is also a relativistic effect.

In the "forward" direction of the electron (source) velocity, the Doppler effect multiplies the photon energy by a factor $[(1 + v/c)/(1 - v/c)]^{1/2} = \gamma\ (1 + v/c)$. In the extreme relativistic case $v^2/c^2 \approx 1$, this factor is close to 2γ. Overall, therefore, the classical emitted photon energy for the cyclotron motion is relativistically increased by a factor $\approx 2\gamma^2$.

The mechanism just described is the one active in the photon emission by "bending magnets" (**Figure 3**). These are the dipole magnets that keep the electrons circulating in a closed orbit within an electron accelerator such as a storage ring. The deflection of the

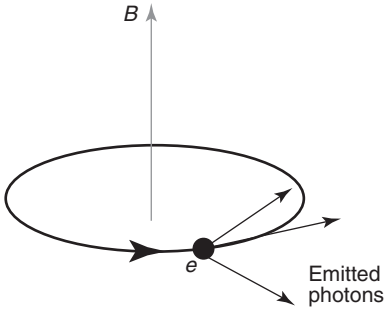

Figure 2 The emission of photons by an electron during its cyclotron motion is a good basis to analyze the mechanism of synchrotron sources. The analysis, however, must be performed for a motion at relativistic velocity, $v \approx c$.

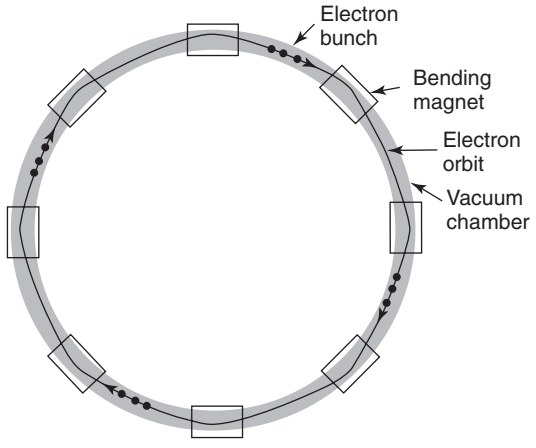

Figure 3 (Dipole) bending magnets are used to keep electrons (grouped in bunches) circulating along closed orbits in the vacuum chamber of a storage ring (top view).

electron trajectory causes a (centripetal) acceleration and therefore the emission of electromagnetic waves. The mechanism is roughly equivalent to that of a portion of a cyclotron orbit, and the characteristics of the emission are also similar – although a rigorous description requires a sophisticated electrodynamics treatment.

In the first approximation, therefore, the center of the spectrum emitted by a bending magnet is close to $2\gamma^2$ multiplied by the classical photon energy given by the cyclotron-frequency, $h\nu = heB/2\pi m_0$. For a typical B-field of 1 T, the classical photon energy would be $\sim 4 \times 10^{-23}$ J or ~ 0.2 meV, well below the ultraviolet and X-ray range. If one takes a typical electron energy of 1 GeV in a storage ring, the γ-value is $\sim 2 \times 10^3$, the factor $2\gamma^2$ becomes $\sim 4 \times 10^6$ and the relativistic emission becomes $\sim 2 \times 10^2$ eV, which falls in the X-ray range.

As discussed later, all types of synchrotron sources exploit this combination of relativistic effects to shift their emission into the ultraviolet and X-ray ranges. In addition to the spectral shift, relativity has another beneficial effect: a shrinkage of the angular range of emission and a corresponding (eqn [1]) increase in the brightness.

This angular-range shrinkage can be easily understood. As shown in **Figure 4a**, a photon emitted in the vertical plane, when observed from the reference frame of the emitting electron, can travel in a direction quite far from that of the electron velocity ("forward" direction). When seen from the laboratory frame, the photon direction changes becoming very close to the same "forward" direction.

The reason is that the relativistic Lorentz transformations include a γ-factor for the "forward" direction coordinate but not for the transverse direction coordinate. When calculating the angle between the photon direction and the "forward" direction as the ratio of the two velocity components, the γ-factor appears in the denominator but not in the numerator. This confines the emission within an angular range $\sim 1/\gamma$ from the "forward" direction. Because of the large value of γ, this relativistic effect strongly collimates the emission enhancing the brightness.

Note, however, that for bending magnets the angular collimation is really only present in the vertical direction. In the horizontal direction (**Figure 4b**), the angular range depends on the portion of the electron orbit "seen" by the detector.

Finally, it should be noted that the brightness (eqn [1]) is also enhanced because relativity boosts the flux. Electrodynamics shows that the power emitted by an accelerated charge is proportional to the square of the acceleration. In a relativistic cyclotron motion, the acceleration is roughly proportional to the speed of light multiplied by the cyclotron frequency, which in turn – as seen – is proportional to γB. Thus, the flux is proportional to $\gamma^2 B^2$, and the large γ-value enables it to reach very high levels.

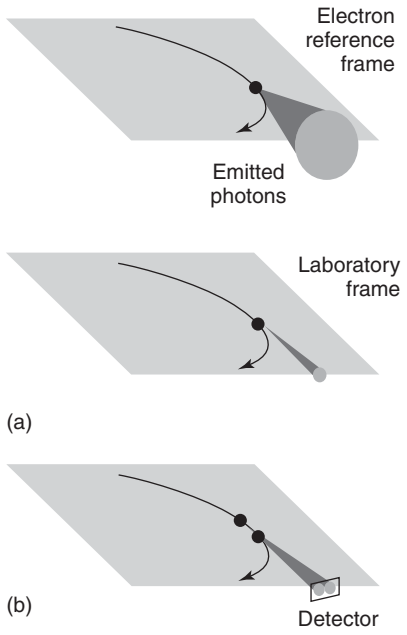

Figure 4 (a) The emission of photons by an electron, whose trajectory is deviated by a bending magnet, occurs over a wide angular range in the electron reference frame. Relativity drastically reduces this angular range when the emission is observed in the laboratory frame. (b) In practice, however, the angular collimation is only present for the vertical direction. In the horizontal direction, electrons at different points of the orbits emit in different directions and the horizontal angular range is set by the portion of the orbit "seen" by the detector.

Main Properties of Synchrotron Sources

Based on the above discussion, one can summarize the main properties of bending magnets and other synchrotron sources in the following way:

- *Spectral domain*: centered in the ultraviolet and X-ray region because of the relativistic factor $\sim 2\gamma^2$ in the emitted photon energies.
- *Bandwidth*: a bending magnet emits over a wide photon energy bandwidth. The reason can be understood by considering an emitting electron as it passes through the bending magnet. Due to the angular collimation, the electron can be imagined as a torchlight with a very narrow beam. A detector (**Figure 5a**) is illuminated by this "torchlight" for a very short time. The corresponding bandwidths of frequencies and photon energies (according to the Fourier theorem and to the uncertainty principle) are inversely proportional to the illumination time and therefore quite large.

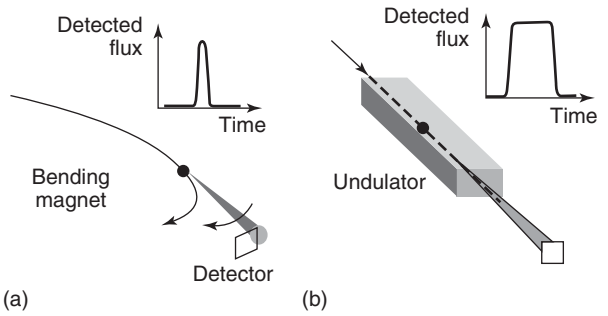

Figure 5 (a) An electron going through a bending magnet emits photons that illuminate the detector only during a short time pulse. This corresponds to a broad photon energy bandwidth. (b) An electron passing through an undulator, instead, illuminates the detector continuously during a longer pulse, producing a narrow bandwidth. The undulator bandwidth is further decreased by other factors.

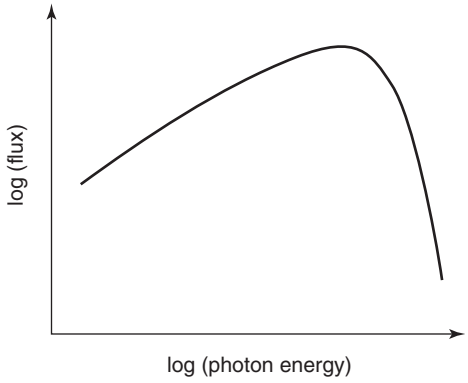

Figure 6 In first approximation, the spectrum emitted by a bending magnet can be imagined as a broad peak. The conventional way to show the spectrum, however, is a log–log plot that transforms a peak-like line shape into the familiar spectrum of bending-magnet synchrotron sources.

A detailed calculation shows that for a bending magnet the photon energy bandwidth is close to the relativistic "cyclotron" photon energy $\approx 2\gamma^2 heB/2\pi m_0$ – so that the relative bandwidth $\Delta h\nu/(h\nu) \approx 1$. In other types of synchrotron sources such as the undulators (see **Figure 5b** and the discussion later), the bandwidth is narrow rather than broad as in bending magnets. Overall, the emitted spectrum of a bending magnet can be roughly imagined as a broad peak with center close to $\sim 2\gamma^2 heB/2\pi m_0$ and $\Delta h\nu/(h\nu) \approx 1$. As shown in **Figure 6**, a log–log plot of this peak gives the familiar synchrotron spectrum.

- *Collimation*: the emission is limited to an angular range $\approx 1/\gamma$.
- *Flux*: high and proportional to $\gamma^2 B^2$.
- *Brightness*: very high because of the high flux and high collimation. In addition, the brightness is also enhanced by the small source area A (eqn [1]). The effective A is determined by the transverse section of the electron beam circulating in the accelerator. In modern storage rings as well as in other accelerators, the trajectories of the circulating electrons are controlled with excellent accuracy. This strongly limits A boosting the brightness.
- *Coherence*: the lateral coherence of a source of electromagnetic radiation increases as the product of the source size times the angular range decreases, until it reaches the "diffraction limit" (for which the product roughly equals the wavelength). Thus, the same geometric factors that influence the brightness (eqn [1]) also determine the lateral coherence. For a bending magnet, the high angular collimation in the vertical direction produces high lateral coherence in the same direction. The longitudinal coherence is determined by the relative bandwidth $\Delta h\nu/(h\nu)$ and, for a bending magnet, it is quite limited. However, the longitudinal coherence can be increased by reducing the bandwidth with a monochromator.

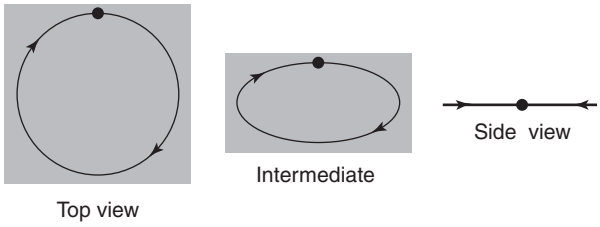

Figure 7 The polarization of the bending magnet emission can be understood by imagining to observe from different points of view an electron moving in the storage ring. It is quite clear, for example, why in the ring plane the emission is linearly polarized.

- *Polarization*: for a bending magnet, the limited angular range confines the emission to directions close to the (horizontal) plane of the storage ring. From their point of view, the emitting electrons (**Figure 7**, right) appear to move along a horizontal line, and their emission is linearly polarized with the photon electric field in the horizontal plane. Slightly out of the plane (**Figure 7**, middle), the observed electron motion is elliptical and the emitted light possesses a circularly polarized component. As discussed later, other synchrotron sources are also linearly or circularly polarized.
- *Time structure*: the electrons circulate around a storage ring grouped in bunches. Every time a bunch passes through a source point such as a bending magnet, a pulse of photons is emitted. Thus, the time structure of a synchrotron source consists of short pulses separated by longer "dark" intervals. The parameters of the time structure depend on those of the storage ring, and the pulse duration can reach in some cases the picosecond range.

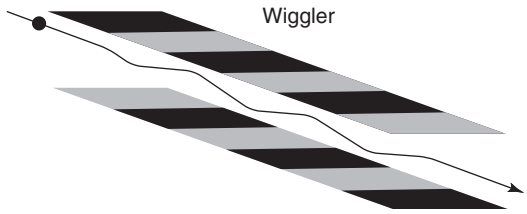

Figure 8 A wiggler is a periodic series of magnets inserted along a straight section of the storage ring. The magnets cause lateral undulations or "wiggles" of the electrons with respect to their otherwise straight trajectory. The resulting photon emission is similar to that of a series of bending magnets.

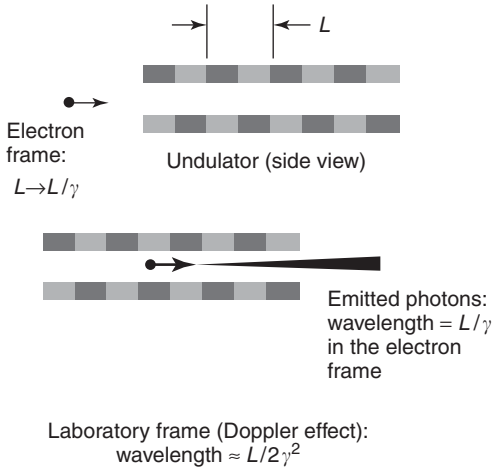

Figure 9 Schematic explanation of how the two relativistic effects (Lorentz contraction of the undulator period and Doppler shift) determine the "central" emitted wavelength and photon energy of an undulator.

Different Types of Synchrotron Sources

The previous discussion primarily dealt with bending magnet sources. Other types of synchrotron sources exist and are briefly reviewed here.

Wigglers

A wiggler (**Figure 8**) is a periodic sequence of dipole magnets inserted in an otherwise straight portion of a storage ring. It produces a series of transverse "wiggles" in the electron trajectory, each roughly equivalent to the electron trajectory in a bending magnet. The emission is thus approximately equivalent to that of a series of bending magnets.

The positive aspects of a wiggler are mainly two. First, the flux and the brightness are multiplied with respect to a single bending magnet by the number of wiggles. Second, the B-field strength can be selected to tune the emission spectrum to a desired value (e.g., to very high photon energies in the hard-X-ray range). This is not possible for bending magnets since their field strength is dictated by the task of keeping the electrons in a closed trajectory around the ring.

Undulators

An undulator is a device similar to a wiggler except that the B-field strength is more limited and the "wiggles" along the electron trajectory are less pronounced. As a consequence, the emission properties are quite different from those of wigglers or bending magnets.

Roughly speaking, the "wiggles" in this case produce angular deviations smaller than $1/\gamma$ with respect to the axis of the undulator. Since the angular spread of the emission is $\sim 1/\gamma$, the emission corresponding to one "wiggle" illuminates the subsequent wiggles, producing coherent interference. As a result, the emitted peak intensity increases with the square of the number of wiggles rather than being proportional to it.

The photon energy spectrum of an undulator is also quite different from that of a wiggler or a bending magnet. First, the bandwidth is much narrower. The reason (**Figure 5b**) is that for weak wiggles the detector is illuminated during the entire passage of the electron-torchlight through the undulator. The resulting longer pulse corresponds to a narrower photon energy bandwidth. This effect is further enhanced by other factors. In essence, therefore, an undulator concentrates the emitted flux of a wiggler into a narrow bandwidth, achieving very high brightness.

This narrow bandwidth is centered at a photon energy which is determined by the undulator period rather than by other parameters (see **Figure 9**). The physical explanation is again rather simple: in the reference frame of an electron moving at relativistic speed through the undulator, the periodic transverse B-field is observed as the combination of a periodic transverse B-field plus a transverse periodic electric field perpendicular to the B-field, both moving at a speed $\sim c$. In other words, it is observed as an electromagnetic wave.

Interacting with this wave, the electron emits waves with the same wavelength. In its reference frame, this is the undulator period L shortened by γ because of the Lorentz contraction. When observed in the laboratory frame, the wavelength is further decreased by a factor $\sim 2\gamma$ by the Doppler effect, becoming $\approx L/(2\gamma^2)$. The corresponding photon energy is $\approx 2\gamma^2 hc/L$.

In addition to this photon energy, the undulator also emits higher harmonics corresponding to its integer multiples. As the B-field increases, the sequence of higher harmonic merges into one broad spectrum corresponding to the wiggler emission.

The fundamental-harmonic photon energy $\approx 2\gamma^2 hc/L$ of an undulator is shifted when the emission is detected along a direction other than the undulator

axis, or when the B-field changes. The reason is similar in both cases: at an angle θ from the "forward" direction, the Doppler factor is no longer $\approx 2\gamma$ and becomes a function of θ. Similarly, as the B-field increases the transverse wiggles decrease the electron speed along the undulator axis and effectively modify the γ-factor in the Doppler shift.

Taking both effects into account, the first-harmonic photon energy of the undulator changes from $2\gamma^2 hc/L$ to

$$h\nu = \frac{2\gamma^2 hc}{L}\left(1 + \frac{K^2}{2} + \gamma^2\theta^2\right) \qquad [3]$$

where the K-factor depends on B: $K \propto BL$. Equation [3] has a very important impact on the operation of undulator sources: by changing the B-field (e.g., the gap between permanent magnets), one can tune the emitted photon energy to a desired value.

Contrary to bending magnets, undulators achieve high angular collimation not only on the vertical direction but also horizontally. In fact, during the entire emission process, the electron stays in a straight trajectory except for small transverse wiggles, and this limits the horizontal angular divergence. This also implies that the lateral coherence is high both vertically and horizontally.

Finally, the undulator emission is linearly polarized with the electric vector in the horizontal plane. The reason is that, when observed from the point of view of the detector, an emitting electron looks like an oscillating charge along a horizontal line.

Helical Wigglers

For many applications of synchrotron sources, it is necessary to have circular polarization. It is seen that circular polarization does exist in the out-of-plane emission of bending magnets. However, the emitted intensity strongly decreases as the direction diverges from the horizontal plane. Therefore, bending magnets can only provide circularly polarized photon beams of moderate intensity.

Dedicated sources for circular polarization are based on special magnet arrays that force the electrons to move along a periodic helical path rather than simply undulating in the transverse direction. Such devices can operate either in the wiggler mode ("helical wigglers") or as undulators.

Linear Accelerator (LINAC) Sources

Almost all synchrotron sources are based at present on electron storage rings. The reason is that electrons in such a ring can circulate after injection for a very long period of time. Photons are thus produced by the same electron beam for hours or days, and this drastically decreases the operation cost.

On the other hand, the emission of photons interferes with the operation of the storage ring limiting the capability of optimizing the electron beam geometry for photon emission. This problem is less severe for LINACs where the electron beam passes only once through the accelerator. However, the electron beam is also used only once to produce photons and this increases the operation cost (notably, the electric power) to prohibitive levels.

A new strategy is emerging in which the electron beam after passing through the accelerator is slowed down giving back most of its energy to the system. With this "energy recovery" scheme the cost of using a LINAC could be reduced to an acceptable level.

Free-Electron Lasers

Standard synchrotron sources are not based on a laser mechanism: they do possess laser-like properties such as high collimation, but they are not lasers. There exists, however, a special class of synchrotron-related sources that operate as lasers: the free-electron lasers (FELs).

A laser is based on two ingredients: optical amplification and the optical cavity. Optical amplification can be achieved in a variety of solid, gas, and liquid media. In the case of FELs, the optically amplifying medium is a relativistic electron beam during its interaction with a wiggler. Under adequate geometric conditions, the electron beam can produce sufficient optical amplification for lasing action.

This approach is implemented with different types of electron accelerators and is widely used to produce high-quality photon beams in the infrared range. However, its implementation becomes more difficult at shorter wavelengths in the ultraviolet and X-ray ranges. In fact, the effectiveness of the FEL optical amplification mechanism decreases with the wavelength. Furthermore, one cannot fabricate an optical cavity for short wavelengths since normal-incidence reflection is extremely limited. Therefore, the optical amplification must be sufficient to produce laser action without the cavity.

The most effective way to overcome these difficulties is the SASE (self-amplified spontaneous emission) mechanism, in which extremely good geometric conditions are achieved for the photon beam in a superconducting LINAC. The corresponding devices are called SASE X-FELs. The SASE mechanism has already been used to produce laser beams with increasing photon energies.

One should note that X-FELs cannot replace synchrotron sources based on storage rings. The lasing

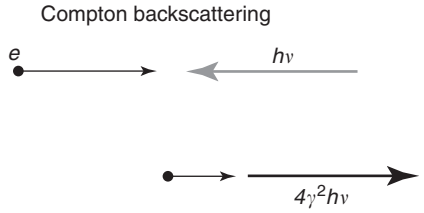

Figure 10 Compton backscattering: a laser beam of photons is sent head-on against a bunch of relativistic electrons. The laser beam is backscattered and its photon energy changes from the visible or infrared domain to X-rays.

mechanism, in fact, produces very high peak brightness over ultrashort pulses (that could reach 100 fs or less). These pulses are excellent for applications that require a high peak brightness but not useful when longer pulses or a quasicontinuum emission is required.

Inverse Compton Scattering Sources

Synchrotron sources have been often proposed for practical applications beyond research, for example in medical radiology. The major obstacle is that standard synchrotron sources have a large size and a high cost. Therefore, they cannot be simply added to the instrumentation of another facility such as a hospital.

The efforts to develop compact storage rings were not too successful, since a small storage ring of sufficiently high energy becomes vulnerable to instabilities and is generally difficult to operate. A promising alternate strategy is based on the inverse Compton scattering mechanism (**Figure 10**).

Imagine a relativistic electron beam sent head-on against a low-energy photon beam. The photons are Compton-backscattered shortening their wavelength. This phenomenon can be easily understood in terms of two Doppler shifts: first, the incoming photon beam is Doppler-shifted in the electron reference frame. Then, the electrons become the sources of the backscattered photons which appear again Doppler-shifted in the laboratory frame. This means that the overall shift factor is $\approx(2\gamma)\ (2\gamma)=4\gamma^2$: an incoming photon energy $h\nu$ in the infrared range can thus produce an X-ray beam with photon energy $4\gamma^2 h\nu$. Depending on the incoming photon energy $h\nu$, the production of X-rays can thus be achieved even with a compact accelerator with moderate γ-factor.

Compton backscattering sources will not be able to reach high brightness and coherence levels. However, they could be suitable for practical applications such as synchrotron radiology, and their size and cost could fit the use in a hospital.

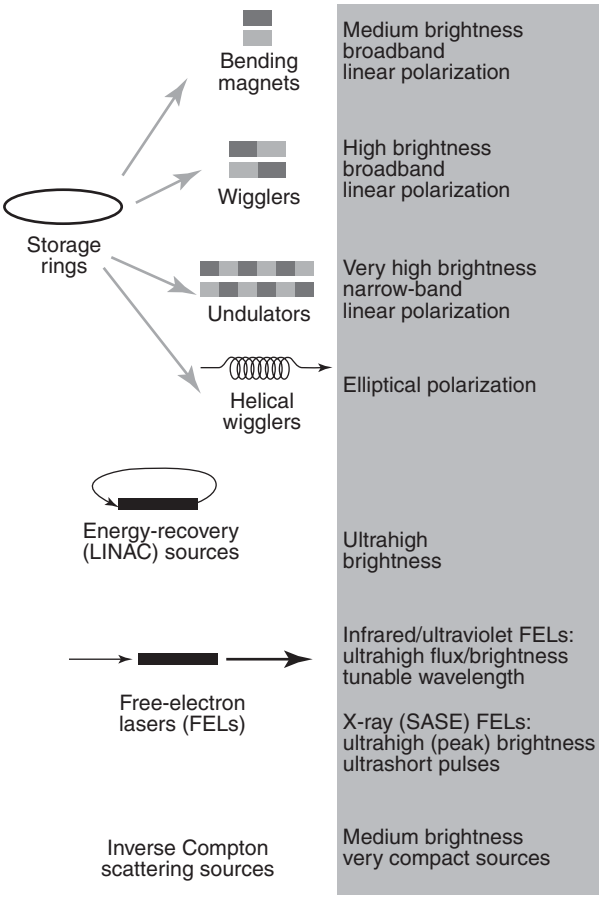

Figure 11 Schematic summary of what can be obtained from different types of synchrotron-related sources.

The Overall Picture

The different types of synchrotron or synchrotron-related sources, either already implemented or under development, provide extreme flexibility in matching the needs of a wide variety of applications. **Figure 11** presents a summary overview of the characteristics of the emission of the different machines.

Practical Use of Synchrotron Sources

Synchrotron sources ceased long ago to be exotic instruments, only used by a tiny minority of scientists. They have become instead standard instruments used by a large part of the research community in diverse disciplines. Dozens of facilities are in operation in many different countries, most of them at no cost for qualified users performing nonproprietary research. Additional programs, for example, those supported by the European Commission, provide support to users for travel and lodging expenses.

Each synchrotron facility serves its users with a variety of instruments. Roughly speaking, the core of the facility is an accelerator such as a storage ring

with its injection and control systems. The emitted photons are collected by beamlines that improve the photon beam characteristics (e.g., by selecting a narrow band of photon energies with suitable monochromators) and convey them to experimental chambers. In the accelerator, the electrons must circulate under ultrahigh vacuum. Many of the beamlines are also under vacuum since no window can be used to separate them from the accelerator without decreasing or completely eliminating the photon beam intensity.

The typical operation cycle of a synchrotron facility begins with the injection of electrons (or positrons) in the accelerator. If this is a storage ring, the electron beam keeps circulating and emitting photons for hours or days and the energy lost through photon emission is restored by radiofrequency cavities. Natural losses steadily reduce the circulating electron beam until a new injection and the beginning of a new operation cycle. In a very few cases such as the Swiss light source (SLS), the injection is performed continuously so that the electron beam can circulate indefinitely and experiments have no time limitations.

Thermal Conductivity at Low Temperatures

T Skośkiewicz, Polish Academy of Sciences, Warsaw, Poland

Heat transport in solids is characterized by thermal conductivity coefficient κ defined by the formula

$$q = -\kappa \nabla T \qquad [1]$$

Heat flow per unit cross-sectional area is proportional to the gradient of temperature. The "minus" sign in eqn [1] indicates that heat flows in the direction opposite to the temperature gradient. There are two main carriers involved in heat transport in solids: thermal vibrations (called phonons) and electrons. The carriers might be scattered by phonons and lattice imperfections. It is assumed that phonons as well as electrons, upon being scattered, diffuse through the material. The simple formula for thermal conductivity coefficient comes from the kinetic theory of gases:

$$\kappa = \tfrac{1}{3}(c\, l\, v) \qquad [2]$$

where v is velocity, l the mean free path of heat carriers, and c the specific heat per unit volume. In case of phonons, v is sound velocity. The typical value of sound velocity in solids is $3\text{–}5 \times 10^3\,\mathrm{m\,s^{-1}}$. Phonons are involved in heat transportation in all materials. Electrons are particularly important in metals. Thermal excitations of electrons in metals are only possible for electrons occupying energy levels close to the Fermi level. Only unoccupied electronic states available in the energy range of the order of thermal excitations participate in the heat transport process. The typical value of Fermi velocity calculated for metals is of the order $10^6\,\mathrm{m\,s^{-1}}$, which is much larger than the velocity for phonons. This is why metals are among the best solid-state heat conductors. At low temperatures, velocity of phonons and Fermi velocity of electrons do not depend on temperature. The heat capacity of electrons might be calculated by employing the free-electron theory; c is proportional to temperature. The heat capacity of phonons, according to the Debye model, is proportional to T^3. The temperature dependence of mean free path for heat carriers depends on the scattering processes. The following scattering processes will be considered; phonon–phonon, phonon–crystal defect, electron–phonon, and electron–impurity. A good assumption is that thermal resistances are additive. Scattering of heat carriers on phonons is temperature dependent because the number of phonons depends on the temperature, leading to a temperature-dependent mean free path. Scattering on defects or impurities results in a mean free path independent of temperature. The thermal conductivity of some specific types of materials is considered in the following sections.

Insulating Crystals

Thermal conductivity in insulating crystals is dominated by phonons. There are two very distinct temperature ranges. At intermediate temperatures, about one-tenth of the Debye temperature, the specific heat of phonons is temperature independent and the mean free path for phonon scattering decreases as $\sim 1/T$ with temperature. According to formula [2], one can expect similar temperature dependence of the thermal conductivity coefficient in this temperature range. At low temperatures, $T \ll \Theta$, the number of phonons is low and phonon–phonon scattering is strongly reduced. Scattering on crystal defects and grain boundaries becomes dominant. The mean free path of phonons for these scattering processes does not depend on temperature. The specific heat in this temperature range is proportional to T^3; thus the thermal conductivity coefficient is

$$K_{\mathrm{ph}} \propto T^3 \quad \text{for } T \ll \Theta \qquad [3]$$

As a result, at intermediate temperatures, a broad maximum of thermal conductivity coefficient is observed. The position of the maximum and the

thermal conductivity coefficient values at low temperatures strongly depend on the purity of the crystal and the number of defects. Examples of thermal conductivity coefficient versus temperature are given in **Figure 1a**. For some insulating crystals, such as diamond and sapphire, with very low concentration of defects and impurities, the thermal conductivity coefficient at the maximum might be larger than that for highly conductive metals such as copper and silver.

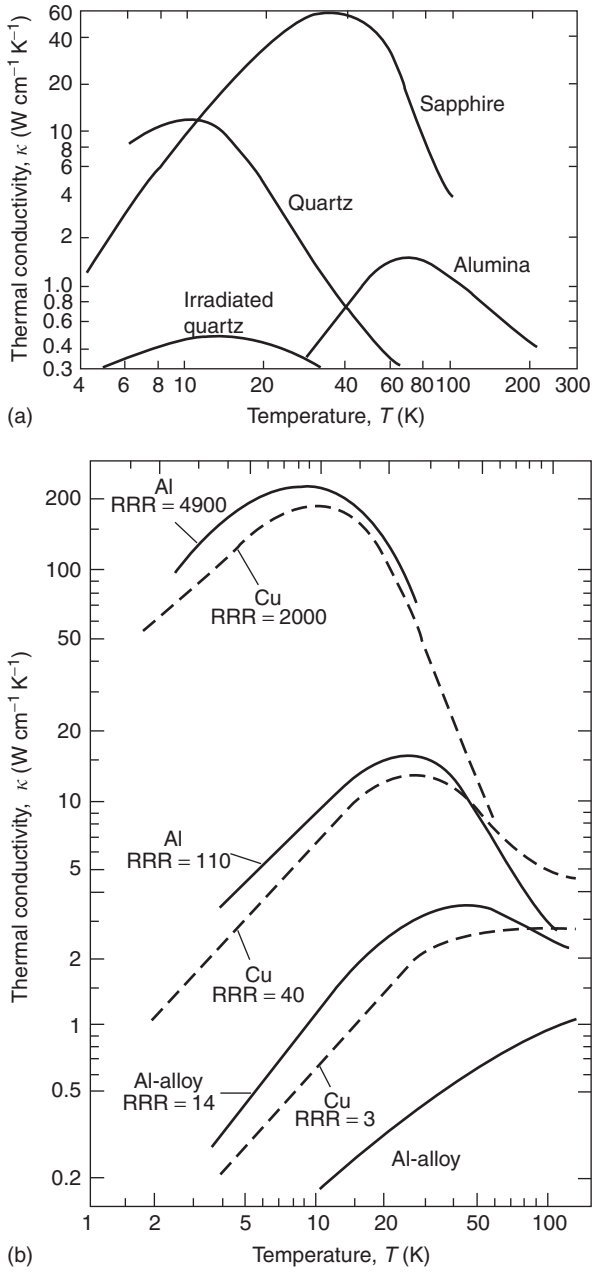

Figure 1 Temperature dependence of the thermal conductivities of (a) some dielectric solids and (b) Al and Cu of varying purity (expressed as their residual resistivity ratio RRR. (Pobell F (1992) *Matter and Methods at Low Temperatures*. Berlin: Springer.)

Metals

Heat transport in metals is mainly due to electrons. The thermal conductivity coefficient is given by formula [2], where c is the electron specific heat proportional to temperature, v the Fermi velocity (independent of temperature), and l the electron mean free path. At temperatures less than 10 K, electrons are mainly scattered at impurity atoms and crystal defects. It makes the electron mean free path to be independent of temperature. Thus the thermal conductivity coefficient K_{el} is proportional to T. At higher temperatures, scattering at phonons has to be taken into account. The number of phonons increases with temperature, which decreases the mean free path of electrons and the thermal conductivity of metals. Here again a broad maximum of thermal conductivity coefficient is observed, but at temperatures lower than that for phonons in dielectric crystals (see **Figure 1b**). In heavily disordered alloys, the electronic thermal conductivity might be reduced so strongly that it becomes comparable with lattice conductivity due to phonons.

Wiedemann–Franz Law

In metals at low temperatures, electrons carry both heat and electric current. Electrical conductivity is independent of temperature, while specific heat of electrons and thermal conductivity coefficient are proportional to temperature. The ratio of thermal conductivity coefficient and electrical conductivity is proportional to temperature

$$\kappa/\sigma = L_0 T \qquad [4]$$

where $L_0 = (\pi k_B/e)^2/3 = 2.45\,\mathrm{W\,\Omega\,K^{-2}}$ is a universal constant called the Lorenz number. The Wiedemann–Franz law [4] holds for low temperatures but is also valid for high temperatures $T > \Theta_D$, where electron transport is limited by large-angle electron–phonon scattering. It is sometimes used for estimation of thermal conductivity coefficient from electrical resistivity measurements.

Noncrystalline Solids

Thermal conductivity of noncrystalline solids is a very special case of heat transport via phonons. An almost universal T^2 temperature dependence of thermal conductivity coefficient is observed for nonmetal glassy solids. Examples are given in **Figure 2**. The

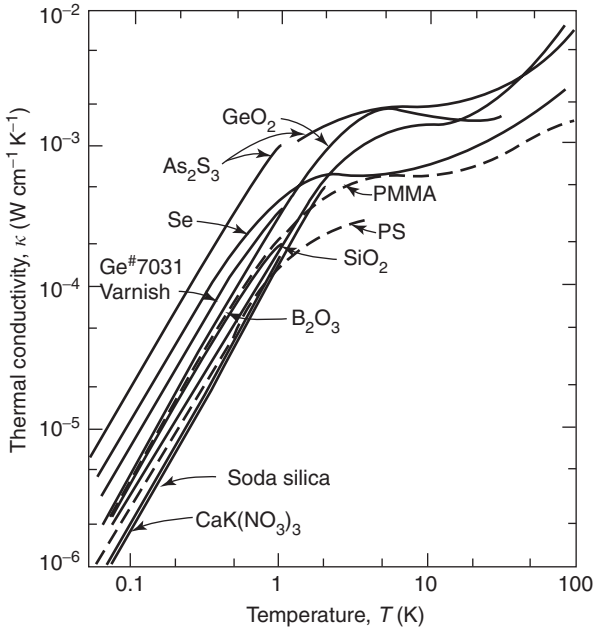

Figure 2 Thermal conductivities of various noncrystalline solids. (Pobell F (1992) *Matter and Methods at Low Temperatures*. Berlin: Springer.)

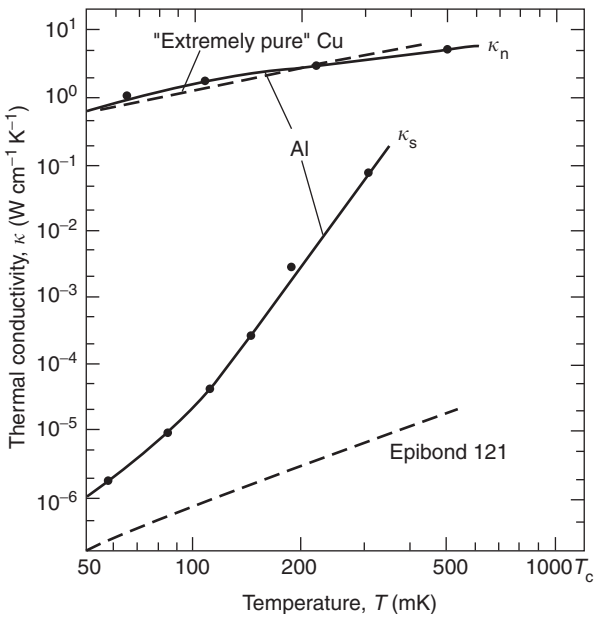

Figure 3 Thermal conductivity of Al in the normal conducting state (compared to Cu) and in the superconducting state (compared to dielectric Epibond 121) at $T > 50$ mK. (Pobell F (1992) *Matter and Methods at Low Temperatures*. Berlin: Springer.)

specific heat of amorphous solids has been observed to vary linearly with temperature below 1 K (e.g., at 25 mK, it is 10^3 times larger than Debye specific heat of crystalline solids). P W Anderson and W A Phillips independently proposed a mechanism for thermal excitations leading to an unusual temperature dependence of specific heat of glasses. They assumed that, in disordered glassy phase, many atoms have more than one position available. Almost equivalent positions are separated by an energy barrier. At low temperatures, there is a finite probability for an atom to tunnel from one position to another. The tunneling gives large contribution to the specific heat, which is proportional to temperature. The mean free path of heat carriers (phonons) is limited by such two energy level scattering centers. Universal T^2 temperature dependence and similar absolute values of thermal conductivity coefficient for various noncrystalline dielectrics show that disorder is the limiting factor for phonon heat transport. Electron heat transport in glassy metals might be negligible at low temperatures.

Superconductors

In the superconducting state of a metal, some of the electrons occupying states in the vicinity of the Fermi level form Cooper pairs. All Cooper pairs being bosons, they condense to the ground state, separated from the excited states of normal electrons by an energy gap ΔE. The pairs cannot be scattered unless the excitation is large enough to break a pair into single electrons, and this is why Cooper pairs cannot carry heat. Only the remaining unpaired electrons in the vicinity of the Fermi level might be carriers in heat transport. The number of these electrons decreases rapidly with temperature and is proportional to $\exp(-\Delta E/\ k_B T)$. The thermal conductivity of a superconductor is a product of normal-state electron thermal conductivity and the number of unpaired electrons:

$$\kappa = T \exp(-\Delta E/k_B T) \qquad [5]$$

At temperatures much lower than the critical temperature, the electronic thermal conductivity of aluminum, one of the best thermal conductors at ambient temperature, is as low as the thermal conductivity of insulators. The thermal conductivity of nonsuperconducting and superconducting aluminum in the temperature range below 1 K is given in **Figure 3**. The thermal conductivity coefficient of copper and insulator Epibond 121 epoxy resin frequently used in low-temperature experiments is also given for comparison. At 50 mK, the thermal conductivity coefficient of superconducting aluminum is less than 10^{-5} of the coefficient for nonsuperconducting aluminum. This property of superconductors opens interesting possibilities in low-temperature experiments. A superconductor might be easily switched into normal state by applying a large magnetic field. A piece of aluminum wire might serve as a thermal switch. At zero magnetic field, the switch is in a superconducting

state and behaves like a thermal insulator, while in presence of the magnetic field its thermal conductivity increases by more than 10^5 times, becoming comparable with the conductivity of the best solid-state thermal conductors.

Nanostructures

Rapid progress in the synthesis and processing of materials in the nanometer length scale has created a demand for better understanding of thermal transport in nanostructures and nanostructured materials. Heat transport in nanoscale systems is still not well understood. Unusual values of thermal conductivity coefficient were experimentally observed. Extremely high thermal conductivity coefficient $6600\,\mathrm{W\,m^{-1}\,K^{-1}}$ was predicted for an isolated carbon nanotube. The room-temperature thermal conductivity coefficient as high as $3000\,\mathrm{W\,m^{-1}\,K^{-1}}$ was measured for a multiwall carbon nanotube with a diameter of 14 nm. Some recent attempts to measure the thermal conductivity of mats of carbon nanotubes gave disappointing results. Due to weak coupling between the carbon nanotubes, the measured thermal conductivity of the mats was found to be much less than expected. On the other hand, extremely low thermal conductivity was reported for mesoscopic GaAs beams supporting a nanostructure bolometric device. The thermal conductivity coefficient for beams of dimensions $0.25 \times 0.15 \times 6\,\mu\mathrm{m}$ (see **Figure 4**) was found to be 10^4 times less than for bulk GaAs.

Superfluid ^{4}He

Among the best heat conductors is superfluid ^{4}He at temperatures above 1 K. Its thermal conductivity might exceed the thermal conductivity of the best metal heat conductors by 10^3 times. The ability of superfluid helium to transport enormous amount of heat might be well explained in terms of a simple two-fluid model. According to the model, superfluid helium consists of two inseparable fluids – normal fluid and superfluid. The equilibrium concentrations of fluids depend on temperature. At lower temperatures, the concentration of the superfluid is larger. A superfluid is a zero-entropy fluid and does not carry

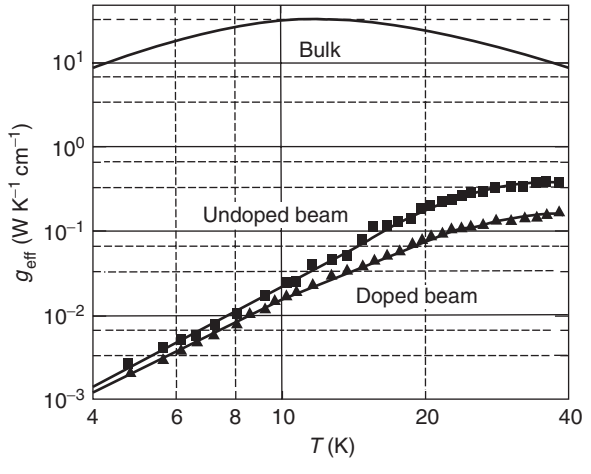

Figure 4 Comparison between the thermal conductivity of doped and undoped beams and that of bulk GaAs. (Fon W, *et al.* (2002) Phonon scattering mechanisms in suspended nanostructures from 2 to 40 K. *Physical Review B* 66: 45302–45305.)

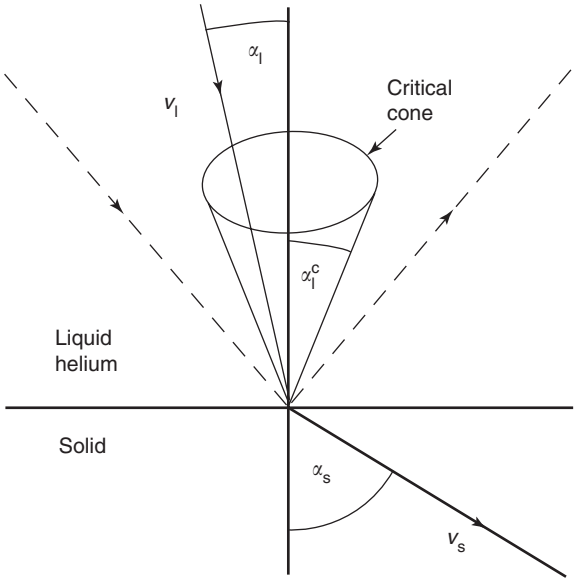

Figure 6 Phonons at the interface between liquid helium and solid body. In real systems the half angle of the critical cone α_l^c is less than 3°.

heat. If heat is supplied at some spot into superfluid helium, it must be transported away if the temperature is to remain constant. The most efficient way of doing this is converting the superfluid component into a normal one. Excess of normal fluid must flow away and be replaced by superfluid. The flow of normal component is a viscous one. Its viscosity increases and thermal conductivity of superfluid helium decreases when temperature is lowered. Experimental data on thermal conductivity of ^{4}He are given in **Figure 5**. Slopes of the curves presented change at 0.6 K, pointing that below this temperature, the process of internal convection described above becomes negligible for heat transport. Longitudinal phonons carry heat only at temperatures below 0.6 K. The specific heat of phonons is proportional to T^3. Since the mean free path of phonons and the sound velocity are independent of temperature, the thermal conductivity of superfluid helium below 0.6 K is proportional to T^3.

Kapitza Resistance

Piotr Kapitza discovered a very interesting phenomenon in 1941. He observed a thermal boundary resistance (the "Kapitza resistance") between liquid helium and a number of solids. The phenomenon, very specific for heat transport at very low temperatures, was explained in terms of acoustic mismatch theory by Kalatnikov. He considered phonon traveling in liquid helium with velocity v_l and striking the liquid–solid

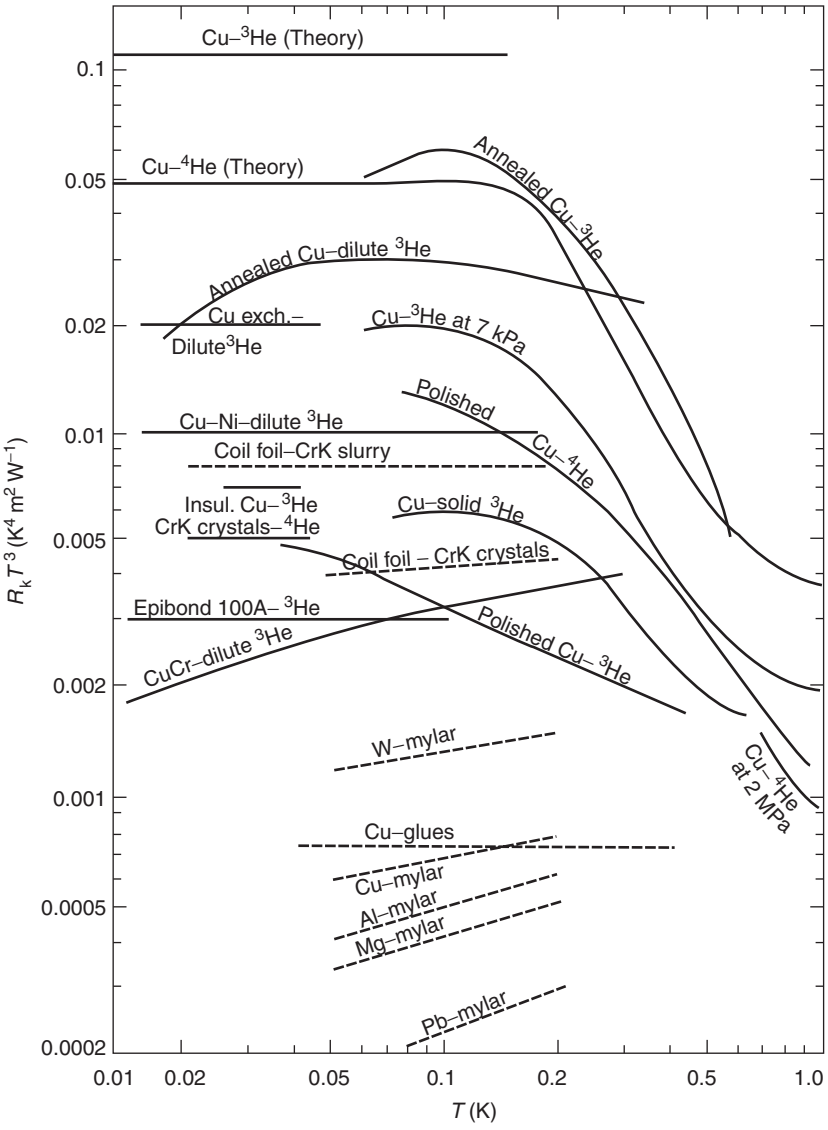

Figure 7 The Kapitza boundary thermal resistivities between liquid ^{3}He or ^{4}He and various solids. Some solid–solid boundary resistivities (dashed lines) have been included. (Lounasmaa OY (1974) *Experimental Principles and Methods Below 1 K*. London: Academic Press.)

boundary at an angle α_l (see **Figure 6**). Snell's law describes refraction of an acoustic wave at the boundary:

$$\sin \alpha_l / \sin \alpha_s = v_l / v_s \quad [6]$$

where the index s refers to the solid. The critical angle given by

$$\alpha_l^c = \arcsin v_l / v_s \quad [7]$$

defines critical cone for incident phonons entering into solid phase. Phonons striking the boundary at angles outside the critical cone are reflected back into the liquid. Below 1 K, the sound velocity in helium is $238\,\mathrm{m\,s^{-1}}$, while in solids it is typically 5×10^3 $\mathrm{m\,s^{-1}}$. It gives a critical angle less than 3° and critical cone solid angle of $2\pi \times 10^{-3}$. It means that the fraction of phonons which may enter the solid is 10^{-3} of phonons hitting the boundary. At thermal equilibrium, the same amount of energy must be transmitted from both sides of the boundary. It was calculated that Kapitza thermal boundary resistivity (resistance per unit of area) is proportional to T^3.

In **Figure 7**, the Kapitza resistivities are given for various solid–liquid and solid–solid boundaries. The Kapitza resistance might create serious problems in heat exchange between helium and solids as well as between different solids at temperatures below 50 mK.

Thermodynamic Properties, General

J M Honig, Purdue University, West Lafayette, IN, USA

Introduction

A general overview of thermodynamic principles is provided herein, with emphasis on topics that are useful in dealing with materials properties. Readers are referred to the "Further reading" section for an in-depth coverage of the subject matter presented here.

The Zeroth Law, Temperature, and Equations of State

The venerable field of thermodynamics rests on four basic laws that are discussed in turn.

The zeroth law asserts that "two bodies in equilibrium with a third are in equilibrium with each other." This seemingly obvious statement of transitive properties has important ramifications: consider systems 1 and 2 surrounded by walls that effectively isolate them from the rest of the universe, but allow them to be independently subject to mechanical deformations via pressures P_1 and P_2 (forces per unit area) that deform their volumes V_1 and V_2. While the systems are separated, these four quantities may be varied independently. However, when joined together and allowed to equilibrate, it is an experience of mankind that only three of the four variables may be independently altered. This is expressed mathematically by the relation $\beta_3\,(P_1, V_1, P_2, V_2) = 0$. Repeat the process for systems 1 and 3, leading to the expression $\beta_2\,(P_1, V_1, P_3, V_3) = 0$. Then by the zeroth law, $\beta_1\,(P_2, V_2, P_3, V_3) = 0$ on combining systems 2 and 3. As long as mutual equilibrium prevails after each combination, system 3 remains unaltered in its union with either system 1 or 2; one can then solve for P_3 in the functions β_2 and β_1 to express

$P_3 = \Phi_1\ (P_2, V_2, V_3) = \Phi_2\ (P_1, V_1, V_3)$, from which the following difference function is constructed: $\Phi_1\ (P_2, V_2, V_3) - \Phi_2\ (P_1, V_1, V_3) \equiv \lambda\ (P_1, V_1, P_2, V_2, V_3) = 0$. Unfortunately, a glaring inconsistency now emerges: the functional dependence of λ on V_3 is absent from the function $\beta_3 = 0$; also, it makes no sense to refer to λ in system 3 when combining systems 1 and 2. To resolve this impasse, let V_3 occur in Φ_1 and Φ_2 so as to cancel out when their difference is constructed. This may be achieved in most general terms by writing $\Phi_1 = f_2\ (P_2, V_2)\ h\ (V_3) + q\ (V_3)$ and $\Phi_2 = f_1\ (P_1, V_1)\ h\ (V_3) + q\ (V_3)$, where h and q are arbitrary functions of V_3. Substitution of the last two equations in the function λ then leads to the relation

$$f_1\ (P_1, V_1) = f_2\ (P_2, V_2) \qquad [1a]$$

Similarly, consistent with the zeroth law,

$$f_1\ (P_1, V_1) = f_3\ (P_3, V_3) \qquad [1b]$$

Reference is now made only to the variables appropriate to each separate system. Equations [1a] and [1b] thus characterize the equilibration process, and they permit one to consider system 1 as a reference standard that determines whether systems 2 and 3 are in equilibrium, according as system 1 is or is not changed when it comes successively in contact with systems 2 and 3. Clearly, the functional interrelation specified by $f_1\ (P_1, V_1)$ is of great significance; therefore, a short-hand notation symbol τ_1, termed the "empirical temperature function" is provided for this function. The relationship $\tau_i = f_i\ (P_i, V_i)$ is known as an "equation of state" for system i. One can thus characterize the empirical temperature of a given system through measurements of its pressure and/or volume. While it has been worked here with mechanical variables, other experimental measurements could have been used in a similar fashion to construct empirical temperatures. Many different methods for monitoring temperature have been employed; these are described in review articles on the subject, such as listed in the "Further reading" section. Only the use of a gas thermometer is briefly discussed here. Other commonly used techniques include measurements of electrical resistivity, thermocouple voltages, paramagnetic susceptibility, pyrometers, and thermal expansion; a description of these and other techniques would be beyond the confines of this article.

The labeling of τ_i as "temperature" obviously introduces a link between physical properties and human sensory perceptions of "hotness levels." The ordering of different hotness levels requires a quantification scheme via an empirical temperature scale; one may employ the equation of state of any suitable material as one indicator of hotness; an enormous multitude of other indicators has been applied for the same purpose (see the "Further reading" section). For present purposes, Boyle's law $f(P, V) = PV = \text{constant} \equiv \tau$ is adopted, which applies to an ideal gas, such as He at low pressure and at a constant temperature well above its critical point. The PV product can then be used as a measure of hotness. A useful quantification scheme is the so-called "Celsius" scale that assigns the values $\tau = 0°\text{C}$ (the original intent, but nowadays assigned a value 0.01°C) and $\tau = 100°\text{C}$ to water that is equilibrated, respectively, with ice and with steam at 1 bar. Let V, V_0, and V_{100} be the volume of He gas at a fixed, low pressure and at temperatures τ, 0°C and 100°C respectively; then τ is specified by

$$\tau = 100(V - V_0)/(V_{100} - V_0) = 100V/(V_{100} - V_0) - 100V_0/(V_{100} - V_0) \equiv T + T_0 \qquad [2]$$

A straight line plot of τ versus V based on the above two assigned points extrapolates to an intercept $T_0 \equiv -100V_0/(V_{100} - V_0)$ which has been found to have the value $-273.15°\text{C}$, where the volume V of the ideal gas would vanish, if the gas could be maintained at lowest temperatures. (Actually, the third law, discussed below, shows that a perfect gas cannot exist at very low temperatures. This, however, does not prevent introducing the ideal gas concept as an excellent approximation to properties of a real gas, and then extrapolating its characteristics to the ultralow temperature range, showing what its properties would be if the gas could be maintained in that range.) The extrapolation to $V = 0$ suggests that there exists a natural lower limit to the hotness levels, and that an absolute temperature scale may be set up by adding 237.15 to the Celsius scale. One thereby establishes the "thermodynamic temperature scale" $T\ (\text{K}) = \tau(°\text{C}) + 273.15$.

Force, Heat, Work, and the First Law of Thermodynamics

In preparation for the next step, let x_i represent a "deformation or thermodynamic coordinate" (such as volume, pressure, temperature, mole number, and the like) that characterizes the thermodynamic state of a given system, and let f_i represent any causative agent by which this particular state may be altered; this is taken to be the "thermodynamic force." Then, the element of work of type i performed "on a system" by its surroundings is specified by $f_i\,\mathrm{d}x_i$; if more than one force brings about a change in x_i, the various contributions must be summed. f_i must

remain sufficiently small so as to avoid turbulent or dissipative effects, otherwise, a whole host of extra-thermodynamic variables would be required to characterize the process. One thus deals with reversible processes that involve only infinitesimal displacements of a system from equilibrium. Also, the force itself may depend on the displacement and may or may not be collinear with the deformation coordinate. These situations are addressed by expressing the work performed on the system when changing its state from $\boldsymbol{x}_1$ to $\boldsymbol{x}_2$ as $W_i = \int_{x_1}^{x_2} \boldsymbol{f}_i(\boldsymbol{x}_i) \cdot \mathrm{d}\boldsymbol{x}_i$, where the force is taken to be a vector and the dot vector product has been introduced. In general, such a line integral depends on the chosen path that takes the system from state $\boldsymbol{x}_1$ to $\boldsymbol{x}_2$, whence this is also the case for the differential quantity $đW = \boldsymbol{f}_i(\boldsymbol{x}_i) \cdot \mathrm{d}\boldsymbol{x}_i$. To emphasize this point, the special symbol $đ$ has been used. It is obviously awkward to have to deal with path-dependent entities; hence, one searches for functions that depend only on the initial and final states of a given process; such entities are known as "functions of state." In the present example, a path-independent work performance may be generated if the force is representable as the gradient of a potential, so that $\boldsymbol{f} = -\nabla\varphi$, whence

$$-W_i = -\int_{x_1}^{x_2} \boldsymbol{f}_i(\boldsymbol{x}_i) \cdot \mathrm{d}\boldsymbol{x}_i = \int_{x_1}^{x_2} \nabla\phi \cdot \mathrm{d}\boldsymbol{x}_i = \phi(x_2) - \phi(x_1)$$

is indeed seen to depend only on the initial and final values of ϕ. The presence of the minus sign indicates that in going from a higher potential $\phi(\boldsymbol{x}_2)$ to a lower potential $\phi(\boldsymbol{x}_1)$, the system does work on the surroundings, the negative of work done by the surroundings on the system.

Mathematical formulations of commonly encountered types of work are briefly listed, but the list is not exhaustive: (1) mechanical pressure – volume work: $đW = -P\,\mathrm{d}V$; (2) enlargement of surface area A: $đW = -\sigma\,\mathrm{d}A$, where σ is the surface tension; (3) gravitational work involved in lifting mass $M\,\mathrm{d}n$ (M is the gram-molecular mass and n is the mole number) through a height z: $đW = gzM\,\mathrm{d}n$, where g is the gravitational constant; (4) electrostatic work (in Gaussian units): $đW = \int \mathrm{d}^3\boldsymbol{r}\boldsymbol{E}\cdot\mathrm{d}\boldsymbol{D}/4\pi = -\int_V \mathrm{d}^3\boldsymbol{r}\boldsymbol{P}\cdot\mathrm{d}\boldsymbol{E}_0$, where $\boldsymbol{E}$, $\boldsymbol{D}$, $\boldsymbol{P}$, $\boldsymbol{E}_0$ are, respectively, the electrostatic field in the presence of the sample, the electric displacement vector, the polarization vector, and the preexisting electrostatic field prior to sample insertion. The first integral must be taken over all space; the second extends over the volume of the sample, since $\boldsymbol{P}$ vanishes outside the confines of the specimen; (5) magnetic work (in Gaussian units): $đW = \int \mathrm{d}^3\boldsymbol{r}\boldsymbol{H}\cdot\mathrm{d}\boldsymbol{B}/4\pi = \int_V \mathrm{d}^3\boldsymbol{r}\boldsymbol{H}_0\cdot\mathrm{d}\boldsymbol{M}$. Here, $\boldsymbol{H}$, $\boldsymbol{B}$, $\boldsymbol{H}_0$, and $\boldsymbol{M}$ are, respectively, the applied magnetic field in the presence of the sample, the magnetic induction, the applied magnetic field prior to insertion of the sample, and the magnetic moment vector. The above shows that work performance can always be determined from first principles; alternatively, it may be measured experimentally. This is of importance in what follows.

"The first law of thermodynamics" states in part that when work $W|_{\mathrm{a}}$ is performed adiabatically (that is, on a system impervious to changes in temperature of the surroundings) thereby changing its state from $\boldsymbol{x}_1$ to $\boldsymbol{x}_2$, then this change is independent of the type of work performed and independent of the path taken to effect this change. In these circumstances, one deals with a function of state, termed energy, here designated as U, that characterizes the $\boldsymbol{x}_1$ to $\boldsymbol{x}_2$ transformation via $\Delta U \equiv U_2 - U_1 = W|_{\mathrm{a}}$. If now, the same process is carried out under nonadiabatic conditions, the $\Delta U = W$ equivalence no longer holds, thus seemingly impairing the usefulness of the energy concept. However, in the nonadiabatic process, additional changes take place that need to be considered.

The first law of thermodynamics asserts that there exists a function of state U, termed the internal energy, such that, for any process whatsoever that takes a system from an initial state $\boldsymbol{x}_{\mathrm{n}}$ to a final state $\boldsymbol{x}_{\mathrm{f}}$, the difference $\Delta U \equiv U_{\mathrm{f}} - U_{\mathrm{n}}$ depends solely on the thermodynamic coordinates $\boldsymbol{x}_{\mathrm{n}}$ and $\boldsymbol{x}_{\mathrm{f}}$ and is independent of the path connecting these states. ΔU can be determined experimentally, or theoretically from $W|_{\mathrm{a}}$. In nonadiabatic changes between the same states, ΔU remains exactly the same, but now the work performance W is different: $\Delta U - W \neq 0$. It is then expedient to introduce a deficit function Q, termed heat transfer, that reinstates the equality in the form: $Q - (\Delta U - W) = 0$. One thus arrives at the following formulation for the first law of thermodynamics:

$$\Delta U = Q + W \quad \text{or} \quad \mathrm{d}U = đQ + đW \qquad [3]$$

where the second formulation applies to an infinitesimal stage of the process; d and $đ$ are used when one deals with infinitesimal processes that are not or are path dependent. Thus, Q and W are two different manifestations of energy in transit across the boundary separating the system from its surroundings. $Q > 0$ (< 0) increases (decreases) the energy of the system via an inflow (outflow) of heat; similarly, for the work transfer $W > 0$ (< 0). While Q, W, $đQ$, $đW$ generally are path dependent, their sum in eqn [3] is not. Thus, given a set of n thermodynamic variables $\boldsymbol{x} = \{x_1, x_2, \ldots, x_n\}$, the function of state U

has the differential form of an analytic function:

$$dU = \sum_{j=1}^{n} (\partial U/\partial x_j)\, dx_j \qquad [4]$$

Clearly, if processes occur totally within the system, there is no transfer of heat or work across the boundaries; then $\Delta U = 0$, which is an expression of the law of conservation of energy in an isolated system. This also disposes off the possibility of having a perpetual motion taking place.

Heat Transfer, Entropy, and the Second Law of Thermodynamics

The next law has been phrased in several different ways: the most common versions involve the statements enunciated by Kelvin and by Planck; these are derived below from more general principles. They are generally presented in elementary textbook discussions that build up to the second law. There is nothing wrong logically with this procedure. However, intellectually it is rather unsatisfactory to base a fundamental thermodynamic principle on statements concerning the operation of a heat engine.

A more general formulation was provided by Carathéodory: in every neighborhood of any state of an adiabatically isolated system, there exist other states that cannot be accessed from it by any process. This statement really provides the proper theoretical background to the second law, but considerable mathematical sophistication is needed to show how this statement leads to the concept of entropy (for a full discussion of this matter see the "Further reading" section). Here, one can simplify matters by noting that just as one connected an adiabatic performance of work to the establishment of a function of state, a transfer of heat can also be used to the same end. Effectively, the first part of the second law of thermodynamics is equivalent to the statement that a reversible infinitesimal transfer of heat to a system $đQ|_r$, though path dependent, is related by a scaling (or integrating) factor λ to a new differential function of state, the empirical entropy s, via $đs = đQ|_r/\lambda$.

The determination of λ is accomplished through a set of tight arguments by considering the process of combining two systems A and B into a compound unit C. Let the heats transferred to the surroundings in an infinitesimal process be designated by $đQ_a$ and $đQ_b$ for the component parts, and by $đQ_c$ for the compound system, $đQ_a + đQ_b = đQ_c$. Then, according to the second law,

$$ds_c = (\lambda_a/\lambda_c)ds_a + (\lambda_b/\lambda_c)ds_b \qquad [5]$$

Let the deformation coordinates of A and B be given by $x_1, x_2, \ldots, x_{n-1}$, t and $y_1, y_2, \ldots, y_{m-1}$, t respectively, where t is the common empirical temperature of the compound system. Mathematically, one can then solve for x_{n-1} in terms of $x_1, x_2, \ldots, x_{n-2}$, t, s_a and for y_{m-1} in terms of $y_1, y_2, \ldots, y_{m-2}$, t, s_b. It is now asserted that: (1) s_c must be independent of $x_1, x_2, \ldots, x_{n-2}$; $y_1, y_2, \ldots, y_{m-2}$; and t. If this were not so, eqn [5] would necessarily contain terms involving the differential quantities $dx_1, dx_2, \ldots, dy_{m-2}$, dt (see eqn [4]). (2) The ratios λ_a/λ_c and λ_b/λ_c cannot depend on these variables; otherwise, statement (1) would be contradicted. (3) λ_c cannot depend on $y_1, y_2, \ldots, y_{m-2}$; for, if it did, then λ_a in eqn [5] would have to depend on these same coordinates in such a manner as to cancel out from the ratio λ_a/λ_c, for consistency with statement (2) and (1). However, λ_a cannot possibly depend on the y-coordinates appropriate to system B. By the same reasoning, λ_c must be independent of $x_1, x_2, \ldots, x_{n-2}$. (4) Furthermore, λ_a and λ_b cannot depend on $x_1, x_2, \ldots, x_{n-2}$ and $y_1, y_2, \ldots, y_{m-2}$, respectively. For, according to (3) these variables are missing from λ_c, whence the ratios λ_a/λ_c and λ_b/λ_c must also be free of these variables, to remain consistent with (1), (2), and (3). However, this argument does not apply to t, which is common to A, B, and C. (5) As a consequence of (1)–(4), the functions λ_a, λ_b, and λ_c can involve at the most, the variables (s_a, t), (s_b, t), and (s_a, s_b, t), respectively. (6) The functional dependences mentioned in (5) must have the form $\lambda_a = \varphi_a(s_a)T(t)$, $\lambda_b = \varphi_b(s_b)T(t)$, and $\lambda_c = \varphi_c(s_a, s_b)T(t)$, in which $T(t)$ is a common though arbitrary function of the empirical temperature t; this function cancels from the ratios λ_a/λ_c and λ_b/λ_c in eqn [5], in consonance with requirement (2). In summary, it is found that

$$\begin{aligned} đQ_a &= T(t)\varphi_a(s_a)ds_a \equiv T(t)dS_a \\ đQ_b &= T(t)\varphi_b(s_b)ds_b \equiv T(t)dS_b \\ đQ_c &= T(t)\varphi_c(s_a, s_b)ds_c \equiv T(t)dS_c \end{aligned} \qquad [6]$$

where S in $dS_a \equiv \varphi_a(s_a)ds_a$, etc., is termed the metrical entropy. As described earlier, one can select any arbitrary function for T; T is thus taken to be identical with the thermodynamic temperature scale of eqn [2]. Further, equilibrium conditions have been assumed throughout, so that all processes must be executed reversibly. Thus, one is led to the result

$$đQ|_r = T\, dS \qquad [7]$$

which relates the state function S to the reversible transfer of heat across the boundaries of the system.

Now, the corollary of the second law is introduced as follows: For any process in a system in (adiabatic),

isolation, the entropy of the final state is never less than that of the intial state. Thus, $\mathrm{d}S|_{\mathrm{a}} \geqslant 0$; the equality holds at equilibrium, and the inequality applies to processes taking place totally within an isolated system; thus, the entropy increases in such processes and reaches a maximum when equilibrium is attained.

Cyclic Processes: The Clausius Inequality

The relation between entropy and heat transfer is clarified by considering a process in which a system is taken reversibly from an initial state n to a final state f, involving a heat exchange $đQ|_{\mathrm{r}}^{\mathrm{n-f}}$. This is to be compared to the heat exchange $đQ|_{\mathrm{i}}^{\mathrm{n-f}}$ accompanying an irreversible process connecting the same states. From the first law, it is found that $đQ|_{\mathrm{i}}^{\mathrm{n-f}} - đQ|_{\mathrm{r}}^{\mathrm{n-f}} = -đW|_{\mathrm{i}}^{\mathrm{n-f}} + đW|_{\mathrm{r}}^{\mathrm{n-f}}; \mathrm{d}U$, being a function of state, has been cancelled out. The above difference cannot vanish, since the two paths must necessarily differ. Thus, the algebraic sum must be either positive or negative. (1) Suppose $đQ|_{\mathrm{i}}^{\mathrm{n-f}} - đQ|_{\mathrm{f}}^{\mathrm{n\text{-}f}} \equiv đQ|_{\mathrm{i}}^{\mathrm{n-f}} + đQ|_{\mathrm{r}}^{\mathrm{f-n}} < 0$, so that $-đW|_{\mathrm{i}}^{\mathrm{n-f}} + đW|_{\mathrm{r}}^{\mathrm{n-f}} = -đW|_{\mathrm{i}}^{\mathrm{n-f}} - đW|_{\mathrm{r}}^{\mathrm{f-n}} < 0$; that is, in going around one cycle (n–f–n), work has been performed on the system and an equivalent amount of heat has been transferred by the system to the surroundings. No other changes have taken place. (2) On the other hand, if the algebraic sum $đQ|_{\mathrm{i}}^{\mathrm{n-f}} + đQ|_{\mathrm{r}}^{\mathrm{f-n}}$ is assumed to be positive, a similar reasoning shows that during the cycle, heat has been introduced into the system, and an equivalent amount of work is obtained. To choose between the alternatives, consider the n–f process for which $đQ|_{\mathrm{i}}^{\mathrm{n-f}} \equiv đQ|_{\mathrm{i}}$, $đQ|_{\mathrm{r}}^{\mathrm{n-f}} = T\,\mathrm{d}S$. Then, under alternative (1) $T\mathrm{d}S > đQ|_{\mathrm{i}}$ in all circumstances, including the case where the n–f process is performed adiabatically, in which case $T\,\mathrm{d}S|_{\mathrm{a}} > 0$. No contradictions have been encountered. By contrast, in alternative (2) $T\,\mathrm{d}S|_{\mathrm{a}} < 0$, a conclusion that is unacceptable. One obtains the important result: $đQ|_{\mathrm{i}} < T\,\mathrm{d}S = đQ_{\mathrm{r}}$. Thus, in a reversible n–f process, the entropy change is matched by a heat transfer $đQ|_{\mathrm{r}}/T$. If the same change is achieved irreversibly, the entropy change is the same but the heat transferred is smaller, the difference between $đQ|_{\mathrm{r}}$ and $đQ|_{\mathrm{i}}$ being made up by effects beyond experimental control. Also, for any process $đW|_{\mathrm{i}} < đW|_{\mathrm{r}}$; the maximum amount of work attainable involves a reversible process. Lastly, for finite changes, $S_{\mathrm{f}} - S_{\mathrm{n}} \geqslant \int_{\mathrm{n}}^{\mathrm{f}} đQ/T$; then, for a cyclic process where $S_{\mathrm{f}} = S_{\mathrm{n}}$, $\oint \mathrm{d}S = \oint đQ/T \leqslant 0$. This latter result, which is consistent with $đQ|_{\mathrm{i}} < đQ|_{\mathrm{r}}$, is known as the Clausius inequality. The above brings up the problem of defining the temperature during irreversible processes; this is generally handled in two ways. One is to assume that the system is anchored to a huge reservoir whose temperature remains essentially fixed, while assuming that the heat transfer is sufficiently rapid to have that temperature also prevail in the system. The second is to note that in irreversible processes, for which departures from equilibrium are "small" (the linear regime of irreversibility), the temperature remains locally defined but varies with position. For more drastic departures from equilibrium, the temperature concept becomes more problematic.

Efficiencies of Cyclic Engines: Kelvin and Planck Statements

One can now deal with the efficiency of any engine that operates in cycles while attached to a hot and a cold reservoir maintained at temperatures T_{h} and T_{c}, respectively. All changes in the universe then occur solely in the surroundings. Let the heat transferred per cycle at the cold and hot junctions be $Q_{\mathrm{c}} > 0$ and $Q_{\mathrm{h}} > 0$, respectively; for the engine to operate, one requires $Q_{\mathrm{h}} - Q_{\mathrm{c}} > 0$, so that less heat is rejected at the cold end than was transferred into the engine at the hot end. Correspondingly, $W = -(Q_{\mathrm{h}} - Q_{\mathrm{c}}) < 0$ represents the amount of work transferable to the surroundings. The efficiency η is defined by the ratio of work output/heat input. The Clausius inequality as applied to the present process reduces to the sum $\sum_{\mathrm{i}} Q_{\mathrm{i}}/T_{\mathrm{i}} = Q_{\mathrm{h}}/T_{\mathrm{h}} - Q_{\mathrm{c}}/T_{\mathrm{c}} \leqslant 0$; this may be converted to the inequality

$$-Q_{\mathrm{c}}/Q_{\mathrm{h}} \leqslant -T_{\mathrm{c}}/T_{\mathrm{h}}$$

Then,

$$\begin{aligned} \eta &= -W/Q_{\mathrm{h}} = 1 - Q_{\mathrm{c}}/Q_{\mathrm{h}} \leqslant 1 - T_{\mathrm{c}}/T_{\mathrm{h}} \\ &= (T_{\mathrm{h}} - T_{\mathrm{c}})/T_{\mathrm{h}} \equiv \eta_{\mathrm{Carnot}} \end{aligned} \quad [8]$$

The following are to be noted: (1) The generality of the approach; no mention is made of what types of cyclic engines are inserted between the two reservoirs. (2) The efficiency relates to the isothermal transfer of heat across the hot and cold junctions. (3) The efficiency for irreversible processes is less than that for reversible ones. (4) The efficiency is never unity since one cannot operate at the unattainable limits (see below) of $T = 0$ or $T \to \infty$. Thus, the efficiency never exceeds the Carnot efficiency η_{Carnot}. (5) η depends solely on the temperature of the "boiler" and "condenser" and, the bigger the temperature difference between them, the larger it is.

Statement (4) leads to Kelvin's statement of the second law: it is impossible to devise an engine operating in cycles that produces no effect other than to extract heat from a reservoir and to perform an equal amount of work. Also, one may infer the Clausius

statement of the second law: it is impossible to devise a machine operating in cycles that transfers heat from a colder to a hotter body without producing other changes in the universe. If this were false, one could transfer heat without loss from the cold to the hot reservoir, so that $-Q_h/T_h + Q_c/T_c \leqslant 0$ with $Q_c = Q_h$, which would lead to the contradiction that $T_h/T_c \leqslant 1$.

Deficit Functions and Their Use in Setting up Functions of State

The following discussion is much simplified by converting the Clausius inequality to an equality through the use of a deficit function $đ\varepsilon > 0$, such that $đQ|_r - đ\varepsilon = đQ|_i$; similarly, $đW|_r + đ\varepsilon = đW|_i$. In a closed universe consisting of system (energy U) and surroundings, (energy U_0) the first law leads to the expression $dU + dU_0 = 0 = đQ|_i + đW|_i + dU_0$, so that

$$T\,dS - đ\varepsilon + đW|_i - dU = T\,dS + đW|_r - dU = 0 \qquad [9]$$

One imposes small deviations from the equilibrium, under a variety of constraints, and subsequently allows the system to relax to its original state. Such small deviations are symbolized by δ. Several cases are considered here:

(1) The system is totally isolated; then $\delta Q = \delta W = \delta U = 0$, and eqn [9] reduces to $T\,\delta S = \delta\varepsilon \equiv T\,\delta\theta \geqslant 0$. Here, $\delta\theta = \delta\varepsilon/T$ has been introduced as the entropy associated with the execution of irreversible processes that are not subject to external control. It is seen immediately that in an irreversible process taking place in an isolated system, the entropy can only increase, a point made earlier. When processes cease and equilibrium prevails, the entropy has achieved a maximum value.

(2) If one allows isoenergetic processes to occur, where $\delta U = 0$ but $\delta Q = \delta W \neq 0$, then eqn [9] reads as $T\,\delta S = \delta\varepsilon + \delta Q|_i = \delta Q|_r$, which merely reinforces the fact that changes in entropy are tracked by reversible heat transfers. Also, if irreversible processes occur, the heat transfer is smaller; the entropy generated by processes outside experimental control is transferred as energy $\delta\varepsilon$.

(3) In isothermal processes for which $\delta T = 0$, eqn [9] specializes to the form

$$\delta(U - TS) \equiv \delta A = \delta W|_i - \delta\varepsilon = \delta W|_r \qquad [10]$$

where a new function of state, the Helmholtz free energy $A \equiv U - TS$ has been generated. This is tracked either by the performance of reversible work or by work over which the experimenter has control plus a component not under his control. If no work is performed, $\delta A = -\delta\varepsilon \leqslant 0$: any spontaneous process under the specified conditions reduces the Helmholtz free energy. When the processes have run their course and equilibrium prevails, A is at a minimum.

(4) One next considers the isothermal–isobaric conditions for which $\delta T = \delta P = 0$. It is now expedient to write $\delta\varepsilon = \delta\varepsilon_m + \delta\varepsilon_t$, where the two terms refer to mechanical (P–V) and nonmechanical types of work; it may be shown that $\delta\varepsilon_m \geqslant 0$ and $\delta\varepsilon_t \geqslant 0$ separately. Equation [9] now becomes

$$\delta(U - TS + PV) \equiv \delta G = \delta W_t|_i - \delta\varepsilon_t = \delta W_t|_r \qquad [11]$$

wherein one introduces a new function of state, the Gibbs free energy $G \equiv U - TS + PV$. This quantity is tracked by reversible work other than mechanical ones; in irreversible processes, the work is augmented by energy transfers not subject to control. In the absence of work, $\delta G = -\delta\varepsilon_t \leqslant 0$, showing that under the stated conditions, the Gibbs free energy diminishes in spontaneous processes until it achieves a minimum at equilibrium.

(5) Isentropic phenomena: here, S is fixed, so that from eqn [9]

$$\delta U = -T\,\delta\theta + \delta W|_i = \delta W|_r \qquad [12]$$

which merely repeats the first law, as specialized to adiabatic conditions. In the absence of work, $\delta U = -T\delta\theta \leqslant 0$, so that under the stated conditions, the energy is reduced and tends to a minimum at equilibrium.

(6) For isentropic–isobaric conditions (P and S fixed), eqn [9] specializes to

$$\delta(U + PV) \equiv \delta H = \delta W_t|_i - \delta\varepsilon = \delta W_t|_r \qquad [13]$$

where yet another function of state, the enthalpy $H \equiv U + PV$, tracked by nonmechanical work, generally augmented by irreversibility effects, has been constructed. When no work is performed under the stated conditions, $\delta H = -T\,\delta\theta \leqslant 0$, so that once more H diminishes in irreversible phenomena and achieves a minimum at equilibrium.

Among the most frequently used functions of state is the chemical potential, derived from eqn [11] as $\mu = (\partial G/\partial n_i)_{T,P,n_{j\neq i}}$, where n_i represents the mole number of species i in the system. The utility of this function arises in part because it involves T and P as independent variables; these are precisely the quantities that are readily subject to experimental control. The second useful feature hinges on the fact that at equilibrium, μ is a minimum. Different phases are associated with different chemical potentials that

vary differently with T and P. The phase among competing phases that prevails under a given set of conditions is the one with the lowest μ. As conditions change, the relative values of μ for the different possible phases are also altered, and a transition from one phase to another takes place whenever the chemical potential of a particular phase falls below that of a previously stable phase. Two phases coexist under conditions where their chemical potentials are the same. This very general subject area has vast ramifications that cannot be explored here.

Standard Formulation for Differentials of State Functions: Maxwell Relations

The above functions of state are summarized in **Table 1**. They lead to the various standard differential forms displayed in part A; note that all work other than mechanical has been excluded. If other types of work are to be included, one must adjoin to these equations, the appropriate work differentials (refer to those listed above).

The process of generating the differentials dH, dA, and dG from dU is called a Legendre transformation. These differential functions of state are very useful in determining the thermodynamic properties of systems. Taking first derivatives leads to the results shown in part B; by taking cross derivatives in either order, one obtains the so-called Maxwell relations shown in part C. Once the equation of state $P = P(T, V)$ or $V = V(T, P)$ is known, one can integrate [I.10] and [I.12] to find S as a function of T and V or T and P. Alternatively, one may employ eqn [I.7] if A or G are known, for example, from statistical mechanics.

Other deductions are found by substituting $S = S(T, V)$ or $S = S(T, P)$ into $U(S,V)$ or $H = H(S, P)$ to obtain $U = U(S(V, T), V) = U(T, V)$, and $H = H(S\ (P, T), P) = H(T, P)$, so that

$$\begin{aligned} \mathrm{d}U &= T(\partial S/\partial T)_V \mathrm{d}T + \left[T(\partial S/\partial V)_T - P\right]\mathrm{d}V \\ &= (\partial U/\partial T)_V \mathrm{d}T + (\partial U/\partial V)_T \mathrm{d}V \end{aligned} \quad [14a]$$

$$\begin{aligned} \mathrm{d}H &= T(\partial S/\partial T)_P \mathrm{d}T + \left[T(\partial S/\partial P)_T + V\right]\mathrm{d}P \\ &= (\partial H/\partial T)_P \mathrm{d}T + (\partial H/\partial P)_T \mathrm{d}P \end{aligned} \quad [14b]$$

Comparing the coefficients leads to the results

$$\begin{aligned} (\partial U/\partial T)_V &= T(\partial S/\partial T)_V \equiv C_V \\ (\partial H/\partial T)_P &= T(\partial S/\partial T)_P \equiv C_P \end{aligned} \quad [15a]$$

$$\begin{aligned} (\partial U/\partial V)_T &= T(\partial S/\partial V)_T - P \\ &= T(\partial P/\partial T)_V - P(V, T) \end{aligned} \quad [15b]$$

$$\begin{aligned} (\partial H/\partial P)_T &= T(\partial S/\partial P)_T + V \\ &= -T(\partial V/\partial T)_P + V(P, T) \end{aligned} \quad [15c]$$

The appropriate Maxwell relations have been introduced on the right-hand side of eqns [15b] and [15c]. The symbols C_P and C_V represent the heat capacities at constant pressure and volume; these are readily measurable as a function of temperature. This permits the determination of U and H as a function of T, with either V or P as a parameter. Equations [15b] and [15c] are known as caloric equations of state; insertion of the equations of state $P(T,V)$ or $V(T,P)$ into these relations, followed by integration, enables one to determine $U = U(T, V)$ and $H = H(T, P)$. Also, from [15a], after measurements of C_V or C_P as a function of T, followed by integration, one can determine $S = S(T, V)$ or $S = S(T, P)$. In a series of lengthy but elementary steps listed in all textbooks, one finds that $C_P - C_V = \alpha^2 VT/\beta$, with $\alpha \equiv V^{-1}(\partial V/\partial T)_P$ representing the isobaric expansion coefficient, and $\beta \equiv -V^{-1}(\partial V/\partial P)_T$, the

Table 1 Standard formulations for thermodynamic functions of state and resulting relations

A. Legendre transformations

From the definitions for $H = U + PV$, $A = U - TS$, $G = U - TS + PV$, and the fundamental relation for dU, one obtains

$\mathrm{d}U = T\ \mathrm{d}S - P\ \mathrm{d}V \qquad \mathrm{d}A = -S\ \mathrm{d}T - P\ \mathrm{d}V$	[I.1, I.3]
$\mathrm{d}H = T\ \mathrm{d}S + V\ \mathrm{d}P \qquad \mathrm{d}G = -S\ \mathrm{d}T + V\ \mathrm{d}P$	[I.2, I.4]

If work other than mechanical is involved, those terms must also be included.

B. First derivatives

$T = (\partial U/\partial S)_V = (\partial H/\partial S)_P \qquad V = (\partial H/\partial P)_S = (\partial G/\partial P)_T$	[I.5, I.6]
$S = -(\partial A/\partial T)_V = -(\partial G/\partial T)_P \qquad P = -(\partial U/\partial V)_S = -(\partial A/\partial V)_T$	[I.7, I.8]

C. Cross-derivatives, Maxwell relations

$(\partial T/\partial V)_S = -(\partial P/\partial S)_V \qquad (\partial S/\partial P)_T = -(\partial V/\partial T)_P$	[I.9, I.10]
$(\partial T/\partial P)_S = (\partial V/\partial S)_P \qquad (\partial S/\partial V)_T = (\partial P/\partial T)_V$	[I.11, I.12]

Equation [I.7] is particularly useful in determining the entropy when the dependence of A or G on T is known from other sources. Equations [I.10] and [I.12] permit substitution for entropy derivatives in terms of information derived from the equations of state.

isothermal compressibility of the material. This difference relation is of importance because it is easier to measure C_P experimentally, whereas the quantity useful in theoretical analysis is C_V. Lastly, insertion of eqn [I.7] into $A = U - TS$ leads to $A = U + T(\partial A/\partial T)_V$; similarly, $G = H + T(\partial G/\partial T)_P$. These are known as "Gibbs–Helmholtz equations," which may be converted into the partial differential forms involving $(\partial A/\partial T)_V = A/T - U/T$ and $(\partial G/\partial T)_P = G/T - H/T$, whose solution, after insertion for U or H yields A or G.

The Third Law of Thermodynamics: Unattainability of Zero Temperature

The "third law of thermodynamics" deals with events as $T \to 0$, where $đQ/T$ might diverge. One first demonstrates that zero temperature is unattainable. Consider the general case where z represents a deformation coordinate and Z is the conjugate variable, such that the first law assumes the form $\mathrm{d}S = T^{-1}[\mathrm{d}U + Z\,\mathrm{d}z] = T^{-1}\{(\partial U/\partial T)\,\mathrm{d}T + [Z + (\partial U/\partial z)]\,\mathrm{d}z\}$. Below, one needs the result of the cross differentiation of this expression with respect to T and z, namely $Z + (\partial U/\partial z) = T(\partial Z/\partial T)$. Special interest now attaches to the case $\mathrm{d}S = 0$, since only under adiabatic conditions, one can hope to reach the lowest possible temperature. Imposing this requirement leads to

$$\mathrm{d}T = \{[Z + (\partial U/\partial z)]/(\partial U/\partial T)\}\,\mathrm{d}z \qquad [16]$$

This relation shows that any change in deformation coordinates under isentropic (adiabatic) conditions necessarily changes the temperature of the system. Insertion of the cross differentiation result leads to the requirement

$$\begin{aligned}\mathrm{d}T &= -T[(\partial Z/\partial T)_z/(\partial U/\partial T)_z]\,\mathrm{d}z \\ &= -[T(\partial Z/\partial T)_z/C_z]\,\mathrm{d}z \\ &= -(T/C_z)(\partial S/\partial z)_T\,\mathrm{d}z, \end{aligned} \qquad [17]$$

where eqn [I.12] with the correspondences P, Z, and V; z was introduced on the right-hand side. Whether $T = 0$ can be achieved or not, thus, hinges on the properties of $(\partial Z/\partial T)_z$ and of (T/C_z) at exceedingly low temperatures. In the experience of mankind, both quantities approach zero as $T \to 0$, but $(\partial Z/\partial T)_z$ does so more rapidly than does C_z/T. Thus, the limit $T = 0$ is unattainable. Moreover, $(\partial S/\partial z)_T \to 0$ in this limit, which is an important statement that becomes part of the third law.

Based on these findings, one can now state the third law of thermodynamics which asserts that as $T \to 0$, the entropy of any system tends toward a least value when the system is in its lowest energy state and, as the thermodynamic coordinates are altered, approaches this value with zero slope. The wording implies that the system must actually have reached its equilibrium state, hence, its lowest energy, on cooling to the lowest possible temperature. Contrary to statements in some textbooks, it is not claimed that $S \to 0$ as $T \to 0$. Liquid mercury under ambient pressure, disordered solid solutions or amalgams, random elemental isotopic abundances, are common counter examples. However, if in any given process these types of ground states are left undisturbed, it is effectively permissible to set $S = 0$ at $T = 0$, much as the gravitational energy of a quiescent system at sea level is assigned an energy zero.

Thermodynamics of Anisotropic Media

Lastly, the deformation of anisotropic solids is considered. Let $\boldsymbol{s}(\boldsymbol{r})$ and $\boldsymbol{s}(\boldsymbol{r} + \mathrm{d}\boldsymbol{r})$ be the displacement vectors that move element A, originally at $\boldsymbol{r}$, to $\boldsymbol{r} + \boldsymbol{s}(\boldsymbol{r})$, and neighboring element B, originally at $\boldsymbol{r} + \mathrm{d}\boldsymbol{r}$ to new locations. For small displacements, $\boldsymbol{s}(\boldsymbol{r} + \mathrm{d}\boldsymbol{r}) \approx \boldsymbol{s}(\boldsymbol{r}) + \mathrm{d}\boldsymbol{r} \cdot \boldsymbol{\nabla}\boldsymbol{s}(\boldsymbol{r})$. Here, $\boldsymbol{\nabla}\boldsymbol{s}(\boldsymbol{r})$ is a matrix (a tensor) with columns $\partial s_x(\boldsymbol{r})/\partial x$, $\partial s_x(\boldsymbol{r})/\partial y$, and $\partial s_x(\boldsymbol{r})/\partial z$, and similarly with $s_y(\boldsymbol{r})$ and $s_z(\boldsymbol{r})$. Now, any matrix with entries M_{ij} may be rewritten as $M_{ij} = (1/2)(M_{ij} + M_{ji}) + (1/2)(M_{ij} - M_{ji})$, involving a symmetric ($\boldsymbol{e}_\mathrm{s}$) and an antisymmetric component, $\boldsymbol{e}_\mathrm{a}$. The matrix for $\boldsymbol{\nabla}\boldsymbol{s}(\boldsymbol{r}) = \boldsymbol{e}_\mathrm{s} + \boldsymbol{e}_\mathrm{a}$ is shown for $\boldsymbol{e}_\mathrm{s}$ in **Table 2**, with entries $e_{ij} = (1/2)[\partial \boldsymbol{s}_i/\partial \boldsymbol{r}_j + \partial \boldsymbol{s}_j/\partial \boldsymbol{r}_i]$. For the $\boldsymbol{e}_\mathrm{a}$ entries, the "+" sign is replaced by "−," so that the diagonal elements of $\boldsymbol{e}_\mathrm{a}$ vanish.

Consider now a dilatation of a solid in which element A at $\boldsymbol{r}$ is displaced by $\boldsymbol{s}(\boldsymbol{r})$ to A', and a neighboring element B at $\boldsymbol{r} + \mathrm{d}\boldsymbol{r}$ is displaced to B' by $\boldsymbol{s}(\boldsymbol{r} + \mathrm{d}\boldsymbol{r})$. The A'–B' separation distance is then $\mathrm{d}\boldsymbol{r}' = \mathrm{d}\boldsymbol{r} + [\boldsymbol{s}(\boldsymbol{r} + \mathrm{d}\boldsymbol{r}) - \boldsymbol{s}(\boldsymbol{r})] \approx \mathrm{d}\boldsymbol{r} + \mathrm{d}\boldsymbol{r} \cdot \boldsymbol{\nabla}\boldsymbol{s}(\boldsymbol{r}) = \mathrm{d}\boldsymbol{r} + \mathrm{d}\boldsymbol{r} \cdot (\boldsymbol{e}_\mathrm{s} + \boldsymbol{e}_\mathrm{a})$. Note that $\boldsymbol{e}_\mathrm{a}$ represents a pure rotation; on rotating the coordinate system by $-\boldsymbol{e}_\mathrm{a}$, one obtains $\mathrm{d}\boldsymbol{r}' = \mathrm{d}\boldsymbol{r} + \mathrm{d}\boldsymbol{r} \cdot \boldsymbol{e}_\mathrm{s}$ in the rotated system. Here, $\mathrm{d}\boldsymbol{r}$ is the row vector $[\mathrm{d}x, \mathrm{d}y, \mathrm{d}z]$ and the $\boldsymbol{e}_\mathrm{s}$ matrix is shown in **Table 2**.

A linear dilatation along x is then specified by $\mathrm{d}x' = (1 + e_{xx})\mathrm{d}x + e_{yx}\mathrm{d}y + e_{zx}\mathrm{d}z$, with similar expressions for $\mathrm{d}y'$ and $\mathrm{d}z'$. Thus, the diagonal element e_{xx} of **Table 2** indicates the fractional lengthening of the solid along the x-axis, and similarly, for y and z. Angular dilatations, on the other hand, involve a displacement $\mathrm{d}l$ whereby $\hat{\boldsymbol{i}}\,\mathrm{d}l$ originally perpendicular to $\hat{\boldsymbol{j}}\,\mathrm{d}l$ ($\hat{\boldsymbol{i}}$ and $\hat{\boldsymbol{j}}$ are orthogonal unit vectors along x and y) now change into $A_x \equiv \hat{\boldsymbol{i}}\,\mathrm{d}l + \hat{\boldsymbol{i}}\,\mathrm{d}l \cdot \boldsymbol{e}_\mathrm{s} = \hat{\boldsymbol{i}}(1 + e_{xx})\,\mathrm{d}l + \hat{\boldsymbol{j}}e_{xy}\,\mathrm{d}l + \hat{\boldsymbol{k}}e_{xz}\,\mathrm{d}l$, and $A_y \equiv \hat{\boldsymbol{j}}\,\mathrm{d}l + \hat{\boldsymbol{j}}\,\mathrm{d}l \cdot \boldsymbol{e}_\mathrm{s} = \hat{\boldsymbol{i}}e_{yx}\,\mathrm{d}l + \hat{\boldsymbol{j}}(1 + e_{yy})\,\mathrm{d}l + \hat{\boldsymbol{k}}e_{yz}\,\mathrm{d}l$. The angle between

Table 2 Matrix entries for deformation of anisotropic materials

A. Entries to the symmetric strain tensor

$$\boldsymbol{e} = \begin{vmatrix} e_{xx}\, e_{xy}\, e_{xz} \\ e_{yx}\, e_{yy}\, e_{yz} \\ e_{zx}\, e_{zy}\, e_{zz} \end{vmatrix} \qquad \begin{matrix} e_{xx} = (\partial s_x/\partial x) & e_{xy} = (1/2)[(\partial s_x/\partial y) + (\partial s_y/\partial x)] = e_{yx} \\ e_{yy} = (\partial s_y/\partial y) & e_{xz} = (1/2)[(\partial s_x/\partial z) + (\partial s_z/\partial x)] = e_{zx} \\ e_{zz} = (\partial s_z/\partial z) & e_{yz} = (1/2)[(\partial s_z/\partial y) + (\partial s_y/\partial z)] = e_{zy} \end{matrix}$$

B. Conventional notation for strain components

$e_1 \equiv e_{xx}$, $e_2 \equiv e_{yy}$, $e_3 \equiv e_{zz}$
$e_4 \equiv 2e_{xy} = 2e_{yx}$, $e_5 \equiv 2e_{xz} = 2e_{zx}$, $e_6 \equiv 2e_{yz} = 2e_{zy}$

C. Conventional notation for stress components

$\sigma_1 \equiv \sigma_{xx}$ pressure along x $\quad \sigma_4 \equiv \sigma_{xy} = \sigma_{yx}$ pressure $\perp x$ along y or vice versa
$\sigma_2 \equiv \sigma_{yy}$ pressure along y $\quad \sigma_5 \equiv \sigma_{xz} = \sigma_{zx}$ pressure $\perp x$ along z or vice versa
$\sigma_3 \equiv \sigma_{zz}$ pressure along z $\quad \sigma_6 \equiv \sigma_{yz} = \sigma_{zy}$ pressure $\perp y$ along z or vice versa

A_x and A_y in the x–y-plane is specified by

$$\cos\,\phi_{xy} = \frac{(\hat{\boldsymbol{i}}\,\mathrm{d}l + \hat{\boldsymbol{i}}\,\mathrm{d}l \cdot \boldsymbol{e}_s) \cdot (\hat{\boldsymbol{j}}\,\mathrm{d}l + \hat{\boldsymbol{j}}\,\mathrm{d}l \cdot \boldsymbol{e}_s)}{|\hat{\boldsymbol{i}}\,\mathrm{d}l + \hat{\boldsymbol{i}}\,\mathrm{d}l \cdot \boldsymbol{e}_s| \times |\hat{\boldsymbol{j}}\,\mathrm{d}l + \hat{\boldsymbol{j}}\,\mathrm{d}l \cdot \boldsymbol{e}_s|} \qquad [18]$$

When the appropriate entries for $\boldsymbol{e}_s$ are introduced and an expansion is carried out to first order in e_{ij}, one obtains (after a large number of elementary steps) $\cos\,\phi_{xy} \approx 2e_{xy}$. Now, introduce the deviation from the right angle by $\Omega_{xy} = \pi/2 - \phi_{xy}$, so that $\cos\,\phi_{xy} \approx \Omega_{xy} \approx 2e_{xy}$. Similarly, $\Omega_{xz} \approx 2e_{xz}$, $\Omega_{yz} \approx 2e_{yz}$.

It is conventional to introduce a more compact notation for the strain components, as shown in part B of **Table 2**; also, one sets up six components of a stress tensor $\boldsymbol{\sigma}$ that induces the strain. Here, $\sigma_i = [\partial(U/V)/\partial e_i]_{S,ej\neq i}$; these are listed in part C of **Table 2**. The element of work is then given by $V\sum_i \sigma_i\,\mathrm{d}e_i$.

With these definitions, the above concepts are embedded in thermodynamics by writing the differential of the energy (of the strained relative to the unstrained body) as

$$\mathrm{d}U = T\,\mathrm{d}S + V\sum_{i=1}^{6} \sigma_i\,\mathrm{d}e_i \qquad [19]$$

One should note the positive sign ahead of the second term: work is done by the system as the strain is diminished. Next, the enthalpy, by $H = U - \sum_{i=1}^{6} \sigma_i (Ve_i)$ is introduced. The enthalpy differential is then given by

$$\begin{aligned} \mathrm{d}H &= \mathrm{d}U - V\sum_{i=1}^{6} e_i\,\mathrm{d}\sigma_i - V\sum_{i=1}^{6} \sigma_i\,\mathrm{d}e_i \\ &= T\,\mathrm{d}S - V\sum_{i=1}^{6} e_i\,\mathrm{d}\sigma_i \end{aligned} \qquad [20]$$

From [19] and [20], Maxwell relations may be constructed in the usual manner; these are listed in **Table 3**: integration then specifies the entropy of the solid in its dependence on σ_i or on e_i under different conditions (for details, see the "Further reading" section).

Table 3 Maxwell relations for anisotropic solids; constant V

$$\frac{1}{V}\left(\frac{\partial S}{\partial e_i}\right)_T = -\left(\frac{\partial \sigma_i}{\partial T}\right)_{e_i} \qquad \frac{1}{V}\left(\frac{\partial S}{\partial \sigma_i}\right)_T = \left(\frac{\partial e_i}{\partial T}\right)_{\sigma_i} \qquad \text{[III.1, III.2]}$$

$$\frac{1}{V}\left(\frac{\partial S}{\partial \sigma_i}\right)_{e_i} = \left(\frac{\partial e_i}{\partial T}\right)_S \qquad \frac{1}{V}\left(\frac{\partial S}{\partial e_i}\right)_{\sigma_i} = -\left(\frac{\partial \sigma_i}{\partial T}\right)_S \qquad \text{[III.3, III.4]}$$

Moreover, from the definition of the stress tensor, it follows that

$$(\partial\sigma_i/\partial e_j)_{S,e_{j\neq i}} \equiv c_{ij}|_S = (\partial\sigma_j/\partial e_i)_{S,e_{j\neq i}} \equiv c_{ji}|_S \qquad [21a]$$

$$(\partial\sigma_i/\partial e_j)_{T,e_{j\neq i}} \equiv c_{ij}|_T = (\partial\sigma_j/\partial e_i)_{T,e_{j\neq i}} \equiv c_{ji}|_T \qquad [21b]$$

which are known as isentropic and isothermal elastic stiffness coefficients. The inverse $(\partial\sigma_i/\partial e_j)_{S,\sigma_{j\neq i}}$ or $(\partial\sigma_i/\partial e_j)_{T,\sigma_{j\neq i}}$ represent isentropic and isothermal compliance coefficients. There also exist six thermal strain coefficients $\alpha_i \equiv (\partial e_i/\partial T)_{\sigma j}$ and six thermal stress coefficients $\delta_i \equiv (\partial\sigma_i/\partial T)_{ej}$ that deal with the temperature variations of the respective coefficients.

This completes the brief survey of commonly used coefficients that characterize the deformation of anisotropic elastic solids.

Application of Thermodynamic Concepts

The basic concepts developed above find many applications in condensed matter physics. Several important uses are briefly listed. Prominent among these is the determination of heat capacities of materials as a function of temperature, from which the energy, enthalpy, and entropy may be found by integration of eqn [15a].

An entire subdiscipline deals with phase equilibria, phase diagrams, phase transitions, and related aspects.

All these topics are ultimately based on the properties of the chemical potential, briefly alluded to in an earlier section of the present article. Phase diagrams obtained from empirical measurements are of cardinal importance in the entire manufacturing process and industrial output of chemicals in developed countries.

Another subdiscipline deals with the properties of matter, energy, and entropy flow, as determined by irreversible thermodynamics.

Thermal properties of materials represent another area of great contemporary interest. Here, the properties of anisotropic media discussed above, represent the proper theoretical background for a rationalization of experimental results.

Results based on the third law of thermodynamics provide the basic theoretical framework for interpreting a large number of studies dealing with properties of materials at ultralow temperatures. The operation of cyclic engines, described briefly above, is another area where thermodynamics plays an important role. Lastly, by considering the various different types of work alluded to in the introduction to the first law, one can extend the above thermodynamic principles to new areas, such as electromagnetic properties, surface adsorption phenomena, curved surfaces, radiation, processes in gravitational fields, and the like. Their detailed discussion must be left to specialized monographs. They form the foundation for explaining many physical characteristics of condensed matter, such as magnetic and electrical properties, the interaction of condensed phases with electromagnetic radiation, and interfacial phenomena.

Thermoelectric and Energy Conversion Devices

J W Sharp, Marlow Industries, Inc., Dallas, TX, USA

Introduction

There are a number of ways of converting thermal to electrical energy and vice versa, and more than one of these have sometimes been referred to as "thermoelectric." Here, thermoelectric refers only to direct conversion between thermal and electrical energy by the Peltier and Seebeck effects. This article discusses the basic engineering and materials science aspects of thermoelectric devices, without proceeding to system issues such as heat exchange and feedback loops for precise temperature control. The discussion is limited to cooling and electrical power generation, setting aside aspects particular to thermoelectric sensors.

This article is composed of two main sections. The first section covers the fundamentals, analysis, and construction of thermoelectric devices. The second section focuses on thermoelectric materials, including those that are established, some that are being developed, and nanostructured formats that are the subject of research.

Thermoelectric Devices

Fundamentals

The fundamentals of a thermoelectric device are displayed in **Figure 1**. Two blocks of semiconductor, one *p*-type (*P*) and the other *n*-type (*N*), are joined by a

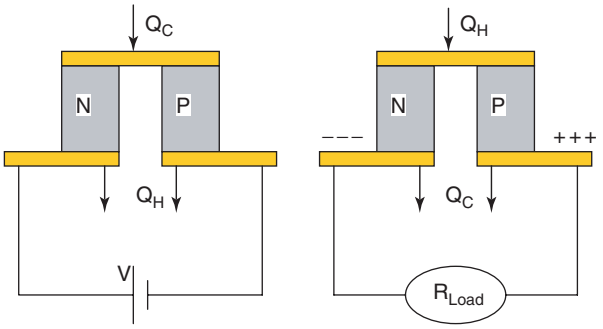

Figure 1 Schematic illustrations of thermoelectric couples in use for cooling (left) and power generation (right). In each case, Q_H and Q_C differ by the work done, either by the voltage source or on the load. For cooling, the heat sink is at the hotter temperature (T_H), while the sink is at the lower temperature (T_C) for power generation.

metal interconnect at one end and connected in series to a voltage source or load at the other end. The two blocks share a common temperature at each end, and thus are thermally in parallel across a temperature difference $\Delta T = T_H - T_C$.

Consider first the cooling mode. When a current (I) is supplied, the metal/semiconductor junctions at one end of the couple are reverse-biased and the junctions at the other end are forward-biased. These are the cooling and heating junctions respectively. At the cooling junctions, thermal energy is absorbed from the lattice to account for the mismatch in energy content of the electric current in the metal compared to the semiconductors. If the two semiconductors were joined directly, heat would be carried away from the reverse-biased junction by the creation and separation of electron–hole pairs. At the heating junctions, the energy mismatch is in the opposite sense and heat is transferred from the charge carriers to the lattice.

In the power generation mode, the applied temperature gradient is opposed by a concentration gradient of the mobile carriers. This is the Seebeck effect, and the Seebeck voltage places the hot junctions in reverse bias and the cold junctions in forward bias. By convention, P and N materials have positive and negative coefficients respectively, and the Seebeck coefficient of the couple is $S = S_P - S_N$.

The thermoelectric effect is a reversible thermodynamic process. In the absence of irreversible processes, which are ignored for the moment, the efficiency of thermoelectric energy conversion should be the Carnot limit. In a cooling device, the Peltier cooling power is ST_CI. If no ΔT is allowed to develop, then this heat is transported without energy cost and the coefficient of performance is infinite. With a temperature gradient, the voltage on the couple is $S\Delta T$, and the ratio of heat pumped to electrical power is $T_C/\Delta T$, the Carnot limit for a refrigerator. In a generation device, the thermal voltage is $S\Delta T$. If a current is flowing, the heat absorbed by the electric current at the heated junctions is ST_HI, and the efficiency is $\Delta T/T_H$, again the Carnot limit. In reality, thermoelectric device efficiencies are far from ideal because both electrical resistance and thermal conduction are significant.

Analysis

Generation Referring again to **Figure 1**, the series electrical and parallel thermal arrangement leads to $R = R_N + R_P$, and $K = K_N + K_P$ for the couple. Relative to the ideal situation, the work done on the load is reduced by the internal resistance of the couple:

$$W = IV = I(S\Delta T - IR) \qquad [1]$$

The heat absorbed to perform this work is increased by thermal conduction, but decreased by resistive heating

$$Q_H = SIT_H + K\Delta T - I^2R/2 \qquad [2]$$

The efficiency is $\eta = W/Q_H$. From eqn [1], the maximum power output occurs for $I = S\Delta T/2R$, obtained when $R_{Load} = R$, and has the value

$$W_{max} = KZ(\Delta T)^2/4 \qquad [3]$$

where $Z = S^2/RK$ is the thermoelectric figure of merit of the couple.

In general, Z for a couple is an extrinsic quantity because the geometry factors in R and K do not cancel. In the case of the P and N blocks having the same length-to-area ratio, Z is an intrinsic quantity that depends only on the Seebeck coefficient, electrical resistivity (ρ), and thermal conductivity (κ) of the P and N materials. Relative to one another, the length-to-area ratios of the P and N blocks can be optimized to give the best Z for the couple:

$$Z_{opt} = S^2/[\sqrt{\kappa_P\rho_P} + \sqrt{\kappa_N\rho_N}]^2 \qquad [4]$$

The maximum efficiency of a thermoelectric generator occurs when $R_{Load} = \gamma R$ and is

$$\eta_{max} = (\gamma - 1)\Delta T/[(\gamma + 1)T_H - \Delta T]$$
$$\gamma = \sqrt{1 + Z(T_C + T_H)/2} \qquad [5]$$

For both power generation and cooling, Z governs the maximum efficiency that is possible for a given pair of materials. This is not too surprising since Z concisely captures the requirements to maximize the

thermoelectric effect and minimize the irreversible processes involved.

ZT varies with temperature. For power generation, ΔT can be so large that the couples gain performance by the use of two or more materials in the N leg, the P leg, or both. In these segmented thermocouples, the segment materials are best chosen not just for their individual ZT values, but also for their compatibility with regard to electrical and thermal fluxes.

Commercially available generation materials have $ZT \sim 1$. For a generation device with a "cold" side near ambient and $\Delta T \sim 400^{\circ}\mathrm{C}$, the optimum efficiency is in the vicinity of 10%. The maximum power output per couple is an extrinsic quantity (eqn [3]), a design parameter that can vary greatly. For common direct generation applications (as opposed to waste heat recovery), $W_{\max}$ is ~ 1 watt per couple.

Cooling In a real thermoelectric device, Peltier cooling is offset in part by resistive heating and thermal conduction. The net rate of cooling is

$$Q_{\mathrm{C}} = ST_{\mathrm{C}}I - I^2R/2 - K\Delta T \qquad [6]$$

The work required to perform this cooling is

$$W = IV = I(IR + S\Delta T) \qquad [7]$$

and the coefficient of performance is

$$\phi = Q_{\mathrm{C}}/W \qquad [8]$$

Both Q_{C} and ϕ can be maximized by varying the current, as shown in **Figure 2**. These special current levels are

$$I_{\mathrm{Q}} = ST_{\mathrm{C}}/R \qquad [9]$$

$$I_{\phi} = S\Delta T/(\gamma - 1)R \qquad [10]$$

Use of eqn [9] in eqn [6] leads to

$$Q_{\max} = K(ZT_{\mathrm{C}}^2/2 - \Delta T) \qquad [11]$$

Similar to power generation, the maximum heat pumping capacity of a couple is an extrinsic quantity that increases with the area-to-length ratio of the thermoelectric blocks.

When $\Delta T = Z(T_{\mathrm{C}})^2/2$, no heat can be pumped. This is the largest ΔT that can be achieved with a single stage thermoelectric refrigerator. For the best available materials operating under the best conditions, the maximum ΔT is $\sim 75^{\circ}\mathrm{C}$ for heat sinking at 300 K.

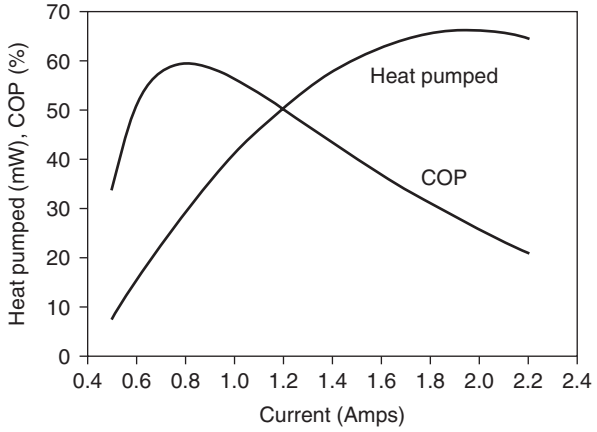

Figure 2 Dependence of heat pumped and coefficient of performance (COP) on supplied current for a typical thermoelectric cooling couple. The couple has Seebeck coefficient, electrical resistance, and thermal conductance of $420\,\mu\mathrm{V\,K^{-1}}$, $56\,\mathrm{m\Omega}$, and $10^{-3}\,\mathrm{W\,K^{-1}}$ respectively. The length-to-area ratio for each leg (P and N) is $28\,\mathrm{cm^{-1}}$. The hot and cold temperatures were taken as 300 K and 260 K.

For values of ΔT below the maximum, some heat can be pumped and the maximum coefficient of performance is given by eqns [8] and [10]:

$$\phi_{\max} = (\gamma T_{\mathrm{C}} - T_{\mathrm{H}})/(\gamma + 1)\Delta T \qquad [12]$$

The curves in **Figure 2** are plots of the current dependence of Q_{C} and ϕ with $T_{\mathrm{C}} = 260\,\mathrm{K}$, $T_{\mathrm{H}} = 300\,\mathrm{K}$, $\gamma = 1.37$, and $K = 10^{-3}\,\mathrm{W\,K^{-1}}$. This value of K is typical for a couple in a small cooling device. If such a device is operated near peak ϕ, then about 25 couples are needed to pump one watt.

Multiple stages In cooling applications, it is common to stack multiple thermoelectric devices to achieve greater temperature differences than possible with a single stage. Devices with six stages are able to reach temperatures as low as 170 K from 300 K, although with a quite low coefficient of performance.

With reference to **Figure 3**, the efficiency of a two-stage device is

$$\Phi = \frac{Q_{\mathrm{C}}}{W_1 + W_2} = \frac{Q_{\mathrm{C}}}{\dfrac{Q_{\mathrm{C}}}{\phi_1} + \dfrac{Q_{\mathrm{C}} + Q_{\mathrm{C}}/\phi_1}{\phi_2}} = \frac{1}{\dfrac{1}{\phi_1} + \dfrac{1}{\phi_2} + \dfrac{1}{\phi_1\phi_2}} \qquad [13]$$

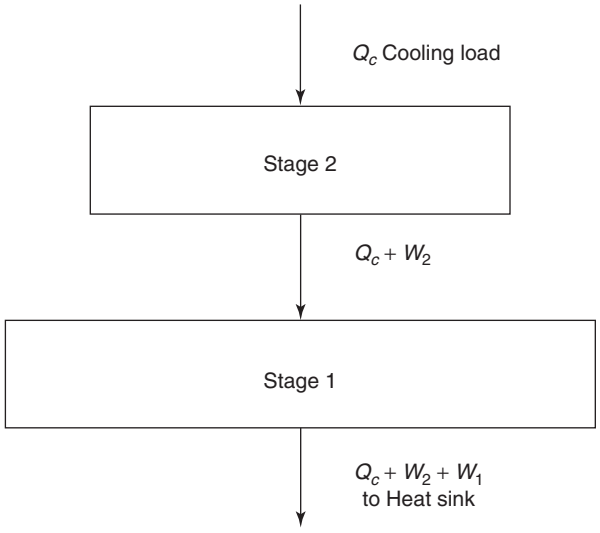

Figure 3 Schematic illustration of a two-stage thermoelectric cooling device showing how the total amount of heat increases from the cooling load to the heat sink. W_1 and W_2 are the electrical power consumed by the first and second stages respectively.

The generalization for n stages, each with the same coefficient of performance, is

$$\Phi = \frac{1}{(1+1/\phi)^n} - 1$$

Construction

Coolers **Figure 4** is a side view of a traditional thermoelectric cooler, which consists of numerous couples connected in series. Soldering the thermoelectric blocks to metal interconnects, usually copper pads that are directly bonded to ceramic plates, makes the connections. The thermoelectric materials are discussed in the next section. For now, some insight into the benefits and deficiencies of the traditional cooler design is provided.

The ceramic plates provide mechanical structure, low thermal resistance, and a flat surface for interfacing with heat transfer plates. The ceramic plate that is heat sunk also accommodates the electrical leads. The most common ceramics are Al_2O_3, AlN, and BeO. Al_2O_3 is the least expensive substrate choice, and has adequate thermal conductivity for many applications. BeO has the highest thermal conductivity of this group at $\sim 220\,W\,m^{-1}\,K^{-1}$, but is less favored due to cost and health concerns. With a thermal conductivity about half that of BeO, AlN is the most prevalent ceramic for applications with a high heat flux. AlN also has a low coefficient of thermal expansion, which is advantageous because contraction and expansion of the ceramic plates during thermal cycling eventually causes cracking within the thermoelectric material or the solder joint.

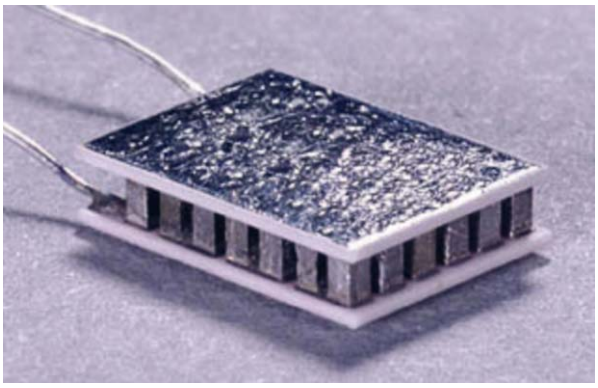

Figure 4 Side view of a commercial thermoelectric cooling module. The module dimensions are $\sim 8\,mm \times 6\,mm \times 2\,mm$ and its components and assembly are discussed in the text. Photo courtesy of Marlow Industries, Inc.

A variety of solders are used within the thermoelectric cooling industry. As a rule, these solders are the same ones used in other electronic applications and are selected for similar reasons, such as ease of manufacturing, strength, and low temperature ductility. One exception is a group of solders that are more than 90% bismuth. These solders have very good thermal cycling fatigue and can be applied directly to thermoelectric materials with acceptable results. To use other solders, it is generally necessary to protect the thermoelectric materials with a metal layer, usually nickel, to prevent interactions.

There are three main technical deficiencies of cooler design as described here. The first, susceptibility to thermally induced stress, has been mentioned already. The other two are thermal resistance of the ceramic plates, and electrical resistance of the interconnects and interfaces. Both of these problems become serious for high watt-density coolers with short elements, and reach their extreme in modules based on thin film materials.

Generators **Figure 1** emphasizes the reversibility of thermoelectric energy conversion. In principle, the same device can be used for both cooling and power generation, and in both cases only the temperatures and the material quality determine the maximum efficiency. In reality though, a cooling device is suitable for generation only if the temperature difference is relatively small and the heat source is at a modest temperature.

The construction of a device for generation under less restrictive conditions is illustrated in **Figure 5**. In this case, the thermoelectric blocks are embedded in insulation that is a component of the finished device. With regard to providing mechanical structure, this

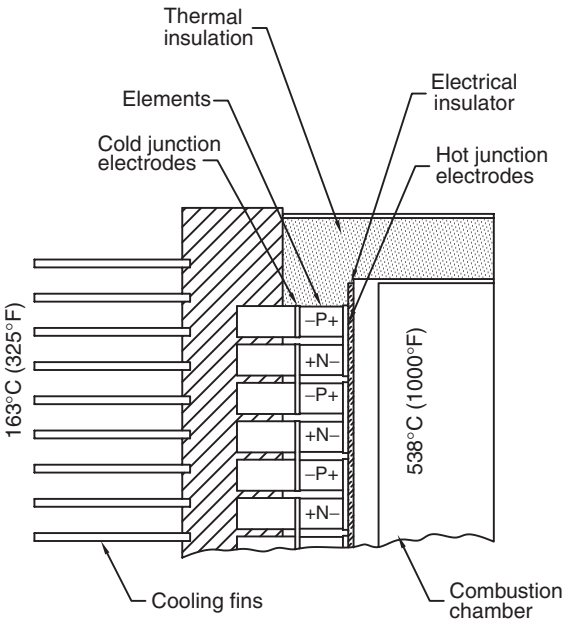

Figure 5 Illustration of the implementation of a thermoelectric generator. Each component of the assembly plays a role in thermal performance, mechanical stability, or chemical isolation. Image courtesy of Global Thermoelectric.

insulation takes the place of the ceramic plates used in cooling devices. Rigidly fixed substrates usually are not part of a generator design because thermal expansion would create destructive levels of stress within the module. A second major difference is in the method of joining the metal interconnects to the thermoelectric materials. This cannot be done with a solder. Two methods are hot pressing and thermal spraying. A third difference is that thermal interface resistances between the device and heat exchange plates are reduced with clamps or springs, rather than solder or rigid epoxies. Finally, thermoelectric generators are likely to be sealed to prevent oxidation of the thermoelectric materials.

Sound construction principles allow thermoelectric generators to survive high temperatures, and large temperature differences between the hot and cold surfaces for very long times. The attractiveness of 20 years of maintenance-free operation has led to their use in applications where maintenance is impossible (interplanetary exploration) or expensive (remote terrestrial locations), even when other technologies offer greater efficiencies.

Thermoelectric Materials

Fundamentals

It has been discussed elsewhere in this encyclopedia why good thermoelectric materials are heavily doped semiconductors with a Seebeck coefficient in the range 200–300 $\mu V K^{-1}$. Empirically, the electrical resistivity tends to lie in the range 1–3 $m\Omega cm^{-1}$ at the optimized carrier concentration. Most semiconductors do not obtain such favorable values of S and ρ simultaneously, and this is part of what makes good thermoelectric materials unique and uncommon.

Even more so, it is the lattice thermal conductivity that sets thermoelectric materials apart. The thermal conductivity values of diamond, fused silica, and common plastics are 500, 1.5, and 0.2 $W m^{-1} K^{-1}$ respectively. Good thermoelectric materials are crystals, and yet their lattice thermal conductivity is $\sim 1 W m^{-1} K^{-1}$, less than that of silica. (The charge carriers typically contribute another 0.5 $W m^{-1} K^{-1}$ to the thermal conductivity at low to moderate temperatures.) The search for new semiconductors with extreme electrical and thermal properties is a fascinating challenge that has attracted the attention of materials scientists, particularly since useful materials first were found in the 1940s and 1950s.

Almost without exception, materials with good Z values are mixtures of two or more compounds that share a crystal structure. The reason for this is the reduction of the lattice thermal conductivity by mass and elastic fluctuations. These mixtures are commonly referred to as "alloys."

Established Materials

Bi_2Te_3 and PbTe alloys dominate commercial cooling and power generation respectively. SiGe alloys and TAGS have been used in some higher temperature-generation applications. BiSb is an alloy with superior low-temperature properties, but it has found no commercial use.

Bi_2Te_3 alloys For operation between 200 and 500 K, the best P and N materials are found in mixtures of Bi_2Te_3, Sb_2Te_3, and Bi_2Se_3. These temperatures cover both cooling and generation from low-grade heat. The P material is approximately 75% Sb_2Te_3 and 25% Bi_2Te_3. A few percent of Se substitution for Te may be found to improve the properties, depending on the method of fabrication. The N material is approximately 90% Bi_2Te_3 and 10% Bi_2Se_3 for room temperature and above. Below room temperature, a formula of 90% Bi_2Te_3, 5% Bi_2Se_3, and 5% Sb_2Te_3 is preferred by some. The P material is autodoped by a slight substitution of Sb for Te, while the N material must be doped with excess Te or a halide. The melting point for all of these alloys is in the vicinity of 600°C.

The P and N materials share a crystal structure that is based on covalently bonded sheets of five atomic layers. The bonding of the atoms in the central Te/Se

layer and the adjacent Bi/Sb layers is octahedral, while the atoms of the outer Te/Se layers are bonded predominantly on one side to three Bi/Sb atoms. van der Waals bonds between outer Te/Se layers connect adjacent sheets more weakly. Not surprisingly, the layered structure results in anisotropic electrical, thermal, and mechanical properties. Electrical and thermal conductivity are higher within the plane of the covalent sheets, while the Seebeck coefficient is nearly isotropic. For *P* material, the figure of merit is essentially isotropic. For *N* material, though, the electrical anisotropy is much stronger and the figure of merit is significantly less for transport perpendicular to the covalent sheets. Single crystals or large grains of these materials exhibit mechanical cleavage that can be a hindrance to device fabrication.

Directional solidification, hot pressing, and plastic deformation can make good *P* material. Historically, directional solidification from a melt has been the most favored approach. Recently, though, researchers and production facilities have found that hot pressing and plastic deformation produce equally good, if not better, *P* material. Good *N* material can be made by directional solidification or plastic deformation. Hot pressing is not satisfactory because it does not produce adequate texture. Bi_2Te_3 and its alloys are brittle at room temperature, and so plastic deformation is performed at temperatures in excess of 400°C.

PbTe alloys PbTe and 75% PbTe + 25% SnTe are good *P* and *N* materials respectively for operation from 500 to 800 K. Direct generation of electricity from combustion heat is the most prevalent application in this temperature range. These materials have melting points ~1200 K, and are stable up to almost 800 K when used in sealed modules. The main path of degradation is sublimation of Te.

PbTe and SnTe have the cubic rock-salt crystal structure. Since the structure and properties are isotropic, hot pressing is a suitable manufacturing method. By stoichiometric variations, PbTe can be made either *P* (excess Te) or *N* (excess Pb). In neither case, though, is the doping level adequate. Higher carrier concentrations can be reached by substitution of Na or K for Pb or a halide for Te.

TAGS TAGS refers to alloys of $AgSbTe_2$ and GeTe, and is *p*-type only. (The name comes from the first letters of the chemical symbols of the constituents.) TAGS has the highest *Z* of *P* materials in the range 500–800 K and has been a mainstay of the radioisotope thermal generators (RTG) used in several space missions. $AgSbTe_2$ and GeTe do not have the same crystal structure, and this presents a problem in the utilization of TAGS. The structure of TAGS can be either rhombohedral (like the low-temperature form of GeTe) or cubic (like $AgSbTe_2$) depending on composition and temperature. Thermal cycles through the transformation temperature can lead to mechanical failure. Another problem is Ag mobility, which becomes worse at higher temperatures.

BiSb BiSb is an *N* material for low temperatures. The crystal structure is hexagonal, and the properties are anisotropic. High-quality crystals are superior to Bi_2Te_3 alloys at temperatures less than 200 K, but these crystals have cleavage planes perpendicular to the direction of current flow. BiSb made by powder metallurgy overcomes this mechanical problem, but loses *Z*. Consequently, BiSb is the best *N* material only at temperatures lower than can be reached by multistage cooling from room temperature.

Materials in Development

In this category, materials that are known to exhibit relatively good thermoelectric performance with the potential for further improvement in *ZT* or other relevant properties are placed. There are too many such materials to attempt even a cursory survey. Any recent volume of the annual International Conference on Thermoelectrics Proceedings is a good source for further reading on new thermoelectric materials. Here, two of the prominent families of new materials are highlighted.

Skutterudites Semiconducting skutterudites have the formula AB_3, where A = Co, Ir, Rh and B = P, As, Sb. The skutterudite materials of most interest for thermoelectric energy conversion are based on $CoSb_3$. Both *p*-type and *n*-type $CoSb_3$ have large values of the power factor. The lattice thermal conductivity is too high, but it can be greatly reduced by heavy doping or alloying. Another way to reduce the thermal conductivity is by introduction of rare-earth or lanthanide elements into voids in the crystal structure, and concurrent substitution of Fe or Ni for some of the Co. The La-Fe-Co-Sb and Ba-Ni-Co-Sb systems have yielded *p*-type and *n*-type formulas respectively with $ZT > 1$ at 600°C. These materials are being developed as components of segmented thermocouples for the next generation of RTGs for space missions.

Cobalt oxides In 1997, $NaCo_2O_4$ was found to be a good *p*-type thermoelectric material at high temperatures, $ZT \sim 1$ at 900–1000 K. This was a surprising discovery because oxides had not been considered good candidates. Cobalt oxides are now a major focus of thermoelectric materials development, particularly in Japan, and these explorations have uncovered a large variety of materials

based on CoO_2 layers that are charge-balanced by anions that reside between the layers. Some of these rival $NaCo_2O_4$ with regard to *ZT*. The cobalt oxides appear to be unusual materials in which a good Seebeck coefficient at nearly metallic hole concentrations might be associated with a mixed valence state of Co.

Nanoscale Materials

Present thermoelectric cooling and generation products are based on homogeneous bulk materials. The quest for higher *ZT*, though, may lead the industry toward inhomogeneous, nanostructured materials.

In this active area of research, the general rationale is to create materials with enough control of structure that S, ρ, and κ can be separately tuned. This is a difficult problem for a variety of reasons. First, the phonon mean free path is already quite low compared to the charge carrier mean free path in most good thermoelectric materials. In these cases, grain size reduction alone is unlikely to improve *ZT*. Second, very small dimensions, $\leqslant 50$ nm, are required to improve the ratio S^2/ρ by modification of the electron and hole state densities. Third, thermoelectric materials are compound semiconductors, and usually the stoichiometry and cleanliness must be controlled precisely to avoid excessive doping and carrier scattering. Also, these materials do not possess great ductility, and unsupported small-scale samples are easily damaged. Adding to these synthesis challenges, measurements, especially evaluation of thermal conductivity, are difficult because of the forms of the nanostructured materials. Nevertheless, the theoretical encouragement for pursuit of nanoscale thermoelectric materials is strong enough that a number of experimental approaches are being tested.

Superlattices Three superlattice systems serve to demonstrate the promise and peril of nanoscale thermoelectric materials. These are $PbTe/Pb_{1-x}Eu_xTe$, Bi_2Te_3/Sb_2Te_3, and $PbTe/PbTe_{1-x}Se_x$.

$PbTe/Pb_{1-x}Eu_xTe$ is a quantum-well system. The layers alloyed with Eu serve as energy barriers to the carriers in the PbTe layers. The study of this system showed, in agreement with theory, that the power factor for transport parallel to the layers could be improved in quantum wells that are sufficiently thin. Thermal conductivity was not measured, but under the safe assumption that it does not increase relative to bulk material, the *ZT* of the PbTe wells is apparently enhanced. The *ZT* of the overall superlattice is not good because the barrier layers are electrically passive but thermally active, and these layers cannot be made arbitrarily thin without losing their effectiveness as barriers.

A quite different approach is exemplified by work on Bi_2Te_3/Sb_2Te_3 superlattices. Here, there appear to be no energy barriers for *p*-type transport perpendicular to the layers. In fact, reported S^2/ρ values are larger than those of the bulk *p*-type alloy in the corresponding direction. Further, measurements by a thin-film method indicate that the cross-plane lattice thermal conductivity is significantly decreased, approaching the theoretical lower limit for a repeat thickness of ~ 4 nm. With improvements in both electrical and thermal properties, *ZT* values exceeding 2.0 are reported. Similar structures of *n*-type Bi_2Te_3/Bi_2Se_3 are not as exceptional, but estimates of the couple *ZT* exceed the bulk benchmark. To translate a high *ZT* in such structures into improved thermoelectric performance, a device design must overcome three hurdles associated with the thinness of the superlattices: contact resistance, interconnect resistance, and thermal resistance of the substrate(s).

In the case of $PbTe/PbSe_{1-x}Te_x$ ($x \approx 0.02$) superlattices, a convincing demonstration of advanced *ZT* has been made. A couple composed of a freestanding, 100-μm thick superlattice and a gold ribbon achieved a ΔT of 44°C. The inferred *ZT* value of the superlattice is 1.3–1.6. In these structures, the $PbSe_{1-x}Te_x$ layers are not continuous; they are spontaneously formed islands in a matrix of PbTe. S, ρ, and ΔT measurements indicate that both electrical and thermal properties are improved compared to bulk PbTe–PbSe alloys. The mechanisms responsible for these improvements are not known. In this case, the method of fabrication, molecular beam epitaxy, might not be viable for commercial thermoelectric applications. The laboratory results, though, have spawned interest in synthesizing similar nanostructures by scalable means.

Nanowires Under certain conditions, anodization of pure aluminum results in a layer of alumina with a dense array of cylindrical pores with their axes perpendicular to the surface and virtually parallel to one another. With pore diameters and spacings as small as 20 nm possible, anodized alumina is intriguing as a template for fabrication of nanowires of many different materials, including thermoelectric ones.

For BiSb, quantum confinement effects are expected for dimensions less than 100 nm. By filling alumina nanopores with Bi or BiSb, it is possible in principle, to test the electrical properties well into the quantum regime. Absolute measurements of the electrical resistivity are difficult, but the normalized temperature dependence can be measured more readily. Such measurements show a crossover from semimetallic to semiconducting behavior as a function of decreasing wire diameter, in support of calculations. This

transformation is advantageous because both electrons and holes contribute to conduction in bulk BiSb, which decreases the Seebeck coefficient. If the band overlap is eliminated, it might be possible to reduce the influence of the holes. Also, the lattice thermal conductivity will be reduced in the nanowire format. Whether these two benefits can overcome the expected decrease of electrical conductivity is not known.

One of the intriguing aspects of thermoelectric nanowire research is that wires with lengths greater than 50 μm have been grown by electrochemistry. If the length can be doubled, then the wires begin to reach the "bulk" regime, and it is conceivable to make couples and devices by established methods. Also, the method appears to be applicable to other materials, including Bi_2Te_3.

Inhomogeneous bulk materials The ideal thermoelectric material might be described as "kilograms of nanostructure." There is a rationale to the nanostructure approach – tailoring the material for separate control of electrical and thermal properties – that is difficult to refute. At the same time, cooling and power generation have extrinsic, peripheral, and economic aspects that require more of the material than a high *ZT*.

Nanoscale inclusions in a thermoelectric matrix, polymer/conductor composites, segmented nanowires, and thermionic/tunneling interfaces are some possible manifestations of the nanostructured bulk concept. As various factors increase motivation for alternative refrigeration and improved energy efficiency, perhaps a discovery in one of these archetypical systems will point the way to new levels of thermoelectric performance.

Thermoelectric Effect

G D Mahan, The Pennsylvania State University, University Park, PA, USA

Introduction

The early researchers in material science discovered a variety of phenomena that collectively were called thermoelectric effects. Now it is realized that the different properties are due to a common origin. There are only two basic thermoelectric phenomena: a volume effect described by a Seebeck coefficient (S), and an interface effect described by a boundary Seebeck coefficient S_B. The boundary Seebeck is due to electrons tunneling through barriers, but has not been well characterized.

The Seebeck coefficient is an important thermoelectric property. It has the units of volts per degree kelvin, and is usually expressed in $\mu V K^{-1}$. Early workers used other symbols, including Q and α. The symbol S is to honor Thomas Seebeck, who discovered the thermoelectric phenomena in 1823. S has a simple experimental definition. Take a bar or wire of length L, and put a slightly different temperature on each end: say $T_0 - \Delta T/2$ on the "cold" end, and $T_0 + \Delta T/2$ on the "hot" end. The temperature difference between the ends is ΔT. If the ends of the bar are electrically insulated, such that no current flows, it is found that a voltage difference ΔV is measured between the ends of the bar. The Seebeck coefficient is the ratio of these two experimental numbers

$$S(T_0) = \frac{\Delta V}{\Delta T}$$

All materials have a nonzero value for S. In many cases it is small: small means less than $1.0\,\mu V K^{-1}$. Generally, good conductors such as metals have a small value for Seebeck, while poor conductors such as insulators have a large value. The Seebeck coefficient depends upon temperature, and vanishes at the absolute zero $T = 0\,K$. The Seebeck is the entropy of the charge carriers divided by the electrical charge.

Two other historic thermoelectric coefficients are related to the Seebeck coefficient. The Peltier effect is the heating or cooling of a junction, between two different metals A and B, as a current flows through an interface between them

$$\frac{dQ}{dt} = J[\Pi_A - \Pi_B]$$

where J is the current density (amperes per area). Now it is known that $\Pi_j = TS_j$ and the Peltier effect is a manifestation of the volume effect. The Thomson effect, due to Lord Kelvin, is the bulk heating of a thermoelectric due to the temperature variations in the Seebeck

$$\frac{dQ}{dt} = \rho J^2 - \tau J \nabla T, \quad \tau = T\frac{dS}{dT}$$

where ρ is the electrical resistivity. Many solids have $S \sim T$, so the Thomson coefficient τ is as large as the Seebeck coefficient.

There are two different reasons to measure the Seebeck coefficient. The first is science. A measurement of $S(T)$ provides important information about the properties of a material. They are discussed later, but one example is the sign of the Seebeck which is determined by the sign of the charge carrier: $S < 0$ for electrons, and $S > 0$ for holes in a semiconductor.

The second reason to measure the Seebeck is to identify materials that could be used in thermoelectric refrigerators or energy conversion devices. There it is shown that the efficiency of such devices is determined by a parameter denoted as Z, which is called "the figure of merit"

$$Z = \frac{\sigma S^2}{K}$$

where σ is the electrical conductivity and K is the thermal conductivity. Each of these important transport coefficients is discussed in separate chapters in this section of the encyclopedia. The Seebeck coefficient plays a major role in the figure of merit, since it enters as the square. The efficiency of thermoelectric devices is an increasing function of Z. The material with the largest Z has the largest device efficiency. There is a continual worldwide quest to find new materials with larger values of Z. Since $Z(T)$ depends upon temperature, this search involves many different materials. Materials with the largest values of Z are narrow gap semiconductors. They typically have values of the Seebeck in the range of $S \sim 250$–$300\,\mu V K^{-1}$. Materials for thermoelectric devices should have large Seebeck coefficients, large values of electrical conductivity, and small values of thermal conductivity.

Transport Theory

This section explains the microscopic origins of the Seebeck coefficient. The most important inputs are the electronic energy bands of the crystal. Two transport coefficients σ and S can be calculated from first principles if one knows enough about the electronic energy bands. The electrical conductivity σ is needed for the calculation of the Seebeck coefficient.

Each energy band $E_j(\boldsymbol{k})$ has a band label j and a wave vector $\boldsymbol{k} = (k_x, k_y, k_z)$. If the energy bands are well separated in energy, each band j contributes to the two transport coefficients σ_j and S_j.

Let $f_j(\boldsymbol{k})$ denote the number of electrons or holes of wave vector $\boldsymbol{k}$ in a band j at temperature T. This distribution consists of an equilibrium term $f_j^{(0)}$ plus a nonequilibrium term δf_j. The equilibrium term is given by the Fermi–Dirac function

$$f_j^{(0)} = \frac{N_j}{e^{\beta[E_j(\boldsymbol{k})-\mu]} + 1}$$

$$E_j(\boldsymbol{k}) = E_{j0} + \varepsilon_j(\boldsymbol{k}), \quad \varepsilon_j(\boldsymbol{k}) = \sum_{\alpha=1}^{3} \frac{\hbar^2 k_\alpha^2}{2m_{j\alpha}}$$

where $\beta = 1/k_B T$, and k_B is Boltzmann's constant.

At low and moderate temperatures, the electrons are in thermal equilibrium near the states of lowest energy: conduction bands in n-type material, and valence bands in p-type material. E_{j0} is the energy of

the band minimum. The kinetic energy in the band is $\varepsilon_j(\boldsymbol{k})$, which has been defined for a band with different effective masses in different directions. The symbol μ denotes the chemical potential.

The numerator contains the degeneracy N_j of the band. $N_j = 2$ for a single band with only spin degeneracy. Many semiconductors have several equivalent conduction or valence bands. For example, silicon has six equivalent conduction bands, and $N_j = 12$ including spin degeneracy.

The equilibrium distribution $f_j^{(0)}$ does not cause currents. Currents are caused by the nonequilibrium term δf_j which is generated by a temperature difference, or an applied electric field. For the present discussion, it is assumed that currents are caused by an electric field $\mathscr{E}_m$ in the direction r_m. The total distribution function is

$$f_j = f_j^{(0)} + \delta f_{jm}\mathscr{E}_m$$

The particle density n_j, and two transport coefficients, are defined as

$$n_j = \int \frac{\mathrm{d}^3k}{(2\pi)^3} f_j^{(0)}(\boldsymbol{k})$$

$$\sigma_j = q_j \int \frac{\mathrm{d}^3k}{(2\pi)^3} v_{jm}\delta f_{jm}(\boldsymbol{k}, T)$$

$$T\sigma_j S_j = \int \frac{\mathrm{d}^3k}{(2\pi)^3} v_{jm}\delta f_{jm}(\boldsymbol{k}, T)[E_j(\boldsymbol{k}) - \mu]$$

where the charge is $q_j = \pm q$, and the electron has $-q$. The velocity is $v_{jm}(\boldsymbol{k}) = \nabla_k E_j(\boldsymbol{k})$.

The above formulas have the interesting feature that the Seebeck coefficient is the ratio of two integrals. The product of $\sigma_i S_i$ is one integral, and one gets S_i on dividing it by σ_i which is another integral. The two integrals differ mainly in the factor of $[E_j(\boldsymbol{k}) - \mu]$. The electrical conductivity is a measure of how much current is being carried by the electrons, while the Seebeck coefficient is a measure of how much energy is being carried by the electrons. The energy factor of $[E_j(\boldsymbol{k}) - \mu]$ is the particle energy minus the chemical potential. Rather than energy, the term "heat" is used. Electrons with $[E_j(\boldsymbol{k}) - \mu] > 0$ are called "hot," while those with $[E_j(\boldsymbol{k}) - \mu] < 0$ are called "cold." The Seebeck is nonzero when there are different densities of hot and cold electrons participating in the transport.

A formula for $\delta f_{jm}(\boldsymbol{k}, T)$ is derived by solving the Boltzmann transport equation. The simple case is when the conducting particles, electrons, or holes, have a relaxation time $\tau_j(\boldsymbol{k})$ that describes the momentum transfer to impurities and phonons

$$\delta f_{jm}(\boldsymbol{k}) = q_j v_{jm}\tau_j(\boldsymbol{k})\left(-\frac{\mathrm{d}f_j^{(0)}(\boldsymbol{k})}{\mathrm{d}E_j(\boldsymbol{k})}\right)$$

From the previous definitions of σ_j and S_j, this choice of distribution function gives simple expressions for these transport coefficients:

$$\sigma_j = q_j^2 \int \frac{\mathrm{d}^3k}{(2\pi)^3} v_{jm}^2\tau_j(\boldsymbol{k})\left(-\frac{\mathrm{d}f_j^{(0)}(\boldsymbol{k})}{\mathrm{d}E_j(\boldsymbol{k})}\right)$$

$$T\sigma_j S_j = q_j \int \frac{\mathrm{d}^3k}{(2\pi)^3} v_{jm}^2\tau_j(\boldsymbol{k})[E_j(\boldsymbol{k}) - \mu] \times \left(-\frac{\mathrm{d}f_j^{(0)}(\boldsymbol{k})}{\mathrm{d}E_j(\boldsymbol{k})}\right)$$

Both the electrical conductivity (σ_{kl}) and the Seebeck coefficient (S_{kl}) are tensor quantities. The above formulas give the *mm* components of these tensors. Other components (*mn*) have the velocity factors $v_{jm}v_{jn}$ in the integrand, instead of v_{jm}^2.

The above formulas are easily evaluated with a knowledge of the energy band dispersion $E_j(\boldsymbol{k})$. The only factor that does not depend upon $E_j(\boldsymbol{k})$, in a simple way, is the quasiparticle lifetime $\tau_j(\boldsymbol{k})$. For the electrical conductivity, a detailed calculation of the lifetime is required in order to obtain an accurate expression. Sometimes this work is also required for the Seebeck coefficient. However, the Seebeck has the advantage that it is the ratio of two integrals. If the lifetime is a constant, independent of $\boldsymbol{k}$, then it can be removed from the two integrals. It cancels from the ratio. If this approximation is valid, the Seebeck is given by

$$S(T) = \frac{k_\mathrm{B}}{q_j}\frac{L_1}{L_0}$$

$$L_j = \int \frac{\mathrm{d}^3k}{(2\pi)^3} v_{jm}^2\left(\frac{E_j(\boldsymbol{k}) - \mu}{k_\mathrm{B}T}\right)^j\left(-\frac{\mathrm{d}f_j^{(0)}(\boldsymbol{k})}{\mathrm{d}E_j(\boldsymbol{k})}\right)$$

The size of the Seebeck coefficient is determined by the ratio of the two fundamental constants $k_\mathrm{B}/|q| = 86.1734\,\mu\mathrm{V\,K}^{-1}$. The ratio L_1/L_0 is dimensionless.

An energy band calculation gives both energies $E_j(\boldsymbol{k})$ and velocities $v_{jk}(\boldsymbol{k})$. The integrals for L_j can be calculated accurately as a function of temperature. The easiest way is to first calculate the function

$D_{j,m}(E)$ defined as

$$D_{j,m}(E) = \int \frac{\mathrm{d}^3 k}{(2\pi)^3} v_{jm}^2 \delta[E_j(\boldsymbol{k}) - E]$$

$$L_{j,m} = \int \mathrm{d}E D_{j,m}(E) \left(\frac{E-\mu}{k_\mathrm{B}T}\right)^j \left(-\frac{\mathrm{d}f_j^{(0)}(E)}{\mathrm{d}E}\right)$$

Evaluating the above expression is now a routine process for computer programs that compute the energy bands of solids. It is not an exact expression for the Seebeck, because of the assumption that the lifetime cancels out from the ratio of the two integrals. However, it gives expressions that are accurate to about 10% for many solids, over a wide range of temperature. Note that $D_{j,m}(E)$ is independent of temperature, and only needs to be computed once.

The above expression will be evaluated for several different types of energy band structures: metals, insulators, and semiconductors.

Metals

Metals have a high density of electrons in their conduction band. The chemical potential μ is typically several electron volts, or more, above the bottom of the conduction band. The function $D(E)$ (its subscripts are dropped) is a smooth function of energy in the neighborhood of μ.

It is expanded in a power series around this point

$$D(E) = D(\mu) + (E-\mu)\left(\frac{\mathrm{d}D}{\mathrm{d}E}\right)_\mu + O(E-\mu)^2$$

$$L_0 = D(\mu)\left[1 + O\left(\frac{k_\mathrm{B}T}{\mu}\right)^2\right]$$

$$L_1 = \frac{\pi^2}{3} k_\mathrm{B}T \left(\frac{\mathrm{d}D(\mu)}{\mathrm{d}\mu}\right)$$

In evaluating these integrals, note that the function

$$\left(-\frac{\mathrm{d}f_j^{(0)}(E)}{\mathrm{d}E}\right) = \frac{\beta}{(\mathrm{e}^x + 1)(\mathrm{e}^{-x} + 1)},$$

$$x \equiv \frac{E-\mu}{k_\mathrm{B}T}$$

is perfectly symmetric in $E-\mu$. Let the new variable of integration be x, and the above integrals become

$$L_j = \int \mathrm{d}x D(\mu + x k_\mathrm{B}T) \frac{x^j}{2[1+\cosh(x)]}$$

The integral vanishes if there are odd powers of x in the integrand. If $j=0$, then the leading term in L_0 must be proportional to $D(\mu)$. If $j=1$, then expand $D(E)$ and take the first derivative to get even powers of x.

The Seebeck coefficient is the ratio of the above two integrals

$$S = \frac{\pi^2}{3} \frac{k_\mathrm{B}^2 T}{e} \frac{\mathrm{d}}{\mathrm{d}\mu} \ln[D(\mu)]$$

This famous formula is called the "Mott relation." It states that the leading term in $S(T)$ is linear in temperature, and the coefficient is determined by the derivative of $D(\mu)$. The formula is usually accurate, since most metals have a Seebeck coefficient that is linear in temperature, particularly at room temperature and higher. If $D(\mu) = D_0 \mu^r$ then

$$\frac{\mathrm{d}}{\mathrm{d}\mu} \ln[D(\mu)] = \frac{r}{\mu}, \quad S \sim r \frac{\pi^2}{3} \frac{k_\mathrm{B}}{q} \frac{k_\mathrm{B}T}{\mu}$$

The last ratio of $k_\mathrm{B}T/\mu \ll 1$ in metals, which makes the Seebeck have a small value.

Figure 1 shows the Seebeck coefficient, in units of $\mu\mathrm{V\,K^{-1}}$, for copper, silver, and gold. For copper, $S(T)$ is linear over a large range of temperature. For silver and gold, there is some deviation from linearity at high temperature. At room temperature, the values are smaller than $2\,\mu\mathrm{V\,K^{-1}}$. It is to be noted that the values are positive. In these metals, the current and heat are carried by electrons, so one might think the Seebeck would be given by the charge on the electron, which is negative. It is positive in these metals since the Fermi surface has regions of negative curvature. No data is shown below 100 K. Each curve has a peak at low temperatures due to phonon drag.

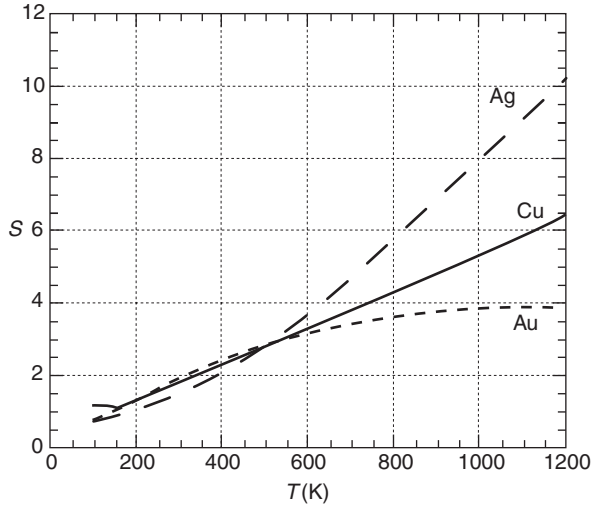

Figure 1 Seebeck coefficient of copper, silver, and gold. Units are microvolts per degree kelvin.

Insulators

Insulators tend to have large values of the Seebeck coefficient, and very small values of the electrical conductivity. There is an energy gap E_g between the occupied energy bands, called valence bands, and the unoccupied bands that are called conduction bands. The probability of exciting an electron from an occupied valence band, to an empty conduction band, is proportional to $\sim\exp(-\beta E_g)$, $\beta = 1/k_B T$. Typically $\beta E_g \gg 1$ and the density of carriers in the conduction band is small. This situation leads to a large Seebeck coefficient.

The chemical potential is located in the energy gap $E_{v0} < \mu < E_{c0}$, where E_{c0} and E_{v0} are the edges of the conduction and valence bands. For the conduction bands, since $\mu < E_{c0}$, the occupation number can be accurately approximated by the Maxwell–Boltzmann limit

$$f_c^{(0)}(\boldsymbol{k}) = N_c \exp\{\beta[\mu - E_c(\boldsymbol{k})]\}$$
$$\left(-\frac{\mathrm{d}f_c^{(0)}(E)}{\mathrm{d}E}\right) = \beta N_c \exp\{\beta[\mu - E_c(\boldsymbol{k})]\}$$

This approximation enables the integrals to be evaluated for the Seebeck coefficient: for example, for the conduction band

$$n_e = N_c e^{\beta(\mu - E_{c0})} \int \frac{\mathrm{d}^3 k}{(2\pi)^3} \, \mathrm{e}^{-\beta\varepsilon_c(\boldsymbol{k})}$$
$$= \frac{N_c}{\lambda_c^3} \, \mathrm{e}^{\beta[\mu - E_{c0}]}$$
$$\lambda_c^3 = \left[\frac{2\pi\hbar^2}{k_B T}\right]^{3/2} \frac{1}{\sqrt{m_x m_y m_z}}$$
$$L_{0c} = N_c e^{\beta[\mu - E_{c0}]} \int \frac{\mathrm{d}^3 k}{(2\pi)^3} \, v_{cl}^2 \mathrm{e}^{-\beta\varepsilon_c(\boldsymbol{k})} = \frac{k_B T}{m_l} \, n_e$$
$$L_{1c} = \left[\beta(E_{c0} - \mu) + \tfrac{5}{2}\right] L_{0c}$$

Identical expressions can be found for the valence band.

Several interesting results are apparent from these expressions:

- The ratio L_1/L_0 has a simple form

$$\frac{L_{1c}}{L_{0c}} = \frac{E_{c0} - \mu + (5/2)k_B T}{k_B T}$$

  Since $k_B T$ is a small energy, the right-hand side of this expression can be a large number such as 10 or 100. In this case, the Seebeck coefficient becomes very large.

- From the expression for the electron density, one can derive

$$\beta[\mu - E_{c0}] = -\ln(n_e) + f(T),$$
$$f(T) = \ln(N_c/\lambda_c^3)$$

  The Seebeck coefficient $S \sim (k_B/q) L_1/L_0 \sim -(k_B/e)\ln(n_e)$ is proportional to the logarithm of the density of electrons. This behavior is found experimentally.

- Similar behavior is found in *p*-type material, with the subscript c replaced by v for the valence band.

The thermal excitations of electrons, across the bandgap of the insulator, makes electron carriers in the conduction band, and hole carriers in the valence bands. Holes are the conducting states of the valence band: they have a positive mass and a positive charge. The Seebeck has to be calculated using formulas that include two conducting channels: electrons and holes

$$\sigma_T = \sigma_c + \sigma_v$$
$$S_T = \frac{\sigma_c S_c + \sigma_v S_v}{\sigma_c + \sigma_v}$$

Using the above formulas for σ_j and S_j gives the effective Seebeck coefficient

$$S_T = \frac{k_B}{q^2}\left[\frac{q_e L_{1c} + q_h L_{1v}}{L_{0c} + L_{0v}}\right]$$
$$= -\frac{k_B}{|q|}\left[\frac{L_{1c} - L_{1v}}{L_{0c} + L_{0v}}\right]$$

where $q_e = -q = -q_h$. It is useful to define the average value of L_{0j} and the difference

$$\bar{L}_0 = \tfrac{1}{2}(L_{0c} + L_{0v}), \qquad \delta L_0 = L_{c0} - L_{v0}$$
$$L_{c0} = \bar{L}_0 + \tfrac{1}{2}\,\delta L_0, \qquad L_{v0} = \bar{L}_0 - \tfrac{1}{2}\,\delta L_0$$

The effective Seebeck is now

$$S_T = -\frac{k_B}{2|q|}\left[\frac{E_g}{k_B T} + \frac{\delta L_0}{2\bar{L}_0}\frac{E_{c0} + E_{v0} - 2\mu}{k_B T}\right]$$

The first term on the right contains the energy gap $E_g = E_{c0} - E_{v0}$ divided by $k_B T$. This term is very large for most insulators. It is called the "bipolar term." It is responsible for the large value of the Seebeck coefficient in insulators.

The second term is much smaller. Usually $\delta L_0 < 2\bar{L}_0$. Divide the formula for the electron density, by the similar expression for the hole density,

and then take the logarithm

$$n_e = \frac{N_c}{\lambda_c^3} e^{\beta[\mu - E_{c0}]}, \quad n_h = \frac{N_v}{\lambda_v^3} e^{-\beta[\mu - E_{v0}]}$$

$$\frac{2\mu - E_{c0} - E_{v0}}{k_B T} = \ln\left[\frac{n_e N_v \lambda_c^3}{n_h N_c \lambda_v^3}\right]$$

Since $\beta[2\mu - E_{c0} - E_{v0}]$ is the logarithm of something, it never gets too large. It vanishes if μ is exactly in the middle of the bandgap.

The bipolar term has the following interpretation. A thermal fluctuation at one end of the material provides enough energy to excite an electron across the energy gap, and make an electron–hole pair. The pair diffuses to the other end of the material, where they recombine. The process carries the amount of heat E_g from one end of the material to the other.

The Seebeck coefficient of an insulator is a relatively large number. It is usually expressed in millivolts per degree, rather than microvolts per degree. If a material with a large Seebeck coefficient is required, there is a salt shaker on your kitchen table.

Semiconductors

Semiconductors are defined here as crystals with a small energy gap between the lowest conduction band and the highest occupied valence band. Actual semiconductors can have energy gaps from zero up to several electronvolts. The best thermoelectric materials have gaps less than 0.30 eV. Intrinsic semiconductors are those with negligible concentration of defects and impurities. They act as insulators, and typically have a high value for the Seebeck coefficient. **Figure 2** shows $S(T)$ for high-purity p-type germanium as measured by T H Geballe and G W Hull. The scale is milli-volts per degree, which is a thousand times larger than the values in **Figure 1**. The peak at very low temperature is due to phonon-drag. They do not measure below 20 K.

Thermoelectric devices must be good conductors. High values of σ are achieved in semiconductors by adding impurites that act as donors of electrons, or acceptors that make holes. Typically, the concentration of such defects is $n \sim 10^{19}\,\mathrm{cm}^{-3}$. At this concentration, at room temperature, the chemical potential $\mu(T)$ is rather close in energy to the band edge. In n-type material, it is close to the conduction band edge, and varies with temperature.

In the case of metals and insulators discussed above, accurate analytical approximations are derived in two limits. (1) For metals, $\mu \gg k_B T$, and $D(E)$ could be accurately expanded in a power series around $E \approx \mu$. (2) Insulators are in the Maxwell–Boltzmann limit, where the chemical potential is well below the conduction band edge. Neither of these two limits applies to the present problem. In this case, numerical results are obtained on the computer.

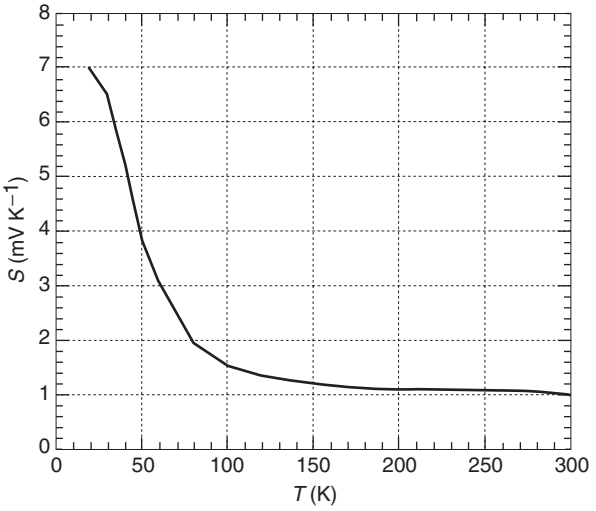

Figure 2 Seebeck coefficient for high-purity p-type germanium as measured by Geballe and Hull. Note the values are in millivolts per degree.

Consider the case in n-type semiconductors that the chemical potential is slightly higher in energy than the conduction band edge E_{c0}. Near the band edge, the kinetic energy is approximately quadratic. Choose $v_{jm} = v_{cz}$

$$E_c(\boldsymbol{k}) = E_{c0} + \frac{\hbar^2}{2}\left(\frac{k_x^2}{m_x} + \frac{k_y^2}{m_y} + \frac{k_z^2}{m_z}\right)$$

$$D_z(E) = \int \frac{d^3k}{(2\pi)^3} v_{cz}^2 \delta[E_c(\boldsymbol{k}) - E]$$

$$= D_0(E - E_{c0})^{3/2}, \quad D_0 = \frac{\sqrt{2m_x m_y m_z}}{3m_z \pi^2 \hbar^3}$$

The density of states for parabolic bands goes as $\sqrt{E - E_{c0}}$. $D(E)$ has a power of 3/2 due to the extra factor of v_{cz}^2 in the integrand. This form for $D(E)$ can be used to calculate the two integrals L_j that are needed for the Seebeck coefficient:

$$x = \frac{E - \mu}{k_B T}, \quad x_0 = \frac{\mu - E_{c0}}{k_B T}$$

$$L_j = \frac{D_0}{2}(k_B T)^{3/2} \int_{-x_0}^{\infty} dx \, \frac{x^j (x + x_0)^{3/2}}{1 + \cosh(x)}$$

Figure 3 shows a graph of L_1/L_0 as a function of x_0 determined by evaluating the integrals on the computer. At $x_0 = 0$, it has the value of 2.833. The

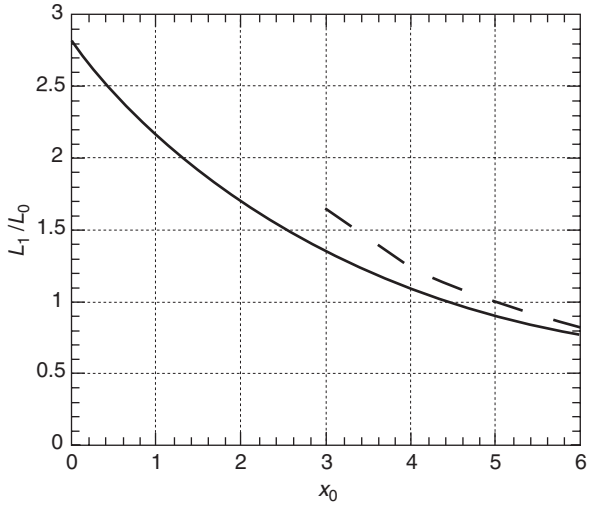

Figure 3 Solid line is the ratio L_1/L_0 when the chemical potential μ is near a band edge E_{c0}. The horizontal axis is $x_0 = (\mu - E_{c0})/k_B T$. Dashed line is the asymptotic expansion at large x_0.

Seebeck is obtained by the ratio of two fundamental constants $k_B/q = 86.2\,\mu V\,K^{-1}$. This gives $S = 244\,\mu V\,K^{-1}$. This high value is typical for the best thermoelectric materials. Their high value is achieved by having the chemical potential near the band edge at a temperature useful for device applications.

At large values of the dimensionless parameter x_0, the above integrals can be evaluated analytically by approximating $(x + x_0)^{3/2} \approx x_0^{3/2} + (3/2)x\sqrt{x_0}$ which gives the ratio

$$\lim_{x_0 \gg 1} \frac{L_1}{L_0} = \frac{\pi^2}{2x_0}[1 + O(1/x_0)]$$

$$\lim_{x_0 \gg 1} S = \frac{\pi^2}{2} \frac{k_B^2 T}{q(\mu - E_{c0})}$$

In this case, the formula derived for metals is found, with $r = 3/2$. This asymptotic expansion is graphed in **Figure 3** as the dashed line.

The largest Seebeck coefficient for a semiconductor is found when it is an insulator. It is very pure, and has a low concentration of defects. Then, the chemical potential is in the gap between the conduction and valence bands. In this case, it has a very small value for the electrical conductivity, and the pure material is not useful for devices. Impurities are intentionally added to the semiconductor to donate electrons to the conduction band, or holes to the valence band. The electrical conductivity increases, and the Seebeck decreases. The best value of the "Power factor" σS^2 is when the chemical potential is near in energy to the minimum of the energy band. The power factor is the numerator in the figure of merit Z mentioned in the "Introduction."

Phonon Drag

If a material is very pure, and free from defects, it is called "intrinsic." The thermopower of an intrinsic material always shows phonon drag at low temperatures. This phenomena happens in all dimensions. A complete theory was derived by Bailyn. It is complicated and will not be reproduced here. Instead, a physical description of the origins of this important contribution is given.

When solving the Boltzmann equation for the lifetime of an electron, the important contributions are the scattering by: defects, phonons, and boundaries. When solving the Boltzmann equation for the lifetime of the phonons, the important contributions to the scattering are from: defects, phonons, electrons, and boundaries. In an intrinsic material, scattering by defects is omitted. In large systems, edge effects and scattering by boundaries are ignored.

Phonon scattering by phonons is caused by anharmonic effects. One phonon divides into two, or two combine into one. The rate of this process increases with temperature, since the number of phonons in the system increases. At high temperature, where anharmonic effects are important, the energy dissipation path of a material in an electric field is:

- The electrons are accelerated by the electric field.
- As they accelerate, they emit phonons, thereby transferring the energy gain from the electric field into phonon energy.
- The phonons dissipate their energy through anharmonic interactions, so the energy from the electric field becomes part of the thermal bath.

At low temperatures, the anharmonic phenomena is ineffective. There are relatively few other phonons thermally excited, and three-phonon processes become rare. Then the energy dissipation path is:

- The electrons are accelerated by the electric field.
- As they accelerate, they emit phonons, thereby transferring the energy gain from the electric field into phonon energy.
- The phonons can only dissipate their energy by giving it back to the electrons.

There is a bottleneck in the dissipation of energy. The electrons and phonons form a closed system that exchange energy back and forth. As the electrons drift along in the electric field, the phonons drift along with them. The amount of energy carried by the combined system is quite large. The Seebeck is a measure of the energy content of the current, and attains high values.

Phonon drag does not affect the electrical resistivity. σ is only affected by the rate that the electrons and phonons scatter from each other. That rate is not affected by phonon drag and there is no peak in the conductivity or resistivity. The thermopower is the only measurement that shows the peak from phonon drag.

The theory of phonon drag includes electrons and phonons. The Boltzmann equations for electrons and phonons become coupled. The coupled equations are usually solved by a variational technique.

In a crystal with defects or impurities, both electrons and phonons can dissipate momentum by scattering from defects at all temperatures. The phonon drag peak is absent in impure materials.

Thin Films, Mechanical Behavior of

S P Baker, Cornell University, Ithaca, NY, USA

Introduction

Materials in the form of thin films (layers having thicknesses of a few micrometers or less) are the basic building blocks of microfabricated or nanofabricated devices such as integrated microelectronic circuits. They are used as electrical conductors and insulators, magnetic layers, optical reflectors and absorbers, chemical passivations and catalysts, and as structural elements. Although often intended for nonmechanical functions, the mechanical properties of thin films are very important. Thin films are typically found attached to much more massive substrates, and the constraint of the substrate can lead to very high stresses in the film. These stresses may, in turn, lead to failure by a variety of mechanisms, including excessive elastic or plastic deformation, void formation, fracture, or delamination. Understanding the stress states in, and the mechanical response of, thin films is thus a prerequisite to optimizing reliability in microfabricated and nanofabricated devices.

Achieving this goal is complicated by the fact that the mechanical behavior of thin films often does not follow the scaling laws developed for bulk materials. Thus, the mechanical properties of thin films must be measured directly. In this article, the sources of stress in thin films, common mechanical property measurements, and some factors that determine non-bulk-like mechanical response in thin films are briefly reviewed.

Thin Film Stresses

While thin films may experience stresses due to externally applied loads, the largest source of stress in a film typically arises from an interaction between the film and substrate. The origins of these stresses can be understood by the simple thought experiment shown in **Figure 1**. In **Figure 1a**, a stress-free film is shown attached to a substrate. Because the film is stress free, one can imagine that it is removed from its substrate without changing dimensions as shown in **Figure 1b**. One can then imagine that some process occurs that changes the in-plane dimensions of the film relative to the substrate. For example, suppose the film shrinks relative to the substrate as shown in **Figure 1c**. Since there is no interaction between the film and the substrate, each attains its equilibrium dimension and remains stress free. The film can then be returned to the substrate by imposing a biaxial stress on the detached film in order to elastically deform it, until it again has the same dimension as the substrate, as shown in **Figure 1d**, and reattaching the film to the substrate, as shown in **Figure 1e**. To complete the thought experiment, the externally applied forces are removed. The final configuration is shown in **Figure 1f**. The film continues to support biaxial stresses, and the substrate distorts elastically due to the forces transmitted across the film/substrate interface.

Any process that changes the equilibrium dimensions of the film and the substrate, relative to each other after the film has been deposited on the substrate, will lead to substrate interaction stresses. These dimensional changes can arise from four different sources: (1) Thermal strains arise due to differential thermal expansion. If the elastic strain in the film is zero at some temperature, T_0, then the elastic strain required in the film to accommodate the thermal strains at any other temperature, T, is

$$\varepsilon_{\text{th}} = \int_{T_0}^{T} (\alpha_{\text{s}}(T) - \alpha_{\text{f}}(T))\, \mathrm{d}T \qquad [1]$$

where $\alpha_{\text{f}}(T)$ and $\alpha_{\text{s}}(T)$ are the (temperature dependent) thermal expansion coefficients of the film and substrate, respectively. (2) Structure evolution strains arise from structural changes that change the density of the film. Grain growth, densification, ion implantation, chemical reactions, and phase changes are common sources. The accommodation strain in such cases is given by

$$\varepsilon_{\text{evol}} = \frac{-e_{\text{T}}}{3} \qquad [2]$$

where e_{T} is the dilatational strain associated with the structure evolution. (3) Epitaxial strains arise when the film is deposited in such a way that there is some crystallographic registry between the film and substrate. If the pertinent in-plane lattice parameters, a_{s} and a_{f}, of the film and substrate, respectively, are not the same, then the elastic strain required in the film is

$$\varepsilon_{\text{epi}} = \frac{a_{\text{s}} - a_{\text{f}}}{a_{\text{f}}} \qquad [3]$$

(4) Surface (interface) stresses arise from the change in bonding at free surfaces and interfaces compared

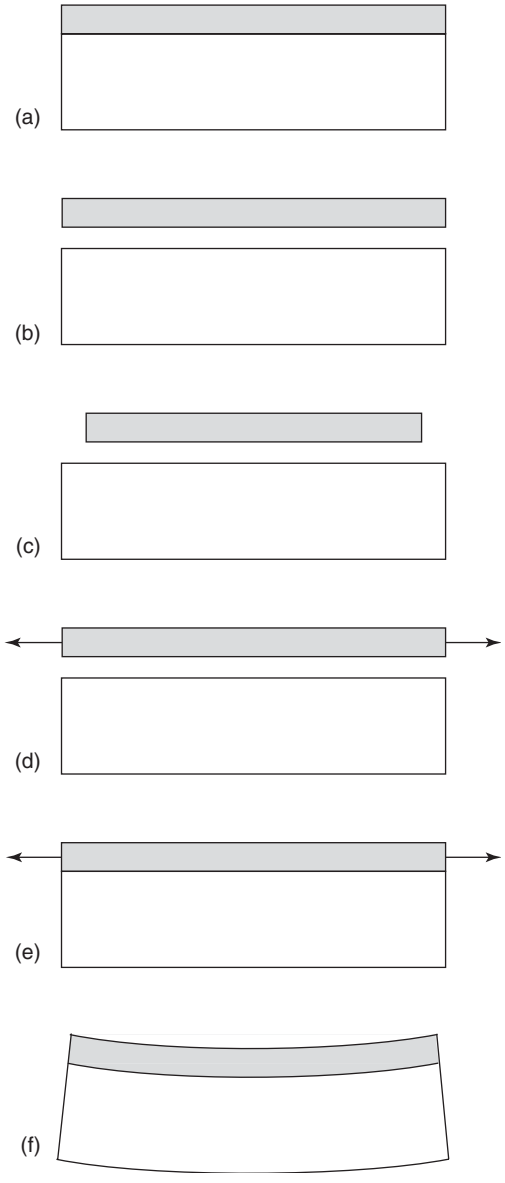

Figure 1 Thought experiment showing how an interaction between a film and substrate leads to high stresses in the film (description in text). Any process that changes the equilibrium in-plane dimension of the film relative to the substrate after the film is attached to the substrate leads to high stresses in the film.

to that in the bulk. While the forces arising from a single interface are small, surface stresses can be significant in multilayer films where the interface density is high. For a multilayer consisting of alternating layers of materials A and B having thicknesses t_A and t_B, respectively, the total stress exerted on the substrate is

$$\sigma_{int} = \frac{2(f_{A/B} + f_{B/A})}{t_A + t_B} \quad [4]$$

where $f_{A/B}$ is the interface force per unit width of A at an A/B interface, and $f_{B/A}$ is the interface force per unit width of B at a B/A interface.

Substrate interaction stresses, particularly those arising from structure evolution strains, are often referred to as "intrinsic," but this terminology should be avoided since the stresses are not intrinsic to either the film or the substrate but rather always arise from an interaction between the two. Because the structure in films can be inhomogeneous, the stresses in films can be inhomogeneous as well.

Measurements of Thin Film Deformation

Measuring mechanical properties in thin films is challenging because of the difficulty in manipulating such a thin object. This problem has been overcome by testing films while they are still attached to their substrates or by using microfabrication or nanofabrication methods to prepare samples without the need to handle the film.

The most common tests are nanoindentation and substrate curvature methods, in which the film is tested while still supported by the substrate. Commercial equipment is available for both of these tests. In nanoindentation, the load and displacement are recorded as a hard tip of a known shape is pressed into the sample surface and removed. By the use of an appropriate analysis model, a measure of elastic stiffness, hardness, and time-dependent behavior can be obtained. Nanoindentation tests are simple to perform, and quantitative information can be obtained from very small (tens of nanometers in diameter), well-located (within some tens of nanometers) volumes of materials. However, the primary disadvantage of nanoindentation lies in distinguishing film properties from substrate influences, which arise as indentations become large and surface influences (mainly due to roughness, surface layers, or particles), which become large as indentations become small.

Substrate curvature tests make use of the curvature shown in **Figure 1f**. If the film is thin and/or compliant relative to the substrate, then the stress in the film is related to the curvature induced via

$$\sigma = Y_s \frac{t_s^2}{6t_f}\left(\frac{1}{R} - \frac{1}{R_0}\right) \quad [5]$$

where R_0 and R are the radii of curvature of the substrate before and after the film is attached, respectively, t_f and t_s are the thicknesses of the film and substrate, respectively, and $Y_s = E_s/(1 - \nu_s^2)$ is the biaxial modulus of the substrate, assumed to be isotropic with Young's modulus, E_s, and Poisson's ratio, ν_s. Equation [5] is known as the Stoney equation and applies when the product of ratios $t_s Y_s / t_f Y_f$ is large, typically greater than ~ 100. R_0 and R are typically measured either by scanning a laser across the sample and observing the position of the reflected beam, or using optical interferometry. The substrate curvature method is very accurate and repeatable, as well as relatively simple and flexible. It is often used *in situ* to measure the stresses that arise in films during deposition or thermal cycling. The main disadvantage is that it is not possible to control the strain without changing the conditions that give rise to that strain (e.g., change in temperature).

Results from substrate curvature measurements conducted *in situ* during thermal cycling of 1 μm thick Cu films are shown in **Figure 2**, and provide an introduction to several unique features of thin film deformation behavior. Such tests are often used because they mimic the thermal cycles that films undergo during manufacture and use. Three sets of data are shown. The solid line indicates data obtained from a computer simulation based on steady-state deformation mechanisms for bulk Cu, including the microstructural length scales of the film. The open and filled circles are data from substrate curvature measurements. The Cu films were prepared identically except that a thin passivation layer was deposited on one, while the other was left with the Cu-free surface exposed. The shapes of the experimental stress–temperature hystereses in **Figure 2** show that the stresses can be much higher in thin films than in comparable bulk materials, particularly at high temperatures.

In recent years, a number of tests have been developed to test free-standing films or parts of films. The two most common examples are bulge tests and microtensile tests. In bulge tests, microfabrication methods are used to remove a section of the substrate from behind a film, and pressure is applied to cause the film to bulge out. With an appropriate analysis model, pressure–deflection data can be converted to stress–strain data. For microtensile tests, free-standing tensile test samples are prepared by first removing the adjacent film material and then

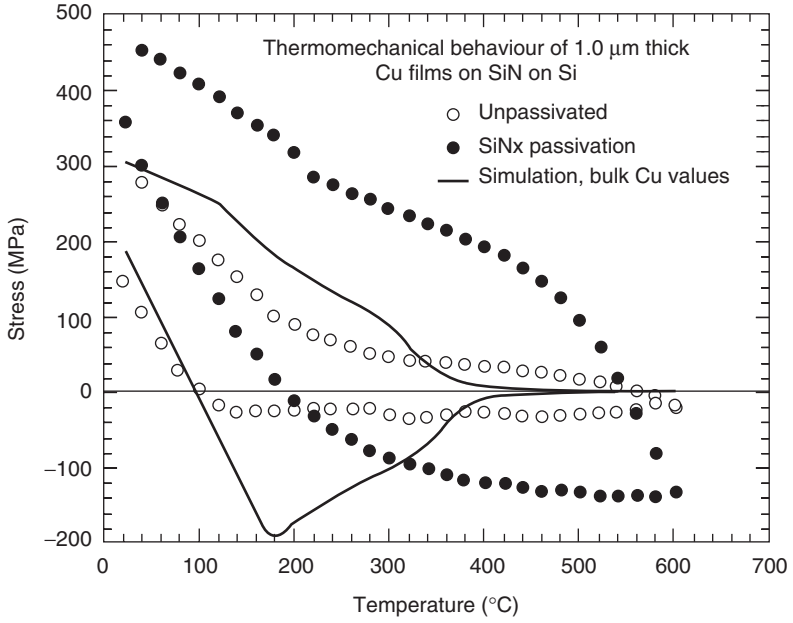

Figure 2 Stresses induced by thermal cycling in Cu films on Si substrates. The films were prepared identically except that a thin SiNx passivation layer was deposited on one. The solid line is a simulation showing the behavior expected based on scaling laws derived for bulk Cu.

removing the substrate from behind the sample, leaving a substrate frame to which the sample remains attached at both ends. Loads are applied to these substrate sections to distort the film. Microfabricated test structures are of great interest for the study of free-standing thin film structures.

Plastic Behavior

As is the case in bulk materials, the plastic behavior of thin films depends on the microstructure. Unlike bulk materials, however, the plastic behavior of thin films is often found to depend on the sample size. In addition, the plastic behavior of thin films is extremely sensitive to conditions at thin film interfaces.

The microstructures of crystalline thin films may be categorized into three groups: Single-crystal films arise primarily when films are deposited epitaxially. Nonepitaxial films are often nanocrystalline (grain sizes $\sim 10\,\text{nm}$) in their as-deposited state. The mechanical behavior of such films is similar to that of "bulk" nanocrystalline materials and is not considered here. If a fine-grained film is annealed, the mean final grain size is often found to be of the same order as the film thickness. Such films typically have "columnar" grain structure (all grain boundaries perpendicular to the plane of the film), in which certain orientations are strongly preferred. For example, in f.c.c. metal films, grains with (1 1 1) and (1 0 0) planes parallel to the plane of the film are most common as they minimize interface and strain energy, respectively.

Dislocation Mediated Plasticity

The high strength of crystalline thin films at low temperatures (**Figure 2**) is due to constraints on dislocation motion. An epitaxial thin film on a substrate provides a simple example of how the constraint of the substrate affects the mechanical behavior of thin films. A film with a capping layer is illustrated in **Figure 3**. A threading dislocation (a dislocation that runs from the top to the bottom of the film) is shown at "**a**" of **Figure 3** in an unstressed film. When a stress is applied, the threading dislocation can relax the applied strain by moving on its glide plane. However, because the film is encapsulated between the substrate and cap layer, the threading dislocation can only move ahead by leaving misfit dislocations behind at the interfaces (indicated by "**b**" in **Figure 3**). The threading dislocation moves forward only when the elastic strain energy relieved by its motion is sufficient to provide the energy required to form the misfit dislocation. Thus, there is a threshold stress (critical stress) for dislocation motion. Since the total strain energy in the film depends linearly on the film thickness and the energy per unit length of the misfit dislocation is approximately constant, the critical stress varies with reciprocal film thickness. A widely used derivation gives

$$\sigma_c = \frac{\sin\phi}{\sin\phi\cos\lambda}\frac{b}{2\pi(1-\nu)t_f} \times \left[\frac{\mu_f\mu_s}{(\mu_f+\mu_s)}\ln\left(\frac{\beta_s t}{b}\right) + \frac{\mu_f\mu_p}{(\mu_f+\mu_p)}\ln\left(\frac{\beta_p t_p}{b}\right)\right] \quad [6]$$

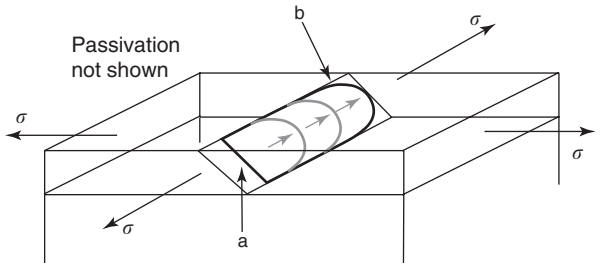

Figure 3 A dislocation gliding on its slip plane in the channel created by a thin film between a substrate and a passivation layer. (a) A threading dislocation extends from the top of the film to the bottom at zero stress. (b) In order to move through the film, the dislocation must leave misfit dislocations at the film/substrate and film/passivation interfaces.

where b is the magnitude of the Burgers vector, ϕ and λ are the angles between the film normal and the glide plane normal, respectively, μ the shear modulus, and β a constant. The subscripts f, s, and p refer to the substrate, film, and passivation layers, respectively.

The concept of critical strain is particularly important in microelectronic devices containing epitaxial semiconductor layers, as the misfit dislocations that form when the critical strain is exceeded can spoil the electronic function of the device. The reciprocal dependence of critical stress on the film thickness predicted by eqn [6] has been observed in epitaxial semiconductor films. However, higher values have also been reported. This may be due to experimental difficulties associated with observing the formation of the first misfit dislocations, or to a lack of appropriate dislocation sources. From a reliability perspective, eqn [6] provides an accurate measure of the minimum thickness at which misfit dislocations may appear in an epitaxial film.

Interestingly, an inverse dependence of strength on thickness is also seen in polycrystalline metal films, although at stress levels much higher than those predicted by eqn [6]. One can obtain such data, for example, by recording the stress at room temperature at the end of thermal cycles as in **Figure 2** for films of various thicknesses. Neither the fact that the yield stress increases as t_f decreases, nor that eqn [6] underpredicts the result, is surprising. As strain increases, a threading dislocation moving through the film must interact with misfit dislocations in its path as well as other threading dislocations and is constrained from long-range motion by grain boundaries, just as in bulk materials. That these events occur in the narrow channel of the film leads to very high stresses indeed. However, while a number of models have been presented, the precise origin of the t_f^{-1} dependence is not yet clear.

The arguments above are based on the assumption that dislocations are preserved at the interfaces. If dislocations are not preserved, then the behavior will be very different. The limiting case is that of a free-standing film, which has no critical strain threshold for dislocation motion and no misfit dislocations to block the threading dislocation motion. A film with one free surface (e.g., **Figure 2**) represents an intermediate case. However, a free surface is not needed to eliminate misfit dislocations. If the resistance to interface sliding is sufficiently low, then the cores of misfit dislocations can spread into the interface. The consequence is that the mechanical behavior of certain film systems (e.g., copper on nitride or oxide layers, as is commonly used in microelectronics) is very sensitive to any variation in interface chemistry that affects interface strength. Stress levels in fully encapsulated films can be varied over a wide range in this manner.

Another example of interface control of properties is multilayer films, in which manipulation of interface strength and density can be used to create exceptionally strong films. For example, by deposition of alternating thin layers with well-bonded, dislocation blocking interfaces, films with strengths approaching the theoretical strength can be generated.

Diffusion Mediated Plasticity

At high temperatures, the high strength of thin films is due to constraints on diffusion, and the difference between thin film behavior and that expected on the basis of bulk scaling laws is even more dramatic. For example, at the low strain rates imposed for the data in **Figure 2**, the simulation predicts that the stress would be relaxed to near zero at temperatures above 400°C, while the real films support significant stresses at these temperatures.

This discrepancy can be understood as follows: **Figure 4** shows a schematic cross section of a film on the substrate with a capping layer. A stress applied in the plane of the film can be relaxed if the material diffuses between the grain boundaries and the interfaces as shown in **Figure 4a**. The simulation in **Figure 2** was obtained by assuming that the interface diffusivity is the same as the grain boundary diffusivity. In order to achieve the stresses seen in the real capped film at high temperatures, interface diffusion must be turned completely off in the simulation and relaxation allowed to occur by other mechanisms, such as thermally activated dislocation glide. While high stresses due to limited interface diffusivity might be expected in tightly bound interfaces such as Al/SiO_2, similar high stresses are often seen in films with interfaces known to have poor adhesion and high diffusivity such as Cu/SiN_x. The reasons for this are presently unknown.

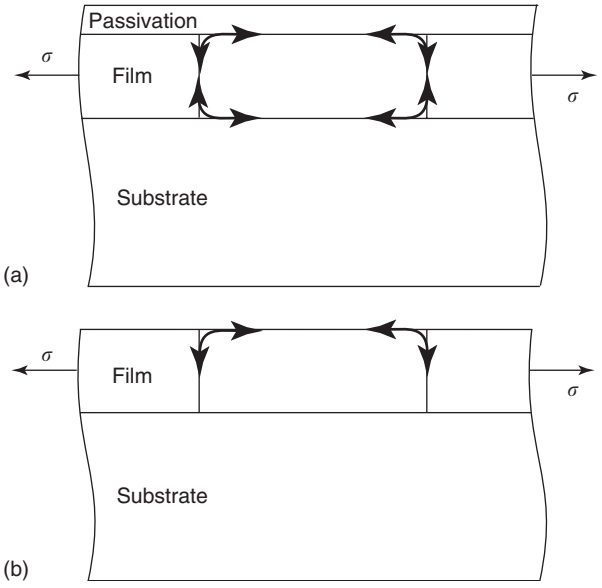

Figure 4 (a) Stresses can be relaxed in a passivated film only if diffusion is allowed along the interfaces. (b) In an unpassivated film, stresses can be relaxed by diffusion between the grain boundaries and the free surface.

An uncapped film provides an interesting case, as shown in **Figure 4b**. Here diffusion is allowed between the grain boundaries and the free surface, but not between the grain boundaries and the interface with the substrate. Tensile stresses, for example, are relaxed by diffusion of material from the free surface into the grain boundaries. Each grain boundary is filled with a wedge of material and the stresses are relaxed near the film surface, but not near the interface. This provides an inhomogeneous stress state with high shear stresses on the interface.

Elastic and Anelastic Behavior

Elastic strain is deformation that is fully recovered upon removal of the applied load. This definition encompasses both elastic deformation that arises from bond stretching and twisting, and anelastic deformation that arises from atomic reconfigurations (e.g., defect motions). Elastic deformation occurs at short timescales (transmitted at phonon velocities) while anelastic deformation is time dependent on a much longer scale.

Elastic deformation depends on the type and density of interatomic bonds in the material. One does not expect radically new types of interatomic bonds in a film just because it is thin. Indeed, the changes that can be expected in elastic constants should be of the order of $N_{\text{defect}}/N_{\text{bulk}}$, the ratio of atoms in nonbulk environments to the number in bulk environments. For example, consider a film comprised of cubic grains with side d having boundaries of width δ. The ratio of grain boundary to interior volume is $3\delta/d$. If the grain interiors have modulus E_{grain} and the boundaries have a modulus of zero (an extreme example!), then the isostrain composite modulus of the film is

$$E = (1 - 3\delta/d)E_{\text{grain}} \qquad [7]$$

For $\delta = 0.2$ nm, one would need $d = 6$ nm$(= t_f)$ to achieve a modulus reduction of only 10%. Given this expectation, a great deal of excitement has accompanied reports of much larger deviations. However, it now appears that all such reports can be attributed to experimental errors.

Anelastic behavior, on the other hand, can be much more prominent in thin films than in bulk. An example can be seen in **Figure 2**. Upon initial heating, the experimental data initially follow the predicted thermoelastic slope. At some point, the data deviate from this slope, indicating the onset of inelastic deformation. Careful inspection reveals that the inelastic strain is compressive, while the applied stress is still tensile. This "negative yielding" is similar to the well-known Bauschinger effect in bulk metals, but is much larger. As is the case with plastic deformation by both dislocation and diffusion mediated plasticity, anelastic recovery is also very sensitive to interface conditions. For example, quite spectacular anelastic recoveries of up to several tenths of a percent strain can be achieved by adjusting interface adhesion.

Two mechanisms, dislocation motion and boundary sliding, that are often used to explain anelastic behavior in bulk metals, probably also account for anelastic behavior in films. For example, consider a film that has been plastically deformed so that loops having the form shown in **Figure 3** have been generated at stress levels above σ_{ch} (eqn [6]). If the applied stress is then reduced below σ_{ch}, it becomes energetically favorable for the dislocation loops to run out of the film, increasing the strain energy (and stress) in the film, but reducing the total energy by reducing misfit dislocation line length. The quasi-2D structure of films can promote grain boundary sliding by allowing grain rotations in the plane of the film. In addition, shear stresses along the film/substrate interface generated by anisotropy or diffusional mechanisms can be relaxed by sliding along the interface, which can also lead to anelastic behavior.

The highly textured nature of films also leads to non-bulk-like scaling behavior. For example, a film composed of a cubic material has lower stiffness, but higher surface energy when (1 0 0) planes are parallel to the plane of the film compared to the case where (1 1 1) planes are parallel to the film plane. Thus, a

transition from (1 1 1) to (1 0 0) orientation (stiff to compliant) with film thickness has been predicted and experimentally verified. For Cu, Ag, and Au, for example, the difference is more than a factor 2. For a given elastic strain, the stresses are then much higher in the (1 1 1) orientations, leading to very inhomogeneous stress states and high shear stresses on the interfaces near (1 1 1)/(1 0 0) grain boundaries.

Fracture and Delamination

Brittle films with sufficiently weak interfaces may fail by delamination from the substrate (**Figure 5a**) or by fracture (**Figure 5b**). The driving force, G, for delamination can be found by comparing the elastic strain energy per unit area of the film far ahead of the delamination crack with that which is far behind the crack. For a straight crack front,

$$G = \frac{1 - \nu_f^2}{2E_f}\sigma^2 t_f \qquad [8]$$

where σ is the stress in the film before delamination.

Several tests have been developed for quantitative assessment of the interfacial fracture toughness, Γ, or the value of G at delamination. If the stress in the film is well known, the thickness at which it delaminates can be used to determine Γ from eqn [8]. In many cases, a highly stressed "superlayer" is added on top of the target film of interest to accelerate the process.

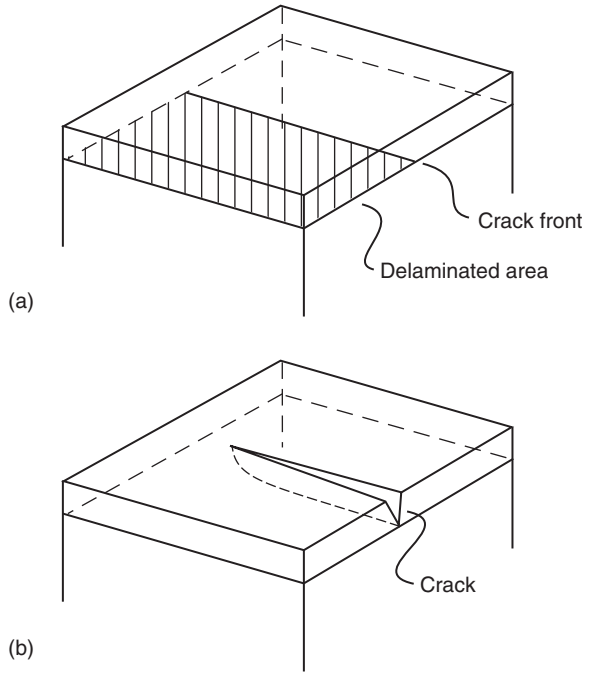

Figure 5 (a) Delamination of, and (b) through thickness (channeling) cracks in a thin film.

While the solution is more complicated, it is straightforward to find Γ for the target interface if the stresses in the layers and their thicknesses are known. In addition, several tests of film adhesion have been developed, which do not require a detailed knowledge of film stress states. In these tests, the film is bonded between two massive substrates and external loads are applied to the substrates to drive a delamination crack. These tests include the four-point bend test, the double-cantilever beam test, and several others.

Because thin films are normally under stress, subcritical delamination is an important failure mode and topic of study. Subcritical delamination occurs when chemical processes assist crack propagation so that films delaminate under conditions where G is less than the value required for rapid or "critical" crack propagation in the absence of chemical assistance. Under constant stress, subcritical delamination may occur very slowly over very long durations and is a particularly insidious failure mode. Recent work suggests that subcritical delamination of thin films is similar to subcritical cracking in glass with a region where crack velocity v depends exponentially on G when the chemical reaction rate is controlling, and a region at higher G where v is independent of G when diffusion of the chemical species to the crack tip is controlling.

Cracks that extend through the film thickness (**Figure 5b**), also known as channeling cracks, are similar to channeling dislocations (**Figure 3**) in that there is a critical stress needed for channeling crack propagation, established by the requirement that the strain energy released by the crack propagation must be sufficient to produce the new surface area and other energy costs associated with the crack. Channeling cracks, such as channeling dislocations, can also form arrays to relax strains and form configurations that depend on both interactions and sources. The mechanics of film cracking are well developed.

Conclusions

Films on substrates normally support very high stresses due to the constraint of the substrate, but do not exhibit the mechanical behavior of chemically equivalent bulk materials, and thus must be separately studied. While a number of dislocation- and diffusion-based mechanistic models for film deformation have been proposed, a complete model capable of predicting the plastic and anelastic behavior of a film based on its microstructure remains elusive. A significant factor in this is that the microstructural configurations that are assumed in such models have not been sufficiently well verified experimentally. In general, thin films follow the rule that "smaller is stronger." This is an area of ongoing development,

and new experimental methods and models are expected to extend a detailed knowledge to smaller length scales and both shorter and longer timescales.

Tight-Binding Method in Electronic Structure

D A Papaconstantopoulos and M J Mehl, Naval Research Laboratory, Washington, DC, USA

Introduction

In the linear combination of atomic orbitals (LCAO) method, the one-electron wave function is expressed as a linear combination of Bloch sums. When such an expansion is made to the wave function in the Schrödinger equation, one obtains a set of simultaneous linear equations that has a nonzero solution if the determinant of the coefficients vanishes, that is,

$$\tilde{H} - \varepsilon\tilde{S} = 0 \qquad [1]$$

The matrix elements in this equation have the form:

$$H_{nm} = \sum_{R_j} \exp[\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{R}_j - \boldsymbol{R}_i)] \times \int \phi_n^*(\boldsymbol{r} - \boldsymbol{R}_i)\tilde{H}\phi_m(\boldsymbol{r} - \boldsymbol{R}_j)\,\mathrm{d}^3r \qquad [2]$$

and

$$S_{nm} = \sum_{R_j} \exp[\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{R}_j - \boldsymbol{R}_i)] \times \int \phi_n^*(\boldsymbol{r} - \boldsymbol{R}_i)\phi_m(\boldsymbol{r} - \boldsymbol{R}_j)\,\mathrm{d}^3r \qquad [3]$$

where $\boldsymbol{R}_i$ and $\boldsymbol{R}_j$ denote the positions of atoms located on orbitals ϕ_n and ϕ_m, respectively. The integrals in the above equations can, in principle, be calculated directly. However, the most common practice has been to follow Slater and Koster (SK), who suggested replacing these integrals by adjustable parameters that could be estimated from experiment, but which are generally determined by fitting to more elaborate electronic structure calculations. The size of the matrices $\tilde{H}$ and $\tilde{S}$ is determined by the number of atoms in the unit cell and the number of atomic orbitals on each site. So for face-centered cubic (f.c.c.), body-centered cubic (b.c.c.), and simple cubic (s.c.) lattices with one atom per unit cell, $\tilde{H}$ and $\tilde{S}$ are 9×9 matrices representing one *s*-function, three *p*-functions, and five *d*-functions. The *f*-states have been omitted in most works, although there have been papers that provide extensions of the SK scheme that include *f*-orbitals. For diatomic lattices, such as hexagonal close-packed (h.c.p.) and diamond and in binary compounds the *spd* model will result in an 18×18 matrix. Often in semiconductors such as Si and Ge, the *d*-states are not included and hence the size of the Hamiltonian is 8×8. The full SK Hamiltonian for a monatomic material could require the determination of 81 parameters between each pair of atoms; however, SK showed that these parameters are related by symmetry operations that considerably reduce their actual number. The resulting independent matrix elements may be found in the tables given by SK. The reader is cautioned that some typographical errors appear in these tables which have been corrected by other authors (see "Further reading" section). Since the above summations are over the interatomic distances R_j, the number of parameters increases for calculations that include more than first nearest neighbors. In practice, no more than the third nearest neighbors are included. The integrals in [2] are three-centered since they are the product of an

atomic wave function $\phi^*(\boldsymbol{r}-\boldsymbol{R}_i)$ centered on the atom at position $\boldsymbol{R}_i$, an atomic wave function $\phi(\boldsymbol{r}-\boldsymbol{R}_j)$ located on the atom at position $\boldsymbol{R}_j$, and a potential function inside the Hamiltonian H, centered on a third atom. These three-center integrals can be reduced to two-center integrals by approximating the potential energy as a sum of spherical potentials located on the same two atoms where the atomic orbitals are located. For the relationships between three- and two-center integrals, see the "Further reading" section. Although working in three-center formalism has the advantage of fitting band structures more accurately, the two-center approximation has the distinct advantage that its parameters are transferable from one structure to another. This property of the two-center scheme makes it suitable to introduce bond-length dependence in the parameters which leads one to implementing a total energy capability in the SK method.

Since the 1960s, there have been numerous applications of tight-binding (TB) theories, in particular, the SK approach, to calculate electronic energy bands, densities of states, and, more recently, total energies. There are two main uses of the TB theory. One is to determine a small number of parameters with the aim of providing a physical insight into the electronic structure without the necessity of going beyond a qualitative description. A classic example of this approach is the universal TB parameters of Harrison. Harrison's TB theory has been of great educational value for a whole generation of scientists. Very recently, extensions to this theory have been provided that greatly improve its accuracy. The other approach is to place emphasis on accurately reproducing the results of first-principles calculations by applying a least-squares procedure using a large number of parameters. The authors of this article have generally followed the second approach. A handbook by Papaconstantopoulos (see "Further reading") has provided TB parameters for most elements in the periodic table, except for those with *f*-states. The handbook provides TB parameters in both two-center and three-center bases as well as in orthogonal and nonorthogonal representations. However, these parameters are fitted to the ground state of each element and have very limited transferability to other volumes and structures. In addition, these TB Hamiltonians are not designed to compute total energies. The NRL-TB scheme on the other hand, which is discussed in the next section, is a two-center nonorthogonal TB method that uses environment-dependent parameters that capture the volume dependence of both the energy bands and the total energy.

To complete this introduction, the attention of the reader is drawn to a simple level of the TB theory, known as the second moment approximation (SMA) which originates from the Friedel model of rectangular density of states for the *d*-bands. The SMA method does not account for the band structure but, at least for the f.c.c. metals, reproduces well the total energy which has led to its wide use in molecular dynamics simulations. This method contains four adjustable parameters fitted to reproduce either experimental quantities or the total energies from first-principles calculations.

NRL Tight-Binding Method

In the (Naval Research Laboratory) NRL-TB scheme, the on-site terms h_{il} are written as a polynomial:

$$h_{il} = a_l + b_l\rho_i^{2/3} + c_l\rho_i^{4/3} + d_i\rho_i^2 \qquad [4]$$

where i labels the atom and l the angular momentum of s, p, and d characters in the present form of the method.

The quantity ρ_i that appears in [4] is an embedded-atom-like "density" per atom given by the expression

$$\rho_i = \sum \exp(-\lambda^2 R_{ij}) F(R_{ij}) \qquad [5]$$

where R_{ij} denotes the position of neighboring atoms from a central atom i, and $F(R_{ij})$ is the cutoff function. The quantities a_l, b_l, c_l, d_l, and λ are 13 parameters to be determined by a least-squares fit to the first-principles results. It is possible, within this scheme, for example, to split the *d*-onsite parameters to t_{2g} and e_g, or going even further, to have different parameters for the three *p*-orbitals and the five *d*-orbitals. It is also to be noted that this scheme has the flexibility of adding more terms in [4] to describe the density contributions from atom A to atom B (and vice versa) in the case of a binary material.

It was shown by SK that the two-center (*spd*) hopping integrals can be constructed from ten independent parameters $H_{ll'm}$, where

$$(ll'm) = ss\sigma, sp\sigma, pp\sigma, pp\pi, sd\sigma, pd\sigma, pd\pi, dd\sigma, dd\pi, \text{ and } dd\delta$$

One notes that in the case of a binary material AB, there will be a set of four additional parameters:

$$(ll'm) = ps\sigma, ds\sigma, dp\sigma, \text{ and } dp\pi$$

In the NRL-TB, each of these parameters is expressed in the form of a second-order polynomial-times an exponential function:

$$H_{ll'm}(r) = (e_{ll'm} + f_{ll'm}r + g_{ll'm}r^2) \times \exp(-t_{ll'm}^2 r) F(r) \qquad [6]$$

where r is the distance between atoms, $F(r)$ the cutoff function as in [5], and $e_{ll'm}$, $f_{ll'm}$, $g_{ll'm}$, and $t_{ll'm}$ are an additional set of 40 parameters (or 56 for the, A–B interactions) to be determined by fitting to the first-principles results. Since one usually fits to a non-orthogonal Hamiltonian, an additional set of 40 parameters is used (56 for A–B) for the overlap matrix following [6]. In cases where the validity of the parameters for interatomic distances much smaller than those in the original databases needs to be extended, one finds that the following form of overlap parameters is more successful:

$$S_{ll'm}(r) = (\delta_{ll'} + p_{ll'm}r + q_{ll'm}r^2 + r_{ll'm}r^3) \times \exp(-s^2_{ll'm}r)F(r) \quad [7]$$

where $p_{ll'm}$, $q_{ll'm}$, $r_{ll'm}$, and $s_{ll'm}$ are the corresponding parameters of the overlap matrix and $\delta_{ll'}$ is the Kronecker delta.

In most of the TB approaches, as well as in all the so-called "glue" potential atomistic methods, one writes the total energy as a sum of a band energy term (sum of eigenvalues) and a repulsive potential $G[n(r)]$ that can be viewed as replacing all the charge density-dependent terms appearing in the total energy expression of the density-functional theory. The NRL-TB method has the unique feature that eliminates G by the following ansatz: a quantity V_0 is defined as

$$V_0 = G[n(r)]/N_e \quad [8]$$

where N_e is the number of valence electrons and $n(r)$ is the charge density. All the first-principles eigenvalues $\varepsilon_i(\boldsymbol{k})$ are then shifted by the constant V_0, and the shifted eigenvalue is defined as

$$\varepsilon'_i(\boldsymbol{k}) = \varepsilon_i(\boldsymbol{k}) + V_0 \quad [9]$$

The result of this manipulation is that the first-principles total energy E is given by the expression

$$E = \sum \varepsilon'_i(\boldsymbol{k}) \quad [10]$$

where the sum is over all occupied bands and all k-points in the Brillouin zone. It is noted that the constant V_0 is different for each volume and structure of the first-principles database. The reader should recognize that each band structure has been shifted by a constant, retaining the exact shape of the first-principles bands. It should also be stressed that all this is done to the first-principles database before one proceeds with the fit that will generate the TB Hamiltonian. The next step is to use a least-squares procedure to fit this database with the shifted eigenvalues ε'_i to the TB Hamiltonian.

A typical database in the NRL-TB method contains, for example in a transition metal, five volumes each for the f.c.c. and b.c.c. structures and often the s.c. lattice to achieve better transferability to other periodic structures or defect structures.

The TB method can also be extended to cover magnetism. In this case, a set of spin-polarized parameters are constructed by fitting to spin-polarized linearized augmented plane wave (LAPW) calculations. Common hopping [6] and overlap [7] parameters are used for the majority and minority spin cases, but separate onsite [4] parameters for each channel are developed. Each channel is then diagonalized separately. A set of paramagnetic TB parameters is constructed by averaging the majority and minority spin onsite parameters. Then, the pressure-induced ferromagnetic-to-paramagnetic transitions are studied by noting whether the spin-polarized or paramagnetic parameters produce lower energies. Currently, well-tested parameters for Fe, Co, and Ni are available.

Technical Procedure

The first-principles calculations were done either with the muffin-tin potential augmented plane wave (APW) method or with the full-potential LAPW method. The small differences between these two approaches, especially for closed packed structures, are within the error one makes after fitting to the TB Hamiltonian.

For the f.c.c., b.c.c., and s.c. structures uniform k-point meshes that include the origin and contain 89, 55, and 35 k-points in the irreducible part of the Brillouin zone, respectively, are used. In most cases, the Hedin–Lundqvist parametrization of the local density approximation (LDA) to the density-functional theory (DFT) is used. In some cases, such as for spin-polarized iron, the generalized gradient approximation (GGA) has been used. Spin-polarized calculations were performed for the appropriate metals in the $3d$ transition series. For a typical transition metal, there are $\sim$4000 eigenvalues and energies in the database. An IMSL package is used, based on a finite-difference Levenberg–Marquardt algorithm, to adjust the 93 parameters involved to reproduce this database by means of a nonlinear least-squares fit, with the total energies typically weighted $\sim$200 times larger than the eigenvalues in a single band. Starting parameters are selected guided by those found in the previous work and it is ensured that the symmetry of the eigenstates is taken into account. This is an important issue because a block-diagonalization of the Hamiltonian avoids the possibility of incorrectly aligning the bands and

preserves the angular momentum character of the states. For details of this symmetrization procedure, refer to the "Further reading" section.

Another issue is the number of bands per k-point used in the fit. Both occupied and empty states are fitted. For example, in the transition metals, the lowest six bands for all k-points are fitted but the bands 7–9 are also included for the four high-symmetry points. With this choice, one obtains reliable values for the SK parameters that correspond to the p-orbitals. The fitting RMS errors are in the range 1–5 mRy for six bands and $\sim$0.5 mRy for the total energies. For the semiconductors, eight bands, divided into four valence and four conduction bands in an s–p basis are fitted. Here, the RMS error is $\sim$5 mRy for the valence bands but much higher for the conduction bands. There is a very significant improvement in the conduction bands upon inclusion of the d-orbitals. However, the s–p basis gives a very good fit to the total energy with an RMS error not exceeding 0.5 mRy.

Ground-State Behavior and Phase Stability

The NRL-TB Hamiltonians have been tested to give the correct ground state for all materials for which TB parameters have been generated. The results are summarized in **Tables 1** and **2**. **Table 1** shows the equilibrium lattice constants and bulk moduli for all of the materials studied, comparing them to first-principles LDA calculations, and to experiment. The equilibrium lattice constant is typically within 1–2% of the LDA value and correspondingly very close to the measured values. In this table, the magnetic elements are spin-polarized in a manner consistent with the observed magnetic structure. Thus, one can find that the ground state of chromium is an anti-ferromagnetic CsCl phase, which is a good approximation to the experimentally observed spin density wave.

Similarly, the equilibrium bulk moduli are in good agreement with the first-principles results, within 10% for most elements. With the exception of Ti, the h.c.p. phases were not fit to first-principles results, but instead predicted as an output of the TB scheme. As a result, the equations of state predicted by the TB model are not as accurate as for the cubic lattices. The largest error is for zirconium, where a is 7% smaller than experiment and c is 8% larger. Yttrium and hafnium also show large discrepancies between the TB model and experiment. The lattice constants for the other elements are within 2% of experiment, consistent with the errors one would find in first-principles calculations. The discrepancies from experiment found in Zr, Y, and Hf can be removed by including h.c.p. and, if necessary, the simple cubic lattice.

For Ti, the GGA calculations were fitted with the h.c.p. and sc lattices. In this more elaborate fit, it was possible to improve on the lattice constants and differentiate between the h.c.p. and omega phases. This TB method succeeds in predicting the correct ground state for all materials presented here. **Figure 1** shows the energy volume curves for a representative sample of materials that crystallize in different structures. The results for all of the elements are summarized in **Table 2**, which shows the equilibrium energy of each of these phases expressed as the difference in energy between that phase and the equilibrium energy of the experimental ground state. The energy of each crystal structure is computed by doing a conjugate-gradient minimization of the total energy with respect to all the parameters in the lattice, internal (atomic positions) as well as external (a, c, etc.). The TB method correctly predicts the ground-state structure for all metals including the ferromagnetic metals iron, cobalt, and nickel. The results are also consistent with the accepted crystal structure for the semiconductors Si and Ge, and with the more complex structures of Mn,Ga, and In.

The fact that this method finds the correct ground states of the h.c.p. metals and the other complex structures that were not included in the fit of the TB parameters should be emphasized.

The robustness of the TB parameters has also been established by studying crystal structures of lower symmetry such as the volume-conserving tetragonal strain, the so-called Bain path. The Bain path of Nb at the experimentally observed equilibrium volume of the b.c.c. phase is shown in **Figure 2**. The energy is properly a minimum for the b.c.c. lattice, where $c/a = 1$, and attains a local maximum at the f.c.c. structure ($c/a = \sqrt{2}$). This shows that the f.c.c. elastic constant associated with tetragonal shear, $C_{11} - C_{12}$, is negative; hence, the f.c.c. structure is unstable.

Elastic Constants

Elastic constants measure the proportionality between strain and stress in a crystal, provided that the strain is not so large as to violate Hook's law. Computationally, the elastic constant is determined by applying a strain to a crystal, measuring the energy versus strain, and determining the elastic constant from the curvature of this function at zero strain. A given strain is associated with a certain linear combination of elastic constants. For cubic systems,

The "CsCl" structure given for Cr is described in the text. Note that gallium has an orthorhombic structure, so values for lattice constants *a* and *b* are both given in the *a* columns.

including diamond, there are three independent elastic constants, C_{11}, C_{12}, and C_{44}. One linear combination of the elastic constants is obtained from the bulk modulus

$$B(V) = VE''(V) = 1/3(C_{11} + 2C_{12}) \qquad [11]$$

where V is the unit cell volume. A second combination is most easily obtained by straining the crystal in the (1 0 0) direction while simultaneously compressing it in the (0 1 0) direction to conserve the volume, with lengths in the (0 0 1) direction remaining fixed. If x is the fractional change in the (1 0 0) direction, then,

$$C_{11} - C_{12} = E''(0)/V \qquad [12]$$

where the function, $E(x)$ measures the energy as a function of strain. Finally, one finds C_{44} by straining the crystal in the (1 1 0) direction and fixing the volume by compressing in the $(1\ \bar{1}\ 0)$ direction. In this case,

$$C_{44} = 2E''(0)/V \qquad [13]$$

Table 2 TB energies discussed in the text. The energy of the experimental ground-state structure is arbitrarily set to zero. All energies are calculated at the equilibrium volume found by the TB fit and are expressed in mRy. Below the common name of each phase is its *Strukturbericht* designation

Note that for diamond the calculation of C_{44} requires the minimization of the total energy with respect to an internal parameter at each strain.

The calculation of elastic constants assesses the ability of the method to determine properties not included in the fitting database. The elastic constants of the cubic materials calculated by the NRL-TB approach are compared to the experimental values in **Table 3**. These calculations were performed at the experimental volume and therefore they are not consistent with the equilibrium value of B found in **Table 1**. The deviation of the calculated C_{11} and C_{12} from the measured values is within 10–15% which is very close to the error one finds when comparing with a direct evaluation from first-principles calculations.

An inspection of **Table 3** reveals somewhat larger errors for C_{44}. A solution to this problem is to fit C_{44} either to LAPW calculations or to experiment. It should be noted here that calculations of C_{ij} in the alkaline-earth metals is problematic because the lattice is extremely soft. One can also note that the method correctly reproduces the sign of the elastic constant difference $C_{12} - C_{44}$, even in the metals rhodium and iridium, and the semiconductors Si and Ge where it is negative. It is worth mentioning that this negative sign cannot be obtained from the standard embedded-atom method.

The resulting elastic constants for the h.c.p. lattice are C_{11}, C_{12}, C_{13}, C_{33}, and C_{44}. The elastic constants found by the NRL-TB method show larger relative deviations from experiment than found in the cubic crystals. These were found from TB parameters fitted only to cubic lattices. It is shown, in the case of Ti, that if one extends the fitting database to include the h.c.p. lattice as well, there is a dramatic improvement in the comparison of TB and measured elastic constants.

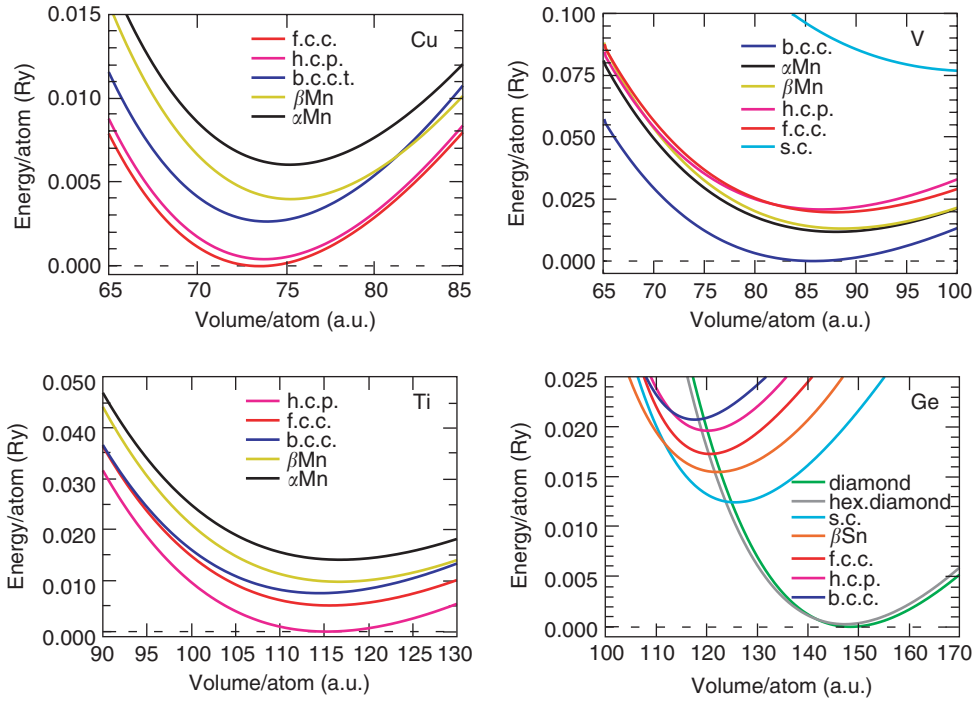

Figure 1 Energy vs. volume curves for various phases of (clockwise from the top left) copper, vanadium, germanium, and titanium, using the NRL-TB parameters described in the text. Note that the method correctly predicts the equilibrium structure.

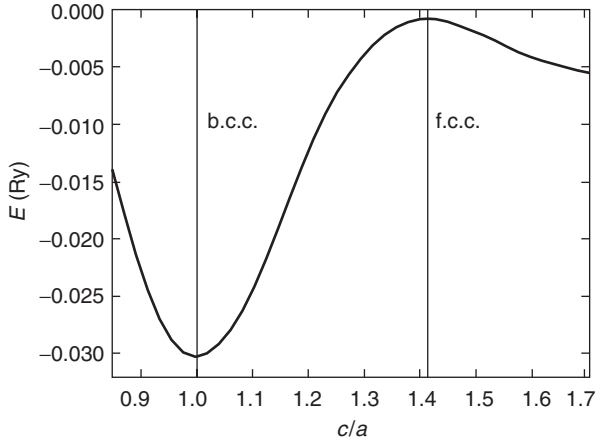

Figure 2 TB calculation of the energy of molybdenum, at the experimental equilibrium volume, under a tetragonal strain, as a function of c/a. The vertical lines denote the positions of the b.c.c. and f.c.c. lattices.

Vacancies

Vacancy formation energies have been calculated by a supercell method. One atom in the supercell is removed and neighboring atoms are allowed to relax around this vacancy while preserving the symmetry of the lattice. The great advantage of the NRL-TB method over first-principles approaches is that one

All elements for which a set of TB parameters have been constructed and for which one has a cubic ground state (except manganese) are presented here. A comparison is made between the results of the TB parametrization and experiment. Calculations were performed at the experimental volume.

can do the calculation in a very large supercell, in a computationally efficient manner, including relaxation. It is found that a supercell containing 128 atoms is sufficient to eliminate the vacancy–vacancy interaction. The vacancy formation energy is given by

$$E_{\text{vac}}(N) = E(N-1,1) - (N-1)E(N,0)/N \quad [14]$$

where $E(M, Q)$ is the total energy of a supercell containing $M + Q$ sites, where M are occupied by atoms and Q are vacant, whence $E(N, 0)$ is N times the energy of one atom in its bulk crystal structure. The experimental lattice constant is used to set the volume of the system, since under experimental conditions the lattice constant of a metal containing isolated vacancies will be the lattice constant of the bulk metal.

Calculated values of the vacancy formation energy of the metals are shown in **Table 4**. (Note that vacancy formation energies for Si and Ge are shown in **Table 6**.) Relaxation around the vacancy was included via a conjugate gradient procedure but it introduced, not unexpectedly, a small effect. Where available, it is compared to both first-principles calculations and experiment. The results for niobium, silver, tantalum, and iridium are in excellent agreement with experiment. The vacancy formation energies for rhodium, tungsten, and platinum do not compare well with experiment. Aluminum is an intermediate case. It is possible that the measured values are not reliable. Otherwise, there may be a need to check these results against first-principles data and perhaps fit to DFT calculations.

Table 4 TB vacancy formation energies compared to first-principles calculations and experiment

Element	*TB*		*LDA*	*Exp.*
	Fixed	*Relaxed*		
Al	0.49	0.40	0.56, 0.84	0.66
Cu	1.29	1.18	1.41, 1.29	1.28 – 1.42

Pb	0.76	0.64		0.54

Energies were computed using a 128-atom supercell. Calculations with the atoms at the primitive lattice sites in the crystal (fixed) and allowing relaxation around the vacancy (relaxed) are shown. First-principles calculations of the vacancy formation energy are given in the column labeled "LDA." The experimental column shows a range of energies if several experiments have been tabulated. Otherwise, the estimated error in the experiment is given.

TB results are from Mehl MJ and Papaconstantopoulos DA (1996) *Physical Review B* 54: 4519. Experimental data are from Schaefer H-E (1987) *Physica Status Solidi A* 102: 47.

Surfaces

Surface energies are also calculated by a supercell technique. A slab of metal is formed by cleaving the crystal along the desired plane, creating two identical free surfaces. The distance between the two surfaces is increased, creating a set of slabs that repeat periodically in the direction perpendicular to the surfaces. The slabs are separated by a large region of vacuum so that the electrons on one slab cannot hop to a neighboring slab. In addition, the slabs must be thick enough, so that the atoms at the center of the slab have the electronic properties of atoms in the bulk material and the two surfaces on the same slab cannot interact with each other. It is found that these criteria are met if slabs containing 25 atomic layers and 7–13 layers between slabs depending on the direction of the surface are used. Care should be taken with respect to the k-point mesh convergence. Depending on the surface and underlying bulk structure, this requires $\sim$200 k-points in the two-dimensional Brillouin zone. The surface energy, expressed as the energy required to create a unit area of new surface, is then given by the formula

$$E_{\text{surf}} = (E_{\text{slab}} - NE_{\text{bulk}})/(2A) \quad [15]$$

where A is the area occupied by one unit cell on the surface of the slab, E_{slab} is the total energy of the slab, N is the number of atoms in the unit cell, and E_{bulk} is the energy of one atom in the bulk at the lattice constant of the atoms in the interior of the slab. In the first surface calculations, the bulk equilibrium lattice parameters with no relaxation or reconstruction at the surface were used. These calculations showed reasonable agreement with experiment indicating that relaxation does not seriously affect the surface energy. However, recently calculations with all atoms completely relaxed were performed, including charge self-consistency. The new results for Nb and several f.c.c. metals show significant differences in the interlayer separations and reconstruction.

The results for the f.c.c. metals are particularly gratifying. For the f.c.c. metals, it is found that $E(1\,1\,1) < E(1\,0\,0) < E(1\,1\,0)$, which means that close-packed surfaces are the most stable for the f.c.c. metals. For the b.c.c. metal surface energies, the

opposite inequality is satisfied, $E(1\,1\,0) < E(1\,0\,0) < E(1\,1\,1)$.

Stacking Faults

Stacking faults are introduced in a crystal by cutting a perfect crystal block along a plane and shifting the upper part with respect to the lower part by a vector $\boldsymbol{f}$, defining the generalized stacking fault energy surface. Local energy minima on this surface are called stable intrinsic stacking faults. In f.c.c. systems and for the (1 1 1) slip plane, the stable stacking fault corresponds to a slip of $a/\sqrt{6}$ in the $\langle 1\,2\,1 \rangle$ direction. The $\langle 1\,2\,1 \rangle$ slip is modeled on a (1 1 1) slip plane by a supercell consisting of nine close-packed (1 1 1) planes of atoms. The primitive vectors of the supercell are

$$\begin{aligned} \boldsymbol{a}_1 &= \frac{1}{2}\,a\hat{y} + \frac{1}{2}\,a\hat{z} \\ \boldsymbol{a}_2 &= \frac{1}{2}\,a\hat{x} + \frac{1}{2}\,a\hat{z} \\ \boldsymbol{a}_3 &= \left(3 + \frac{q}{6}\right)a\hat{x} + \left(3 + \frac{q}{6}\right)a\hat{y} - \left(3 - \frac{q}{3}\right)a\hat{z} \end{aligned} \qquad [16]$$

where q is the stacking fault displacement of the atoms in the boundary layer along the vector f in the $\langle 1\,1\,2 \rangle$ direction. At $q = 0$, the atoms are in f.c.c. positions and at $q = 1$, at the h.c.p. positions. Since the calculations are computationally intensive because of the nine planes of atoms and the 4730 k-points used in the irreducible part of the Brillouin zone, the NRL-TB method proves to be very efficient. The results of the stacking fault energy as a function of the displacement q are shown in **Figure 3**. The results correctly predict the qualitative effect that the energies for Ir are much larger than that for the noble metals and they also are in agreement with full-potential linearized muffin-tin orbital (FLMTO) results for Al, Ag and Ir. Finally, the value at the maximum energy in **Figure 3** has been used to extract the unstable stacking fault energy γ_{us}, which is used together with the surface energy γ_{surf} to establish the Rice criterion for ductility,

$$D = 0.3\gamma_{us}/\gamma_{surf} \qquad [17]$$

One finds, in agreement with experiment, that the noble metals have the largest values of D.

Phonons

Phonon frequencies at high-symmetry points in the Brillouin zone computed with the NRL-TB model using the frozen phonon approximation are compared with experimentally measured values in **Table 5**. In this table, results from metals and semiconductors have been included. The agreement with experiment is similar to that with elastic constants. For most modes the TB results are within 15–20% of experiment, which is also comparable to phonon frequencies obtained directly from first-principles calculations. For

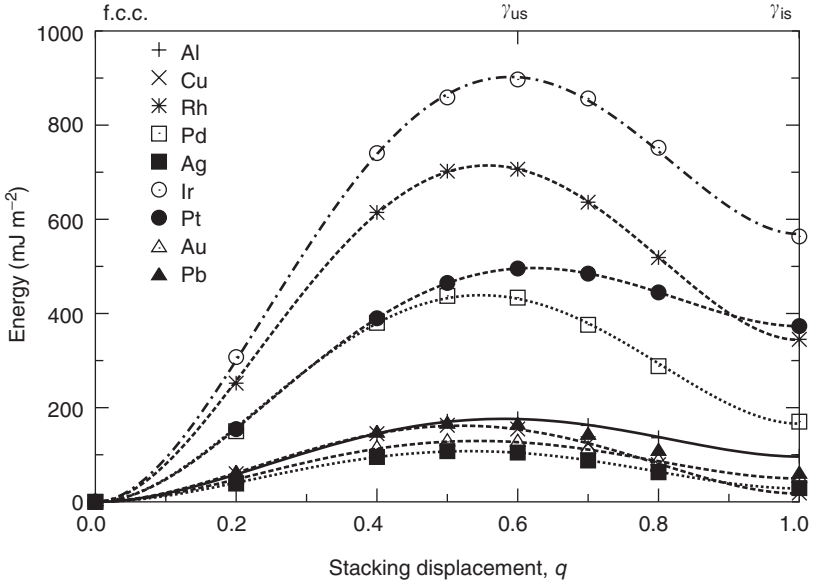

Figure 3 Stacking fault energy as a function of the parameter q in [16] for the elemental f.c.c. metals, as determined by the NRL-TB method. The labels γ_{us} and γ_{is} indicate the positions of the unstable and intrinsic stacking faults, respectively, while the f.c.c. label on the left vertical axis indicates the position of the ground-state bulk structure. (Mehl MJ, Papaconstantopoulos DA, Kioussis N, and Herbranson M (2000) *Physical Review B* 61: 4894.)

some materials, larger errors as for the L_1, and W_2 modes in silicon, and the P and N modes in niobium have been found. This issue has been addressed in a recent paper on Nb, where by augmenting the first-principles database by including the energies at displacement of 0.005 lattice coordinates for the high symmetry points P and N, the overall fit of the

phonon spectrum has been drastically improved. **Figures 4** and **5** show the phonon dispersion curves of Si and Ge that indicate a good agreement with the measured spectra.

Point Defects

Point defects in the semiconductors Si and Ge have been calculated. Point defects are a major source of disorder in semiconductors, since they are thermodynamically favored to occur at finite concentrations and temperatures. Because they are far more mobile than perfectly bonded atoms, they dominate

Table 6 Formation energies E_f (ideal) and relaxation energies ΔE_f (relaxed), in eV, for point defects computed using the TB model and comparison to DFT/LDA results

Since the structure of the ideal split interstitial is not uniquely defined, the energy listed under ideal is actually the relaxed formation energy.

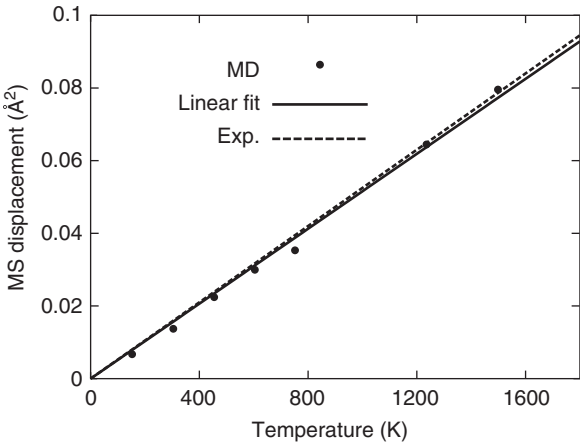

Figure 6 Mean-squared displacement of atoms in diamond-structured silicon as a function of temperature, as determined by TBMD. The dots represent the TBMD data, and the lines are linear (solid) and higher-order representations of the experimental data. (From Batterman BW and Chipman DR (1962) *Physical Review* 127: 690.)

diffusion. The formation energy of such defects strongly influences their concentrations and is, therefore, an important material property.

Table 6 lists the formation energies of three interstitial configurations: the tetrahedral, hexagonal, and 110 split, for Si and Ge. These defect energies were computed using a cubic supercell at the equilibrium lattice constant with 216 atoms, sampling the Brillouin zone at the Γ point. The relaxed configurations were obtained by a conjugate-gradient algorithm using as a criterion the force on each atom to be less than $3\,\mathrm{meVA}^{-1}$. The formation and relaxation energies of all three interstitial configurations are within 10% of the range of LDA calculations for Si but not as good for Ge. On the other hand, the relaxed geometries show more serious discrepancies from *ab initio* results.

Finite Temperature Properties from Molecular Dynamics

The TB method described above can be used with the NRL-TB molecular dynamics (TBMD) package developed by Kirchhoff *et al.* to determine thermodynamic properties. For example, the TBMD package can be used to describe computed mean square displacements, and pair correlation functions as a function of temperature, as well as thermal expansion, in silicon, germanium, and gold. It is also possible to extract phonon-dispersion curves from the velocity autocorrelation function determined in an MD simulation.

As an example of the power of the method, one can describe the calculation of the mean-squared displacement of diamond structure silicon as a function of temperature. The calculation used a 512-atom unit cell, evolving at constant energy with fixed initial kinetic energy for 2000 time steps of length 2.0 fs. As seen in **Figure 6**, results are compared with the experimentally determined values, computed from the experimental measurements of the temperature dependence of broadening of the X-ray diffraction peak. The agreement is excellent.

Very recently, de Silva and co-workers used the NRL-TB parameters for Au to present a very interesting simulation of the formation, evolution, and breaking of Au nanowires.

Multicomponent Systems

The above work was confined to single-component systems. The method is extendable to systems with more than one atomic species by making two modifications. First, one adds additional terms to the onsite energies [4] which couple the density from atoms of type *i* to atoms of type *j*. Second, one notes that the SK parameters $ps\sigma$, $ds\sigma$, $dp\sigma$, and $dp\pi$, which in the single-atom case are equivalent (within a sign) to $sp\sigma$, $sd\sigma$, $pd\sigma$, and $pd\pi$, respectively, are now independent parameters. These complications raise the total number of parameters from 93 in the single-atom case, to 330 for two-atom type systems.

This method has been applied to several compounds, including Nb–C, Pd–H, Fe–Al, Pt–O, and Cu–Au. For Cu–Au, the energy of a variety of structures was computed, and it was found that the expected ordered phases (the $L1_2$, Cu_3Au, and $L1_0$ CuAu) were stable, while other structures were not. However, the advantage of the TB model is that one can compare to structures which are not found experimentally, allowing one to explore configurations that might occur locally in an alloy but which do not form long-range ordered states. To check the correctness of the Cu–Au parameters in this case, it is compared to the cluster-expansion and first-principles

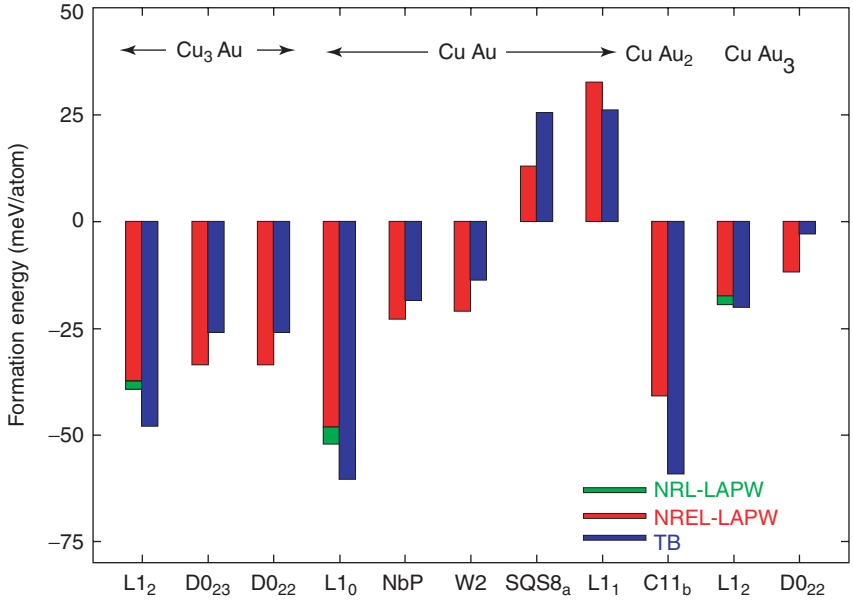

Figure 7 Formation energy of several ordered phases in the Cu_xAu_{1-x} system, calculated using the TB parameters (blue bars), and compared to first-principles calculations performed by Ozoliņš *et al.* (red bars). (The structure notation is from Ozoliņš V, Wolverton C, and Zunger A (1998) *Physical Review B* 57: 6427.) On this scale, the cluster-expansion energies are indistinguishable from the corresponding LAPW results. For comparison, the first-principles LAPW results (green bars), which were used in the Cu–Au TB fitting process are also plotted.

calculations of Ozoliņš *et al*. **Figure 7** shows formation energies computed for several ordered phases in the Cu_xAu_{1-x} system, and compares them to the energies obtained by Ozoliņš *et al*. It is found that the agreement is excellent.

Time-Resolved Optical Spectroscopies

B Deveaud, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Introduction

Spectroscopy basically consists in retrieving information on any system through the use of optical information as a function of wavelength. The examples are countless, and the field is of major importance. For example, the structure of the hydrogen atom has been decoded through the sequence of absorption lines known as the Balmer series. Optical spectroscopy of solids is known to have provided invaluable information over the years, however, when it comes to dynamical properties, one faces right away the challenge that the typical timescales in solids can be incredibly short: 100 fs is a time that cannot be considered as a limit but rather as typical of a wide range of processes. Therefore, the development of ultrafast spectroscopic technique.

Ultrafast optical spectroscopy is particularly useful when we try to obtain information on very short timescales, where other techniques cannot reach the necessary time resolution. The very high frequency of light, 5×10^{14} Hz in the visible range, indeed allows nowadays to reach time limits of the order of a few cycles of the light field only. It is even anticipated that the reduction of the laser wavelength toward X-rays, will allow breaking the barrier of the femtosecond, and therefore entering the attosecond regime. We will not describe here the different techniques which allow to produce ultrashort light pulses, the reader only needs to know that convenient means exist that can produce pulses as short as 5 fs. Once we have such pulses at our disposal, spectroscopic techniques will allow us to probe the properties of materials with a time resolution basically given by the pulse length. Basically the spectroscopy will try to probe all properties of interest in the material, trying for example to get information on the dynamics of the distribution function of charge carriers, or of any quasiparticle in the system.

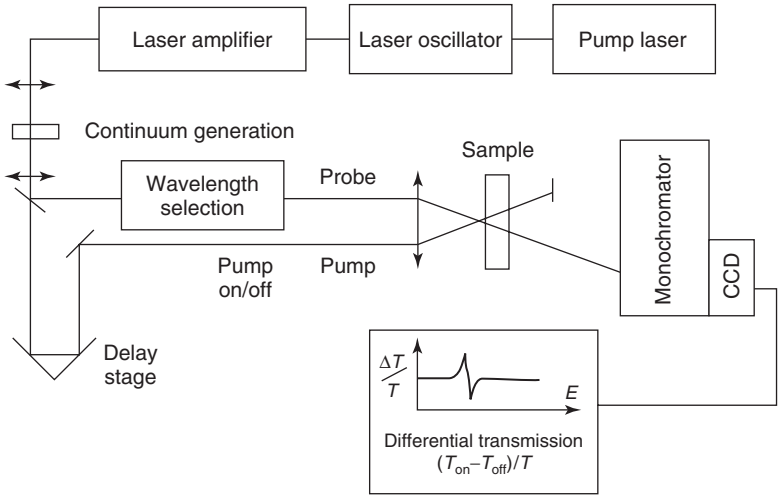

Figure 1 Schematic arrangement of a P&P experiment. A titanium sapphire laser oscillator usually creates short pulses. These pulses might be used directly to perform the experiment, leading to a measurement bandwidth limited by the Fourier transform-limited width of the pulses. It is often useful to create a larger bandwidth by focusing an intense laser pulse onto a dielectric medium. This however necessitates the use of a laser amplifier to obtain large enough pulse energy. The pump pulse is properly filtered to provide the required excitation energy and focused on the sample. The broad and less intense probe pulse is delayed by a delay stage and focused at the center of the pump spot. The changes in transmission are then recorded on the probe beam, and are usually very small so that differential techniques have to be used. The plotted quantity is usually the difference probe signal with and without the pump pulse.

Two techniques are classified along two main categories, the linear techniques, which rely on the probing of the linear response of the system, and the nonlinear techniques, which specifically aim at the probing of the nonlinear response of a given system. Most examples are taken from studies in the field of semiconductors, although the techniques may clearly be applied to all optically active materials, which basically cover more or less any kind of material system.

Linear Techniques

Absorption and Reflectivity

The first technique to be used in the field of ultrafast spectroscopy has been the pump and probe technique (P&P). This technique is indeed applicable as soon as you have a short light pulse. The idea behind the words being that you send a short light pulse on a sample, thereby modifying its properties. The changes in the properties of the system are probed in the time domain by a second pulse (the probe), time delayed with respect to the first one simply by a change in the path of this second beam. A schematic arrangement of a typical P&P setup is displayed in **Figure 1**.

Two basic arrangements may be employed; in the first one, the absorption changes are probed as a function of time after the arrival of the first pump pulse. In the second arrangement, the changes in reflectivity are measured. It is easy to show that the two types of changes are very directly linked to one another, however, the interpretation of the absorption changes being, in general, easier. The absorption P&P technique will then be preferred when usable, that is to say when the absorption of the sample is not too large. This has been applied very effectively to the understanding of semiconductor nanostructures.

An important aspect of such techniques is that, even if the pump pulse has to be as broad spectrally as imposed by the Fourier transformation of the time variation of the pulse (a 100 fs Gaussian pulse has to be 800 GHz broad), it is usually very important that absorption can be probed over a much larger spectral range, and techniques to obtain very broad pulses (so-called "white light continuum") have been developed over the years. An example of P&P absorption in a quantum well, showing the appearance of a spectral hole is shown in **Figure 2.** The spectral hole appears because of a reduction of the absorption at the energy of the exciting pulse, a large fraction of the available final states being occupied. The absorption is reduced, at the energy of the exciting pulse, over typical times corresponding to the relaxation of

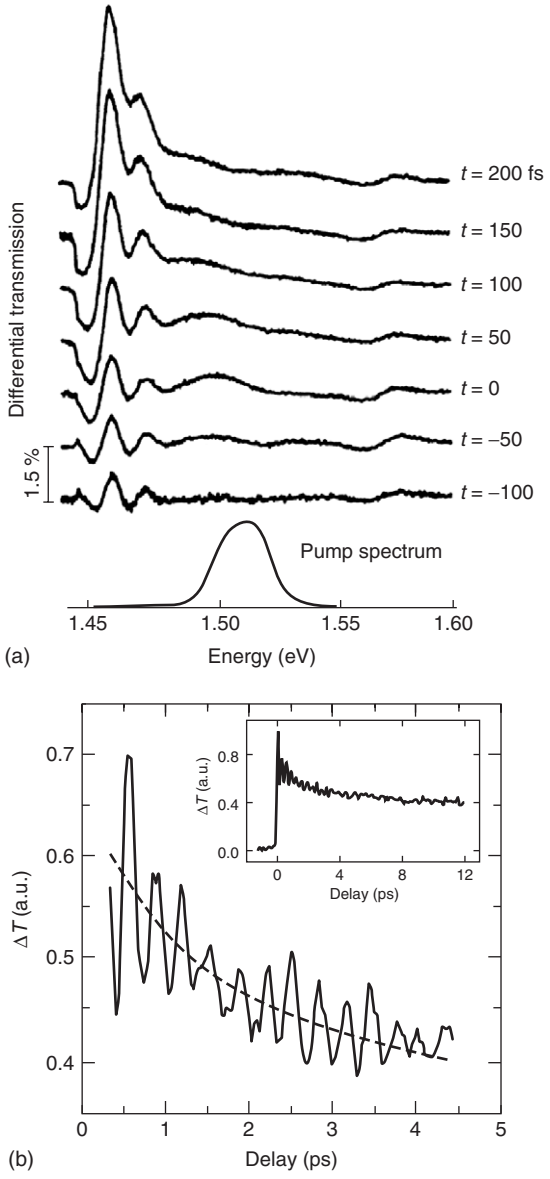

Figure 2 (a) P&P absorption spectrum of a GaAs multiquantum well system for a negligible delay between pump and probe. A clear spectral hole is observed at the energy position of the pump, which disappears with a typical time corresponding to the electron dephasing (less than 100 fs in the present case). The strong oscillations around 1.45 eV correspond to the effects of Coulomb correlations at the exciton energy. (Reproduced with permission from Knox W, Hirlimann C, Miller DAB, Shah J, Chemla DS *et al.* (1986) Femtosecond excitation of nonthermal carrier populations in GaAs quantum wells. *Physical Review Letters* 56: 1191–1193.) (b) P&P absorption signal of F centers in KBr, showing directly the oscillations of the electron wave packet after a short pulse excitation. The F center, sometimes called color center because it gives rise to the color of the crystal, is linked with an anion vacancy occupied by a single electron. The period of the oscillations is obtained from the Fourier power spectrum of the signal and corresponds to 0.33 ps. The inset shows the P&P signal over a larger time range. (Reproduced with permission from Nisoli M, DeSilvestri S, Svelto O, Scholz R, Fanciulli R, *et al.* (1996) Single-electron subpicosecond coherent dynamics in KBr F centers. *Physical Review Letters* 77: 3463–3466.)

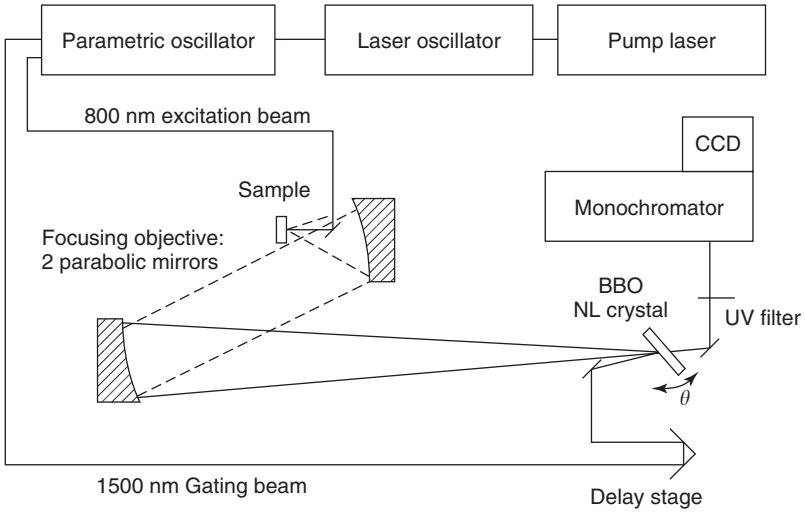

Figure 3 Schematic arrangement of an upconversion luminescence experiment. Short pulses are usually created by a titanium sapphire laser oscillator. These pulses might be used directly to perform the experiment in the case of nonresonant experiment. In the case of resonant excitation of a system, the upconverted signal can only be discriminated when the gating laser pulse is at a different energy. This can be obtained by using a parametric oscillator. The pulse from the oscillator is used to excite the sample. The luminescence is collected by reflective optics to avoid dispersion in the objective (dispersion would be a major problem in luminescence due to the very large bandwidth of the signals to be studied) and focused onto a nonlinear crystal tuned at the proper angle for phase matching with the gating pulse. This gating pulse, coming out from the parametric oscillator, is properly delayed and also focused on the nonlinear crystal. Proper phase matching allows the generation of photon addition: one photon coming from the luminescence signal, the other one from the gating beam. Thus the process is only efficient during the presence of the gating pulse, leading to a limit time resolution simply corresponding to the width of the gating pulse. After the nonlinear crystal, proper filtering and standard detection techniques may be used to only record the upconverted photons that are produced in a different wavelength range to the other signals.

the photoexcited carriers (here, less than 100 fs). Further, the changes in the electron and hole distributions can be monitored very directly, with one main difficulty due to the combined presence of electrons and holes excited in the system.

Luminescence

Another way to probe the dynamics of charge carrier changes, especially in semiconductors, is to probe the properties of the light emitted by the sample. Once again the emitted spectrum will be an image of the changes in the distribution functions of electrons and holes. Luminescence techniques have advantages and drawbacks compared to P&P. The main difficulty being that the photon detector must possess the appropriate time resolution (in P&P, the pulse itself detects the changes, and therefore has the appropriate duration). On the other hand, luminescence is a background free technique, which allows probing very weak changes usually not accessible to P&P where the signal sits on a preexisting background.

A typical femtosecond luminescence setup is sketched in **Figure 3**. The reader will be able to recognize the delay stage already present in the P&P technique. The main difference is that the pump here does not excite the sample but is used to open an optical gate pulse; this pulse is now called the gate pulse (the gate sits between two crossed polarizers). Two main kinds of optical gates are used: the first one historically was a Kerr gate, where the polarization of the signal is changed during the presence of

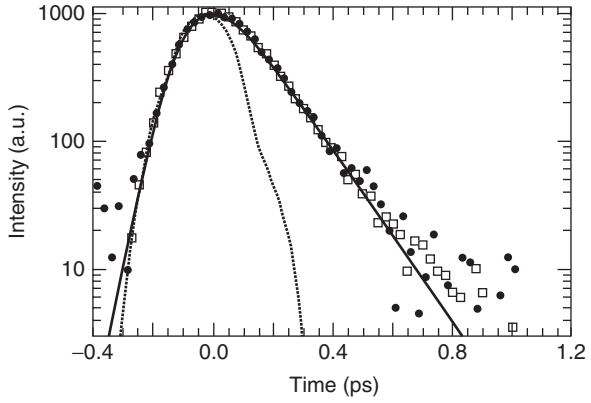

Figure 4 Upconverted luminescence signal form a diacetylene polymer chain. The chain is excited nonresonantly at 400 nm. The signal decay is very fast because of nonradiative transfer of the excitons into a triplet state (within less than 100 fs in the present case). The dotted line corresponds to the upconversion of the laser pulse, giving the time resolution of the experiment (here 70 fs) as well as a precise determination of the zero time delay. (Reproduced with permission from Haacke S, Berrehar J, Lapersonne-Meyer C, and Schott M (1999) Dynamics of singlet excitons in 1D conjugated polydiacetylene chains: a femtosecond fluorescence study. *Chemical Physics Letters* 308(5–6): 363–368.)

the gate, allowing opening this gate for a very short time only. This has the advantage of being a broadband technique (broadband meaning that the device is basically insensitive to the wavelength of the luminescence photons), but has the drawback of needing a very large pulse power for the polarization switching of the Kerr cell. The most efficient technique nowadays is the use of a nonlinear crystal, which is tuned so as to produce sum frequency photons, adding one photon from the signal and one from the gating pulse. The sum-frequency signal is only generated during the presence of the gating

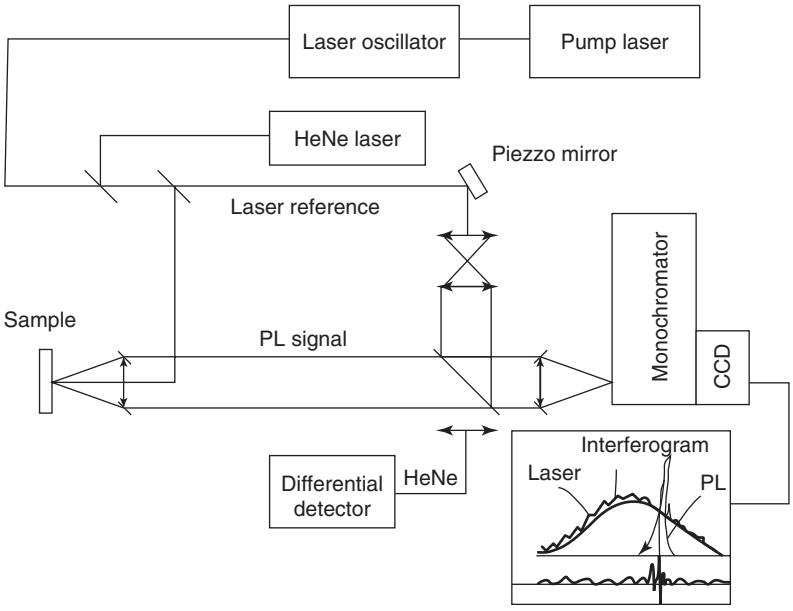

Figure 5 Schematic arrangement of a spectral interferometry experiment. Short pulses are usually created by a titanium sapphire laser oscillator. The pulses are then split into two parts within a Mach Zehnder interferometer: one part is used to excite the luminescence of the sample and the second part is used as a reference pulse. The luminescence and the reference beam are recombined at the other end of the interferometer and focused onto the entrance slit of a monochromator. One therefore observes, in the case the luminescence signal keeps some coherence with the exciting pulse, interference fringes between the luminescence signal and the reference pulse. Of course the total signal is a sum of the interference term and the two separate signals that have to be subtracted to keep only the interesting term. Being fully coherent, the interference spectrum is simply the Fourier transform of the time evolution of the coherent luminescence signal. Therefore, a reverse Fourier transform allows recovering the time behavior from the spectral behavior. Such a setup necessitates absolute stability within better than $\lambda/10$, which cannot be obtained easily with a cryostat in one of the arms of the interferometer. The whole interferometer is therefore actively stabilized through the use of a control beam coming from a HeNe laser driving a piezo mirror.

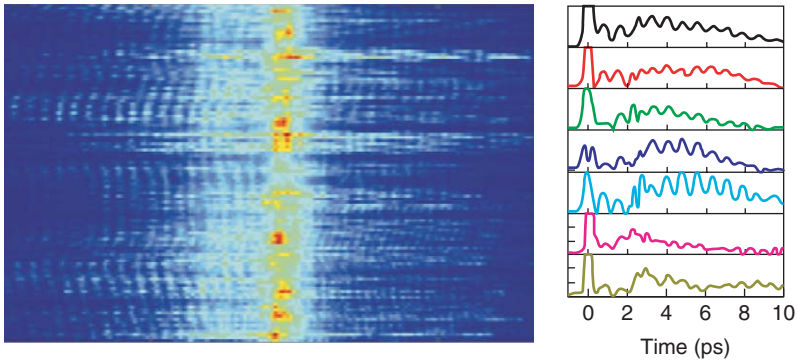

Figure 6 Spectral interferogram obtained for excitons in a GaAs quantum well. The horizontal axis corresponds to the wavelength, and the vertical axis to the angle of emission. Indeed as the signal is coherent and linked with disorder of the interfaces of the quantum well, it does give rise to speckles. The time behavior, and therefore the interferogram are different for each speckle as evidenced through the results of Fourier transformation. (Reproduced with permission from Hayes G, Deveaud B, Savona V, and Haacke S (2000) Speckle-averaged resonant Rayleigh scattering from quantum-well excitons. *Physical Review B* 62(11): 6952–6955.)

pulse, and is spectrally well separated from the luminescence photons. Once again, the time resolution of the experiment is given by the length of the gate. One difficulty, in femtosecond luminescence by upconversion, is that the wavelength of the signal and that of the pump may be very different. It is therefore very important to avoid any dispersion on the path of the signal. Reflective optics will be preferred to the simpler refractive systems, which may easily distort the timing of the signal by as much as a picosecond.

A typical luminescence signal is shown in **Figure 4** showing that, indeed, the time resolution of the experiment can be limited by the pulsewidth down to the shortest times. In this case, the short luminescence signal is just a measure of the very short lifetime of the excited state of the polymer.

Spectral Interferometry

Spectral interferometry is a heterodyne detection technique. It allows obtaining spectral and temporal information on the coherent dynamics of an optically excited system. The schematics of the experiment are displayed in **Figure 5** and shows that the properties of the signal are obtained by correlating these with the exciting beam in a Mach–Zehnder-type interferometer. The two overlapping beams are spectrally filtered in a monochromator, which Fourier transforms the time correlation into spectral oscillations (see **Figure 6**). The time behavior of the coherent part of the signal can be recovered by taking the Fourier transform of the spectral interference figure. This technique is unique in the sense that it probes the coherence of the system through a fully linear technique. It has however a major drawback which is that the interferometer has to be stabilized within much better than the wavelength of light, and that this is a large size interferometer usually incorporating a cryostat. The stabilization scheme is therefore much more difficult than for usual interferometers.

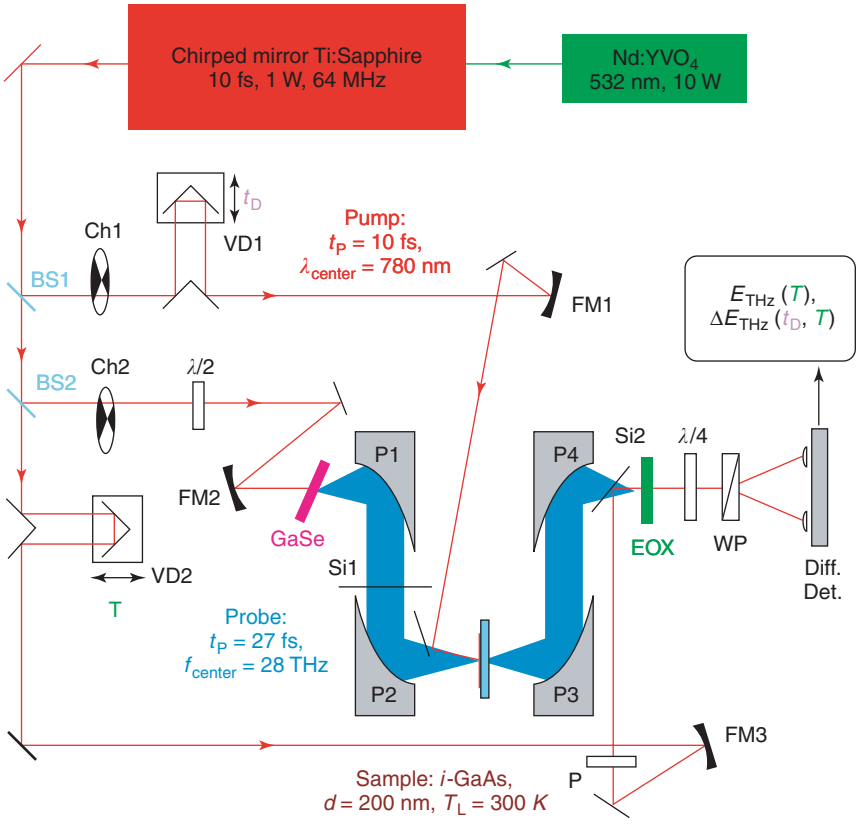

Figure 7 Schematic arrangement of a teraHertz P&P experiment. In the optimal setup, 10 fs pulses are generated by an optimized oscillator. Focusing of such short pulses onto a $GaSe_2$ crystal allows producing a single-cycle teraHertz pulse covering a large frequency range, basically extending from 1 up to 40 THz. The principle of the experiment is similar to standard P&P, which means that a pump pulse excites the sample, which is then probed after some delay by the teraHertz pulse. The detection of the changes occurring in the teraHertz pulse is performed via the use of a gating pulse onto a photoconductive switch. This has the major advantage of allowing recording the changes in the electric field of the teraHertz pulse, rather than its intensity. As a result, one may access both the changes in the real and imaginary parts of the susceptibility of the sample after the pump has hit the sample. (Courtesy A Leitenstorfer, with the permission of the author.)

TeraHertz Probing

One emerging field in ultrafast spectroscopy is very similar to P&P schemes, but utilizes as a probe teraHertz pulses. Such techniques require still rather complex setups, but are very promising in terms of the amount of information one can get. One possible design of the experiment can be found in **Figure 7**, and one can readily appreciate this complexity. This is basically a P&P system, the probe being generated by proper focusing of a laser beam onto a GaSe crystal. The transmitted teraHertz probe needs however another gate pulse in order to time resolve the variations of the probe pulse. Basically, on an experimental side, this adds up the complexity of the usual P&P techniques and of upconversion luminescence. As a result, it is possible to obtain both the real and the imaginary part of the dielectric constant as a function of time. Such a very interesting result is depicted on **Figure 8**, which evidences the build-up of screening in an optically excited semiconductor.

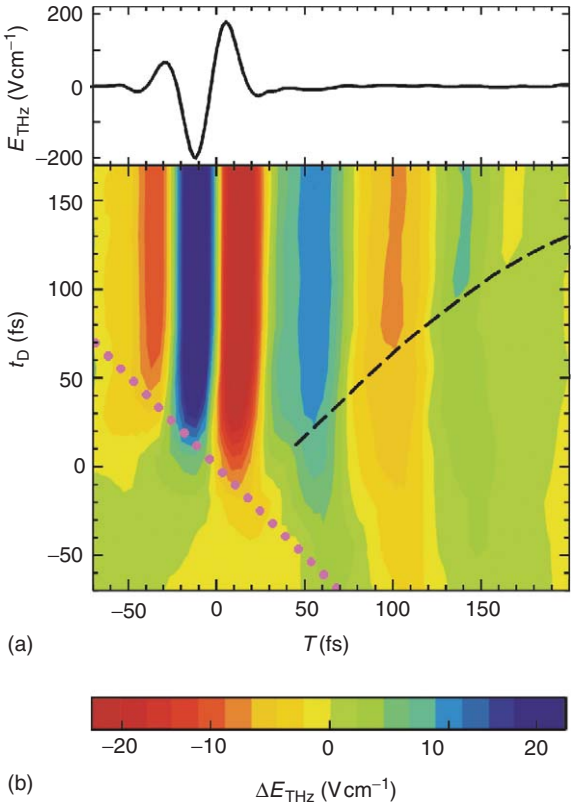

Figure 8 TeraHertz pulse changes after traveling through a sample of GaAs excited with a strong interband pulse creating a high-density plasma. Evidence for the build-up of manybody interactions is obtained from such an experiment. This is a two-time chart, T axis displays the changes in the electric field in the teraHertz pulse as it passes, the t_D axis corresponding to the delay between the arrival of the interband pulse and the teraHertz pulse on the sample. The color code corresponds to the electric field in the teraHertz pulse. (Reproduced with permission from Huber R, Tauser F, Brodschelm A, Bichler M, Abstreiter G *et al.* (2001) How many-particle interactions develop after ultrafast excitation of an electron-hole plasma. *Nature* 414(6861): 286–289.)

Nonlinear Techniques

Although P&P techniques rely on the nonlinearities of the system to obtain some signal, they are not primarily interested in getting at a measure of these nonlinearities. Nonlinear properties of optically active materials can also be used to probe the dynamics of the system, as well as to test their own dynamics. The most usually employed technique to this aim is four-wave mixing which allows a wide range of experimental configurations, each probing specific aspects of the dynamics of the system, all being labeled under the generic term "four-wave mixing" because the description of the nonlinearities require at least four photon fields. In principle, four-wave mixing relies on the creation of a polarization grating in the material with the first two pulses, and then on the diffraction of a third beam on this grating, giving rise to the fourth, wave mixing signal, highly sensitive to the nonlinearities of the system.

Two-Beam Self Diffraction

In the two-beam self diffraction configuration, only two incident beams arrive on the sample (see **Figure 9**). The first beam, with a direction corresponding to the wave vector $\boldsymbol{k}_1$, creates a polarization in the sample. The second beam, arriving after some delay τ with a direction corresponding to the wave vector $\boldsymbol{k}_2$, first generates a grating by interaction with the polarization left from the first pulse, and simultaneously self diffracts on this grating it has just created. This technique is a very simple way to get information about the coherence dynamics of the system.

The nonlinear signal, detected in the $2\boldsymbol{k}_2-\boldsymbol{k}_1$ direction does not need to be temporally resolved. In simple cases, it may simply be detected by a slow detector, leading to the signal behavior depicted in the inset of **Figure 9**. The decay of the nonlinear signal corresponds directly to the dephasing of the coherence of the polarization created by the first pulse, as the grating will not be generated if the initial polarization has been dephased. More complex systems may lead to more complex behaviors such as for example a signal at negative times, that is, when the probe arrives before the pump has even hit the sample. The study of such unexpected behavior has brought major improvements in our understanding of the nonlinearities in semiconductors.

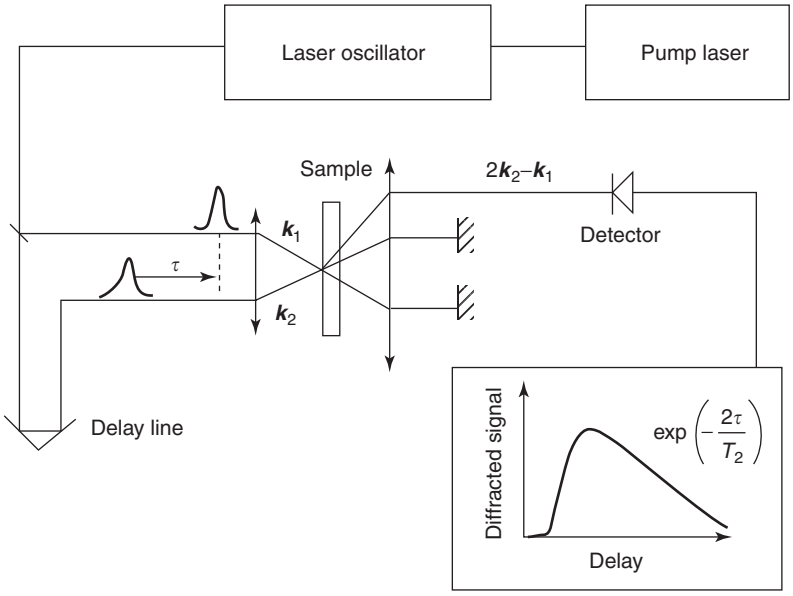

Figure 9 Schematic arrangement of a two-pulse four-wave mixing experiment (FWM). Short pulses are usually created by a titanium sapphire laser oscillator. These pulses may be used directly to perform the experiment, leading to a measurement bandwidth limited by the Fourier transform limited width of the pulses. Often, a better spectral resolution is needed, which can be obtained by pulse-shaping technique (basically filtering of the pulse) at the expense of the time resolution, as imposed by the Fourier transform of the spectrum. The first pulse of wave vector $\boldsymbol{k}_1$ is focused on the sample. The second pulse of wave vector $\boldsymbol{k}_2$ is delayed by a delay stage and focused together with the first pulse. The changes in the diffracted signal intensity, in the direction $2\boldsymbol{k}_2-\boldsymbol{k}_1$, are recorded as a function of the delay between the two pulses. The signal usually shows a clear asymmetry to long delays, the decay being exponential with a decay constant corresponding to half the dephasing time of the polarization excited in the sample.

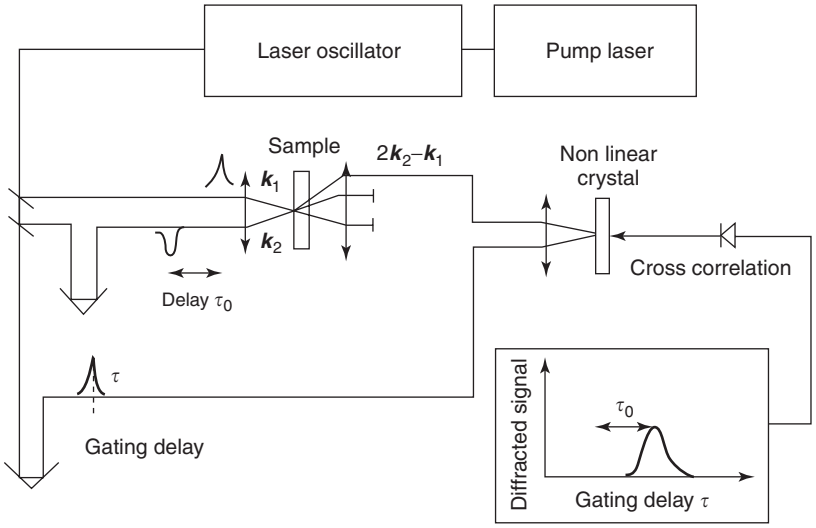

Figure 10 In the case of a resonance that is inhomogeneously broadened, the diffracted signal appears in the form of a photon echo. The diffracted pulse is emitted by the sample after the second pulse, with a delay corresponding to the delay between the two interfering pulses. Once again the intensity decays with the dephasing of the polarization, however, the decay constant is now a factor 1/4 of the dephasing time. The discrimination between homogeneous and inhomogeneous dephasing may be obtained from the time resolution of the diffracted signal, which corresponds to the addition of a gate similar to that used in upconversion luminescence.

Photon Echo

If the system would be homogeneously broadened, the integrated intensity of the four-wave-mixing signal would directly give some information on the coherence time of the polarization in the system. If, on the contrary, the system is inhomogeneously broadened, the nonlinear signal is delayed after the arrival of the second pulse. Basically, this diffracted

signal appears at a delay equal to the time separation between the first two pulses. This is a direct signature of the inhomogeneous nature of the system under study, which cannot be observed directly with the previous setup. Such an echo signal can easily be recorded by time resolving the diffracted signal. In such a case, one gets both the information about the broadening of the system, and also on the dephasing because the signal intensity decays with a characteristic time given by the coherence properties of the material. This technique gives of course more information on the system but necessitates an optical gate similar to the one described in the paragraph devoted to ultrafast luminescence (see also **Figure 10**).

Three-Beam Four-Wave Mixing

In the three-beam configuration, the two beams that create the grating and the probe beam all have different directions $\boldsymbol{k}_1$, $\boldsymbol{k}_2$, and $\boldsymbol{k}_3$, which will generate a phase conjugate signal in the direction $\boldsymbol{k}_1 + \boldsymbol{k}_2 - \boldsymbol{k}_3$. This configuration is very rich as it allows playing with any combination of delays between the different pulses. For example, if the first two pulses arrive at the same time, and the third one is delayed the situation is very similar to the self-diffraction technique, with a clear asymmetry in the process that allows distinguishing in principle homogeneous dephasing from inhomogeneous dephasing. The other configurations are very useful as, depending on the arrival sequence of the pulses on the sample, dephasing events of the ground state or of the excited state of the system can be probed selectively.

Measurement of the Pulse

Most of the techniques that have been described up to now implicitly assume that the ultrashort pulses are either perfectly characterized, or at least well behaved. One of the advantages of the Ti:Sapphire laser is that it is indeed reasonable to assume in most cases that the pulse is indeed close to a transform-limited pulse (specially in the case of a pulse duration of the order of 100 fs, in the near infrared region). When one wants to use more exotic pulses, exotic in the sense that they might be in a different wavelength window, or that they have a shorter duration, things become more complex. In particular, it becomes very difficult to keep a constant phase of the different Fourier components of the pulse over the entire wavelength range. A 10 fs pulse extends basically from 700 up to 900 nm. It becomes then necessary to characterize the pulse, the difficulty being that simple characterization schemes would need to use a pulse much shorter than the pulse to be characterized, which obviously cannot be the case anymore.

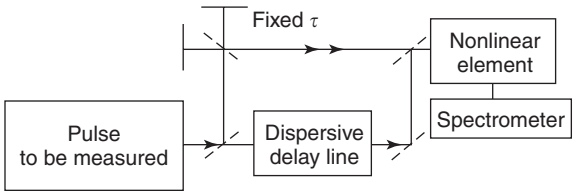

Figure 11 Sketch of the pulse measurement techniques called SPIDER or FROG. The pulse to be measured is split into two parts in a Mach Zehnder interferometer. One of the split pulses is delayed with respect to the other, and they are recombined at the surface of a nonlinear crystal. A monochromator and CCD allow recording the spectral interferogram, which allows retrieving the full information of the pulse via proper computer adjustment of the observed interferogram.

New techniques have been devised which have been given strange acronyms such as FROG (for Frequency Resolved Optical Gating) or SPIDER for (Spectral-Phase Interferometry for Direct Electric-field Reconstruction). They are somewhat based on the same principle, which is sketched in **Figure 11**, which consist in using the pulse itself as a reference for the measurement. This kind of technique is well known in the case of longer pulses, where the pulse is easier transform limited, and where the length of the pulse is the most interesting information one is trying to retrieve. Then the pulse is split into two parts, traveling different length, and recombined in front of a nonlinear crystal. The doubling efficiency is measured as a function of delay, giving rise to a symmetrical figure, the autocorrelation trace, directly related to the pulse length for the case of symmetrical pulse. In the case where the pulse would not be symmetrical, the measurement of the intensity of the frequency-doubled light is not sufficient. Basically what one needs to perform is a spectral interferometric measurement, which gives much more information than only the intensity. However, even if the spectral information contains much more than the integrated intensity, this information is not enough to retrieve directly the whole electric field, because it is obtained through autocorrelation of the pulse. The full information can however be retrieved through proper adjustment of the observed spectra, which is nowadays done through self-adjusting computing techniques.

Transistors

Y Hirayama, NTT Basic Research Laboratories, Kanagawa, Japan

Introduction

A transistor is a three-terminal device, where the voltage or current applied to one terminal controls the current flow between the other two terminals. Transistors are designed to have current or voltage gain, which means a drivability of multistep transistor circuits. Submicron lithography and self-alignment have been used to improve the high-frequency operation of transistors. Transistors are key devices in cutting-edge semiconductor integrated circuits.

There are mainly two types of transistors, bipolar and field effect transistors. Transistors have been made on many systems, mainly semiconductor systems, including Si, SiGe, and III–V semiconductors. Since this encyclopedia concerns condensed matter physics, the basic principles of transistor operation and the fundamental performance of transistors, with emphasis on III–V semiconductor transistors, are discussed. Although the basic principles can be applied to many different systems, detailed discussions of transistor structures, transistor materials, processing, and circuit designs are omitted due to space constraints. (See "Further reading" section for details.)

Transistors, that is, three-terminal control devices, are important not only for electrical applications but also for physics studies. Several transistor devices often used in the study of transport physics at low temperatures are also discussed in the second half of this article.

Bipolar and Hetero-Bipolar Transistors

The principal operation of the (hetero) bipolar transistor is schematically shown in **Figure 1**. Although a bipolar transistor with *n*-type emitter, *p*-type base, and *n*-type collector (*n–p–n* transistor) is assumed in this figure, similar parameters are applicable to a

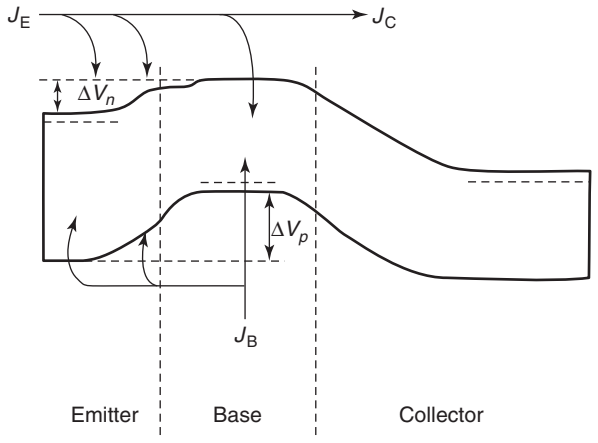

Figure 1 Schematic band diagram of a HBT with graded emitter-base junction. The schematic current flow, which determines the transistor operation, is also shown.

p–n–p transistor. In the bipolar transistor, the most important factor determining transistor operation is current gain, that is, the ratio between J_C and J_B, where J_C and J_B are corrector current and base current, respectively. When this ratio becomes larger than unity, the transistor has a gain. The current injected from the emitter passes through the base and reaches the collector. When the diffusion constant of electrons in the *p*-type base is small or the base layer is thick, the probability of electron transmission to the collector decreases. Some amount of the base current also diffuses to the emitter. Calculating all these factors results in the current gain h_{fe} determined by the emitter injection efficiency:

$$h_{fe} = \frac{n_E}{p_B}\frac{v_e}{v_h}\frac{N_{CB}}{N_{CE}}\frac{N_{VB}}{N_{VE}}\exp\left(\frac{\Delta E_g}{KT}\right) \qquad [1]$$

where n_E and p_B are, respectively, the emitter and base doping concentration, v_e (v_h) is electron (hole) effective velocity toward the collector (toward the emitter) at the corrector-side (emitter-side) base edge, and, N_{CB} and N_{CE} (N_{VB} and N_{VE}) are densities of states in the conduction (valence) band for base and emitter, respectively. $\Delta E_g = E_{ge} - E_{gb}$ is the bandgap difference between emitter and base semiconductors.

For a thick emitter, v_h is determined by $v_h = D_h/L_E$, where D_h is the hole diffusivity in the emitter region and $L_E = \sqrt{D_h \tau_E}$ is the diffusion length. τ_E is the recombination lifetime in the emitter region. In the case of the thin base with $W_B \ll L_B$, v_e is represented as

$$v_e = D_n/(L_B \sinh(W_B/L_B)) = D_n/W_B$$

where D_n, L_B, and W_B are the electron diffusivity in the base region, electron diffusion length in the base, and the base thickness, respectively. In this situation,

$$h_{fe} = \frac{n_E}{p_B}\frac{L_E}{W_B}\frac{D_n}{D_h}\frac{N_{CB}}{N_{CE}}\frac{N_{VB}}{N_{VE}}\exp\left(\frac{\Delta E_g}{kT}\right) \qquad [2]$$

In the case of a homojunction bipolar transistor, such as an Si bipolar transistor, $\Delta E_g = 0$, and h_{fe} is mainly determined by $n_E/p_B/W_B$. In order to maintain a suitable high value of h_{fe}, $n_E/p_B \sim 100$–1000 is typically chosen. The hole density of the base, p_B, usually becomes 10^{17}–$10^{18}\,cm^{-3}$ for the emitter electron density, n_E, of 10^{20}–$10^{21}\,cm^{-3}$. The current gain also increases with decreasing base layer thickness. However, the base resistance increases with decreasing p_B and W_B, so that there is a limitation to how far these parameters can be decreased in actual transistors. Si bipolar transistors are widely used in high-speed semiconductor circuits, owing to the many improvements in techniques for forming the emitter and base junctions, in isolation methods, and in the degree of self-alignment between the different device regions. Silicon is an indirect bandgap semiconductor and has a long recombination lifetime, so that the situation $W_B \ll L_B$ and a low-base resistance can be achieved even for a small p_B. However, direct bandgap semiconductors, such as GaAs, have a short recombination time, and the high n_E/p_B ratio necessary for the high-current gain is not possible. Therefore, it is difficult to build high-performance homojunction bipolar transistors from III–V semiconductors.

When heterojunctions are used, $\exp(\Delta E_g/kT)$ makes the most important contribution to h_{fe}. Improved transistor performance is expected by combining silicon-based transistors and Si/SiGe heterojunction systems. Furthermore, the large bandgap difference in III–V semiconductors enables one to use direct bandgap semiconductors in heterobipolar transistors (HBTs). This is because the term $\exp(\Delta E_g/kT)$ sufficiently compensates for the small n_E/p_B, and a thin base layer with high-carrier density becomes available. HBTs using many kinds of III–V semiconductor materials have been demonstrated.

At an abrupt heterojunction between different semiconductors, there is a discontinuity in the energy of the conduction-band minima and valence-band maxima. An energy barrier in the conduction band at the emitter–base junction tends to retard the flow of electrons from the emitter to the base. To avoid the barrier in the conduction band, a graded-alloy composition at the emitter–base junction has been used as shown in **Figure 1**. However, it is noteworthy that the barrier at the emitter–base junction is advantageous for high-speed operation because of the higher-energy electron injection from the emitter to the base. Therefore, an optimal design of the graded junction is necessary in actual HBTs.

For HBTs, many kinds of heterostructures have been studied. **Figure 2** shows a comparison of the breakdown electric field of HBTs composed of Si/SiGe, InGaP/GaAs, InP/InGaAs, and GaN/InGaN material systems. The breakdown electric field of nitride-based HBTs is much higher than those reported for HBTs composed of other material systems. Therefore, GaN-based HBTs have recently received much attention as candidates for high-power and high-speed devices in the future. Here, the typical structures and characteristics of HBTs are discussed using GaN-based HBTs as examples. **Figure 3** illustrates the schematic structure of the GaN/InGaN HBTs. In this peculiar device, the graded region is formed between the base and collector to reduce electron scattering at the collector barrier, because the same bandgap material (GaN) is used for both the emitter and corrector. A regrowth InGaN base contact is adopted to decrease the series resistance of the base. Actually, how to make a good contact to a thin base layer is a very important issue for HBTs with a thin base layer, and efforts to resolve this issue are underway for many heterostructure HBTs. The common emitter current–voltage characteristics of GaN/InGaN HBT with a $50\,\mu m \times 30\,\mu m$ emitter area are shown in **Figure 4**. The maximum collector gain exceeds 2000

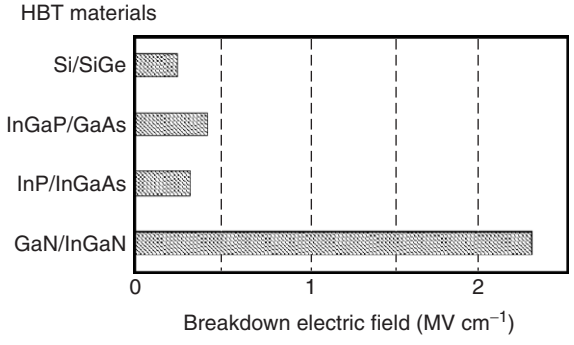

Figure 2 Comparison of breakdown electric field of HBTs composed of various material systems.

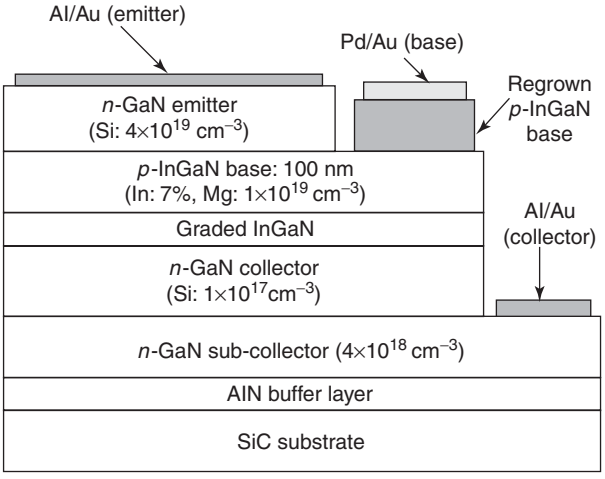

Figure 3 GaN/InGaN HBT structure with a regrown *p*-InGaN extrinsic base layer.

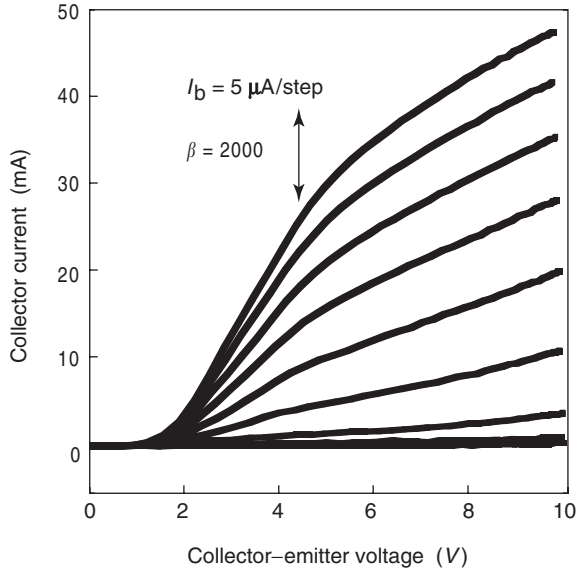

Figure 4 Common-emitter current–voltage characteristics of a GaN/InGaN HBT at room temperature. Base current is 5 μA/step.

in this device. Although this current gain is still less than the maximum gain of 5000 for Si/SiGe systems and 50 000 for InP-based systems, the current gain for GaN-based systems has increased almost two orders of magnitude from the year 2000.

Field Effect Transistors: MISFET, MESFET, and HEMT

Bipolar transistors use both majority and minority carriers in semiconductors. There is, however, another type of transistor, where only the majority carriers are used and their density is controlled by an electric field effect. This type of transistor is called a field effect transistor (FET) and is widely used in many semiconductor systems. Several types of FETs are schematically shown in **Figure 5**. Metal–insulator–controlled semiconductor FETs (MISFETs) are shown in **Figure 5a**. When a positive bias is applied to the gate, conductive electrons start accumulating at the semiconductor–insulator interface. Due to the confinement by the electric field, the accumulated electrons have a two-dimensional (2D) nature. The threshold voltage, V_{th}, where electrons start accumulating, is determined by the semiconductor properties and interface characteristics. The density of accumulated charge, Q, is proportional to the gate bias and is represented as

$$Q = ne = C_g(V_g - V_{th}) \quad [3]$$

where n, e, and C_g are the area density of electrons, electron charge, and capacitance of the gate insulator, respectively. When the bias is applied between the source and drain (V_d), the drain current (I_d) is determined by the carrier density (n) and the mobility of the carrier (μ). In the case of small V_d, where carrier density is constant over the whole device,

$$I_d = \frac{Z}{L}\mu ne V_d \quad [4]$$

where Z and L are the channel width and length of the MISFET. In the case of the MISFET, ne is expressed by eqn [3], then

$$I_d = \frac{Z}{L}\mu C_g(V_g - V_{th})V_d \quad [5]$$

With increasing V_d, the carrier density near the drain edge decreases and finally becomes zero (pinch-off) at around $V_d = V_g - V_{th}$. Further increasing V_d results in an almost constant drain current independent of V_d, because a balance is achieved between the pinch-off of the carrier and the high electric field concentrating in the pinch-off region. Therefore, I_dV_d characteristics of MISFETs, schematically shown in **Figure 6**, are separated into linear and saturated regions. The drain current in the saturated region, I_{ds}, is approximately expressed as

$$I_{ds} = \alpha\frac{Z}{L}\mu C_g(V_g - V_{th})^2 \quad [6]$$

where α is a constant close to unity.

In the case of Si, silicon dioxide (SiO_2) is used as the gate insulator. Therefore, the FET is normally called metal-oxide–semiconductor FETs (MOSFETs). It is also possible to accumulate conductive holes by applying negative bias to the gate. Combining *n*-type

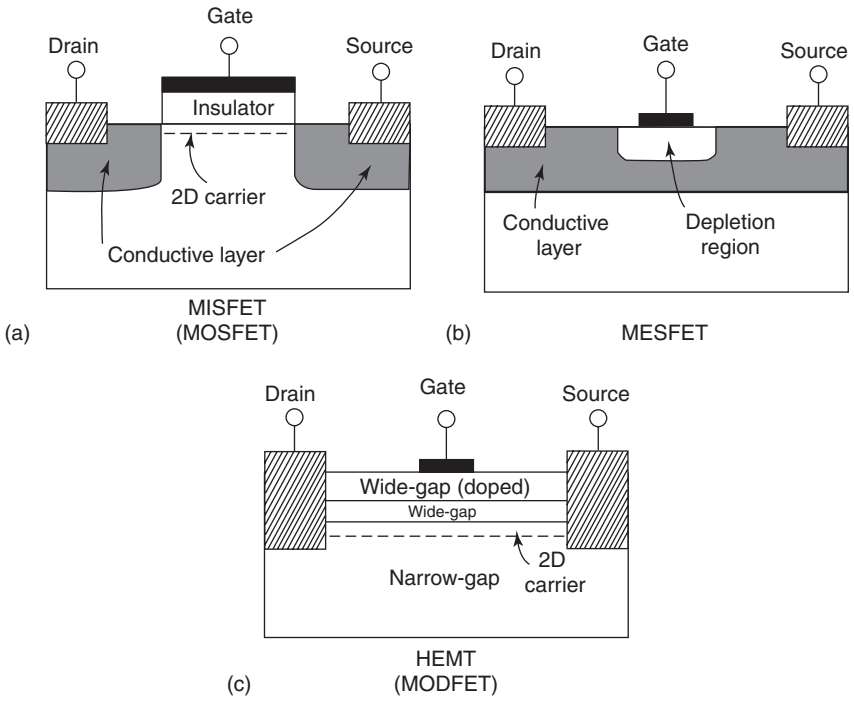

Figure 5 Schematic diagrams of field effect transistors (FETs). (a) MISFET (MOSFET), (b) MESFET, and (c) HEMT (MODFET).

(electron transport) MOSFETs and *p*-type (hole transport) MOSFETs results in complementary MOSFET devices (CMOS devices). The Si MOSFET and CMOS devices are the most important devices in the very large scale integrated circuits used in microprocessors and semiconductor memories.

In MISFET devices, some other combinations of insulators and semiconductor materials are also possible. A good example is the InP MISFET, where electrons can accumulate at the interface between the InP and insulator, such as Al_2O_3. However, the conductive carriers cannot be accumulated at the interface when the density of states of the interface defects is very large, as is the case at insulator–GaAs interface.

To avoid a direct and uncontrollable leakage current between the drain and source, *n*-type (*p*-type) MISFETs are fabricated on *p*-type (*n*-type) or semi-insulating materials. For the purpose of distinguishing these two types of MISFETs, the former is called an inversion-type MISFET and the latter an accumulation-type MISFET. For both types, the gate-induced carriers need to contact the source- and drain-conductive regions (doped regions) so that an overlap between source- (drain-) conductive regions and gate is essential for the FET operation. The self-alignment process allows one to make such an overlap without increasing the capacitance between the gate and source (drain).

Another type of FET is the metal–semiconductor FET (MESFET). **Figure 5b** is a schematic diagram of a MESFET. In this device, conductive carriers are supplied from the 3D doping layer, and the number of conductive carriers is controlled by a depletion region spreading from the Schottky metal gate. The

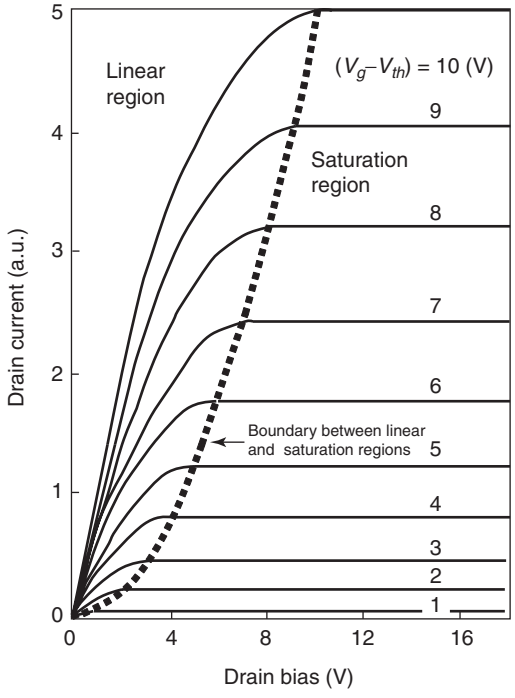

Figure 6 Schematic drain current-drain bias characteristics of a MISFET (MOSFET). Actual value of the drain current depends on device parameters and carrier mobility.

conductive layer thickness is determined by subtracting the depletion region thickness (W_d) from the total thickness of the doping layer. For the *n*-type conducting channel,

$$W_d = \sqrt{\frac{2\varepsilon(V_{bi} - V_g)}{eN_d}} \qquad [7]$$

where V_{bi}, ε, and, N_d are the built-in potential of the Schottky gate, dielectric constant of semiconductor, and donor density of the doping layer, respectively. The area density of the conductive carrier can be easily estimated from the conductive layer thickness, and the drain current is determined by eqn [4] in small V_d regions. Forming the conductive layer involves several techniques, such as ion-implantation and epitaxial growth.

Finally, there is the high-electron-mobility transistor (HEMT) which is shown in **Figure 5c**. The HEMT utilizes conductive carriers accumulated at the hetero-interface between wide- and narrow-gap semiconductors. A triangular-shaped confinement potential at the interface defines the conductive carrier in a thin 2D channel. Modulation doping, that is, doping in the wide-gap semiconductor and conductive carriers at the interface, enables one to separate conductive carriers from dopant impurities, which results in a strong suppression of impurity scattering. Therefore, HEMTs are also called modulation-doped FETs (MODFETs). The density of the 2D electron system is controlled by the gate bias and the I_dV_d characteristics are roughly represented by eqns [3]–[6]. The most widely studied HEMT devices are based on the AlGaAs/GaAs system; however, many different material combinations, such as InAlAs/InGaAs and AlGaN/GaN systems, have been developed recently.

High-frequency FETs are key devices in recent optical communications technology, where they enable the practical use of 40 Gbit s^{-1}. **Figure 7** summarizes current gain cut-off frequencies (f_T's) for various kinds of FETs. Among them, InP-based HEMTs, where a conductive two-dimensional electron gas (2DEG) channel is formed in the InAlAs/InGaAs heterostructures lattice-matched with InP substrate, have achieved record f_T's for a wide range of gate lengths (L_g's) by many research groups. The effective saturation velocity of InAlAs/InGaAs HEMTs is 2.7×10^7 cm s^{-1}, $\sim$1.3 times higher than that of GaAs-based HEMTs. Moreover, higher electron mobility and sheet-carrier density of the 2DEG at the InAlAs/InGaAs hetero-interface reduce channel and parasitic charging times, and make possible the effective use of higher saturation velocity. The current record f_T for a discrete device is beyond 400 GHz.

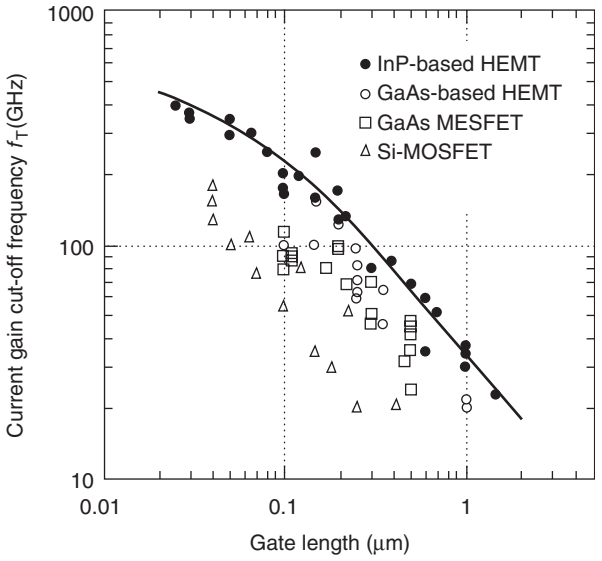

Figure 7 Current gain cut-off frequencies for various kinds of FETs.

Integrated circuits (ICs) based on InP have been developed with the aim of achieving a 100 Gbit s^{-1} class communications technology. The schematic structure of such an IC is shown in **Figure 8**. A 0.1 μm-gate InAlAs/InGaAs HEMT is integrated with InAlAs Schottky diodes, metal resistors, and metal-insulator-metal (MIM) capacitors in this example. The mushroom-shaped gate improves transistor performance.

Modulation-doped HEMT structures are important not only as cutting-edge room-temperature devices but also as key devices for studies of low-temperature physics. The 2D electron system at the AlGaAs/GaAs interface has the highest mobility at low temperatures, and has been very important in quantum Hall effect research. Mobility up to 10^7 cm^2 V^{-1} s^{-1} has been obtained in several laboratories in the USA, Europe, and Japan. The mobility is still limited by background impurities; therefore, it can be improved by increasing electron density. Recently, Bell Laboratories used a sophisticated MBE technique and two-side modulation-doping, and achieved mobility of around 3×10^7 cm^2 V^{-1} s^{-1}.

Backgated Structures

The backgated structure, where carrier density is modulated from the back side by a voltage applied to the backgate, is also attractive. Although the gate capacitance limits high-frequency applications, the density control from the back side enables one to use the free surface for many kinds of structures. When

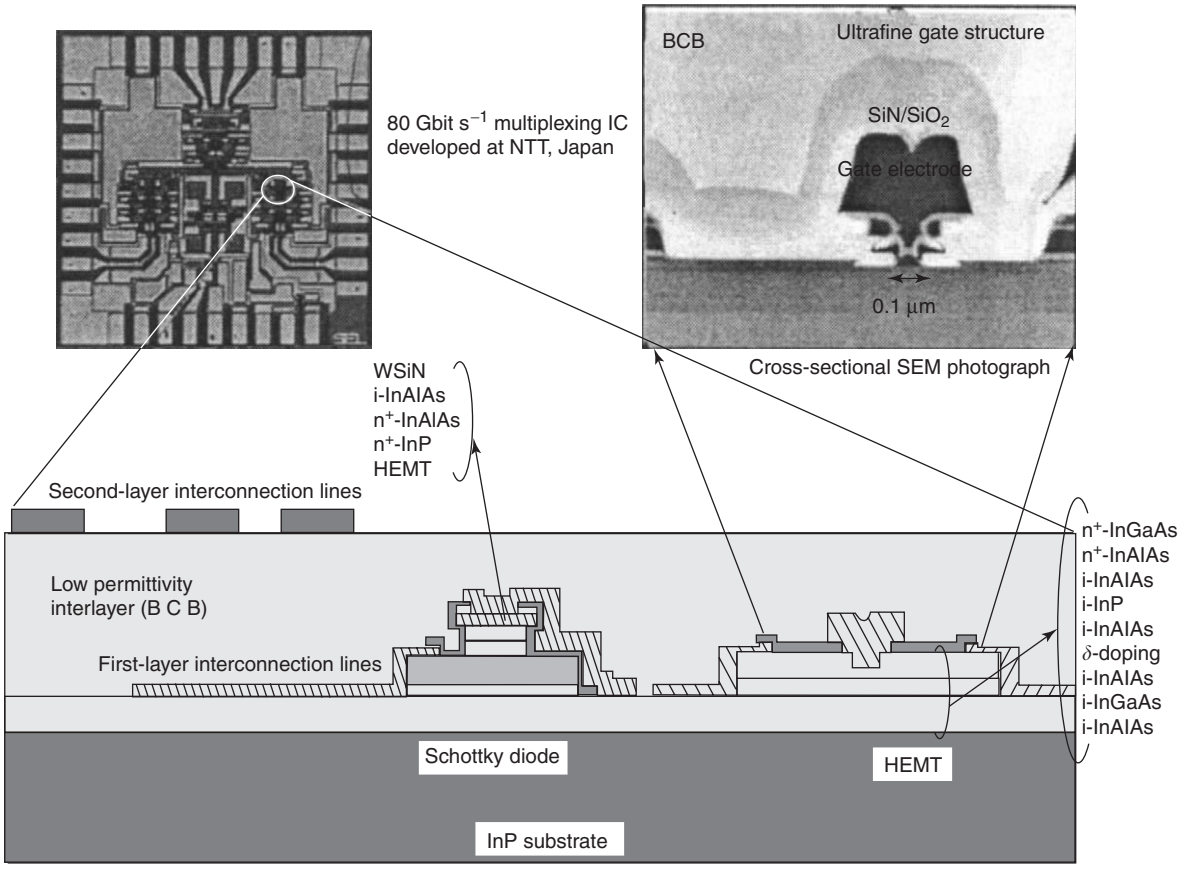

Figure 8 Schematic diagram of an InP-based HEMT IC.

fine structures are formed on the surface side, the structure behaves as a density-tunable mesoscopic system.

An example of a backgated heterostructure is shown in **Figure 9**. In this example, the 2D electron system accumulates at the hetero-interface between AlGaAs and GaAs. Conductive electrons are supplied from the ohmic contacts as in Si MOSFETs. The threshold voltage of the 2D electron accumulation is determined by the balance between surface charge and backgate bias. In case of the GaAs, the surface charge is frozen at low temperatures and the surface Fermi level is not pinned at the midgap. These features help in accumulating 2D electron systems with a small threshold voltage at low temperatures. Once the 2D electron system is accumulated at the hetero-interface, its density can be precisely controlled by the backgate bias, that is, an electric field applied between the 2D electrons and the backgate.

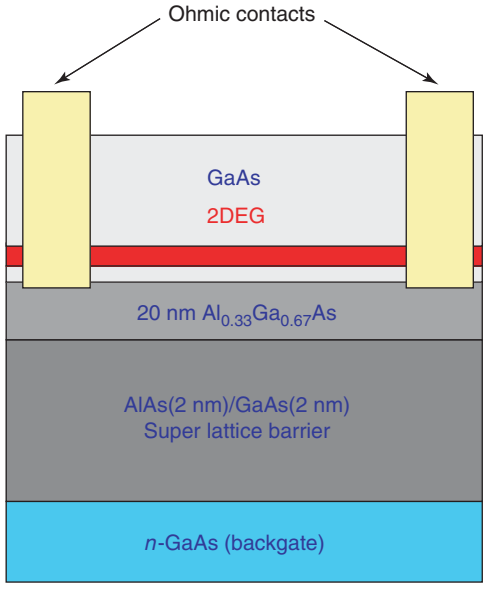

Figure 9 Example of a backgated heterostructure.

In-Plane-Gate Transistor

Transistors, that is, three-terminal devices, have been applied to confine electron systems to low dimensions, such as one and zero dimensions. When a pair of split Schottky gates is formed on a semiconductor heterostructure, such as AlGaAs/GaAs, the 2D electron system under the gates is depleted by

a negative gate bias applied to the Schottky gates (see **Figure 10a**). The small distance between the two gates results in a narrow electron channel, which shows clear 1D features at low temperatures.

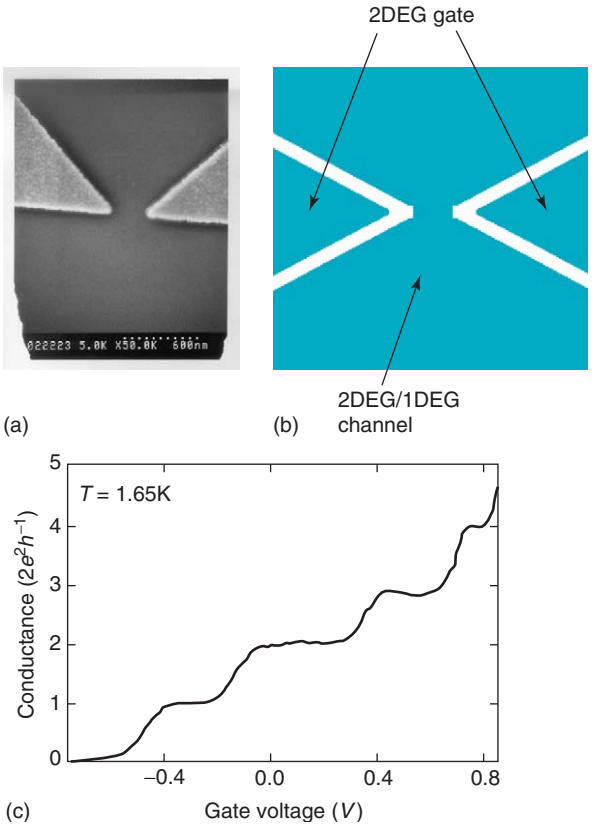

Figure 10 Quantum point contacts (QPCs) fabricated by the FET technique. (a) Split Shcottky gate QPC, (b) in-plane-gate QPC, and (c) typical characteristics of an in-plane-gate QPC fabricated on InSb quantum-well structure.

Quantized conductance characteristics have been observed for such narrow and ballistic 1D channels, which are called quantum point contacts.

A unique transistor structure, called the in-plane-gate transistor, is formed by separating a 2D electron system into three parts using insulated lines as shown in **Figure 10b**. These insulating lines are made by trench etching or ion implantation. When a negative bias is applied to two side gates against the center region, the depletion region spreads from the insulating lines and a 1D channel is formed in the center channel. As shown in **Figure 10c**, quantized conductance characteristics have been reported, reflecting the successful formation of such a channel. Although the in-plane-gate FET is limited to a 1D system from the operation principle, three-terminal structures are made without Schottky gates. Therefore, the in-plane-gate FET is beneficial for many narrow-gap semiconductors, where the formation of a good Schottky gate is difficult.

Single–Electron Transistor

In FETs, the number of carriers in the channel is determined by the gate bias through capacitance coupling. By combining FETs and nanotechnologies, it becomes possible to realize the structure schematically shown in **Figure 11a**. There is a small channel, like a quantum dot, which is separated from the source and drain by two barriers. The barrier height is set high enough to protect normal current flow, but low enough to permit tunneling coupling between the quantum dot and source (drain). The charge in the quantum dot increases linearly with the gate bias as represented by $Q = C_g V_g + Q_0$, where Q is the

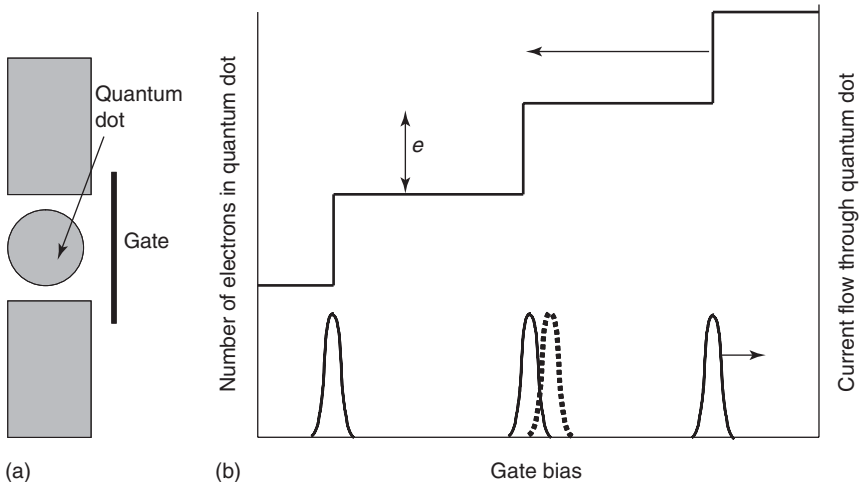

Figure 11 (a) Schematic diagram and (b) schematic operation principle of an SET. The position of the conductive peak is extremely sensitive to the charge balance in the circumstances schematically shown by the dotted lines.

charge in the quantum dot, C_g gate capacitance, V_g gate bias, and Q_0 the background charge determined by the balance of the quantum dot in the system. When electrons accumulate in the quantum dot, Q should be an integer multiple of e, the charge of a single electron. This discrete nature of the charge is not important for a large system, but becomes essential for a small system such as the quantum dot, where $\Delta V_g = e/C_g$ becomes larger than the thermal broadening, kT/e. This situation is fully satisfied for the small quantum-dot system at low temperatures, and such three-terminal structures are called single-electron transistors (SETs).

A schematic diagram of an SET operation is shown in **Figure 11**. According to the increase in the gate bias, the charge in the quantum dot increases along a step function Ne (N: integer). A current flow, that is, electron flow, should be accompanied by a change of the number of electrons in the quantum dot. Therefore, the current flow is limited only in the condition where N can change with $\Delta N = 1$. On the other hand, the current flow is blocked when N is constant (Coulomb blockade).

Some SET characteristics are shown in **Figure 12**. The quantum dot has a circular disk shape in this example. The interval of current peaks determined by $\Delta V_g = e/C_g$ decreases with increasing bias. This is because an increase in the disk size with gate bias results in increased gate capacitance. In addition to the classical charging effect, quantum effects, such as the formation of zero-dimensional energy states, become important in small quantum dots. The zero-dimensional energy levels are represented by the diagram in **Figure 12b** for the parabolic confinement, which is a good approximation of the disk-shaped quantum dot. Here, $\hbar\omega_0$ represents the zero-dimensional energy-level separation arising from the parabolic confinement. The zero-dimensional energy levels degenerate at zero magnetic field, where $\omega_c = 0$. Each energy level can include two electrons with different spins. Therefore, ΔV_g increases for $N = 2, 6, 12, \ldots$ where the zero-dimensional energy separation should be compensated by the gate bias in addition to e/C_g. Such periodic features have actually been observed as shown in **Figure 12a** for a circular quantum dot. This periodic feature comes from the same principle as the periodic table of real atoms, so that these SETs are sometimes called semiconductor artificial atoms.

At low temperatures, the conductive peak becomes sharp as experimentally shown in **Figure 12a**. Furthermore, the peak position shifts when the charge situation around the quantum dot is slightly modified as schematically shown in **Figure 11b**. Therefore, the conductance change in an SET operates as a very sensitive electrometer. Recently, the single electron motion in semiconductor nanostructures was detected by using the SET-based highly sensitive electrometer.

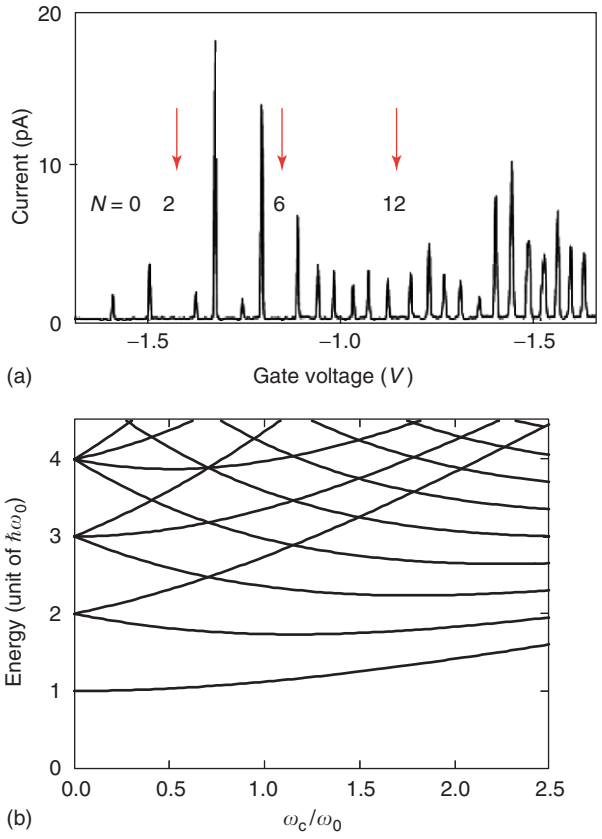

Figure 12 (a) Current vs. gate voltage characteristics experimentally observed for the disk-shaped SET. The current peak interval becomes wider for N (the number of electrons in the quantum dot) of $2, 6, 12, \ldots$, as shown by arrows. Such characteristics are explained by the zero-dimensional energy levels formed in the circular quantum dot and shown in (b). This energy diagram is calculated for a parabolic confinement potential, $V = m\omega_0^2(x^2 + y^2)/2$. $\hbar\omega_c$ is the cyclotron energy separation in the perpendicular magnetic field.

Transition-Metal Compounds, Electronic and Magnetic Properties of

J B Goodenough, University of Texas at Austin, Austin, TX, USA

Introduction

The electronic and magnetic properties of transition-metal compounds are imparted by the *d* and/or 4*f* electrons of the transition-metal compounds. (This article does not cover the actinides.) The outer *s* and *p* electrons of these compounds, which are primarily responsible for the chemical bonding, are split by an energy gap E_g between filled anionic bonding bands and empty cationic antibonding bands. The *s* and *p* states contribute to the electronic and magnetic properties of the transition-metal compounds through covalent mixing with the *d* and/or 4*f* orbitals.

The 4*f* electrons always form localized $4f^n$ configurations as on a free atom unless a $4f^n/4f^{n+1}$ redox couple is overlapped by the Fermi energy (the electrochemical potential) ε_F of a partially filled broadband of itinerant-electron states, in which case hybridization of the 4*f* and itinerant electron states creates massive itinerant electrons called heavy fermions. The *d* electrons, on the other hand, may be localized, itinerant, or vibronic depending on the relative strengths of the intra-atomic and the inter-atomic interactions and how the competition between these two is modulated by disturbances of the periodic potential of a crystalline array of the like atoms or by elastic and thermal energies.

The intra-atomic energies are those of the free transition-metal atom as modified by covalent mixing with the ligand orbitals. The Hamiltonian for the electrons of a free atom has three components of descending magnitude:

$$H = H_o + U + \lambda \boldsymbol{L} \cdot \boldsymbol{S} \qquad [1]$$

where H_o corresponds to the energy of a single electron moving in the field of a nucleus of effective charge $+(Z - \sigma_l)e$. The atomic number Z is reduced by a screening σ_l of the other atomic electrons; σ_l depends on the orbital angular momentum quantum number l of the electron being screened from the nuclear charge $+Ze$. The energy U is the electrostatic energy required to add an electron to a configuration of *d* or 4*f* orbitals and is a measure of the separation of successive ionization energies; $U = J_c - J_{ex}$ has two components, a Coulombic repulsion J_c and a quantum-mechanical correction J_{ex} that keeps electrons of parallel spin in different orbitals by the Pauli exclusion principle. The last term in eqn [1] gives rise to the multiplet splitting of a $^{2S+1}L_J$ term, where Russell–Saunders coupling applies to the d^n and $4f^n$ configurations of total angular momentum quantum number $\boldsymbol{J}=\boldsymbol{L}+\boldsymbol{S}$; $\boldsymbol{L}$ and $\boldsymbol{S}$ are the total orbital and spin angular-momentum quantum

numbers. The atomic magnetic moment is

$$\boldsymbol{\mu}_{\mathrm{A}} = -g_{\mathrm{L}}\boldsymbol{J}\mu_{\mathrm{B}} \qquad [2]$$

where g_{L} is the Landé spectroscopic splitting factor and μ_{B} is the Bohr magneton.

In a solid, the "interatomic interactions" depend on the expectation value for an electron to transfer to a neighboring atom without a change of energy as a result of the perturbation H' of the free-atom potentials by their proximity to one another:

$$b_{ij} \equiv (\psi_i, H'\psi_j) \approx \varepsilon_b(\psi_i, \psi_j) \qquad [3]$$

where ε_b is a one-electron energy and (ψ_i, ψ_j) is the overlap integral of the initial and final atomic orbitals occupied by the electron. The subscripts refer to atoms at $\boldsymbol{R}_i$ and $\boldsymbol{R}_j$ in the crystal. Electron transfers between states of the same energy are treated in the first-order theory ($\Delta E \sim b$) and between states separated by an energy Δ or U in the second-order theory ($\Delta E \sim b^2/\Delta$ or b^2/U). The tight-binding bandwidth for electrons transferring between like atoms of a periodic array of crystallographically equivalent sites with $U = 0$ is given by

$$W_b \approx 2zb \qquad [4]$$

where z is the number of like nearest neighbors and b is the b_{ij} for these nearest neighbors. The crossover from localized-electron behavior (intra-atomic interactions dominant) to itinerant-electron behavior (interatomic interactions dominant) occurs where

$$W_b \approx U \qquad [5]$$

This crossover is known as the "Mott–Hubbard transition."

The localized electrons occupy an n-electron configuration d^n or f^n located at a single transition-metal atom and having an energy corresponding to that of a redox couple d^{n-1}/d^n or f^{n-1}/f^n. Successive redox couples are separated by an energy U. The itinerant electrons, on the other hand, belong equally to all the like atoms of a periodic array on crystallographically equivalent sites; they are described by a band of single-electron energies of width W_b that is occupied by electrons in accordance with the Pauli exclusion principle and the Fermi–Dirac distribution function. In this limit, a $U < W_b$ is assumed to be screened by the other electrons so as to make $U = 0$. For narrower bandwidths W_b, this "electronic Fermi-gas model" must be modified by the introduction of a finite $U < W_b$. This problem can be treated by mass-renormalization techniques that transform the electrons into a "quasiparticle Fermi liquid."

Impurities, lattice defects, and substitutional dopants all disturb the periodic potential of an array of transition-metal atoms in a solid. These disturbances narrow the effective width of W_b by introducing localized states (Anderson localized states) at the top and bottom of a band of itinerant-electron states above and below, respectively, a "mobility edge." If the Fermi energy ε_{F} lies in the energy range of localized states, the conductivity is described as "variable-range hopping" between these localized states.

The Mott–Hubbard transition is not smooth as originally assumed; it is a first-order transition that may give an abrupt volume change, but generally it introduces the coexistence of two different equilibrium bond lengths at crossover. In the latter case, the resulting bond-length fluctuations at high temperatures order at lower temperatures so as to give long-range-ordered atomic clusters, a charge-density wave (CDW), or a charge-ordered (CO) state in order to minimize the elastic energy. The elastic energies associated with local site deformations are also minimized by cooperative ordering. Examples of local site distortions are displacements of a cation from the center of symmetry of its interstice, cation clustering, valence disproportionation, and an orbital ordering that either lowers the local site symmetry or increases its deformation from cubic symmetry.

The electronic and magnetic properties of the d electrons of transition-metal compounds are strongly influenced not only by whether they occupy states with $W_b < U$, $W_b \approx U$, or $W_b > U$ but also by order–disorder transitions. Order–disorder transitions are driven by the heat $T\Delta S$ associated with disorder. Heat also drives disordering of long-range magnetic order, which removes magnetostrictive and/or exchange-strictive deformations of the crystal symmetry; and by increasing the crystal volume, it may induce changes from antiferromagnetic to ferromagnetic coupling, that is, "exchange inversion," below a long-range magnetic-ordering temperature.

In mixed-valent compounds, the transport properties also depend critically on whether the time $\tau_{\mathrm{h}} \approx \hbar/W_b$ for an electron to hop from one atom to a like nearest neighbor is $\tau_{\mathrm{h}} > \omega_{\mathrm{R}}^{-1}$, $\tau_{\mathrm{h}} \approx \omega_{\mathrm{R}}^{-1}$, or $\tau_{\mathrm{h}} < \omega_{\mathrm{R}}^{-1}$, where ω_{R}^{-1} is the period of an optical-mode vibration that would trap the charge carrier at a single site as a "small dielectric polaron."

In the following sections, the metal–ligand interactions are first introduced to construct ligand-field orbitals having the same symmetries as the atomic d orbitals. The interactions between the ligand-field orbitals of neighboring metal atoms are then discussed for $W_b < U$, $W_b \approx U$, and $W_b > U$. Next, the significance of the radial extension of the ligand-field orbitals and the location of the Fermi energy relative

to the edges of the broad filled and empty bands is presented in the context of illustrative examples of the varied phenomena that are encountered in these materials.

Metal–Ligand Interactions

Redox Couples f^n or d^n

The description of the outer electrons of a primarily ionic transition-metal compound begins with a point-charge model; the electrostatic Madelung energy E_M of that model generally lowers the most energetic ligand (anion) p orbitals an energy ΔE_p below the lowest unoccupied redox energy of the transition-metal atom. A $\Delta E_p \leqslant 0$ may pin the antibonding redox couple at the top of the bonding ligand-p band; in this case, the redox couple can commonly be treated by the molecular-orbital or band theory. However, back electron transfer from the anion across an energy $\Delta E_p > 0$ to an empty d or f orbital on the cation is treated in the second-order perturbation theory to give a stabilization energy $\Delta E \sim (b^{ca})^2/\Delta E_p$ of occupied bonding states that tends to compensate for the loss in electrostatic Madelung energy E_M of the point-charge model; the empty antibonding d or f orbitals of the d^n or f^n configuration are correspondingly destabilized by an energy ΔE. As noted in eqn [3], the expectation value for a back electron transfer depends on the cation–anion overlap integral in b^{ca} and, therefore, on the relative symmetries of the interacting orbitals. Consequently, symmetry arguments are used to develop a parametrized second-order description of the "ligand-field orbitals"; these orbitals take account of the interactions between the d or f electrons and the anions. Next, the metal–metal, metal–anion–metal, and/or metal–anion–anion–metal interactions are introduced; the ligand-field orbitals either remain localized or become itinerant depending on the relative strengths of these inter-atomic interactions and the intra-atomic energy U_{eff} for the atomic ligand-field orbitals.

Rare-Earth $4f^n$ Configurations

The rare-earth $4f$ electrons are tightly bound to their atomic nucleus and are largely buried within a $5s^2 5p^6$ core-electron cloud that prevents strong overlap of the $4f$ orbitals with the orbitals of the neighboring ligands. Consequently, the $4f^n$ configurations remain localized with a $U_{eff} \gg W$, and any splitting of the individual f-orbital energies by interaction with the ligands is smaller than the intra-atomic multiplet splittings by $\lambda \boldsymbol{L} \cdot \boldsymbol{S}$. Therefore, the localized $4f^n$ configurations in a compound retain their atomic magnetic moment $\boldsymbol{\mu}_A = g_L \boldsymbol{J} \mu_B$ of eqn [2]. Nevertheless, the interactions with the ligands contribute, along with the "magnetic dipole–dipole $4f^n$ interactions," to the weak "spin–spin interatomic exchange" interactions between $4f^n$ configurations that are responsible for long-range magnetic order at low temperatures and also to the "magnetocrystalline anisotropy" that introduces a preferred orientation of $\boldsymbol{\mu}_A$ relative to the crystallographic axes and an associated "magnetostriction" below the magnetic-ordering temperature. Long-range ordering of the spins $\boldsymbol{S}$ induces long-range ordering of the orbital angular momenta $\boldsymbol{L}$ by the spin–orbit coupling $\lambda \boldsymbol{L} \cdot \boldsymbol{S}$, and interactions with the ligands order the orbitals responsible for $\boldsymbol{L}$, and therefore $\boldsymbol{J}$, relative to the crystallographic axes and also induce the anion displacements responsible for the magnetostriction. Magnetostriction reflects the orientation of the atomic moments; "exchange striction" reflects changes in the binding energy due to magnetic order and, therefore, reflects the symmetry of the long-range magnetic order.

The d-Block d^n Configurations

The five d orbitals of a free atom are degenerate, but with more than one electron or hole in a d^n manifold, the spin degeneracy is removed by the ferromagnetic direct-exchange interactions between electron spins in orthogonal atomic orbitals. The Pauli exclusion principle keeps electrons of the same spin in different d orbitals, which reduces the energy $U = J_c - J_{ex}$ by the intra-atomic exchange energy J_{ex}. These spin–spin exchange interactions produce the "Hund intra-atomic exchange field H_{ex}" responsible for the Hund highest multiplicity rule for the free atom. The splitting between states of different spin for a given orbital will be designated Δ_{ex}.

The atomic orbitals f_m with azimuthal orbital angular momentum operator L_z, where $L_z f_m = -i\hbar \, \partial f_m/\partial\phi = \pm m\hbar f_m$ with $m = -l, \ldots, +l$, have the angular dependencies for $l = 2$:

$$f_0 \sim (\cos^2\theta - 1) \sim [(z^2 - x^L) + (z^2 - y^2)]/r^2$$

$$f_{\pm 1} \sim \sin^2\theta \, \exp(\pm i\phi) \sim [yz \pm izx]/r^2 \qquad [6]$$

$$f_{\pm 2} \sim \sin^2\theta \, \exp(\pm i2\phi) \sim [(x^2 - y^2) \pm i2xy]/r^2$$

In an isolated octahedral site, the xy and $(yz \pm izx)$ orbitals only overlap the neighboring O–2p_π orbitals while the $[(z^2 - x^2) + (z^2 - y^2)]/r^2$ and $(x^2 - y^2)/r^2$ orbitals only overlap the O–2s and O–2p orbitals. These two groupings of orbitals are distinguished by symmetry as a twofold-degenerate set of e orbitals and a threefold-degenerate set of t orbitals (**Figure 1**). The electron-transfer (resonance energy integrals

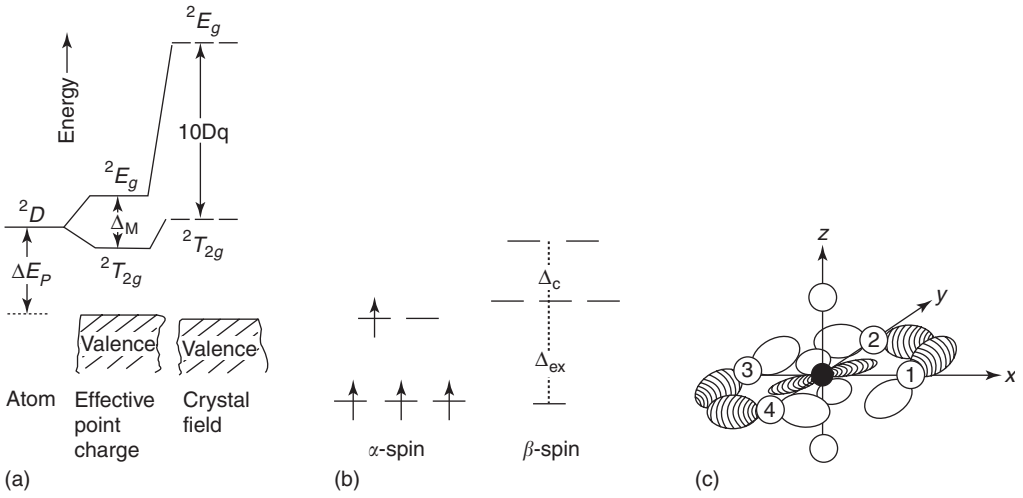

Figure 1 Schematic crystal-field splitting of the *d*-state manifold of a transition-metal atom M in an octahedral site: (a) the one-electron d^1 configuration ($\Delta_{ex} = 0$); (b) the high-spin d^4 configuration, and (c) $\phi_{xy} = p_y^{(1)} + p_x^{(2)} - p_y^{(3)} - p_x^{(4)}$ that hybridizes with a d_{xy} orbital.

$b^{ca} \equiv (f_m, H'\phi_o) \approx \varepsilon_{mo}(f_m, \phi_o)$ describing the expectation of a virtual charge transfer to an empty cation-*d* orbital from a same-symmetry sum of near-neighbor oxygen orbitals ϕ_o contain both an overlap integral (f_m, ϕ_o) and a one-electron energy ε_{mo} that are larger for σ-bonding than for π-bonding, that is, $b_\sigma^{ca} > b_\pi^{ca}$. Therefore, the antibonding *e* states of a σ-bond are raised higher by the energy $\Delta E \equiv (b^{ca})^2/\Delta E_p$ than are the antibonding *t* states of a π-bond. The resulting cubic-field splitting is

$$\Delta_c = \Delta E_\sigma - \Delta E_\pi = \Delta_M + (\lambda_\sigma^2 - \lambda_\pi^2)\Delta E_p + \lambda_s^2 \Delta E_s \quad [7]$$

where Δ_M is a purely electrostatic energy that is small and of uncertain sign due to the penetration of the ligand-p^6 electron cloud by the cation-*d* wave function. The dimensionless covalent-mixing parameters are seen to be

$$\begin{aligned} &\lambda_\sigma = b_\sigma^{ca}/\Delta E_p, \quad \lambda_\pi = b_\pi^{ca}/\Delta E_p \\ &\lambda_s = b_s^{ca}/\Delta E_s \end{aligned} \quad [8]$$

in which ΔE_p and ΔE_s are the point-charge energy gaps between the degenerate atomic *d* orbitals and the ligand *p* and *s* orbitals, respectively. The second-order ligand-field wave functions are

$$\begin{aligned} \psi_t &= N_\pi(f_t - \lambda_\pi \phi_\pi) \\ \psi_\sigma &= N_\sigma(f_e - \lambda_\sigma \phi_\sigma - \lambda_s \phi_s) \end{aligned} \quad [9]$$

where N_π and N_σ are normalization constants that constrain a one-electron state to contain a single electron.

Covalent mixing extends the ligand-field wave functions out over the anions, thereby reducing the electron–electron Coulomb energy *U* from its atomic value. For an octahedral-site cation, the ligand-field *U* is larger for electrons in the π-bonding *t*-manifold than for those in the σ-bonding *e*-manifold, that is, $U_t > U_e$.

As an aside, attention is drawn to the earlier crystal-field model in which the covalent component to the orbitals is neglected and the cubic-field splitting is simply parametrized as $\Delta_c = 10\,Dq$. In this model also, the symmetry arguments distinguish the *e* and *t* manifolds in a cubic field or other splittings in lower symmetry, but the energy of the atomic *d*-state manifold is conserved and the crystal-field wave functions are simply the atomic wave functions f_m. Although this parametrized model allows interpretation of spectroscopies that measure the energy splittings, it fails completely to account for a lowered ligand-field *U* and for the interatomic interactions between like atoms that are responsible for long-range magnetic order where a $W_b < U_{eff}$ is found or for metallic conductivity where a $W_b > U_{eff}$ occurs.

If a *d*-block transition-metal ion occupies a tetrahedral site, similar considerations apply, but in this case the *t* orbitals have a larger orbital overlap and are raised higher in energy than the *e* orbitals by the cubic-field splitting Δ_c. Early crystal-field calculations give the relative values of Δ_c for the two cases as

$$\Delta_c(\text{tetrahedral}) \approx (4/9)\Delta_c(\text{octahedral}) \quad [10]$$

The *d*-electron Hamiltonian that includes the interactions with the ligand *p* and *s* orbitals is

$$H = H_o + J_c + (\Delta_c - J_{ex}) + (\lambda \boldsymbol{L} \cdot \boldsymbol{S} + \Delta_{nc}) \quad [11]$$

where Δ_{nc} is a noncubic component of the ligand-field splitting arising from a distortion of the site symmetry. Since the octahedral-site Δ_c is the same order of magnitude as the intra-atomic exchange energy Δ_{ex}, the $d^4 - d^7$ octahedral-site configurations may be either high-spin t^3e^1, t^3e^2, t^4d^2, t^5e^2 where $\Delta_{ex} > \Delta_c$ or low-spin t^4e^0, t^5e^0, t^6e^0, t^6e^1 where $\Delta_c > \Delta_{ex}$. Moreover, lowering of the site symmetry to tetragonal or orthorhombic may stabilize an intermediate-spin d^5 or d^6 configuration t^4e^1 or t^5e^1, respectively. The larger the covalent mixing parameters $\lambda_\sigma > \lambda_\pi$, the smaller is Δ_{ex} and the larger is Δ_c. Moreover, the effective energy U_{eff} required to add an electron to a d^n manifold to make it d^{n+1} must take into account Δ_c as well as Δ_{ex}. For an octahedral-site cation, the U_{eff} for $n = 3$ and $n = 8$ is increased by Δ_c; for $n = 5$ it is increased by Δ_{ex} if $\Delta_c < \Delta_{ex}$, and for $n = 6$ by Δ_c if $\Delta_c > \Delta_{ex}$.

By splitting the $m = \pm 2$ energies of eqn [6] into real $(x^2 - y^2)$ and xy components, the operator $L_z = -i\hbar\partial/\partial\phi$ makes the azimuthal component of the orbital angular momentum imaginary, which means that the two e orbitals have $m = 0$ and the t manifold has orbitals with $m = 0, \pm 1$. It follows that configurations with zero, three, or six t electrons have their orbital angular momentum completely quenched (i.e., $L = 0$) to first order, and a spin-only atomic moment $\boldsymbol{\mu}_A = gS\mu_B$ with $g \approx 2$ is a fair approximation.

The octahedral-site splitting may leave an orbital degeneracy, as occurs with high-spin Mn(III):t^3e^1 or Cu(II):t^6e^3, for example, or with high-spin Fe(II):t^4e^2 or Co(II):t^5e^2. In this case, the cubic site symmetry is unstable relative to a site distortion that removes the orbital degeneracy. This instability is known as a "Jahn–Teller distortion." In a crystal, a long-range-cooperative site distortion, that is, orbital ordering, minimizes the elastic energy that resists the distortion and lowers the space-group symmetry of the crystal. Cooperative Jahn–Teller distortions may transform isotropic 3D interatomic spin–spin interactions into a ferromagnetic interaction in one crystallographic direction and an antiferromagnetic interaction in another as is illustrated by $LaMnO_3$ (*vide supra*). Removal of a t^n-orbital degeneracy ($n = 1, 2, 4$, or 5) may either quench the orbital angular momentum or enhance it so as to gain a further splitting by the spin–orbit coupling $\lambda \boldsymbol{L} \cdot \boldsymbol{S}$, where σ-bonding electrons determine the magnetic order, a long-range collinear-spin configuration below a magnetic-ordering temperature introduces long-range order of the orbital angular momenta through $\lambda \boldsymbol{L} \cdot \boldsymbol{S}$ even where the concentration of orbitally degenerate cations is not large. Therefore, below a long-range magnetic-ordering temperature, distortions that enhance $\boldsymbol{L}$ and introduce a large magnetostrictive component scale with the concentration of cations with the t-orbital degeneracy. On the other hand, spin–orbit coupling prevents a cooperative ordering of the orbital momenta in the paramagnetic state of disordered spins; so cooperative distortions setting in above a magnetic-ordering temperature quench the orbital angular momenta. The two types of distortion can be distinguished as they have opposite sign. This situation is beautifully illustrated in **Figure 2** by the spinel system $Ni_{1-x}Fe_x[Ni_xCr_{2-x}]O_4$ in which the tetrahedral-site Ni(II):e^4t^4 are the Jahn–Teller ions.

The $A[B_2]X_4$ spinel structure consists of a close-packed-cubic array of anions X; the electrostatic Madelung energy is minimized by an ordering of the B cations on half of the octahedral sites and the A cations on tetrahedral sites of the interstitial space of the $[B_2]X_4$ array. The $Ni_{1-x}Fe_x[Ni_xCr_{2-x}]O_4$ spinel also illustrates how the crystal-field splittings influence the site-preference energies of transition-metal cations. Sites that leave the higher-energy d orbitals empty are stabilized relative to those that leave them occupied. The Cr(III) ion has the configuration t^3e^0 in an octahedral site and e^2t^1 in a tetrahedral site, which gives it a strong octahedral-site preference. The high-spin Fe(III) ion with configurations t^3e^2 or e^2t^3 has little site preference. The Ni(II) ion, on the

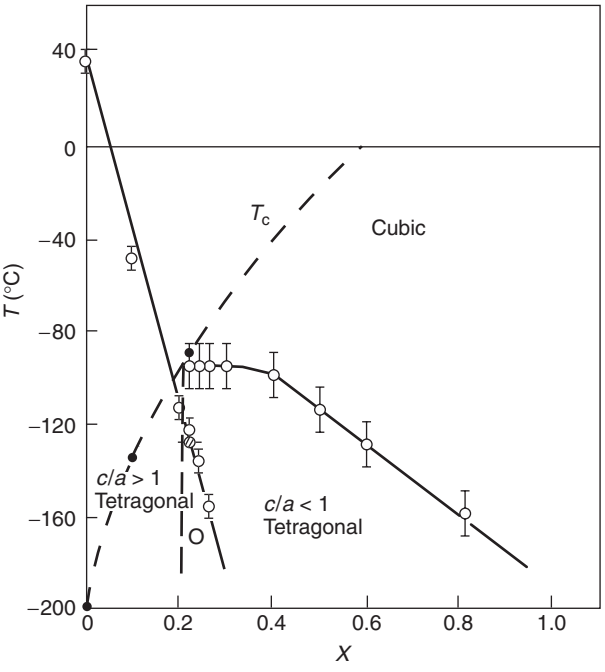

Figure 2 Phase diagram of the spinel system $Ni_{1-x}Fe_x[Ni_xCr_{2-x}]O_4$. Solid lines are tetragonal-cubic transition temperatures T_t. The O-orthorhombic phase may be a coexistence of tetragonal $c/a > 1$ and $c/a < 1$ phases. (After Arnott RJ, Wold A, and Rogers DB (1964) *Journal of the Physics and Chemistry of Solids* 25: 161.)

other hand, has an octahedral-site configuration t^6e^2 as against e^4t^4 in a tetrahedral site, which gives it a definite octahedral-site preference; but it is forced into the tetrahedral sites of the spinel by the Cr(III) ions, which have a stronger octahedral-site preference.

Ionic size also determines site preference. Smaller cations prefer tetrahedral sites, the *d*-block transition-metal cations of intermediate size, with the exception of Mn(II) and Cu(I), prefer octahedral sites, and the larger rare-earth ions prefer a greater oxygen coordination. Where a smaller cation is forced by electrostatic Coulomb energies into an octahedral site, it may be unstable relative to a cooperative displacement from the center of symmetry of its interstice. Such a displacement introduces a local electric-dipole moment, and a cooperative parallel displacement gives a "ferroelectric polarization" analogous to a "ferromagnetic magnetization." Therefore, such a displacement is referred to as a ferroelectric-type displacement even though the cooperativity may involve antiparallel displacements to give an antiferroelectric analogous to an antiferromagnet in which neighboring spins are aligned antiparallel. Lighter transition-metal cations of a given *d*-block can be stabilized in octahedral sites in their highest valence states, that is, with a d^0 configuration, but as the cation size decreases with increasing atomic number and formal valence state, the site preference changes from octahedral to tetrahedral. It is the ions with sizes at crossover to a tetrahedral-site preference that undergo ferroelectric displacements. In the 3*d* row, the T(IV) has an octahedral-site preference, but if the structure forces the Ti–O bond length to be greater than its equilibrium value, as occurs in the perovskite $BaTiO_3$, the Ti(IV) ions may undergo a cooperative ferroelectric displacement. In $BaTiO_3$, there are three successive cooperative displacements; on lowering the temperature, the Ti(IV) ions are displaced first toward one near-neighbor O^{2-} ion, then toward two, and finally toward three. The smaller V(V) cation, on the other hand, has a definite tetrahedral site preference, but when forced into an octahedral site as in V_2O_5, it forms a short double bond V═O indicating molecular-orbital formation with both p_σ and the two p_π orbitals. The V(IV) may also form a $(V{=}O)^{2+}$ vanadyl ion with an occupied d_{xy} orbital in the plane perpendicular to the d_{yz} and d_{zx} orbitals involved in the π molecular orbitals. In the 4*d* block, it is the Nb(V) ion that corresponds to the Ti(IV) and the Mo(VI) that corresponds to the V(V). In the 5*d* series, the W(VI) corresponds to the Ti(IV), and WO_3 is an antiferroelectric without a stretching of the W–O bond length by a counter cation as in $BaTiO_3$.

Finally, it is noteworthy that where a transition-metal cation is deprived of its stable oxygen coordination, as occurs in the oxygen-deficient perovskite $BaZr_{1-x}In_xO_{3-0.5x}$, water may enter the oxygen vacancies at lower temperatures ($T \leqslant 400^\circ C$) to introduce OH^- anions and protonic conduction; the Zr(IV) ion is stable in eightfold oxygen coordination and definitely prefers a sixfold over the fivefold oxygen coordination just as the large Ba^{2+} ion prefers a 12-fold over the 11-fold coordination.

Metal–Metal Interactions

A measure of the strength of the interatomic cation–cation interactions is also the energy integral b_{ij} of eqn [3]. Direct cation–cation electron transfers b^{cc} between cations sharing a common site edge or face are distinguished from cation–anion–cation transfers b^{cac} that occur across an anion. The latter interactions are possible because the shared anion-*p* component (neglecting the smaller anion-*s* component for simplicity) of the ligand-field wave functions provides a significant overlap of the wave functions on neighboring cations. For a $(180^\circ - \phi)$ cation–anion–cation interaction, the electron transfer integrals b_σ^{cae} across a common anion-p_σ orbital must be distinguished from the smaller b_π^{cac} across a common anion-p_π orbital; in a 90° cation–anion–cation interaction, the electron transfer integral is $b_{\pi\sigma}^{cac}$ as it occurs across an anion-*p* orbital that σ-bonds with the *d* orbital on one cation and π-bonds with the *d* orbital on the other cation. With the ligand-field wave functions of eqn [9], these integrals become

$$b^{cc} = \varepsilon_{cc}(\psi_i, \psi_j) \qquad [12]$$

which varies sensitively with the interatomic separation *R*,

$$\begin{aligned} b_\pi^{cac} &\approx \varepsilon_\pi \lambda_\pi^2 \\ b_\sigma^{cac} &\approx \varepsilon_\sigma \lambda_\sigma^2 \cos\phi \\ b_{\pi\sigma}^{cac} &\approx \varepsilon_{\pi\sigma} \lambda_\pi \lambda_\sigma \end{aligned} \qquad [13]$$

Two general conclusions follow. First, there is a critical cation–cation separation R_c below which the tight-binding bandwidth of eqn [4] is $W_b \approx 2zb^{cc} > U_{eff}$ and suppresses the localized-electron behavior to introduce the *d* electrons into either itinerant-electron states or cation-cluster molecular orbitals. Second, it is possible to have itinerant and localized electrons coexisting on the same atom. For example, $(180^\circ - \phi)$ cation–anion–cation interactions dominate in an AMO_3 perovskite, which has a simple cubic array of corner-sharing $MO_{6/2}$ octahedra with

a larger A-site cation in the body center. A $b_\sigma > b_\pi$ and a $U_e < U_t$ allow a $W_\sigma > U_e$ or a mixed-valent $\tau_h < \omega_R^{-1}$ of e electrons in the presence of $W_\pi < U_t$ as is illustrated by metallic and magnetic $SrFeO_3$ and the metallic ferromagnet $La_{0.7S}Sr_{0.3}MnO_3$.

The criterion for itinerant versus localized behavior in a mixed-valent compound is somewhat different from that in a single-valent compound. In a mixed-valent compound, electron transfer between atoms of a redox couple does not require overcoming an energy gap U_{eff}. However, the time $\tau_h \approx \hbar/W$ for an electron to transfer from one atom to another must be compared to the period $\omega_R^{-1} \approx 10^{-12}$ s of an optical-mode local vibration that traps a charge carrier. If the ligands have time to relax to an equilibrium position that distinguishes the smaller size of a cation of higher charge, then the stronger covalent bonding at the smaller site raises the energy of the empty antibonding orbitals above those of the occupied orbitals by ε_p as occurs with a redox couple in solution. The atomic relaxations thus self-trap a charge carrier, localizing it to a single site by introducing a small energy barrier between occupied and empty states. The self-trapped carriers are called "dielectric small polarons"; they move diffusively with a small activated mobility

$$\mu = (eD_o/kT)\exp(-\Delta G_m/hT) \qquad [14]$$

in which $\Delta G_m = \Delta H_m - T\Delta S_m$ is the free energy required to equalize the energies of the orbitals on neighboring sites. This mobility contrasts with that for an itinerant electron:

$$\mu = e\tau_s/m^* \qquad [15]$$

where τ_s is the mean free time between scatterings of the electronic charge carrier from aperiodicities in its periodic potential and m^* is the effective carrier mass. The crossover from polaronic to itinerant electronic behavior occurs where $\tau_h \approx \omega_R^{-1}$ or the polaron bandwidth is $W \approx \hbar\omega_R$. The polaronic bandwidth is reduced from the tight-binding bandwidth W_b of eqn [5] as

$$W = W_b \exp(-\lambda\varepsilon_p/\hbar\omega_R) \qquad [16]$$

where $\lambda \sim \varepsilon_p/W_b$ is a measure of the strength of the electron–lattice coupling. The transition from polaronic to itinerant electronic behavior in a mixed-valent compound would generally occur where U_{eff} remains a little larger than W_b, but Coulomb interactions between the charge carriers may slow τ_h and induce charge ordering at higher charge concentrations. Moreover, local site distortions at Jahn–Teller ions increase ε_p, which stabilizes polaronic behavior to larger values of W_b. Moreover, the virial theorem dictates a first-order transition from localized to itinerant electronic behavior, and the conditions under which the two types of crossover are found appear to be similar.

A first-order transition at $W_b \approx U_{eff}$ leads to bond-length instabilities; the two coexisting equilibrium bond lengths order at lower temperatures in a variety of ways to give such unusual phenomena as high-temperature superconductivity in copper oxides or a colossal magnetoresistance in manganese and cobalt oxides with a perovskite structure. At higher temperatures, bad-metal behavior with an unusual temperature dependence of the resistivity is found. As the temperature is increased, the bandwidth narrows and a smooth transition from itinerant to vibronic to polaronic behavior may be encountered.

The interatomic interactions of interest in the localized-electron regime $W_b < U_{eff}$ are the spin–spin interactions. The origin of the spin–spin interactions is in the quantum-mechanical exchange term J_{ex} entering U, so the spin–spin interactions are referred to as "exchange interactions."

The most general form of the bilinear interatomic spin–spin coupling between localized spins at $\boldsymbol{R}_i$ and $\boldsymbol{R}_j$ is

$$V_{ij} = S_i \cdot \boldsymbol{K}_S \cdot S_j + S_i \cdot \boldsymbol{K}_A \cdot S_j \qquad [17]$$

where $\boldsymbol{K}_S$ and $\boldsymbol{K}_A$ are symmetric and antisymmetric tensors. The first term reduces to an isotropic and an anisotropic component, $-2J_{ij}\boldsymbol{S}_i \cdot \boldsymbol{S}_j - 2\boldsymbol{S}_i \cdot \Gamma \cdot \boldsymbol{S}_j$, where $\Gamma \sim (\Delta g/g)^2$ represents a symmetric tensor and Δg is the deviation of the spectroscopic splitting factor from $g = 2$. The antisymmetric term can be reduced to $-2\boldsymbol{D}_{ij} \cdot \boldsymbol{S}_i \times \boldsymbol{S}_j$, where the Dzialoshinskii vector $\boldsymbol{D}_{ij} \sim (\Delta g/g)$ has its axis determined by the crystal symmetry. A quantitative description of the magnetization $M(T)$ of a ferromagnetically aligned subarray may require inclusion of a biquadratic term $-2\gamma_{ij}(\boldsymbol{S}_i \cdot \boldsymbol{S}_j)^2$ where the magnitude of a cation–cation interaction varies sensitively with the cation separation R. In addition, the coexistence of localized and itinerant electrons (or molecular-orbital electrons) adds an additional term H_{ex}^D, so the full phenomenological expression for the spin–spin interactions becomes

$$H_{ex} = H_{ex}^D - \sum_{ij}{}' \{J_{ij}\boldsymbol{S}_i \cdot \boldsymbol{S}_j + \gamma_{ij}(\boldsymbol{S}_i \cdot \boldsymbol{S}_j)^2 + \boldsymbol{D}_{ij} \cdot \boldsymbol{S}_i \times \boldsymbol{S}_j + \boldsymbol{S}_i \cdot \Gamma \cdot \boldsymbol{S}_j\} \qquad [18]$$

Measurement of the magnetic susceptibility $\chi_m \equiv M(T)/H_a$, where H_a is an applied magnetic

field, reveals whether localized spins are present in a compound and the character of the dominant spin–spin interactions, which may be ferromagnetic ($J_{ij}>0$) or antiferromagnetic ($J_{ij}<0$). In the absence of localized spins, a compound may be diamagnetic ($\chi_m<0$) or paramagnetic ($\chi_m>0$), but χ_m is normally small and temperature independent in this case. However, superconductors exhibit a transition below their critical temperature from a $\chi_m>0$ in the normal-metal state to a $\chi_m<0$ in the superconductive state. Localized spins, on the other hand, give a temperature-dependent paramagnetic susceptibility $\chi_m(T)>0$ that reflects not only the magnitudes of the atomic magnetic moments, but also the character of the spin–spin interactions. Moreover, the spin–spin interactions stabilize long-range magnetic order below a ferromagnetic Curie temperature T_c or an antiferromagnetic Néel temperature T_N. Several types of magnetic order are found.

"Ferromagnetism" refers to a parallel alignment of spins that gives a saturation magnetization $M_s(0)=\sum_i N_i\mu_{Ai}$ at $T=0$ K, where N_i is the number per unit volume of a transition-metal cation with moment μ_{Ai} and the sum is over all the different kinds of transition-metal cations that are present. The zero-field saturation magnetization $M_s(T)$ decreases with increasing temperature T, falling sharply to zero at $T=T_c$. In this case, the paramagnetic susceptibility obeys a Curie–Weiss law

$$\chi_m = C/(T-\theta) \qquad [19]$$

where the Curie constant for a single spin species is

$$C = Ng^2J(J+1)\mu_B^2/3k \qquad [20]$$

and the Weiss constant $\theta = CW$ reflects the strength of the ferromagnetic interactions through the W of the internal Weiss molecular field WM that aligns the spins. Short-range order above T_c makes the $\chi_m^{-1}(T)$ plot bend from linear as χ_m^{-1} approaches zero, which makes $T_c \leqslant \theta$.

"Antiferromagnetism" refers to a magnetic order that leaves the zero-field saturation magnetization $M(T)=0$ at all temperatures below a Néel temperature T_N. Néel antiferromagnetism consists of two like ferromagnetic subarrays aligned antiparallel to one another to give $M_s(T)=M_1(T)-M_2(T)=0$. In this case, a $W<0$ makes the Weiss constant of the Curie–Weiss law $\theta<0$, and χ_m^{-1} is finite at $T_N>0$. The antisymmetric term $\boldsymbol{D}_{ij}\cdot\boldsymbol{S}_i\times\boldsymbol{S}_j$ of eqn [18] may cant the spins of an antiferromagnet to give a weak ferromagnetism. That this weak ferromagnetic component is not due to an impurity is beautifully illustrated by α-Fe_2O_3, which has the crystallographic

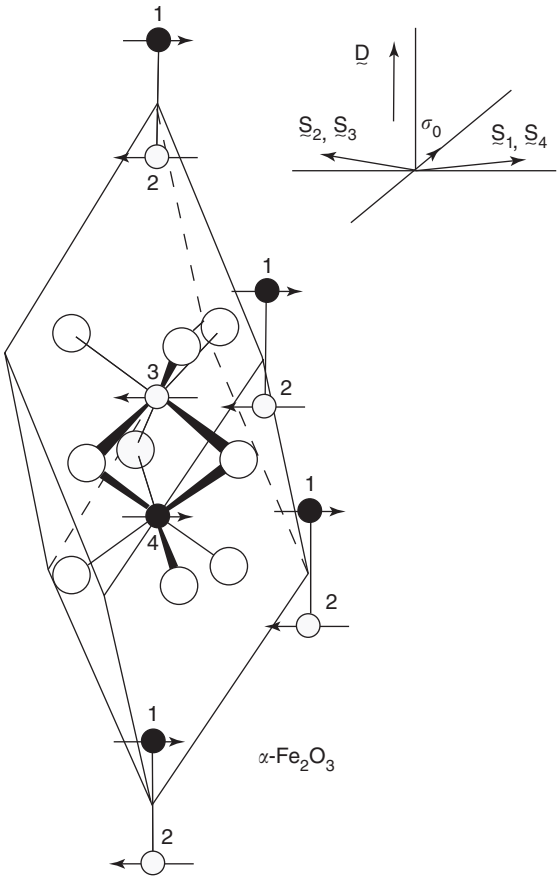

Figure 3 Antiferromagnetic spin configurations found in α-Fe_2O_3 in the temperature interval $250\,K<T<953\,K$ and the spin canting responsible for a weak ferromagnetic component σ_0. (After Shull CG, Strauser WA, and Wollan EO (1951) *Physical Review* 83: 333.)

and magnetic structure shown in **Figure 3** at room temperature. The weak ferromagnetic component has been used in magnetic recording. In this structure, the Dzialoshinskii vector $\boldsymbol{D}_{ij}$ is oriented parallel to the c-axis, so spin canting occurs if the spins lie in the basal plane. Dipole–dipole interactions orient the spins in the basal plane of α-Fe_2O_3 in the temperature interval $250\ K<T<T_N=953$ K; but below the Morin temperature $T_M=250\,K$, the spin orientation switches to the c-axis and the weak ferromagnetic component disappears abruptly.

"Ferrimagnetism" refers to an antiferromagnetic coupling of two ferromagnetic subarrays with magnetizations $M_1(T)$ and $M_2(T)$ where $M_s(T)=M_1(T)-M_2(T)\neq 0$ at all temperatures. Normally, $M_s(0)\neq 0$ in a ferrimagnet, but $Fe_2(SO_4)_3$ is an example where the Fe(III) atoms of the two subarrays are in sites that are crystallographically inequivalent, so $M_s(T)\neq 0$ although $M_s(0)=0$. The inverse paramagnetic susceptibility of a ferrimagnet is hyperbolic, approaching a Curie–Weiss law with $\theta<0$ at

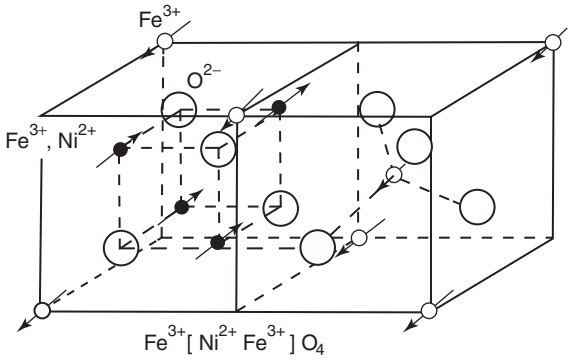

Figure 4 Ferrimagnetic order of $Fe[NiFe]O_4$. (After Hastings JM and Corliss LM (1953) *Reviews of Modern Physics* 25: 114.)

high temperatures, but falling to zero at a Curie temperature $T_c > 0$. The most celebrated ferrimagnets are the ferrospinels, which have an antiferromagnetic coupling of tetrahedral-site and octahedral-site cations. **Figure 4** illustrates the magnetic order in $Fe[NiFe]O_3$, where the octahedral-site cations are bracketed in the formula. In this case, the Fe(III) moments cancel one another and the net magnetization per formula unit is due to the nickel with $\mu_{Ni} \approx 2\mu_B$. Interestingly, substitution of Ni(II) by a nonmagnetic Zn(II) ion increases the magnetization because the Zn atoms prefer tetrahedral sites: $Zn_xFe_{1-x}[Ni_{1-x}Fe_{1+x}]O_4$ has a magnetization per formula unit for small x of $\mu_{mol} = (2 + 8x)\mu_B$. A rhombohedral component of the ligand field at an octahedral site of the spinel structure splits the t manifold into a nondegenerate a_1 orbital ($m = 0$) of lower energy and a twofold degenerate e_π-orbital manifold with $m = \pm 1$. Consequently, substitution of an Fe(II) for Ni(II) on the octahedral sites introduces mobile spins associated with the mixed iron valence, but it has little effect on the magnetocrystalline anisotropy. On the other hand, substitution of Co(II) for Ni(II) leaves the spinel an insulator but introduces a large magnetocrystalline anisotropy that increases linearly with the cobalt concentration as a result of splitting of the e_π-orbital degeneracy by $\lambda \boldsymbol{L} \cdot \boldsymbol{S}$.

"Spin-density wave (SDW)" refers to a noncollinear spin configuration that has a propagation vector $\boldsymbol{q}$ with a wavelength that may be either commensurate or incommensurate with a lattice period. Parallel alignment of near-neighbor spins in a ferromagnet or within a subarray of a Néel antiferromagnet or ferrimagnet may oppose weaker antiferromagnetic interactions between next-near-neighbor spins of the array. In this case, the crystal compensates either by changing its structure so as to weaken the antiferromagnetic interactions or by forcing the spins to become canted or, more commonly, to form an SDW.

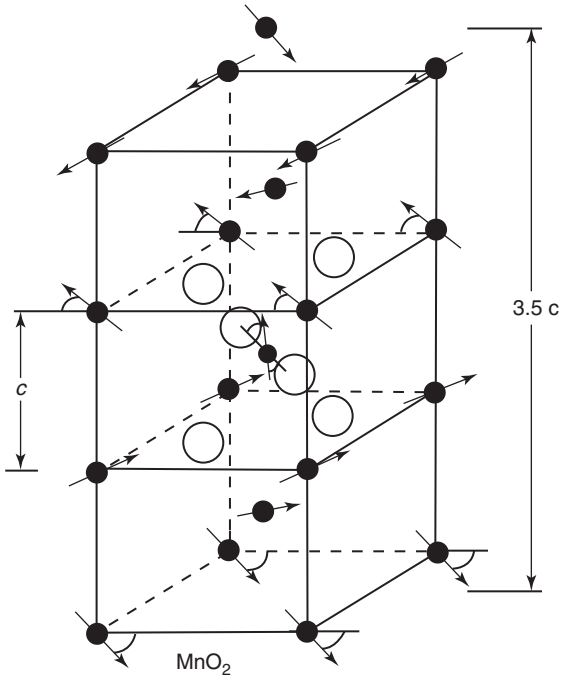

Figure 5 Spiral-spin configuration propagating parallel to the c-axis of MnO_2 (oxygen coordination shown for only one cation; cf. **Figure 9** for rutile structure). Turn angle between spins in successive (0 0 1) planes is $2\pi/7$. (After Erickson RA (1953) *Physical Review* 90: 779; Yoshimori A (1959) *Journal of the Physical Society of Japan* 14: 807.)

An SDW has an $M_s(T) = 0$ below T_N and is, therefore, antiferromagnetic. **Figure 5** illustrates a simple spiral-spin (helical) configuration found in the rutile structure of MnO_2. Canting of the octahedral-site spins is found in the tetragonal spinel $Cu[Cr_2]O_4$. **Figure 6** illustrates the spiraling of this canted-octahedral-site configuration observed in $Co[Cr_2]O_4$.

"Metamagnetism" refers to the transformation of antiferromagnetic order to ferromagnetic order in a moderate applied magnetic field. For example, an SDW having ferromagnetic nearest-neighbor interactions is transformed at 50 K in MnP to a ferromagnet on which a weak SDW component is superimposed.

An analogous, but not strictly metamagnetic, situation is found in some double perovskites $La_2M_aM_bO_6$ where ordering of the M_a and M_b cations introduces ferromagnetic M_a–O–M_b interactions within slabs, but leaves antiferromagnetic M_a–O–M_a and M_b–O–M_b interactions across antiphase boundaries. The ferromagnetic slabs are oriented antiparallel to one another in zero magnetic field, but the large magnetization of a slab allows a modest applied magnetic field to create a parallel orientation of the slabs except for spiral-spin interfaces centered at the antiphase boundaries.

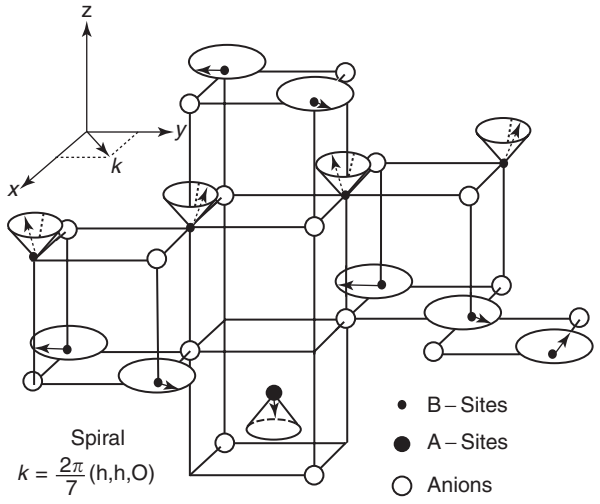

Figure 6 Complex spiral-spin configuration found in the spinel Co[Cr_2]O_4. Spiral propagates along the [1 1 0] direction. (After Dwight K and Manyuk N (1969) *Journal of Applied Physics* 40: 1156.)

"Frustrated systems" are those where strong antiferromagnetic interactions are unable to align all near-neighbor spins antiparallel to one another. This situation occurs, for example, in a close-packed plane or among the octahedral sites of a spinel. Frustration lowers the temperatures below which long-range magnetic order is found and leads to compromise spin configurations. In a close-packed plane with antiferromagnetic interactions between nearest neighbors, for example, the spins order at 120° rather than 180° with respect to one another.

"Spin glasses" are compounds containing ferromagnetic clusters in an antiferromagnetic matrix. Since the clusters are randomly distributed, the coupling between the clusters is frustrated, and the ferromagnetic regions assume random orientations below a spin-glass freezing temperature T_g. A "cluster glass" consists of antiferromagnetic clusters in a ferromagnetic matrix.

Several processes contribute to the microscopic origins of the spin–spin interactions.

"Direct exchange" between spins in orthogonal orbitals is ferromagnetic; it is a "potential exchange" as it does not involve electron transfer. The intraatomic exchange splitting Δ_{ex} responsible for Hund's highest multiplicity rule for the free atom is a direct exchange.

Interactions between spins on two atoms with overlapping orbitals is a "kinetic exchange." Two features are controlling, conservation of the spin angular momentum in the transfer and an angular dependence for electron spins having only the two directions α and β:

$$\alpha = \alpha' \cos(\theta/2) + \beta \sin(\theta/2) \qquad [21]$$

where θ is the angle between localized spins on the two neighboring atoms. Therefore, the spin-independent electron-transfer integral b_{ij} of eqn [3] is replaced by a spin-dependent integral

$$t_{ij}^{\uparrow\uparrow} = b_{ij}\cos(\theta/2) \quad \text{or} \quad t_{ij}^{\uparrow\downarrow} = b_{ij}\sin(\theta/2) \qquad [22]$$

"Superexchange" refers to interactions that require overcoming an energy barrier ΔE; in this case, the electron transfer is virtual and is treated in a second- or higher-order perturbation theory. Two cases must be distinguished:

1. If the overlapping orbitals are each half-filled, electron transfer is constrained by the Pauli exclusion principle to be antiferromagnetic and

$$\Delta E_{ex}^{S} \approx -|t_{ij}^{\uparrow\downarrow}|^2/U_{eff} = \text{const} + J_{ij}\boldsymbol{S}_i \cdot \boldsymbol{S}_j \qquad [23]$$

   where $\Delta E = U_{eff}$ corresponds to the interaction in a single-valent compound; the $J_{ij} \sim (2b_{ij}^2)/4S^2U_{eff}$ reduces to $2b^2/U_{eff}$ for nearest neighbors with $S = 1/2$.
2. If the overlapping orbitals are "half-filled and empty" or "filled and half-filled," ΔE_{ex} favors a ferromagnetic charge transfer and

$$\Delta E_{ex}^{S} = \text{const} - J_{ij}\boldsymbol{S}_i \cdot \boldsymbol{S}_j \qquad [24]$$

   with $J_{ij} \approx (2b_{ij}\Delta_{ex}/4S^2U_{eff}^2)$ follows from a third-order perturbation theory.

With half-filled t^3 configurations, the $(180° - \phi)$ t^3e^0–O–t^3e^0 interactions of the $RCrO_3$ (R=rare-earth) and $Sr_{1-x}Ca_xMnO_3$ perovskites are all antiferromagnetic as are the t^3e^2–O–t^3e^2 interactions in the $RFeO_3$ perovskites. An antisymmetric $\boldsymbol{D}_{ij} \cdot \boldsymbol{S}_i \times \boldsymbol{S}_j$ exchange term cants the antiparallel spins by a few degrees to give a weak ferromagnetic moment. On the other hand, the double perovskite La_2NiMnO_6 with ordered Ni(II) and Mn(IV) exhibits ferromagnetic Ni(II): t^6e^2–O–Mn(IV):t^3e^0 superexchange interactions. In the perovskite $LaMnO_3$, the cooperative Mn(III)-site distortions of **Figure 7** remove the *e*-orbital degeneracy of the t^3e^1 configuration and introduce $(180° - \phi)$ Mn(III)–O–Mn(III) superexchange interactions that are ferromagnetic in (0 0 1) planes ($\lambda_\sigma > \lambda_\pi$) and antiferromagnetic between basal planes. Here also, a spin canting gives a weak ferromagnetic component. However, dilution of the Mn(III) ions in $LaMn_{1-x}Ga_xO_3$ introduces regions of orbital disorder at lower temperatures that are ferromagnetic in three dimensions because locally cooperative distortive fluctuations favor electron transfer when a half-filled and an empty *e*-orbital overlap. This 3D

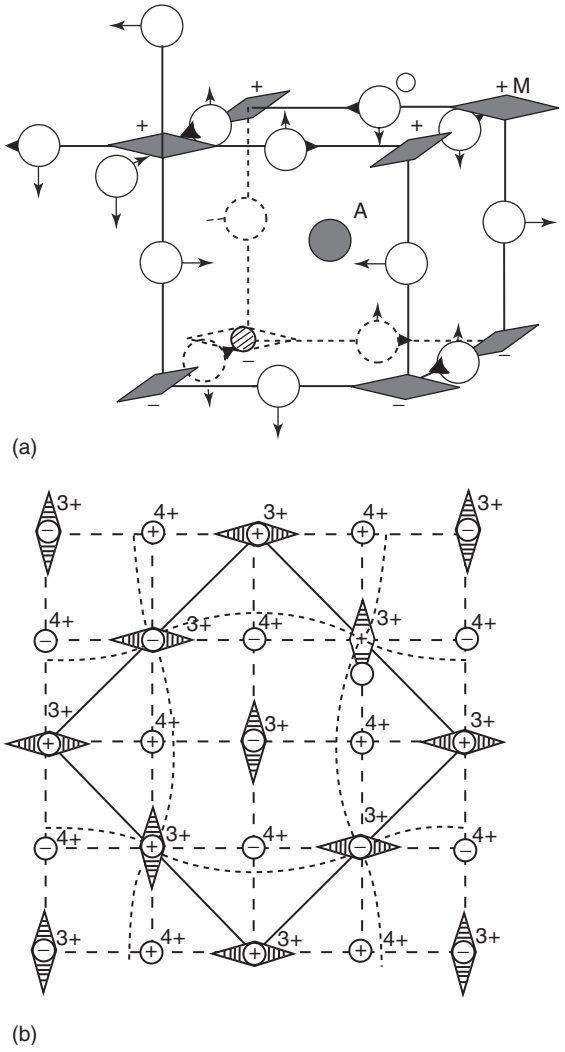

Figure 7 (a) Ordering of occupied *e* orbitals into (0 0 1) planes of $LaMnO_3$ and associated oxygen displacements. This cooperative orbital ordering is superimposed on a cooperative rotation of the $MnO_{6/2}$ octahedra (shown by arrows). Cooperative rotations bend the $(180^\circ - \phi)$ B–O–B bond angle in ABO_3 perovskites when the geometric tolerance factor $t \equiv (\text{A–O})/\sqrt{2}\,(\text{B–O}) < 1$; (A–O) and (B–O) are the equilibrium (A–O) and (B–O) bond lengths. (b) Charge, orbital, and spin [up (+), down (−)] ordering in $La_{0.5}Ca_{0.5}MnO_3$.

ferromagnetic interaction represents a "vibronic superexchange." Where the ferromagnetic Curie temperature T_c of the orbitally disordered regions is higher than the Néel temperature T_N of long-range antiferromagnetic order in the orbitally ordered matrix, an applied magnetic field stabilizes the orbitally disordered phase relative to the orbitally ordered phase to convert a spin glass into a ferromagnet.

"Semicovalent exchange" involves a two-electron transfer from a single anion-*p* orbital, one to each of the two cations on opposite sides in a $(180^\circ\text{–}\phi)$ cation–anion–cation interaction. Since the two transferred electrons have opposite spins, the rules for ferromagnetic versus antiferromagnetic coupling are the same as those for superexchange. A $U_{\text{eff}} \approx 0$ for the itinerant O–2*p* electrons gives semicovalent exchange the form $-J_{ij}\mathbf{S}_i \cdot \mathbf{S}_j$ with $J_{ij} \approx (2b_{ij}^2/8S^2\Delta)$, where $\Delta = \Delta E_p$ is the "charge-transfer energy gap." To illustrate the significance of the semicovalent-exchange component to the total exchange, consider again the $(180^\circ - \phi)\ t^3e^0 - \text{O} - t^3e^0$ interactions in the $RCrO_3$ and $Ca_{1-x}Sr_xMnO_3$ perovskites

$$\Delta E_{\text{ex}}^S \approx -\sum_{ij}{}' (2b_{ij}^2/4S^2)[1/U_{\text{eff}}) + (1/2\Delta)] \qquad [25]$$

Whereas the superexchange interactions treat only the π-bonding t^3–O–t^3 interactions, semicovalent exchange also includes the σ-bonding interactions if a $(\Delta_{ex}/\Delta)^2$ multiplier is added. A $\Delta \leqslant U_{\text{eff}}$ in $RCrO_3$ and $Ca_{1-x}Sr_xMnO_3$ makes the semicovalent-exchange component dominant to give a total exchange-energy parameter $J_{ex} \sim \langle \cos^2\phi > \rangle$ (cf. eqn [13]). A $T_N \sim \langle \cos^2\phi \rangle$ in an RMO_3 perovskite family signals localized-electron antiferromagnetism.

"Double exchange" occurs in mixed-valent transition-metal compounds in which a mobile spin has a $\tau_h < \omega_R^{-1}$ in the presence of localized spins. The mobile spin couples to the localized spin by the Hund intra-atomic exchange field to give a ferromagnetic interaction with a spin-dependent $t_{ij}^{\uparrow,\uparrow} = b_{ij}\cos(\theta/2)$ in the tight-binding formula of eqn [4], so

$$H_{\text{ex}}^D \approx -Nc(1-c)zb_{ij}\cos(\theta/2) \qquad [26]$$

where Nc is the concentration of mobile charge carriers and $(1-c)z$ is the fraction of near-neighbor sites that are empty. Polaronic charge carriers do not introduce a double-exchange coupling as their τ_h is long compared to the time for a spin to relax to a disordered orientation. Equation [24] is the de Gennes formulation that he applied to the metallic ferromagnetic compositions of the system $La_{1-x}Sr_xMnO_3$; it assumes the coexistence of conductive $(\tau_h < \omega_R^{-1})$ σ-bond electrons in the presence of localized spins $S = 3/2$ from the π-bond t^3 manifold. The original Zener formulation for double exchange in this system constrained the $\tau_h < \omega_R^{-1}$ to a Mn^{3+}–O–Mn^{4+} two-manganese polaron that he assumed to move diffusively, but with no motional enthalpy ($\Delta H_m = 0$). In fact, the electrons of *e*-orbital parentage undergo a crossover with increasing x from polaronic to itinerant electronic behavior in this system. **Figure 8** shows a small compositional and temperature range where the Zener model is applicable; it also reveals a discontinuous change in T_c at the transition from Zener to de Gennes double-exchange as predicted from the

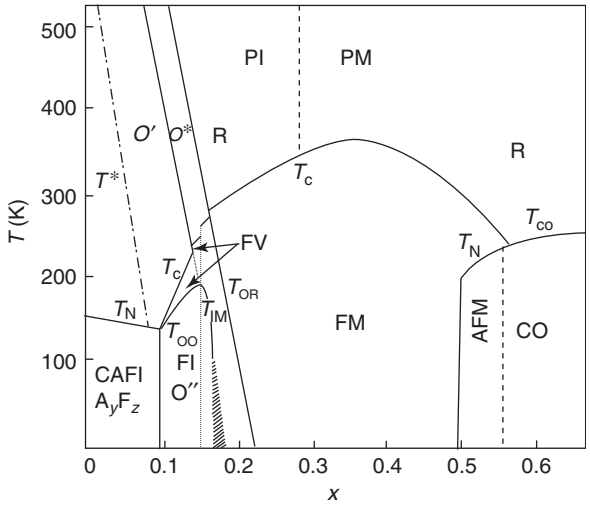

Figure 8 Phase diagram of the system $La_{1-x}Sr_xMnO_3$. CAFI=canted-spin type-A antiferromagnetic insulator [ferromagnetic (0 0 1) planes coupled antiparallel with orbital ordering of **Figure 7a**]. FI, FV, and FM=ferromagnetic insulator, vibronic conductor (Zener polarons), and de Gennes metal, respectively. AFM=type-A antiferromagnetic metal. CO=charge-ordered phase. O′ and O″ refer to different orbitally ordered orthorhombic phases, O* to an orbitally disordered orthorhombic phase, and R to a rhombohedral phase. PI and PM are, respectively, paramagnetic-insulator and paramagnetic-metal phases. (After Goodenough JB and Zhou J-S (2001) *Structure & Bonding* 98: 87.)

virial theorem for a transition from polaronic to itinerant-electron conduction. An orbital ordering that lifts the degeneracy of the σ^* band of *e*-orbital parentage stabilizes the AFM phase of **Figure 8**; metallic, ferromagnetic (0 0 1) planes are coupled antiparallel to one another along the *c*-axis by t^3–O–t^3 superexchange. However, charge and orbital ordering in $La_{0.5}$ $Ca_{0.5}$ MnO_3 traps the mobile charge carriers to give zigzag ferromagnetic chains coupled antiparallel to one another in the (0 0 1) planes, see **Figure 7b**. The Mn^{3+} ions are confined to stripes of zigzag chains, as shown in the CO phase in **Figure 8**.

The spinel Fe_3O_4 has mixed Fe(II) and Fe(III) valence states on the octahedral sites, and an antiferromagnetic Fe–O–Fe superexchange interaction couples antiparallel to the tetrahedral-site and octahedral-site spins to give a ferrimagnetic moment per Fe_3O_4 molecule of $\sim 4\,\mu_B$; the spins of the two Fe(III) ions cancel one another, and the ferromagnetic alignment of the octahedral-site spins reduces the spin-disorder scattering for motion of the minority-spin electrons in the presence of the localized majority-spin electrons to give a $\tau_h \leqslant \omega_R^{-1}$ between room temperature and a CDW Verwey transition temperature $T_V \approx 120\,K$. The mobile electrons give a ferromagnetic double-exchange interaction between the octahedral-site cations below room temperature. Fe_3O_4 represents another situation where itinerant and localized spins can coexist on the same atom. However, at higher temperatures spin-disorder scattering converts a $\tau_h \leqslant \omega_R^{-1}$ to a $\tau_h > \omega_R^{-1}$, and the mobile electrons become polaronic.

"Indirect exchange," also known as Yaffet–Kittel–Kasuya–Yosida (YKKY) exchange, is a coupling of localized spins by a partially filled band of itinerant electrons; it is an extension of the de Gennes double exchange to a broad itinerant-electron band. Intra-atomic exchange stabilizes an itinerant-electron spin density parallel to the localized spin in the vicinity of the transition-metal atom, but this itinerant-electron spin density decreases at larger distances, reversing sign in a series of oscillations. If a neighboring localized spin is close enough to be overlapped by the parallel spin density, then the localized spins are coupled ferromagnetically; but if the antiparallel spin density overlaps the neighboring spins, they couple antiferromagnetically. The extension of the parallel spin-density domain increases as the concentration of itinerant electrons decreases and their effective mass increases.

Additional Illustrative Examples

Spinels

The dominant interaction in the ferrospinel Fe[NiFe]O_4 is the antiferromagnetic 135° t^3–O–e^2 interaction between half-filled σ-bonding orbitals on the tetrahedral-site Fe(III):e^2t^3 and the octahedral-site Ni(II):t^6e^2 and Fe(III):t^3e^2 ions.

In an A[M_2]O_4 spinel in which the tetrahedral-site A cation has no spin, the only spin–spin interactions are those between octahedral-site transition-metal atoms M. The octahedral-site cations in the spinel structure of **Figure 4** share only octahedral-site edges; they interact with one another by M–M and 90° M–X–M interactions. The octahedral-site Cr(III):t^3e^0 cations in Zn[Cr_2]O_4, Zn[Cr_2]S_4, and Cd[Cr_2]S_4 all have ferromagnetic 90° Cr–X–Cr interactions by direct exchange and t^3–$p_{\pi\sigma}$–e^0 superexchange whereas the t^3–t^3 interactions are antiferromagnetic by superexchange. The antiferromagnetic t^3–t^3 interactions decrease exponentially with increasing Cr–Cr separation, that is, with increasing lattice parameter on going from Zn[Cr_2]O_4 to Zn[Cr_2]S_4 to Cd[Cr_2]S_4. The 90° Cr–X–Cr interactions, on the other hand, increase significantly on going from an oxide to a more covalent sulfide. Experimentally, Cd[Cr_2]S_4 is a ferromagnetic insulator, the Cr–Cr interactions in Zn[Cr_2]S_4 are just strong enough to convert the ferromagnetic coupling into an SDW, and in Zn[Cr_2]O_4 stronger antiferromagnetic Cr–Cr interactions are frustrated to give a low T_N.

As pointed out above, Fe_3O_4 is a good electronic conductor because of mixed Fe(III) and Fe(II) valence states on the octahedral sites. On the other hand, Mn_3O_4 and Co_3O_4 are insulators because the Mn(II) and Co(II) ions occupy tetrahedral sites having a different potential energy for the M(II)/M(III) couple than that at the octahedral sites. With Mn(III):t^3e^1 on octahedral sites, Mn_3O_4 undergoes a cooperative Jahn–Teller orbital ordering that distorts the spinel from cubic to tetragonal symmetry; the room temperature axial ratio is c/a=1.16. Fe_3O_4 is a Néel ferrimagnet with ferromagnetic double-exchange coupling among the octahedral sites whereas antiferromagnetic t^3–t^3 interactions between octahedral-site Mn(III) lead to a complex magnetic order. Co_3O_4 is a Néel antiferromagnet because the octahedral-site Co(III):t^6e^0 ions are in their low-spin state with $S = 0$ and the tetrahedral sites consist of two interpenetrating face-centered-cubic arrays as in the diamond structure with antiferromagnetic t^3–O–t^3 superexchange interactions between the Co(II):e^4t^3 ions.

Rutiles

The MX_2 compounds with X = F or O crystallize in the rutile structure of **Figure 9**. This structure has a body-centered-tetragonal array of octahedral-site cations that share edges along the c-axis; these c-axis chains share octahedral-site corners. The anions form sp^2 σ-bonds with three cation neighbors and π-bond with two quasidegenerate t orbitals, e_π; the other t orbital, $d_{||}$, is directed along the c-axis where it overlaps with the corresponding $d_{||}$ orbitals of two next-near-neighbor cations. The MO_2 oxides illustrate several features discussed above.

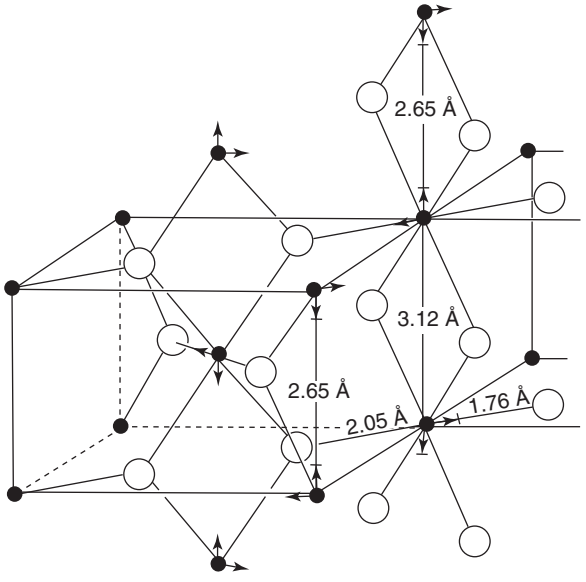

Figure 9 The tetragonal rutile structure and the cation displacements (arrows) found in VO_2 at $T < 67°C$.

The bottom of the empty 3d bands of TiO_2 lies $\sim$3 eV above the top of the filled O–2p bands, which makes TiO_2 an insulator and a crystal transparent. However, the elastic energy that would resist displacement of a Ti(IV) from the center of its interstice is not large, which is why $BaTiO_3$ and $PbTiO_3$ are ferroelectrics. In TiO_2, there is no spontaneous displacement, but displacements in an electric field give TiO_2 a large dielectric constant, which makes TiO_2 a white pigment widely used in paint and the finishing of paper. The itinerant-electron 3d bands can be doped n-type, in which case n-TiO_2 can be used for photoelectrolysis. Removal of oxygen is accommodated by an ordering of the oxygen vacancies into "shear planes" that separate slabs, n rutile cells wide, in a Ti_nO_{2n-1} family of shear structures. Ti(IV) octahedra share common faces across a shear plane, and electrostatic forces displace the cations toward opposite site faces; itinerant electrons reside on the Ti cations within the rutile slabs. The formation of shear planes allows cooperative displacements of the Ti(IV) cations, which reduces the cost in elastic energy. The shear-plane phenomena are associated with cations that also exhibit ferroelectric displacements in other contexts. At low temperatures, the itinerant electrons within the 3d bands of a slab condense into $d_{||} - d_{||}$ homopolar bonds to form pairs of Ti(III) displaced toward one another. In Ti_4O_7, these two-electron bonds are mobile and disordered in a small temperature interval above the long-range ordering temperature $T_t \approx 160\,K$. The mobile electron pairs represent bipolarons.

Above 67°C, the single 3d electron of a V(IV) cation occupies overlapping itinerant-electron bands of $d_{||}$ and e_π parentage; the metallic conductivity is nearly isotropic. The $d_{||}$ band is formed by strong V–V interactions along the c-axis: the π^* bands by strong e_π–O:2p_π–e_π interactions with nearest and next-nearest neighbors. Below 67°C, these itinerant electrons condense into $d_{||}$–$d_{||}$ homopolar bonds and the smaller V(IV) cations are also displaced toward a corner-sharing oxygen by a rocking of the pairs to form molecular clusters consisting of two vanadyl $(V{=}O)^{2+}$ cations bonded by a homopolar V–V bond. The oxygen atoms that bridge a V–V bond each belong to another such cluster. The resulting monoclinic-tetragonal first-order transition at T_t = 67°C produces an insulator–metal transition across which the formation of the V=O vanadyls lifts the π^* bands above the Fermi energy, leaving the $d_{||}$ band half-filled, and V–V pairing introduces a gap in the narrow $d_{||}$ band that localizes the electrons in homopolar bonds. This localization of electrons to a

molecular cluster is to be distinguished from formation of a 1D CDW as envisioned by a "Peierls distortion" in which the electrons of the pairs remain itinerant.

In CrO_2, the Cr–Cr separation along a *c*-axis chain is too large ($R > R_c$) for the $d_{||}$ electrons to form a band of itinerant-electron states; they form localized $d_{||}^1$ states separated from a $d_{||}^2$ configuration by a finite energy gap ($U - W_{||}$). The remaining single e_π electron occupies a π^* band of itinerant-electron states. This band is one-quarter filled, and extrapolation of the superexchange rules to band magnetism would predict ferromagnetic correlations among the e_π electrons. Alternatively, the de Gennes model of double-exchange with strong intra-atomic exchange between the localized $d_{||}$ and itinerant e_π electrons also predicts ferromagnetism. Both considerations apply, and CrO_2 is a ferromagnetic metal. Below the Curie temperature T_c, the *c*-axis expands as a result of "exchange striction"; the half-filled $d_{||}^1$ orbitals would be stabilized by antiferromagnetic superexchange, but their parallel alignment removes the *c*-axis bonding by the $d_{||}$ electrons because the Pauli exclusion principle prevents $d_{||}$-electron transfer if the spins are parallel.

In MnO_2, both the $d_{||}$ and the e_π electrons are localized and a $d_{||}^1 e_\pi^2$ manifold means that both sets of orbitals are half-filled, which leads to antiferromagnetic interactions between nearest and next-nearest neighbors by superexchange. Since both nearest and next-nearest neighbors share a common O–2p_π orbital, the antiferromagnetic interactions along the *c*-axis are stronger than those between nearest neighbors, and the competition leads to the antiferromagnetic spiral-spin configuration propagating along the *c*-axis that is illustrated in **Figure 5**.

The 4*d* electrons have a greater radial extension than the 3*d* electrons, so they have larger overlap integrals with neighboring atoms than do the 3*d* orbitals. Consequently, NbO_2 and MoO_2 do not have localized 4*d* electrons; they both form *c*-axis M–M pairs, but without the rocking of the pairs that occurs in VO_2. The homopolar-bond states of NbO_2 lie below the bottom of the π^* band of e_π-orbital parentage, and NbO_2 is a semiconductor below $T_t \approx 800^\circ C$. With one additional 4*d* electron, MoO_2 has one electron per formula unit in the π^* bands and is a metal. Low-spin Ru(IV) and Rh(IV) are also accessible in octahedral sites of an oxide, but they contain too many 4*d* electrons to allow stabilization of homopolar bonds in M–M pairs. With two and one hole per formula unit, respectively, in the $d_{||}$ and π^* bands, these oxides are metallic and retain the rutile structure to lowest temperatures.

Energy Bands and Redox Couples

Electron Energies

In an ionic model of a compound, which is illustrated in **Figure 10** for MnO, the energy E_I required to remove the last electron from the cation and place it on an O^- ion at infinite separation is more than compensated by the electrostatic Madelung energy $E_M > E_I$ that is gained by assembling the point charges in a crystalline array. Conservation of energy raises the cation energy levels and lowers the anion energies. The crystalline electric field at the octahedral-site Mn^{2+} of MnO raises the Mn:3d^5 level into the energy gap $E_g \approx 6$ eV between the filled O^{2-}:2p^6 and empty Mn^{2+}:4s^0 bands. Covalent back transfer of electrons from the O^{2-} to the Mn^{2+} ions reduces E_M, but it introduces a compensating quantum-mechanical repulsion between the bonding O-2*p* and antibonding Mn-4*s* orbitals to retain a large E_g. The covalent mixing and the like-atom interactions broaden the bonding and antibonding *s* and *p* states into bands of one-electron itinerant-electron states, and it is convenient to label the upper bonding bands as O^{2-}:2p^6 bands and the lower antibonding bands as Mn:4s^0.

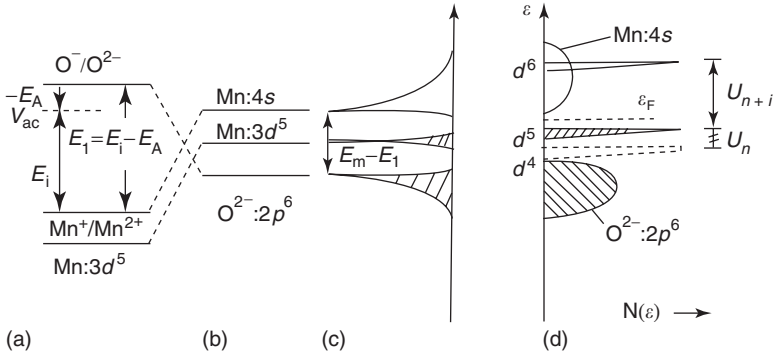

Figure 10 Schematic construction of electronic energies from the point-charge model, (a) and (b), to energy bands for Mn:4s^0 and O^{2-}:2p^6 in (c) and (d).

Where a d^n or $4f^n$ manifold falls in the energy gap E_g, as occurs in MnO, further oxidation of the cation is possible. Similarly, where an empty d^{n+1} manifold lies in the gap, reduction of the cation is possible if this manifold is not too close in energy to the bottom of the broad *s* and *p* antibonding bands. In the case of octahedral-site manganese, three valence states are stable: Mn(II), Mn(III), and Mn(IV) corresponding to Mn(III)/Mn(II) and Mn(IV)/Mn(III) redox couples lying in the gap. The splitting $U_{\text{eff}} - U_\sigma$ between the Mn(II):t^3e^2 and Mn(III):t^3e^1 energies is small; in fact, W_σ approaches U_σ in the perovskites $LaMnO_3$ and $SrMnO_3$ containing Mn(III) and Mn(IV), respectively, and a $\tau_h < \omega_R^{-1}$ for the σ^* electrons makes $La_{0.7}Sr_{0.3}MnO_3$ a ferromagnetic metal.

Since $E_M - E_I$ decreases on going from the halides (group VII) to the oxides and chalcogenides (group VI) to the pnictides (group V) and down any column of the periodic table to heavier anions, the energy gap E_g between bonding and antibonding *s* and *p* bands decreases accordingly. Consequently, the higher cation valence states accessible in an oxide may not be available in a sulfide or selenide. For example, the Mn^{2+}:d^5 manifold lies below the S^{2-}:$3p^6$ energy in the point-charge model, so the Mn(IV) state is not accessible in the chalcogenides. MnS_2 is $Mn^{2+}(S_2)^{2-}$, for example, in contrast to $Mn^{4+}(O^{2-})_2$ in MnO_2. However, where a d^n manifold lies close to the top of the bonding anion-*p* bands, covalent mixing raises antibonding states of *d*-orbital symmetry to the top of the broad bonding bands; the redox couple becomes pinned at the top of the bonding bands and changes from primarily *d* to primarily anion-*p* character as the d^n manifold falls below the anion-p^6 energy in the point-charge model. Where the anion component becomes dominant, the electronic states of the redox couple are itinerant; and where both the hole concentration and the anion character in these itinerant antibonding states are large enough for a cooperative condensation of the holes into purely anion antibonding states of anion–anion pairs, diatom anions are formed.

Rare-Earth Compounds

An energy $U > E_g \gg W$ separates the $4f^n$ and $4f^{n+1}$ localized-electron manifolds of the rare-earth ions. Therefore, they have a single R^{3+} valence state unless a $4f^n$ configuration falls within E_g, as occurs for the Ce^{3+}:$4f^1$ and Pr^{3+}:$4f^2$ or the Eu^{2+}:$4f^7$ in an oxide. However, the R-5*d* orbitals are itinerant, and covalent bonding pushes the antibonding 6*s* and 6*p* states above the bottom of the 5*d* band. Normally the 5*d* band is empty, but it can accept electrons. Doping EuO with Gd substitution for Eu, for example, creates shallow one-electron donor states below the bottom of the 5*d* conduction band just as substitution of P for Si creates *n*-type silicon. In EuO, the Eu:$4f^7$ level lies $\sim$1.1 eV below the bottom of the 5*d* band; the $4f^7$–O–$5d^0$ superexchange interactions are ferromagnetic and stronger than the antiferromagnetic $4f^7$–O–$4f^7$ interaction because of the large U_{eff} between $4f^7$ and $4f^8$ as well as the smaller overlap integrals. In the $Eu_{1-x}Gd_xO$ system, the YKKY indirect exchange by itinerant 5*d* electrons initially increases the ferromagnetic Curie temperature T_c with *x*; but as *x* increases, the extension of the ferromagnetic 5*d* volume about a rare-earth atom decreases to below a nearest-neighbor separation; the YKKY interaction becomes antiferromagnetic, and T_c decreases with a further increase of *x*. $Eu_{1-\delta}O$ contains polaronic $\tau_h > \omega_R^{-1}$ holes in the Eu(III)/Eu(II) redox couple. On the other hand, annealing in a Eu atmosphere creates $EuO_{1-\delta}$, and the oxygen vacancies trap two electrons. On cooling $EuO_{1-\delta}$ below the Curie temperature T_c, the 5*d* states with spin parallel to the $4f^7$ spin $S = 7/2$ are stabilized relative to the 5*d* states of antiparallel spin by direct intra-atomic exchange. The spin degeneracy of the two-electron trap state is also removed, the energy of the antiparallel trapped electron is raised above the bottom of the parallel-spin 5*d* conduction band. As a result, $EuO_{1-\delta}$ transforms from a semiconductor to a metal on cooling through T_c as is illustrated in **Figure 11**. Just above T_c, the carriers thermally excited into the 5*d* band stabilize regions of short-range ferromagnetic order by double-exchange electron transfer; ferromagnetic alignment reduces the spin-disorder scattering of the mobile electrons, and their stabilization by the intra-atomic exchange interaction confines the mobile electrons to the region of short-range ferromagnetic order. A mobile electron confined to clusters of short-range ferromagnetic order is called "magnetic polarons." In an external magnetic field, the size of the ferromagnetic clusters grows; at a percolation threshold, the compound undergoes a drop in electrical resistance. This magnetoresistance is large in EuO.

The valence state of a rare-earth ion is defined by its occupied $4f^n$ configuration. $Eu_{1-\delta}O$ is in a mixed Eu^{3+}/Eu^{2+} valence state since the holes occupy the Eu^{3+}/Eu^{2+} $4f^6/4f^7$ couple. GdS, on the other hand, has the Gd configuration $4f^75d^1$, and the itinerant 5*d* electrons that make GdS a metal are valence electrons. Therefore, the Gd of GdS is considered to be in the trivalent state corresponding to a localized $4f^7$ configuration. SmS has its $4f^6$ level just below the bottom of the 5*d* band; pressure increases the width of the 5*d* band, and above 6.5 kbar the 5*d* band overlaps the $4f^7$ level. A first-order contraction of the

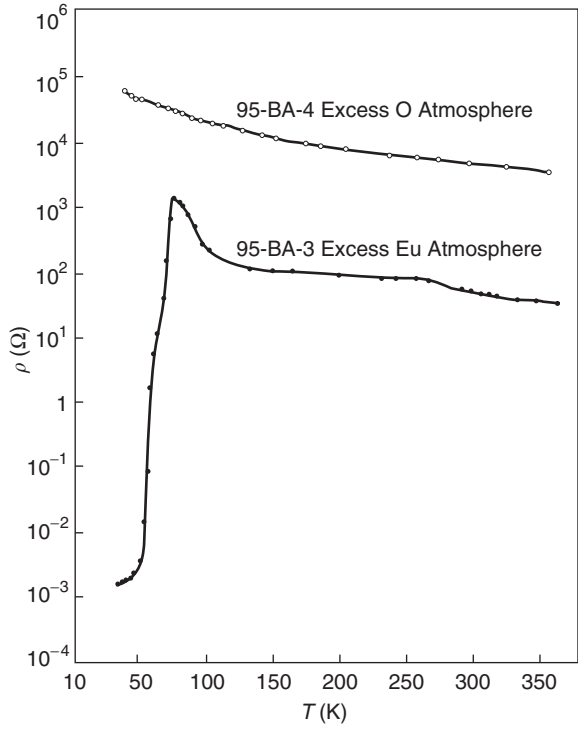

Figure 11 Resistivity vs. temperature for EuO annealed in a europium-rich atmosphere ($EuO_{1-\delta}$) and an oxygen-rich atmosphere ($Eu_{1-\delta}O$). (After Oliver MR, Dimmock JO, McWhorter AL, and Reed TB (1972) *Physical Review B* 5: 1078.)

rocksalt structure at crossover raises the $4f^6$ level into the $5d$ band to where 0.5 electrons per Sm are donated to the $5d$ band. Hybridization of $5d$ and $4f$ states creates "heavy fermions" at the Fermi energy and the compound is said to be in an intermediate-valence state.

Transition-Metal *d*-Block Compounds

The smaller U_{eff} of the d-block transition-metal compounds makes localized $4d$ and $5d$ spins relatively rare; localized spins associated with $3d$ electrons are common, but they may also be itinerant as discussed above for oxides with a rutile structure. The existence of four valence states for vanadium in V_2O_5, VO_2, V_2O_3, and VO shows that the $U_{\text{eff}} = U_\pi$ separating octahedral-site t^1, t^2, and t^3 configurations is in the neighborhood of 2 eV, which makes $W \approx U_{\text{eff}}$ in these compounds. Both VO_2 and V_2O_3 exhibit insulator–metal transitions due to cation clustering, V_2O_5 contains short V═O bonds due to displacement of the V(V) from the center of symmetry of its interstice, and VO is a semimetal exhibiting V–V bond-length fluctuations. On the other hand, the Ti–Ti interactions in metallic TiO make $W > U_\pi$; it becomes a conventional superconductor below $T_{cs} = 1$ K.

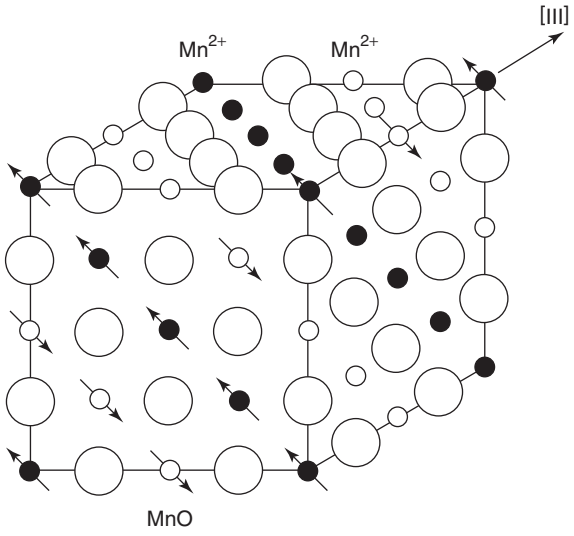

Figure 12 Spin configurations of antiferromagnetic MnO. (After Shull CG, Strauser WA, and Wollan EO (1951) *Physical Review* 83: 333.)

For a given valence state, the effective nuclear charge seen by the d electrons increases on going to heavier atoms of a given d-block and the redox energy is correspondingly stabilized. However, in an octahedral site, the splitting U_{eff} between a Cr(III):t^3e^0 and a Cr(II):t^3e^1 configuration is increased by the cubic-field splitting Δ_c, which is why CrO has not been prepared; the Cr(III)/Cr(II) level lies close to the bottom of the $4s$ band. However, CrS has been prepared; it has hexagonal rather than cubic close-packing of the anions (NiAs rather than NaCl structure) with a cooperative Jahn–Teller orbital ordering that distorts the structure from hexagonal symmetry. The d^5 configuration of MnO is more stable than the d^6 configuration of $Fe_{1-\delta}O$ because a $U_{\text{eff}} = U_\pi + \Delta_{ex}$ separates the Fe(III):t^3e^2 and Fe(II):t^4e^2 octahedral-site states. Since the majority-spin electrons occupy different d orbitals, they are more tightly bound to the nucleus than the minority-spin electron, which is why the minority-spin electron of Fe_3O_4 can have a $\tau_h \approx \omega_R^{-1}$.

The antiferromagnetic order in MnO is illustrated in **Figure 12**. The dominant interactions are 180° Mn(II)–O–Mn(II) antiferromagnetic superexchange interactions between half-filled t^3 and e^2 configurations; these interactions order parallel the spins of a (1 1 1) plane, whereas the t^3–t^3 superexchange interactions across shared octahedral-site edges within these planes are antiferromagnetic. Parallel spin alignment makes these t^3–t^3 interactions nonbonding, whereas those between neighboring, antiparallel (1 1 1) planes are bonding. Consequently, MnO distorts from cubic to rhombohedral ($\alpha > 60°$)

symmetry on cooling through T_N as a result of exchange striction. Similar antiferromagnetic 180° e^2–O–e^2 superexchange interactions are dominant in $Fe_{1-\delta}O$ and CoO, but these compounds exhibit a distortion below T_N that is due to a large magnetostriction; the orbital degeneracies of the Fe(II):t^4e^2 and Co(II):t^5e^2 configurations are removed by an enhancement of the orbital angular momentum once long-range collinear ordering of the spins allows ordering of the orbital angular momentum through the spin–orbit coupling $\lambda \boldsymbol{L} \cdot \boldsymbol{S}$. $Fe_{1-\delta}O$ becomes rhombohedral ($\alpha < 60°$) below T_N with spins oriented parallel to the [1 1 1] axis in opposition to the dipole–dipole forces; CoO becomes tetragonal ($c/a < 1$) and the dipole–dipole interactions force the spins a little away from the tetragonal c-axis.

Pinning of a redox couple at the top of an anion-p band replaces the gap U_{eff} with a charge-transfer gap $\Delta = \Delta E_p$. The Ni(II):t^6e^2 configuration of NiO is pinned at the top of the O–2p bands, and a $\Delta < U_{eff} = U_\sigma + \Delta_{ex}$ makes semicovalent exchange the dominant antiferromagnetic Ni(II):e^2–O–Ni(II):e^2 interaction responsible for its high Néel temperature. In NiS, the Ni(I):t^6e^3 configuration is at the top of the S–3p bands. At temperatures $T > 350$°C, NiS has the NiAs structure, but it transforms into the peculiar millerite structure at lower temperatures. It is possible to retain the NiAs structure at low temperatures by quenching from above 650°C. This metastable phase undergoes a first-order insulator–metal transition at a Néel temperature $T_N = 264$ K. On lowering the temperature through T_N, there is an abrupt increase in volume with only a small distortion of the structure as the width of the σ^* band of e-orbital parentage changes from $W_\sigma \approx U_{eff} = U_\sigma + \Delta_{ex}$ to $W_\sigma < U_{eff}$; the Mott–Hubbard transition is not smooth.

The lattice instabilities occurring where $W \approx U_{eff}$ are more commonly expressed by either stabilization of a CDW or, in a mixed-valent compound, by a dynamic spinodal phase separation. For example, the low-spin Ni(III):t^6e^1 configuration in the $RNiO_3$ family of **Figure 13** is pinned at the top of the O–2p bands; this single-valent family undergoes a transition from an antiferromagnetic insulator with $W < U_\sigma$ to metallic $LaNiO_3$ with $W > U_\sigma$ as the $(180° - \phi)$ Ni–O–Ni bond angle increases with increasing size of the rare-earth R^{3+} ion. The samples in the shaded area exhibit bond-length fluctuations and stabilization of a CDW below a $T_t = T_N$ that are characteristic of the lattice instabilities encountered at crossover. Below the insulator–metal transition T_{MI}, a distortion to monoclinic $P2_1/n$ symmetry reflects bond-length fluctuations that become static for R = HO,…, Lu, Y with long-range ordering of Ni (III) ions distinguished by alternating covalent and ionic Ni–O bond lengths. Moreover, applying

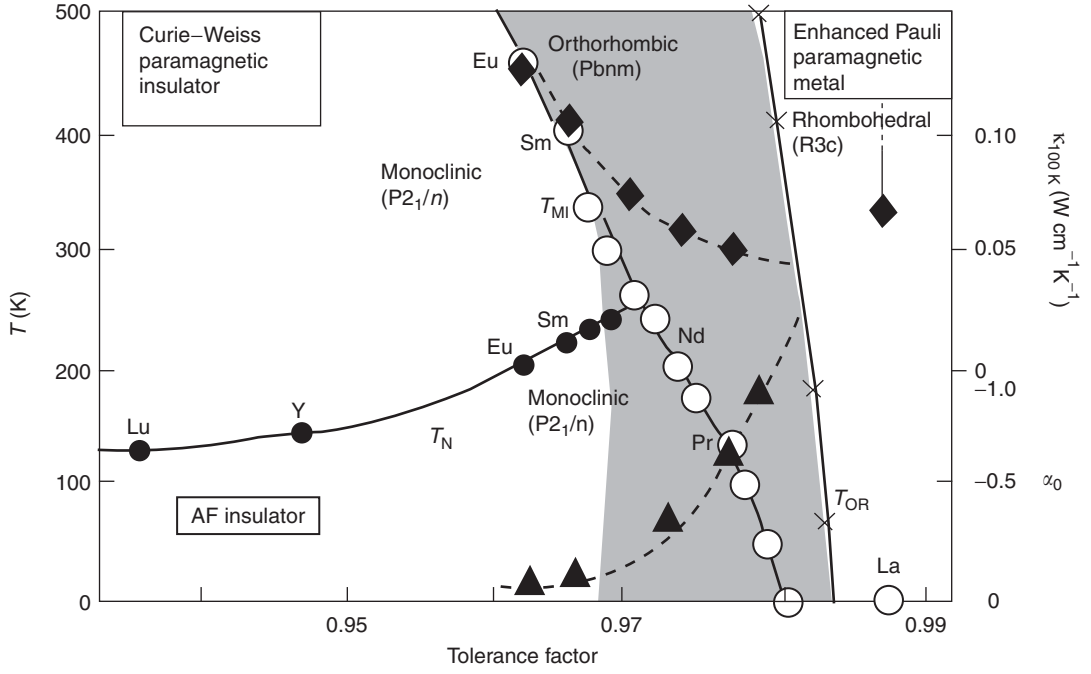

Figure 13 Schematic phase diagram of the $RNiO_3$ (R=rare-earth) family. The triangle symbol is for the $^{18}O/^{16}O$ isotope effect, the diamond is for the lattice contribution to the thermal conductivity at 100 K; both of these signal bond-length fluctuations in the shaded region. In the nonshaded region, a $T_N \sim \langle \cos^2\phi \rangle$ indicates localized-electron antiferromagnetism; $LaNiO_3$ is metallic. pressure to $PrNiO_3$ lowers $T_{MI} = T_N$ until it terminates at a first-order transition to a quantum-critical-point phase.

Pinning of a redox couple at the top of the O–2*p* bands may also be revealed by oxidation of the transition-metal array. For example, the $x = 0$ composition of the layered $Li_{1-x}CoO_2$ cathode material contains low-spin Co(III):t^6e^0 and is a charge-transfer-gap semiconductor. However, the t^5/t^4 Co(IV)/Co(III) redox couple is pinned at the top of the O–2*p* bands, and removal of Li from between adjacent CoO_2 layers of edge-shared octahedra creates a two-phase region $0.1 < x < 0.4$ in which a semiconductive phase and a metallic phase of smaller Co–Co separation coexist as a result of a $\tau_h \approx \omega_R^{-1}$. At $x > 0.6$, peroxide formation at the surface leads to the loss of oxygen as gaseous O_2.

The high-temperature copper-oxide superconductors provide an example where strong electron–lattice interactions in a mixed-valent system at the $\tau_h \approx \omega_R^{-1}$ crossover leads to a remarkable physical phenomenon. In these layered oxides, the $x^2 - y^2$ orbital of the Cu(III)/Cu(II) couple is pinned at the top of the O–2*p* bands of a CuO_2 sheet. The $(CuO_2)^{2-}$ planes of the single-valent parent compounds are antiferromagnetic insulators, but removal of electrons from these sheets induces a transition from the antiferromagnetic phase to a metallic phase that is not superconductive. Superconductivity appears in an intermediate $\tau_h \approx \omega_R^{-1}$ crossover phase where there is a strong electron coupling to bond-length fluctuations that order into a traveling CDW (or stripes) phase at low temperatures as is illustrated in **Figure 14** for the $La_{2-x}Sr_xCuO_4$ system.

Introduction

The distinguishing feature of transmission electron microscopy (TEM) is its ability to form images of atomic arrangements at localized regions within materials. It provides a view of the microstructure, that is, the variations in structure from one region to another, and the interfaces between them. TEM plays a critical role whenever macroscopic properties are controlled or influenced by defects or interfaces, for example, in the development of advanced structural materials with their complex microstructure of second phases or electronic materials which rely on the exquisite control of interfaces and multilayers. X-ray or neutron diffraction provide quite complementary information. These techniques can determine the average structure of complex materials very precisely, but not the structure of a local region or individual nanostructure. As condensed matter physics moves toward the study of ever more complex materials, and at the same time interest in nanoscale physics and devices is increasing, TEM or its scanning counterpart STEM, is finding a rapidly increasing role in basic condensed matter physics research.

The unique role of the TEM arises because electrons are charged particles, and therefore, unlike X-rays or neutrons, are able to be accelerated and precisely focused by electromagnetic fields. The scattered beams can be collected by a lens, and refocused to form a true real space image in the manner of an optical microscope, where each point in the image corresponds to a specific point in the object. Electrons also interact much more strongly with matter and electron diffraction can be performed on materials of nanometer dimensions. For accelerating voltages of 100–1000 kV, the electron wavelength ranges from 0.004 to 0.001 nm, orders of magnitude lower than atomic spacings in materials. It would therefore appear relatively trivial to form atomic resolution images of materials. However, it is only very recently that atomic resolution imaging could be said to be at all trivial. The major limitation was realized early in the history of the microscope to be the high inherent aberrations of a round magnetic lens. Spherical aberration is the dominant aberration, and leads to a ray deviation of $C_s\alpha^3$, where α is the semiangle of the objective lens. With electron lenses, C_s is of the same order as the focal length. This means that only very small apertures could be used, and since microscope resolution is given by $0.61\lambda/\sin\alpha$, where λ is wavelength, the best resolution would be limited by diffraction to $\sim 50\lambda$.

It took ~ 50 years from the development of the first transmission electron microscopes in the 1930s to achieve sufficient electrical and mechanical stability to allow imaging of crystal lattices at 0.2–0.3 nm resolution in the 1980s. Over the next 20 years, resolution improved incrementally to 0.1–0.2 nm. Now electron microscopy is in the midst of a revolution. Thanks to the development of solid-state devices, specifically the computer and charge-coupled-device (CCD) detectors, a series of nonround magnetic lenses can be used to correct the aberrations of the (round) objective lens. The gain in resolution over the last few years is comparable to that seen in the last few decades, an extraordinary advance that has pushed TEM into the sub-Ångstrom regime for the first time in history.

Aberration-correction brings more than just resolution; better resolution brings increased sensitivity, and recent results have demonstrated the imaging of single atoms within materials and on their surfaces, together with their spectroscopic identification by electron energy loss spectroscopy (EELS). Furthermore, entirely new modes of microscopy now appear feasible. Aberration-correction is allowing the objective aperture to be opened up, and, just as in an optical microscope, the depth of focus reduces. We are seeing the beginnings of three-dimensional (3D) TEM.

Electron Optics of the Microscope: STEM Versus TEM, Reciprocity

Figure 1a shows a schematic ray diagram for conventional TEM. The specimen is illuminated through a condenser aperture and transmitted electrons are gathered by the objective lens and recombined into an image. Historically, the size of the condenser aperture has always been chosen to be as small as practically possible to provide a close approximation to parallel illumination. This is required for diffraction contrast imaging, when only one diffracted beam is passed through the objective aperture. With parallel illumination crystal defects such as dislocations, precipitates, and interfaces are observable, and many details of their atomic structure can be obtained by detailed analysis of image contrast (e.g., lattice shifts across an interface, the

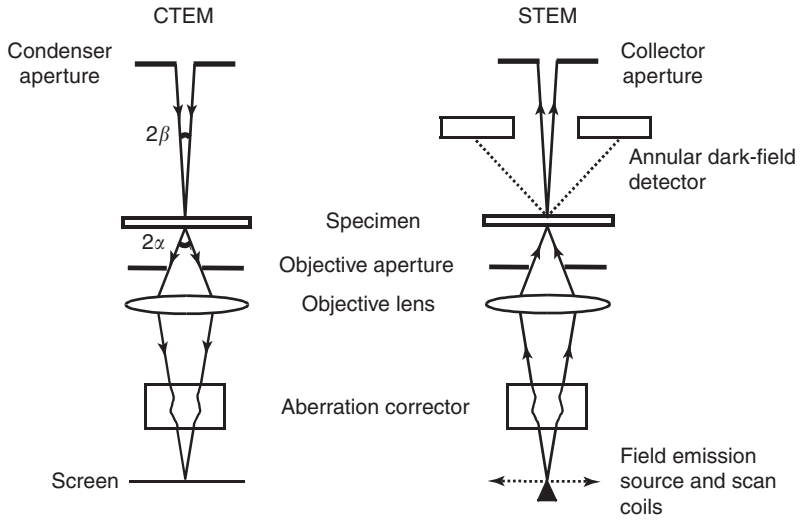

Figure 1 Ray diagrams for (a) the TEM and (b) the STEM, showing the reciprocal nature of the optical pathways. The TEM image is obtained in parallel, the STEM image pixel by pixel by scanning the probe. The STEM also provides simultaneous annular dark-field (ADF) imaging. Actual microscopes have several additional lenses and the beam limiting aperture positions may differ.

intrinsic or extrinsic nature of stacking faults, coherency strains of precipitates, Burgers' vectors of dislocations). Nearly parallel illumination provides a long coherence length in the specimen, approximately λ/β, where β is the illumination semiangle. For small β many lattice spacings are illuminated in phase, an example of coherent imaging. If the objective aperture α is opened up to include several diffracted beams, the conventional TEM lattice-imaging mode is obtained, often known as high-resolution electron microscopy (HREM), another example of coherent imaging.

In scanning transmission electron microscopy (STEM) the electron beam is focused to a small probe and scanned across the specimen. **Figure 1b** shows the ray diagram; detectors are used to pick up a signal, which is used to form an image pixel by pixel as the probe is scanned. The STEM allows complete flexibility in choice of detector, and multiple detectors are normally used giving complementary information. An annular dark field (ADF) detector collects electrons scattered out of the beam and gives an image of mass thickness, that is, a signal that increases with increasing scattering cross section and specimen thickness; a hole appears dark. A bright-field signal can also be detected using an on-axis detector (holes appear bright). If the bright-field detector subtends a small angle β at the specimen, then it is clear from comparing the two ray diagrams in **Figure 1** that the only difference in the optics of the two forms of microscope is the direction of the electron beam. The major source of image contrast is elastic scattering, for which only the scattering angle is important not the direction of propagation (an example of time-reversal symmetry). This illustrates the principle of reciprocity, where interchange of source and detector leads to the same image, and explains why images formed in bright-field STEM may show identical contrast behavior to those in TEM. If the bright-field collector aperture is small, these images are coherent images exactly equivalent to bright-field TEM images.

Reciprocity applies even if aberration correctors are added to both columns. In TEM the corrector is placed after the specimen to correct the objective lens aberrations, while in STEM it is placed before the specimen, the purpose being again to correct the aberrations of the objective lens (now used as a probe-forming lens). **Figure 1** makes clear that for the same set of aberration parameters and equivalent angles before and after the specimen, the same images are to be expected, and this is seen experimentally. However, reciprocity does not mean the images will have the same signal-to-noise ratio. Before aberration-correction, the angle β necessary to ensure good coherent imaging conditions was so small that the STEM image used only a small fraction of the electrons passing through the specimen. This resulted in noisy images and unnecessary specimen irradiation. With aberration-correction, not only can the objective aperture α be made much larger, but β can also be increased and STEM bright-field imaging becomes a useful practical possibility.

The primary motivation for the STEM has been its ability to detect signals other than the bright-field image, in particular, the ADF image. Based on the concept of a coherence width in the specimen, if the angle β is sufficiently large, the coherence width in

the specimen is below the typical atomic spacings in materials. Although the third dimension along the beam direction must also be considered, the ADF image does represent a good approximation to incoherent imaging. An incoherent image gives a simple relationship between the object and image as in a camera, and is easier to interpret than a coherent image. The very different characteristics of coherent and incoherent imaging will be discussed in the next section.

Finally, one of the major uses of STEM has been for microanalysis, which uses one or more additional signals generated as the beam passes through the specimen. Perhaps the most important of these is inelastic scattering, which allows elemental identification from inner-shell excitations. The fine structure at the absorption edges carries information about the electronic structure of the excited atom. For these purposes, EELS is comparable to X-ray absorption spectroscopy, but is available with the spatial resolution of the probe. Spectroscopy of individual atomic columns in a crystal has been demonstrated, including, recently, the spectroscopic identification of a single impurity atom within one atomic column. In the so-called spectrum-imaging mode, one complete spectrum is recorded for each pixel in the image. Similar information can be obtained on a TEM using an imaging filter, which produces 2D images corresponding to particular energy losses. A set of such images at different energy losses is somewhat equivalent to a spectrum image on the STEM. However, reciprocity does not apply to inelastic scattering and there are important differences between TEM and STEM: in the TEM the inelastically scattered electrons must be focused by the image-forming lens which leads to problems with chromatic aberration, whereas in the STEM there are no lenses after the specimen. For this reason atomic column resolution has yet to be achieved in the TEM.

Energy dispersive X-ray spectroscopy, known as EDX or EDS, collects X-rays emitted as the atom relaxes into its ground state following inner-shell excitation, and the X-ray energy is again characteristic of the element. The peak resolution is much lower than for EELS, but the peaks lie on a lower background. The major problem is the low efficiency of collection. X-rays are emitted over 4π steradians and only a small fraction can be collected by the detector, whereas the corresponding core loss electrons are forward peaked and a high fraction can be collected for EELS. This is probably the reason that atomic-resolution EDX analysis has yet to be demonstrated. Other possible imaging signals include the secondary electrons for imaging surfaces and visible photons (cathodoluminescence) for mapping optical properties.

Finally, microdiffraction, or more recently nanodiffraction patterns can be recorded with an imaging detector in STEM. This is very useful for identifying minority phases within bulk materials or new phases not possible to synthesize in large volumes, and also for quantitative measurements of charge modulation. For long wavelength modulations, electron diffraction is much more sensitive than X-ray diffraction because of the cancellation of the scattering due to the electrons and nucleus; electron scattering sees the imbalance of charge, whereas X-ray scattering sees the total electron density and is less sensitive to small changes.

For much of the history of electron microscopy it has not been possible to have high-resolution STEM and TEM imaging in a single machine. In recent years however, great advances have been made in instrument design, and it is now possible to purchase microscopes that will give good performance in any desired mode of operation, often simply at the push of a button. It is possible today to purchase an instrument with two aberration-correctors, one before the specimen to correct the probe and one after the specimen to provide parallel-detection phase contrast imaging.

Principles of Image Formation

Coherent Imaging

With parallel illumination, a crystal aligned near a zone axis will generate a set of diffracted beams leaving the sample at specific angles, as depicted in **Figure 2a**. The objective lens brings these beams to a focus in its back focal plane to form the diffraction pattern. In diffraction contrast imaging, one diffracted beam is passed through a small objective aperture and the resulting image represents a map showing the distribution of diffracted intensity from the specimen. The crystal lattice is unresolved, but the image is useful for studying defects and interfaces. To resolve the crystal lattice itself the objective aperture is opened up to include more than one diffracted beam. Now each point in the image receives contributions from multiple diffracted beams that interfere to generate image contrast, which depends on their relative phases. The principles of coherent phase contrast lattice imaging are best illustrated for the idealized case of a thin sample where multiple scattering can be ignored. The incident electron wave function takes the form of a plane wave ψ_0 which interacts with the electrostatic potential of the specimen $\phi(r)$ (ignoring magnetic fields for now). Here, lowercase letters refer to 3D variables while upper case variables refer to the two transverse dimensions

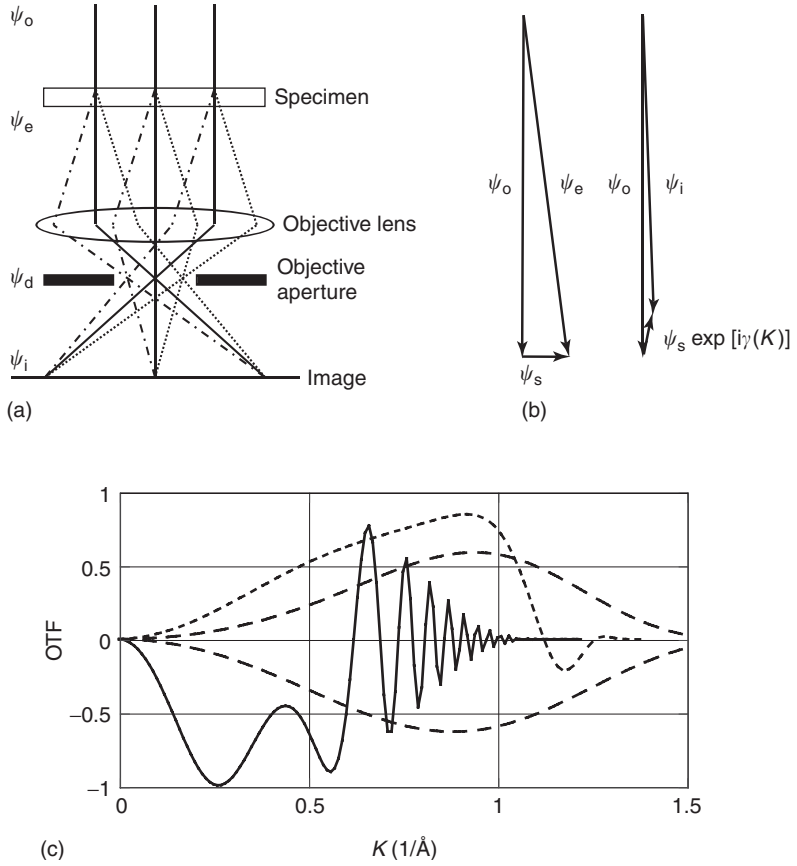

Figure 2 (a) Ray diagram for coherent phase contrast imaging of a crystal. Diffracted beams emerge from the specimen at specific angles and are brought to a focus in the back focal plane of the objective lens. They are recombined in the image plane. Imaging is therefore two consecutive Fourier transforms. (b) Vector diagram for a weak phase object showing the incident beam, a small scattered beam with $\pi/2$ phase change and the resultant transmitted beam. Lens aberrations are used to rotate the phase of the scattered beam an additional $\pi/2$ to create amplitude contrast from the phase changes. (c) Contrast transfer functions for an uncorrected 300 kV microscope, solid line ($C_s = 0.6$ mm, $\Delta f = -45$ nm, energy spread 2 nm typical for a Schottky field emission source), a corrected 300 kV microscope, dotted line ($C_s = -37\,\mu$m. $C_5 = 100$ mm, $\Delta f = 5$ nm, energy spread 1 nm typical for a cold field emission source), and a 200 kV microscope with full correction of all 5th-order aberrations, dashed line ($C_s = 23\,\mu$m. $C_5 = -2$ mm, $C_7 = 100$ mm, energy spread 1 nm). The upper trace is for $\Delta f = 1$ nm giving white atom contrast in a thin specimen, the lower one is for $\Delta f = -2$ nm giving black atoms.

normal to the direction of beam propagation, z; for example the position vector $\boldsymbol{r} = (R, z)$ and the electron wave vector $\boldsymbol{k} = (K, k)$. Assuming an incident beam of unit amplitude, a thin specimen acts as a weak phase grating, refracting the incident beam but not changing its amplitude: the exit face wave function is given by

$$\psi_e(\boldsymbol{R}) = \exp\{-i\sigma\phi(\boldsymbol{R})\} \approx 1 - i\sigma\phi(\boldsymbol{R})$$

where $\sigma = 2\pi me\lambda/h^2$ is the interaction constant and $\phi(\boldsymbol{R}) = \int \phi(r)\,dz$ is the projected potential. Phase changes in the exit wave therefore map the projected potential of the specimen. These phase changes can be represented vectorially by generation of a scattered wave $\psi_s(\boldsymbol{R}) = -i\sigma\phi(\boldsymbol{R})$ which is oriented at $\pi/2$ to the incident wave, as shown in **Figure 2b**. Entering the objective lens, the diffracted amplitude ψ_d is just the Fourier transform of the exit face wave function

$$\psi_d(\boldsymbol{K}) = \delta(0) - i\sigma\phi(\boldsymbol{K})$$

where the delta function at $\boldsymbol{K} = 0$ is just the unscattered beam. For a crystal aligned to a zone axis the diffraction pattern consists of a set of sharp diffracted beams at specific directions ($\boldsymbol{K}$ vectors). With a pure phase object, none of the individual diffracted beam intensities shows an image. To form an image of ψ_s, the diffracted beams must be passed through the objective lens and interfered with the unscattered beam. As shown in **Figure 2b**, the phase of the scattered beams should ideally be rotated an additional $\pi/2$ to convert the phase changes to perfect amplitude contrast. In this ideal case the image amplitude would become $\psi_i(\boldsymbol{R}) = 1 \pm \sigma\phi(\boldsymbol{R})$ and the intensity $I(\boldsymbol{R}) = |\psi_i(\boldsymbol{R})|^2 = 1 \pm 2\sigma\phi(\boldsymbol{R})$, depending on the

sense of rotation of the scattered wave with respect to the unscattered wave. In practice, since there are no phase plates for electrons, the only available source of additional phase changes are lens aberrations and defocus. The phase change introduced by the objective lens is referred to as the transfer function phase factor $\exp[i\gamma(\boldsymbol{K})]$ where

$$\gamma(K) = \pi\left(\Delta f \lambda K^2 + \tfrac{1}{2} C_3 \lambda^3 K^4 + \tfrac{1}{3} C_5 \lambda^5 K^6\right)$$

if only the rotationally symmetric aberrations are included so that $K = |\boldsymbol{K}|$. Here Δf is defocus, C_3 is the third-order spherical aberration coefficient, usually referred to simply as C_s before aberration-correction became viable, with typical values of the order of 1 mm. Now that C_s can be corrected, the fifth-order spherical aberration coefficient C_5 takes over as the limiting aberration. The diffraction amplitude transmitted by the lens becomes

$$\psi_d(\boldsymbol{K}) = \delta(0) - i\sigma\phi(\boldsymbol{K}) \exp[i\gamma(\boldsymbol{K})]$$

and for small phase changes the intensity becomes

$$I(\boldsymbol{R}) = 1 - 2\sigma\phi(\boldsymbol{R}) \otimes f(\sin \gamma(\boldsymbol{K}))$$

The phase changes $\phi(\boldsymbol{K})$ contribute to the image with a contrast given by $\sin \gamma(\boldsymbol{K})$, which is therefore referred to as the phase contrast transfer function, and the image is given by a convolution of the projected potential with the Fourier transform of $\sin \gamma(\boldsymbol{K})$.

The different aberrations depend on spatial frequencies to different powers and can therefore only be balanced over a finite range. **Figure 2c** shows examples for some uncorrected and aberration-corrected microscopes. Note that phase contrast imaging provides no contrast at zero spatial frequency because there is negligible additional phase change from lens aberrations. The uncorrected microscope shows rapid contrast oscillations at high spatial frequencies where the $C_s K^4$ term increases very rapidly; such oscillations are largely avoided in the corrected microscopes. The substantial drop in contrast at high spatial frequencies is due primarily to the finite energy spread of the beam. In this regard, the cold field emission gun is preferable to the Schottky thermal field emission gun. One characteristic of phase contrast is immediately apparent. The defocus phase factor is used to balance the dominant term in spherical aberration, but changes sign either side of Gaussian focus. In many cases, it is possible to reverse the image contrast on changing the focus (see **Figure 2c**) and atoms may look black or white in a phase contrast image. This can also happen if the specimen becomes thicker and additional relative phase changes occur between the diffracted beams due to dynamical diffraction (multiple scattering). The exit face wave function no longer relates simply to projected potential and becomes increasingly nonlocal. The general expression for the image intensity is

$$I(\boldsymbol{R}) = |\psi_e(\boldsymbol{R}) \otimes P(\boldsymbol{R})|^2$$

the square of a convolution of the exit face wave function with the point response function of the objective lens. The point response function is just the Fourier transform of the transfer function phase factor,

$$P(\boldsymbol{R}) = \int A(\boldsymbol{K}) e^{2\pi i \boldsymbol{K}\cdot\boldsymbol{R}} e^{i\gamma(K)}\, d\boldsymbol{K}$$

where $A(\boldsymbol{K}) = 1$ over the range of the objective aperture. Because the image is given by a square of the convolution, sum and difference spatial frequencies can appear, and for these reasons image simulations are normally required to relate a phase contrast image to an object.

Incoherent Imaging

Incoherent imaging provides a simple relationship between the object and image

$$I(\boldsymbol{R}) = O(\boldsymbol{R}) \otimes |P(\boldsymbol{R})|^2$$

where the object $O(\boldsymbol{R})$ is blurred by the resolution function of the imaging device. Strictly, this applies only when each point on the object emits independently of its neighbors so that there are no permanent phase relationships between them and no persistent interference can occur. The coherence length of the Sun on Earth is ~ 0.02 mm, so that observation on a larger length scale is effectively incoherent. This is the kind of imaging familiar from the camera, for example, where changing focus merely blurs the image but does not invert the contrast. It also applies to optical microscopy if a large aperture condenser lens is used to give effectively incoherent illumination, as first analyzed by Lord Rayleigh in 1895.

In the STEM, $|P(\boldsymbol{R})|^2$ is the intensity profile of the probe (see **Figure 1b**). Not every image takes the form of a simple convolution, as seen already for the case of the small axial detector. The requirement for an incoherent image is that all of the scattering (or other generated signal) be collected by the detector. In the case of inelastic scattering or X-ray emission, it is relatively simple to collect all of the signal, or at least a representative fraction of it. In the case of

elastically scattered electrons it is not so obvious, because collecting all of the transmitted electrons will give no image contrast; the specimen does not absorb any electrons, it only scatters them, and partial detection of the scattering is therefore necessary to generate an image.

The reason that collecting all of the scattering results in an incoherent image is that the detected signal is then insensitive to any interference that may be occurring amongst different scattered beams. Interference rearranges intensity but the total scattering is constant, by conservation of energy. The annular detector provides a close approximation to incoherent imaging because it can be arranged to average over a large number of diffracted beams. The inner detector angle should also be large to avoid being dominated by a few low-order beams around the inner hole. In practice, the image still shows strong incoherent characteristics even if the inner angle is just larger than the objective aperture angle, which is a mode that gives highly efficient dark-field imaging of single atoms and was the original motivation for the introduction of the detector by Crewe and co-workers.

High-angle scattering comes from the sharpest part of the atomic potential, the nucleus, and its intensity is proportional to the square of atomic number (Z). An annular detector with a large hole therefore gives an image showing strong Z-contrast, also referred to as a high-angle annular dark-field (HAADF) image. With a sufficiently small probe it is possible to achieve an atomic-resolution Z-contrast image in which atomic columns are seen bright (consistent with it being a dark-field image) and their relative contrast is approximately given by their projected mean square atomic number. The atomic-resolution contrast again comes from the interference of diffracted beams, except that no phase plates are necessary to create the intensity. The total intensity on the detector rises and falls as the probe scans the lattice because of interference between the diffracted beams reaching the detector, as shown in **Figure 3a**. Each beam takes the form of a disk the size of the objective aperture (the incident beam in STEM). Interference occurs wherever the disks overlap and there are two or more different pathways that can interfere. The conditions for optimum defocus are that the entire area of overlap shows the strongest possible interference as the probe scans. This is quite different from the conditions for optimum phase contrast with a (small) bright-field detector, and for the example depicted, the bright-field detector covers no overlaps and will show no image.

Smaller spacings will give diffraction disks further apart with smaller regions of overlap and lower

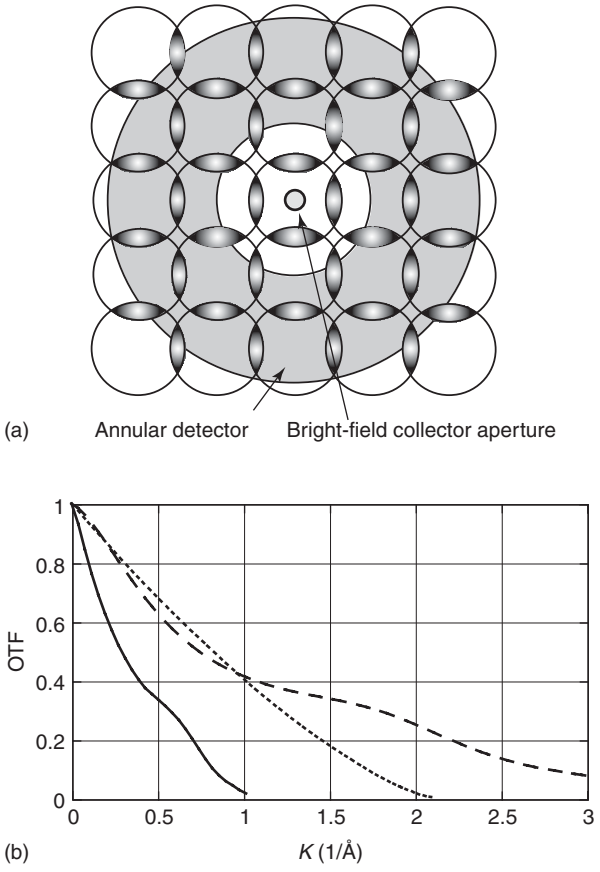

Figure 3 (a) Schematic showing overlapping diffraction disks on the STEM annular detector. The regions of overlap show interference as the probe scans leading to an atomic resolution image. Note, for the spacings depicted, the bright-field detector covers no overlaps and shows no image. (b) Incoherent object transfer functions for an uncorrected 300 kV STEM: solid line (conditions correspond to those in **Figure 2** except $\Delta f = -34$ nm), a corrected 300 kV STEM; dotted line (as **Figure 2** except $\Delta f = 2$ nm), a 200 kV STEM with correction up to 5th order; dashed line (as **Figure 2** except $\Delta f = 0$ nm).

maximum contrast. The incoherent transfer function is therefore a slowly decreasing function of spatial frequency, and is obtained from the Fourier transform of the image intensity,

$$I(\boldsymbol{K}) = O(\boldsymbol{K}) \cdot |P(\boldsymbol{K})|^2$$

The transfer function is just the Fourier transform of the probe intensity, and is referred to as a modulation transfer function, $|P(\boldsymbol{K})|^2$, or object transfer function. Generally, this remains a positive function even as defocus is varied so inverted contrast is not observed. **Figure 3b** shows incoherent transfer functions corresponding to the coherent contrast transfer functions of **Figure 2c**.

Figure 4 compares aberration-corrected coherent and incoherent images of $SrTiO_3$ in the $\langle 1\,1\,0 \rangle$

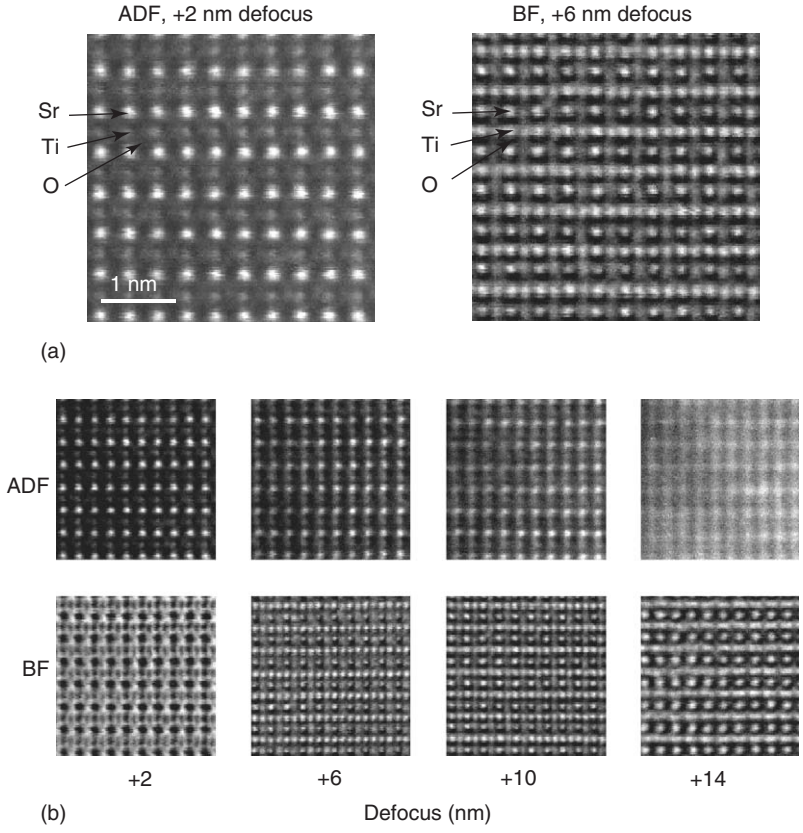

Figure 4 Comparison of incoherent and coherent imaging of $SrTiO_3$ in the $\langle 1\,1\,0 \rangle$ projection in a 300 kV aberration-corrected STEM (a VG Microscope's HB603U with Nion aberration corrector, conditions as in **Figures 2** and **3**). A defocus series was taken using ADF and coherent BF detectors simultaneously. (a) The ADF image shows good *Z*-contrast, with O barely visible. The phase contrast BF image shows the O columns with high contrast; however, the bright features between the Sr columns are double periodicity artifacts. (b) A through focal series with 4 nm defocus steps from the position of optimum ADF defocus showing how the incoherent ADF image contrast slowly blurs while the phase contrast image shows many different forms of contrast. Images are raw data and show some instabilities. (Courtesy of M F Chisholm, A R Lupini, and A Borisevich.)

projection, obtained simultaneously in an aberration-corrected STEM. There is one optimum focus for the *Z*-contrast image, where the Sr column is brightest and the TiO column less bright. A small peak is present at the oxygen column position but is difficult to detect above the noise because of its low *Z*. In the phase contrast image, a good image of the oxygen columns is obtained at a defocus of $+6$ nm, but other images are seen at other defocus values.

The TEM as a Nano-Laboratory

The TEM is a very versatile instrument and is more like a nano-laboratory than an optical instrument, with a large array of imaging and spectroscopic methods available to probe materials at the atomic scale. Imaging modes are available for magnetic fields (Lorentz imaging, Foucault imaging, holography), and movies have been taken of flux line motion in superconductors. Many applications desire measurements under conditions other than the high vacuum, room temperature environment that is standard for TEM; phase transformations can be observed with a heating holder; studies of catalysis benefit from imaging in an active gas environment; many condensed matter physics investigations require low temperatures; nanowires can be observed while being stretched with simultaneous measurement of conductance. *In situ* microscopy also benefits from aberration-correction because it is possible to maintain resolution with a larger gap between the objective lens pole pieces.

Future Directions

The achievement of aberration-correction in TEM is likely to be seen as one of the most significant events in the history of the microscope. Aberration-correction substantially improves vision at the atomic scale, through better resolution and better contrast, for the first time giving useful sensitivity to single atoms within materials and on their surfaces.

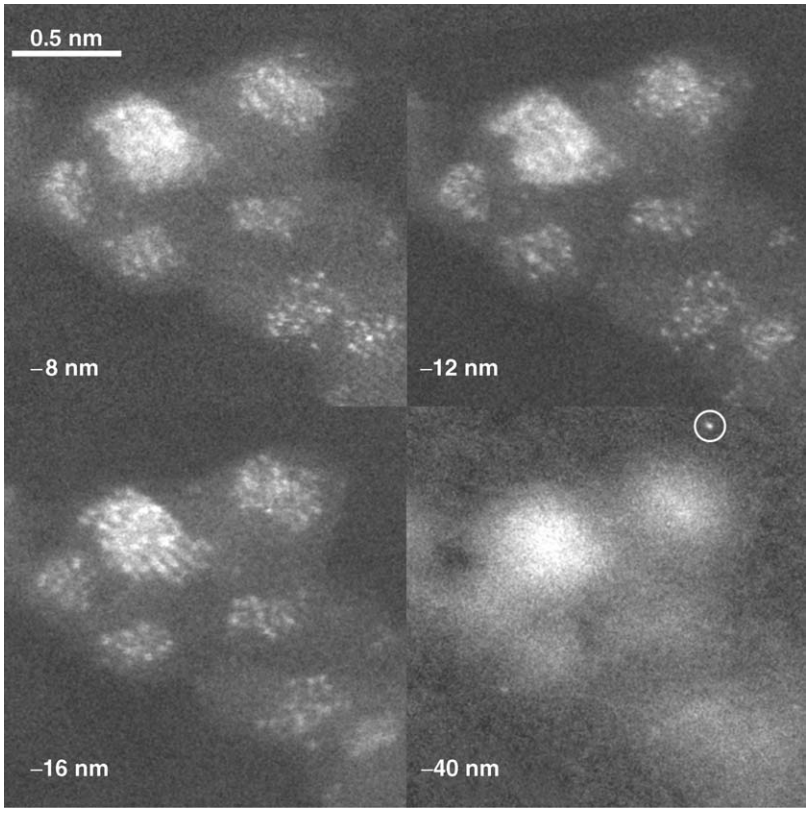

Figure 5 Four frames from a through-depth series of ADF images of a Pt_2Ru_4 catalyst supported on γ-alumina taken using a 300 kV VG Microscope's HB603U with Nion aberration corrector. The alumina is three-dimensional with thin, raft-like Pt–Ru clusters on its surface. Pt atoms are brighter spots and Ru atoms are less bright. Different clusters are resolved at different depths, until, at -40 nm defocus, the carbon support film is reached and a single Pt atom comes into focus (circled). (Image courtesy A Borisevich and A R Lupini.)

Equal improvements apply to spectroscopy. These developments promise a new level of insight into the physics of interfaces, defects, and nanostructures, issues relevant to the majority of materials and devices of a technological world.

A TEM image presents a 2D projection of a 3D specimen. Stereo techniques have been used to obtain information on the third dimension, and recently, full 3D tomography has been demonstrated at nanometer resolution from a series of images taken over a large range of sample tilts. Aberration-correction allows larger objective aperture angles to be utilized, and sub-nanometer depth resolution with sub-Ångstrom lateral resolution is likely to be achieved within the next few years. This allows the possibility of 3D STEM through depth slicing. Just as in optical confocal microscopy, a series of images taken at different focus settings can be reconstructed into a 3D object. **Figure 5** shows four sections of a 3D data set showing catalyst atoms at different depths on a high surface area alumina support.

Transport in Two-Dimensional Semiconductors

P T Coleridge, Institute for Microstructural Sciences, Ottawa, ON, Canada

Introduction

Although many characteristics of two-dimensional behavior can be seen in samples where the thickness is less than the mean free path of the carriers, true two-dimensional transport requires a system where the energy associated with motion in one dimension, normally taken as the vertical direction, is quantized. The importance of the semiconductor industry and Moore's law (the observation that the number of transistors in an integrated circuit grows exponentially with time) has meant that much of the experimental information on two-dimensional systems has been obtained using semiconductors. The lateral and vertical dimensions of semiconductor devices have both been systematically shrinking since the 1970s and vertical dimensions are now typically less than 30 nm. This is only a fraction of the de Broglie wavelength, and the electrons are therefore confined by potentials that quantize the motion in the vertical direction. For device modeling, involving room temperature operation, it is often adequate to treat the carriers classically, but at low temperatures they behave as a quantized two-dimensional layer. These systems exhibit a variety of new and interesting phenomena which are studied not only for their fundamental physical significance but also because they involve mechanisms and processes that might be exploited to overcome the fundamental limits that Moore's law is now facing.

One characteristic of two dimensions is that screening of the Coulomb interaction is significantly weaker than that in three dimensions. Surface gates can, therefore, be used very effectively to manipulate electron densities in an underlying two-dimensional semiconductor layer. This property is exploited to make devices of further reduced dimensionality, with lateral dimensions significantly less than 100 nm, and which exhibit one-dimensional and zero-dimensional behavior.

Because the semiconductor material can be grown with very high purity, and because dopants used to introduce carriers can be physically separated from the carriers, the mean free path of the carriers at low temperatures is increased by several orders of magnitude over typical room temperature values. The application of magnetic fields introduces two new length scales, the cyclotron radius and the magnetic length. In these high-purity systems, fields of only a few hundred gauss are sufficient to reach the high-field limit, and the transport properties are then almost totally dominated by magnetic field effects.

Growth of Two-Dimensional Layers

To achieve the strong confinement needed to form a two-dimensional layer requires an artificial growth technique. Molecular beam epitaxy (MBE) is commonly used: a heated, single-crystal substrate is exposed to a flux of elemental atoms in an ultrahigh vacuum (UHV) environment. Under suitable conditions, growth occurs layer by layer at a rate of typically one monolayer per second. The sources are held in heated Knudsen cells (K-cells) with shutters in front of them that can interrupt the flux and can be used to form interfaces with atomic resolution. Because of the UHV environment, there are few impurities and extremely clean layers can be grown.

An example is illustrated in **Figure 1a**: a narrow quantum well of GaAs (typically 10–20 nm) is surrounded by layers of $Ga_{1-x}Al_xAs$ with $x \sim 30\%$. The quantum well is "modulation" doped, that is, the Si donor atoms are separated from the well by undoped spacer layers, so the electrons transfer to the well leaving the remote donors ionized. Motion in the vertical or growth direction (chosen as the z-axis) is quantized with an energy E_0 but two degrees of freedom remain for motion in the x- and y-directions and

$$E(k) = E_0 + \frac{\hbar^2}{2m^*}(k_x^2 + k_y^2)$$

The potential distribution shown is a combination of conduction band offsets produced by changing the alloy concentration and electrostatic potentials produced by the ionized donor atoms and the free electrons. The most commonly used two-dimensional electron gas structures, rather than using a square quantum well, have a single GaAs/(Ga, Al) As interface with doping in the (Ga, Al)As and with the electrons then confined to a triangular shaped well. Many computer programs are available for calculating such band diagrams in terms of self-consistent solutions of the Schrödinger and Poisson equations (see "Further reading" section).

In silicon the metal-oxide-semiconductor-field effect transistor (MOSFET) structure (see **Figure 1b**) has been extensively developed for integrated circuits

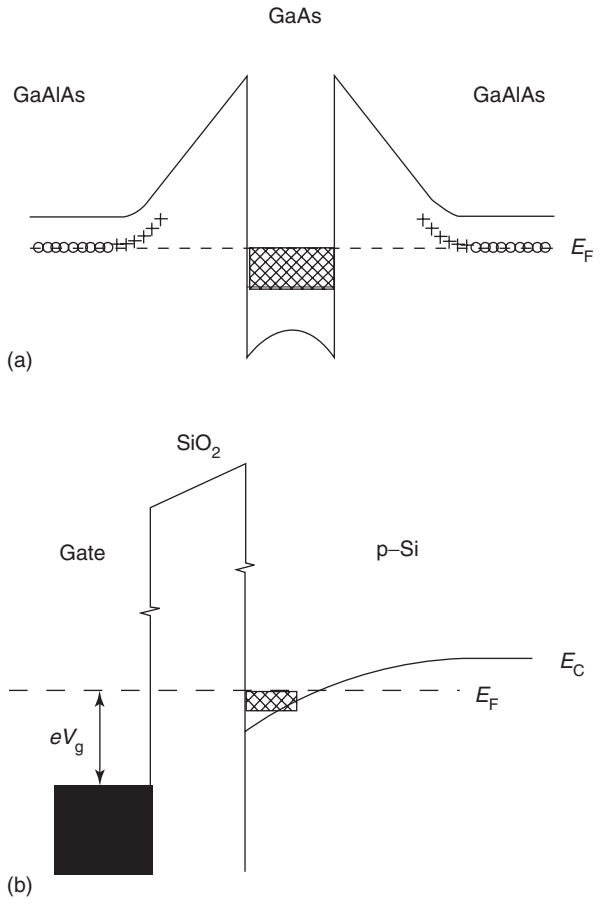

Figure 1 Schematic band diagrams: (a) modulation-doped GaAs quantum well showing ionized (+) and neutral (o) donors with electrons transferred to the quantum well; (b) Si-MOSFET showing an approximately triangular potential well and two-dimensional electron layer formed by applying a voltage V_g to the surface gate.

and also gives rise to a two-dimensional layer. In this case, a high-purity silicon oxide layer is grown on a clean surface of single-crystal silicon and then covered with a metallic gate. Applying a potential between the gate and the bulk silicon (into which ohmic contacts have been implanted) draws in electrons (or holes) and confines them in a triangular well. In this case no doping is needed, the main scattering mechanisms are unwanted defects in the oxide layer and surface roughness.

Basic Transport Properties and Characterization

Two-dimensional semiconductor samples are usually characterized in terms of a density and mobility. This implicitly assumes a simple Drude model, with only one set of carriers. For a magnetic field B, applied in the z-direction normal to the two-dimensional layer, the components of the conductivity tensor describing the response to an in-plane electric field (E_x, E_y) are then

$$\sigma_{xx} = \sigma_{yy} = \frac{\sigma_0}{1 + \mu^2 B^2}$$
$$\sigma_{xy} = -\sigma_{yx} = -\frac{\mu B \sigma_0}{1 + \mu^2 B^2} \qquad [1]$$

where the zero-field conductivity $\sigma_0 = n_s e \mu$ with n_s the sheet carrier density and μ the mobility. The mobility is related to a scattering time τ by $\mu = e\tau/m^*$, where m^* is the effective mass. The cyclotron frequency ω_c, describing motion in a magnetic field, is given by eB/m^* so $\mu B = \omega_c \tau$.

Inverting the conductivity tensor gives the resistivities that are usually measured experimentally:

$$\rho_{xx} = \rho_0 = \frac{1}{\sigma_0}, \qquad \rho_{xy} = \frac{B}{n_s e} \qquad [2]$$

The slope of the Hall resistance ρ_{xy} gives the density which can then be used with the longitudinal resistivity ρ_{xx} to determine a mobility. According to this model, ρ_{xx} is independent of the magnetic field but a significant magnetoresistance (and nonlinear increase of ρ_{xy}) is sometimes observed associated with the existence of more than one set of carriers with different mobilities. A multiband extension of the Drude model can be used to analyze such data, with separate densities and mobilities for each set of carriers, but care should be taken in interpreting these results as the model may not be valid when there is significant scattering between the several sets of carriers.

Measurement Geometries

Examples of some of the geometries used experimentally to determine resistivities are illustrated in **Figure 2**. For a Hall bar (**Figure 2a**), the resistivities are related to the measured resistances R_{ij} by $R_{xx} = (L/W)\rho_{xx}$ and $R_{xy} = \rho_{xy}$, where W and L are, respectively, the width of the Hall bar and the spacing between potential contacts. Values of ρ_{xx} are usually expressed in ohms/square to emphasize that a geometrical factor is needed. For ρ_{xy}, the Hall voltage and the current both scale with the width, so it is a particular characteristic of two dimensions that the Hall resistance should be independent of the geometry. In practice, spurious contributions from ρ_{xx} often appear, for example, if the potential probes are misaligned, but these can be eliminated by averaging results obtained with both directions of the magnetic field.

The Van der Pauw geometry (**Figure 2b**) is especially convenient because, provided the contacts are

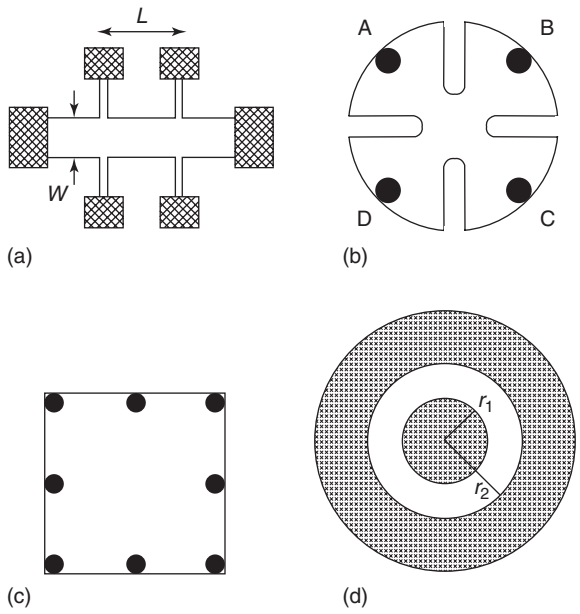

Figure 2 Resistance measuring geometries with metallic contacts shown: (a) Hall bar with source and drain and two pairs of voltage contacts; (b) Van der Pauw geometry designed to minimize errors associated with contact placement; (c) Van der Pauw geometry which can also be used as a pseudo-Hall bar; and (d) Corbino geometry used to measure conductivity rather than resistivity.

small and at the edges of the sample, ρ_{xx} can be obtained without needing to know the spacing between contacts. In this case

$$\rho_{xx} = \frac{\pi}{\ln 2} \frac{R_{\mathrm{AB,CD}} + R_{\mathrm{BC,DA}}}{2} f$$

where $R_{\mathrm{AB,CD}}$ is the resistance measured with the current through contacts A and B and voltage at contacts C and D. The factor f, which depends on the ratio $R_{\mathrm{AB,CD}}/R_{\mathrm{BC,DA}}$, is 1.0 when the ratio is 1, 0.96 with a ratio of 2, and 0.82 for a ratio of 5. The Van der Pauw method can also be used with multiple contacts on the edge of a square sample (**Figure 2c**). Comparing values obtained with different sets of contacts then provides a convenient check on the reproducibility of the results and this configuration can also be used as a pseudo-Hall bar.

In the Corbino geometry (**Figure 2d**), the circular symmetry means the two-terminal resistance R_{12} depends not on the resistivity but rather on the conductivity according to

$$R_{12} = \frac{1}{2\pi\sigma_{xx}} \ln \frac{r_2}{r_1}$$

where r_1 and r_2 are, respectively, the inner and outer radii between the two contacts. Although the Hall resistance cannot be obtained directly in this measurement, the mobility can be determined from the quadratic increase of R_{12} with the magnetic field (cf. eqn [1]) and the density then deduced from the zero-field conductivity σ_0.

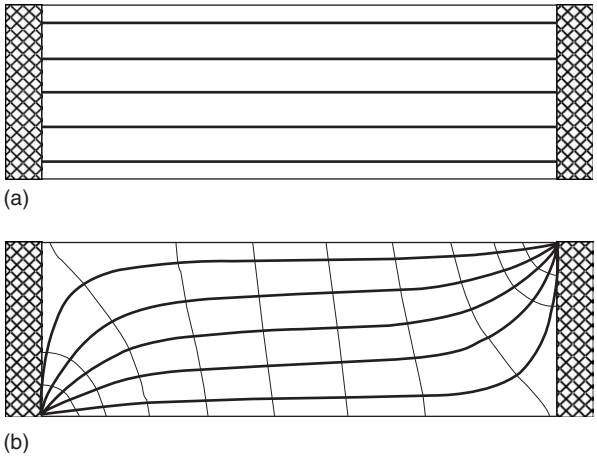

Figure 3 Current and electric field lines in a Hall bar: (a) in zero magnetic field when ***E*** and ***J*** both run parallel to the edges and (b) in a magnetic field with $\rho_{xy}/\rho_{xx} = 10$. The electric field lines meet the contacts normal to the contact edges, but because the current lines (bold) must be approximately normal to the electric field lines, they enter and exit at the corners of the contacts.

At low temperatures, the mobility of many two-dimensional systems can be very large – for example, in modulation-doped GaAs/GaAlAs heterojunctions, values of over $100\,\mathrm{m}^2(\mathrm{Vs})^{-1}$ are common. Quite modest magnetic fields are then sufficient to reach the high-field regime $\mu B \gg 1$ where the transport is dominated by the Hall resistance. In zero magnetic field, the current and electric field lines are parallel (as is illustrated in **Figure 3a**) with the electric field normal to the edges of the metallic contact pads. Inside the semiconductor, in the high-field regime, $\rho_{xy} \gg \rho_{xx}$ and the current and field lines become approximately orthogonal. At the contacts, the electric field must remain normal to the metallic edge, so the current must flow parallel to the edge of the contact and can only enter and exit at the corners of the Hall bar (see **Figure 3b**). Reversing the magnetic field moves these critical points to opposite corners and means the high current density now flows in different regions. This can be important if the semiconductor is inhomogeneous.

This behavior emphasizes, when investigating samples where $\rho_{xy} \gg \rho_{xx}$, the need to ensure that potential probes are well separated from the current contacts if reliable values of ρ_{xx} are to be obtained. It also means that the two-terminal resistance of a Hall bar is essentially just $\rho_{xy} + (L/W)\rho_{xx}$ which is dominated, at high fields, by the Hall resistance.

In the high-field regime, transport becomes very sensitive to inhomogeneities in the semiconductor. Density variations affect mainly the Hall voltage and cause currents to tend to follow the contours of constant density. If very different voltages are measured at contacts that are nominally equivalent, this usually indicates inhomogeneities. In devices where large-density gradients are intentionally introduced, for example with gates, this type of behavior dominates. Transport properties are then frequently analyzed using the Landauer–Buttiker formalism, in terms of one-dimensional current paths running along regions of high-density gradients. Under quantum Hall conditions, when Hall resistances are quantized, the transmission coefficients associated with these current paths are also quantized.

Quantum Mechanical Treatment of Magnetic Field

Semiclassically, cyclotron motion in a magnetic field occurs with an angular frequency $\omega_c = eB/m^*$ (independent of energy) and a cyclotron radius $R_{cycl} = m^* v/eB$, where v is the velocity. Quantum mechanically, magnetic fields are introduced by replacing $\hbar \boldsymbol{k}$ in the Schrödinger equation with $\hbar \boldsymbol{k} - e\mathbf{A}$ where $\boldsymbol{A}$ is the vector potential. The continuous energy distribution in zero field is replaced by a ladder of discrete Landau levels with energies $(n_L + (1/2))\hbar\omega_c$ where the Landau level index $n_L \geqslant 0$. The wave function depends on the choice of gauge. Although theoretically the Landau gauge is often used, the closest connection with the semiclassical result is made by choosing the symmetric gauge with $\boldsymbol{A} = 0$ at the center of the orbit. In this case, the wave function (without normalization) is given by

$$\psi_{n_L}(r, \phi) = \exp(\mathrm{i} n_L \phi) r^{n_L} \exp(-r^2/4l_m^2)$$

where ϕ is the azimuthal angle and the characteristic length $l_m = (\hbar/eB)^{1/2}$ is called the magnetic length. This can be considered a "race-track" orbit with a spread of l_m and a mean radius $(2n_L)^{1/2} l_m$ that is slightly less than the semiclassical radius of $(2n_L + 1)^{1/2} l_m$. This difference is small but has important consequences.

In general, the orbits need not be circular but rather follow a Fermi contour determined by the band structure of the material. This is particularly the case for holes where multiple bands may exist within a small energy range. In this case (as is discussed in more detail in the article on the de Haas–van Alphen effect in metals), the energy is still quantized into Landau levels but the cyclotron radius and effective mass of the orbit become orbital averages.

Each Landau level is highly degenerate, corresponding to orbits with different centers. The degeneracy per unit area, eB/h, corresponds to one orbit center in an area πl_m^2. In addition to this basic degeneracy, there is also a twofold spin degeneracy and (sometimes, e.g., in Si-MOSFETs) a valley degeneracy. The total degeneracy is usually expressed in terms of a filling factor ν $(= n_s h/eB)$, which relates the number of filled Landau levels in a magnetic field B (including any degeneracies) to the sheet carrier density n_s.

As illustrated in **Figure 4a**, the Landau level degeneracy means the energy of electrons in a filled Landau level is the same as that of the equivalent electrons in zero field. For electrons in a partially filled level, however, there is an excess energy (see **Figure 4b**) which can be identified, thermodynamically, with the magnetization associated with the orbital moment of the cyclotron orbits. Although the

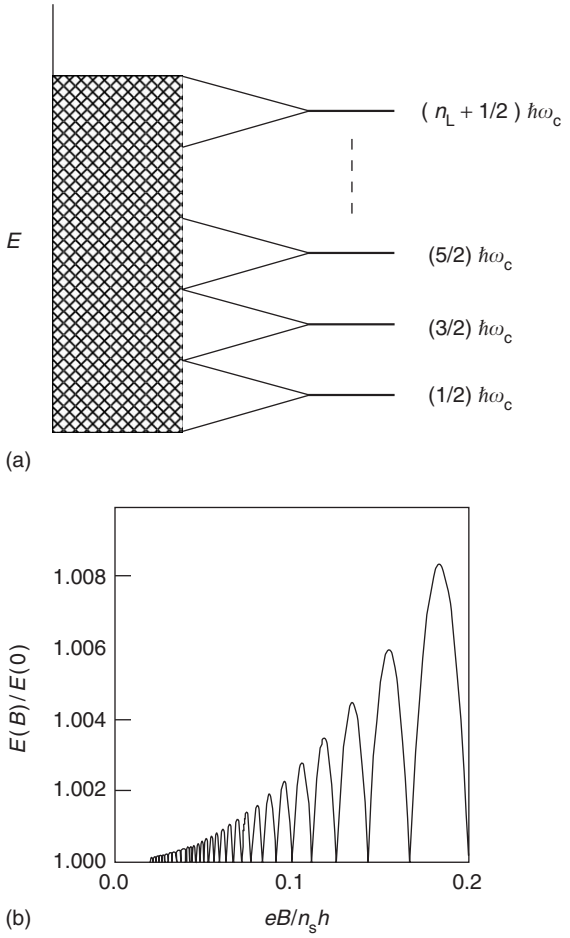

Figure 4 (a) Collapse of uniform, zero-field, energy distribution onto full Landau levels that have the same average energy. (b) Extra energy associated with partially filled Landau levels that gives rise to the Landau diamagnetism.

oscillating part of this magnetization may be washed out by temperature or disorder, the quadratic background term (ΔE_L) persists. The corresponding magnetization, $(-\partial \Delta E_L/\partial B)$, is known as the Landau diamagnetism.

The effect of uniform magnetization M distributed over an area A can be described by an equivalent current $I_s = M/A$ circulating round the edge of the sample. Any gradient of the chemical potential across the sample ($\delta\mu$), such as might be induced by the electric field in a Hall measurement, will induce a corresponding gradient in the magnetization in the bulk of the sample. This implies there is a difference, $\delta I_s = (1/A)(\partial M/\partial \mu)\delta\mu$, between the effective circulating currents on the two sides of the sample. With contacts (see **Figure 5**), $\delta\mu$ can be detected and identified as a potential difference, and δI_s can be accommodated as an extra source/drain current. The ratio $e\delta I_s/\delta\mu$ appears as a Hall conductance which, because of the special geometry associated with two dimensions, is also a Hall conductivity. Using the Maxwell relation $(\partial \boldsymbol{M}/\partial\mu)_{\mathbf{B}} = (\partial N/\partial \boldsymbol{B})_{\mu}$ (where $N = n_s A$), this can be written as $e(\partial n_s/\partial \boldsymbol{B})_{\mu}$, so the total Hall conductivity, including the usual Drude contribution term described by eqn [1], becomes

$$\sigma_{xy} = -\sigma_{yx} = -\omega_c \tau \sigma_{xx} + e(\partial n_s/\partial \boldsymbol{B})_{\mu} \qquad [3]$$

The extra "edge state" or "Streda" contribution is essential for a detailed understanding of the Hall effect in two-dimensional systems. In some instances, notably in the integer quantum Hall regime, σ_{xx} is actually zero in the bulk and current is carried only at the edges. More generally, "edge" currents and "bulk" currents both exist.

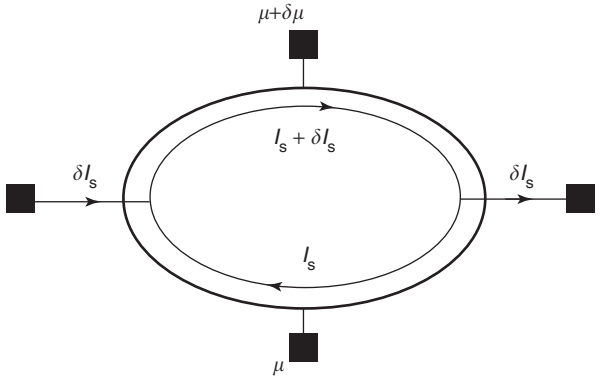

Figure 5 Schematic illustration of the origin of the "edge state" Hall conductance that results from gradients in the magnetization induced by gradients in the chemical potential. (Adapted from MacDonald AH (1994) Les-Houches lecture proceedings, with permission.)

Disorder Broadening of the Landau Levels

Although the density of states illustrated in **Figure 4a** shows infinitely sharp Landau levels, they are, in practice, broadened by disorder. At low fields and with dirty samples (see **Figure 6a**), this disorder broadening is larger than the spacing between the centers of the Landau levels, and the Landau level structure is only a minor perturbation on the constant, background, density of states. In clean systems, at higher fields, the Landau level spacing eventually becomes larger than the broadening and the levels then separate (**Figure 6b**). As noted above, each Landau level is twofold spin degenerate, and at high enough fields the Zeeman splitting associated with the spins can become large enough such that each Landau level splits into two spin-resolved levels (**Figure 6c**).

With Lorentzian broadening, the density of states associated with the ladder of Landau levels is given by the Fourier expansion

$$g(E) = g_0\left[1 + 2\sum_{s=1}^{\infty} \exp\left(\frac{-\pi s}{\omega_c \tau_q}\right) \times \cos\left(\frac{2\pi s E}{\hbar\omega_c} - s\pi\right)\right] \qquad [4]$$

where the Landau level width (Γ_L) has been expressed in terms of a single particle or quantum

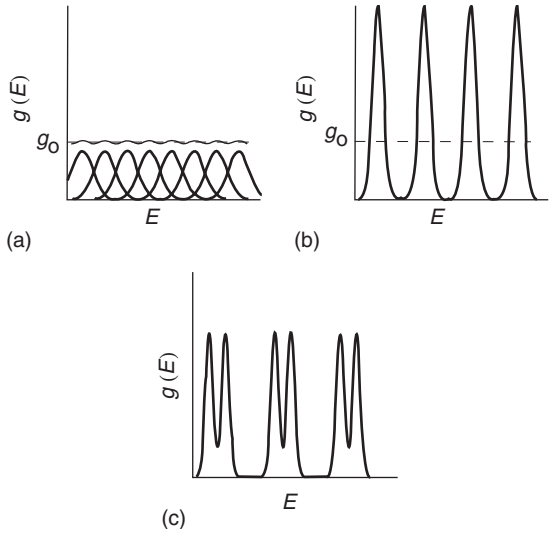

Figure 6 Landau level density of states. (a) At low fields, when the Landau level spacing is sufficiently small compared with the broadening produced by disorder that the levels overlap and the density of states deviates from the zero field value g_0 by only a small amount. (b) At higher fields, the spacing becomes large enough that the levels separate. (c) In high enough fields, the spin splitting becomes sufficiently large that each doubly degenerate Landau level splits into two spin-resolved levels.

lifetime $\tau_q (= \hbar/2\Gamma_L)$. For the situation shown in **Figure 6a**, only the fundamental term in the expansion ($s = 1$) is important and the higher harmonics are strongly damped.

The lifetime τ_q, determined by the impurity scattering, is sometimes identified (incorrectly) with the scattering time obtained from the mobility in eqn [1]. The mobility is related to a transport lifetime given by

$$\frac{1}{\tau_{tr}} = n_{imp}\frac{m^*}{\pi\hbar}\int_0^\pi (1-\cos\theta)|V(q)|^2\,d\theta \qquad [5]$$

where $q = 2k_F \sin(\theta/2)$ is the momentum change associated with scattering through an angle θ, $V(q)$ is the Fourier transform of the scattering potential, and n_{imp} is the density of impurities. The weighting factor $(1-\cos\theta)$ reflects the fact that scattering events with a large momentum change contribute more to the resistivity than small angle events.

Provided the final density of states in the scattering process remains the same, that is, for strongly overlapping Landau levels, the broadening is given by

$$\frac{1}{\tau_q} = n_{imp}\frac{m^*}{\pi\hbar}\int_0^\pi |V(q)|^2\,d\theta \qquad [6]$$

without the weighting factor. In remotely doped two-dimensional systems, where the ionized donors are displaced from the two-dimensional layer, $|V(q)|^2$ is strongly peaked near $q = 0$ and $\tau_q \ll \tau_{tr}$. In this case, the scattering time obtained from the mobility should not be used to determine the Landau level broadening.

At higher fields, when the Landau levels start to separate, the final density of states in the scattering process becomes strongly energy dependent. The scattering rates then become very dependent on where the Fermi level lies within the Landau level and the broadening has to be determined self-consistently. The Landau level shape becomes closer to Gaussian, rather than Lorentzian, with a width (Γ_G) obtained using the self-consistent Born approximation (SCBA) as

$$\Gamma_G = \left[\frac{\hbar^2\omega_c}{2\pi\tau_q}\right]^{1/2} \qquad [7]$$

τ_q is the quantity defined above in eqn [6]. The fact that Γ_G increases as $B^{1/2}$ can be understood physically in terms of a scattering rate ($\sim\Gamma_G$) proportional to the final density of states in the Landau level which is itself proportional to B/Γ_G. For Gaussian broadening, the damping of the fundamental term in the Fourier expansion analogous to eqn [4] is given by $\exp(-2\pi^2\Gamma_G^2/\hbar^2\omega_c^2)$. Using eqn [7], this is exactly the same (i.e., $\exp(-\pi/\omega_c\tau_q)$) as for Lorentzian broadening, so there is a smooth crossover from the low-field behavior, with overlapping Lorentzians, into this medium-field regime of nonoverlapping Gaussians.

In even higher fields, when the cyclotron radius becomes smaller than the characteristic correlation length of the scattering potential, it is no longer valid to use eqns [6] and [7] and the broadening is expected to become independent of B. For GaAs-based heterojunctions, with a donor spacer layer of typically 40 nm, this occurs for fields above ~ 2 T.

Transport Coefficients

The development of an oscillating Landau level structure in the density of states modifies the conductivity (and resistivity) coefficients. At low fields, this can be accounted for by replacing the density in eqns [1] and [3] by an effective density $n_{eff} = n_s g(E_F)/g_0$ and the transport time τ by $\tau_0 g_0/g(E_F)$ (where τ_0 is the zero-field value of τ_{tr}). Inverting the conductivity tensor then gives

$$\rho_{xx} = \rho_0\left(1 + 2\frac{\Delta g}{g_0}\right) \qquad [8]$$

with $\Delta g = g(E_F) - g_0$ and where a term of order $\hbar\omega_c/E_F$ has been neglected.

For ρ_{xy}, the situation is a little more complicated. In eqn [3] for σ_{xy}, oscillations appear that are both in phase with Δg and in quadrature. For the in-phase oscillations, the contributions from each of the two terms are large but of opposite sign and they substantially cancel leaving a residual component a factor of order $(\omega_c\tau_0)^{-2}$ smaller. Whether this term or the quadrature term dominates depends on the relative values of τ_q and τ_0. For $\tau_q \approx \tau_0$, the two are comparable; when $\tau_q \ll \tau_0$, the quadrature term always dominates and maxima in ρ_{xx} correspond to ρ_{xy} crossing the linear background term ($B/n_s e$).

When the Landau levels become well separated, it is still valid to take $n_{eff} \sim g(E_F)$, provided the Fermi level lies inside a Landau level. For $\omega_c\tau \gg 1$, the expression for σ_{xx} can be rewritten as

$$\sigma_{xx} = e^2 D^* g(E_F)$$

where $D^* = R_{cycl}^2/2\tau$ is a diffusion coefficient. This can be interpreted as a diffusion process with conduction taking place by electrons hopping between orbits with centers spaced, on an average, by the cyclotron radius. Taking τ as $\tau_0 g_0/g(E_F)$, one recovers eqn [8] above. More generally, τ acquires a

complicated dependence on the relative magnitudes of R_{cycl}, l_m, and the correlation length that characterizes the scattering potential.

When the Fermi level lies in the gap between Landau levels, $g(E_F) = 0$ and $\sigma_{xx} \approx 0$. The conductivity is then determined by other processes such as activation to the adjacent levels. The limit of $\sigma_{xx} \to 0$ is the integer quantum Hall regime where σ_{xy} (and ρ_{xy}) are quantized and where ρ_{xx} also tends to zero.

Typical Experimental Results

Figure 7 shows an example of the Shubnikov–de Haas and Hall effects measured in a (Ga,Al)As/GaAs heterojunction. At low fields, spin is not resolved and the minima in ρ_{xx} appear at even filling factors given by $\nu = n_s h/eB$. The density determined from the period of the oscillations agrees well with that derived from the low-field Hall coefficient. This is to be expected because the (linear) Hall resistance extrapolates accurately through the middle of the plateaus that appear at higher fields. If $\delta\rho_{xx}$ is the deviation of ρ_{xx} from the mean value, and $\delta\rho_{xy}$ the deviation of ρ_{xy} from the linear term $(B/n_s e)$, then it can be seen that $\delta\rho_{xx}$ and $\delta\rho_{xy}$ oscillate in quadrature. As noted above, this is expected for a modulation-doped structure where $\tau_{tr} \gg \tau_q$.

Above ~ 2 T, ρ_{xx} approaches zero at the minima, corresponding to well-separated Landau levels, and above ~ 4 T spin starts to be resolved and odd filling factors become visible in both ρ_{xx} and ρ_{xy}. This is initiated when the Zeeman splitting of the Landau levels becomes comparable with the broadening. Once spin splitting appears, it is strongly enhanced by the exchange interaction that results from the spin polarization associated with unequal numbers of filled spin-up and spin-down Landau levels. This induces a "boot-strapping" effect and causes the spin splitting to rapidly become fully resolved.

At low fields, the amplitude of the Shubnikov–de Haas oscillations is damped exponentially, shown in **Figure 8** in a Dingle plot. The damping can be attributed to both disorder broadening of the Landau levels and to the thermal spread of the Fermi function. For each harmonic s in the expansion given in eqn [4], there is a corresponding thermal damping term $sX_T/\sinh(sX_T)$, where $X_T = 2\pi^2 k_B T/\hbar\omega_c$. This saturates to 1 at low temperatures but at higher temperatures can be used experimentally to obtain effective masses from the temperature dependence of the oscillation amplitude. Often, only the fundamental term ($s = 1$) is relevant and in the present instance, where this is so, the data can be corrected very easily for thermal damping using the well-known value of $0.067m_e$ for the effective mass of GaAs. The corrected amplitudes are then given by (cf. eqns [4] and [8])

$$\Delta\rho_{xx} = 4\rho_0 \exp(-\pi/\mu_q B) \qquad [9]$$

Here a quantum mobility ($\mu_q = e\tau_q/m^*$) has been introduced in analogy with the standard transport mobility. The good agreement between theory and experiment, in particular the fact that the intercept of $4\rho_0$ is given correctly, confirms that in this low-field regime the theory outlined above is valid and, in particular, that σ_{xx} is proportional to the square (not the first power) of the density of states.

The slope of the Dingle plot gives a quantum mobility $\mu_q = 1.58\ m^2\ (Vs)^{-1}$, 10 times smaller than the transport mobility of $15.3\,m^2\,(Vs)^{-1}$. This confirms

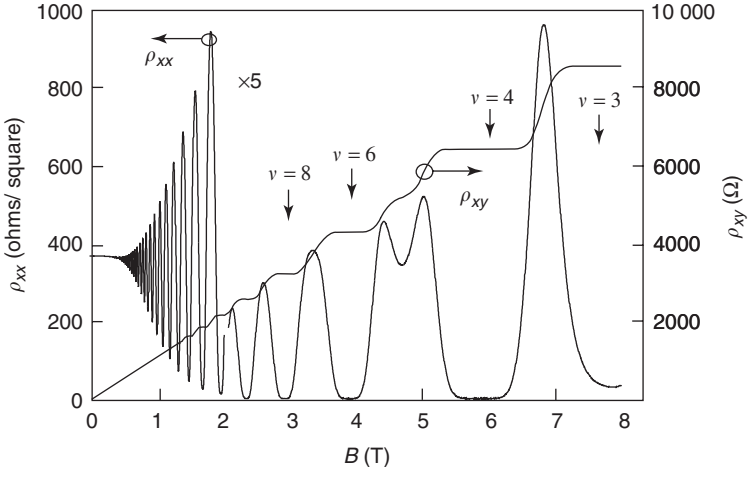

Figure 7 Shubnikov–de Haas oscillations and Hall effect in a modulation-doped GaAs/$Ga_{0.7}Al_{0.3}As$ heterojunction measured at 1.18 K. Electron density was $5.6 \times 10^{15}\,m^{-2}$ and mobility $15.3\,m^2\,(Vs)^{-1}$.

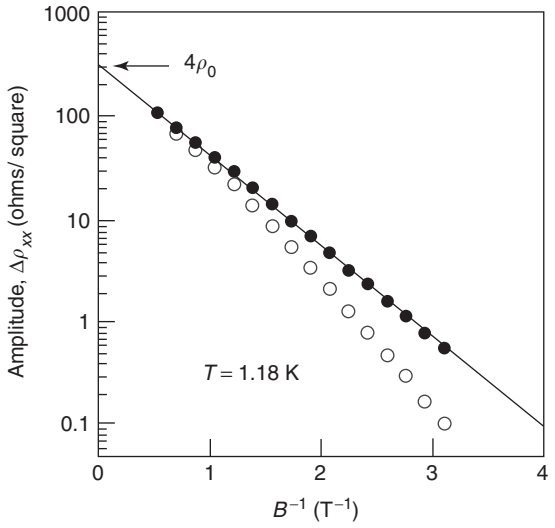

Figure 8 Dingle plot for low-field resistivity data shown in **Figure 7**. Open symbols represent amplitudes, as measured. Solid symbols have been corrected for thermal damping as described in the text.

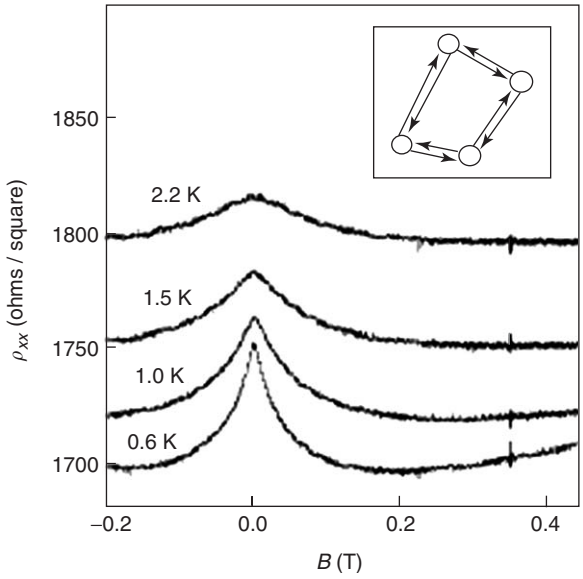

Figure 9 Weak localization in a *p*-SiGe sample with a density of $5.7 \times 10^{15}\,\mathrm{m}^{-2}$ for temperatures between 0.6 and 2.2 K. The narrowing of the peak as the temperature is lowered results from increased phase breaking times. The inset shows schematically the scattering paths, in opposite directions, that interfere coherently to increase the resistance at $B = 0$.

directly in this sample (where the distance by which the dopants are set back from the interface is 6 nm) that small angle scattering dominates. In higher-mobility GaAs/(Ga, Al)As heterojunctions where larger spacer layers are used, the ratio $\mu_{\mathrm{tr}}/\mu_{\mathrm{q}}$ is even larger, typically 20 or more.

In **Figure 7**, in the region above 2 T where the minima in ρ_{xx} approach zero, the Hall resistance develops flat plateaus at values of $\rho_{xy} = h/ve^2$. This is the integer Hall effect which appears when the Fermi level is pinned in localized states between the Landau levels. In cleaner samples when the Landau levels initially separate, there are few localized states between them and the Fermi energy can jump between Landau levels without the appearances of well-defined plateaus. In such samples, other structures also become apparent at high fields and low temperatures. This is the fractional quantum Hall effect which appears when exchange and Coulomb interaction energies, within the Landau level, become large. New gaps appear in the density of states, most strongly at filling factors 1/3 and 2/3 which give rise to new zeroes in ρ_{xx} and associated plateaus in ρ_{xy}. Both the integer and fractional quantum Hall effects are discussed in more detail elsewhere in this encyclopedia.

Weak Localization and Interaction Effects

At very low magnetic fields, additional magnetoresistance features are often seen. The example in **Figure 9**, for a two-dimensional hole gas in an (SiGe) quantum well, shows a peak around $B = 0$. This is associated with weak localization where electrons scattered around closed paths in opposite directions interfere coherently (see inset). At $B = 0$, this produces an increased back-scattering and increased resistance. With small applied magnetic fields, the flux through the closed path induces an extra Aharonov–Bohm phase, of opposite sign for the two directions, which suppresses this scattering and reduces the resistance. A value for the phase breaking time can be obtained from the width of the magnetoresistance peak. This is typically one or two orders of magnitude longer than the transport lifetime and increases with decreasing temperature as T^{-p} where p is of order 1. The weak localization correction to the conductivity

$$\Delta\sigma_{xx}^{\mathrm{WL}} = \frac{pe^2}{\pi h} \ln T$$

is of order e^2/h. Although quite obvious in the example shown, it can be difficult to detect in lower-resistivity (higher-mobility) samples where it is of the same order of magnitude but is only a very small correction to a Drude conductivity, many orders of magnitude larger.

In addition to the weak localization term, there is also a Coulomb interaction correction, of a similar order of magnitude, and also with a $\ln(T)$ dependence. This can be distinguished from the weak localization by the much smaller sensitivity to the

magnetic field. In a famous paper published by Abrahams, Anderson, Lee, and Ramakrishnan in 1981, it was shown that in two dimensions and in the absence of interactions, all systems are insulating at $T = 0$, that is, ultimately, at low T, weak localization will dominate, however large the high temperature conductivity is. More recently, it has become evident that when interactions are strong, particularly the F_0^σ Landau parameter that renormalizes the spin susceptibility, the interaction correction is of the opposite sign to the weak localization term and may become sufficiently large to overcome it. This results in metallic behavior as $T \rightarrow 0$ (i.e., a reduction in resistance) and there is the possibility of a crossover from insulating to metallic temperature dependence as a function of density. Details of this phenomenon are not yet fully worked out and it remains an active area of research.

Introduction

> God made solids, but surfaces were the work of the Devil
> W Pauli

The ultimate goal of surface science is to unravel the atomic structure, electronic and vibrational properties of solid surfaces and adsorbates. All of them are combined into our understanding of the microscopic mechanism responsible for a wide variety of physical properties and chemical reactions taking place at surfaces. Various techniques have been employed to investigate clean and adsorbate covered surfaces using appropriate probes such as photons, electrons, ions, thermal atoms, and neutrons. The photonic probe has several advantages over other massive particles. The spectral resolutions are incomparably better than those attained by other spectroscopies. The temporal resolutions are now down to femtoseconds

that allow real-time monitoring of electronic and vibrational dynamics as well as surface chemical reactions. By using nonlinear optical processes, it is possible to eliminate the response from the bulk, and the information on the surface is selectively obtained. Thus, optical probe yields a huge amount of indispensable knowledge in surface science.

When atoms or molecules are adsorbed on metal surfaces, their electronic and vibrational properties are modified depending on the bonding sites, geometries, and the change of charge distribution and occupancy in the molecular orbitals by the chemical bond to the substrate.

In this atricle, the surface study with photonic probes is presented with a focus on nonlinear and time-resolved spectroscopies for the electronic and vibrational properties of metal surfaces and adsorbates.

Photoelectron Spectroscopy

Photoelectron spectroscopy (PES; X-ray photoemission (XPS) from deep core levels and ultraviolet photoemission (UPS) from valence state) is one of the most versatile tools to study the electronic properties of atoms, molecules and solids. As illustrated in **Figure 1a**, in photoemission, photons of well-defined energy are absorbed by the process of electronic excitation. If the photon energy is high enough to ionize the sample, the kinetic energy distribution (photoemission spectrum) of the emitted electrons provides the electronic properties of the initial electronic states in a simplified single-particle picture. Angle-resolved photoemission provides information of the dispersion curve of delocalized electrons in solids, or localized electrons in atomic and molecular orbitals in their initial states.

Core level PES is a powerful technique to study surface atomic structure and chemical reactivity of surfaces. For example, surface atoms of a clean Si(1 0 0) are reconstructed to form a buckled asymmetric dimer structure (see **Figure 2** for the top and side view of the $c(4 \times 2)$ reconstructed Si(1 0 0) surface at low temperature). With the help of the electron diffraction pattern and the atomic-resolved image using a scanning tunneling microscope, high-resolution Si $2p$ photoelectron spectroscopy, which employs a bright photon source of synchrotron radiation, enables the deconvolution of the Si $2p$ spectrum to identify the upper and lower Si atoms in the topmost dimer row as well as Si atoms in the second layer and in the bulk. By observing the change of each component upon adsorption of molecules on the surface, one is also able to study the chemical reactivity at the topmost surface layer at the atomic level.

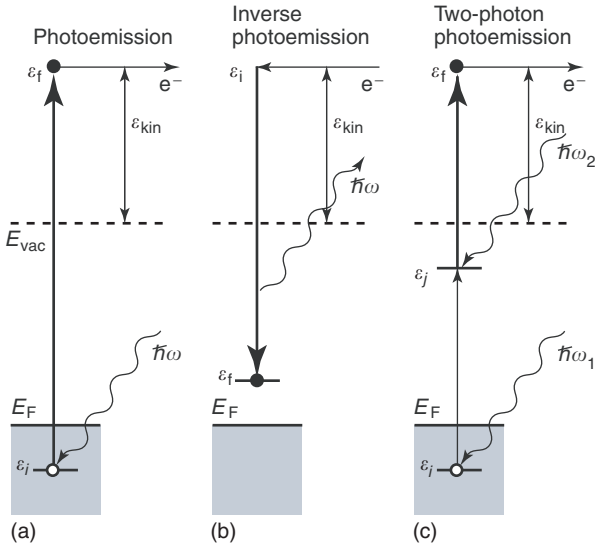

Figure 1 Schematic energy diagram for (a) photoemission, (b) inverse photoemission, and (c) two-photon photoemission. The kinetic energy ε_{kin} of photoelectron and incident electron is measured relative to the vacuum level E_{vac}.

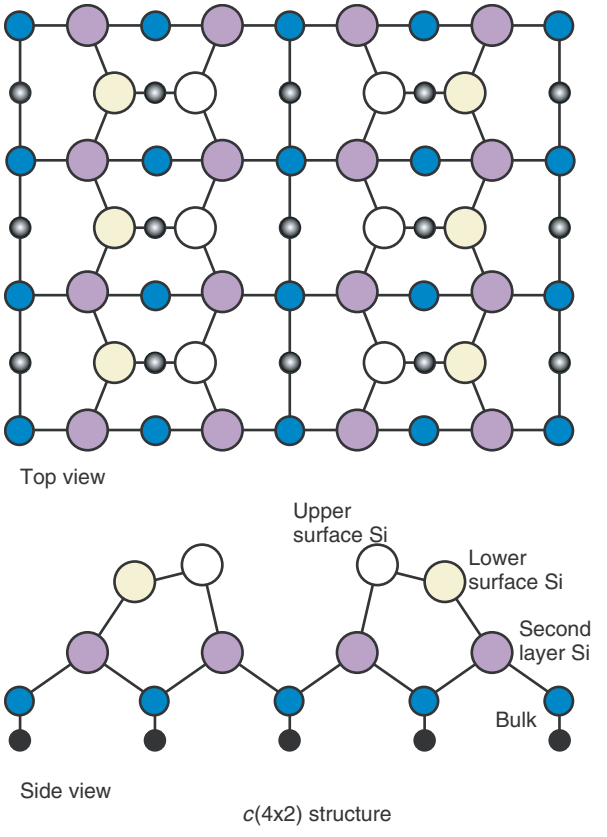

Figure 2 Top and side view of a $c(4 \times 2)$-buckled asymmetric dimer row reconstruction of a Si(1 0 0) surface at low temperature.

Photoemission is also very useful for the study of adsorbates on solid surfaces. A comparison of the photoelectron spectra before (gas-phase) and after adsorption enables one to study the change of electronic properties, in particular, the change of chemical environments and the nature of the atomic or molecular orbitals responsible for the bonding as well as the geometric arrangement at the surface.

The energy range accessible to photoemission is limited to the initial state below the Fermi level (E_F) and to final states above the vacuum level (E_{vac}). The unoccupied states between E_F and E_{vac} can be investigated by means of inverse photoemission (IPS) (**Figure 1b**). This is a time-reversal process of photoemission, which observes the radiative transition of the incident electron into the unoccupied state above E_F. For a fixed energy of the incoming electron, the energy spectrum of the emitted photons directly reflects the electronic properties of the initially unoccupied states.

X-ray absorption spectroscopy (XAS) using bright synchrotron radiation is a powerful tool to study local electronic and atomic structure of solids and adsorbates. The information on the local electronic properties can be extracted from the X-ray absorption spectrum in the vicinity of an absorption edge of an atom, whereas detailed structural properties can be determined from the extended X-ray absorption fine structure (EXAFS), having a series of oscillations due to an interference between the outgoing and backscattered photoelectron wave on the high photon energy side of the absorption edge. The kinetic energy of the photoelectron increases and the de Brogli wavelength becomes shorter with an increase in incident X-ray energy. At a certain wavelength, the interference with the scattered wave from the surrounding atoms produces a constructive or destructive effect on photoionization. This results in the oscillatory behavior in the X-ray absorption coefficient, and analyzing these oscillations close to the absorption energy of a particular atom determines the atomic number, distance, and coordination number of the atoms. In extending EXAFS to surface analysis, the weak signal and surface sensitivity is ensured by detecting the Auger electron emission (escape depth of $\sim 20\,\text{Å}$) of an atom as a function of photon energy.

XAS, in which a core-electron at ε_c is excited to an unoccupied state ε_a above E_F, is also a powerful method for studying the electronic properties of adsorbates. In particular, a sudden creation of the core-hole pulls down the energy level of the outer adsorbate orbitals by the intra-adsorbate Coulomb interaction U so that XAS measures the excitation energy,

$$E_{XAS} = \varepsilon_a - U_{ac} - \varepsilon_c = I - A - U_{ac} \qquad [1]$$

where I and A are the ionization potential and the electron affinity level of the adsorbate, respectively. In the X-ray absorption process, the charge state of the adsorbate remains neutral in the absence of the metal–adsorbate mixing so that no final relaxation shift due to the image screening contributes to E_{XAS}. However, the XAS spectrum crucially depends on the energy position of the unoccupied state relative to E_F in the presence of the core-hole. When it ends up above E_F, the excited state has a finite lifetime due to the decay into the unoccupied part of the metal and the XAS spectrum exhibits a Lorentzian shape accompanied with the so-called "Fermi edge singularity" (IR divergence) at E_F, corresponding to the onset of absorption. In the opposite case where it is pulled down below E_F, an absorption edge appears due to simultaneous excitation of a low-energy electron–hole pair (EHP) in the metal.

These optical processes have different final states for adsorbates, that is, a neutral for optical excitation in XAS, a positive ion for PES, and a negative ion for IPS. An appropriate point of view is to consider the electron states of an N electron system and the $N \pm 1$ electron system left behind after an electron is removed or added by photoemission and inverse photoemission, respectively. For a bulk solid with very large N, the final states do not differ from the initial state. However this is not the case for adsorbates. In PES, for example, a hole created in the core level or narrow valence states by the photoemission process forms a local positive charge and attracts screening electrons. In the case of XPS, one measures

$$E_{XPS} = -\varepsilon_c - \upsilon_c = I - \upsilon_c \qquad [2]$$

where υ_c, the core-level, shifts upward by the hole imaged potential. This is an extra-adsorbate screening in which the compensating charge builds up at the surface. It is also noted that there are other types of intra-adsorbate relaxation followed by an interplay of different dynamic screening processes: (1) charge transfer from the substrate into the initially unoccupied state if it shifts down below E_F by the core-hole potential, (2) extra-adsorbate screening of the core-hole by the surface response of the substrate. These dynamic core-hole screening processes play an essential role in the interpretation of the XPS spectra of adsorbates on metal surfaces. A similar argument also holds for IPS. The final states probed by IPS differs from that involved in the final states of the XAS or PES processes, unless the addition of an extra

electron does not perturb the ground states of the adsorbates. For a negatively charged adsorbate in the final state of and IPS, the induced positive charge at the metal surface binds the electron more strongly, and IPS measures,

$$E_{\mathrm{IPS}} = -\varepsilon_{\mathrm{a}} + \nu_{\mathrm{a}} = A + \nu_{\mathrm{a}} \qquad [3]$$

that is, the downward relaxation shift from ε_{a}.

In addition to XPS, the UPS study of the valence orbitals of adsorbed molecules provides rich information on the nature of bonding to the substrates. For adsorption of carbon monoxide (CO) – the most extensively studied molecule – the UPS spectrum on a Si surface exhibits a similar order of the valence orbitals (5σ, 1π, and 4σ) as in the gas phase. This indicates that CO retains much of its valence structure in the gas phase upon adsorption on a Si surface. On metal surfaces, on the other hand, the 5σ orbital belonging to the carbon atom shows a substantial downward shift relative to the 1π and 4σ orbitals when compared to their ionization energies in the gas phase. This evidences that the highest occupied 5σ (HOMO) orbital is responsible for the chemical bond formation to the substrate as schematically illustrated in **Figure 3**. Upon CO chemisorption, charge transfer (back donation) occurs from the substrate into the lowest unoccupied molecular orbital (LUMO) $2\pi^*$. Since $2\pi^*$ which can be observed by IPS orbital has an antibonding character with respect to the C–O bond, the partial occupancy weakens the C–O bond strength, thereby causing the elongation of the bond distance and the decrease in the frequency of the C–O stretch mode. It is important to note that the electronic properties of the $2\pi^*$ states, such as the position above E_{F} and broadening due to hybridization with the substrate electrons, play important roles in the de-excitation processes of a core-hole created in XAS and XPS from the C and O 1*s* level.

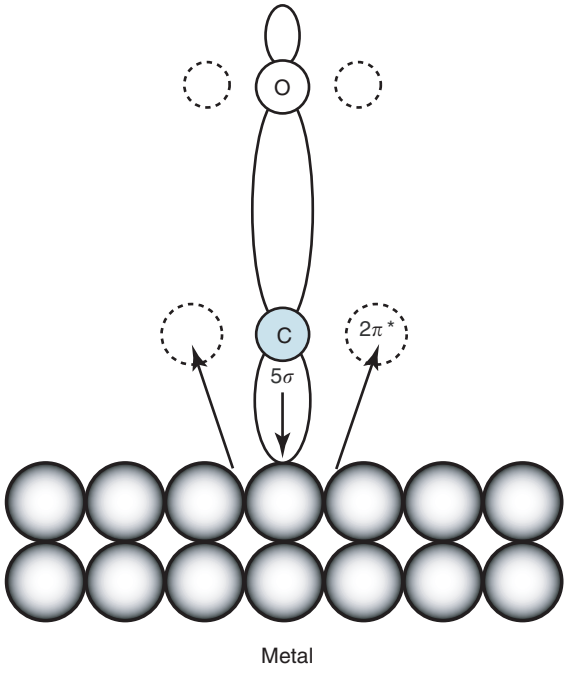

Figure 3 CO chemisorption on a metal surface.

Two-Photon Photoemission

Photoemission occurs not only by absorbing a single photon exceeding the work function ϕ but also by successive absorption of two photons of energy $\hbar\omega_1$ and $\hbar\omega_2$ under the conditions

$$\hbar\omega_1 < \phi \quad \text{and} \quad \hbar\omega_1 + \hbar\omega_2 > \phi \qquad [4]$$

Hereafter all the energies are referred to E_{F}, unless otherwise stated. Two-photon photoemission (2PPE) illustrated in **Figure 1c** is a variant of PES, which allows investigation of unoccupied electronic states located between E_{F} and the vacuum level (E_{vac}) of a metal or semiconductor. In the 2PPE process, the first pump photon $\hbar\omega_1$ excites an electron from an occupied state below E_{F} to an intermediate state between E_{F} and E_{vac}. Upon absorption of a second probe photon $\hbar\omega_2$ during the survival time of the electron in a transiently populated intermediate state (including virtual transition), electrons are excited above E_{vac} forming final photoelectron states, whose kinetic energy distribution curve gives a 2PPE spectrum. 2PPE spectroscopy thus combines both the advantages of traditional one-photon photoemission and IPS spectroscopies, and provides a unique opportunity which allows a simultaneous observation of occupied and unoccupied excited states in metals and semiconductors.

The spectral feature of the 2PPE depends not only on the electronic properties of the initial and intermediate states but also on the excitation photon energy. It has been well established that a peak in the 2PPE spectrum can be easily assigned to an initial or intermediate state, depending on the peak shift with $\hbar\omega_1$ and $\hbar\omega_2$. When a coherent two-photon excitation from an occupied state ε_i below E_{F} brings an electron above E_{vac}, the photoelectron kinetic energy E_{kin} measured from E_{F} shifts as

$$E_{\mathrm{kin}} = \hbar\omega_1 + \hbar\omega_2 + \varepsilon_i \qquad [5]$$

When it is due to two independent processes, a transient population in an intermediate state ε_j by $\hbar\omega_1$ and a subsequent excitation above E_{vac} by $\hbar\omega_2$, it

varies with $\hbar\omega_2$, that is,

$$E_{\text{kin}} = \hbar\omega_2 + \varepsilon_j \qquad [6]$$

Figure 4a schematically illustrates the possible excitation pathways leading to final photoelectron states. This energy diagram is composed of a bulk continuum and a localized surface state below E_F of a metal substrate, and an unoccupied state between E_F and E_{vac}. This diagram can be viewed as the simplest version of a clean metal surface such as Cu(1 1 1) and Ag(1 1 1) having the occupied surface state and unoccupied image potential state. **Figure 4b** depicts E_{kin} as a function of $\hbar\omega = \hbar\omega_1 = \hbar\omega_2$. The incoherent step-by-step single photon process (a) gives a slope = l, while the coherent two-photon process (b) gives a slope = 2. Their extrapolations to $\hbar\omega \to 0$ determine ε_i and ε_j. At a resonant excitation ($\hbar\omega = \varepsilon_j - \varepsilon_i$), two peaks arising from the initially occupied surface state and unoccupied intermediate states are amalgamated to a single resonance narrowing peak.

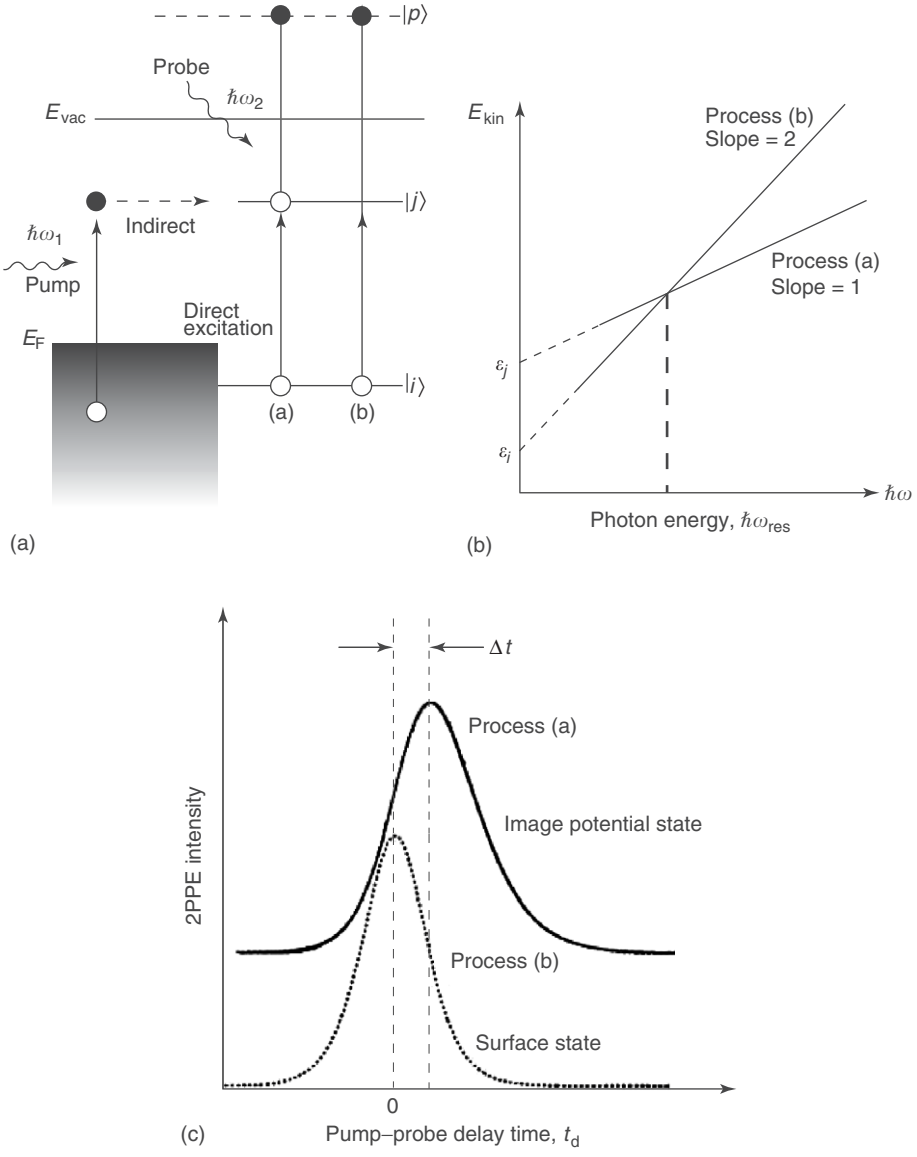

Figure 4 (a) Elementary excitation processes in two-photon photoemission. When a surface state and a continuum of the substrate are available for initial states $|i\rangle$, there are two paths leading to a temporal population in the intermediate state $|j\rangle$. One is direct excitation leading to step-by-step one-photon transition, and another is an indirect process via scattering of the photoexcited electron from a continuum. If there is no surface state like Cu(1 0 0), only the latter nonresonant process is possible. There are two paths leading to a final photoelectron state $|p\rangle$ via (a) step-by-step one-photon process, and (b) direct two-photon ionization process from $|i\rangle$. (b) $\hbar\omega$ dependence of the photoelectron kinetic energy, and $\hbar\omega_{res} = \varepsilon_j - \varepsilon_i$ is a resonant excitation. (c) 2PPE intensity (cross-correlation trace) for the occupied surface state and for the unoccupied image potential state with a finite lifetime.

Image Potential States at Metal Surfaces

One of the most successful applications of energy-, and time-resolved 2PPE is an observation of image potential states at metal surfaces and a direct determination of the lifetimes. When an electron is placed at a distance z from a metal surface, it induces an image charge as a consequence of a many-body screening by the conduction band electrons in a metal. The electron in front of a metal surface forms the Rydberg-like bound states by a potential consisting of the attractive image potential $V(z) = -(e^2/4\pi\varepsilon_0)(1/4z)$ on the vacuum side, and a repulsive crystal barrier at the image plane on the metal side. In a hydrogenic model with a finite repulsive surface barrier, the image potential states have the energies

$$E_n = -\frac{0.85}{(n+a)^2}\ (\text{eV}) \qquad [7]$$

where n is the principal quantum number and a is the so-called quantum defect due to the finite probability of the electron penetrating into the bulk.

The wave functions of these states localized at the surface decay exponentially into the bulk. Compared to the electronic states in the bulk, image potential states have relatively long lifetimes. **Figure 5a** depicts the band structure including an occupied surface

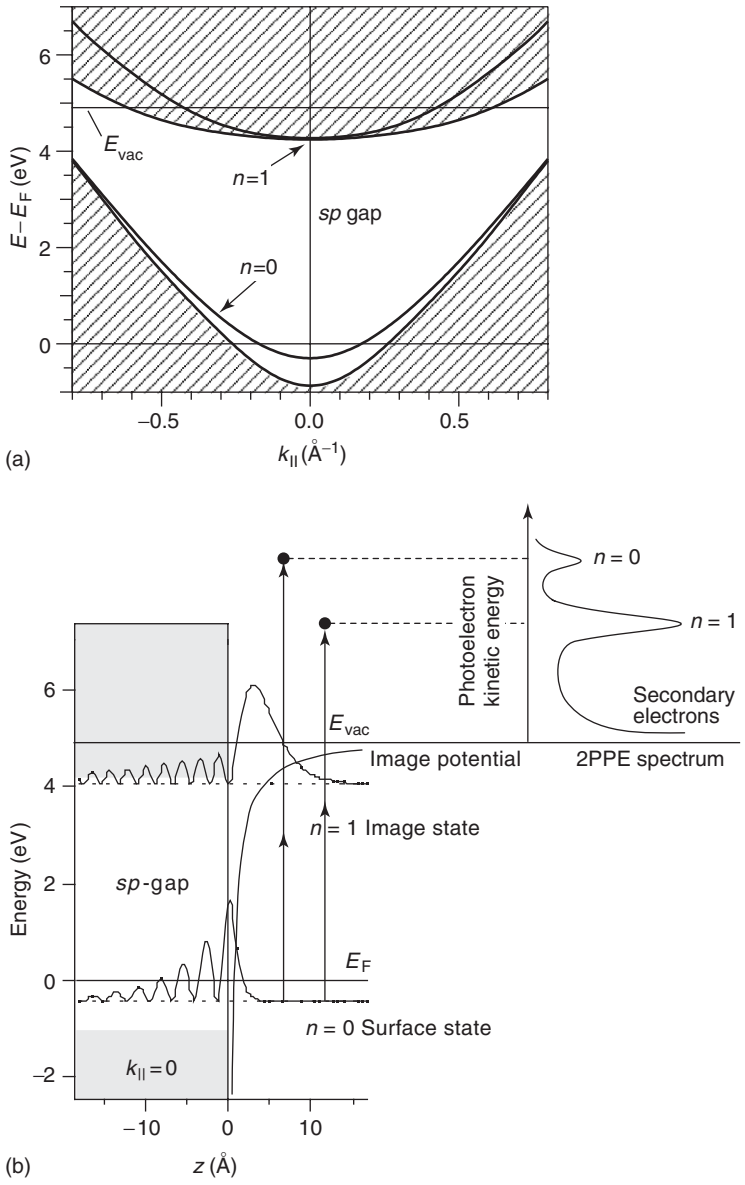

Figure 5 (a) Band structure of Cu(1 1 1) along $k_{||}$. (Modified figure with permission from Smith NV (1985) Phase analysis of image states and surface states associated with nearly-free-electron band gaps. *Physical Review B* 32: 3549–3555; © American Physical Society.) (b) Image potential state and its wave function at $k_{||} = 0$. A typical 2PPE spectrum is also shown. (Courtesy of M Wolf, Free University Berlin.)

state ($n = 0$) and an unoccupied image potential state ($n = 1$) of a Cu(1 1 1) along $k_{||}$. **Figure 5b** illustrates their wave functions at $k_{||} = 0$, whose extent of the penetrations into the bulk depend on their position relative to the projected *sp*-bandgap in the bulk band structure. A typical 2PPE spectrum including photoexcited secondary electron emission is also shown in **Figure 5b**.

Pump–Probe 2PPE Spectroscopy

A great capability of 2PPE lies in the ultrafast time-resolved pump–probe nonlinear spectroscopy to study the carrier dynamics at surfaces using laser pulses with the duration of several tens of femtoseconds. It is a natural extension of the energy-resolved 2PPE by introducing a time delay between the pump and probe photons, which allows the direct measurement of the lifetime of the intermediate state such as the image potential states on metal surfaces. The key quantity to govern the physics underlying TR-2PPE is the relative timescale among energy (population) relaxation time T_1, dephasing time T_2, and pulse duration t_p. It is well known in the context of quantum optics and ultrashort laser pulse phenomena that in the case $t_p \gg T_2$, there is no coherent superposition of the polarization and electromagnetic field oscillations. The memory of the medium is only through the change of the population. This is a case where the rate equation (no coherence effect) approach is appropriate for describing the temporal response of the excited population. In this treatment, the temporal change of the material system occurring within T_2 is averaged so that only the dynamical response beyond a timescale of T_2 is taken into consideration.

On the other hand, in a case $t_p < T_2$, namely when the exciting pulse duration becomes comparable with, or even shorter than the phase relaxation time of the excited medium, and in the presence of a pump and probe overlap during a dynamical change of photo induced polarization, a model including coherent interaction between the photon field and the transition dipole moment is required to describe the temporal response of the system. Central issues involved in the analysis of the transient 2PPE signal in order to deduce reliable T_1 of the image potential states are: (1) how to determine the lifetime T_1 of the image potential state using pulses $t_p \gg T_1$, (2) how to accurately determine the pump–probe delay time $t_d = 0$, (3) how the total dephasing time T_2 (or pure dephasing time T_2^*) plays a role, (4) how the pulse duration affects the transient signal. Some of the answers to these questions have been presented by Hertel *et al*. in 1996 in their study of the electron dynamics at a Cu(111) surface. A precise measurement of t_d can be made utilizing the non-resonant 2PPE process from the surface state as a reference. The peak position of the cross-correlation for the surface state determines the true time zero of the pump pulse with respect to the probe pulse. Due to the finite T_1 of the image potential state, on the other hand, the maximum of the cross-correlation trace appears at the positive t_d after the pump pulse has passed its maximum, as schematically illustrated in **Figure 4c**. The solution of the optical Bloch equations for the density matrix elements characterized by T_1 and T_2 allows the determination of T_1 (order of several to tens of femtoseconds), which is much shorter than t_p.

Vibrational Properties of Adsorbates

Among the various techniques to probe solid surfaces, surface vibrational spectroscopy enables one to study the chemical nature of surfaces and adsorbates. In particular, when combined with other techniques of surface analysis such as electron diffraction, infrared reflection–absorption spectroscopy (IRAS) has established its firm position to determine bonding sites and adsorbate geometry through the selection rule of a dipole transition. An incident IR beam at the angle of θ to the surface normal is decomposed into *s*- and *p*-polarized components (see **Figure 6**). Since the phase change of the *s*-component upon reflection at the surface is always near π for any θ, the total field becomes zero at the surface. On the other hand, the normal component of the *p*-polarized light increases with an increase in θ. The phase change remains small until at large θ, and rapidly drops toward $\pi/2$ at the grazing incidence. The normal component of the total *p*-polarized field reaches its maximum just before falling to zero at grazing incidence. These differences between the *s*- and *p*-polarized field gives the selection rule for the vibrational excitation of adsorbates, that is, the vibrational modes with a dipole moment normal to the surface are excited in IRAS.

Figure 7 shows several fundamental types of adsorption and their corresponding vibrational spectra

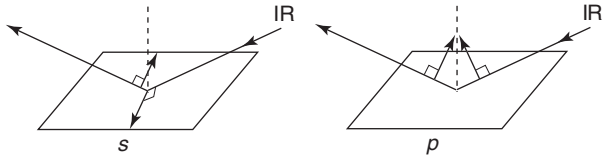

Figure 6 Electric field vector of the *s*- and *p*-polarized IR incidence and reflection.

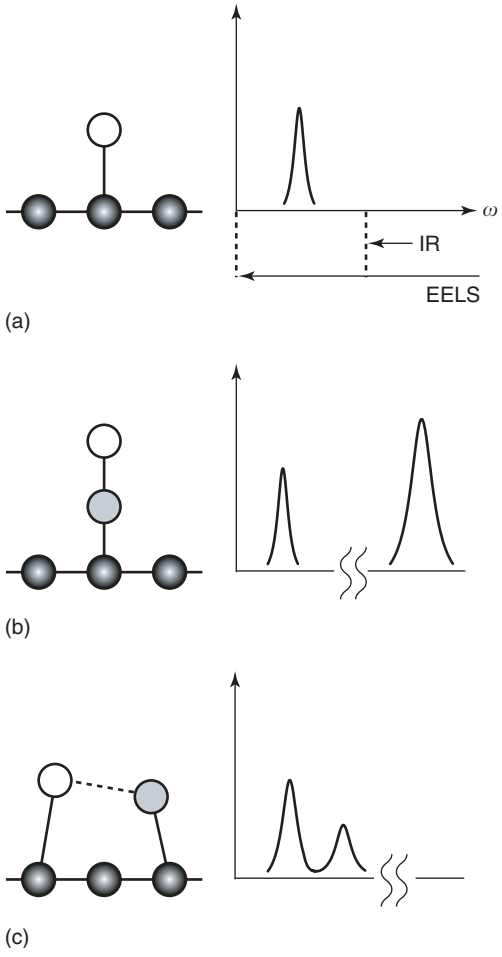

Figure 7 Schematic representation of some fundamental adsorption types of an atom and a diatomic molecule with their corresponding vibrational spectra.

observed by IRAS and energy loss spectroscopy (EELS). For simplicity, the mass of the adsorbate is assumed to be much lighter than that of the substrate atom with which the adsorbate forms the chemical bond. **Figure 7a** illustrates an atom adsorbed at on-top site of a substrate. In this simplest case, one observes a low-energy (in far infrared region) mode corresponding to the stretching vibration between substrate atom and adsorbed atom. For a doubly bonded atom in a symmetric bridge position one LEES peak at a lower energy compared to an atom adsorbed at on-top site is also observed. The single peak splits to double peaks with the different intensity for an adsorption site of lower symmetry.

Figure 7b illustrates a case of a diatomic molecule at on-top site and the molecular axis is perpendicular to the substrate (see also **Figure 3**). The low-frequency mode detected by EELS corresponds to the stretch vibration between a bonded atom of an adsorbed molecule and a substrate atom or derives from the vibration of the whole molecule against the substrate. The high-frequency mode observed by EELS as well as by IRAS is the intramolecular stretch vibration normal to the surface. For a diatomic molecule adsorbed at symmetric bridge site, these peaks shift to the lower energies. In the case of a CO molecule on metal surfaces, a larger back donation of electrons from the substrate into the $2\pi^*$ orbital of a bridge or high coordination sites such as three and four hollow sites on f.c.c.(111) and f.c.c.(100) surfaces, respectively, causes a substantial red-shift of the C–O stretch frequency. This helps a determination of the adsorption site of a CO molecule.

A fundamental issue of a diatomic molecule adsorption includes whether the molecule dissociates to two constituent atoms , each of which bonds to the substrate as a separate entity. The absence of the intramolecular stretch mode evidences a dissociation of a molecule upon adsorption. In this case, two loss peaks will be observed in the EELS spectrum, as being indicative of the vibrations between isolated two constituent atoms and the substrate, as depicted in **Figure 7c**.

Among myriad of experiments for carbon monoxide (CO) on metal surfaces, **Figure 8** shows the IRAS spectrum of CO/Pt(1 1 1) at the coverage $\theta = 0.5$ and temperature of 95 K. As illustrated in the figure, CO molecules occupy both the on-top and bridge sites and form a $c(4 \times 2)$ ordered structure at this coverage, and the corresponding peaks are observed at the red-shifted position compared to the gas-phase CO at $2130\,\mathrm{cm}^{-1}$. The Pt–C stretch mode for the on-top site was also seen in this spectrum.

EELS is also one of the most prevalent techniques in surface vibrational spectroscopy and to study electronic excitation as well as elementary excitations, such as surface phonons or surface plasmons. Vibrational EELS can be considered as the electron-analog of Raman scattering spectroscopy. A monochromatic electron beam with a primary energy of a few electron volts is incident onto adsorbate-covered surfaces, and loss features of the scattered electron are observed at the energy corresponding to the vibrational excitations. The selection rules that determine whether a vibrational band can be observed depend upon the nature of the substrate and also the experimental geometry, that is, the angles of the incident and (analyzed) scattered beams with respect to the surface. For metal substrates and a specular geometry, scattering is predominantly by a long-range dipole scattering. In this case, only those vibrational modes giving rise to a dipole change normal to the surface can be observed. In an off-specular geometry, electrons lose energy to the surface species by a short-range impact scattering. In this case, the

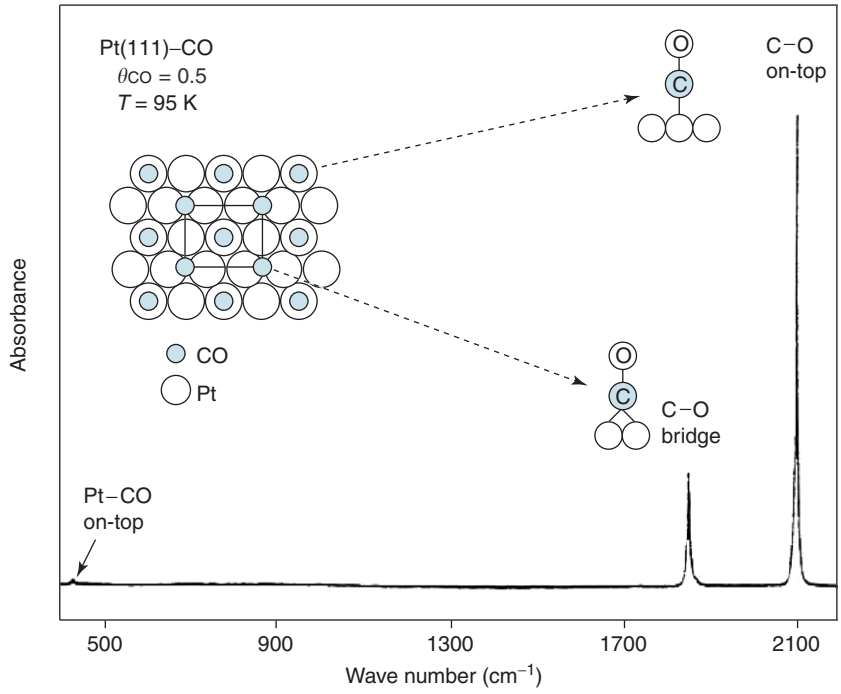

Figure 8 IR absorption spectrum of the $c(4 \times 2)$-ordered structure of CO on Pt(1 1 1) at coverage $\theta = 0.5$ and $T = 95$ K. (Reproduced from Schweizer E, Persson BNJ, Tushaus M, Hoge D, and Bradshaw AM (1989) The potential energy surface, vibrational phase relaxation and the order–disorder transition in the adsorption system Pt(1 1 1)–CO. *Surface Science* 213: 49–89, with permission from Elsevier.)

loss features are relatively weak but all vibrations may be observed. Angular distribution of the inelastically scattered electrons provides rich information of the structure and geometry of adsorbates. Thus, EELS has several advantages (high sensitivity, variable selection rules, and spectral acquisition to below $400\,\mathrm{cm}^{-1}$) and disadvantages (ultrahigh vacuum environment and poor spectral resolution) over IRAS. As a good example, **Figure 9** shows the EELS spectrum of the ordered $c(4 \times 2)$ CO adlayer at the overage of $\theta = 0.5$ on Pt(111) at 92 K (same system as **Figure 8**). It clearly shows the Pt–C stretch modes associated with the on-top and bridge-bonded CO molecule at 470 and $380\,\mathrm{cm}^{-1}$, respectively. In EELS, the Pt–C and C–O stretch modes show comparable intensity, because of the fact that the intensity of the vibrational loss in the dipole scattering mechanism is proportional to the inverse of the loss energy.

Vibrational Relaxation

The IRAS spectrum is represented by

$$I(\hbar\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \mathrm{d}t\, \mathrm{e}^{-\mathrm{i}\hbar\omega} \frac{\langle Q(t)Q(0) \rangle}{\langle Q^2 \rangle} \qquad [8]$$

where $Q(t)$ is the Heisenberg representation of the normal mode coordinate Q of the vibrational degree of freedom, and the brackets indicate the ensemble average of the system. In the absence of the inhomogeneous broadening associated with the structural disorder of an admolecular layer, one may assume a damped oscillator with a frequency of $\hbar\Omega$,and write

$$\begin{aligned} Q(t) &= Q_0 \exp[\mathrm{i}\hbar\Omega t - \Gamma|t|] \\ Q_0 &= 1/(2m^*\hbar\Omega)^{1/2} \end{aligned} \qquad [9]$$

which gives the Lorentzian lineshape of IRAS,

$$I(\hbar\omega) = \frac{1}{\pi} \frac{\Gamma}{(\hbar\omega - \hbar\Omega)^2 + \Gamma^2} \qquad [10]$$

where the half-width-at-half-maximum is expressed as a sum of T_1 (energy or population relaxation time caused by the energy transfer to a heat bath of the system) and T_2^* (pure dephasing time associated with a random modulation of the vibrational frequency due to anharmonic coupling to low-frequency modes);

$$\Gamma = \frac{1}{T_2} = \frac{1}{2T_1} + \frac{1}{T_2^*} \qquad [11]$$

The possible candidate of T_1 for adsorbates on metals is an excitation of EHPs as well as surface and bulk phonons in the substrate. The dephasing time T_2

is defined with respect to the decay of the amplitude of the vibration, and T_1, with respect to the decay of the population. This accounts for the factor 2 in the first term. The possible mechanism responsible for T_1-relaxation crucially depends on the vibrational frequency. For adsorbates whose vibrational frequency is higher than the bulk and/or surface phonons in the substrate, the energy relaxation requires multiple phonon emissions in order to satisfy the energy conservation. For a typical example of a stretching vibration of hydrogen on an Si surface, T_1 (of an order on nanosecond) due to multiple phonon emission increases with temperature. In contrast, on metal surfaces damping through excitation of an EHP in the substrate shortens T_1 down to a few picoseconds. The relative contributions of T_1, T_2^*, and inhomogeneous broadening to the line width can be estimated from the coverage and/or temperature dependence of the IRAS spectrum. For example, T_2^* becomes infinite at very low temperatures where there are no thermal fluctuations to produce pure dephasing. The effect of pure dephasing manifests itself not only in the change of the line width, but also the frequency shift with temperature.

The Lorentzian lineshape of eqn [10] is modified to an asymmetric one with a tail at the lower or higher energy side, as a result of vibrational energy damping due to EHP excitation in metals, and/or by the dipole–dipole coupling between neighboring molecules. In the case of EHP damping, it is represented by the Fano-type lineshape, characteristic to any optical transition of the discrete–continuum system. It is also remarked that in the presence of the structural disorder in the incomplete monolayer of adsorbates, the Gaussian rather than Lorentzian lineshape fits better to the IRAS spectrum.

Nonlinear Surface Vibrational Spectroscopy – Sum-Frequency Generation

Optical second harmonic generation (SHG) and sum-frequency generation (SFG) are the second-order nonlinear process, which forbidden in a medium with inversion symmetry. They arise from a polarization that depends quadratically on the incoming electric fields. **Figure 10** schematically illustrates the SFG process as well as a simple energy diagram for a vibrational excitation. Here a matching of the wave vector components along the surfaces $k_{||,\mathrm{sum}} = k_{||,\mathrm{ir}} + k_{||,\mathrm{vis}}$ determines the direction of the sum-frequency output. The vibrational SFG process is a multi-photon mixing process in which an IR wave of $\hbar\omega_{\mathrm{ir}}$ mixes with a visible wave of $\hbar\omega_{\mathrm{vis}}$ to yield an output at $\hbar\omega_{\mathrm{sum}}$. By scanning the IR beam, the SFG signal exhibits a similar vibrational absorption spectrum observed by IRAS. The SFG surface vibrational

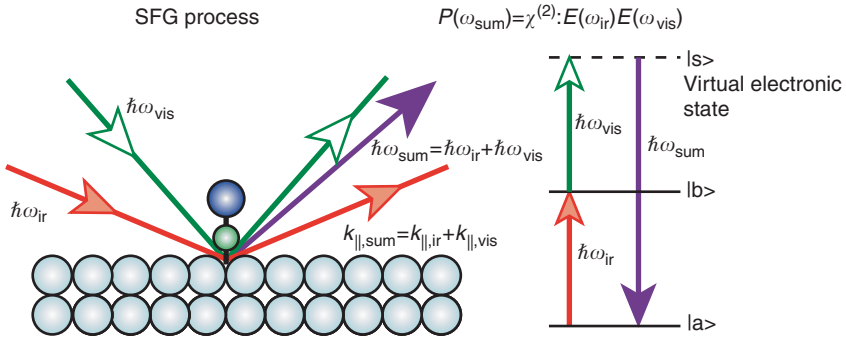

Figure 10 Elementary process of IR–visible vibrational SFG.

spectroscopy allows *in situ* studies of adsorbates with excellent spatial, spectral, and temporal resolution. It can be applied to any surfaces and interfaces accessible by light. Within the dipole approximation, the polarizability of a third-rank tensor is given by

$$P(\hbar\omega_{\text{sum}} = \hbar\omega_1 + \hbar\omega_2) = \chi^{(2)} : E(\hbar\omega_1) : E(\hbar\omega_2) \qquad [12]$$

where $\omega_1 = \omega_2$ for SHG, while $\omega_1 = \omega_{\text{ir}}$ and $\omega_2 = \omega_{\text{vis}}$ for SFG. If the medium has inversion symmetry, the fields $E(\hbar\omega)$ and $-E(\hbar\omega)$ induce $P(\hbar\omega_{\text{sum}})$ and $-P(\hbar\omega_{\text{sum}})$, respectively. This implies $\chi^{(2)} = 0$ in the case of a centrosymmetric medium. In other words, $\chi^{(2)}$ has a finite value at the surface where the inversion symmetry is broken. This is the basis for the surface sensitivity and specificity of SHG and SFG.

The second-order SFG nonlinear susceptibility $\chi^{(2)}$ at $\hbar\omega_{\text{sum}}$ is given by

$$[\chi]^{(2)}_{ijk} = \frac{\mu_k^{ba}}{\hbar\omega_{\text{ir}} - \hbar\Omega + \text{i}(1/T_2)} \times M_{ij}(\hbar\omega_{\text{sum}})(n_a - n_b) \qquad [13]$$

where $\mu_k^{ba} = \langle b|\mu_k|a\rangle$ is the vibrational transition dipole along the k-axis, and n_a and n_b are the populations in the ground and excited vibrational levels, respectively,

$$M_{ij}(\hbar\omega_{\text{sum}}) = \sum_s \left[\frac{\langle b|\mu_j|s\rangle\langle s|\mu_i|a\rangle}{\hbar\omega_{\text{sum}} + \hbar\omega_{as} + \text{i}/T_2^{sa}} - \frac{\langle b|\mu_i|s\rangle\langle s|\mu_j|a\rangle}{\hbar\omega_{\text{sum}} + \hbar\omega_{sb} + \text{i}/T_2^{sb}} \right] \qquad [14]$$

is proportional to the Raman scattering susceptibility of the vibrational transition, where the sum is over the virtual states $|s\rangle$ and $\hbar\omega_{\text{sum}}$ is assumed not to be resonant with any electronic transition. One may immediately notice that the vibrational mode must be both IR and Raman active. The matrix elements of $\chi^{(2)}$ are understood as a sequence of optical transitions starting from the vibrational ground state $|a\rangle$ to an excited state $|b\rangle$, induced by the IR photon with $\hbar\omega_{\text{ir}}$, followed by a second transition to intermediate virtual states $|s\rangle$ by the visible photon with $\hbar\omega_{\text{vis}}$. A photon with sum frequency $\hbar\omega_{\text{sum}}$ is then emitted upon de-excitation returning to the initial state. When the so-called nonresonant contributions $\chi^{(2)}_{\text{NR}}$ due to the off-resonant adsorbate or substrate response is included, the total SFG susceptibility is expressed as

$$\chi^{(2)}_{\text{tot}} = \chi^{(2)}_{\text{RES}} + \chi^{(2)}_{\text{NR}}, \quad \chi^{(2)}_{\text{NR}} = Ae^{\text{i}\phi} \qquad [15]$$

where A is the amplitude of the nonresonant susceptibility and ϕ its phase relative to the vibrational resonance. The vibrational SFG spectrum given by $|\chi^{(2)}_{\text{tot}}|^2$ is affected by $\chi^{(2)}_{\text{NR}}$. If it is negligible or the observed SFG spectrum is deconvoluted to eliminate the contribution of $\chi^{(2)}_{\text{NR}}$, the spectrum is essentially similar to the IR absorption spectrum. **Figure 11** compares the IR absorption spectrum (a) and SFG spectrum (b) of the ordered $c(2 \times 2)$ structure at the coverage of 0.5 of CO on Cu(1 0 0) at 100 K and 120 K, respectively. The IR lineshape is well reproduced by a Lorentzian (dashed line) with a tail at higher frequency due to a dipole–dipole interaction between the neighboring CO molecules. The absence

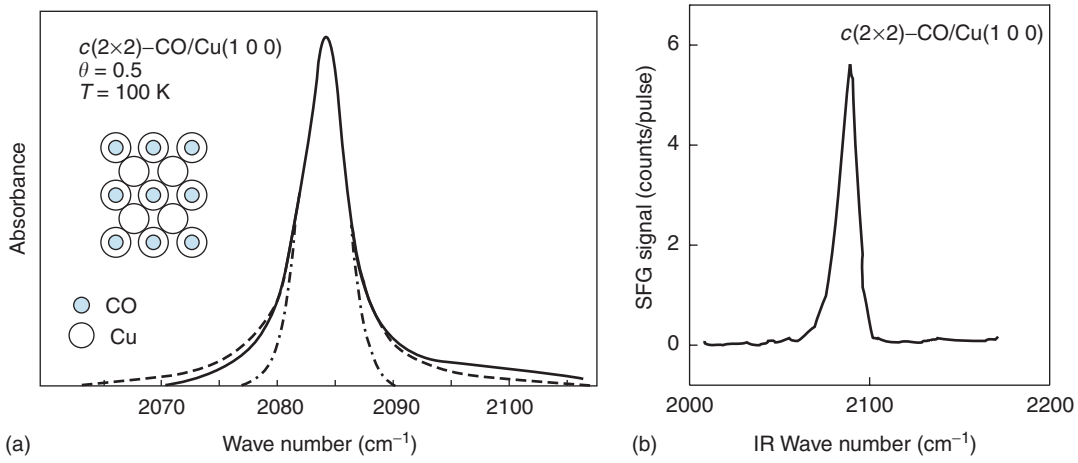

Figure 11 (a) IR absorption spectrum of the C–O stretch mode (dashed and dot-dashed curves are Lorentzian and Gaussian fit, respectively) and SFG spectrum of an ordered $c(2 \times 2)$ adlayer of CO at coverage $\theta = 0.5$ on Cu(1 0 0). of the spectral change with temperature of 20–30 K reveals that the line width ($4.6\,cm^{-1}$) is predominantly determined by the vibrational energy relaxation time of $T_1 = 1.2$ ps due to EHP excitations in the substrate. On the other hand, the SFG spectrum observed using an IR pulse of 4 ps duration showed broader width than the IR absorption spectrum due to poor spectral resolution. For ω_{ir} and ω_{vis} or ω_{sum} near vibrational and electronic excitations, double (IR and visible)-resonant SFG occurs when the corresponding vibrational and electronic transitions are coupled. This reminds one of the surface enhanced Raman scattering of adsorbed molecules on metal surfaces, and enables both the vibrational and electronic properties of adsorbed molecules to be explored as a novel two-dimensional surface spectroscopy.

Pump–Probe SFG – Direct Determination of Dephasing Time

One of the important aspects of vibrational SFG spectroscopy lies in the fact that SFG response is proportional to the population difference $n_a - n_b$ between the ground and excited states. In addition to the SFG signal in the frequency domain, SFG measurement in a time-domain can be performed by introducing a time delay t_d between input pulses. The vibrational relaxation time of adsorbates on surfaces can be directly measured using different pulse sequences, as schematically shown in **Figure 12**. In the case of (a), an intense IR pump pulse (IR1) tuned to the vibrational resonance at a surface, saturates the fundamental $v = 0 \rightarrow 1$ transition. After a certain time delay t_d, a pair (IR2 and visible) of weak probe pulses generates a sum-frequency polarization proportional to the population difference $n_a(t_d) - n_b(t_d)$. The output at sum frequency decays as a function of t_d with a time constant determined by the population relaxation time T_1 of the excited state. This type of pump–probe SFG experiment was applied to a $c(2 \times 2)$ CO on Cu(1 0 0), and $T_1 = 2.0$ ps was obtained. This accounts for 60% of the line width of the IRAS spectrum shown in **Figure 11**.

A different type of transient SFG shown in (b) measures a dephasing time T_2, when t_d is set between IR1 and visible pulse without probe IR2. With this technique, the IR1 resonantly excites the vibrational polarization in a coherent manner, and this coherence decays due to dephasing as $\exp(-t/T_2)$. When the visible pulse, delayed by t_d, is less than or comparable to T_2 is incident on the surface, it probes the remaining coherence. From the decay of the SFG intensity as a function of t_d, T_2 can be deduced. This coherent decay is the so-called free induction decay

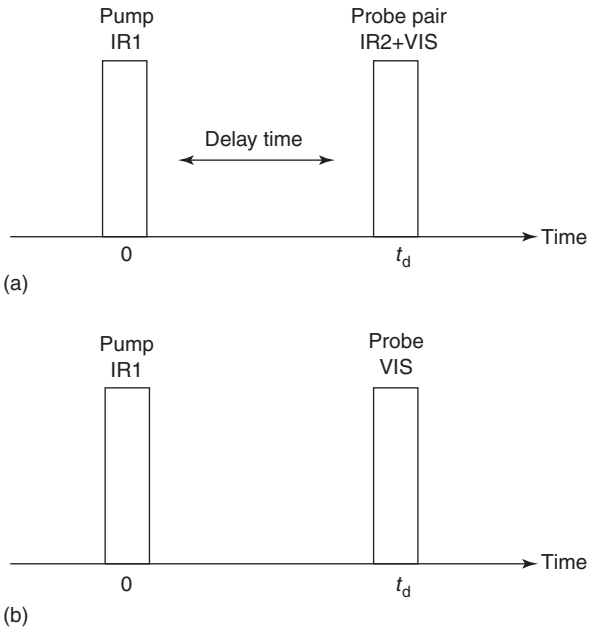

Figure 12 Pulse sequences of time-resolved SFG. (a) an intense IR pump pulse (IR1) tuned to the vibrational resonance at a surface, saturates the fundamental $v = 0 \rightarrow 1$ transition. After a certain time delay t_d, a pair (IR2 and visible) of weak probe pulses arrives at the surface. The output at sum frequency decays as a function of t_d with the population relaxation time T_1 of the excited state. (b) IR1 resonantly excites the vibrational polarization in a coherent manner, and this coherence decays due to dephasing as $\exp(-t/T_2)$. When the visible pulse, delayed by t_d, is less than or comparable to T_2 and is incident on the surface, it probes the remaining coherence. From the decay of the SFG signal, T_2 can be deduced. This coherent decay is the so-called FID.

(FID). In the absence of the coherent optical mixing, the transient SFG intensity $S(t_d)$ evaluated by the time integration of the polarization $|P(t,t_d)|^2$ decays with a time constant $-2/T_2$ as a function of t_d,

$$S(t_d) \propto e^{-2t_d/T_2} \qquad [16]$$

The coherent optical mixing effect occurs in the overlap between $E_{ir}(t)$ and $E_{vis}(t - t_d)$, and causes a shift of the maximum of the SFG intensity from $t_d = 0$. For negligible overlapping between the infrared and visible pulse, T_2 estimated from a decay slope of $S(t_d)$ does not depend on the pulse shape as far as their durations are sufficiently shorter than T_2. It is also remarked that the time resolution of SFG–FID is determined by the rising edge at the negative t_d. **Figure 13** depicts a characteristic behavior of $S(t_d)$, which explains the experimental result for the C–O stretch mode of CO/Ru (0 0 1). In this experiment, the ultrashort pump pulse (800 nm, 110 fs) was used for upconversion of the transient IR-polarization. $T_2 =$ 2 ps was deduced from the decay slopes of $S(t_d)$.

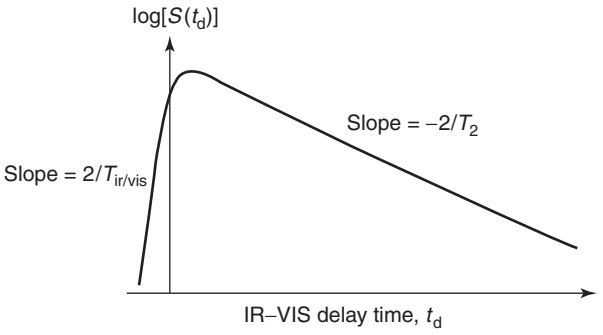

Figure 13 Overall feature of the logarithmic plot of the transient SFG intensity $S(t_d)$ as a function of a time delay between IR pump and visible probe pulse. The rising edge at a negative t_d depends on the pulse shape and determines the time resolution, while the slope at positive t_d gives $-2/T_2$ as far as $T_2 \gg T_{IR/VIS}$.

The same SFG–FID experiment at 350 K gave $T_2 = 1.2$ ps. Because of the temperature independent $T_1(\simeq 2\,\text{ps})$ due to EHP excitations in the substrate, the temperature dependence of T_2 originates from that of T_2^* due to anharmonic coupling with the low-frequency frustrated translational mode.

It should be emphasized that T_2 is reliably determined from a decay slope of the transient SFG intensity observed using sufficiently shorter IR and visible pulse than T_2. The line width of the time-resolved SFG spectra, however, depends on the delay time and is influenced by the pulse duration. When the time-resolved spectrum is observed with the pulse of duration comparable to or much shorter than T_2, no reliable T_2 determination is possible from the line width measurement. A similar phenomenon is also found in energy- and time-resolved 2PPE spectroscopy.

Perspectives

The study of electronic and vibrational dynamics at surfaces is a basis to gain deep insight into a wide variety of electronic and vibrational mediated surface reactions. In particular, nonlinear and time-resolved optical spectroscopies using ultrafast laser pulses continue to provide indispensable knowledge to ward complete understanding of microscopic characteristics of electronic and vibrational dynamics at surfaces. The recent advances in laser technology with pulse duration below several tens of femtoseconds are expected to open a novel way of quantum control of surface reactions.

Tunneling Devices

D Dragoman, University of Bucharest, Bucharest, Romania
M Dragoman, National Institute for Research and Development in Microtechnology (IMT), Bucharest, Romania

Introduction

Tunneling is the phenomenon of propagation at constant energy of quantum wave functions across classically forbidden regions. In a classically forbidden region, the energy of the quantum particle is less than the potential energy so that the quantum wave function cannot penetrate the forbidden region unless its dimension is smaller than the decay length of the quantum wave function.

Tunneling plays a crucial role in almost any modern electronic and optoelectronic device. The development of tunneling devices has been intensified in the last decades and has paralleled the technological achievements that made possible the fabrication of ballistic structures. Constant-energy propagation, as that implied in the tunneling process, implies that (1) thermal excitation is negligible and (2) inelastic scattering processes are absent. Even if the first condition can be achieved at low temperatures, ballistic transport is indispensable in ensuring the second requirement.

A rough classification of tunneling devices distinguishes between single-barrier tunneling devices, double-barrier or resonant tunneling devices, superlattices, and single-electron transistors. This classification is mainly followed in the presentation of the unique features of tunneling devices and the focus is on electron tunneling.

Single-Barrier Tunneling Devices

Electron transport takes place along the direction of an applied electric field. The direction of electron propagation is denoted as x and one may consider that it is possible to separate the electron motion in the transverse (along y and z) and longitudinal (along x) directions, such that the x-dependent part of the envelope electron wave function $\Psi(x,y,z) = \psi(x)\varphi(y,z)$ satisfies in the ballistic collisionless transport regime the time-dependent Schrödinger equation

$$\left(-\frac{\hbar^2}{2}\frac{\mathrm{d}}{\mathrm{d}x}\frac{1}{m(x)}\frac{\mathrm{d}}{\mathrm{d}x} + V(x)\right)\psi(x) = E\psi(x)$$

Here m is the effective electron mass in the conduction band and V is the potential energy. Conduction electron tunneling across a single barrier is easily modeled considering the x-dependent potential energy as being predominantly due to conduction band discontinuities, which occur suddenly at the interface between two different materials and are constant in each material layer. (In general, space charge effects at the interface smoothen the discontinuity; they should be accounted for by a self-consistent solution of both Poisson and Schrödinger equations.) The tunneling structure is then composed from three regions in which both effective masses m_i and potentials V_i ($i = 1,2,3$) vary, as shown in **Figure 1**, such that V_1, $V_3 < E$ and $V_2 > E$. Under these conditions, in each layer the electron wave function can be expressed as a superposition of forward- and backward-propagating waves in the x-direction with wave number $k_i = \hbar^{-1}\sqrt{2m_i(E - V_i)}$:

$$\psi_i(x) = A_i \exp(\mathrm{i}k_i x) + B_i \exp(-\mathrm{i}k_i x)$$

The wave number $k_2 = -\mathrm{i}\gamma_2$ is purely imaginary in the barrier region for electron propagation, and takes real values in the other regions in which electron propagation is allowed. The value of the coefficients A_i, B_i is obtained by imposing the continuity condition for the wave function and $(\mathrm{d}\psi/\mathrm{d}x)/m$. If the barrier is situated between $x = 0$ and $x = L$, these conditions enable one to relate A_1, B_1 to $A_3 \exp(\mathrm{i}k_3 L)$, $B_3 \exp(-\mathrm{i}k_3 L)$ through a transfer matrix with elements M_{ij}, $i,j = 1,2$ such that

$$\begin{aligned} M_{11} &= (1/2)[(1 + v_3/v_1)\cosh(\gamma_2 L) \\ &\quad - \mathrm{i}(v_3/v_2 - v_2/v_1)\sinh(\gamma_2 L)] \\ M_{21} &= (1/2)[(1 - v_3/v_1)\cosh(\gamma_2 L) \\ &\quad - \mathrm{i}(v_3/v_2 + v_2/v_1)\sinh(\gamma_2 L)] \\ M_{22} &= M_{11}^*, \quad M_{12} = M_{21}^* \end{aligned}$$

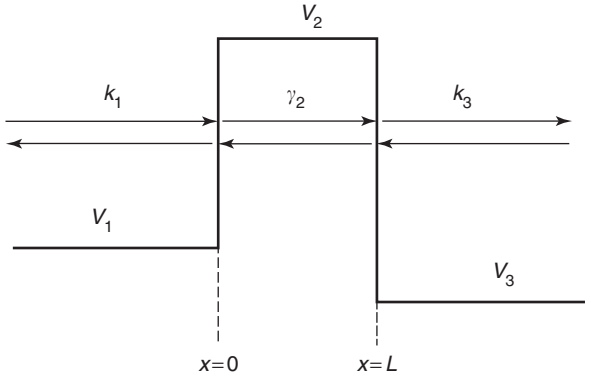

Figure 1 Geometry of a single-barrier tunneling phenomenon.

with $v_1 = k_1/m_1$, $v_2 = \gamma_2/m_2$, $v_3 = k_3/m_3$. The transmission probability of the barrier, defined as $T = v_3|A_3|^2/(v_1|A_1|^2) = v_3/(v_1|M_{11}|^2)$, is

$$T = \frac{4v_1v_3}{(v_1+v_3)^2 + [(v_1^2+v_2^2)(v_2^2+v_3^2)/v_2^2]\sinh^2(\gamma_2 L)}$$

From this expression, it follows that for $\gamma_2 L \gg 1$, the transmission probability depends exponentially on the barrier width L, $T \propto \exp(-2\gamma_2 L)$, or at low temperatures where all electrons that participate in transport have energies close to the Fermi energy E_F, $T \propto \exp\left[-2L\sqrt{2m_2(V_2 - E_F)}/\hbar\right]$. The same exponential factor appears in the expression of the current density through the barrier, which is proportional to the electron transmission probability at low temperatures. Other dependencies of the current density on the height and width of the potential barrier are found for finite temperatures or for different barrier shapes (a triangular barrier is a better description of electron tunneling at high applied voltages).

The current across a barrier connected to two electron reservoirs (contacts) at quasi-Fermi energies E_{F1} and E_{F2} is given by

$$I = \frac{2e}{h}\int T(E)[f_1(E) - f_2(E)]\mathrm{d}E$$

where $f_i(E) = 1/[1 + \exp[(E - E_{Fi})/k_B T]$ is the Fermi–Dirac distribution function at the contacts, which can be approximated at low temperatures with $f_i(E) \propto \vartheta(E_{Fi} - E)$, with ϑ being the step function. $T(E)$ in the expression above should include, if necessary, the contribution of all input and output modes of a ballistic conductor. This expression of the current is valid irrespective of the details of the region characterized by the transmission probability T, that is, it is valid for both single-barrier and multibarrier tunneling.

The electron transmission through a single-barrier model is relevant to vacuum microelectronics as well as for the scanning tunneling microscopy technique. The recently developed vacuum microelectronics studies micrometer-scale devices that operate with ballistic electrons in vacuum. These devices have the potential to operate at higher frequencies, higher power, and in a wider temperature range, even under irradiation conditions, than devices based on semiconductor technology since in vacuum, electrons travel faster and with less energy dissipation. Prompted by these advantages, vacuum microelectronic devices include flat-panel field emission displays, in which electrons tunnel from a solid surface into vacuum, electron sources for microscopes, miniaturized microwave power amplifiers, and X-ray generators. Scanning tunneling microscopy, on the other hand, is a method of mapping solid surfaces with atomic resolution. In this case, electrons tunnel from the last atom of the tip apex of the probe to single atoms of the surface under study. Scanning tunneling microscopy is also a spectroscopy method for single molecules on surfaces and a powerful technique of manipulating the surface structure.

Resonant Tunneling Devices

Resonant tunneling occurs in structures consisting of two thin barriers for electron propagation separated by a quantum well region with width L in which the electron is free to propagate with a wave vector k. The geometry of the structure is represented in **Figure 2**. The matrix formulation briefly discussed in the previous section can be employed in this case also if the potential energy has a step-like variation. The total transmission matrix M with elements M_{ij}, $i, j = 1, 2$, is obtained by multiplying the transmission matrices of the left barrier, M_l, of free propagation across the quantum well, and of the right barrier M_r. The transmission probability T of the whole structure is expressed, as above, in terms of M_{11}, that takes the expression

$$M_{11} = M_{l,11}M_{r,11}\exp(-\mathrm{i}kL) + M_{l,12}M_{r,21}\exp(\mathrm{i}kL)$$

since the free propagation matrix is diagonal with elements $\exp(-\mathrm{i}kL)$ and $\exp(\mathrm{i}kL)$. It can be shown that

$$T = \frac{T_l T_r}{(1 - \sqrt{R_l R_r})^2 + 4\sqrt{R_l R_r}\cos^2\theta}$$

with

$$\theta = kL + (\arg M_{l,12} + \arg M_{r,21} - \arg M_{l,11} - \arg M_{r,11})/2$$

where T_l, T_r are the transmission probabilities through the left and right barrier individually, and R_l, R_r the corresponding reflection probabilities. Even if T_l and T_r are small so that $1 - \sqrt{R_l R_r} \cong (T_l + T_r)/2$, the

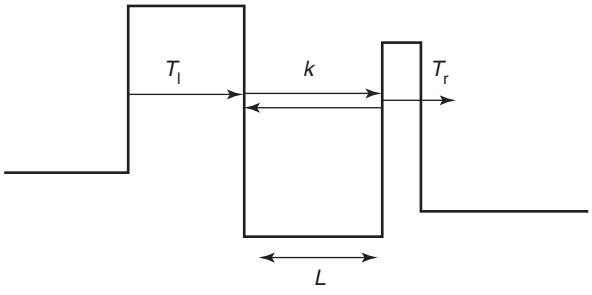

Figure 2 Geometry of the double-barrier tunneling phenomenon.

total transmission probability can still achieve large values at resonance, that is, if $\theta = (2n+1)\pi/2$ with n integer, for which $T_{res} = 4T_l T_r/(T_l + T_r)^2$. The resonant value of the transmission probability is unity if $T_l = T_r$, and can be approximated with $4T_{min}/T_{max}$ when T_l and T_r are very dissimilar, with $T_{min} = \min(T_l, T_r)$ and $T_{max} = \max(T_l, T_r)$. At resonance, that is, when the energy of the incident electrons equals one of the resonance energy values, the electrons are not only transmitted with high probability across the structure, but they are also transmitted in a shorter time than in off-resonance conditions. For this reason, resonant tunneling devices are also ultrafast devices.

Close to resonance, the transmission probability can be approximated with

$$T(E) = \frac{\Gamma_l \Gamma_r}{(\Gamma_l + \Gamma_r)^2/4 + (E - E_{res})^2}$$

where E_{res} is the resonance energy for which $\theta(E) = (2n+1)\pi/2$, and $\Gamma_l = (dE/d\theta)T_l/2$, $\Gamma_r = (dE/d\theta)T_r/2$ (divided by $\hbar$) represent the rates at which an electron placed in the well of width L leaks out through the left and right barrier, respectively. Near resonance, the transmission probability is very sensitive to the electron energy or to the position of the resonant energy level. The ease with which this last parameter can be controlled by applying a voltage across the double-barrier structure led to the development of a host of devices based on resonant tunneling.

Coherent versus Incoherent Resonant Tunneling

In the calculation of the transmission probability of the resonant tunneling structure, the coherent transport has been assumed, that is the electron wave function is assumed to be transmitted from left to right in a single quantum mechanical process. This assumption is justified if the time spent by an electron in the resonant state (the eigenstate lifetime) is much smaller than the scattering time. If this is not the case, sequential tunneling occurs, in which the electron first tunnels into the well, loses memory of its phase, and then tunnels out from the well. Despite the differences between coherent and sequential resonant tunneling, the expression of the net current flow near resonance is the same for the two cases.

Resonant Tunneling Diodes

One of the first applications of resonant tunneling structures was the resonant tunneling diode (RTD),

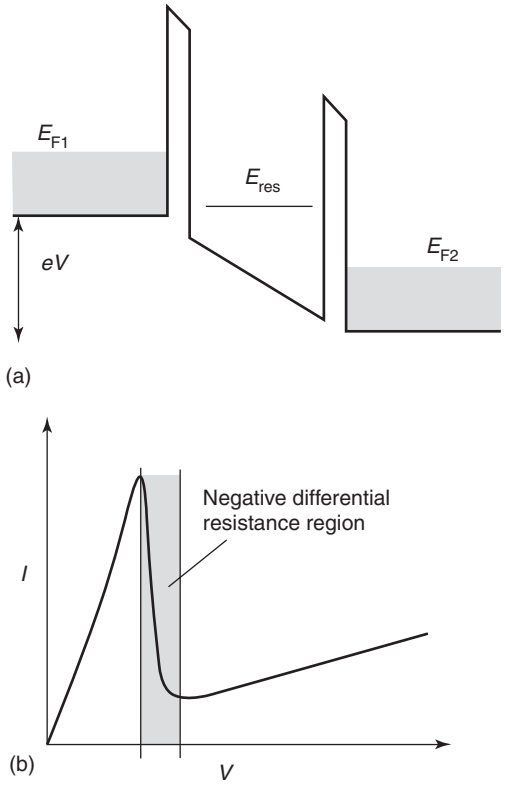

Figure 3 (a) Schematic representation of a resonant tunneling diode, and (b) its I–V characteristic.

which is a biased double-barrier structure that has only one resonance energy level on which electrons from the left contact (emitter) can tunnel (see **Figure 3a**). The main characteristic of the RTD is the occurrence of a negative differential resistance region, as shown in **Figure 3b**. Although the electrons in the emitter region have energies between the bottom of the conduction band and the Fermi energy E_{F1}, the resonance level in the well acts as a filter that allows further propagation of only those electrons with energy E_{res}; when the applied bias is sufficiently high for the resonance energy level to fall below the conduction band edge in the left emitter region, no electrons can tunnel into the right contact (collector) with a Fermi energy E_{F2}, and the current is expected to drop. Therefore, the I–V characteristic exhibits a negative differential resistance region. It is important to note that the RTD can work at room temperature, unlike most mesoscopic devices that function well only at low temperatures.

Optoelectronic Devices Based on Resonant Tunneling

Optoelectronic devices based on resonant tunneling incorporate mesoscopic structures such as quantum

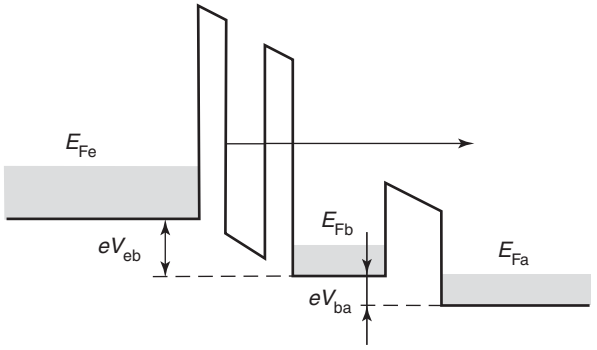

Figure 4 Schematic representation of the resonant tunneling injection hot electron laser.

wells, quantum wires, or quantum dots, which are used to generate, modulate, or detect electromagnetic radiation. In these devices, resonant tunneling is usually employed to enhance the high-speed response since the transfer rate of electrons through resonant tunneling structures is much faster than the drift and diffusion processes. Moreover, since resonant tunneling acts as an energy filter for the incident electrons, it can be used to remove the carrier speed limitations due to carrier thermalization.

In lasers, for example, based on the enhancement of the stimulated emission of radiation in an active mesoscopic medium placed inside a resonant cavity for the electromagnetic radiation, the modulation bandwidth can be improved by the injection of carriers in the active region through resonant tunneling. This tunneling injection laser is a hybrid design between quantum well tunneling lasers and active media quantum well lasers.

In more sophisticated tunneling injection lasers, as in that represented in **Figure 4**, it is possible to control the energy E of (hot) electrons in the active region through two voltages V_{eb} and V_{ba} applied, respectively, between the emitter and base regions, and between the base and active regions of the structure. The base and active regions are separated by a barrier that acts as a hot electron launcher. The Fermi energy levels in the emitter, base, and active regions are denoted in **Figure 4** by E_{Fe}, E_{Fb}, and E_{Fa}, respectively. In this device, called resonant tunneling injection hot electron laser, ultrafast gain switching is caused by the change in the injection energy rather than by carrier injection rate variations.

High modulation speeds are achieved by employing electron tunneling across the spacer region that separates the electron reservoir from the modulating structure, for example, in the device known as barrier-reservoir and quantum well electron transfer modulator (**Figure 5**). Here, however, the position of the resonant energy level E_{res} in the quantum well

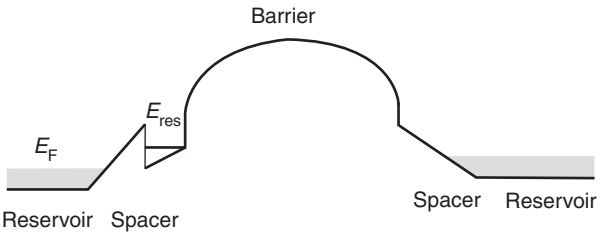

Figure 5 Schematic conduction band diagram of the barrier-reservoir and quantum well electron transfer modulator.

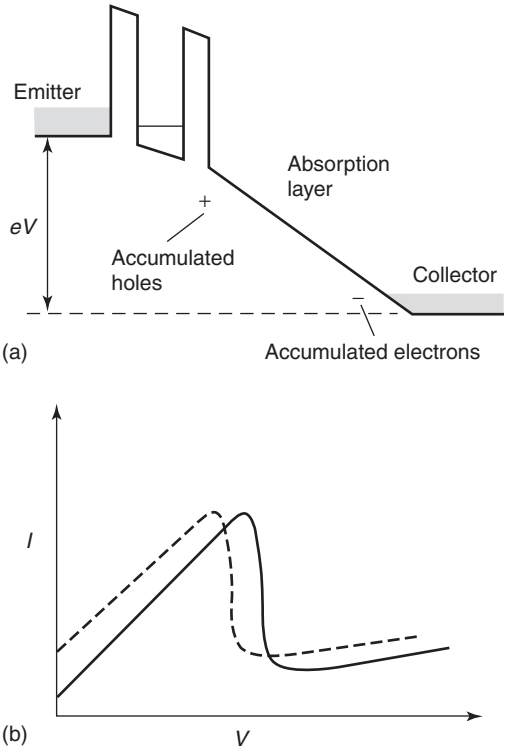

Figure 6 (a) Schematic conduction band diagram of the resonant tunneling photodetector, and (b) the I–V characteristic in the absence (—) and presence (- - - -) of light.

relative to the Fermi level E_F of the left electron reservoir is also essential. When an applied voltage drops the resonant energy level from above E_F (when it is empty) to below E_F (when it is filled), the absorption coefficient and refractive index for an incident electromagnetic radiation spectrum change, proportional to the applied voltage.

Resonant tunneling photodetectors have also been developed. They consist (see **Figure 6a**) of a resonant tunneling structure followed by a thick layer that absorbs the incident electromagnetic radiation. The photogenerated electrons and holes are separated spatially by the external voltage applied on the structure, which drops almost entirely on the absorption layer, and accumulates at the collector and the resonant barriers of the RTD, respectively.

Consequently, the applied electric field is partially screened and the *I–V* characteristic of the resonant tunneling structure, which exhibits a negative differential resistance region, is shifted to lower voltages in the presence of light absorption, as shown in **Figure 6b**. The responsivity of the photodetector is extremely high if biased near the peak voltage.

Resonant Tunneling Devices Based on Coupled Quantum Wells

A quantum resonant structure consists of a quantum well surrounded by thin barrier layers. What happens when another quantum well and another thin barrier is added to the structure? Depending on the height and width of the common barrier, the electrons confined in one quantum well can interact or not with the electrons confined in the other. The first case corresponds to coupled quantum wells, in which the electron wave function is extended throughout the entire structure, whereas the second case corresponds to a succession of noninteracting quantum wells, the electrons localized in one well being able to propagate across the structure only through sequential tunneling between adjacent wells.

In two identical coupled quantum wells, the energy degeneracy of the resonant levels in individual quantum wells is removed, the electron wave function splitting into a symmetric and an antisymmetric part, Ψ_{sym} and $\Psi_{antisym}$, respectively, as depicted in **Figure 7**. Nonidentical coupled wells, with different energy levels in the individual wells, can be brought to resonance by applying a bias that aligns two energy levels in the quantum wells. In this case, the electron wave function, which is initially confined in one well or another becomes delocalized and splits into a symmetric and an antisymmetric part. Coupled quantum wells have hosts of applications in electronics, optoelectronics, and even quantum computing.

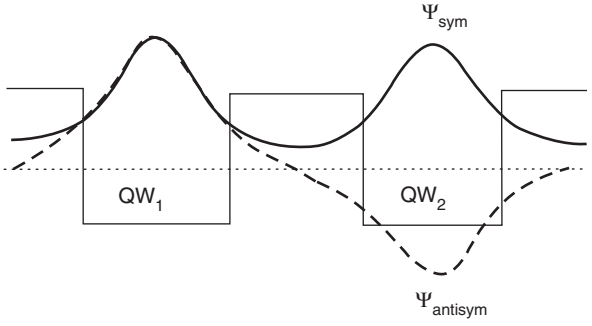

Figure 7 Splitting of the electron wave function into a symmetric and an antisymmetric part, when two identical quantum wells, QW_1 and QW_2, are brought in close proximity.

Quantum Well Tunneling Lasers

The resonant tunneling phenomenon is essential in lasers based on inter-sub-band transitions, where the radiation is caused by transitions between two resonant levels, 1 and 2, with populations N_i, $i = 1,2$, in an active quantum well in either the conduction or the valence band. In this case (see **Figure 8**), resonant tunneling assures the population inversion between the resonant levels E_1 and E_2 needed to enhance the stimulated emission of radiation. The condition $N_2 > N_1$ can only be achieved if the conduction electrons on the lower energy level can leak out from the quantum well through a resonant channel at the same energy level as E_1. Population inversion is thus created by resonant tunneling into an adjacent, coupled quantum well, which has a discrete energy level aligned to E_1. Such quantum tunneling lasers involve only the resonant transport of electrons if both active and coupled quantum wells are in the conduction band, but can also involve transport of both electrons and holes when the coupled quantum wells are situated in different bands. Often, electron injection into the active quantum well is also performed through resonant tunneling for improved efficiency and speed. Cascades of quantum well tunneling lasers can be used to enhance the power of the emitted radiation. Quantum well tunneling lasers are the future of low-energy high-wavelength radiation sources.

Modulators Based on Coupled Quantum Wells

The delocalization of electron wave function in nonidentical coupled quantum wells brought at resonance can be used to modulate an incident electromagnetic radiation. The modulation principle is based on the change of the binding energy of the excitons that can form in the system, and consequently, of the absorption coefficient and refractive index. In this type of modulator, presented in **Figure 9**, the lowest energy electron and hole states are confined in the first and second well of the conduction and valence bands,

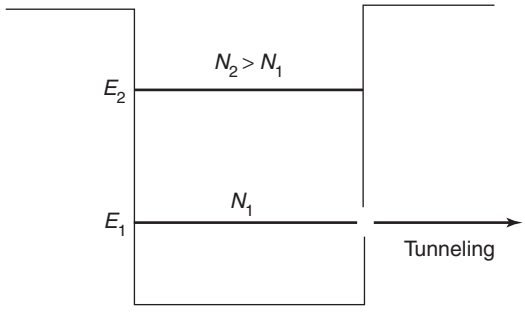

Figure 8 Population inversion mechanism in quantum well tunneling lasers.

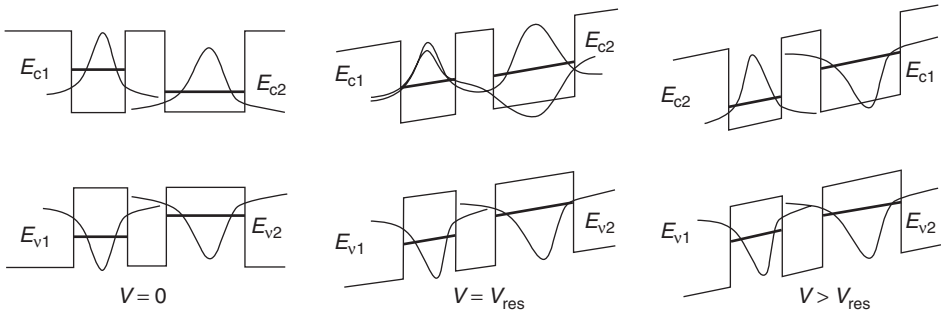

Figure 9 Dependence of the electron and hole wave functions of the applied bias in a modulator based on coupled quantum wells.

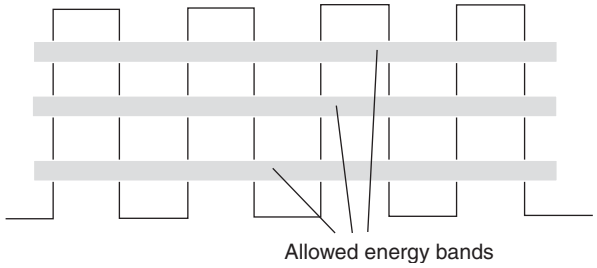

Figure 11 Conduction electron allowed and forbidden energy bands in the periodic potential of a superlattice.

respectively, when no potential is applied on the structure. In this case, excitons (bound electron–hole states) form between the electron and hole states confined in the same well, that is, between E_{c1} and E_{v1}, and E_{c2} and E_{v2}, respectively. At resonance, when the electron states are brought at the same level by an applied bias $V = V_{res}$, the electron wave function becomes delocalized, a further increase in bias inducing an interchange in the confined electron wave functions compared to the no-bias case. Assuming that the hole states in the quantum wells do not couple, the final exciton states and their respective binding energies are different from the no-bias case, since they form between the same hole levels but interchanged electron levels, that is, they form between E_{c2} and E_{v1}, and E_{c1} and E_{v2}, respectively.

Coupled Quantum Wires for Quantum Computing Applications

When two identical quantum wires, QWR_1 and QWR_2, are coupled, an electron wave function localized initially in one wire becomes confined in the other after a certain propagation length L, as shown in **Figure 10**; this situation is similar to a coupler between two parallel optical waveguides. It is then possible to identify the location of the electron wave function with one of the possible logic values 0 or 1, a superposition of the two quantum bit states occurring for propagation lengths smaller than L. Quantum operations can then be implemented by modulating the height of the common barrier by an applied bias.

Superlattices

When multiple identical quantum wells are coupled, the conduction electrons sense a periodically varying potential with a periodicity that is no longer that on the atomic scale, but on a mesoscopic scale. The periodicity of the potential energy imposes (as in bulk materials, where the periodicity is that of the lattice) the development of permitted and forbidden electron energy bands (see **Figure 11**), with positions and widths that depend on the exact form of the periodic potential and that can be controlled at will using advanced semiconductor techniques. This artificial lattice is called a superlattice. The possibility of engineering the position and width of conduction electron energy bands as well as the dispersion relation turn superlattices into extremely useful devices, with particular applications in optoelectronics, for electromagnetic fields with wavelengths comparable to the superlattice period. Then, the allowed and forbidden energy bands also develop for electromagnetic fields, similar to the allowed and forbidden energy bands of electrons in bulk materials.

Single-Electron Devices

Unlike resonant tunneling devices that are based on the discrete spectrum of resonant energy levels in a

well connected to electron reservoirs through thin barriers, single-electron devices are based on the discrete nature of electric charge that can be transferred from a conducting island (quantum dot or metallic cluster) connected through thin barriers to electron reservoirs. These devices are based on the Coulomb blockade phenomenon, which predicts the opening of a Coulomb gap in the tunneling density of states. Because of the Coulomb interaction between electrons in the island, tunneling of one electron requires an energy $e^2/2C$, where C is the capacitance between the island and the environment. This energy can be interpreted as an activation energy or, equivalently, as the opening of an energy gap of width e^2/C because, not only electrons at the Fermi level need an extra energy $e^2/2C$ to tunnel into the island but so do the holes. The contribution to this charging effect of energy quantization in ballistic islands renders the theory of single-electron tunneling more difficult.

Single-Electron Transistor

The single-electron transistor, depicted schematically in **Figure 12**, is the best-known single-electron device. It consists of a gated quantum dot or metallic cluster (generically, an island) separated by tunnel junctions from leads, and is characterized by an oscillating behavior of the conductance with density. The period of oscillations corresponds to the addition of one electron to the island. If the tunnel junctions that separate the gated island from the environment are modeled as a parallel combination of a tunneling resistance R_i and a capacitance C_i, $i = 1, 2$, the electrostatic energy of the gated island with N electrons and charge $Q = Ne$ is

$$E = -QV_gC_g/C + Q^2/2C - eV(N_1C_2 + N_2C_1)/C$$

or, to within an additive constant

$$E = (Q - Q_0)^2/2C - eV(N_1C_2 + N_2C_1)/C$$

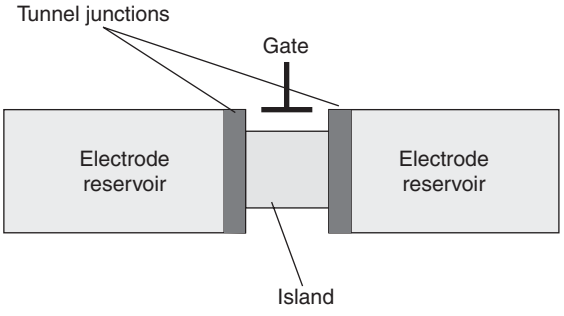

Figure 12 Schematic representation of a single-electron transistor.

where V_g is the gate voltage, V is the voltage applied between the leads, C_g is the island-gate capacitance, the total island capacitance is $C = C_1 + C_2 + C_g$, N_i is the number of electrons passed through the tunnel barrier i so that $N = N_1 - N_2$, and $Q_0 = C_gV_g$ is the external charge. Energy minimization allows only discrete values of energy for a given Q_0 due to charge quantization. At $V = 0$, when $Q_0 = Ne$ with N an integer, increasing or decreasing N by 1 requires an energy difference $e^2/2C$ and hence the opening of a Coulomb gap, whereas no energy gap in the tunneling density of states appears when $Q_0 = (N + 1/2)e$, since the states with $Q = Ne$ and $Q = (N + 1)e$ are degenerate and the charge fluctuates between them even at zero temperature. The occurrence of the energy gap at all gate voltages except those for which $Q_0 = (N + 1/2)e$ leads to the appearance of periodic sharp peaks in the conductance value at low temperatures. The spacing between the peaks is given by $\Delta V_g = e/C_g$, voltage difference that is exactly compensated for by the tunneling into or from the island of one electron.

These considerations are valid for metallic clusters isolated by thin barriers from external leads. In semiconductor quantum dots, the discretization of the energy levels inside the dots imposed by size constrictions must be accounted for in addition to charge discretization. In this case, electron tunneling implies the matching of the Fermi energy in the leads to a discrete energy level outside the Coulomb gap, both the amplitude and the position of the conductance peaks depending on the discrete levels of the dot. The gate voltage spacing ΔV_{gN} between the $(N-1)$th and the Nth peaks of the conductance increases from the e/C_g value in metallic clusters with $\Delta E_N/e : e\Delta V_{gN} = e^2/C_g + \Delta E_N$, where ΔE_N is the energy spacing of the levels of the structure; measurement of the position of conductance peaks can serve in this case as a spectrometric method for determining the discrete energy levels of the island. The amplitude of the conductance peaks depends on the discrete levels in the dot since it depends on the tunneling matrix elements, which can have different values for different energy levels in the dot.

Single-electron transistors are used as supersensitive electrometers since for applied voltages V slightly above the Coulomb blockade threshold, the current is extremely sensitive to the gate voltage, being able to measure sub-single-electron variations in the external charge. This technique of detecting subelectron charge variations has been recently proposed as the reading method for the results of quantum computations performed with solid-state Kane computers.

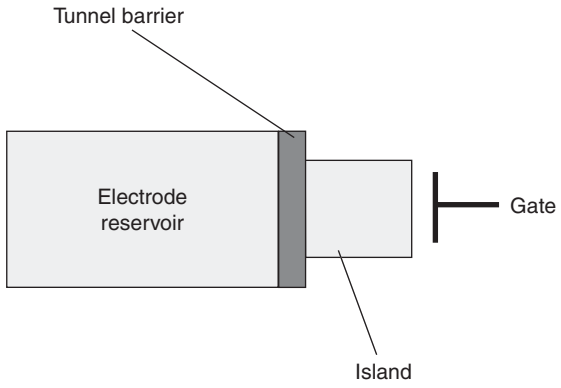

Figure 13 Schematic representation of a single-electron box.

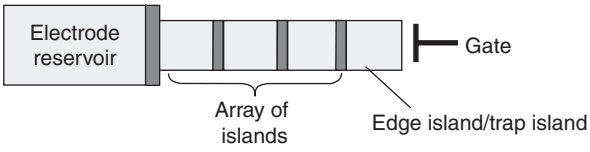

Figure 14 Schematic representation of a single-electron trap.

Other Single-Electron Devices

The simplest single-electron device is the single-electron box, which consists of a gated island separated from an electron source by a single tunnel barrier (**Figure 13**). The electrostatic energy of the box has the same expression as for the single-electron transistor but with $V = 0$, the charge of the island Q being a step-like function of Q_0, that is, of the gate voltage, the distance between neighboring steps being $\Delta Q_0 = e$. This Coulomb staircase is observable only at low temperatures; otherwise, it is smeared out by thermal fluctuations.

The single-electron trap is a generalization of the single-electron box in which the single tunnel junction is replaced by a linear array of islands separated by tunnel junctions (see **Figure 14**). Unlike single-electron boxes, where the number of electrons in the box is fixed by the gate voltage, single-electron traps may be in one of the several charged states of the edge island within certain ranges of applied gate voltages. This device is characterized by multistability, the charge state of the edge island (the trap) depending on its prehistory.

A single-electron turnstile, represented in **Figure 15**, is a linear array of islands connected through tunneling junctions to electron reservoirs, only one element of the array being gated. When no voltage is applied between the electron reservoirs, the device acts as a single-electron trap, whereas for an applied voltage an electron is always picked up from the emitter when the gate voltage V_g increases, and is delivered to the collector when V_g decreases. For a periodically varying gate voltage, an electron is transferred from emitter to collector for each period. When each island in the linear array is gated and phase-shifted RF waveforms are applied on each gate electrode, the device is called single-electron pump (see **Figure 16**). No voltage needs to be applied in this case between the electron reservoirs, the electron being transferred in a direction determined by the running wave of the electric potential.

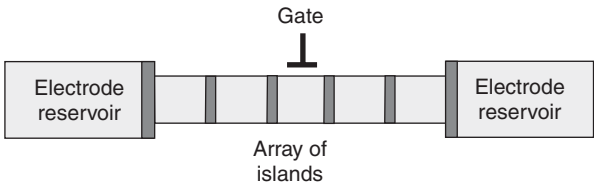

Figure 15 Schematic representation of a single-electron turnstile.

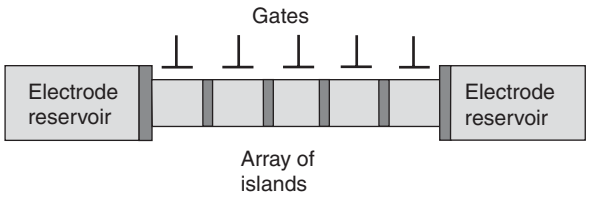

Figure 16 Schematic representation of a single-electron pump.

Single-electron tunneling devices have been proposed as standards for DC currents (especially single-electron turnstiles and pumps), temperature and resistance, for the detection of infrared radiation, and have interesting prospects for digital applications. Novel features and new applications of single-electron devices are expected to occur in systems with superconducting electrodes.

Nomenclature

C	capacitance between the island and the environment
C_g	island-gate capacitance
e	electron charge
E	energy
E_F	Fermi energy
E_{res}	resonant energy level
E_{ci}	bound state i in the conduction band
E_{vi}	bound state i in the valence band
$f(E)$	Fermi–Dirac distribution function
I	current
k	wave number
L	length
m	effective electron mass in the conduction band
M_{ij}	transfer matrix elements
N	population of an energy level
N_i	number of electrons that pass through tunnel barrier i
Q	island charge
Q_0	external charge
R	reflection probability
R_i	tunneling resistance of junction i
T	transmission probability
V	potential energy; also applied voltage
V_g	gate voltage
ΔV_{gN}	gate voltage spacing between the $(N-1)$th and the Nth peaks of the conductance
Γ	tunneling rate
ϑ	step function
$\Psi(x, y, z)$	electron wave function

Valence Photoemission

G Margaritondo, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

The basic features of this technique are discussed, beginning with its historical development. Angle-resolved (band mapping) and angle-integrated techniques are analyzed as well as a series of experimental approaches – photon polarization studies, experiments as a function of the photon energy, photoemission resonances and techniques affected by low signal level such as time-resolved photoemission, two-photon photoemission spectromicroscopy, and spin-polarized photoemission – requiring the use of powerful photon sources, such as undulators or ultraviolet lasers. Finally, high-resolution photoemission studies of superconductors and of other correlated systems are briefly discussed.

Historical Background: The Photoelectric Effect

The photoelectric effect, discovered by Hertz in 1887, is the basis of some of the most powerful techniques capable of analyzing the electronic structure of condensed-matter systems – the techniques collectively labeled as "photoemission spectroscopy." Even before the development of such techniques, the photoelectric effect had a fundamental (and often not correctly understood) impact on the history of modern science.

The main milestones after Hertz's work were Thompson's 1897 discovery of the electron, Einstein's 1905 hypothesis on the photon, and Millikan's 1918 reluctant experimental validation of Einstein's hypothesis. Einstein derived the photon hypothesis with a purely thermodynamic argument and used it to predict the frequency threshold in the photoelectric effect, which was not experimentally verified until the late 1910s.

The photoelectric effect provided, in this way, an experimental basis for quantum mechanics. This is undeniably a very significant contribution to the development of modern physics. The next scientific impact of the photoelectric effect – its practical use in spectroscopy – came almost 40 years later.

The reason for this long delay is the surface sensitivity of the photoelectric effect. In order to become a photoelectron, an electron in a solid must first absorb a photon to increase its energy above the photoelectric threshold. Since the threshold is of the order of several electronvolts, the photon must be in the X-ray or ultraviolet spectral range. Photons of this kind can penetrate quite deep in the solid before being absorbed. On the other hand, excited electrons can travel only over a very short distance before losing energy.

As a consequence, photoelectrons originate only from a thin slab near the surface of the sample. They carry information on the electronic structure of that slab, which typically consists of a very few atomic planes. If the surface is contaminated, the information is spurious. A suitably clean solid surface can be obtained by several different methods such as cleaving, scraping, and *in situ* growth. However, most clean surfaces do not stay clean unless under ultrahigh vacuum (pressure $< 10^{-9}$ Pa). This level of vacuum could not be routinely achieved before the 1960s, and this explains the long delay in the use of the photoelectric effect in spectroscopy.

After solving the vacuum and contamination problems, photoemission spectroscopy initiated a steady growth. This expansion was accelerated in the late 1960s by the advent of synchrotron radiation sources. With their help, photoemission became the premier tool for probing the electronic structure of solids and condensed systems in general.

The Information Content of Angle-Resolved Photoemission

The basic photoemission spectroscopy experiment adopts the following strategy (**Figure 1**): photons of a specific energy $h\nu$ are used to bombard the ultraclean surface of the solid under investigation and to extract photoelectrons. The photoelectrons are collected and their flux per unit time is analyzed as a function of the kinetic energy. This approach can be used to

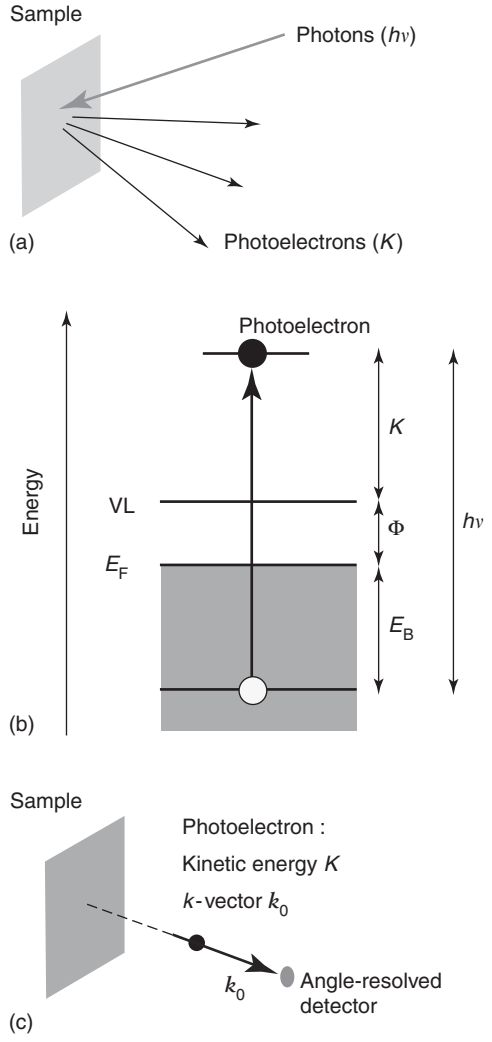

Figure 1 (a) The photoelectric effect is the foundation of photoemission spectroscopy. (b) The kinetic energy K of a photoelectron is determined by the photon energy $h\nu$, by the work function Φ, and by the initial energy of the electron in the solid or binding energy E_B; VL is the vacuum level; and E_F is the Fermi level. (c) In angle-resolved photoemission, photoelectrons are collected selecting their direction of emission. This determines not only the energy of the photoelectron but also its k-vector k_0.

study both core electrons and valence electrons: here, the analysis is limited to valence electrons. Nowadays, most photoemission experiments on valence electrons are performed by selecting the direction of emission of the collected photoelectrons. This technique is often called angle-resolved photoelectron spectroscopy (ARPES).

Figure 1a shows the essential points as far as the energy analysis is concerned in the case of a metallic solid. The zero of the photoelectron kinetic energy is called the "vacuum level" (VL). The distance between VL and the Fermi level (E_F) is the "work function," Φ. The kinetic energy K of a photoelectron is given by Einstein's equation:

$$K = h\nu - E_B - \Phi \qquad [1]$$

where E_B, the energy distance between the energy of the electron in the solid and E_F, is called the "binding energy." Equation [1] shows that by measuring K and knowing Φ and $h\nu$, the initial energy of the electron in the solid E_B can be derived.

Although this is a very valuable piece of information, the state of the electron in the solid is not completely defined by its energy. In the standard theoretical framework of solid-state physics, the state $|\boldsymbol{k}\rangle$ for a crystalline solid is defined by the crystal momentum vector $\boldsymbol{k}$, according to the Bloch theorem. The real objective of angle-resolved photoemission is thus to obtain information on $\boldsymbol{k}$.

Angle-resolved photoemission (**Figure 1b**) measures the k-vector, $\boldsymbol{k}_0$, of the free photoelectron outside the solid. In fact, $|\boldsymbol{k}_0| = (2m_0K)^{1/2}/h$, and the direction of $\boldsymbol{k}_0$ is equivalent to that of the free photoelectron. The problem, therefore, is to derive $\boldsymbol{k}$ from $\boldsymbol{k}_0$.

This is not a trivial task since many factors can influence the relation between the two vectors. In particular, the passage from the solid to vacuum changes the vector component perpendicular to the surface. Several clever schemes were developed to solve this problem.

The situation is much simpler when the system under investigation has a two-dimensional (or one-dimensional) character, for example, it is a low-dimensional crystal or a crystal surface. In that case, only the parallel component of $\boldsymbol{k}$ matters, which is in most cases equal to the measured parallel component of $\boldsymbol{k}_0$.

Angle-resolved photoemission experiments can thus experimentally probe the $E_B(\boldsymbol{k})$ function in different directions. The $E_B(\boldsymbol{k})$ function is equivalent to the so-called "band structure" of crystalline solids; therefore, the technique is known as "band mapping."

Figure 2 shows an example of band mapping, including the raw photoemission data and the corresponding plot of the $E_B(\boldsymbol{k})$ curve. It should be noted that the raw photoemission results are often plotted, not as the collected photoemission intensity versus the energy E_B, but in the form of momentum distribution curves (MDCs), that is, plots of the photoemission intensity for constant E_B as a function of the direction of the photoelectron (which coincides with the direction of $\boldsymbol{k}$). In many cases, in fact, extracting $E_B(\boldsymbol{k})$ curves is easier when the data are plotted as MDCs.

In some cases, photoelectrons are detected without selecting a specific direction and mixing together a

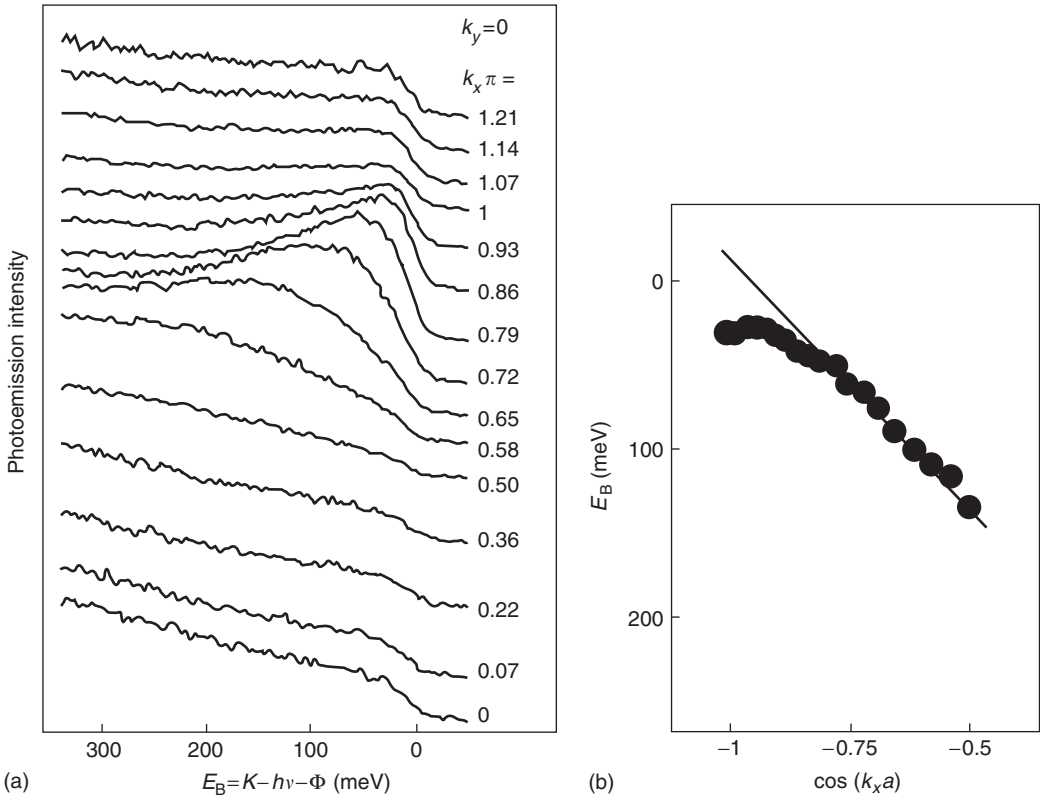

Figure 2 An example of the band-mapping technique (unpublished data from Abrecht M, Ariosa D, Cloëtta D, Margaritondo G, and Pavuna D). (a) Raw angle-resolved photoelectron energy distribution curves for an optimally doped ($x = 0.15$) strained crystalline film of LSCO ($La_{2-x}Sr_xCuO_{4-\delta}$); the different curves correspond to different *k*-vector directions along the Γ–X line. Note the dispersing feature in the low-E_B region. (b) Plot of the position of the dispersing feature, illustrating part of the "band structure" of the system.

broad range of directions. This is required when the signal level is too low and is done using angle-averaging electron energy analyzers. Furthermore, angular scrambling automatically occurs for polycrystalline samples and, to some extent, for sample surfaces cleaned by scraping.

In all these cases, plots of the photoelectron distribution in energy (energy distribution curves (EDCs)) tend to reproduce the electron "density of states." The information content is, of course, reduced with respect to that of angle-resolved photoemission.

Techniques Based on Synchrotron Sources

Several different parameters in addition to the photoelectron energy and direction can be controlled during a valence-electron photoemission experiment, simplifying the extraction of information from the data. These parameters include the photon energy, polarization and direction of incidence, as well as the photoelectron spin polarization. In most cases, the practical control of such parameters requires using a synchrotron photon source.

The superior flux and brightness of a synchrotron source enhances the signal level, facilitating all types of photoemission experiments. This is particularly important in techniques with chronically low signal levels such as spin-polarized photoemission, as discussed later.

Furthermore, synchrotron sources provide polarized photons and photons with tunable photon energy in the X-ray and ultraviolet range required for photoemission. The first feature is directly exploited to probe the symmetry of the valence electronic states.

The theoretical background of this approach is quite simple. The emission of photoelectrons requires an excitation process triggered by the photon absorption. For a given initial electronic state, the excitation may or may not be allowed depending on the symmetry of the initial and final electron state as well as on the polarization (and on the propagation direction) of the photon. By carefully analyzing the

photon polarization dependence of photoemission data, the symmetry of the initial state of the electron in the solid can thus be identified.

The final state of the photoemission process is the state of the photoelectron in vacuum. The photoemission data analysis, however, can be simplified by conceptually decomposing the photoemission process into different steps, including the optical excitation of the initial-state electron to a high-energy state in the solid. This makes the analysis of polarization effects equivalent to that of (ultraviolet or X-ray) optical absorption spectra. **Figure 3** shows an early example of this simple and powerful way to exploit polarization effects.

Interesting photoemission experiments are also performed using the circular polarization of specialized synchrotron sources, such as the "helical wigglers." These experiments provide very valuable information, notably about magnetic systems.

With the same type of analysis, one can understand the dependence of the photoemission process on the photon energy. The emission of photoelectrons depends on the optical excitation probability and, therefore, on the corresponding matrix element. The matrix element depends both on the initial state and on the final state of the excitation. When studying a given initial state with energy E_B, different photon energies correspond to different final states and, therefore, to different matrix element values. These "matrix element effects" can significantly alter the photoemission spectra, producing in some cases spurious and misleading results.

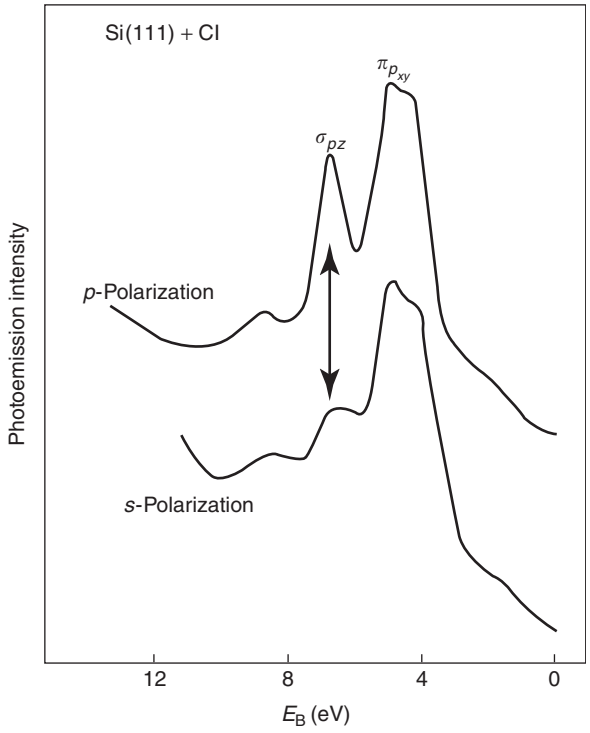

Figure 3 Photon polarization effects in the (angle-integrated) photoemission spectra of a cleaved Si(1 1 1) surface covered by chemisorbed chlorine. Note the strong decrease of the feature at $E_B = 6$–7 eV as the photon polarization changes from *p* to *s*. By analyzing the data in terms of the optical excitation induced by the photon absorption, the symmetry of the initial electronic state corresponding to this feature was identified as σ_{pz}. (Source: Schluter M, Rowe JE, Margaritondo G, Ho KM, and Cohen ML (1976) *Physics Review Letters* 37: 1632–1635.)

As a general rule, at high final-state energies, the final states are free-electron-like and the matrix element effects become negligible. In general, however, valence-electron photoemission studies are conducted with rather low photon energies (15–30 eV) and are not automatically immune from matrix element effects. The use of low $h\nu$'s is, in fact, preferable since the transition probability tends to increase for valence electrons, leading to higher signal levels. Furthermore, for a constant resolving power $h\nu/\Delta h\nu$, the absolute photon energy resolution $\Delta h\nu$ becomes better for smaller $h\nu$'s.

The best way to identify matrix element effects and to avoid mistakes in the data interpretation is to take photoemission spectra at several different photon energies and to compare the results. This procedure requires, of course, a photon source with tunable photon energy, that is, a synchrotron source. Among the suitable types of synchrotron sources, bending magnets emit a broadband of $h\nu$'s from which the desired value can be filtered with a monochromator. An undulator source automatically provides a narrow band of photon energies centered at a tunable value; however, further monochromatization is almost always required for photoemission experiments.

The possibility of controlling the photon energy offered by synchrotron sources opens up many experimental opportunities besides the identification of matrix element effects. Consider, for example, the surface sensitivity of photoemission experiments. It is seen that photoelectrons are only emitted from a thin slab near the sample surface. The thickness of this slab, called "escape depth," changes with the photoelectron kinetic energy K (see **Figure 4**), which in turn depends (eqn [1]) on the photon energy.

Therefore, by changing the photon energy, the surface sensitivity, as required for each experiment, can be increased or decreased. Roughly speaking, experiments with K-values higher than 100 eV or lower than 50 eV tend to be less surface-sensitive than experiments with K values ranging between 50 and 100 eV.

The photon energy tunability is also helpful in identifying the character of each detected initial electronic state. Matrix element effects can, in fact, be

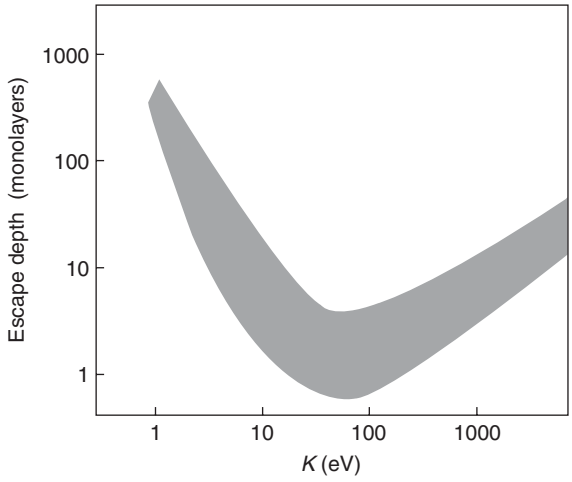

Figure 4 The escape depth of photoelectrons plotted as a function of the kinetic energy is slightly different from material to material. For all samples, however, the data fall in the shaded area and exhibit a minimum (corresponding to the maximum surface sensitivity of photoemission experiments) at $K = 50$–$100\,\text{eV}$.

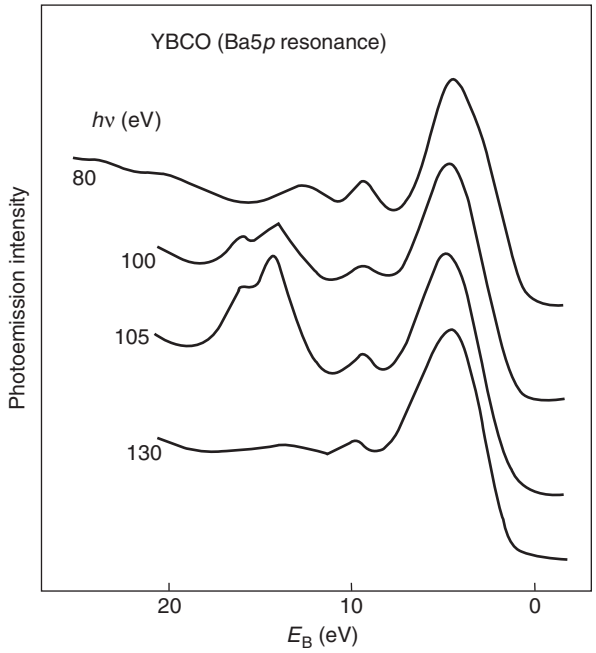

Figure 5 Photoemission spectra for the YBCO high-temperature superconductor reveal a resonating feature at $E_B = 14$–$18\,\text{eV}$ when the photon energy is near the Ba5*p* absorption edge. This photoemission resonance immediately identifies the feature as due to Ba-related states. (Source: Onellion M, Chang Y, Niles DW, Joynt R, Margaritondo G, Stoffel NG, and Tarascon JM (1987) *Physics Review* B36: 819.)

exploited for "labeling" the initial state. This is a rather difficult task except in the case of "photoemission resonances."

Several phenomena can produce very rapid and strong variations of the intensity of certain photoemission features. A resonance typically occurs for photon energies near a core-level X-ray absorption threshold of a given element and affects valence states related to the same element. Therefore, a resonating photoemission feature can be immediately attributed to the concerned element. **Figure 5** shows an example of this powerful approach.

The tunability of synchrotron sources is also exploited in specialized photoemission techniques in which the photon energy is continuously scanned rather than kept constant. One should note, in particular, the constant initial state (CIS) technique, in which both $h\nu$ and the kinetic energy K of the photoelectron are scanned while keeping their difference constant. According to eqn [1], this implies that $E_B = h\nu - K - \Phi$ stays constant; therefore, the photoemission intensity reflects the properties of the final states of the excitation more than those of the initial state of constant energy. This technique can thus be used to explore empty valence states.

Techniques Requiring High-Brightness Synchrotron Sources or Ultraviolet Lasers

The importance of the very high flux and brightness of synchrotron sources for the implementation of techniques with intrinsically low signal levels has already been mentioned. Consider, for example, the difficulties in achieving high lateral resolution in a photoemission experiment. In general, the photoelectron detector must collect the signal from a rather large sample area in order to reach a reasonable signal level. This implies that the investigated electronic structure is averaged over the same area. In the case of nonhomogeneous samples, the averaging could lead to misleading results.

High lateral resolution is often desirable, moving from "photoemission spectroscopy" to "photoemission spectromicroscopy." The corresponding decrease in signal level, however, must be avoided by using a high-brightness synchrotron source, such as an undulator.

The same requirement is present for time-resolved photoemission. In a standard photoemission experiment, the signal must be accumulated over a certain period of time to reach an acceptable signal-to-noise ratio. This is of the order of several seconds per data point and of several minutes per spectrum, making it impossible to study time-dependent phenomena faster.

The great interest of such phenomena triggered a substantial effort – based on high-brightness sources – to decrease the data-taking time. The most spectacular results are achieved with short laser pulses,

either alone or in conjunction with synchrotron sources. The required photon energies for photoemission are obtained by multiplying the photon energy of low-$h\nu$ ultrashort laser pulses with nonlinear optical devices.

Such frequency-multiplied pulses can be used to excite photoelectrons directly. Another possible approach, called "two-photon photoemission," consists of using a low-$h\nu$ laser pulse to bring valence electrons into an excited state and then to use a synchrotron pulse to extract them as photoelectrons, as shown in **Figure 6**. This approach is used to study the dynamic properties of excited states.

Techniques in this class can reach the picosecond or subpicosecond time range. Their impact is likely to be enhanced by the ongoing development of ultrabright-pulsed ultraviolet lasers based on the self-amplified spontaneous emission (SASE) mechanism.

Spin-polarized photoemission is another valence-electron technique that is chronically affected by low signal levels. Experiments discriminating the spin polarization of the photoelectrons require special detectors with typically limited effectiveness. These difficulties notwithstanding, spin-polarized photoemission has evolved to become one of the most important subfields in this domain, providing extremely valuable information, for example, on the valence states of magnetic systems.

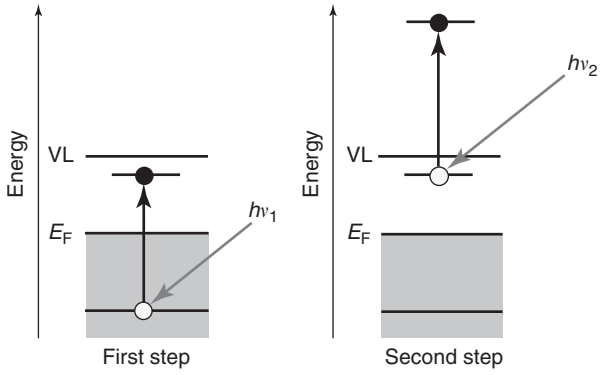

Figure 6 Schematic illustration of a two-step photoemission process involving a low-$h\nu$ laser photon ($h\nu_1$) bringing a valence electron into an excited state and a synchrotron photon ($h\nu_2$) to extract it as a photoelectron.

Valence Photoemission of Correlated Systems

The discovery of high-temperature superconductors and many subsequent experimental and theoretical

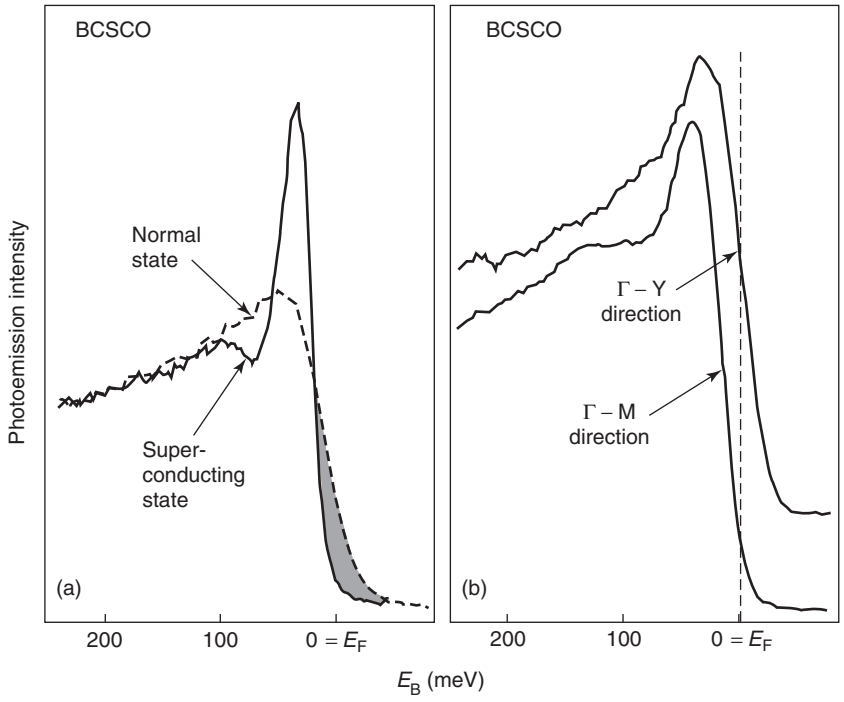

Figure 7 (a) High-resolution photoemission spectra taken on the high-temperature superconductor BCSCO at temperatures corresponding to the normal and superconducting state reveal the opening of the superconducting gap (shaded area). (Source: Hwu Y, Lozzi L, Marsi M, La Rosa S, Winokur M, Davis P, Onellion M, Berger H, Gozzo F, Lévy F, and Margaritondo G (1991) *Physics Review Letters* 67: 2573.) (b) Superconducting-state spectra taken for the same compound along different crystallographic directions reveal the anisotropy of the superconducting gap. (Source: Kelley RJ, Ma J, Quitmann C, Margaritondo G, and Onellion M (1994) *Physics Review* B50: 590.)

results increased the need of experimental probes to study electron correlation. Photoemission was able to play an important role, thanks to a substantial increase in its energy resolution levels.

Roughly speaking, phenomena related to the formation of chemical bonds affect valence electrons within 10–20 eV of the Fermi level. Except in specialized cases, their study with photoemission techniques does not require an energy resolution better than ≈ 100 meV. On the other hand, correlation phenomena occur on a smaller energy scale. A typical example is provided by the superconducting gap, which even for high-temperature superconductors does not exceed a few tens of meV. The study of such phenomena requires energy resolutions better than 50 meV, and in some cases ~ 1–2 meV.

Experimental systems capable of achieving these performances have been developed and are used to explore superconductors as well as other correlated systems. **Figure 7a** shows a typical example of these experiments: the opening of the superconducting gap during the corresponding phase transition in the high-temperature superconductor bismuth strontium copper oxide (BCSCO).

Note the high-energy edge in the normal-state spectrum, corresponding to the Fermi level. In the superconducting state, the edge recedes revealing the opening of the superconducting gap. Furthermore, the spectrum exhibits other interesting features (e.g., the strong quasiparticle peak immediately after the gap and the subsequent "dip") that have generated much debate.

Figure 7b shows an example of the valuable information that can be extracted with this approach. Superconducting-state spectra taken along different directions reveal different values of the gap, ruling out theoretical models that predict isotropy.

Correlated systems can exhibit rather "exotic" phenomena departing from the standard framework of solid-state physics. The theoretical background of almost all phenomena in solid state is provided by Landau's Fermi liquid, in which the free electrons of a Fermi gas are replaced by dressed quasiparticles with electron-like properties. The soundness of this theoretical background is evident in most photoemission results: for example, the spectrum of metallic samples (**Figure 8**) typically exhibits a Fermi-level cutoff reflecting the Fermi–Dirac distribution.

High-resolution photoemission experiments on low-dimensional systems sometime reveal phenomena departing from the Fermi-liquid framework. **Figure 8**, for example, also shows photoemission spectra of one-dimensional metallic systems that do not exhibit the Fermi-edge cutoff.

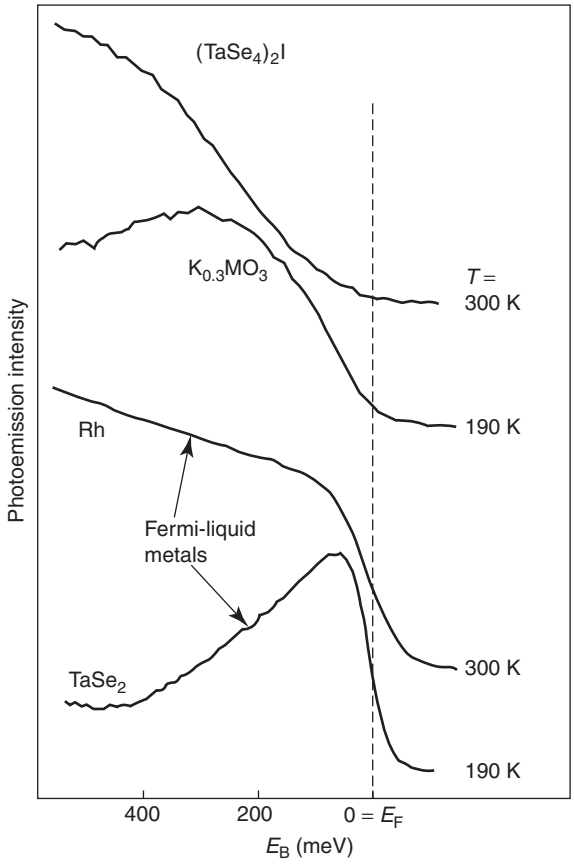

Figure 8 Bottom: photoemission spectra of three-dimensional and two-dimensional metals exhibit a clear edge at the Fermi level, as predicted for Fermi liquids. Top: one-dimensional metals often depart from this framework. (Source: Perfetti L (2002) Ph.D. thesis, EPFL: Lausanne.)

Experiments in this subdomain are trying to validate other possible theoretical frameworks to replace the Fermi liquid in highly correlated low-dimensional systems, such as the "Luttinger liquid." In extreme cases, such frameworks could lead to exotic phenomena, such as the replacement of holes as elementary excitations by spin-carrying spinons and charge-carrying holons. The validation of these theoretical hypotheses is an ambitious objective of high-resolution valence photoemission.

Correlation affects not only the initial state of the photoemission process but, in fact, the entire phenomenon also. The simplest approach to analyze photoemission spectra considers the electrons (or the Fermi-liquid quasiparticles) as a gas of independent particles. The emitted photoelectron is thus treated as an isolated entity. This is not really correct, in particular for correlated systems, and the photoemission process should be rigorously treated as the transition from a many-body correlated state to another many-body state plus a free electron. This, of course, complicates the treatment, but also enhances the

quality and quantity of information that can be extracted from the photoelectric effect.

van der Waals Bonding and Inert Gases

J S Rutherford, National University of Science & Technology, Bulawayo, Zimbabwe

Introduction

By van der Waals forces, one means those weak bonding interactions which occur between neutral, closed-shell atoms or molecules, and are not characterized by the contact of specific atomic groupings within these molecules, as is the case with hydrogen bonding and donor–acceptor complexation. They are called van der Waals forces because of their relation to the van der Waals equation of state for a fluid phase:

$$\left(p + \frac{a}{V^2}\right)(V - b) = nRT$$

which was the first successful attempt to model the behavior of real gases, by introducing corrections to the ideal gas law to take into account both the attractive forces between molecules (which are assumed to reduce the effective pressure by an amount a/V^2) and the finite molecular volumes, through the excluded volume b.

The van der Waals equation can be made identical for all species by choosing reduced variables based on the critical constants of the substance:

$$p_r = \frac{8T_r}{3V_r - 1} - \frac{3}{V_r^2}$$

Here $p_r = p/p_c$, where p_c is the critical pressure, and V_r and T_r are similarly defined. This result suggests that the behavior of any fluid should follow a law of corresponding states, that is, it should be identical for all species when treated in terms of the reduced variables. This law is found to be a good approximation experimentally. This observation, however, does not give specific support to the van der Waals equation, since any similar two-parameter equation would also conform to the law of corresponding states, albeit with different numerical results.

Nature of van der Waals Forces

van der Waals forces may be classified into three types: electrostatic, induction, and dispersion. Most textbooks only mention the most important interaction in each class, that is, the dipole–dipole, dipole-induced dipole, and London dispersion contributions, as these are always significant when they occur. Nevertheless, and particularly where the absence of a permanent molecular dipole arises through cancellation, by symmetry, of strong bond dipole moments, the effects of the higher electrostatic moments can make major contributions. Examples of such molecules are linear CO_2 (quadrupole) and tetrahedral CF_4 (octopole).

The energies of these main interactions at a distance r are given by the following formulas, where μ is the permanent molecular dipole moment, α_1 and α_2 are the polarizabilities of the two species a and b, I_1 and

l_2 their ionization potentials, and ε is the permittivity of vacuum:
Dipole–dipole (fixed):

$$-\frac{\mu^2}{4\pi\varepsilon_0 r^3}(2\cos\theta_a\cos\theta_b - \sin\theta_a\sin\theta_b\cos\varphi)$$

Here, θ_a and θ_b are the angles the dipoles make with the vector r, and ϕ is the angle between their projections along r.
Dipole–dipole (free) (Keesom energy):

$$-\frac{2\mu^2}{(4\pi\varepsilon_0)^2 k_B T r^6}$$

Dipole-induced dipole (Debye):

$$-\frac{\mu^2\alpha}{(4\pi\varepsilon_0)^2 r^6}$$

Dispersion (London):

$$-\frac{3\alpha_1\alpha_2 I_1 I_2}{2(I_1+I_2)(4\pi\varepsilon_0)^2 r^6}$$

Potential Energy Functions

The basic features of a bonding interatomic potential $U(r)$ are: (1) $U(r)$ is a maximum when the internuclear separation $r=0$, (2) $U(r)\to 0$ as $r\to\infty$, and (3) for some intermediate equilibrium separation r_e, U has a minimum $U(r_e)=\varepsilon$, where ε is the binding energy. For these requirements to be satisfied by a model potential function, the function must include at least two components, one a repulsive interaction which dominates when $r<r_e$, and the other an attractive interaction dominant when $r>r_e$. This in turn means that, except for the simplest model of all, the hard-sphere potential which corresponds to van der Waals original model, the potential function must consist of at least two terms with opposite signs.

The hard-sphere potential is exceptional, in that it employs a discontinuous function

$$U(r) = \infty, \qquad r<r_e$$
$$U(r) = -C_6/r^6, \quad r\geqslant r_e$$

Typically, continuous interatomic potentials have been developed from the Mie function

$$U(r) = -C_n/r^n + C_m/r^m$$

with n and m positive, and usually integers. This function has the necessary form provided $n>m$.

In the case of van der Waals forces, the attractive term may be assumed, as a first approximation, to vary as r^{-6}, in which case the resulting potential function is the Lennard–Jones (n, 6)-potential. The repulsive part of the potential is common to all types of bonding, mainly being due to the mutual repulsion of overlapping closed-shell electron clouds at shorter distances, but its effective n is not easy to estimate. In the case of the Born–Lande (i.e., simple Mie type) potential for ionic interactions, where $m=1$, n is commonly taken to be ~ 10; the results are not very sensitive to its precise value. Historically, the van der Waals interaction has commonly been treated using the Lennard–Jones (12,6)-potential

$$U(r) = -C_6/r^6 + C_{12}/r^{12}$$

alternatively written as

$$U(r) = 4\varepsilon\left\{\left(\frac{\sigma}{r}\right)^{-6} - \left(\frac{\sigma}{r}\right)^{-12}\right\}$$

where ε is the binding energy and σ the value of r (other than infinity) where $U(r)$ is zero. The popularity of the (12, 6)-potential is partly due to its mathematical simplicity, for, if one substitutes $x=(\sigma/r)^{-6}$, then

$$U(r) = 4\varepsilon(x - x^2)$$

and, for example, can readily show that $r_e = 2^{1/6}\,\sigma$.

Dipole–dipole interactions in fluid phases are readily included in the Lennard–Jones potential, since when averaged it behaves as r^{-6}; however, in solids the fixed orientations of the dipole moments require to be handled explicitly. The result is the Stockmayer potential

$$U(r,\theta_a,\theta_b,\phi) = 4\varepsilon\left\{\left(\frac{\sigma}{r}\right)^{-6} - \left(\frac{\sigma}{r}\right)^{-12}\right\} - \frac{\mu^2}{4\pi\varepsilon_0 r^3} \times (2\cos\theta_a\cos\theta_b - \sin\theta_a\sin\theta_b\cos\varphi)$$

where the angular coordinates are the same as before.

The repulsive term used in the Lennard–Jones potential is unsuitable for accurate work. First of all, because of the weak nature of the van der Waals attractive forces, the relative magnitude of the repulsive interactions at the equilibrium distance is much greater than for other types of bonding. For the (12, 6)-potential, the repulsive contribution calculates to be as large as the net binding energy, compared to only $\sim 10\%$ for the Born–Lande potential. In addition, typically 99% of an atom's electron density is contained within its van der Waals radius, and so the overlap interaction involves electronic

wave functions in their region of exponential decay toward infinite r. Hence, the repulsive contribution can be improved by replacing the r^{-n} term by an exponential, creating the (exp, 6)-potential

$$U(r) = A \exp(-Br) - C_6/r^6$$

where A and B are arbitrary fitted constants.

Potential functions such as the Lennard–Jones potential that have two adjustable parameters can be fitted to the experimental parameters r_e and ε, and are consistent with the law of corresponding states. However, if additional parameters, such as the three required by the (exp, 6)- potential are introduced, the law of corresponding states can only be satisfied if the potential functions for the various species are conformal, that is, the terms are constrained such that the potential curves have the same shape function in units of r_e and ε. Where the actual potential function can be mapped very accurately by experiment, an even more complicated theoretical form may be needed to fit it. Such is the case for the pure pairwise interactions of inert gas atoms, where Rydberg–Klein–Rees analysis may be applied to derive the form of the potential from vibrational or rotational–vibrational spectroscopic measurements on the corresponding van der Waals dimer molecules.

Such functions are useful in calculating atom–atom pair potentials for small and medium-sized molecules. However, accurate lattice energy calculations cannot ignore interactions that are not pairwise additive, although in this regard it is usually considered to be sufficient to include the Axilrod–Teller three-center term

$$\nu_{ABC} = \frac{(3 \cos \theta_a \cos \theta_b \cos \theta_c + 1)}{(r_{AB} r_{BC} r_{AC})^3}$$

where θ_a is the angle between r_{AB} and r_{AC}, etc.

van der Waals Radii

van der Waals radii can be defined in the same way as covalent, ionic, and metallic radii are for interactions. Since it is normally possible to find cases where atoms of the same element in adjacent molecules are in contact, the van der Waals radii can be defined as

$$r_A = R_{AA}/2$$

and, since the repulsive part of the interatomic potential becomes dominant at essentially the same distance for any element A regardless of the element B with which it is in contact, the van der Waals radii are effectively additive in the sense

$$R_{AB} = r_A + r_B$$

Table 1 gives a number of values.

However, such values have to be treated with caution on two accounts. The first is that the minimum energy structure of a condensed phase of a complex molecular species is determined by the large number of (mainly) pairwise interactions between its constituent atoms in contact, which may require, given the relative internal rigidity of the molecules, some of these interactions not to be at their individual equilibrium distances. Because the potential well is so shallow, an individual contact can vary considerably from the predicted minimum with little energy change.

The second effect is the variation of the van der Waals radius with angle relative to an internal covalent bond. A particularly well-studied example is that of Cl–Cl interactions in crystals of both the element itself and many organochlorine compounds.

Phases and Phase Equilibria

The presence of van der Waals attractive forces for a molecular species leads to the stabilization of condensed phases at lower temperatures. However, the fact that the potential energy wells are wide and shallow, is reflected in a number of their physical properties. The low cohesive energies correspond to low melting points and boiling points, and the slow variations in pair potential with distance near the minimum result in large compressibilities and thermal expansivities.

As far as the boiling point is concerned, it is possible to make this correlation quantitative. The constants in the van der Waals equation can be related to hard sphere intermolecular potential as

$$a = 4\pi c/3d^3 \quad \text{and} \quad b = 2\pi d^3/3$$

where the attractive potential at $r > d$, the collision diameter, is given by $-C/r^6$.

Thermodynamic arguments provide an approximate value for the self-cohesive energy of a liquid at its boiling point T_b of $\sim 7RT_b$, assuming the ratio of the molar volumes V_g/V_l of the two fluid phases is $\sim 10^3$. When the work term $p\Delta V$ and the translational energy of the gas is added to this value, the enthalpy of vaporization of the liquid at the boiling point becomes roughly $9.5\,RT_b$, in line with Trouton's empirical rule. Thus, the boiling point of the liquid can be directly related to its cohesive self-energy.

Unlike the gas/liquid case, a solid and fluid in equilibrium comprise a system in which the two phases present differ in symmetry properties. The fluid is spatially homogeneous and rotationally isotropic, while the solid normally conforms, at least in ideality, to one of the space symmetry groups.

Some other properties depend on the fact that the van der Waals forces are virtually nondirectional except when fixed-orientation dipole–dipole interactions are involved. For even a small molecule, the overall energy of the system is principally determined by the net effect of a large number of these pairwise interactions at or near their minimum energy distance, and so the total volume of a particular model configuration which has been stabilized in terms of the elimination of residual forces, is a fair estimate of its relative energy. In other words, if one treats the molecules as having hard van der Waals surfaces, arrangements with similar packing fractions are likely to have similar total van der Waals energies. This tendency manifests itself in the frequent occurrence of polymorphism for molecular crystals.

An allied phenomenon is the existence of mesophases, phases intermediate in order between solids and liquids, for a number of molecular compounds. Such phases, having both enthalpy and entropy higher than the regular solid but lower than the liquid, may be stable at intermediate temperatures, and include plastic crystals and liquid crystal phases of various types.

Liquid Structure

Models of the structure of liquids are of two types. In one approach, first introduced by Bernal, a randomly packed aggregate of identical objects (ball bearings, plasticine spheres, etc.) is analyzed in terms of the distribution of nearest neighbors in number and distance. The definition of nearest neighbors here depends on the presence of a shared face of their space-filling Voronoi polyhedra. Such models typically show an average coordination number of about 13, compared to 12 for a regular close-packed array of equal spheres.

The other approach to modeling such liquids is by computer simulation. Either the Monte Carlo technique or molecular dynamics may be used. In either method, a number of molecules are given starting positions within a hypothetical volume of the bulk liquid in the form of a cube, and the density is maintained constant by imposing periodic boundary conditions. In the Monte Carlo technique, the coordinates are randomly adjusted one at a time, in such a way as to produce a series of configurations of individual energy per molecule U_N, consistent with the Boltzmann distribution $\exp(-U_N/kT)$.

In a molecular dynamics simulation, the molecules move simultaneously, each under the net force arising from the pair potentials with its neighbors, according to Newton's laws

$$m\frac{\mathrm{d}^2R}{\mathrm{d}t^2} = -\sum_{j\neq i}\frac{\partial}{\partial R_{ij}}U(R_{ij})$$

and the subsequent position and motion of the molecules is recorded over a series of very short time intervals.

Both types of simulation serve to provide estimates of thermodynamic quantities such as configurational energy and heat capacity, while the structure of any type of model may be compared to the experimental radial distribution function derived from diffraction experiments. For a monatomic species, the radial distribution function is

$$N(r) = 4\pi r^2 g(r) N/V \, \mathrm{d}r$$

where $g(r) = 1$ corresponds to a completely uniform distribution. In liquids, $n(r)$ is zero when r is less than the minimum contact distance, and fluctuates around the parabolic form corresponding to $g(r) = 1$, as shown in **Figure 1** for argon.

Structures of van der Waals Solids

Only recently there have been serious attempts to predict the crystal structures of other than the simplest molecules. The close-packed structures of the inert gases can be derived as having the maximum packing fraction for hard spheres, and other ideal

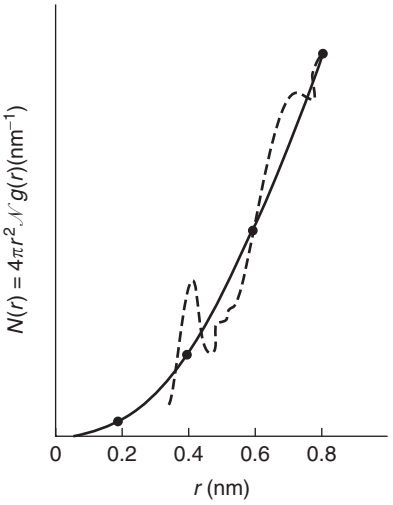

Figure 1 Radial distribution function for liquid argon. Solid line: random distribution $g(r) = 1$. Dashed line: observed distribution. (Prepared by Ladd MFC (1994) *Chemical Bonding in Solids and Fluids*. Chichester: Ellis Horwood.)

geometric forms, such as rods or disks, can be treated similarly, but for the general molecule, even assuming it has a rigid conformation and a hard van der Waals surface, it is very difficult to establish a global minimum in the lattice energy. However, the experimental frequency of occurrence of the individual space group types was interpreted by Kitaigoroskii as a preference for those symmetry operations containing a translational component (i.e., screw axes and glide planes) operations that allow the bumps of one molecular surface to be fitted into the hollows of its neighbors, and so increase the packing fraction. Arrangements of molecules in such preferred space groups are often the starting point for structure prediction using an overall minimization of the lattice energy.

Molecular Crystals of the Elements

As might be expected, the crystal structures of the solid inert gases have much in common with those of the elemental metals, despite the different cohesive forces, since both are based on the effective packing of spheres. All the inert gases have a cubic close-packed phase, while He and Ne show hexagonal close-packed structures. Helium becomes body-centered near its melting point.

Of the diatomic elements, hydrogen and nitrogen are closest to spherical, and show cubic and hexagonal close-packed phases, either in a distorted form or with freely rotating molecules. Oxygen and fluorine have similar monoclinic low- and cubic high-temperature phases, while the remaining halogens have the same layer herringbone-crystal arrangement typified by Cl_2 (s).

The other molecular elements (P_4, S_8, Se_8, etc.) have low-symmetry structures based on the packing of irregular molecules.

Vapor Transport Processing: Mechanisms

D Gall, Rensselaer Polytechnic Institute, Troy, NY, USA

Introduction

The deposition of materials from the vapor phase has become a major processing technique that is essential for nearly all of today's high-technology industries. Atoms or molecules are deposited onto surfaces to form coatings or thin films ranging in thickness from one atomic layer ($\sim$0.3 nm) to hundreds of micrometers. In many applications, the coating is applied in order to alter the physical properties of the underlying bulk material, while in other cases the entire functionality of a material or device is performed by the deposited layer(s) with the bulk material simply providing mechanical support. Examples of the former include hard wear-resistant lubricious coatings on bearings and cutting tools, optical reflective and antireflective coatings on windows and lenses, thermal barrier coatings in gas-turbines, biocompatible layers for implants, decorative coatings on consumer products, barrier layers to protect against diffusion, oxidation, corrosion, and ultraviolet radiation in food packaging, automotive applications, and on various polymeric or metallic components. Examples where the primary functionality is achieved by the deposited layers themselves include integrated microelectronic devices, micro-electromechanical devices, magnetic memory disks, optical waveguide circuitry, and solid-state lasers and lighting. Such complex devices are achieved by depositing multiple layers from the vapor phase and lithographic patterning in the plane of the films, yielding a vast variety of engineered three-dimensional (3D) structures.

This article introduces the key processes that occur during thin film deposition from the vapor phase and gives an overview of the most commonly used techniques. The deposition process includes a source which provides atoms or molecules in vapor phase, the transport of the depositing species from the source to the substrate, and the actual deposition process at the substrate and growing layer.

Process Steps: Source, Transport, and Deposition

Deposition techniques are commonly referred to as physical vapor deposition (PVD) and chemical vapor deposition (CVD) based on the phase of the material at the source. In the case of PVD, solid materials are vaporized by heating them at the source using electrical heating, electron beams (e-beam evaporation), or lasers (pulsed laser deposition (PLD)). An alternative to heating the solid source material is the use of energetic ions which knock out atoms into the vapor phase by an atomic momentum transfer, which is referred to as sputtering. In CVD, the source material is a gas, an evaporated liquid, or a solid that is chemically converted to a vapor, such as the conversion from Ga (solid) to GaCl (vapor).

The second step during the deposition process is the transport of the depositing species in the vapor phase from the source to the substrate. This process is strongly influenced by the pressure at which the process is operated since the mean free path λ_{mfp} of a molecule in a gas is inversely proportional to the pressure p. At room temperature and atmospheric pressure, λ_{mfp} is $\sim$100 nm. It increases as the pressure decreases according to

$$\lambda_{mfp} = 10^{-2}/p \qquad [1]$$

Here, the units p and λ_{mfp} are Pa and m, respectively. Thus, at pressures below 10^{-2} Pa ($1\,\text{Pa} = 7.5\times 10^{-3}\,\text{Torr} = 10^{-5}\,\text{atm}$), the molecules travel more than 1 m, which typically corresponds to a direct path from chamber wall to chamber wall. The vapor transport is characterized by the Knudsen number Kn defined by

$$Kn = \lambda_{mfp}/L \qquad [2]$$

where L is the characteristic length scale, for example, the source–substrate distance or a pipe diameter through which vapor is flowing. The transport is then divided into

$$\text{molecular flow} \quad Kn > 1 \qquad [3a]$$

$$\text{intermediate flow} \quad 1 > Kn > 0.01 \qquad [3b]$$

$$\text{viscous flow} \quad Kn < 0.01 \qquad [3c]$$

Evaporation is typically done at low pressures, below $\sim 10^{-2}$ Pa, that is, $Kn > 1$. Therefore, the atoms or molecules do not scatter with other species and move on a straight path from the source to the substrate. Under such high-vacuum conditions, the geometrical arrangement of source(s) and substrate are the primary factors influencing the deposition uniformity. In contrast, CVD is mostly done at pressures above $\sim$1 Pa ($Kn < 0.01$) where the molecules experience

many collisions and the transport is described by a viscous flow with vapor-phase diffusion and more complex gas flow patterns. A third category of processes, typically those which utilize plasmas, operate in the crossover intermediate range, where molecules experience several collisions during their travel from source to substrate but do not completely thermalize. There are exceptions to this categorization, for example, gas-source molecular beam epitaxy (GS-MBE), which is a CVD technique that operates at high-vacuum ($<10^{-2}$ Pa) pressures.

The third step in the deposition process is the actual deposition, that is, the processes that occur at the substrate and the growing layer surface, including adsorption, chemical reactions, surface diffusion, and the effect of energy input in various forms. The sticking coefficient S_c is defined as the probability of an impinging atom or molecule to react with the surface and become incorporated in the growing layer. S_c is nearly unity for many PVD processes where the vapor pressure of the deposited material at the substrate temperature is small compared to the deposition flux. In contrast, S_c is often much smaller (e.g., 10^{-3}) for CVD processes since, in this case, a chemical reaction needs to occur for the deposition molecule to chemically bond with the layer. An advantage of low S_c is the ability to coat complex surface morphologies uniformly, however, at the cost of a reduced deposition rate.

The energy input onto the surface affects both the surface chemistry and the atomic arrangement which, in turn, determines the composition and microstructure. The substrate temperature T_s is a parameter that is important for all deposition techniques. In many cases, multiple thermally activated processes, including surface chemical reactions and surface diffusion, occur simultaneously. Varying the temperature typically results in large changes in layer properties, since the rate R for these processes depends exponentially on T_s:

$$R \propto \exp(-E_a/kT_s) \qquad [4]$$

Here, k is the Boltzmann constant and E_a the activation energy for a given process.

In addition to thermal activation, there are various other energy sources that affect the layer growth during deposition. Many deposition techniques use plasmas that create energetic ions that impinge onto the substrate with energies ranging from ~ 1 to ~ 1000 eV. This energy is much higher than the thermal energy ($kT = 0.025$ eV at room temperature). Other energy sources are photons during photoassisted deposition (typically 1–3 eV), and chemical energy, carried in reactive molecules (typically 1–20 eV), which are common during CVD or reactive PVD.

Evaporation

Evaporation is a vapor deposition technique where the source material is heated so that it evaporates or sublimes. This is typically done in a high vacuum with a background pressure below 10^{-2} Pa, so that the evaporated atoms do not scatter on their path from the source to the substrate. The evaporation flux can be calculated using the vapor pressure p_v, which is defined as the pressure at which either a solid or a liquid is in equilibrium with the vapor (for a given temperature and element). The Clausius–Clapeyron equation provides the following expression for the temperature dependence of p_v:

$$p_v = p_0 \exp(-\Delta H_e/kT) \qquad [5]$$

where ΔH_e and p_0 are the heat of evaporation and a prefactor, respectively. **Figure 1** shows the vapor pressures for various elements as a function of temperature, indicating the validity of eqn [5] over a large temperature range, and above and below the melting points. At equilibrium, the flux from the condensed phase (solid or liquid) to vapor and the flux from the vapor to the condensed phase are equal. Consequently, the evaporation flux Φ_e is equal to the flux that a vapor exerts on a surface at a given temperature and pressure, which is obtained from the kinetic gas theory

$$\Phi_e = \frac{N_A}{(2\pi MRT)^{1/2}} p_v \text{ molecules cm}^{-2} \text{ s}^{-1} \qquad [6]$$

Here, N_A, M, and R are Avogadro's number, the molecular weight, and the gas constant, respectively.

The heating of the source for evaporation is typically done by resistive or electron-beam (e-beam) heating. For resistive heating, the source material is placed in direct contact with a tungsten filament, in a refractory metal sheet which has various shapes and openings, or in a ceramic crucible which is heated by a tungsten wire. The disadvantage of direct heating is that heaters and support materials are required to be at high temperatures, which causes contamination and limits the evaporation of high-melting-point materials. E-beam heating eliminates these disadvantages: electrons are emitted from a filament and accelerated onto the source material by a potential of several thousand volts. This yields a high temperature at the point where the e-beam impinges while the bulk part of the source material, which is contained in a water-cooled crucible, remains cold.

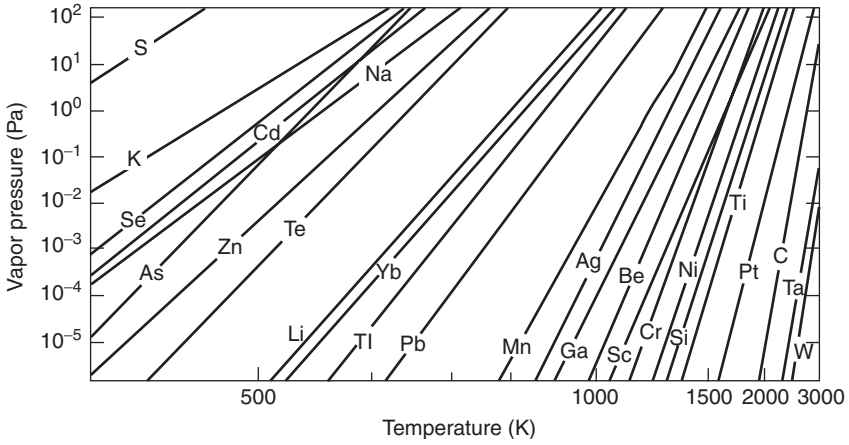

Figure 1 Vapor pressures for various materials.

A completely different approach for evaporation is employed during PLD, where high-power laser pulses are absorbed by a target material and converted into a combination of thermal, chemical, and mechanical energy. The evaporant is ejected from the target and forms a plume, which consists of energetic atoms and particles that travel through the vacuum to the substrate.

Sputter Deposition

Sputtering is the process where energetic particles impinge onto a target material and knock-out surface atoms. This process is widely used as a source for PVD. In contrast to evaporation, the source material remains cold during sputtering. Thus, sputter deposition is particularly well-suited for deposition of high-temperature materials which are hard to evaporate. In addition, sputtering typically yields a range of energetic particles that impinge onto the substrate and the growing layer and strongly influence the microstructure.

A generic schematic of a sputter deposition arrangement is shown in **Figure 2**. The target, consisting of the source material, is placed facing the substrate. A negative voltage of typically 0.2–5 kV is applied to the target (cathode). The substrate may be grounded and becomes the anode. An inert working gas, usually Ar, is introduced into the chamber and its pressure, typically between 0.1 and 10 Pa, is kept constant by controlling the inlet flow while continuously pumping. Positively charged ions are accelerated toward the target where they sputter target atoms, which then travel in the vapor phase and get deposited on the substrate. The sputter process also yields free electrons which are accelerated away from the cathode and, by collisions in the vapor phase, ionize gas atoms yielding more ions and electrons

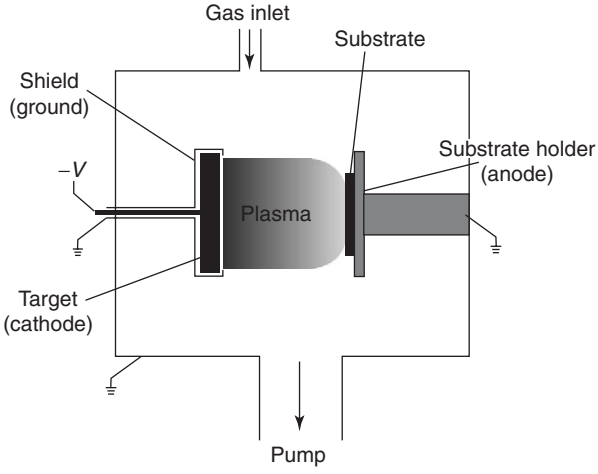

Figure 2 Generic schematic of a sputter deposition system.

which continue the sputter process. This chain reaction yields a charge neutral mixture of energetic electrons and ions between the target and the substrate, which is termed plasma or glow discharge because the excited ions often emit visible photons when relaxing to their ground state.

There is a wide range of specific arrangements and techniques to achieve the desired layer compositions and microstructures by sputtering. The following sections will introduce some common concepts and terms.

"Magnetron sputtering" refers to the use of magnetic fields to improve the ionization per electron. This technique lowers the pressure required to sustain a plasma and, in turn, yields higher deposition rates. **Figure 3** shows a schematic of a planar magnetron arrangement. Magnets are placed behind the target to form curved field lines parallel to the surface. Free electrons are accelerated by the negative target potential and, due to the Lorentz force, exhibit

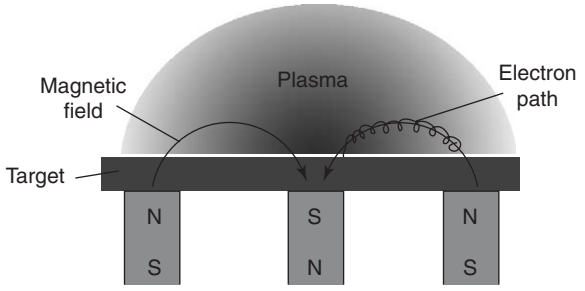

Figure 3 Planar magnetron arrangement for sputter deposition.

a spiral-motion circling along the magnetic field lines. Since the field lines bend back toward the target, the electrons are effectively trapped. They, therefore, remain much longer in the chamber than they would in the absence of magnets where they travel on straight paths from the target to the chamber wall. The confinement of electrons close to the target increases the ionization rate and, consequently, the plasma density.

"Ion-beam sputtering" utilizes a geometrically confined plasma to create energetic ions, which are directed and accelerated toward a target by grids in Kaufman-type ion guns. Such an approach allows a low pressure in the deposition chamber itself, with a mean free path of the depositing species far exceeding the target–substrate distance. This technique is less commonly used for deposition purposes but is very popular, for example, to acquire depth-profile measurement by photoelectron or Auger electron spectroscopy, to create specific 3D structures in a focused ion-beam system, or to prepare transmission electron microscopy samples by ion milling.

"Radio frequency (RF) sputtering" is primarily used to deposit insulating materials. During the above-described DC-sputtering process, ions impinge on the target and electrons are emitted, yielding an electric current which flows from the grounded substrate and chamber wall to the target. However, in order for this current to be sustained, the target material needs to be conductive. In contrast, RF electric fields cause oscillating electrons which can acquire sufficient energy for ionization, yielding a plasma that does not require electrons from the target. The electrons in such an RF-plasma have a much higher mobility than the ions, causing more electrons than ions to impinge onto the target. The insulating target, however, forces the currents of impinging electrons and ions to be equal, which yields a negative target self-bias. This (DC) self-bias causes the ions to be accelerated toward the target which results in the sputtering process.

"Compound targets" can be utilized to deposit compound coatings. The sputtering rate of the different elements in the target varies. However, this does not affect the emitted composition, since in steady state the sputtered composition corresponds to the bulk target composition. Nevertheless, unequal atomic transport efficiencies from the target to the substrate may cause the coating composition to vary from the target composition, requiring an adjustment of the target composition to achieve the desired coating.

"Co-sputtering" is the simultaneous deposition from two or more targets to create compound layers. In contrast to the use of compound targets, co-sputtering provides great flexibility in composition which is controlled by the relative power applied to each target. A disadvantage of co-sputtering is the non-normal arrangement of substrate and targets, which may yield lateral composition variations in the deposited layer.

An alternative approach for compound deposition is "reactive sputtering," which uses, in addition to the inert processing gas, a reactive gas (e.g., N_2, O_2, and CH_4), which provides elements such as C, N, and O to the layer. For example, TiN hard coatings are deposited using a metallic Ti-target and an Ar–N_2 gas mixture. The process control for reactive sputtering has its own challenges due to the surface reaction of the target, also called target poisoning. This is particularly true for the deposition of oxides where the presence of oxygen in the deposition chamber can lead to the formation of an insulating surface oxide on the target, which dramatically reduces the deposition rate and alters the layer composition.

An important aspect of sputter deposition is the presence of energetic particles that impinge on the substrate and typically cause a densification of the layer microstructure. The majority of sputtered particles have energies of a few electronvolts. However, "backscattered atoms" can have hundreds of electronvolts, which is sufficient to cause significant bulk displacements and crystalline defects. Backscattered atoms are most important during deposition of high-atomic-weight materials at low pressures. For example, in an Ar–Ta head-on atomic collision (during sputtering of a Ta-target with Ar), the momentum of the Ar is inverted while only a small amount of energy is transferred to the heavy Ta atom. If the Ar-ion loses its charge during this process (likely), it will move from the target to the substrate with an energy of several hundred electronvolts.

Bombardment of the substrate can be purposely enhanced by adding a negative "substrate bias," which accelerates ions from the plasma toward the substrate with a defined energy. In addition, the magnetic field lines during magnetron sputtering can

be designed so that some of them reach the substrate. This method is termed "unbalanced magnetron sputtering" and results in a high plasma density at the vicinity of the substrate. The ions in the high plasma density are then again accelerated toward the substrate with a bias, causing a high flux of ion irradiation with corresponding effects on the microstructure and texture of the deposited layers.

Chemical Vapor Deposition

Chemical vapor deposition (CVD) utilizes chemical reactions of volatile compounds with other gases to form nonvolatile solid deposits on a substrate. In contrast to PVD, where the vapor phase of the depositing species is obtained from a solid source, CVD employs gas-phase compounds that typically enter the deposition system through flux-controlled gas inlets. CVD is widely used in the semiconductor industry for the deposition of epitaxial (single-crystal) layers as well as various insulating and metallic thin films. Advantages of CVD include the possibility of uniformly depositing on complex-shaped surfaces, the relatively low cost for equipment and operation, and the compatibility with other processing steps. Many chemical reactions occurring during CVD can be divided into the following types:

1. *Pyrolysis*. It is the thermal decomposition of volatile compounds on hot substrates into a solid phase and gaseous by-products. An example is the decomposition of $SiH_4(g)$ into Si(s) and $H_2(g)$.
2. *Oxidation*. It is carried out using either O_2 gas or an O-containing compound, for example, during the deposition of alumina hard coatings by the reaction: $2AlCl_3(g) + 3H_2(g) + 3CO_2(g) \rightarrow Al_2O_3(s) + 3CO(g) + 6HCl(g)$.
3. *Reduction*. These reactions are typically obtained by employing H_2 gas to reduce halides and fluorides. For example, W-plugs, for contacts in integrated circuits, are deposited using $WF_6(g) + 3H_2(g) \rightarrow W(s) + 6HF(g)$.
4. *Displacement*. These reactions yield solid compounds. This category includes the very important metalorganic (MOCVD) processes such as those used for the growth of compound semiconductors. For example, GaAs is grown by the reaction: $(CH_3)_3Ga(g) + AsH_3(g) \rightarrow GaAs(s) + 3CH_4(g)$. The advantage of organic compounds as precursors is their high volatility at relatively low temperatures, which provides much better process control than techniques which require liquid or solid sources in the reactor. An example of the latter is the growth of GaAs by a reversible process that is achieved by $AsCl_3$ gas which reacts with molten Ga to form GaCl(g). This process requires the Ga source and the substrate to be kept at different temperatures within the same reactor to achieve the reaction: $As_4(g) + As_2(g) + 6GaCl(g) + 3H_2(g) \rightarrow 6GaAs(s) + 6HCl(g)$.

The thermodynamic data of the various chemical species during CVD processes are critical to assess the feasibility of new deposition schemes. In many cases, the gas and the surfaces are in quasiequilibrium; thus, the various partial pressures can be predicted from the changes in the Gibbs free energy of the relevant chemical reactions, and suitable temperatures for the substrate, chamber walls, and possible sources can be determined. Nevertheless, kinetic barriers for reactions and diffusion may limit reaction rates and lead to nonequilibrium conditions during operation since finite gas flow and deposition rates are essential for the ultimate goal of actually depositing a layer.

The understanding of gas transport during CVD processes is essential to design reactors that provide good utilization of process gases, high growth rates, and layer thickness uniformity. The latter requires an equal amount of reactant to all substrate surfaces, which is a nontrivial problem which typically requires computer modeling that includes gas transport as well as chemical reactions at the surface and in the gas phase. For most CVD systems, the operating pressures are high enough so that gas transport occurs in the viscous flow regime. The flow velocity is a critical parameter. If it is too high, it causes a turbulent flow and a corresponding nonuniform deposition. However, a low gas velocity causes a relatively thick boundary layer between the stationary substrate and the laminar stream. This reduces deposition rates since both gaseous reactants and by-products must pass through this boundary layer. Many CVD reactors exhibit zones which are kept at different temperatures and/or concentrations leading to gas transport by convection, in addition to the viscous transport and diffusion transport, which are due to pressure gradients and molecular motion, respectively.

There exists a multitude of CVD variations, as well as hybrid techniques that combine PVD and CVD processes. Some examples include low-pressure as well as atmospheric-pressure CVD, or plasma-enhanced CVD (PECVD). The latter process utilizes a glow discharge within the reactor to catalyze chemical reactions at low temperatures. Energetic collisions within the plasma cause chemically reactive ions, radicals, and molecular fragments which consecutively react at the substrate surface to result in layer growth. PECVD techniques are successfully

applied for the growth of nitrides, carbides, and amorphous group IV elements, including a-Si, and diamond-like C.

Vapor Transport Processing: Models and Simulations

C Bernard and M Pons, LTPCM-ENSEEG, St. Martin d'Hères, France

Introduction

The aim of macroscopic modeling of reactors for growing thin films starting from a gas phase is to prepare the way for designing and optimizing them by linking the parameters of the apparatus itself to its performance (uniformity, quality, selectivity, etc. of the deposit). This involves mainly linking the properties of the film, which depend on its growth rate, composition, and microstructure, to the process parameters: activation mode, substrate temperature, pressure, composition, and flow rate of the gaseous reactant phase and geometry of the reactor. Modeling helps to understand the various phenomena that occur during thin film growth, as these phenomena cannot always be analyzed experimentally. The models are based on the fundamental laws of physics and chemistry and can be used to quantify the role of the various phenomena, visualize them, and modify them by altering operating procedures. They are a complement to experimental methods (diagnostics, preparation) and one of their objectives is to help in designing equipment.

This technique, referred to in this article as CVD (chemical vapor deposition), has been used since the early days of the microelectronics industry. Compared to other techniques (sputtering, sublimation, or evaporation) CVD is extremely flexible. It offers the possibility of checking the structure and composition of the film, obtaining good uniformity, and relatively high growth rates (a few $\mu m\ h^{-1}$). One of the important advantages of this technique is its ability to deposit "conformal" films (i.e., films of uniform thickness on irregular surfaces).

The examples of simulation presented in this article look essentially at generic cases corresponding to microelectronics applications, as this is one of the sectors in which there is the greatest demand. While the construction of new CVD reactors is still largely on the basis of trial and error, and on adjusting existing equipment to meet requirements, the present trend is to combine simulation models with an experimental knowledge in designing, optimizing, and evaluating new reactors.

After an introduction that looks at the various modeling methods, examples illustrating transfer and reactivity phenomena are discussed. The purpose of these examples is not to establish the state of the art with regard to numerical simulation, but to show various levels of complexity.

The models and simulations discussed are restricted to the thermal approach to CVD. Plasma and laser contributions are noted for information purposes only, as they would require further development for both the models and the reaction approaches.

The Various Ways of Modeling and Simulating the CVD Process

Principle

In the CVD process, the reactive molecules containing atoms of the material to be deposited are introduced in the form of gas precursors diluted in an inert carrier gas into a reaction chamber containing the substrates. The chemical reactions must be activated. Only thermal activation is discussed here.

A coating growth is the result of heterogeneous reactions. Controlling the process involves determining the species at the origin of the reactions and thus their history inside the reactor. Generally speaking, the various stages involved are as follows (**Figure 1**):

- convective and diffusive transport of the reactants from the entrance of the reactor to the reaction area,
- chemical reactions in the gas phase leading to intermediate species,
- convective and diffusive transport of the chemical species to the surface,
- adsorption of these species on the surface of the substrate,
- heterogeneous reactions catalyzed by the surface,
- desorption of the reaction products, and
- convective and diffusive transport of the products from the surface to the outlet from the reactor.

Macroscopic modeling methods draw on thermodynamic, kinetic, and transport databases and involve (1) thermodynamic equilibrium calculations, (2) kinetic calculations, and (3) heat and mass transfer calculations linked to the kinetic and/or thermodynamic calculations.

Thermodynamic Approach

The thermodynamic approach is an unavoidable stage in any method for modeling gas-phase growth processes. It is used to determine whether a material can be made from a gas phase and, based on this preliminary study, to choose the potential gas precursors and ranges of operating conditions. In most cases, thin films are prepared from the vapor phase by CVD in reactors that work at constant temperature and pressure. If it is assumed that equilibrium is reached in the reactor, it is the total Gibbs energy function of the chemical system in action that will be minimum. To determine the nature and proportions of the phases present at equilibrium, a description of the Gibbs energies of all the phases must be available. Indeed, by knowing the Gibbs energy of an element or compound, it is possible to derive all its other thermodynamic properties and in particular the most important for this type of study, namely entropy, enthalpy, and heat capacity at constant pressure (**Tables 1** and **2**).

The Gibbs energy is expressed as a function of enthalpy and entropy as follows:

$$G = H - TS$$

However, as neither can be described in an absolute manner, a reference state must be used to situate each of these state functions and describe them in the databases to be interrogated for the equilibrium calculation. The convention adopted for entropy involves taking a zero value for each phase at 0 K. For enthalpy, the convention adopted by the Scientific Group Thermodata Europe (SGTE) was chosen. The reference will be the enthalpy of the stable phase of the element in question at 298.15 K, under a pressure of 1 bar; this will be referred to as "HSER" for "enthalpy standard element reference." Hence the Gibbs energy ${}^0G_i^{\Phi}(T)$ for the pure element i, referred to as the enthalpy of its stable state Φ at 298.15 K: ${}^0H_i^{\Phi}$ (298.15 K) at temperature T will be written as

$$GHSER_i = {}^0G_i^{\Phi}(T) - {}^0H_i^{\Phi}\ (298.15\ \mathrm{K})$$

Table 1 Thermodynamic and transport data

Transport data		*Thermodynamic data*	
λ :	Thermal conductivity ($W\,m^{-1}\,K^{-1}$)		
ρ :	Density ($kg\,m^{-3}$)		
μ :	Dynamic viscosity ($kg\,m^{-1}\,s^{-1}$)	${}^0G_i^{\alpha}(T)$:	Standard Gibbs energy of formation for species i of structure α ($J\,mol^{-1}$)
v :	Velocity ($m\,s^{-1}$)	${}^0H_i^{\alpha}$:	Standard enthalpy for species i of structure α ($J\,mol^{-1}$)
T :	Temperature (K)	c_p :	Heat capacity at constant pressure ($J\,mol^{-1}\,K^{-1}$)
P :	Pressure (Pa)	R :	Universal gas constant ($8.314\,J\,mol^{-1}\,K^{-1}$)
g :	Gravity ($g = 9.81\ m\ s^{-2}$)		
D_{ij} :	Binary diffusion coefficient ($m^{-2}\,s^{-1}$)		
D_i^T :	Multicomponent thermal diffusion coefficient ($kg\,m^{-1}\,s^{-1}$)		
ε :	Radiative emissivity		
ε/k :	Ratio of maximum energy of attraction in Lennard-Jones interaction potential and the Boltzmann constant (K)		
σ :	Collision diameter in Lennard-Jones interaction potential (A)		

Table 2 Thermodynamic data required for equilibrium modeling

Functions	*Formalism for n species*
Entropy	$S = -\left(\frac{\partial G}{\partial T}\right)_{P,n}$
Enthalpy	$H = G - T\left(\frac{\partial G}{\partial T}\right)_{P,n}$
Specific heat at constant pressure	$c_p = -T\left(\frac{\partial^2 G}{\partial T^2}\right)_{P,n}$

Table 3 Polynomial description of the Gibbs energies of the various species involved in the CVD process

Species	*Gibbs energy referred to stable phase*
Stable structure Φ of element i	${}^0G_i^{\Phi}(T) - {}^0H_i^{\Phi}(298.15\ K) = f_i(T)$
Metastable structure φ of element i	${}^0G_i^{\varphi}(T) - {}^0H_i^{\Phi}(298.15\ K) = f_i(T)$
Pure gas i	${}^0G_i^{gas}(T) - {}^0H_i^{\Phi}(298.15\ K) = f_i(T) - RT\ln P$
Solid compound A_aB_b	${}^0G_{A_aB_b}^{\Phi}(T) - a\,{}^0H_a^{\Phi}(298.15\ K) - b\,{}^0H_b^{\Phi}(298.15\ K) = f_{A_aB_b}(T)$

The Gibbs energy function can then be stored in the databases in the form of a temperature-dependent polynomial: $f_i(T)$. The classic formula is that adopted by the SGTE:

$$GHSER_i = a + bT + cT\ln T + dT^2 + eT^3 + fT^{-1} + gT^{-7} + hT^{-9} = f_i(T)$$

The Gibbs energy function of the classic species found in CVD (elements, gases, and compounds) using the polynomial description is given in **Table 3**. In contrast, the variable-composition condensed phases, which fall into three groups (substitutional solid solutions, ordered phases, and phases with an order–disorder transformation) are described by more sophisticated models that are not discussed in this article.

Consequently, in a simple system with N constituents involving no solid solution phases, the total Gibbs energy of the system that has to be minimized can be calculated at any moment in the following way:

$$G_{tot} = \sum_{i=1}^{N} q_i(f_i(T) + d_i RT\ln P_i)$$

where q_i corresponds to the number of moles of the constituent i, and d_i has the value 1 for a gas of partial pressure P_i and 0 for a condensed phase.

This Gibbs energy, representative of all the phases present or likely to be present in the reactor, is then minimized in the space of the N constituents, taking care to maintain the mass balance of each of the elements present in the chemical system and reproducing the experimental conditions that are to be tested. This minimization provides information on the nature of the various phases present at equilibrium and their respective proportions. These calculations are all the more useful as they can be carried

out beforehand, which may give an initial idea of the feasibility of a process. Moreover, after the most promising chemical system has been adopted, these minimizations lead to the most suitable ranges of parameters.

This approach is based on restrictive assumptions. The first supposes that thermodynamic equilibrium is reached; the greater the deposition temperature and pressure or dwell time, the more this assumption is justified. The second is based on the fact that the reactor is assimilated to a closed system at fixed pressure and temperature. However, this approach means that it is not necessary to choose a set of reaction equations, in contrast to the kinetic approach. It is followed by using numerous programs associated with interactive databases.

The Kinetic Approach

Between the injection orifice and substrate in a reactor, the gas molecules interact to form new species that may react with the surface in very different ways from those of the initial molecules. In order to simulate the process, it is necessary to know the reaction paths followed by these molecules (paths consisting of elementary stages formed essentially of unimolecular or bimolecular reactions) and the associated kinetic constants. Understanding the reaction mechanisms means constructing, analyzing, and reducing the complex chemical systems involved. When the data have been obtained, for a fixed pressure and temperature, solving a set of ordinary differential equations provides a change in concentration as a function of time. It should be noted that an "infinite" interaction time gives values for the thermodynamic equilibrium representing the maximum efficiency of the process.

The main problems with this approach are validating the proposed reaction paths and the difficulty in obtaining the data. For example, for the deposition of simple elements such as silicon, several dozen simultaneous homogeneous and heterogeneous reactions have been identified and many reduced chemical models have been proposed. Setting up databases involves spectrometer measurements, quantum mechanics, and statistical thermodynamic calculations. Generally, the kinetic constants for homogeneous reactions are expressed by Arrhenius-type laws. Theoretical approaches similar to those used with homogeneous reactivity are only just emerging for heterogeneous reactions. Predicting and establishing surface reaction paths are more difficult in the heterogeneous phase than in the homogeneous phase as the surface entities are much more complex. An important step forward in the field of kinetic formalism was made with the Chemkin code from Sandia laboratories.

Heat and Mass Transfer Approach

In order to understand the dynamic nature of the process, thermodynamic and/or kinetic approaches must be linked to heat and mass transfer models. Transfer models are sets of differential equations and boundary conditions describing the flow, energy, and mass transfers and appearance/destruction of the species due to chemical reactions at a macroscopic scale. The macroscopic equations describing the various stages of the process are general and can be applied to a wide spectrum of processes. Many recent reviews have given the state of the art in this field. However, it is constantly changing in order to meet the need to understand new reactive systems. Major research is being carried out into the formulation of chemical reactivity models and transport databases. The former are independent of any particular geometry but must be completely integrated into the simulation cycle. A description of the reaction paths, in particular in plasmas, is the major factor limiting the applicability of these models. In contrast, nonreactive hydrodynamic models and purely thermal models have proved to be helpful in designing equipment.

Figure 2 gives a general view of the simulation strategies. It is clear that a single model or single modeling technique cannot provide access to the very wide field of operation of the equipment, and in particular, the plasma equipment. Generally speaking, each module provides access to a part of the physicochemical problem and the various modules must be connected with user-friendly interfaces.

The reactor models are used to calculate the velocity, temperature, and concentration fields of the neutral species associated with the experimental conditions.

Some of the aspects shown in **Figure 2** are supported by calculation codes available in the market. Calculation codes capable of simulating a large part of the transfer and reactivity models for thermally activated CVD are currently available in the market. For the present, they are an unavoidable point of departure for initiating new research in the field of CVD process engineering. Simulators can be found for plasma-assisted reactors that are adapted to experimental conditions and/or excitation modes. Linking these with simultaneous transfer models is one of the objectives of the numerous research projects in progress. While the links to be made between different codes theoretically pose no major scientific problem, the quantification of reactor

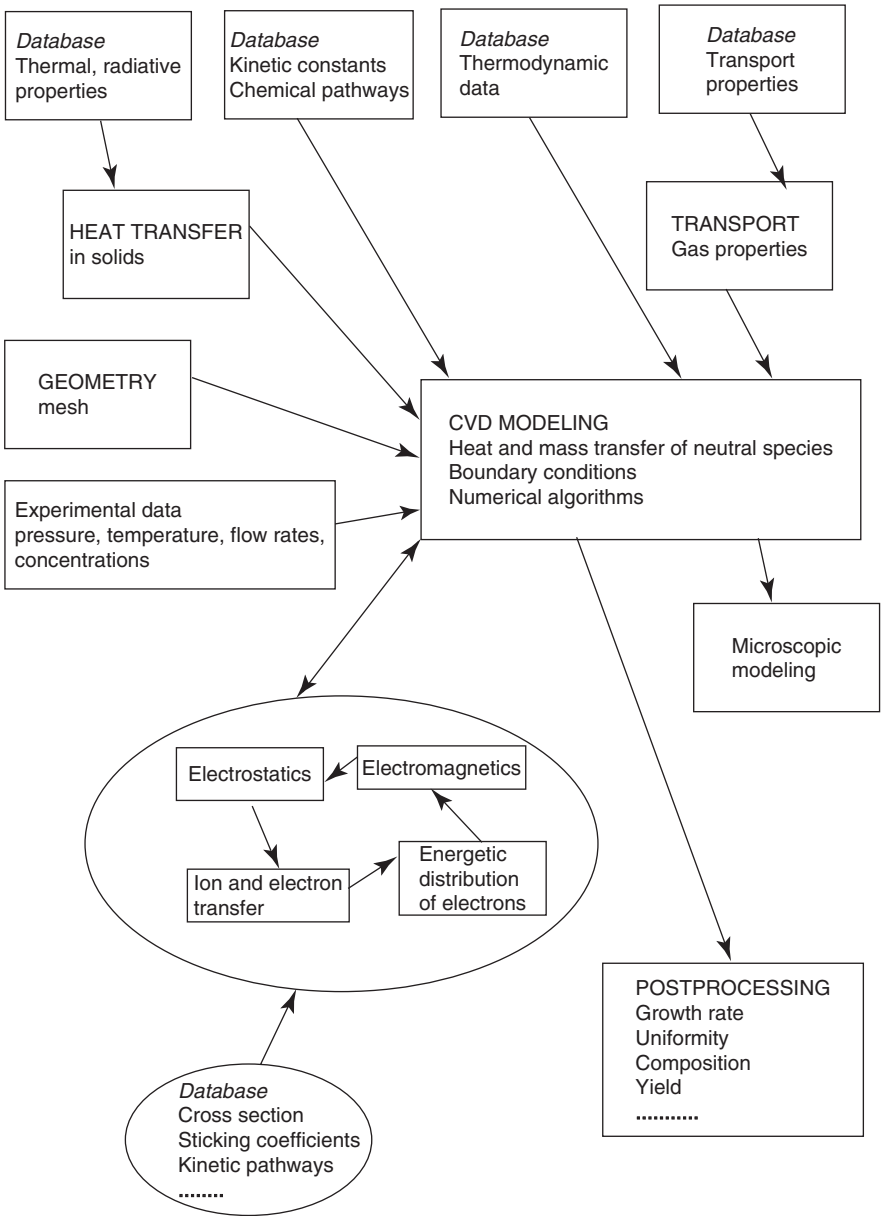

Figure 2 Schematic representation of reactor modeling strategies. The squares indicate the various models required to solve problems where only neutral species are taken into account (thermal CVD). The ellipses represent the additional modules for plasmas (plasma CVD).

performance and reactor optimization calls for close collaboration among specialists in process engineering, materials preparation, physics, and gas phase diagnostics. This is one of the reasons why few chemical systems have reached maturity. In practice, the models proposed were developed through intuitive approximations and past experience, and are based on experimental validation (*in situ* diagnostics of the gas phase and characterization of the layers obtained). However, *in situ* measurements are not usual in production reactors but can be performed in research reactors. Any quantitative or qualitative technique with enough spatial and temporal resolution can help to validate the proposed models. To make progress, it is essential to link these techniques to modeling efforts.

The core of the state of the art of CVD models includes mainly a model of transfer (or transport) phenomena, which must be supplemented by various submodels. The first is a chemical model describing the mechanisms of homogeneous and heterogeneous reactivity for a given process as a function of the preparation conditions. The second is a model based on the kinetic theory of gases for predicting the

transport properties of the gas mixture. The third is a thermal transfer model describing radiative effects coupled with the classical conductive and convective effects. Finally, the last model, which is still at the development stage, is a microscopic one linking calculated macroscopic values to film properties. All of these models require (1) thermodynamic, kinetic, thermal, and transport databases, (2) a description of the reactor geometry and operating conditions.

Heat and mass transfer and reactivity models are now well formalized. For some years now, the numerical encoding of these equations has been included in the main commercial codes that were previously dedicated to fluid mechanics calculations. Many physical and chemical models are included as standard ones. For example, the CFDACE code used for the calculations presented below includes most of the specific requirements of CVD reactor modeling. The transport properties, $\lambda, \mu, D_{ij}; D_i^T$, may be calculated directly from the kinetic theory of gases. A directly accessible thermodynamics database can be modified in order to include the missing specific gas species of the chemical system during the study. The code handles multicomponent gas mixtures, ordinary diffusion, and thermodiffusion. It is possible to describe homogeneous and heterogeneous reactions with Arrhenius-type or more complex laws, thanks to a link with the Chemkin code. Specific resolution algorithms for this type of reactivity are available. Thermal models include radiative transfer for gray bodies as well as for transparent ones. All the options are available via the user interface, which does not call for a detailed knowledge of the numerical techniques. However, when all these phenomena are added together, it is clear that there is need for caution. A knowledge of the models and their implications for the results is still essential.

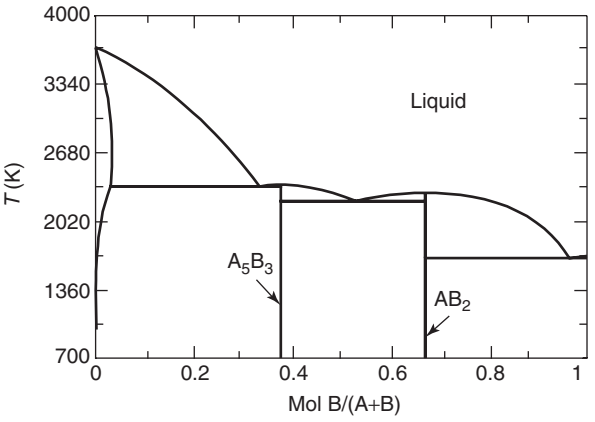

Figure 3 A–B phase diagram.

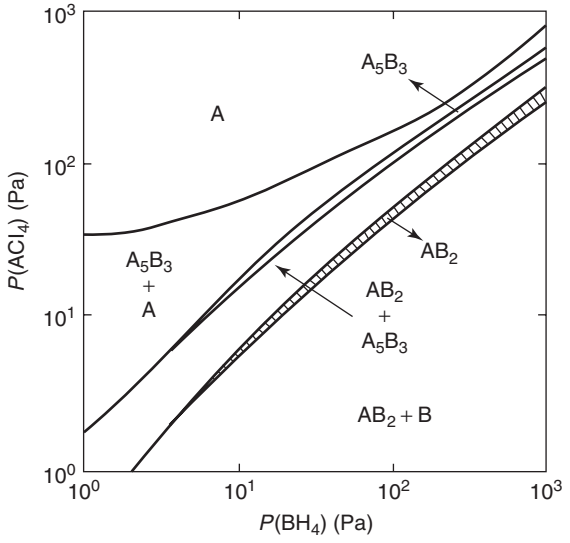

Figure 4 Calculated CVD phase diagram: $T = 1000$ K, $P_{tot} = 10^5$ Pa, $P_{Ar} = 9 \times 10^4$; initial gas mixture: $ACl_4 + BH_4 + H_2 + Ar$.

Databases and Examples

In order to be able to use the available software, the various data in the experimental temperature and composition field must be available. The data (**Table 1**) required to build a complete model are thermodynamic data (c_p, H, S), transport data $(\lambda, \mu, D_{ij}, D_i^T)$, kinetic data (k_r, k_{-r}), and radiative data (ε).

In the case of thermodynamic data, there are major databases and minimization software for calculating equilibrium in multicomponent systems. All these databases and software are interfaced with one another and can be interrogated online or installed on a PC. However, in spite of efforts by database managers, the thermodynamic values may not be completely consistent with one another, and the user will therefore always have to test their consistency at the outset in the context of his own chemical system.

As an example, the type of highly important classical information that an experimenter may hope to obtain from a simulation of his deposition experiment can be illustrated by the CVD diagram. Consider, for example, a compound AB_2 to be deposited on a substrate B using a gas mixture containing ACl_4, BH_4, H_2, and Ar (which could be the case of a deposit of silicon-rich conducting silicide on a silicon substrate). The compound AB_2 is situated in the binary diagram A–B shown in **Figure 3**, which has been optimized previously and simultaneously in the databases with the thermodynamic data of the phases concerned. Simulation of the CVD deposit at a given temperature T and fixed total pressure and neutral gas dilution leads to the diagram shown in **Figure 4**.

This indicates the nature of the phases deposited on the substrate, which is assumed to be neutral, as a function of the initial composition of the injected gas phase. A case such as this, where the domain favorable to the deposition of the phase AB_2 is fairly small, fully illustrates the interest of this type of approach.

More information on available databases and software can be obtained in particular from the (European, Canadian, and American) members of the SGTE.

With regard to transport data, most software include the calculation of these properties directly at each point of the mesh with a temperature and composition known during the calculation. The only data to be provided are the Lennard-Jones parameters $(\sigma, \varepsilon/k)$ and heat capacity c_p, which are used to calculate all the properties of the nonpolar molecules with sufficient accuracy.

The aim of the various examples presented below is to describe the transport and reactivity phenomena so as to demonstrate the potential of the simulation tools and not to propose an exhaustive overview of the problems and technological solutions. Classical geometry will be used for this purpose. It is an axisymmetrical, vertical reactor that has been widely used in research and manufacturing (**Figure 5**).

In this type of reactor, flow takes place perpendicular to the surface of the substrate. The substrate and its support may be fixed or rotating. Slow rotations ($\omega = 10$ rpm) are often used to avoid dissymmetry effects. Fast rotations ($\omega = 100-1000$ rpm) modify the transport. Reversed reactors, in which the gases enter through the bottom, are used to modify or eliminate natural convection phenomena. They are rarely used owing to the difficulties involved in installing the substrate.

The walls are usually cooled to avoid any deposition there. Lamps may heat the substrate directly in a few seconds. The various phenomena encountered when using a generic fast-heating reactor of the type shown in **Figure 6** are described.

Influence of Carrier Gas Pressure

A mixture containing silane ($100\,cm^3\,min^{-1}$ standard conditions) diluted in argon or hydrogen ($2000\,cm^3\,min^{-1}$ standard conditions) is introduced at a temperature of 300 K at the top of the reactor. The temperature of the substrate is fixed at 923 K and the walls are cooled (300 K). When the carrier gas is argon, natural convection phenomena due to gravity effects can be observed as soon as the pressure reaches 1.33×10^4 Pa (**Figure 7**). When hydrogen is used as a carrier gas, these only occur close to atmospheric pressure. This first simulation can be used to visualize and quantify the relations existing between the geometry, the nature of the gas, the temperature, and the flow facies.

The most complex thermal effects associated with the flow and reactivity phenomena may also be

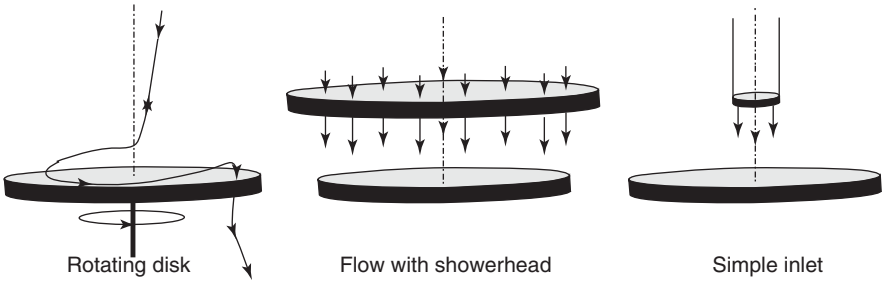

Figure 5 Schematic representation of the various technologies for axisymmetrical vertical reactors.

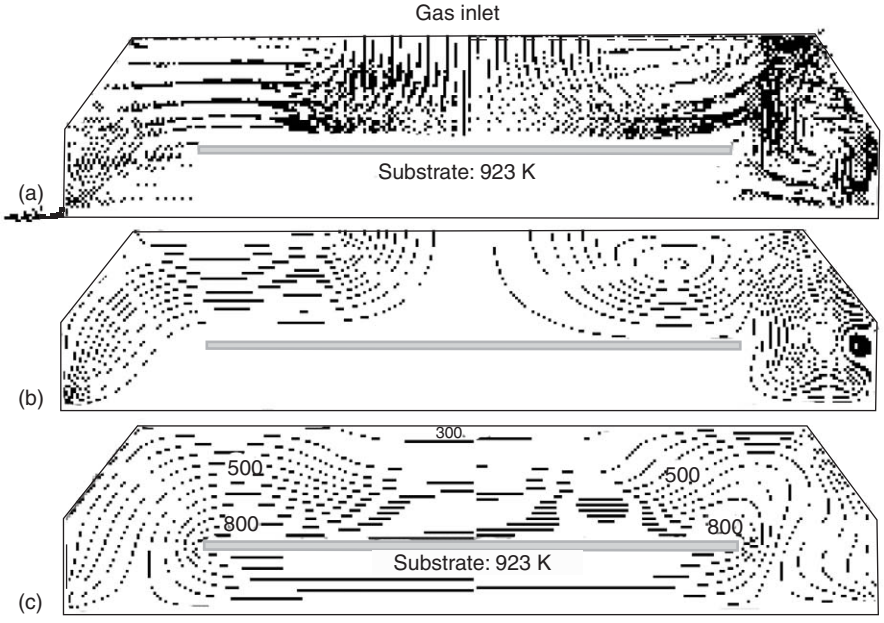

Figure 7 Influence of pressure on velocity field (a) streamlines, (b) and temperature fields, and (c) left – $P = 1333$ Pa, right – $P = 13\,333$ Pa. The initial mixture is Ar ($2000\,cm^{-3}\,min^{-1}$) and silane ($100\,cm^{-3}\,min^{-1}$).

simulated using available tools. However, it is not possible to calculate the growth rate and uniformity of the composition and thickness of the deposited film with this approach. One of the industrial challenges is to be able to check these factors. Multiconstituent mass transfers and homogeneous and heterogeneous reaction paths must therefore be added to the previous models. The deposition of silicon using silane is discussed as an example. The real chemical system has been reduced for pedagogical reasons and must not be used as such without a preliminary study.

Influence of Reactivity

The homogeneous reactions and associated kinetic constants (kmol, s, K) in the gas phase are

$$SiH_4(g) \rightarrow SiH_2(g) + H_2(g)$$
$$k_{1f} = 2.43810^{10} \exp\left(\frac{-24075}{T}\right)$$

$$SiH_2(g) + H_2(g) \rightarrow SiH_4(g)$$
$$k_{1r} = 1.80910^{5} \exp\left(\frac{3042}{T}\right)$$

$$Si_2H_6(g) \rightarrow SiH_4(g) + SiH_2(g)$$
$$k_{2f} = 1.58410^{12} \exp\left(\frac{-20063}{T}\right)$$

$$SiH_4(g) + SiH_2(g) \rightarrow Si_2H_6(g)$$
$$k_{2r} = 7.77110^{7} \exp\left(\frac{5120}{T}\right)$$

The two gas species SiH_2 and Si_2H_6 are produced by homogeneous reactions.

The heterogeneous reactions and sticking coefficients (γ) of the gas species leading to silicon deposition are

$$SiH_4(g) \rightarrow Si_s + 2H_2(g)$$
$$\gamma_1 = 1.0810^{8} T^{-0.8822} \exp\left(\frac{-19052}{T}\right)$$

$$Si_2H_6(g) \rightarrow 2Si_s + 3H_2(g)$$
$$\gamma_2 = 4.9610^{16} T^{-3.253} \exp\left(\frac{-20219}{T}\right)$$

$$SiH_2(g) \rightarrow Si_s + H_2(g) \quad \gamma_3 = 1.0$$

Figure 8 represents the temperature and mass fraction fields of silane, silylene, and disilane. Silylene is formed at the highest temperatures and as its reactive power is very great, the entire mass formed is consumed to prepare the silicon film. Disilane appears at lower temperatures and as it is less reactive, its concentration increases. The contributions of silylene and disilane are only of the order of 1% for this process. In the field of microelectronics, these variations may have a harmful effect on circuit preparation.

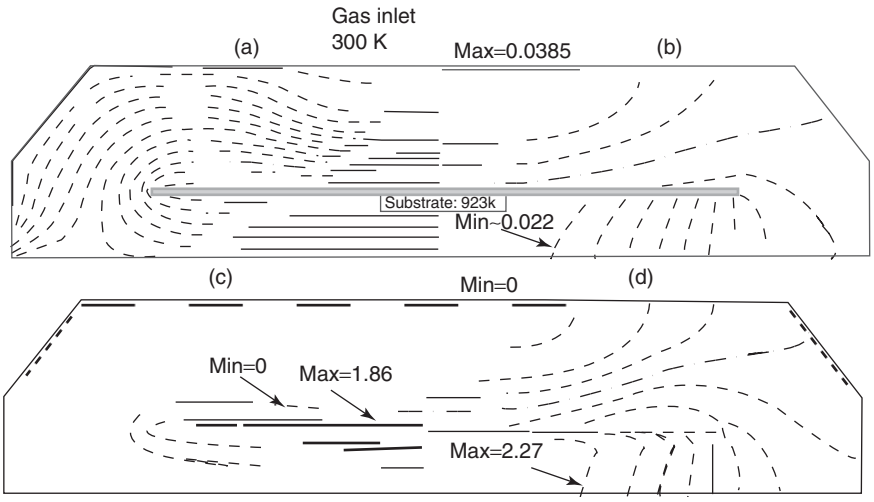

Figure 8 (a) Temperature field, (b) mass fraction field for silane, (c) silylene ($\times 10^6$), and (d) disilane ($\times 10^5$).

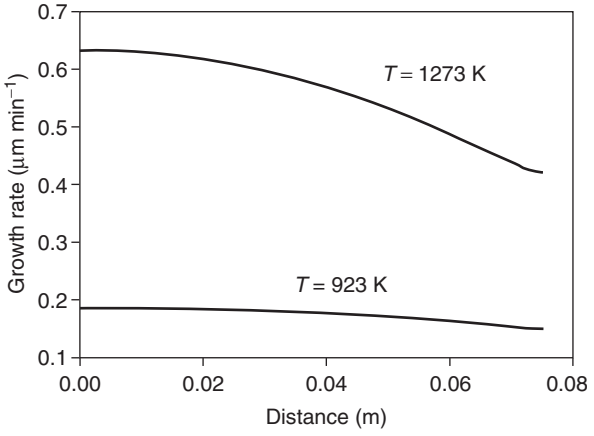

Figure 9 Growth rate as a function of substrate radius.

The process may be optimized on the basis of these results. For example, a reduction in pressure from 1333 Pa to 133 Pa leads to uniform deposits but the growth rate decreases. The same is true with a reduction in temperature (**Figure 9**).

Conclusion

The various models that can be built to simulate the phenomena occurring during film preparation by thermal CVD have been discussed. Similarly, the information required to use the models has been listed and illustrated with generic examples that reflect only a small proportion of the potential of such simulations. In practice, the phenomena are examined through a large number of interconnected submodels: thermodynamics, kinetics, heat transfers, mass transport, etc. Models of nonreactive transfers of momentum and energy are perfectly able to reveal the different modes of hydrodynamic operation of reactors. Models that take into account kinetic phenomena, even in a simplified manner, can be used for a more detailed simulation of all the mechanisms involved in the CVD process. Simulation models combining heat and mass transfers and local thermodynamic equilibrium extend thermodynamic calculations to dynamic systems. They only simulate experimental conditions for which equilibrium is reached at all points of the reactor, which is justified when the temperature is high and/or for long dwell times.

A large corpus of knowledge in terms of databases and simulations can be used regularly by specialists able to assess their scope, evaluate the contribution of the various modeling techniques, and integrate them in an overall program whereby they can be validated.

In the case of thermally activated CVD, the development of simulation tools and databases is the result of much research that has been carried out over the past 20 years. In contrast, much less attention has been paid to noncontinuous phenomena occurring at very low pressure or to modeling PECVD (plasma-enhanced chemical vapor deposition) and photo-CVD reactors. The development of these models is much more recent and simulation tools have not yet reached the same degree of sophistication.

One of the challenges for the future lies in the development of microscopic models and their links with the macroscopic approach presented here.

Overview

Optical scattering is ever present in the disordered world that surrounds us. It gives rise, for example, to the diffuse blue illumination of the sky and the whiteness of clouds, milk, and paint. Together with emission, absorption, and free propagation, optical scattering governs the light presented to the eye and to photographic and electrooptic imaging systems. In this article, the propagation of light and other parts of the electromagnetic spectrum within disordered media is described. Those aspects of scattering that are common to electromagnetic waves from the radio frequency to the X-rays are emphasized. Many of the illustrations are drawn from microwave measurements for which it is possible to determine both the amplitude and phase of the wave. Since the precise configuration of a random sample is by definition unknown, a statistical approach is required, as is the case in the study of electronic waves in conductors.

The observed electromagnetic field can be represented by the complex number, $A_n \exp(i\varphi_n)$, with amplitude A_n, phase φ_n, and discrete polarization index n. Though the electromagnetic field in static multiple-scattering samples varies randomly in space due to the superposition of randomly phased partial waves, the field at a given point is as temporally coherent as the source, which may be a highly coherent laser beam. The interference of scattered laser light produces a speckled intensity pattern with a correlation length of the field on the order of the wavelength, λ. The intensity and phase within a microwave speckle pattern on the output surface of a random sample is shown in **Figure 1**. Since the field at a point is the sum of a large number of statistically independent terms, associated with various scattering trajectories, it must be a Gaussian random variable, with a Gaussian distribution for the complex field. Since the intensity transmission coefficient from some incident mode a to some outgoing mode b is proportional to the square of the field, $T_{ab} = A_{ab}^2$, the probability distribution of normalized, polarized intensity may be expressed as $P(s_{ab}) = \exp(-s_{ab})$, where $s_{ab} = T_{ab}/\langle T_{ab} \rangle$ is the transmitted intensity normalized to its average value over an ensemble of random sample realizations, represented by $\langle \cdots \rangle$.

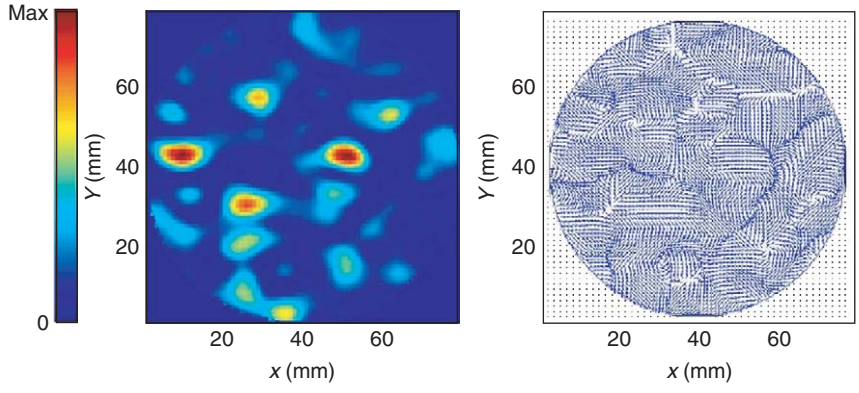

Figure 1 The near-field intensity speckle pattern of microwave radiation and the distribution of the phase at the output surface of a random sample (cylindrical waveguide filled randomly with dielectric spheres).

Early studies of multiply scattering light, a century ago, concentrated on optical flux in stellar and planetary atmospheres. These studies utilized the radiative transfer theory, which is akin to the phenomenological Boltzmann approach, used for computing atomic scattering or electron transport. Until two decades ago, optical studies dealt almost exclusively with weakly scattering natural and synthesized materials. In these media, the optical transport mean free path, ℓ, in which the direction of light is randomized, greatly exceeded the optical wavelength, λ. The evolution of photon density or intensity was shown to satisfy a diffusion equation, which gave a result for average transmission which is equivalent to Ohm's law in electron conduction. The diffusion equation also provided the photon time-of-flight distribution, which determined the sensitivity of the steady-state field to internal motion of the sample or variations of the incident frequency. Similarly, the diffusion equation determined the spatial intensity distribution on the input surface, which determined coherence of the reflected light.

The neglect of interference in calculations of average transport led to the diffusion equation, while the neglect of long-range spatial correlation by the assumption of Gaussian statistics resulted in the Rayleigh probability distribution for intensity. It has become increasingly apparent in the last two decades that the role of interference in average transport and of extended spatial correlation in intensity statistics cannot be neglected in multiple-scattering samples in which wave trajectories cross. As a result of these effects, flux does not self-average within a single sample configuration. Giant fluctuations appear in the total transmission, which is defined as the sum of transmission coefficients over the output modes for a given incident mode, $T_a = \sum_b T_{ab}$. Enhanced fluctuations of total transmission are due to the crossing of wave trajectories, which are also responsible for the phenomenon of universal conductance fluctuations. At the same time, average optical transport may be dramatically modified by the approach to photon localization, which is analogous to electron localization in many respects.

Optical and microwave measurements showed that the presence of long-range correlation of intensity within a sample led to enhanced fluctuations of total transmission over the value predicted if fluctuations in intensity were short range as are the fluctuations in the field. This represents a breakdown of Gaussian statistics of the field which leads to enhanced fluctuations in intensity. The presence of enhanced intensity fluctuations can be seen in an ensemble of quasi-1D random samples, in which the sample length is much greater than the diameter of its cross section. In such quasi-1D samples, modes are completely mixed so that the statistics of the field are the same at every point of the output surface. Though the field distribution on the output surface over a random ensemble of quasi-1D samples is no longer Gaussian, the field for the subset of samples with the same value of total transmission is a Gaussian random variable. The intensity distribution for a random ensemble with a distribution of values of total transmission can thus be regarded as a mixture of Rayleigh distributions with mixing proportions given by the distribution of transmission. As a result, non-Gaussian statistical properties of propagation can be characterized by the variance of the total transmission normalized to its ensemble average value, $\mathrm{var}(s_a) = \langle (\delta s_a)^2 \rangle$, where $\delta s_a = s_a - \langle s_a \rangle$ and $s_a = T_a / \langle T_a \rangle$. The value of $\mathrm{var}(s_a)$ is equal to the degree of correlation of transmitted intensity at remote points on the output surface or for distinct transverse transmission modes, b and b', at which the correlation in the field vanishes: $\mathrm{var}(s_a) = \langle \delta s_{ab} \delta s_{ab'} \rangle \equiv \kappa$. In systems without dissipation or gain, the degree of correlation κ is inversely proportional to the dimensionless conductance, g, which is the key parameter in electronic conductance and may be defined for classical waves in analogy with the Landauer formula for electronic conductance, $g = \sum_{ab} T_{ab} = \sum_a T_a$, $\kappa = 2/3 \langle g \rangle$.

Intensity correlation is large when the dimensionless conductance is small. The divide between extended diffusing waves and spatially localized waves is estimated to occur at $g \approx 1$ and $\kappa \approx 1$, where henceforth $\langle g \rangle$ will be denoted by g. The value of g is determined by the local strength of scattering and the dimensions of the sample. Localization occurs when wave trajectories are likely to return to a coherence volume, $V_c = (\lambda/2)^d$, in a d-dimensional sample before escaping from the sample. Wave interference then dominates transport and further enhances the return of the wave to points within the medium. Since the average number of returns of a wave to a coherence volume always exceeds unity in sufficiently large one- and two-dimensional scattering media, photon localization may be expected and indeed has been observed. In 3D samples, photon localization is more difficult to achieve. The threshold for localization is reached when $k\ell < 1$, where $k = 2\pi/\lambda$ is the wave vector. This is the same condition as the Ioffe–Regel criterion for electron localization.

Photon localization has been predicted and observed in nearly periodic 3D samples with appropriate structure such that a photonic bandgap would have been formed in the absence of disorder. Within the photonic bandgap, the wave is evanescent and propagation is forbidden in any direction. When the

sample is disordered, localized states are introduced into the bandgap, in a manner analogous to the occurrence of localized electronic states within the bandgaps of semiconductors and insulators. Key statistical properties of electromagnetic waves in samples with homogeneous disorder depend upon the closeness to the photon localization transition, which can be precisely determined using statistical measures of fluctuations and correlation of optical intensity. Observing the photon localization transition in 3D samples allows the study of the Anderson localization transition between extended and localized waves without the complication of particle interactions, which are unavoidable for electrons.

A crucial indicator of the nature of wave propagation is the variation of average transmission with a sample scale. For diffusive waves in energy-conserving systems, transmission falls inversely with the sample thickness, whereas it falls exponentially for localized waves. Contrary to the case of electronic transmission, in which the particle number is conserved, scaling of optical transmission is strongly affected by the degree of absorption or gain in a sample. When optical absorption plays a role, diffuse transmission falls exponentially as well, so that for light, scaling measurements alone are not sufficient to determine the localization threshold.

The optical speckle pattern gives a distinctive fingerprint of the coherence of the light scattered from a particular realization of a random sample (**Figure 1**). This is also revealed by an interference process called "weak localization" in which the diffuse nature of radiation is maintained, though with a suppressed diffusion coefficient. A strongly related process can be directly observed in retro-reflection: when averaged over an ensemble of configurations, a coherent backscattering peak emerges in the angular distribution of the reflected light, with a maximum intensity equal to exactly twice the background intensity. Ensemble averaging can be readily performed in colloidal samples. The angular profile of the coherent backscattered light is the Fourier transform of the intensity distribution on the input surface for point illumination, which has a spatial extent of the order of the mean free path ℓ. The diffuse random walk of photons generates a characteristic triangular coherent backscattering peak, whose width is inversely proportional to $1/k\ell$.

The study of multiple scattering in dynamic turbid samples opens up the possibility of probing the motion inside the sample. The transmitted speckle pattern is completely randomized when the change in the total path of the scattered waves is of order λ. Since the length of the wave trajectory is greatly increased within a random medium, even small rearrangements of scatterers modify the speckle pattern. Measurements of temporal correlation, called diffuse wave spectroscopy, make it possible to monitor microscopic motion on the length scale of nanometers and on the timescale of nanoseconds.

Apart from the similarities between optical and electronic transport arising from their dual wave and particle nature, there are numerous differences between light and electrons. Photons have zero mass, making their dispersion law linear, rather than parabolic. This has strong consequences for the speed of photons in resonant media. Photons also have no charge and many electronic phenomena such as the Aharonov–Bohm effect have no photonic equivalent. The absence of photon charge makes it more difficult to localize photons than electrons in random 3D samples. Nonetheless, a Hall effect for photons can be predicted and observed. Another striking difference applies to the optical scattering cross section relative to the geometric cross section, which falls rapidly with particle size for particles smaller than a wavelength. The strength of scattering is optimized at Mie resonances in larger particles. The storage of energy at wavelengths near Mie resonances slows the propagation of light. A final important difference is related to the spin. Whereas fermionic electrons are repelled by the Pauli exclusion principle, photons are bosons and can exhibit stimulated emission and lasing. The study of random lasers provides a probe of long-lived modes of a random medium in which lasing is facilitated.

Radiative Transfer and Diffusion

The phenomenological radiative transfer equation is a Boltzmann equation for the specific intensity $I_v(r,t)$ describing the flow of photons in a disordered medium at position r, at time t, and with velocity $\boldsymbol{v} = c\hat{\boldsymbol{v}}$,

$$\partial_t I_v + \boldsymbol{v}\cdot\nabla_v I_v + \left(\frac{1}{\tau_{\text{abs}}} + \frac{1}{\tau_{\text{scat}}}\right) I_v = S(\boldsymbol{r},t) + \int \mathrm{d}\hat{\boldsymbol{v}}'\, W(\boldsymbol{v},\boldsymbol{v}') I_{v'} \qquad [1]$$

This equation features all relevant processes: propagation (first two terms on the left), absorption (rate $1/\tau_{\text{abs}}$) and scattering to other directions (rate $1/\tau_{\text{scat}}$) collectively referred to as extinction, emission $S(\boldsymbol{r},t)$, and scattering from other directions (rate $W(\boldsymbol{v},\boldsymbol{v}')$ per solid angle).

Absorption and emission are incoherent processes, whereas scattering is, in principle, coherent. A classical limit of radiative transfer is to neglect scattering and to assume steady (local) thermal equilibrium between absorption and re-emission, as expressed by

Kirchhoff's theorem: $\tau_{abs} \times S = B_\nu(T)$, with $B_\nu(T)$ the Planck function for the local temperature $T(\boldsymbol{r})$. The approximate solution of the radiative transfer eqn [1] becomes,

$$I_\nu(\boldsymbol{r}) \approx B_\nu[T(\boldsymbol{r} - \boldsymbol{v} \cdot \tau_{abs})] \qquad [2]$$

showing that photons emerge from within one absorption length $v\tau_{abs}$ along the line of sight. This statement explains the limb darkening of the sun, and the solar absorption lines at the Balmer series of hydrogen. A modification of this approach also applies to photon diffusion in warm resonant gases.

The source, which may be a coherent laser beam, is often not in thermal equilibrium with absorption in the medium. It then becomes important to include scattering. Scattering integral renders the radiative transfer equation difficult to solve. A popular simplification is the diffusion approximation. The angular dependence of I_ν is expanded only up to the isotropic and dipolar terms, which describe the energy density, $E(\boldsymbol{r}, t) = c^{-1} \int \mathrm{d}\hat{\boldsymbol{v}}\, I_\nu(\boldsymbol{r}, t)$, and the energy current density, $\boldsymbol{J}(\boldsymbol{r}, t) = \int \mathrm{d}\hat{\boldsymbol{v}}\, \hat{\boldsymbol{v}} I_\nu(\boldsymbol{r}, t)$:

$$I_\nu = \frac{1}{4\pi}[Ec + 3\hat{\boldsymbol{v}} \cdot \boldsymbol{J} + \cdots] \qquad [3]$$

This leads to the following diffusion equation for the energy density,

$$\partial_t E(\boldsymbol{r}, t) - D\nabla^2 E(\boldsymbol{r}, t) + \frac{1}{\tau_{abs}} E(\boldsymbol{r}, t) = \frac{4\pi}{c} S(\boldsymbol{r}, t) \qquad [4]$$

The diffusion equation describes a random walk of photons with an average step length $\ell_{scat} = c\tau_{scat}$, and an angular redistribution described by $W(\hat{\boldsymbol{v}}.\hat{\boldsymbol{v}}')$ for each step. Scattering is now entirely described by the diffusion constant, D. It is found that $D = 1/3c^2\tau_{tr}$, with the transport mean free time,

$$\tau_{tr}^{-1} = \int \mathrm{d}\hat{\boldsymbol{v}}' W(\hat{\boldsymbol{v}} \cdot \hat{\boldsymbol{v}}')[1 - \hat{\boldsymbol{v}} \cdot \hat{\boldsymbol{v}}'] = \tau_{scat}^{-1}[1 - \langle \cos\theta \rangle]$$

Equation [4] can only be solved if boundary conditions are specified. One usually imposes the condition that no current enters the medium. An important application is to the stationary transmission of light through a disordered, nonabsorbing slab between $z = 0$ and $z = L$ and an imbedded source layer, $S(z) = (c/4\pi)\delta(z - z_s)$. In the absence of internal reflection at the sample boundary due to a mismatch between the average refractive indices, the angular distribution of transmission is given by

$$T(\theta) = \frac{z_s + z_0}{L + 2z_0} \times \left(1 + \frac{3}{2}\cos\theta\right) \qquad [5]$$

where $z_0 = \frac{2}{3}\ell = \frac{2}{3}c\tau_{tr}$ is the extrapolation length beyond the sample interface, at which the intensity extrapolates to zero and τ_{tr} is the transport mean free time. This length increases when there is internal reflection at the sample interface due to a mismatch of effective refractive indices. The diffuse transmission decays with increasing thickness as $1/L$.

Dynamics

In weakly scattering systems, an initial ballistic burst of unscattered radiation is transmitted through the sample followed by a broad pulse with a profile described by the diffusion equation (**Figure 2**). The ballistic light, which must be filtered from the predominant multiply scattered light, is utilized in optical coherence tomography to image inhomogeneous tissues for noninvasive medical diagnostics and to monitor a wide spectrum of human pathologies based upon residual coherence in scattered light. Diffusive light rapidly reaches an asymptotic single exponential decay reflecting the sum of the leakage rate of light out of the lowest diffusion mode and absorption. In pulsed microwave measurements, in quasi-1D random dielectric media, a breakdown of the diffusion model is seen in the nonexponential decay of transmission at long time. This may be understood as the result of increasing impact of weak localization as the rate of crossing of optical trajectories within the sample increases in time. Alternatively, it may be understood as a manifestation of the increasing role of

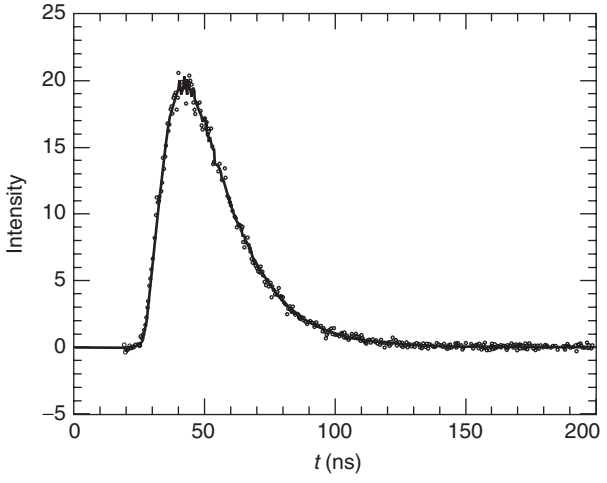

Figure 2 Time-of-flight distribution in an ensemble of quasi-1D samples of 1.3 cm diameter polystyrene spheres randomly packed in a copper tube of diameter 7.3 cm and length 100 cm with reflecting walls and open ends at a spheres volume fraction of 0.52 is obtained by averaging the temporal response to a 1 ns pulse at carrier frequency 19 GHz over 4096 sample configurations. The continuous line is the prediction of diffusion theory. (Sebbah *et al.* (2000) *Physical Review E* 62: 7348.)

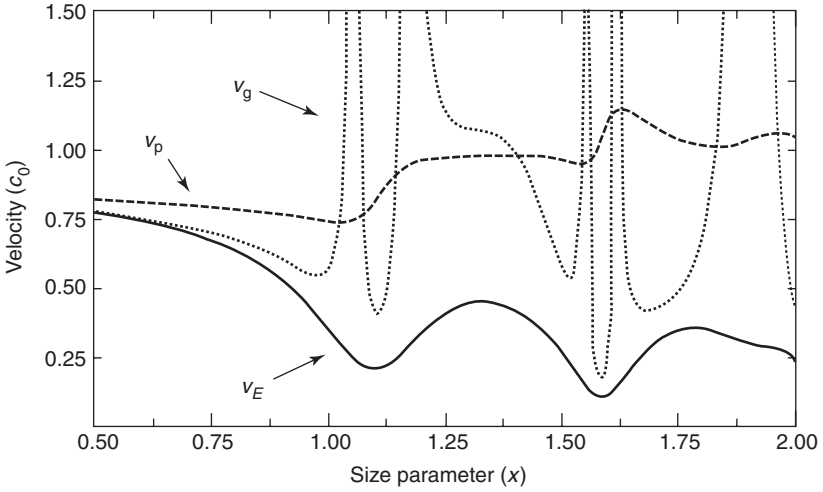

Figure 3 Energy transport velocity calculated for light propagating in a random medium filled with dielectric Mie spheres with refraction index 2.73 and volume fraction 0.36, as a function of their size a ($x = 2\pi a/\lambda$). The energy velocity v_E differs from the group velocity v_g and phase velocity v_p of the effective medium, especially near Mie resonances. (van Albada *et al.* (1991) *Physical Review Letters* 66: 3132.)

longer-lived modes at later times. Such modes tend to have greater density far from the sample surface so that the wave does not readily escape the sample.

Many wave phenomena can be explained in terms of a classical scalar wave equation for the complex wave $\psi = \mathrm{A}\exp(\mathrm{i}\varphi)$ in the presence of a source S,

$$\frac{\varepsilon(\boldsymbol{r})}{c_0^2}\partial_t^2\psi(\boldsymbol{r},t) - \nabla^2\psi(\boldsymbol{r},t) = S(\boldsymbol{r},t) \qquad [6]$$

The energy and current densities are expressed, respectively, as

$$E = \tfrac{1}{2}c_0^{-2}\varepsilon(\boldsymbol{r})|\partial_t\psi|^2 + \tfrac{1}{2}|\nabla\psi|^2$$

and

$$\boldsymbol{J} = \mathrm{Re}(\partial_t\psi\nabla\psi^*)$$

For a wave packet that is closely centered around angular frequency ω, and wave vector $\boldsymbol{k}$, $E \approx \varepsilon(\boldsymbol{r})(\omega/c_0)^2|\psi|^2$ and $\boldsymbol{J} \approx \boldsymbol{k}(\omega/c_0)|\psi|^2$, and the phase shift seems to disappear explicitly from the picture.

Though the velocity of light might be defined as a fluctuating quantity in a random medium, $c(\boldsymbol{r}) = c_0/\sqrt{\varepsilon(\boldsymbol{r})}$, where $\varepsilon(\boldsymbol{r})$ is the fluctuating local dielectric constant that gives rise to optical scattering, it is expected that, on a macroscopic level, the diffusion constant may be expressed in terms of an average transport velocity, v_E, $D = \frac{1}{3}v_E\ell$. The transport velocity may be taken as the ratio of the average current density and average energy density, calculated for a wave packet centered at frequency ω and wave number $\boldsymbol{k}$,

$$v_E = \frac{\langle J(\boldsymbol{r})\rangle}{E(\boldsymbol{r})} = \frac{kc_0^2}{\omega}\frac{\langle|\psi|^2\rangle}{\langle\varepsilon(\boldsymbol{r})|\psi|^2\rangle} \qquad [7]$$

$\boldsymbol{k}$ and ω are expected to be related by some effective medium dispersion law $\boldsymbol{k} = \omega/v_p$, featuring the phase velocity v_p. Near scattering resonances, the field inside the particles is greatly enhanced, and $v_E \ll v_p$. **Figure 3** shows a calculation of v_E for particles with an index of refraction $m = 2.73$ and volume fraction of 0.36, corresponding to TiO_2 powder. The transport velocity is seen to drop considerably near resonance.

Mesoscopic Optics

In the classical radiative transfer theory, light has been treated as photons, and not as classical electromagnetic waves. However, wave aspects of propagation are crucial if one is to understand fluctuations and correlations in multiply scattering samples in which the wave is temporally coherent. Because the regime, in which the wave is temporally coherent in electronic samples, is intermediate between the microscopic atomic scale and the macroscopic scale, it is termed mesoscopic. This term has been used to describe propagation of temporally coherent classical waves even in macroscopic samples.

Field Correlation

A full description of transport must include the interference of waves. A speckle pattern results from

the superposition of all partial waves arriving at different points of the scattered wave (**Figure 1**). The field fluctuates with the variation of some parameter p such as position, scattering angle, frequency, or time, as a result of the random phases and amplitudes of partial waves, and can be written as $\psi(p) = \psi_1(p) + \psi_2(p) + \cdots$. It is reasonable to assume that all $\psi_i(p)$ are independent, since they have visited so many different scatterers. As a result, the central limit theorem imposes complex-valued Gaussian statistics on the measured field $\psi(p)$. In addition to the Rayleigh distribution for the intensity, a second consequence of Gaussian statistics is the Siegert relation between correlations of intensity and field,

$$\begin{aligned}\langle I(p_1)I(p_2)\rangle &= \langle \psi(p_1)\psi(p_1)^*\psi(p_2)\psi^*(p_2)\rangle \\ &= \langle I(p_1)\rangle\langle I(p_2)\rangle \\ &\quad + |\langle \psi(p_1)\psi^*(p_2)\rangle|^2 \end{aligned} \quad [8]$$

The field correlation usually decays rapidly with $p_1 - p_2$. The Seigert relation is useful since intensity correlations are easier to measure than field correlations, particularly at optical frequencies.

Under a wide variety of circumstances, wave and particle aspects of propagation are Fourier transform pairs. An important example concerns the field correlation function C_E with frequency shift ν, which is the Fourier transform of the "photon time-of-flight distribution" $P(t)$ for the random ensemble,

$$P(t) = \langle |\psi(t)|^2 \rangle = \int \mathrm{d}\nu\, C_E(\nu)\exp(-\mathrm{i}2\pi\nu t) \quad [9]$$

A demonstration of this relation in microwave measurements is shown in **Figure 4**. The spectral width of the field correlation function can be identified with the width of leaky diffuse modes of the sample, and is associated via eqn [9] to the inverse of the mean photon dwell time in the sample. In a manner analogous to eqn [9], the field correlation function with a shift in wave vector, associated with an angular shift in the far field, equals the Fourier transform of the photon intensity distribution on the surface. When both the incident and scattered waves are shifted by the same angle, as when the sample is rotated, the field correlation function with angular shift equals the point spread function, which is the spatial distribution of light on the sample surface associated with excitation at a point. In this case, the field correlation in reflection gives the same angle variation found in the coherent backscattering peak. Either the intensity correlation with scattered angle or the intensity distribution with position on the input surface can be analyzed within an appropriate

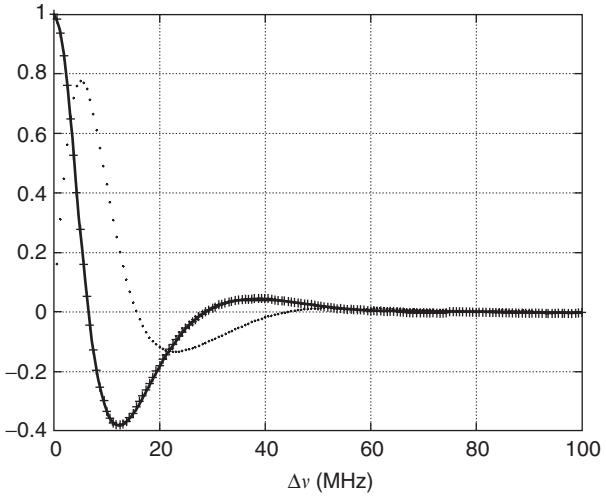

Figure 4 Real and imaginary parts of the field correlation function with frequency shift of the microwave field transmitted in an ensemble of random polystyrene samples in the range 18.5–19.5 GHz. The solid line is the real part of the Fourier transform of the time-of-flight distribution shown in **Figure 2**. (Sebbah *et al.* (2000) *Physical Review E* 62: 7348.)

transport model to give ℓ. As a third example of the relationship between photon distributions and wave correlation, the angular distribution of the scattered intensity $I(\theta)$ and the spatial correlation function of the field are Fourier conjugates. The field within a random medium becomes uncorrelated because of the random phasing of waves arriving at a point from all directions. Within the bulk of the medium, the angular distribution is isotropic, with an uncertainty of $1/\ell$ in the absolute value of the wave number. The normalized field correlation function is

$$F_E(\Delta r) = (\sin(k\Delta r)/k\Delta r)\exp(-\Delta r/2\ell) \quad [10]$$

A measurement of $F_E(\Delta r)$ is shown in **Figure 5**. The right-hand side is just the diffraction-limited Green function for the complex field. The relation between spatial correlation and the Green function is reminiscent of the fluctuation–dissipation theorem. Equation [10] has found important applications in modern seismic imaging.

A final application of Gaussian statistics is quasi-elastic light scattering in multiply scattering media. Diffuse wave spectroscopy measures the time correlation function of the intensity, $C(\tau)$, to retrieve the mean Stokes–Einstein translational diffusion constant of dynamic colloidal suspensions.

Intensity Correlation

Intensity correlations can be subject to non-Gaussian contributions that do not obey the Seigert relation

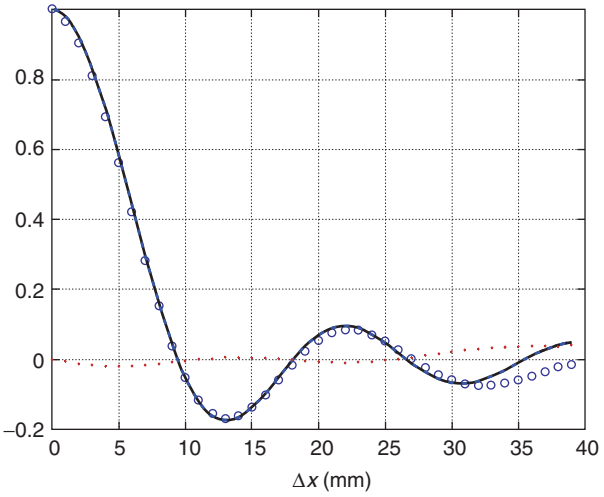

Figure 5 Real and imaginary parts of the spatial field correlation function of the microwave field transmitted in an ensemble of random polystyrene samples in the range 18.5–19.5 GHz. The solid line is the theoretical prediction. (Sebbah *et al.* (2000) *Physical Review E* 62: 7348.)

discussed earlier. These are seen to be long range. As a result, optical flux summed over different incoming or outgoing spots does not self-average. Similarly, the fluctuations of the electronic conductance are greatly enhanced over the value predicted without including correlation between values of intensity for different incident and outgoing modes. Its variance has a universal magnitude, equal to 2/15 in diffusive samples, independent of sample size and scattering strength. This is known as "universal conductance fluctuations" in electronic physics. Calculations and experiments have shown that the relative importance of non-Gaussian correlations is governed by the ensemble average of g.

The cumulant correlation function of transmitted intensity with displacement of either the source or the detector, ΔR and Δr, respectively, or rotation of the corresponding polarizations, $\Delta\Theta$ and $\Delta\theta$, can be expressed as the sum of three terms, with distinctive spatial and polarization dependencies. Let ΔQ and Δq represent the shifts of the source and the detector, respectively, with either position or polarization angle. Each term involves only the sum or the product of the square of the field correlation function, $F = |F_E|^2$ or a constant. The leading-order ("C_1") term is the product $F(\Delta Q)F(\Delta q)$ and decays rapidly with displacements of either the source or detector. The next ("C_2") term is proportional to the sum $F(\Delta Q) + F(\Delta q)$ and decays to half its value when only one of the sources and detectors is displaced. Finally, the third ("C_3") term is proportional to $F(\Delta Q)F(\Delta q) + [F(\Delta Q) + F(\Delta q)] + 1$ and correlates any state of the source to any state of the detector

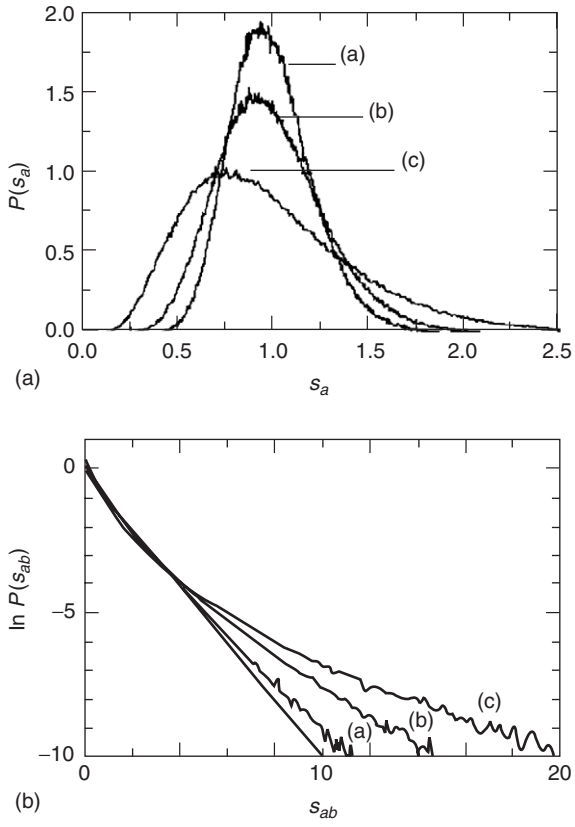

Figure 6 Distributions of total transmission (a) and intensity (b) of microwave radiation transmitted through quasi-1D samples of polystyrene spheres with different values of the variance of normalized transmission equal to the degree of nonlocal correlation: var(s_a) = 0.045 (a); 0.075 (b), and 0.30 (c). (Stoytchev and Genack (1997) *Physical Review Letters* 79: 309.)

as a result of the constant contribution. The C_2 and C_3 terms represent long-range non-Gaussian correlations. If the source is unaffected, $\Delta Q = 0$, so that $F(\Delta Q) = 1$, the cumulant intensity correlation for displacement or polarization rotation may be written as

$$C(\Delta q) = F(\Delta q) + \kappa[F(\Delta q) + 1] \qquad [11]$$

Equation [11] holds both for steady state and for pulsed excitation of a random sample. For pulsed transmission, the degree of correlation depends upon the time delay, t, and line width, σ, of the incident pulse and increases with t. For both steady-state and pulsed measurements, the probability distribution of intensity depends only upon κ. Thus, the degree of correlation determines the statistics of waves in random media (**Figure 6**).

Probability Distributions

The probability distribution of intensity or total transmission is determined exclusively by κ, since

fluctuations in average transmission occur due to extended correlation on the output surface of the sample. Since the intensity distribution is a negative exponential for a fixed value of s_a, the intensity distribution may be written as

$$P(s_{ab}) = \int_0^\infty \mathrm{d}s_a \, P(s_a) \frac{1}{\pi s_a} \exp\left(-\frac{s_{ab}}{s_a}\right)$$

This expression is equivalent to the relation between corresponding moments, $\langle s_{ab}^n \rangle = n! \langle s_a^n \rangle$.

Phase Statistics

At points in the speckle pattern at which the intensity is zero, singularities exist in the spatial distribution of the phase φ_{ab}. The phase, whose tangent equals the ratio of in- and out-of-phase components of the field for a single polarization, is undefined when the amplitude A_{ab} vanishes. It jumps by π-radians as a null in the intensity is traversed, and varies by 2π as such a phase singularity is circled (**Figure 1**). In the diffuse regime, the phase itself is uniformly distributed between $-\pi$ and π and does not provide much useful information. The time delay of a narrow-frequency-band incident pulse crossing the medium is the frequency derivative of the phase, $\tau = \varphi' \equiv \mathrm{d}\varphi/\mathrm{d}\omega$. In nonabsorbing diffusive media, the time delay fluctuates strongly with displacement and has an average value of $\langle \tau \rangle = L^2/6D$, which coincides with the time delay predicted by the diffusion theory of eqn [4]. The variance of τ diverges as a result of the large spectral derivative of the phase near phase singularities.

Both the phase delay time distribution $P(\mathrm{d}\varphi/\mathrm{d}\omega)$ and the joint distribution $P(I, \mathrm{d}\varphi/\mathrm{d}\omega)$ can be calculated for diffusive waves, assuming complex-valued Gaussian statistics. In **Figure 7**, the theoretical prediction assuming Gaussian statistics and the measurements of the joint distribution $P(I, \mathrm{d}\varphi/\mathrm{d}\omega)$ are shown. $P(I, \mathrm{d}\varphi/\mathrm{d}\omega)$ is a Gaussian function for a fixed value of I centered at $\langle \tau \rangle$, with a variance which is inversely proportional to I. For localized waves, the intensity is correlated with the delay time, since at a transmission resonance at which the intensity is high, the dwell time is long. As a result, the average delay time increases with intensity.

Coherent Backscattering

Coherent backscattering is a pertinent counter example of the statement that multiple scattering destroys all interference effects, and an illustration of how mesoscopic wave–particle duality can be

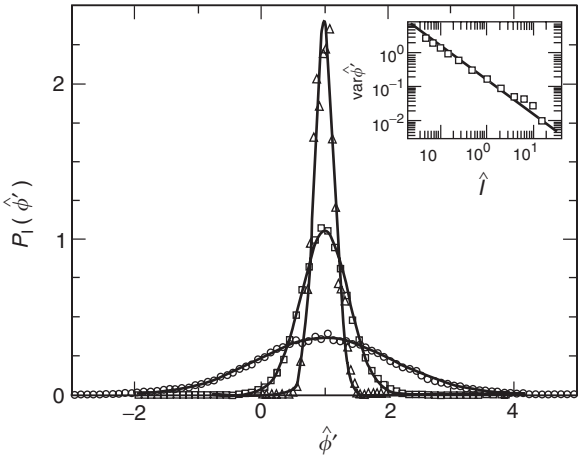

Figure 7 Probability distributions for the normalized delay time $\hat{\varphi}' \equiv \mathrm{d}\varphi/\mathrm{d}\omega / \langle \mathrm{d}\varphi/\mathrm{d}\omega \rangle$ in transmission for fixed values of the normalized intensity I. Circles: $I = 0.1$, squares: $I = 1.0$, and triangles: $I = 10$. The Gaussian curves denote the theoretical predictions. Inset: normalized variance $(\Delta\hat{\varphi}')^2$ of the delay time at fixed normalized intensity I, $(\Delta\hat{\varphi}')^2 = Q/2I$; the solid line gives the theoretical prediction with $Q = 0.31$. (Genack *et al.* (1999) *Physical Review Letters* 82: 715.)

employed. Consider a typical random walk of a wave along an arbitrary sequence of scatterers before being reflected back toward the light source. In the radiative transfer picture, all interference effects are assumed to be washed out upon averaging over all configurations of the particles, and the intensity due to waves following two paths would be given by $|\psi_1|^2 + |\psi_2|^2$. However, in the wave picture, two oppositely propagating waves will always interfere constructively at the source. The reflection of energy is then given by

$$\begin{aligned} R(\theta = \pi) &= |\psi_1 + \psi_2|^2 = |\psi_1|^2 + |\psi_2|^2 + 2\mathrm{Re}(\psi_1 \psi_2^*) \\ &= 2(|\psi_1|^2 + |\psi_2|^2) \end{aligned} \quad [12]$$

which is twice the answer obtained from radiative transfer. Coherent backscattering is a direct consequence of the reciprocity principle. The angular line profile of coherent backscattering is the Fourier transform of the distribution of distances between the entry and exit of reflected photons, and as such a very sensitive way of probing the path length distribution of reflected photons. The algebraic long-range nature of this distribution generates a triangular cusp which is seen in **Figure 8**. It is noticed that the enhancement factor of 2 is lowered when the ℓ/λ ratio approaches unity. This has been attributed to loop-type photon paths in the random medium, which then become numerous and give a flat contribution to the background.

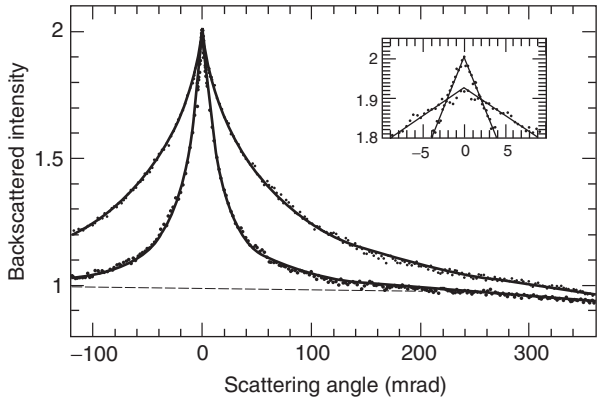

Figure 8 Coherent backscattering of light measured, with two different values for the transport mean free path ℓ. The typical angular width varies as λ/ℓ. Narrow cone: a sample of $BaSO_4$ powder with $\ell/\lambda = 4$, Broad cone: TiO_2 sample with $\ell/\lambda = 1$. The inset confirms the triangular cusp predicted by diffusion theory, and also shows that the maximum enhancement factor is lowered for the sample with small ℓ/λ. (Wiersma *et al.* (1995) *Physical Review Letters* 74: 4193.)

Photon Localization

A key indicator of the nature of propagation in a random medium is the Thouless number, δ, which is the ratio of the typical frequency width and frequency spacing between states of a random medium, $\delta = \delta\nu/\Delta\nu$. The inverse of the level spacing is the density of states of the sample. In the absence of absorption or gain, the Thouless number is equal to the dimensionless conductance, $\delta = g$, which is, in turn, essentially the inverse of κ, introduced earlier. The onset of localization occurs at the point at which $\delta\nu = \Delta\nu$, that is, $\delta = 1$. For $\delta < 1$, transport is inhibited since modes in different blocks, into which one may imagine the sample to be divided, do not overlap.

In order to localize photons, scattering can be maximized by utilizing radiation at a Mie resonance with high-index dielectric spheres. In order not to wash out the resonance, the volume fraction of scatterers should not be too high, while their density should not be too low. At the same time, localization can be facilitated by utilizing low-dimensional sample geometries. Results of microwave propagation in a waveguide containing random mixtures of alumina spheres with index of refraction $m = 3.14$ and volume fraction of 0.068 are shown in **Figure 9**. A narrow window of localization is observed just above the first Mie resonances in a range in which δ achieves its lowest value of just under unity.

The barrier to localizing radiation, even in random media in which the wave is resonant with scatterers, can be seen from a dynamical perspective. $\delta\nu$ drops sharply at resonance, as can be seen in the sharp peak in the average dwell time $\langle \tau \rangle$ (**Figure 9**). This does not result in a diminished value of the Thouless number δ, however, because it is countered by an increase in the density of states corresponding to a drop in $\Delta\nu$. In electronic systems, g can be obtained from the measurement of the conductance G, since $G = (e^2/h)g$, whereas for classical waves it can be found from the measurement of the total transmission T_a, since $g = N\langle T_a \rangle$, where N is the number of transverse modes and for a quasi-1D system given by

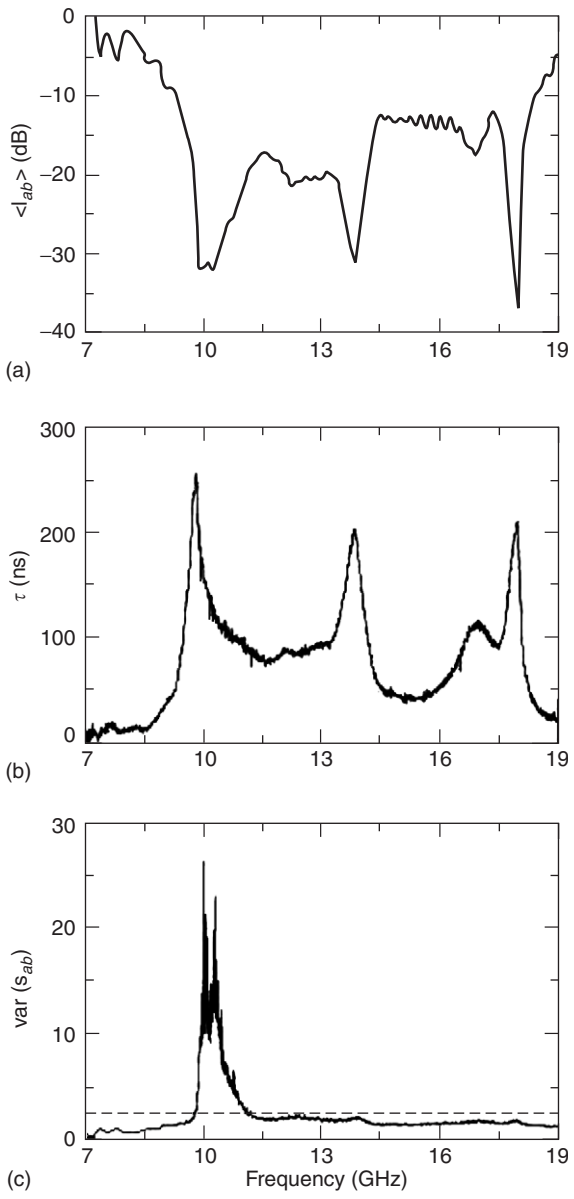

Figure 9 Frequency variation of the (a) average transmitted intensity $\langle I_{ab} \rangle$, (b) average photon transit time, $\tau = \langle s_{ab} \mathrm{d}\varphi_{ab}/\mathrm{d}\omega \rangle$, and (c) var($s_{ab}$) in an ensemble of quasi-1D samples of 0.9 cm diameter alumina spheres contained in a copper tube of diameter 7.3 cm and length 90 cm with reflecting walls and open ends at a spheres volume fraction of 0.067. The dashed line in (c) indicates the localization threshold. (Chabanov and Genack (2001) *Physical Review Letters* 87: 153901.)

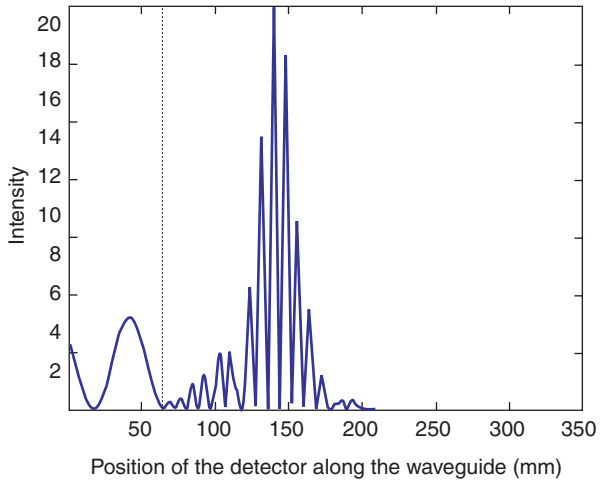

Figure 10 Intensity profile of a localized mode at 14.47 GHz inside a 1D waveguide for a particular random alternation of air and high-index dielectric slabs. The dotted line indicates the interface between the empty waveguide section (left) and the random waveguide section (right).

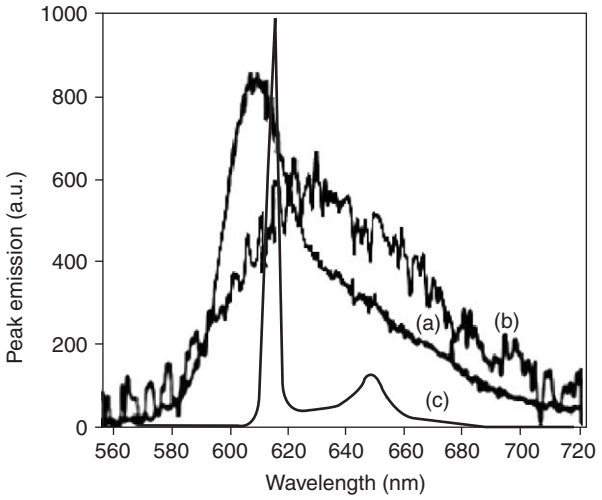

Figure 11 Emission spectra (b) and (c) of a colloidal solution of TiO_2 nanoparticles in rhodamine-640 for increasing pump power, as compared to emission spectrum *a* of pure solution. (Lawandy N M, *et al.* (1994) *Nature* 368: 436.)

$N = Ak^2/2\pi$, in terms of the cross section A of the sample and the wave number $\boldsymbol{k}$. For diffusive waves in nonabsorbing quasi-1D samples of length L, Ohm's law applies: $g = N\ell/L$.

When L exceeds the localization length, $\xi = N\ell$, g falls below the critical value of order unity. Beyond this point, the transmission falls exponentially $\langle T_a \rangle \sim \exp(-L/2\xi)$. In localized samples with $\delta < 1$, the intensity falls exponentially inside the sample between resonances with localized modes. On resonance with a localized mode, the intensity is exponentially localized around a point in the medium. An example of a single localized mode in a 1D random microwave waveguide is shown in **Figure 10**. For a wave resonant with a wave localized near the center of a sample, the wave may rise exponentially in the first half of the sample and then fall exponentially in the second half to produce a value of transmission near unity. States within a medium in which $\delta < 1$, may be coupled when two or more states overlap spatially and spectrally. In this case, the excitation in the coupled modes may extend throughout the medium and provide a path for strong transmission over a spectral range greatly exceeding the width of a single isolated localized state. Such "necklace" states may dominate transmission in many circumstances. Examples of a single localized mode and of two coupled modes in a 1D random microwave waveguide are shown in **Figure 10**.

Random Laser

Though scattering within a laser cavity generally degrades laser performance, stimulated emission can be facilitated in a multiply scattering medium with gain, since the optical dwell time within such media can be enhanced by scattering, thereby increasing the opportunity for stimulated emission. The presence of gain in random media, pumped by an external laser, favors long scattering paths within the gain medium and may facilitate laser action. In diffusive amplifying media, the line width of states of the medium greatly exceeds the typical level spacing $\Delta\nu$, so that many spectrally and spatially overlapping modes are excited simultaneously. Propagation in such systems with "nonresonant" feedback may be described in terms of photon diffusion and incoherent pumping of material energy levels. Emission spectra are narrowed and the temporal profile is greatly shortened above a threshold in pump power (**Figure 11**).

Laser emission in a series of distinct peaks has been observed in thin samples with strong scattering, in which $k\ell \sim 4$. Narrow peaks, observed in the emission spectrum of a semiconductor powder shown in **Figure 12**, are a direct manifestation of laser oscillation with resonant feedback in specific modes. In these samples, the wave is still diffusive, since $\delta > 1$, but the presence of gain allows a few longer-lived optical modes of the excited region to be selected for laser action so that distinct peaks are observed in the lasing spectrum.

The threshold for random lasing is not appreciably lowered below the one for amplified spontaneous emission in homogeneous media, since even though multiple scattering hinders the escape of emission from the medium, the excitation region is shallow

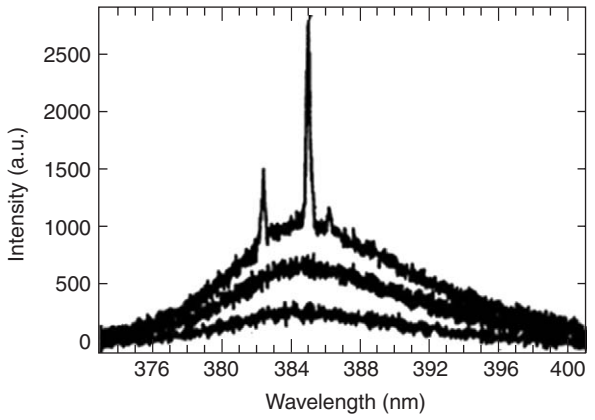

Figure 12 Spectra of emission from a 6 mm thick ZnO powder film for increasing excitation intensity (from bottom to top). (Cao H, *et al.* (1999) *Physical Review Letters* 82: 2278.)

because the flow of the incident pump light into the system is impeded. This limitation has been overcome in localized samples, such as 1D layered media, since modes localized deep within the sample can be resonantly excited by the pump laser. Emission from the excited medium will then occur in long-lived modes which overlap the excitation region. This leads to lasing at low threshold in pump power. In such systems, $\delta\nu \ll \Delta\nu$, and lasing proceeds by resonant feedback. Simulations in one and two dimensions have shown that laser modes are spatially localized and identical to the localized modes of the system without gain.

X-Ray Absorption Spectroscopy

T Jo, Hiroshima University, Higashi-Hiroshima, Japan

Introduction

X-ray absorption spectroscopy is used to measure and study the absorption intensity of incident X-rays in matter such as atoms, molecules, and condensed systems as a function of its energy or wavelength. The recent development of synchrotron radiation as a brilliant source of continuous X-ray has stimulated X-ray absorption spectroscopy. In X-ray absorption spectra, the intensity discontinuously increases at a critical incident energy and the spectra extend to higher energies. The critical incident energy is called the absorption edge or simply the edge. An absorption edge corresponds to the minimum energy needed for ionization by exciting a core electron in atoms and molecules, or that needed to excite a core electron into unoccupied states above the Fermi level in solids. In the absorption spectra, there are structures. Structures from the edge to several tens of eV are called X-ray absorption near edge structure (XANES), and those from the edge to several hundreds of eV are called extended X-ray absorption fine structure (EXAFS). The term X-ray absorption fine structure (XAFS) is also used to represent both XANES and EXAFS. In addition to the energy, X-ray is specified by the polarization, the control of which has recently become feasible in synchrotron radiation. A lot of information about electronic and atomic structures in solids is obtained from X-ray absorption spectroscopy. Here, information about electronic structures obtained from XANES is described. For information about atomic structure obtained from EXAFS, the reader is referred to the "Further reading" section. Since X-ray absorption is a quantum mechanical phenomenon, the electron–photon interaction and the derivation of the expression of the absorption spectrum with the use of Fermi's golden rule are discussed first.

Electron–Photon Interaction

For a system with an electron, the unperturbed Hamiltonian is assumed without the radiation field given by

$$\mathscr{H}_0 = \frac{p^2}{2m} + v(\boldsymbol{r})$$

where m, $\boldsymbol{r}$, and $\boldsymbol{p}$ denote the mass, the position vector, and the momentum of the electron, respectively, and $v(\boldsymbol{r})$ the potential energy acting on the electron. In the presence of the radiation field, the Hamiltonian is, with the use of the vector potential $\boldsymbol{A}(\boldsymbol{r},t)$ and the scalar potential $\phi(\boldsymbol{r},t)$, both of which are $\boldsymbol{r}$ and time (t) dependent, written as

$$\mathscr{H} = \frac{1}{2m}(\boldsymbol{p} + \mathrm{e}\boldsymbol{A}(\boldsymbol{r},t))^2 + v(\boldsymbol{r}) - e\phi(\boldsymbol{r},t)$$

with the charge of electron $-e$. Then the time-dependent perturbation due to the radiation field, that is, the electron–photon interaction $W(t)$ is, neglecting a very small $\boldsymbol{A}^2$ term, written as

$$W(t) = \frac{e}{2m}(\boldsymbol{p}\cdot\boldsymbol{A}(\boldsymbol{r},t) + \boldsymbol{A}(\boldsymbol{r},t)\cdot\boldsymbol{p}) - e\phi(\boldsymbol{r},t)$$

One adopts the Coulomb gauge $\nabla\cdot\boldsymbol{A}(\boldsymbol{r},t) = 0$ and $\phi(\boldsymbol{r},t) = 0$. Then,

$$W(t) = \frac{e}{m}(\boldsymbol{A}(\boldsymbol{r},t)\cdot\boldsymbol{p})$$

For systems with many electrons, $\boldsymbol{p}$ is replaced by the summation $\sum_i \boldsymbol{p}_i$, where $\boldsymbol{p}_i$ denotes the momentum of the ith electron. $W(t)$ represents the annihilation of a photon upon exciting an electron from the state with a lower energy to that with a higher energy (absorption) or the creation of a photon accompanied by the transition of an electron from the state with a higher energy to that with a lower energy (emission). In X-ray absorption, the state with the lower energy is a core state of an atom and that with the higher energy is an unoccupied valence state.

X-Ray Absorption Spectra

Let $|i\rangle$ be a many-body initial state of X-ray absorption, where core states and valence states up to the Fermi level are occupied by electrons. Let $|f\rangle$ be the fth many-body final state of X-ray absorption, where a core electron of an atom is transferred to an

unoccupied valence state upon absorbing a photon with energy $\hbar\omega$. Then, according to Fermi's golden rule, the transition probability per unit time from the initial state to the final state by the perturbation $W(t) = We^{-iwt}$, that is, the X-ray absorption spectrum $F(\omega)$ as a function of ω is expressed as

$$F(\omega) = \frac{2\pi}{\hbar} \sum_f |\langle f|W|i\rangle|^2 \delta(E_i + \hbar\omega - E_f)$$

where E_i and E_f denote the energy of $|i\rangle$ and $|f\rangle$, respectively. $F(\omega)$ is proportional to the ω-dependent absorption coefficient. The core hole has a lifetime due to the Auger process and decays exponentially with time. Then the δ function must be replaced by the Lorenzian $(\Gamma/\pi)/[(E_i + \omega - E_f)^2 + \Gamma^2]$ with the lifetime broadening Γ.

Spectra in a One-Electron Picture

Let the following three conditions be satisfied: (1) The matrix element $\langle f|W|i\rangle$ is dependent on ω only weakly. (2) The energy of $|i\rangle$ is expressed as the summation of occupied one-electron energies

$$E_i = \varepsilon_c + \sum_k \varepsilon_k$$

where ε_k and ε_c denote the energies of occupied conduction-band states with the wave vector k and of the core state, respectively. (3) The energy of $|f\rangle$ is also expressed as the summation of one-electron energies as

$$E_f = \varepsilon_{k'} + \sum_k \varepsilon_k$$

where $\varepsilon_{k'}$ denotes the energy of the conduction-band state with the wave vector k' unoccupied in $|i\rangle$; the one-electron states are not affected by the core hole produced in the final state of X-ray absorption. Then the absorption spectrum is expressed as

$$F(\omega) \sim \sum_{k'} \delta(\varepsilon_c + \hbar\omega - \varepsilon_{k'})$$

This means that, aside from the constant factor, $F(\omega)$ is approximately proportional to the density-of-states (DOS) of unoccupied conduction-band states, and this expression is widely used to obtain information about unoccupied states in solids.

Final-State Interaction

There are many examples where $F(\omega)$ is different from the expected DOS above the Fermi level ε_F. The attractive interaction of a core hole acting on the valence electron, which is produced in the final state, causes a reconstruction of both occupied and unoccupied valence states. This is called the final-state interaction. In the following, some examples of the same are presented.

Fermi Edge Singularity

In some metals, the core absorption spectra are known to exhibit singular behavior as a function of the incident photon energy near the absorption threshold just above ε_F. In **Figure 1**, such examples observed in alkali metals for p core absorption are shown, where the spectra exhibit a spike just above ε_F.

If the condition (3) described in the last section is not satisfied, then the photoproduced core hole acts as an attractive potential on conduction electrons. Consider a constant negative matrix element V representing the scattering of electrons, which is independent of electron wave numbers, that is, the

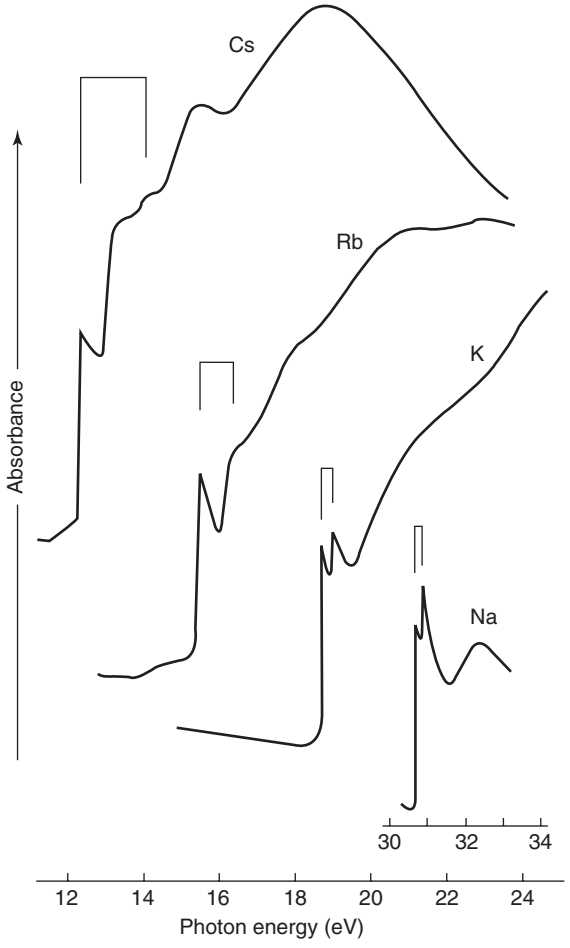

Figure 1 Optical absorption spectra of outermost *p*-shell electrons in Na, K, Rb, and Cs. Pairs of spikes linked by vertical bars correspond to the core spin–orbit splitting. (Reproduced with permission from Ishi T, *et al.* (1977) *Journal of Physical Society of Japan* 42: 876–881.)

δ function-type potential. Then $F(\omega)$ is, near ε_F, expressed as

$$F(\omega) \propto \left(\frac{1}{\hbar\omega + \varepsilon_c - \varepsilon_F}\right)^{\alpha}$$

where the index α is given by $\alpha = -2VN(\varepsilon_F)$ with the DOS at ε_F of the conduction electron $N(\varepsilon_F)$. α is a dimensionless parameter of $O(1)$. Since V is negative, α is positive and $F(\omega)$ is, therefore, enhanced for $\hbar\omega + \varepsilon_c$ near ε_F. This is called the Fermi edge singularity (or anomaly). In metals, the excitation energy starts continuously from zero due to the presence of ε_F. To the external perturbation V, the response of conduction electrons accompanied by low-energy excitations, which are peculiar to metals, causes the singularity.

Satellite Structures

The core hole produces another structure in the absorption spectrum. For example, in metallic cerium compounds, the localized $4f$-level is often just below ε_F and $|i\rangle$ is expressed as a superposition of the $4f^0$ configuration with a smaller weight and the $4f^1$ one with a larger weight due to the hybridization between the $4f$-state and the conduction band. By the $3d \rightarrow 4f$ X-ray absorption, the $4f^0$ configuration is transferred to the $4f^1$ one and the $4f^1$ one to the $4f^2$ one, both of which are accompanied by a $3d$ core hole. $V(<0)$ denotes the attractive potential of the core hole acting on the $4f$-electron and, $U(>0)$, the $4f$–$4f$ repulsion. Then the energy of $4f^1$ is $\sim V$ and that of $4f^2$ is $\sim 2V + U$ in the final state, if measured from a suitable origin of energy. The absorption spectrum is then characterized by the main peak ($4f^2$) and the satellite ($4f^1$) separated by $\sim|V + U|$. Combined with other X-ray spectroscopies, X-ray absorption gives information about U and the relative weight of $4f^0$ and $4f^1$ in $|i\rangle$. Similar satellite structures are observed in many systems, including transition-metal compounds, and they are used to extract information about electronic structures.

Multiplet Structures

In the $3p$ (or $2p$) $\rightarrow$ $3d$ X-ray absorption for insulating $3d$ transition-metal compounds, in addition to the $3d$–$3d$ multipole interaction, the strong $3d$–$3p$ (or $3d$–$2p$) multipole interactions, both of which are described by the Slater integrals, contributes to the energy splitting in the final state and the splitting is reflected in the spectrum. This is called the multiplet structure and is usually peculiar to the atomic configuration in the initial state. The multiplet structure, therefore, often plays the role of a fingerprint in identifying the configuration. Multiplet structures are also observed in the $4d$ (or $3d$) $\rightarrow$ $4f$ X-ray absorption for $4f$ rare-earth compounds.

Selection Rules for Electric Dipole Transition

Since the electric field $\boldsymbol{E}(\boldsymbol{r}, t)$ is expressed as $\boldsymbol{E}(\boldsymbol{r}, t) = \partial\boldsymbol{A}(\boldsymbol{r}, t)/\partial t$ for $\phi = 0$, the relation $\boldsymbol{A}(\boldsymbol{r}, t) = (-\mathrm{i}/\omega)\boldsymbol{E}(\boldsymbol{r}, t)$ is obtained with noting the time-dependent factor $\mathrm{e}^{-\mathrm{i}\omega t}$. Then the time-independent part of the electron–photon interaction W is rewritten as $W = -\mathrm{i}(\mathrm{e}/m\omega)\boldsymbol{E}(\boldsymbol{r}) \cdot \boldsymbol{p}$, where $\boldsymbol{E}(\boldsymbol{r}) = \boldsymbol{E}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}$ represents the plane wave with the amplitude of electric field $\boldsymbol{E}$ and the wave vector $\boldsymbol{k}$. Furthermore, $\boldsymbol{p}$ in W can be replaced by $\boldsymbol{r}$ with the use of the commutation relation

$$\frac{\boldsymbol{p}}{m} = \dot{\boldsymbol{r}} = \frac{\mathrm{i}}{\hbar}[H_0, \boldsymbol{r}],$$

$$H_0|i\rangle = E_i|i\rangle, \qquad H_0|f\rangle = E_f|f\rangle$$

and the relation $\hbar\omega = E_f - E_i$ in the absorption spectrum $F(\omega)$ in terms of Fermi's golden rule. Then

$$F(\omega) = \frac{2\pi}{\hbar}\sum_f |\langle f|\boldsymbol{E}(\boldsymbol{r}) \cdot e\boldsymbol{r}|i\rangle|^2 \delta(E_i + \hbar\omega - E_f)$$

is obtained. For systems with many electrons, $e\boldsymbol{r}$ is replaced by $e\sum_i \boldsymbol{r}_i$, the electric dipole of a system. $\boldsymbol{E}(\boldsymbol{r})$ is expanded as

$$\boldsymbol{E}(\boldsymbol{r}) = \boldsymbol{E}(1 + \mathrm{i}\boldsymbol{k} \cdot \boldsymbol{r} + \cdots)$$

The contributions to the spectrum of the first and second terms are called the electric dipole (E1) and the quadrupole (E2) transitions, respectively, and so on. The wave length of photons with energy from several eV to several keV is in the range of several thousand Å to several Å. It is much larger compared to the spatial extension of the atomic wave function of a core electron of a few or several tenths of Å, that is, $\boldsymbol{k} \cdot \boldsymbol{r} \ll 1$. This means that the dominant contribution to the spectrum is the E1 transition.

Let a system be in spherical symmetry, where $|i\rangle$ and $|f\rangle$ are specified by the values of total angular momenta J and J', respectively, and the values of their z components J_z and J_z', respectively. In the E1 transition, there exists an allowed relation between J and J', that is, the condition of the nonzero matrix element of the electric dipole operator. This is called the selection rule of the total angular momentum.

The inversion operator I transforms $\boldsymbol{r}$ into $-\boldsymbol{r}$. Since $I^2 = 1$, the eigenvalue of I is either $+1$ (even parity) or -1 (odd parity). In order to have a nonzero matrix element for $\langle i|\boldsymbol{r}|f\rangle$, the initial and final states must have parities different from one another. For a transition of a single electron, let l and l' be the orbital angular momentum of the initial (core) and final (valence) states, respectively. Then $l - l' = \pm 1$ and the spin states must be the same. For a system with many electrons and a spin–orbit coupling, $J - J' = 0, \pm 1$ (but $J = J' = 0$ is forbidden).

By choosing the electric polarization of an incident photon, the difference in the z component of angular momenta between the initial and final states is controlled. $\boldsymbol{E}\cdot\boldsymbol{r}$ in the above expression of $F(\omega)$ is, with their x, y, and z components, expanded as $E_x x + E_y y + E_z z$ or, with use of the spherical harmonics $Y_{lm}(\theta,\phi)$, expanded as

$$\boldsymbol{E}\cdot\boldsymbol{r} = \sum_{\mu=-1,0,1} E_\mu \sqrt{\frac{4\pi}{3}} Y_{1\mu}(\theta,\phi) r$$

where $E_\pm = (\pm E_x - \mathrm{i}E_y)/\sqrt{2}$ and $E_0 = E_z$. For the photon polarized along the z axis ($\mu = 0$), that is, the quantization axis, $J'_z - J_z = 0$. For the left (right) circularly polarized photon ($\mu = +1(-1)$), $J'_z - J_z = +1(-1)$.

Dichroism and Sum Rules

The difference in X-ray absorption between two kinds of incident polarizations is called dichroism, since the difference in absorption means the difference in the color of substances in the visible light region. Recently, due to the development of synchrotron radiation, both linearly and circularly polarized X-rays with high polarization became available and, their extensive use has led to various kinds of dichroism studies being carried out.

In the above expression of $F(\omega)$ in terms of Fermi's golden rule, $|\langle i|W|f\rangle|^2$ is rewritten as $\langle i|W^+|f\rangle\langle f|W|i\rangle$ with W^+ being the Hermite conjugate of W. If $F(\omega)$ is integrated with respect to ω in the region to cover E_f's for a given W, and $|f\rangle$'s can be regarded as a complete set, one obtains, with the closure relation $\sum_f |f\rangle\langle f| = 1$,

$$\int F(\omega)\,\mathrm{d}\omega = \frac{2\pi}{\hbar}\langle i|W^+W|i\rangle$$

that is, the integrated intensity being the expectation value of W^+W in the initial state. By employing this, some sum rules that relate the integrated intensities to physical quantities of the valence state are derived.

For ferromagnets, the difference between the right- and left-circular-polarizations with respect to the direction of magnetization is called magnetic circular dichroism. Let $I_+(I_-)$ be the integrated absorption intensity for the left (right)-circular-polarization and let I_0 be the integrated absorption intensity for $\mu = 0$ (linear polarization) from the core state with one-electron orbital angular momentum l_1 to the valence state with l_2 by the E1 transition. Then the relation

$$\frac{I_+ - I_-}{I_+ + I_0 + I_-} = \mathrm{sign}(l_1 - l_2)\frac{\langle L_z\rangle}{l_2 n_h}$$

is known as the L_z sum rule, where $\langle L_z\rangle$ and n_h denote the expectation value of the z component of the orbital angular momentum and the number of holes in the valence state, respectively. By the core spin–orbit interaction, the spectrum often splits into two regions. Let $(I_+ - I_-)_+((I_+ - I_-)_-)$ be the integrated dichroic intensity for the $j_+ = l_1 + \frac{1}{2}(j_- = l_1 - \frac{1}{2})$ region. If the separation between the two regions is sufficiently large, the relation

$$\frac{(I_+ - I_-)_+ - (l_1+1)/l_1(I_+ - I_-)_-}{I_+ + I_0 + I_-} = A(l_1,l_2)\frac{\langle S_z\rangle}{n_h} + B(l_1,l_2)\frac{\langle T_z\rangle}{n_h}$$

is satisfied and it is known as the S_z sum rule, where $\langle S_z\rangle$ and $\langle T_z\rangle$ denote the expectation values of the z components of the spin and the spin dipole defined by

$$\boldsymbol{T} = \sum_i [\boldsymbol{s}_i - 3\boldsymbol{r}_i(\boldsymbol{r}_i\cdot\boldsymbol{s}_i)/r_i^2]$$

respectively, in the valence state; $A(l_1,l_2)$ and $B(l_1,l_2)$ are the known rational functions of l_1 and l_2. A combined use of both the L_z and S_z sum rules has recently been a standard method of site-selective determination of both $\langle L_z\rangle$ and $\langle S_z\rangle$ from dichroic data. In some cases, the mixing between j_+ and j_- regions can be appreciable due to the core–valence multipole interaction, although they are apparently separated, that is, $|f\rangle$'s in each region cannot be regarded as a complete set. Then the deviation from the S_z sum rule can be appreciable. It may also be noted that there is a sum rule to relate the integrated dichroic intensity for two kinds of linear polarizations to a component of the quadrupole moment.

Nomenclature

$\boldsymbol{A}$	photon vector potential
e	unit of charge of an electron
$\boldsymbol{E}$	electric field
E_i, E_f	energies of the initial and final states of X-ray absorption
$F(\omega)$	X-ray absorption spectrum
$\hbar$	Planck's constant/2π
$\mathscr{H}, \mathscr{H}_0$	Hamiltonian operators with and without the radiation field
$\boldsymbol{k}$	wave vector of electric field
L_z	z component of total orbital angular momentum in units of $\hbar$
m	mass of an electron
$\boldsymbol{p}$	linear momentum of an electron
$\boldsymbol{r}$	position vector
$\boldsymbol{s}_i$	spin vector of the ith electron
S_z	z component of total spin in units of $\hbar$
$\boldsymbol{T}, T_z$	total spin dipole vector and its z component
Γ	lifetime broadening
ε_k	energy of an electron with the wave vector k
ε_F	Fermi level
ϕ	photon scalar potential
ω	photon frequency

X-Ray Sources

A Pifferi, CNR – Institute of Crystallography, Rome, Italy

X-ray is nowadays one of the most powerful tools to investigate hard and soft matter, hence the necessity to develop new sources to achieve more high-intensity beams.

Introduction

X-ray was the name given by W C Roentgen to the highly penetrating rays, which emanated when high-energy electrons struck a metal target. On 8 November 1895, he noted for the first time this phenomenon and on 28 December 1895, he astonished the scientific world with his preliminary report *Ueber eine neue Art von Strahlen* (along with experimental radiographs and by the X-ray image of his wife's hand) given to the president of the Wurzburg Physical-Medical Society. A few weeks later, C H F Muller was able to construct in his Hamburg factory the first commercial X-ray tube for one of the local hospitals. This was a milestone of what was to become a major technical industry. X-ray technology is one of the most important inventions of the nineteenth century. It plays a major role in our daily life.

Conventional Sources

X-Ray Tube

Whenever a charged particle is accelerated or decelerated, it emits energy in the form of photons. This process takes place within an X-ray tube to create X-rays. At one end of the tube is the source of electrons or the cathode, and at the other end of the tube is the metal target, or anode. To produce X-rays, electrons are accelerated from the cathode to the anode with a high voltage. When the electrons hit the anode, they are quickly stopped. This rapid change in speed causes the emission of X-ray photons. These X-rays are commonly called brehmsstrahlung or "braking radiation." Bremsstrahlung is the German word for slowing down or braking; this radiation can be considered radiation, resulting from the braking or projectile electrons by the nucleus.

An electron that completely avoids the orbital electrons on passing through an atom of the target may travel sufficiently close to the nucleus of the atom to come under its influence. Since the electron is negatively charged and the nucleus is positively charged, there is an electrostatic force of attraction between them. As the electron approaches the nucleus, it is influenced by a nuclear force much stronger than the electrostatic attraction. As it passes by the nucleus, it is slowed down and deviated in its course, leaving with reduced kinetic energy in a different direction. This loss in kinetic energy reappears as an X-ray photon.

If all the energy carried by an electron is transformed into radiation, the energy of an X-ray photon is

$$E_{\max} = h\nu_{\max} = \text{eV}$$

where $E_{\max}$ is the maximum possible energy, h the Planck's constant, $\nu_{\max}$ the photon frequency, e the charge of the electron, and V the acceleration potential. If the frequency is substituted with the wavelength, the above expression becomes

$$h\nu_{\max} = hc/\lambda_{\min} = \text{eV} \quad \text{and}$$
$$\lambda_{\min} = hc/\text{eV} = 12\,398/V$$

The energy contained in each bremsstrahlung photon emitted from an X-ray tube extends from that associated with the peak electron energy all the way down to zero. In other words, when an X-ray tube is operated at 70 kVp, bremsstrahlung photons with energies ranging from 0 to 70 keV are emitted, creating a typical continuous X-ray emission spectrum. Since total conversion of the electron energy into radiation is not a highly probable event, the radiation of the highest intensity is obtained at a longer wavelength compared to $\lambda_{\min}$ (1.5 times). **Figure 1** shows some X-ray continuous spectra as a function of the accelerating voltage.

If the bombarding electrons have sufficient energy, they can knock an electron out of an inner shell of the target metal atoms. Then electrons from higher states drop down to fill the vacancy, emitting X-ray photons with precise energies determined by the electron energy levels. These X-rays are called characteristic X-rays. In summary, characteristic X-rays are produced by transitions of orbital electrons from outer to inner shells. Since the electron binding energy for every element is different, the characteristic X-rays produced by the various elements are also different. This type of X-radiation is called characteristic radiation because it is characteristic of the target element. The effective energy characteristic X-rays increase with increasing atomic number of the target element. The characteristic lines of this type of spectrum are called K, L, and M and correspond to the transition from higher energy orbital to the K, L, and M orbital. When the two orbitals involved in the transition are adjacent then the line is called α, if they are separated by another shell the line is called β (**Figure 2**).

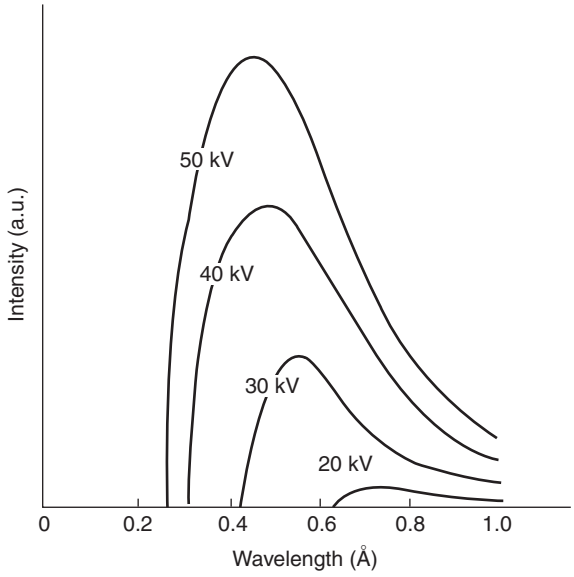

Figure 1 X-ray radiation spectra as a function of accelerating voltage.

For example, K electrons for tungsten anode have binding energies of 69.5 keV, and L electrons are bound by 12.1 keV. Therefore, the characteristic X-ray emitted has energy of

$$69.5 - 12.1 = 57.4 \text{ keV}$$

Sealed Tube and Rotating Anode Sources

The X-ray tube is a large diode valve, which is designed to produce fast moving electrons and then cause the electrons to decelerate rapidly in a vacuum environment. A conventional generator consists of a high-voltage power supply electronically controlled, applied between the anode and the cathode. In **Figure 3** the sketch of a sealed tube is showed.

It consists of a cathode with a filament that emits the electrons that are accelerated under vacuum by the high voltage. The electrons hit the anode and produce the characteristic X-ray spectrum relative to the metal of the anode. The high vacuum is necessary because the presence of gas molecules would decrease the efficiency of the tube. Normally this type of source is highly inefficient because only 0.1% of power used is transformed into X-ray, the rest is dissipated as heat. In the rotating anode the anode

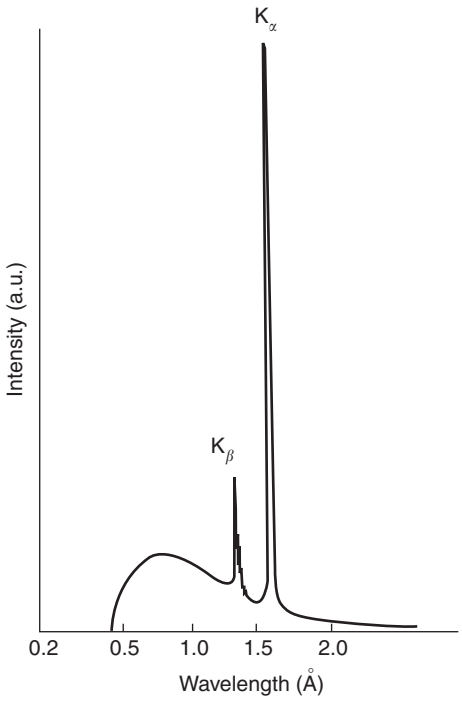

Figure 2 Characteristic lines K_α and K_β of Cu spectra superimposed on the brehmsstrahlung.

has a cylindrical shape, and to increase the efficiency of the X-ray beam the anode is continuously rotated. Thus the electron beam hits the metal of the anode in different positions permitting a better dissipation of heat. The increasing of the intensity of the beam may be quite an order of magnitude in respect to a sealed tube.

The intensity of a K line can be calculated using the equation:

$$I_K = Bi(V - V_K)^{1.5}$$

where B is a constant, i the electrical current, and V_K the excitation potential of the K series. If the accelerating potential $V = 4V_K$ is applied, the Kα line is 90 times more intense than the white radiation of the equivalent wavelength (I_W). In this condition the ratio I_K/I_W is a maximum.

Synchrotron Sources

Synchrotron radiation (SR) is emitted when charged particles moving with relativistic speeds are forced to follow curved trajectories in magnetic fields. The first visual observation of SR was in 1948 from the General Electric synchrotron in the USA, during investigations into the design and construction of accelerators suitable for the production of very high

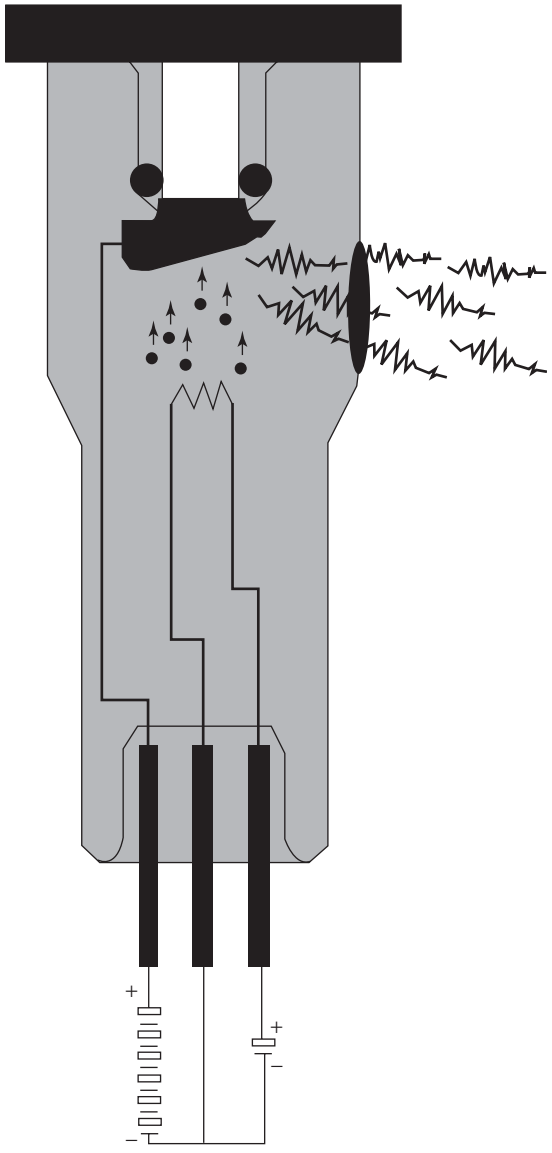

Figure 3 Sketch of a sealed X-ray tube.

energy electrons. Over the next 50 years, an explosive growth in the building of accelerators optimised for SR production has turned this interesting radiative energy into a valuable research tool.

Whenever charged particles undergo an acceleration, they emit electromagnetic radiation. An electron oscillating at radiofrequencies in an antenna emits radio waves. When electrons are subjected to an acceleration perpendicular to their velocity, for example, when they pass through a magnetic field, their direction is changed and they begin to travel in a circular path. Charged particles moving under the influence of an accelerating field emit electromagnetic radiation. The energy of this radiation is dependent on the velocity of the particle. The total instantaneous power P emitted by an electron

moving on a circular orbit is

$$P = \frac{2e^2cE^4}{3R^2(m_0c^2)^4} = \frac{2e^2c\gamma^4}{3R^2} \qquad [1]$$

where P is the energy emitted per unit time, e is the particle charge, c the speed of light, E the energy of the particle, m_0 its mass at rest, and R the bending radius of the orbit. The emitted radiation has very different characteristics in dependence of the velocity v of the particle. If $v \ll c$ the emitted pattern is identical to the well-known dipole radiation field (**Figure 4a**). When the speed increases to almost light velocity, the whole power is compressed into a narrow cone in forward direction tangentially to the orbit (**Figure 4b**). The radiation emitted is called synchrotron radiation. The quantity γ in eqn [1], which is the ratio of the total energy to the rest energy of the particle, is of considerable importance since it is related to the opening angle $\Delta\Psi$ of the cone of radiation in the perpendicular plane of the orbit by

$$\Delta\Psi \cong 1/\gamma$$

where $\Delta\Psi$ is expressed in radians.

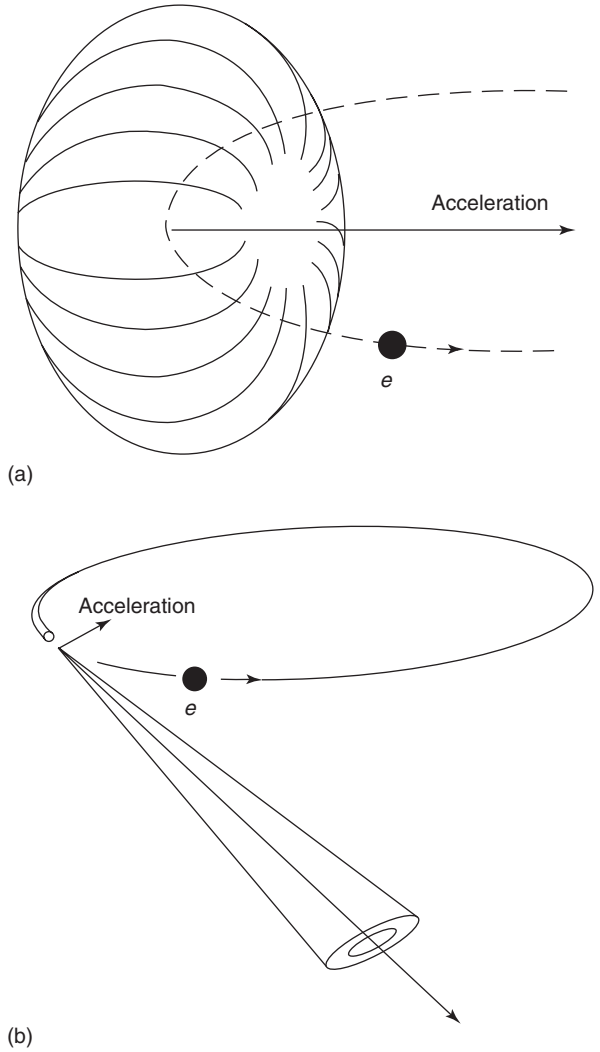

Figure 4 Emission pattern of radiation from centripetally accelerated electrons: (a) nonrelativistic case $v \ll c$, (b) relativistic case $v \cong c$.

A storage ring synchrotron consists of an arrangement of devices, where charged particles travel at essentially the speed of light in evacuated pipes under the influence of magnets, which are positioned around a closed orbit. Acceleration is achieved by the application of radio frequency electric fields at RF cavities along the circumference of the ring. The magnetic fields are increased synchronously with the acceleration in order to keep the particles on the constant radius path. Such accelerators can be used with protons or electrons, and even with heavier positive ions. The particles travel in the closed loop for periods of several hours while synchrotron radiation is emitted from all curved parts of the orbit.

In general, three kinds of magnets are used to make the necessary magnetic fields: bending magnets, wigglers, and undulators.

Bending Magnets

In bending magnets, a simple dipole structure is used to constrain the electrons in a curved path. The radiation emitted is extremely intense and extends over a broad wavelength range from the infrared through the visible and ultraviolet, and into the soft and hard X-ray regions of the electromagnetic spectrum. A typical output curve for a bending magnet source has a smooth spectral distribution with a broad maximum near the so-called critical wavelength. This critical wavelength depends on the square of the energy of the electrons and the bending radius in the dipole. In practical units of angstroms, it can be calculated as

$$\lambda c = 18.64/(B * E^2)$$

where B (the dipole field) is in tesla and E (the ring energy) is in GeV. The critical wavelength (or energy) has the property that one-half of the power is radiated above this wavelength and one-half below.

Wigglers

High-field wiggler magnets are often used as sources in order to increase the flux at shorter wavelengths. It is best to think of a wiggler as a sequence of bending magnets of alternating polarities, which gives a $2N$ enhancement in the flux, where N is the number

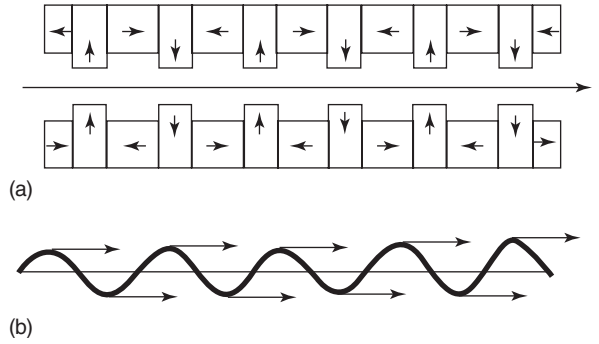

Figure 5 (a) The arrangement of magnets within a wiggler. Horizontal arrows indicate permanent magnet, vertical arrows indicate magnetic steel. (b) The trajectory of an electron beam within a wiggler. The arrows symbolize the emitted synchrotron radiation.

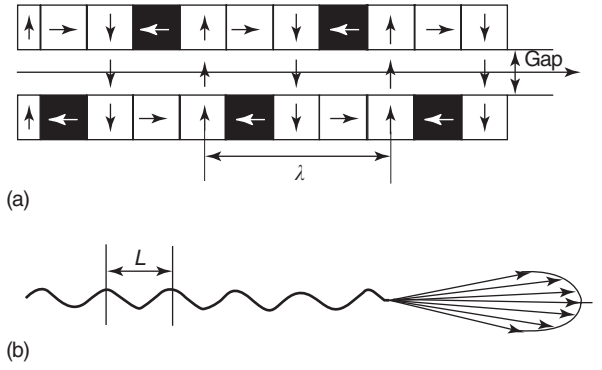

Figure 6 (a) The arrangement of magnets within an undulator. (b) The characterization of the undulator radiation. *L* is the period length.

of poles (**Figure 5**). Each magnet bends the electron beam through an angle which is large compared with mc^2/E. The properties of wiggler SR are thus very similar to that of dipole radiation with a reduction in the critical wavelength as a consequence of the higher field. For superconducting wiggler magnets a value of 6 T, as opposed to around 1.2 T for conventional dipoles, would be typical. The characteristics of the synchrotron radiation from the wiggler are the same as from the bending magnet, and so, the critical energy plays a determinant role. To reach the same spectral range as from the bending magnets, the magnetic flux density within the wigglers must be the same as within the bending magnets; if the magnetic field in the wiggler is higher than the ring bending magnet field, the wiggler spectrum extends to a higher photon energy. The photon flux as well as the central intensity of the radiation emitted by the wiggler is the same as from the bending magnet but more intensive by a factor Np, where Np is the number of poles within the wiggler.

Undulators

An undulator magnet is similar to a wiggler, in that it is also a succession of alternating magnetic poles (**Figure 6a**). However, in this case the angle of bend in each pole is of the order of mc^2/E, so that the small angular divergence due to the emission pattern of synchrotron radiation is not significantly increased. The radiation emitted at the various poles interferes coherently resulting in the emission of a pencil-shaped beam (**Figure 6b**) peaked in narrow energy bands at the harmonics of the fundamental energy. For N poles, the beam's opening angle is decreased by $N^{1/2}$ and thus the intensity per solid angle increases as N^2.

Figure 7 shows the performance in terms of brilliance of bending magnets, wigglers, and undulators for a 6 GeV energy synchrotron with a current in the ring of 100 mA.

Synchrotron radiation characteristically is highly polarized and continuous. Its intensity and frequency are directly related to the strength of the magnetic field and the energy of the charged particles affected by the field. Accordingly, the stronger the magnetic field and the higher the energy of the particles, the greater the intensity and frequency of the emitted radiation. The high intensity, broad spectral range, and other properties such as collimation, polarization, pulsed-time structure, partial coherence, make synchrotron radiation a powerful tool for basic and applied studies in biology, chemistry, medicine, and physics, as well as in applications to technology such as X-ray lithography, micromechanics, materials characterization, and analysis. Brilliance of synchrotron sources, up to $\sim 10^{10}$ larger than an X-ray tube, is mostly due to much smaller angular divergence. This is important because many experiments use small samples (e.g., protein crystals) that can use only a tiny fraction of radiation emitted by the tube. Much higher intensity makes it possible to observe very weak signals not observable with a tube source; much tighter angular collimation is especially important for small samples, for example, protein crystals, high pressure applications etc. By the use of special optical elements such as monochromators, single energies may be selected among the continuous spectrum of SR; this energy tunability is of extreme importance, especially for experiments driven near the absorption edge of specific elements.

Fourth Generation Light Sources

Future sources will be similar to existing storage ring sources. Some experiments require higher brightness,

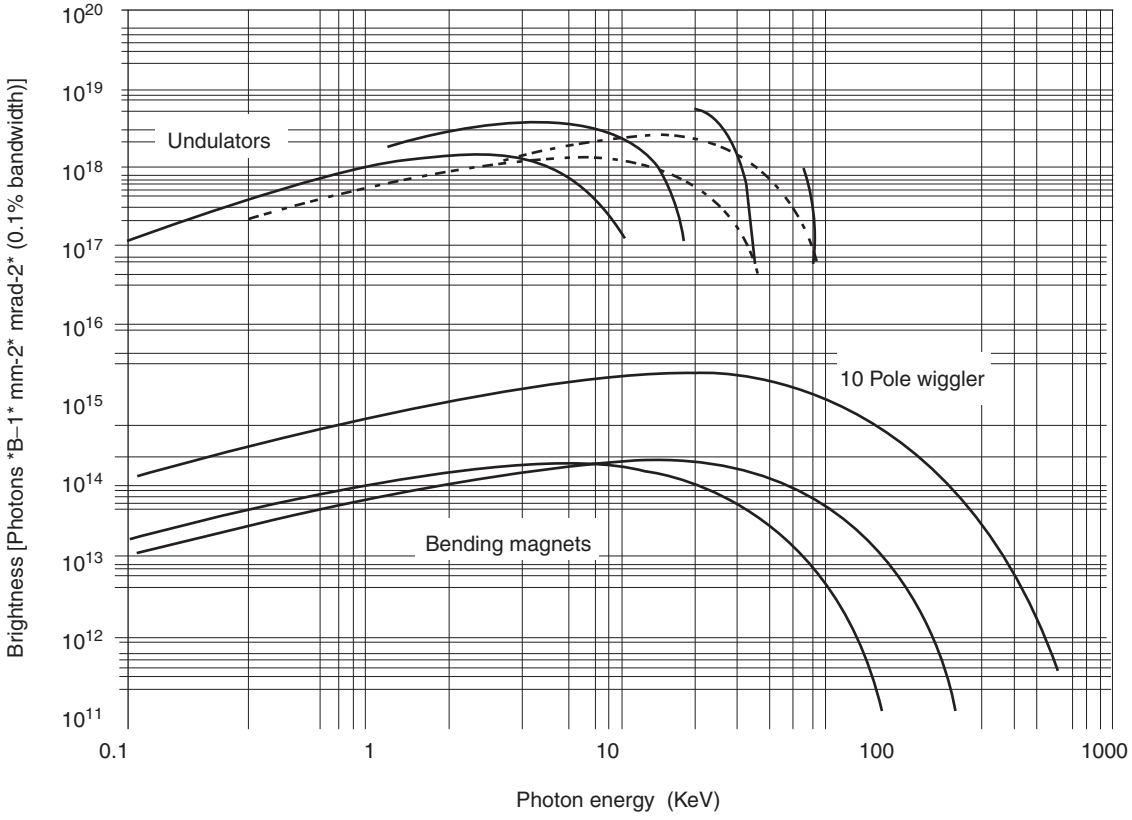

Figure 7 Plot of brilliance vs. photon energy for a storage ring of 6 GeV energy and 100 mA current.

coherence, peak power, or an extension of some other property of the radiation. Present sources are far from fundamental limits on the brightness and power of the radiation that can be produced. Concepts for future sources have been pursued at several laboratories, but the direction for the development of fourth generation light sources has been pointed out on free electron lasers (FELs). Such sources would produce radiation with brightness several orders of magnitude higher than undulators on third-generation rings. The graph in **Figure 8** shows the trend of the growth of the brilliance of X-ray sources starting from the beginning of the twentieth century.

Radiation from an FEL has much in common with radiation from a conventional optical laser, such as high power, narrow bandwidth, and diffraction limited beam propagation. One of the main differences between the two lasers is the gain medium: in a conventional laser the amplification comes from the stimulated emission of electrons bound to atoms, either in a crystal, liquid dye, or a gas, whereas the amplification medium of the FEL are "free" (unbound) electrons. The free electrons are stripped from atoms in an electron gun and are then accelerated to relativistic velocities. While the electrons are propagating in an undulator, the interaction with

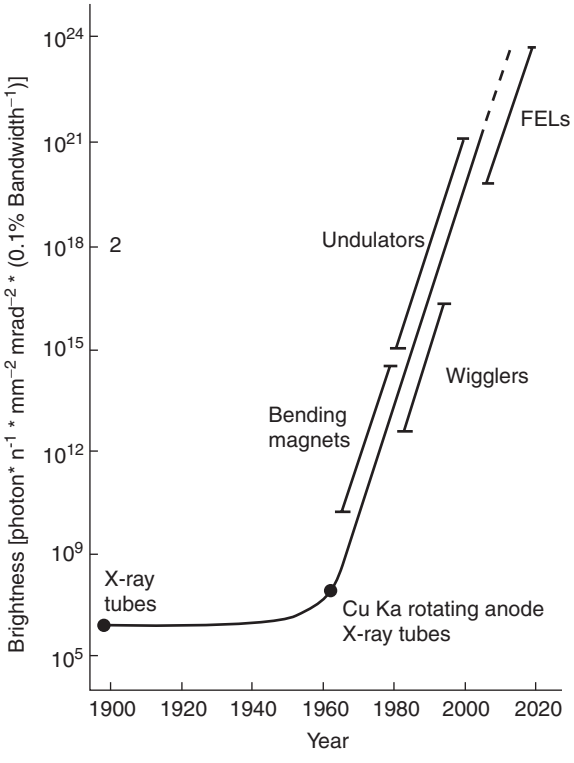

Figure 8 Trend of the brightness of X-ray sources plotted starting from the beginning of 1900.

an electromagnetic radiation field leads to an exponential growth of the radiation emitted by the electrons. This amplification of radiation is initiated by an increasingly pronounced longitudinal density modulation of the electron bunch. The initial radiation field can be an external one, for example, a seed laser, or an "internal" field, that is, the spontaneous emission of the undulator. In the latter case it is called a self amplified spontaneous emission (SASE) FEL. Oscillating through the undulator, the electron bunch then interacts with its own electromagnetic field created via spontaneous emission. Depending on the relative phase between radiation and electron oscillation, electrons experience either a deceleration or acceleration: electrons that are in phase with the electromagnetic wave are retarded, while the ones with opposite phase gain energy. Through this interaction a longitudinal fine structure, the so-called micro-bunching which amplifies the electromagnetic field is established. The longitudinal distribution of electrons in the bunch is "cut" into equidistant slices with a separation corresponding to the wavelength λ_{ph} of the emitted radiation, which causes the modulation. More and more electrons begin to radiate in phase, which results in an increasingly coherent superposition of the radiation emitted from the micro-bunched electrons. The more intense the electromagnetic field gets, the more pronounced the longitudinal density modulation of the electron bunch and vice versa. The characteristics of FEL radiation are high power, short pulse length (pico to femtoseconds), narrow bandwidth, spatial coherence, and wavelength tunability.

Laser Plasma X-Ray Sources

The concept for X-ray lasers goes back to the 1970s, when physicists realized that laser beams amplified with ions would have much higher energies than beams amplified using gases. Nuclear explosions were even envisioned as a power supply for these high-energy lasers. In X-ray lasers, a pulse of light strikes a target, stripping its atoms of electrons to form ions and pumping energy into the ions ("exciting" or "amplifying" them). As each excited ion decays from the higher energy state, it emits a photon. Many millions of these photons at the same wavelength, amplified in step, create the X-ray laser beam. Compact short-pulse high-power X-ray sources can be produced by focusing, on a solid target, ultrashort laser pulses of low or moderate energy (from several to ten or a hundred millijoules) but of high intensity ($\geqslant 10^{15}\,\mathrm{W\,cm^{-2}}$). For example, subpicosecond laser pulses can produce X-ray pulses of high power and short duration (in the picosecond range). With respect to hard and soft X-ray emission, such laboratory X-ray sources offer the following advantages over conventional X-ray sources such as synchrotrons: a greater compactness, an easier access, a lower cost, a shorter pulse length, and a smaller source size.

Conclusions

The future of the research in the field of X-ray sources will be more and more bonded to the possibility of optically manipulating the radiation, and obtaining a selective detection of the photons in order to perform even more accurate, spatial, and temporal analysis. The use of these new methodologies of detection is already paving the way to develop new X-ray sources and to study new physical phenomena which were until now, inaccessible.

X-Ray Standing Wave Techniques

M J Bedzyk, Northwestern University, Evanston, IL, USA

Introduction

The X-ray standing wave (XSW) technique provides an element-specific structural probe by using X-ray reflectivity to generate a "two-beam" interference field that in turn induces a spatial dependence to the X-ray spectroscopic yields from atoms within the field. The XSW technique is primarily used for resolving the atomic-scale structure at surfaces, interfaces, and thin films with applications spanning a wide scientific range including materials science, solid-state and soft-condensed-matter physics, environmental chemistry, geochemistry, biochemistry, and electrochemistry.

As a fundamental wave phenomenon, the superposition of two coherently coupled X-ray plane-waves localizes the X-ray intensity into interference fringes of an XSW field (**Figure 1**). This effect, which is produced by an X-ray reflection, makes it possible to attain a periodic structural probe with a length scale equivalent to the XSW period:

$$D = \frac{\lambda}{2 \sin \theta} = \frac{2\pi}{Q} \qquad [1]$$

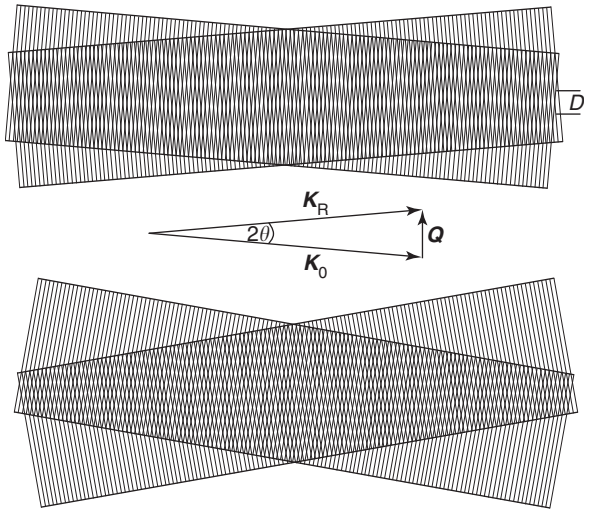

Figure 1 Top: a standing-wave field formed from the superposition of two traveling plane waves of wavelength λ and intersection angle (scattering angle) 2θ. The standing-wave period is D as defined in eqn [1]. Middle: the two traveling planes waves are represented in reciprocal space by wave vectors $\boldsymbol{K}_0$ and $\boldsymbol{K}_R$. $K_0 = K_R = 2\pi/\lambda$. The standing wave is defined by standing-wave vector $\boldsymbol{Q}$ defined in eqn [2]. Bottom: same as the top, but with a larger 2θ angle and, therefore, a smaller period D.

where λ is the X-ray wavelength, 2θ is the scattering angle between the two coherently coupled wave vectors $\boldsymbol{K}_R$ and $\boldsymbol{K}_0$, and $\boldsymbol{Q}$ is the scattering vector defined as

$$\boldsymbol{Q} = \boldsymbol{K}_R - \boldsymbol{K}_0 \qquad [2]$$

Q can also be referred to as the standing-wave vector, since it points perpendicular to the equal-intensity planes of the XSW and has a magnitude that is the reciprocal of D.

This two-beam reflection condition can be produced by: (1) strong Bragg diffraction from a single crystal, (2) strong Bragg diffraction from a periodically layered synthetic microstructure, (3) total external reflection (TER) from an X-ray mirror, or (4) weak kinematical Bragg diffraction from a single-crystal thin film. Single-crystal Bragg diffraction generates an XSW with a period equivalent to the diffraction plane spacing, typically between 0.5 and 10 Å. Cases (2) and (3) occur at small incident angles (θ) (or small Q) and therefore, according to eqn [1], will generate an XSW with a much longer period, typically 20–2000 Å. An XSW can be used as an element-specific spatial probe via the photoelectric effect, which can be observed by photoelectron, photo-ion, fluorescence, or Auger electron emission.

The XSW technique is used to investigate bulk-impurity structures in single crystals and a wide range of surface, interface, and thin film structures. These include semiconductor, metal and oxide surfaces, electrochemical interfaces, and organic membranes. In all cases, the XSW phase is directly linked to the substrate reflecting (or diffracting) lattice planes or interfaces, and can thereby be used to directly determine the absolute positions of the selected elements relative to these substrate planes. The accessibility of synchrotron radiation sources (with high brightness, energy tunability, and linear polarization) dramatically increases the sensitivity and applicability of the XSW technique.

XSWs Generated by Single-Crystal Dynamical Bragg Diffraction

An XSW generated by single-crystal Bragg diffraction can be used to determine the three-dimensional (3D) lattice location of bulk impurity atoms and surface adsorbates. Dynamical diffraction theory, which solves Maxwell's equations in a periodic dielectric with appropriate boundary conditions, is used to describe the fields inside and outside of the crystal.

Theory

Consider the two-beam Bragg diffraction condition, described in **Figure 2**, where the incident and the Bragg-diffracted X-ray plane waves are expressed as

$$\begin{aligned}\boldsymbol{E}_0(\boldsymbol{r},\ t) &= \boldsymbol{E}_0\ \exp[-\mathrm{i}(\boldsymbol{K}_0\cdot\boldsymbol{r}-\omega t)]\\ \boldsymbol{E}_H(\boldsymbol{r},\ t) &= \boldsymbol{E}_H\ \exp[-\mathrm{i}(\boldsymbol{K}_H\cdot\boldsymbol{r}-\omega t)]\end{aligned} \quad [3]$$

Here $\boldsymbol{E}_0$ and $\boldsymbol{E}_H$ are the complex E-field amplitudes associated with the incident and diffracted X-ray plane waves, $\boldsymbol{K}_0$ and $\boldsymbol{K}_H$ are the respective complex wave vectors inside the crystal, and ω is the X-ray frequency. The two wave vectors are coupled according to the Laue condition:

$$\boldsymbol{H} = \boldsymbol{K}_H - \boldsymbol{K}_0 \quad [4]$$

where $\boldsymbol{H} = h\boldsymbol{a}^* + k\boldsymbol{b}^* + l\boldsymbol{c}^*$ is a reciprocal lattice vector. The scalar equivalent of the Laue condition reduces to Bragg's law, $\lambda = 2d_H \sin\theta_\mathrm{B}$, where $d_H = 2\pi/|\boldsymbol{H}|$ is the lattice spacing of the $H = hkl$ crystal diffraction planes, and θ_B is the geometrical Bragg angle. The interference between the incident and diffracted plane waves results in a standing-wave field. The normalized intensity of the total E-field that gives rise to the XSW field is

$$\begin{aligned}I(\theta,\ r) &= \frac{|\boldsymbol{E}_0+\boldsymbol{E}_H|^2}{|\boldsymbol{E}_0|^2}\\ &= [1+R(\theta)+2\sqrt{R(\theta)}\cos(v(\theta)-\boldsymbol{H}\cdot\boldsymbol{r})]\\ &\quad\times\begin{cases}1; & \text{above the surface}\\ \mathrm{e}^{-\mu_z(\theta)z}; & \text{at depth } z \text{ below the surface}\end{cases}\end{aligned} \quad [5]$$

where the reflectivity R is related to the E-field amplitude ratio as

$$R = \left|\frac{\boldsymbol{E}_H}{\boldsymbol{E}_0}\right|^2 \quad [6]$$

and the XSW phase, v, is identical to the relative phase between the two E-field amplitudes,

$$\frac{E_H}{E_0} = \left|\frac{\boldsymbol{E}_H}{\boldsymbol{E}_0}\right|\exp(\mathrm{i}v) \quad [7]$$

From eqns [1] and [5], one can conclude that, for Bragg diffraction, the XSW periodicity is equal to the lattice d-spacing of the hkl diffraction planes, that is, $D = d_H$.

In the following discussion, the most common case of σ-polarized symmetrical Bragg diffraction from a semi-infinite crystal with $1^\circ < \theta_\mathrm{B} < 89^\circ$ is assumed. **Figure 2** shows the case of σ-polarization with the vector directions of the two E-fields pointing perpendicular to the scattering plane defined by the two wave vectors. The incident and exit angles of the two wave vectors with respect to the surface are equivalent for a symmetric reflection.

From dynamical diffraction theory, the E-field amplitude ratio is defined as

$$\frac{E_H}{E_0} = -\sqrt{\frac{F_H}{F_{\bar{H}}}}(\eta \pm \sqrt{\eta^2-1}) \quad [8]$$

where F_H and $F_{\bar{H}}$ are the $\boldsymbol{H}$ and $-\boldsymbol{H}$ structure factors, which describe the superposition of the coherent X-ray scattering from the N atoms within the unit cell as

$$\begin{aligned}F_H &= |F_H|\exp(\mathrm{i}\phi_H)\\ &= \sum_{n=1}^{N}[f_n^0(H)+\Delta f_n'(\lambda)+\mathrm{i}\Delta f_n''(\lambda)]S_n(\boldsymbol{H})D_n(\boldsymbol{H})\end{aligned} \quad [9]$$

where $S_n(\boldsymbol{H}) = \exp(\mathrm{i}\boldsymbol{H}\cdot\boldsymbol{r}_n)$ is the geometrical phase factor for the nth atom located at $\boldsymbol{r}_n$ relative to the unit cell origin. $D_n(\boldsymbol{H}) = \exp(-M_n)$ is the Debye–Waller temperature factor for the nth atom. $\Delta f_n'$ and $\Delta f_n''$ are the real and imaginary wavelength-dependent

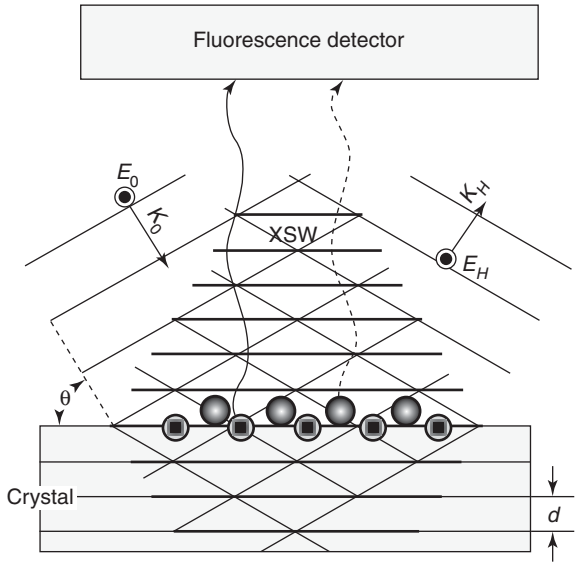

Figure 2 XSW field formed in a crystal and above its surface by the interference of incident and Bragg-diffracted X-ray plane waves. The XSW period is equal to the d-spacing d. Aligning an XSW nodal (or antinodal) plane with an atomic plane will minimize (or maximize) the characteristic fluorescence yield from that atomic plane.

anomalous dispersion corrections to the atomic form factor $f_n^0(H)$. η is the normalized angle parameter defined as

$$\eta = \frac{-\Delta\theta \sin(2\theta_B) + \Gamma F_0}{\Gamma\sqrt{F_H F_{\bar{H}}}} \qquad [10]$$

In this equation, $\Delta\theta = \theta - \theta_B$ is the relative incident angle. $\Gamma = (r_e\lambda^2)/(\pi V_c)$ is a scaling factor, where $r_e = 2.818 \times 10^{-5}$ Å is the classical electron radius and V_c is the volume of the unit cell. (To separate the real and the imaginary parts of a complex quantity A, the notation $A = A' + iA''$ is used, where A' and A'' are real quantities.) From eqns [6] to [10], it can be shown that the reflectivity approaches unity over a very small arc-second angular width w, defined as

$$w = \Delta\theta_{\eta'=-1} - \Delta\theta_{\eta'=1} = \frac{2\Gamma\sqrt{F'_H F'_{\bar{H}} + F''^2_0 - F''_H F''_{\bar{H}}}}{\sin 2\theta_B} \qquad [11]$$

This is the "Darwin width" of the reflectivity curve or "rocking curve."

Using the above dynamical diffraction theory equations (eqns [7]–[10]), one can show that the relative phase, v, of the standing-wave field decreases by π radians as the incident angle is scanned from the low-angle side to the high-angle side of the rocking curve. According to eqn [5], this causes the standing-wave antinodal planes to move by a distance of $(1/2)d_H$ in the $-\boldsymbol{H}$ direction. Also from eqn [5], if $\Delta f''_n = 0$, then $R = 1$, and the intensity at the antinode is four times the incident intensity $|\boldsymbol{E}_0|^2$, and there is zero intensity at the node. The case of $I = 4$ at the antinode assumes that the field is being examined above the surface or at a shallow depth where $\exp(-\mu_z z) \approx 1$.

The Darwin width w is dependent on both the structure factors and the wavelength of the incident X-ray beam. For a typical low-index, strong Bragg reflection from an inorganic single crystal, the angular width is within the range of $w = 5$–$100\,\mu$rad for X-rays with $\lambda = 0.5$–2 Å. **Figure 3a** shows a calculated rocking curve $R(\eta')$ and the corresponding phase $v(\eta')$ for the GaAs (1 1 1) Bragg reflection at $E_\gamma = 15$ keV. In this case, $w = 40.7\,\mu\text{rad} = 8.39$ arcsec. Semi-empirically, for the reflectivity curve, FWHM $= 1.2\,w$. Referring to the identical $R(\theta)$ curve in **Figure 3b**, notice that the center of the rocking curve is shifted slightly above the geometrical Bragg angle θ_B by $\sim 34\,\mu$rad. This shift is the result of refraction at the crystal–air interface. In general, this shift is $\Delta\theta = \Gamma F'_0/\sin 2\theta_B$. The asymmetry in the reflectivity curve, namely, the further diminishing from $R = 1$ as the angle is increased through the strong Bragg condition, is due to the movement of the XSW. On the high-angle side ($\eta' < -1$), the XSW antinodes align with the strong X-ray absorption planes in the crystal (see **Figure 4**). Therefore, absorption is higher than average on the high-angle side and weaker on the low-angle side ($\eta' > 1$) for this case.

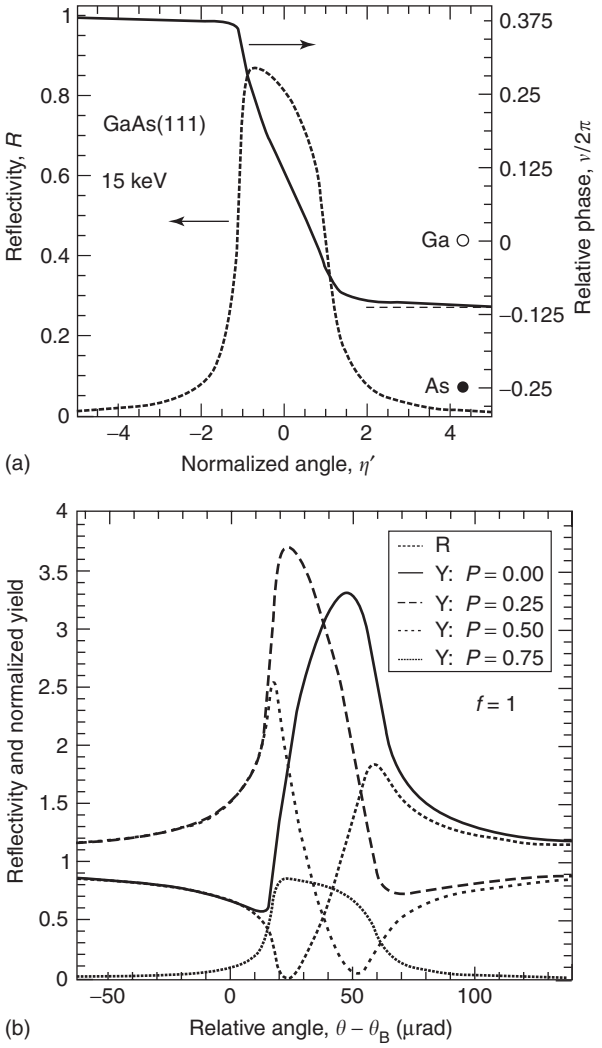

Figure 3 (a) The theoretical angle η' dependence of the reflectivity R and XSW phase $v/2\pi$ for the GaAs(1 1 1) Bragg reflection at $E\gamma = 15$ keV. (b) The corresponding theoretical angle $\Delta\theta$ dependence of the reflectivity and normalized fluorescence yields (eqn [15]) for coherent positions $P_{111} = 0.0, 0.25, 0.5$, and 0.75 with coherent fraction $f_{111} = 1$ and $Z(\theta) = 1$. Referring to **Figure 4**, this calculation has Ga at the 0, 0, 0 and As at the 1/4, 1/4, 1/4 position of the cubic zinc blende unit cell. Therefore, the $P_{111} = 0$ curve is the E-field intensity at the Ga site and the $P_{111} = 0.75$ (or $= -0.25$) curve is the E-field intensity at the As site. The dashed horizontal line in (a) represents the phase $\phi/2\pi$ of the structure factor. The respective phases of the geometrical structure factors for the Ga and As sublattices are illustrated with respect to the phase scale on the right-hand side of (a).

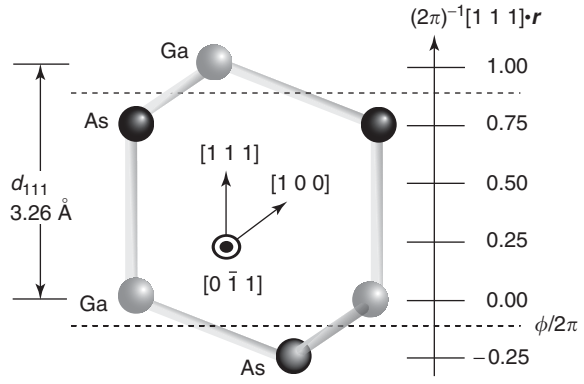

Figure 4 A [0 $\bar{1}$ 1] projection of the zinc-blende GaAs structure showing the [1 1 1] projected scale for the lattice positions in units of the d_{111} *d*-spacing. The horizontal dashed lines represent the phase of the GaAs (1 1 1) structure factor at 15 keV.

The exponential damping factor in eqn [5] accounts for attenuation effects within the crystal, in which case the effective absorption coefficient is defined as

$$\mu_z(\theta) = \frac{\mu_0}{\sin\theta_B}\left[1 + \frac{F''_{\bar{H}}}{F''_0}\left(\frac{E_H}{E_0}\right)'' + \frac{F''_{\bar{H}}}{F''_0}\left(\frac{E_H}{E_0}\right)'\right] \quad [12]$$

where $\mu_0 = (2\pi/\lambda)\Gamma F''_0$ is the linear absorption coefficient. The second and third terms in eqn [12] account for the extinction effect that strongly limits the X-ray penetration depth $1/\mu_z$ for a strong Bragg reflection. For example, the penetration depth for 15 keV X-rays at the GaAs (1 1 1) Bragg reflection ranges from 2.62 μm at off-Bragg conditions to 0.290 μm at the center ($\eta' = 0$) of the Bragg rocking curve. The general expression for this minimum penetration depth or extinction length is

$$\Lambda_{ext} = V_c\left[4d_H r_e\left(F''_0 + \sqrt{|F_H||F_{\bar{H}}|}\right)\right]^{-1} \quad [13]$$

XSW Photo-Effect Yields

The XSW field established inside the crystal and above the crystal surface induces photoelectron emission from atoms within the field. The excited ions, in turn, emit characteristic fluorescence X-rays and Auger electrons. In the dipole approximation, the photoelectric effect cross section is proportional to the *E*-field intensity at the center of the atom. (It is necessary to consider higher-order multipole terms in the photoelectric cross section under special conditions; for example, XSW induced photoemission that is not angle-integrated.) For the discussion that follows, the dipole approximation is assumed, in which case the normalized X-ray fluorescence yield is defined as

$$Y(\theta) = \int I(\theta, \boldsymbol{r})\rho(\boldsymbol{r})\,\exp[-\mu_f(\alpha)z]\mathrm{d}\boldsymbol{r} \quad [14]$$

where $\rho(\boldsymbol{r})$ is the normalized fluorescent atom distribution and $\mu_f(\alpha)$ is the effective absorption coefficient for the emitted fluorescent X-rays, which is dependent on their takeoff angle α. Upon integration, the normalized XSW yield is given as

$$Y(\theta) = [1 + R(\theta) + 2\sqrt{R(\theta)}f_H \times \cos(v(\theta) - 2\pi P_H)]Z(\theta) \quad [15]$$

where the parameters f_H and P_H are the coherent fraction and coherent position, respectively. In more general terms, f_H is the amplitude and P_H is the phase of the ***H***th-order Fourier coefficient of the normalized distribution function

$$F_H = \int_{uc} \rho(\boldsymbol{r})\exp(\mathrm{i}\boldsymbol{H}\cdot\boldsymbol{r})\mathrm{d}\boldsymbol{r} = f_H\,\exp(2\pi\mathrm{i}P_H) \quad [16]$$

$Z(\theta)$ is the effective-thickness factor, which is discussed below. $Z(\theta) = 1$ for atoms above the surface of the crystal and at a depth much less than the extinction length, $Z(\theta) \sim 1$.

Referring to **Figure 5**, in an XSW experiment, the reflectivity rocking curve $R(\theta)$ and the fluorescence yield $Y(\theta)$ are acquired simultaneously while scanning in θ through each *hkl* Bragg reflection of the sample crystal. For each *hkl* XSW data set, a rocking curve calculated according to dynamical diffraction theory and convoluted with the emission function of the upstream monochromator is fitted to the experimentally measured $R(\theta)$ to fix the absolute angle scale. This is then used for fitting the convolution of eqn [15] to the measured $Y(\theta)$. From this fit, the coherent fraction f_H and the coherent position P_H are obtained. The off-Bragg yield, which is also obtained from the fit to the measured data, is used for overall normalization of the yield, which gives the fluorescent atom concentration or surface coverage. In **Figure 3b**, calculated $Y(\theta)$ curves are shown for $Z(\theta) = 1$, $f_{111} = 1$, and $P_{111} = 0.0$, 0.25, 0.5, and 0.75. These calculated curves are for the GaAs (1 1 1) reflection at $E_\gamma = 15$ keV. The origin of the zinc blende unit cell was chosen to coincide with a Ga atom. Referring to **Figure 4**, the + (1 1 1) polarity of this noncentrosymmetric crystal structure has Ga at the top of the bilayer and As at the bottom. Therefore, the $P_{111} = 0$ curve corresponds to the expected K fluorescence yield for Ga atoms, and the $P_{111} = 0.75$ corresponds to that of As K fluorescence. The

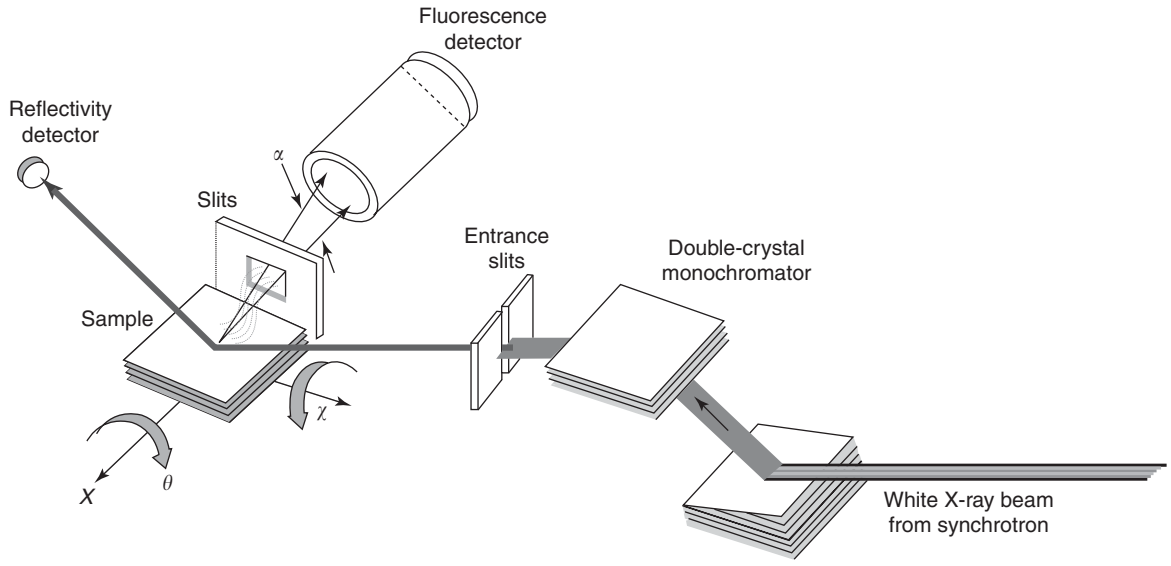

Figure 5 Depiction of a typical XSW experimental setup. The beam from a synchrotron beamline is monochromated and collimated by an asymmetrically cut, grazing incidence, Si single crystal; the second (nondispersive) symmetrically cut Si monochromator crystal is used to return the incident beam to a horizontal direction. While stepping the incident angle θ of the sample through the reflection, the reflected intensity and fluorescence spectrum are simultaneously collected by two separate detector systems.

marked change in the angular variation of $Y(\theta)$ for each increment of 0.25 in d-spacing is the basis for the spatial sensitivity of the Bragg diffraction XSW. If the GaAs(1 1 1) wafer were to be flipped over, the $(\bar{1}\,\bar{1}\,\bar{1})$ rocking curve would look essentially the same ($|F_{\bar{1}\bar{1}\bar{1}}|$ is 1.5% smaller than $|F_{111}|$ due to anomalous dispersion). However, the Ga and As XSW fluorescence yields would be essentially switched around, since the XSW antinodes pass through the Ga atomic layers when scanning in angle through the (1 1 1) reflection, and pass through the As atomic layers for the $(\bar{1}\,\bar{1}\,\bar{1})$.

Extinction Effect and Evanescent-Wave Emission

The effective-thickness factor $Z(\theta)$ in eqn [15] accounts for the θ dependence of the penetration depth of the primary X-ray field (extinction effect) in conjunction with the escape depth, Λ, of the outgoing secondary fluorescence X-rays. For atoms at the crystal surface (e.g., adsorbates) or at a depth much smaller than the extinction depth, the effective-thickness factor is constant at $Z(\theta) = 1$. For atoms evenly distributed throughout the semi-infinite crystal,

$$Z(\theta) = \frac{\mu_0(\sin\theta_B)^{-1} + \mu_f(\alpha)}{\mu_z(\theta) + \mu_f(\alpha)} \qquad [17]$$

where $\mu_z(\theta)$ is the effective absorption coefficient of the incident X-rays (eqn [12]), and $\mu_f(\alpha)$ is the effective absorption coefficient of the outgoing fluorescence X-rays from the crystal at takeoff angle α. To achieve surface sensitivity of substrate atoms, it is possible to reduce α to a value approaching the critical angle α_c of the fluorescence X-rays. Under such conditions, $\mu_f(\alpha)$ dominates over $\mu_z(\theta)$ in eqn [17] and, therefore, the effective thickness factor is constant at $Z(\theta) = 1$. The value of $\mu_f(\alpha)$ is dependent on the wavelength λ_f of the fluorescence and the index of refraction calculated at $\lambda = \lambda_f$. The index of refraction is

$$n = 1 - \delta - i\beta \qquad [18]$$

where

$$\begin{aligned} \delta &= \frac{1}{2\pi} N_e r_e \lambda^2 = \frac{1}{2}\,\Gamma F_0' \\ \beta &= \frac{1}{4\pi}\mu_0\lambda = \frac{1}{2}\,\Gamma F_0'' \end{aligned} \qquad [19]$$

and N_e is the effective electron density of the refractive medium. From the index of refraction, $\mu_f(\alpha)$ can be obtained as

$$\mu_f(\alpha) = \frac{2\sqrt{2}\pi}{\lambda_f}\left[\sqrt{(2\delta - \alpha^2)^2 + 4\beta^2} + 2\delta - \alpha^2\right]^{1/2} \qquad [20]$$

At takeoff angles much greater than the critical angle (i.e., $\alpha \gg \alpha_c = \sqrt{2\delta}$), $\mu_f = \mu_0/\sin\alpha$. Below the critical angle, refraction effects dominate and the escape depth $\Lambda = \mu_f^{-1}$ approaches $1/4(N_e r_e)^{-1/2}$.

The evanescent-wave emission effect can be used to remove the extinction effect of bulk fluorescence in XSW experiments. This is important, since for $\alpha \gg \alpha_c$, the extinction effect tends to dominate over the standing-wave effect, causing loss of phase (positional) sensitivity.

Structure Determination Using Coherent Fraction and Coherent Position

The coherent fraction f_H senses the spread in the spatial distribution of the fluorescent atoms. For simplicity, f_H is subdivided into three factors:

$$f_H = Ca_H D_H \qquad [21]$$

where C is the ordered fraction, a_H is the geometrical factor, and D_H is the Debye–Waller factor. All three factors range in value from 0 to 1.

Consider the general case of a discrete distribution having the same atom located at N different unit cell positions $\boldsymbol{r}_j = x_j\boldsymbol{a} + y_j\boldsymbol{b} + z_j\boldsymbol{c}$, plus an added random distribution of the same atoms. The ordered fraction C is the fraction of the atoms in the distribution that are coherent (or are crystallographically registered) with the substrate crystal lattice. If the occupation fractions of the atoms for the ordered positions are $c_1, c_2, \ldots, c_N$, respectively, the ordered fraction is

$$C = \sum_{j=1}^{N} c_j \qquad [22]$$

At this point, it is useful to define the normalized geometrical structure factor S_H for the ordered fluorescent-selected atoms:

$$S_H = \frac{1}{C}\sum_{j=1}^{N}[c_j \exp(\mathrm{i}\boldsymbol{H}\cdot\boldsymbol{r}_j)] \qquad [23]$$

The geometrical factor is defined as

$$a_H = |S_H| \qquad [24]$$

and the coherent position is defined as

$$P_H = \frac{\arg[S_H]}{2\pi} \qquad [25]$$

It is to be noted that the origin for the set of $\boldsymbol{r}_j$ (and, therefore, the origin of P_H) in the unit cell is the same as was arbitrarily chosen for generating the structure factor F_H used in eqns [8]–[12]. For the simple case of one atomic site, $N = 1$, $a_H = 1$, and P_H is the projected $\boldsymbol{H}\cdot\boldsymbol{r}/2\pi$ fractional d-spacing position of the atomic site. For the case of two equally occupied atom sites, the geometrical factor reduces to

$$a_H = \left|\cos\left[\frac{\boldsymbol{H}\cdot(\boldsymbol{r}_1 - \boldsymbol{r}_2)}{2}\right]\right| \qquad [26]$$

The coherent position in this case is the averaged fractional d-spacing position of the two sites. If the two equally occupied sites have a separation of exactly one-half of a d-spacing along a particular $\boldsymbol{H}$, then $a_H = 0$ for that particular $\boldsymbol{H}$. This is analogous to a forbidden reflection in crystallography. Again, for the case of two sites separated by one-half of a d-spacing, if the site occupation fractions are 2/3 and 1/3, the geometrical fraction will be $a_H = 1/3$, and the coherent position will equal the position of the 2/3 occupied site.

In XSW analysis, the Debye–Waller factor D_H accounts for the time-averaged spatial distribution in the $\boldsymbol{H}$ direction due to thermally induced vibrations of the fluorescence-selected ordered atoms about their average lattice positions. In general, individual D_H factors can be assigned to the individual sites. In addition to including the dynamic (thermal vibration) distribution, one can also include the static (spatial disordering) distribution. Generally, D_H can be expressed in terms of the mean-square vibrational amplitude along the $\boldsymbol{H}$ direction $\langle u_H^2 \rangle$, as

$$\boldsymbol{D}_H = \exp(-M) = \exp\left(\frac{-2\pi^2\langle u_H^2\rangle}{d_H^2}\right) \qquad [27]$$

XSW measurements are not restricted to being made along the surface-normal direction (i.e., $\boldsymbol{H}$ perpendicular to the crystal surface). They can be performed with respect to any sufficiently strong Bragg reflection of a crystal. A 3D triangulation of the atom site can be obtained by combining XSW measurements by using three mutually noncollinear diffraction vectors. In triangulating an atomic site, the point symmetry of the surface can be used to reduce the number of required XSW measurements.

Direct-Space Imaging

The XSW measured coherent fraction and position are model-independent and correspond to the amplitude f_H and phase P_H of the $\boldsymbol{H}$th Fourier coefficient of the fluorescence-selected atomic distribution. Therefore, based on the Fourier inversion of eqn [16], the distribution $\rho(\boldsymbol{r})$ of each fluorescent atomic species can be synthesized directly by the Fourier summation

$$\begin{aligned}\rho(\boldsymbol{r}) &= \sum_H \rho_H = \sum_H f_H \exp[\mathrm{i}(2\pi P_H - \boldsymbol{H}\cdot\boldsymbol{r})] \\ &= 1 + 2\sum_{\substack{H\neq -H \\ H\neq 0}} f_H \cos[2\pi P_H - \boldsymbol{H}\cdot\boldsymbol{r}]\end{aligned} \qquad [28]$$

The above simplification to a summation of cosine terms makes use of $f_0 = 1$, and the symmetry relationship analogous to Friedel's law that makes $f_{\bar{H}} = f_H$ and $P_{\bar{H}} = -P_H$. Since the summation is limited to allowed bulk reflections, the image $\rho(\boldsymbol{r})$ generated

from the XSW measured f_H and P_H values, is limited to being a projection into the primitive unit cell of the bulk crystal. The quality (resolution) of the XSW image will depend on the extent in reciprocal space over which the set of f_H and P_H values were measured.

As a simple example, consider the Ge diamond-cubic crystal structure (identical to zinc blende shown in **Figure 4**, but with Ga and As replaced by Ge). In **Figure 6**, the 1D projection of the Ge Fourier components ρ_{hhh} are plotted over an interval corresponding to the d_{111} 1D unit cell and then summed according to eqn [28] to produce the 1D image. The extra oscillations are due to truncating the sum and zeroing all terms higher than $hhh = 888$.

The resolution of the image in a given [hkl] direction is equivalent to one-half of the smallest d-spacing that has been entered into the summation in that direction. This imaging method in 3D is especially useful for solving multisite surface adsorbate phases. After this typically 0.5 Å resolution model-independent analysis step, the measured f_H and P_H values can be used to refine the parameters of a structural model (suggested by the imaging method). This previously discussed model-dependent analysis method has a typical resolution of 0.03 Å.

Solution to Phase Problem

Unlike conventional diffraction methods, the XSW method does not lose phase information and can, therefore, be used directly to map the direct-space structure from the set of Fourier coefficients collected in reciprocal space. The XSW measurement does not lose phase information, because the detector of the E-field is the fluorescent atom itself, lying within the spatial region where the fields interfere coherently with each other. In contrast, in conventional diffraction measurements, the relative phase between the diffracted and incident fields is lost, because the intensities of the incident and scattered fields are detected far from this region of coherent spatial overlap.

It should be stressed that the Bragg XSW positional information acquired is in the same absolute coordinate system as used for describing the substrate unit cell. This unit cell and its origin were previously chosen when the structure factors F_H and $F_{\bar{H}}$ (as defined in eqn [9]) were calculated and used in eqns [8], [10], and [12]. The XSW phase (v) is directly linked to the phase (ϕ_H) of the structure factor. Referring to **Figures 3a** and **4**, v approaches $\phi + \pi$ at angles well below the strong Bragg condition and v approaches ϕ, far above. This corresponds precisely to the XSW antinodes shifting inward, from being halfway between the diffraction planes on the low-angle side to being coincident with the diffraction planes on the high-angle side. This XSW-antinode-asymptotic-limit definition for the hkl diffraction

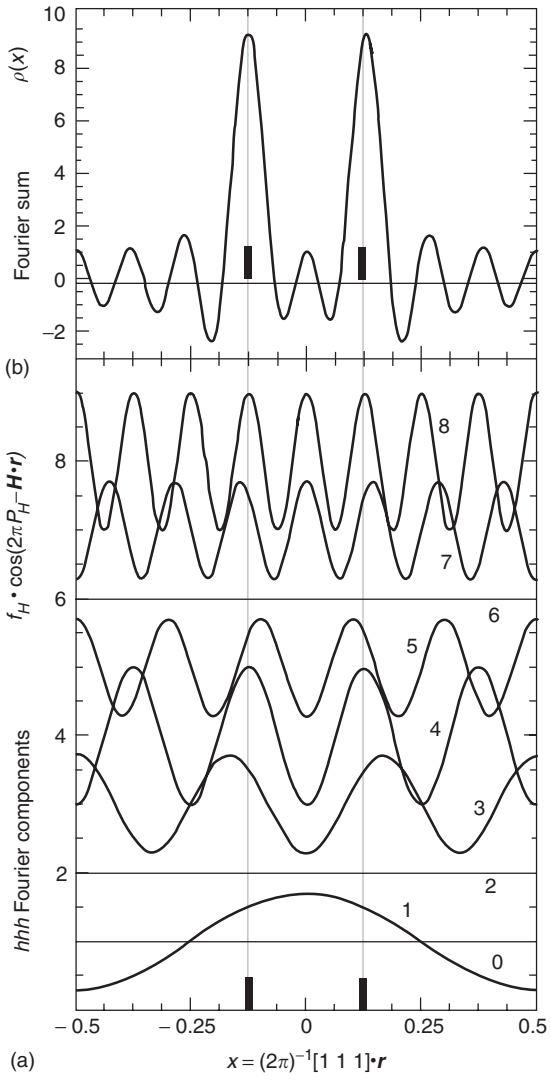

Figure 6 (a) The 1D spatial dependence of the *hhh* Fourier components (ρ_{hhh}, $h = 0-8$) for the distribution of Ge atomic centers in the diamond-cubic structure. (Each curve is given a vertical offset of $+h$.) This is identical to the GaAs zinc-blende structure shown in **Figure 4**, but with Ga and As replaced by Ge. The spatial interval corresponds to the 1D unit cell along the [1 1 1] direction that has a lattice constant corresponding to d_{111} and has two equally occupied Ge sites at $x = \pm 1/8$ (two vertical lines). The h dependence of the amplitude f_{hhh} and phase P_{hhh} for each Fourier component is calculated from eqns [23]–[26] for the case of $C = 1$ and $D_{hhh} = 1$. In this case $f_{hhh} = a_{hhh} = |cos(\pi h/4)|$. This makes $f_{000} = f_{444} = f_{888} = 1$, $f_{111} = f_{333} = f_{555} = f_{777} = 1/\sqrt{2}$, and $f_{222} = f_{666} = 0$. $P_{111} = P_{777} = P_{888} = 0$, and $P_{333} = P_{444} = P_{555} = 1/2$. (b) The calculated 1D image $\rho(x)$ of Ge atom centers as summed over the terms from $hhh = 000$ to 888 based on eqn [28]. The curves in (a) can also represent the phase and period of the XSW at the high-angle side ($\eta' < -1$) of the Bragg peak for the case of $\Delta f'' = 0$.

planes, defines the diffraction planes as coinciding with the maxima of the real part of the $\boldsymbol{H}$th Fourier component of the scattering density function, which is expressed as $\max\{\mathrm{Re}[F_H \exp(-i\boldsymbol{H}\cdot\boldsymbol{r})]\}$. Consequently, the correct values for f_0, $\Delta f'$, and $\Delta f''$ must be used to compute the structure factor F_H in order to assure an accurate determination of the absolute lattice position of an impurity or adsorbate atom. This is typically quite straightforward, unless the incident energy is near an absorption edge for one of the atoms in the bulk crystal.

"Ideal Crystals" versus "Real Crystals" in Bragg Diffraction XSW

According to eqn [11], the intrinsic Darwin width for a typical strong Bragg diffraction peak in the reflection geometry is between 5 and 100 μrad. To produce useful quantitative information from an XSW measurement, the measured reflectivity curve should reasonably match theory. Only a few exceptionally high-quality crystals qualify as ideal crystals according to this criterion, for example, Si, Ge, GaAs, and calcite. Most real single crystals contain internal imperfections that result in mosaic spreads that exceed their intrinsic Darwin widths. These mosaic spreads can reduce the reflected intensity and subsequently smear out the standing-wave effect. For these real crystals, the measured reflectivity curves cannot be fitted directly by the ideal theoretical reflectivity described by eqn [6]. To make the Bragg diffraction XSW technique adaptable to applications on real crystals, a number of theoretical and experimental methods have been developed. The most formal method is the modification of the XSW theory to include the effect of crystal imperfection on Bragg diffraction. On the other hand, one can make XSW applications under certain conditions where the stringent requirements of the conventional theory are relaxed. One such condition is when a Bragg reflection occurs near the back-reflection geometry, typically when $87^\circ < \theta_B < 90^\circ$. Under this condition, eqn [11] breaks down, and the intrinsic Darwin width is magnified to milliradians. Another condition is when the crystal is very thin; under this condition the kinematical theory can replace the dynamical theory in calculating the Bragg reflection. Both of these special cases, which are discussed briefly below, are important alternatives when the conventional XSW technique cannot be applied.

An additional practical method for applying XSW to real crystals takes advantage of the high brilliance of X-ray undulators at third-generation synchrotron sources. With such a source, sufficiently high X-ray intensities can be delivered with beams slitted down to microns in cross section, thus making it possible to illuminate one isolated "perfect" grain at the sample surface.

The Special Case of Back-Reflection XSW

As just mentioned, one means of circumventing the problem of analyzing less-than-perfect crystals is to use dynamical diffraction at Bragg angles approaching 90°. In this back-reflection geometry, the angular Darwin width is measured in milliradians instead of microradians.

For $\theta_B > 88^\circ$, the conventional dynamical diffraction theory breaks down. This is due to an approximation in the conventional theory that treats the spherical asymptotes of the dispersion surface in reciprocal space as planes. With an extended dynamical diffraction theory, the Bragg reflectivity and the standing wave E-field intensity can be properly described for $87^\circ < \theta_B < 90^\circ$. In this regime, the Bragg reflectivity has a much smaller energy width and a much broader angle width. For a given d-spacing, the largest angle width occurs at a wavelength of

$$\lambda_b = 2d_H\left(1 - \frac{\Gamma(F_0' - F_H')}{2}\right) \qquad [29]$$

In this case, $\Gamma = 4r_e d_H^2(\pi V_c)^{-1}$. For wavelengths slightly smaller, the angular width can be expressed as

$$w = \Delta\theta_{y=1} - \Delta\theta_{y=-1} \qquad [30]$$

where $\Delta\theta_{y=1}$ and $\Delta\theta_{y=-1}$ are the angular displacements from 90° of the low- and high-angle sides of the strong Bragg diffraction condition, respectively. For a symmetric reflection,

$$\Delta\theta_{y=\pm 1} = \sqrt{2(1 - \sin\theta_B) + \Gamma(F_0' \mp F_H')} \qquad [31]$$

The back-reflection XSW (BRXSW) technique has been primarily applied to metal and oxide crystals, whose rocking curves typically exhibit angular mosaicity up to ~0.1°. BRXSW is mostly used in combination with XPS (rather than XRF) for ultrahigh vacuum (UHV) surface science measurements of adsorbed molecules and for site-specific valence-band photoemission studies.

The Special Case of Thin-Film Bragg Diffraction XSW

The development of Bragg diffraction XSW from thin films is partially driven by the fact that many crystals can be grown as high-quality μm-thick films but not as large-size crystals. Similar to Bragg diffraction from a bulk crystal, Bragg diffraction from a

crystalline thin film also generates an X-ray standing-wave field. Because the thickness of the film is much less than the extinction depth, kinematical diffraction theory can be used as a good approximation to calculate the intensity of the field. The rocking curve angular width $w \sim 1/N$, where N is the atomic layer thickness of the film. The analytical procedure is fully analogous to that for bulk-reflection XSW. However, the small thickness results in very weak peak reflectivity (typically 0.01%), and consequently, very weak (typically 1%) modulation of the XSW-induced fluorescence yield from an atom within or above the film. To observe this small modulation above the statistical fluctuation, a large number of fluorescence counts must be collected at each angle step of the XSW scan.

XSWs Generated by TER

While a single-crystal XSW provides a high-resolution probe well suited for atomic-scale structural determination, this XSW period is too fine a scale to profile larger nanostructures – such as the diffuse-ion distribution at the solid–liquid interface and organic self-assembled multilayers. To extend the XSW technique to the nanoscale and beyond, one can employ a long-period XSW generated by TER from a mirror surface or generated by Bragg diffraction from a periodically layered synthetic microstructure (LSM). Because the reflection condition in these two cases occurs at much smaller angles, the XSW period, D, is much longer. For TER, in particular, D varies from 1 μm to 10 nm as θ increases through the TER condition.

TER–XSW Theory

During TER, the interference between the incident and the specular reflected X-ray plane waves produces an XSW above the mirror surface (inset to **Figure 7**). An evanescent wave is induced below the surface. The nodal (and antinodal) planes of this periodic E-field intensity pattern above the surface are parallel to the surface and have a variable period of $D = \lambda/(2\sin\theta)$, as defined in eqn [1]. The TER condition occurs between $\theta = 0$ and $\theta = \theta_c$, the critical angle. The corresponding XSW period is very long, ranging from $D = \infty$ to $D = D_c = \lambda/2\theta_c$, the critical period. From eqn [19] and $\theta_c = \sqrt{2\delta}$, the critical period can be written as

$$D_c = \frac{1}{2}\sqrt{\frac{\pi}{N_e r_e}} \qquad [32]$$

Aside from small anomalous dispersion effects, the critical period is wavelength independent. D_c is a materials property dependent on the electron density, N_e. For an Au mirror $D_c = 80$ Å, and for an Si mirror $D_c = 200$ Å. The directly related critical scattering vector is $Q_c = 2\pi/D_c$.

This TER condition is, in fact, the zeroth-order Bragg diffraction condition, or the condition when $\boldsymbol{H} = 0$ and $d_H = \infty$. Therefore, the above derivations from dynamical diffraction theory for single-crystal Bragg diffraction can be applied to the case of TER by substituting F_0 for F_H. In this case, eqn [10] becomes

$$\eta = \eta' + i\eta'' = \frac{-2\theta^2 + \Gamma F_0}{\Gamma F_0} \qquad [33]$$

with the substitutions

$$\eta' = 1 - 2x^2 \quad \text{and} \quad \eta'' = 2x^2 y \qquad [34]$$

where $x = \theta/\theta_c$ is the normalized angle parameter, and $y = \beta/\delta$ is the absorption factor. From eqn [8], the complex E-field amplitude ratio becomes

$$\begin{aligned}\frac{E_R}{E_0} &= -(\eta \pm \sqrt{\eta^2 - 1}) \\ &= \frac{x - \sqrt{x^2 - 1 - iy}}{x + \sqrt{x^2 - 1 - iy}} = \left|\frac{E_R}{E_0}\right| \exp(iv)\end{aligned} \qquad [35]$$

where E_R is the complex amplitude of the reflected plane wave. This amplitude ratio is identical to that derived from classical Fresnel theory. For the simple case of no absorption, where $\beta = 0$, the reflectivity is

$$\begin{aligned}R &= \left|\frac{E_R}{E_0}\right|^2 \\ &= \begin{cases} 1, & 0 \leqslant x \leqslant 1 \\ 8x^4 - 8x^3\sqrt{x^2 - 1} + 4x\sqrt{x^2 - 1} & \\ \quad -8x^2 + 1, & x > 1 \end{cases}\end{aligned} \qquad [36]$$

and the phase is

$$v = \begin{cases} \cos^{-1}(2x^2 - 1), & 0 \leqslant x \leqslant 1 \\ 0, & x > 1 \end{cases} \qquad [37]$$

Referring to **Figure 7a**, the phase at the mirror surface decreases from π to 0 as the mirror is tilted through the total reflection condition. Thus, at the mirror surface, where $z = 0$, the reflected plane wave is completely out of phase with the incident plane wave when $\theta = 0$. As the incident angle is increased, the phase decreases smoothly until it is completely in phase at $\theta = \theta_c$. Therefore, at $\theta = 0$, a standing-wave node is at the mirror surface, and the first antinode is at infinity. As θ increases, the first antinode moves in from infinity toward the mirror

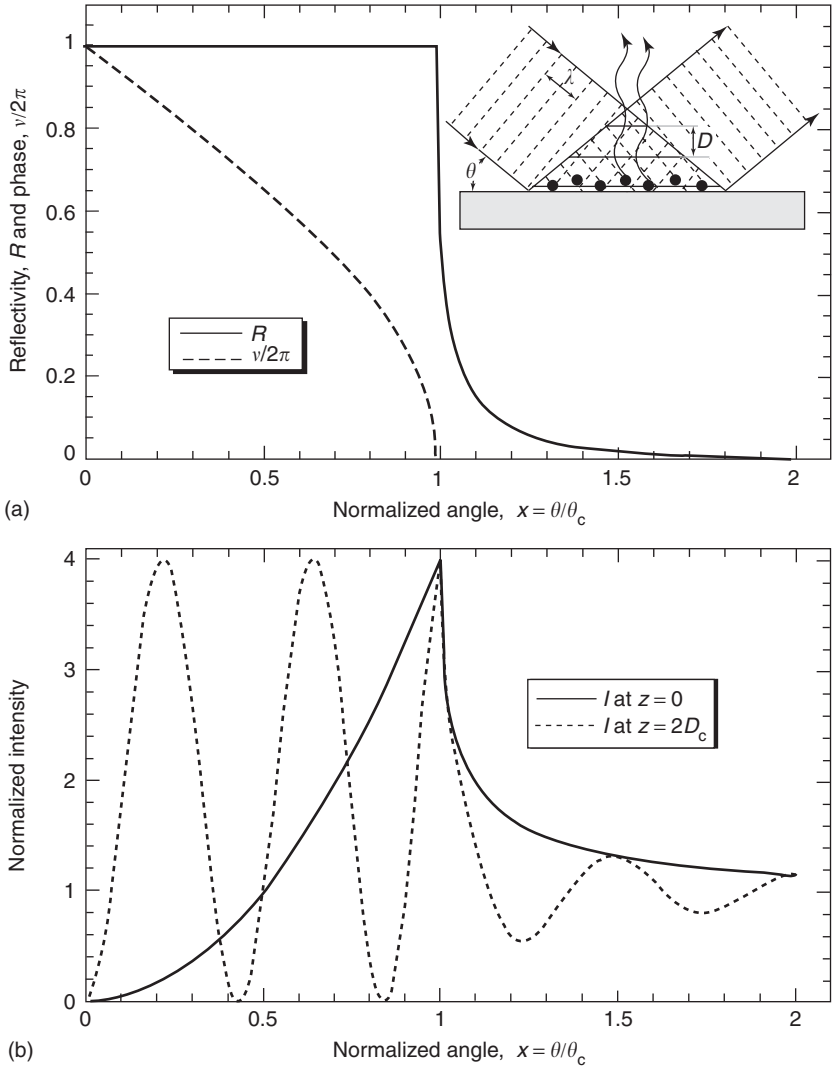

Figure 7 Under the condition of TER from an ideal mirror surface with no absorption ($\beta = 0$): (a) The angular dependence of the reflectivity R and relative phase v of the reflected X-ray plane wave (or phase of the XSW relative to the mirror surface); (b) the angular dependence of the normalized E-field intensity at the mirror surface ($z = 0$) and at a distance $z = 2D_c$ (160 Å for Au mirror, 400 Å for Si mirror). The inset depicts how the XSW field is formed above a mirror surface by the interference between an incident and a specular-reflected X-ray plane wave.

surface, until it coincides with the mirror surface upon reaching $\theta = \theta_c$. At the same time, the second-, third-, and higher-order antinodes of the standing wave also move toward the surface, as the period D decreases based on eqn [1].

The normalized E-field intensity above the mirror surface can be expressed as

$$I(\theta, z) = \frac{|\boldsymbol{E}_0 + \boldsymbol{E}_R|^2}{|\boldsymbol{E}_0|^2} = 1 + R + 2\sqrt{R}\cos(v - Qz) \qquad [38]$$

Figure 7b shows the angular dependence of the E-field intensity at $z = 0$ (the mirror surface) and at $z = 2D_c$. The fluorescence signal for an ideally narrow single atomic plane fixed at these heights would have the same angular dependence.

The normalized fluorescence yield from an arbitrary distribution of atoms $\rho(z)$ above the mirror surface can be obtained by integrating over all values of z:

$$Y(\theta) = \int_{z=0}^{z=\infty} I(\theta, z)\rho(z)\,\mathrm{d}z \qquad [39]$$

With $I(\theta, z)$ calculated from eqn [38], the atom distribution profile $\rho(z)$ can be obtained by assuming a modeled distribution and fitting it to the measured yield $Y(\theta)$. For the specific cases of δ-function atomic

distributions in a plane at $z = xD_c$, there are $x + (1/2)$ modulations between $\theta = 0$ and $\theta = \theta_c$. The extra 1/2 modulation is due to the π phase shift in v.

With TER–XSW, the Fourier transform of an atom distribution is measured over a continuous range in $Q = 2\pi/D$, with variable period D ranging from ~ 100 Å to 1 μm. Therefore, TER–XSW is ideally suited to measure surface and interface structures of length scales in the range of 50–2000 Å.

The above treatment accurately describes the X-ray E-fields at and above the mirror surface for the simple case of an interface with vacuum (or air). To apply TER–XSW as a probe for studying liquid–solid interfacial structures or organic films deposited on a solid surface, it is necessary to include reflection, refraction, and absorption effects from the layers that lie between the substrate surface and the vacuum (or air). This can be accomplished by making use of Parratt's recursion formulation to calculate the transmitted and reflected fields at any interface. These same fields can then be calculated at any point within the slab by appropriately accounting for the X-ray absorption and refraction effects on the fields as they travel from the interface to the point. The TER–XSW method is primarily used to profile nanoscale heavy-atom (or -ion) distributions in organic films and at electrified liquid/solid interfaces.

XSWs from Layered Synthetic Microstructures

For Bragg diffraction purposes, an LSM is fabricated (typically by sputter deposition) to have a depth-periodic layered structure consisting of 10–200 layer pairs of alternating high- and low-electron-density materials, such as Mo and Si. Sufficient uniformity in layer thickness is obtainable in the range between 10 and 150 Å (d-spacing of fundamental diffraction planes from 20 to 300 Å). Because of the rather low number of layer pairs that affect Bragg diffraction, these optical elements (when compared to single crystals) have a significantly wider energy band pass and angular reflection width. The required quality of an LSM is that experimental reflection curves compare well with dynamical diffraction theory, and peak reflectivities are as high as 80%. Therefore, a well-defined XSW can be generated and used to probe structures deposited on an LSM surface with a periodic scale equivalent to the rather large d-spacing. To a good approximation, the first-order Bragg diffraction planes coincide with the centers of the high-density layers of the LSM. Above the surface of the LSM, the XSW period is again defined by eqn [1]. The reflectivity can be calculated by using Parratt's recursion formulation. This same optical theory can be extended to allow the calculation of the E-field intensity at any position within any of the slabs over an extended angular range that includes TER. Then, eqn [39] is used to calculate the fluorescence yield. The LSM–XSW method is primarily used

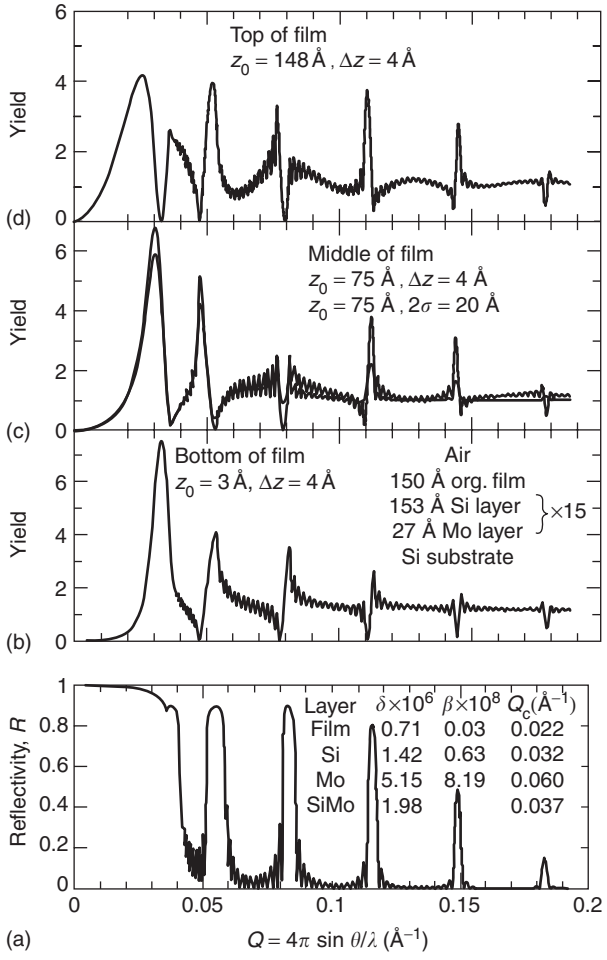

Figure 8 An XSW simulation at $E\gamma = 18.5$ keV for an Si/Mo multilayer (LSM) with $d = 180$ Å, $t_{Si} = 153$ Å, $N = 15$ layer pairs, an Si substrate and a 150 Å thick organic film on top. Each interface was given a $\sigma = 3$ Å Gaussian smear to simulate roughness. The index of refraction values for each type of layer (plus the weighted average Si/Mo LSM) are listed in (a). The angular dependence of the (a) reflectivity and (b)–(d) fluorescence yields for 4 Å thick uniform atomic distributions at the (b) bottom, (c) middle, and (d) top of the organic film are shown. Also shown in (c) is the case of a 20 Å wide Guassian distribution. This Q range includes the zeroth (TER) through 5th-order Bragg peaks. The XSW period in the air (or vacuum) is $D = 2\pi/Q$. This is also a good approximation for the XSW period inside the organic film, except when refraction effects are appreciable, i.e., $Q < 2Q_c^{Film}$. More precisely, $D_{Film} = 2\pi/(Q^2 - (Q_c^{Film})^2)^{1/2}$ for $Q > Q_c^{Film}$. The sharp drop in R at $Q = Q_c^{Si}$, corresponds to the excitation of a resonant cavity mode that has a node at the top of the organic film and a node at the bottom of the first Si layer. At this precise angle, the E-field intensity in the middle of this combined Si-film slab is much higher than $4|\boldsymbol{E}_0|^2$, as can be seen in (b).

to determine the atomic (or ionic) distributions in deposited organic films or at electrified liquid–solid interfaces. As an example, the simulated reflectivity and fluorescence yields for a $d = 180$ Å Si/Mo LSM is shown in **Figure 8**. It can be noted that the modulation pattern of the yield is very sensitive to the height and width of the fluorescent atom layer within an organic film deposited on the LSM.

X-Ray Topography

J Baruchel and J Härtwig, ESRF, Grenoble, France

Introduction

A major use of X-rays, ever since they were discovered over a century ago, has been and still is the visualization of the inside of systems, opaque for other probes. Whatever the imaging process used, it implies an inhomogeneous response of the sample to the beam. Recently, X-ray imaging techniques have dramatically progressed, in connection with the improvements in sources (synchrotron radiation), detectors, and computer image processing. Among these new features, three-dimensional imaging with spatial resolution in the micrometer range (microtomography), the sensitivity enhancement associated with phase contrast imaging, and new X-ray microbeam-based imaging approaches such as fluorescence or diffraction microtomography are discussed below.

This section is devoted to another way of obtaining X-ray images, based on Bragg diffraction: the "X-ray topographic" techniques (the "historical" name is retained: it is widely used, but misleading because it suggests that these techniques are surface techniques, whereas very often they are used to probe the bulk of single-crystal samples). They were mostly developed in the late 1950s and 1960s to visualize defects and distortions in crystals. Work performed on silicon made the routine production of large perfect crystals, as used by the microelectronics industry, possible. These techniques are nondestructive and sensitive to a large range of distortions (typically in the 10^{-3}–10^{-8} range). Understanding the main contrast mechanisms implies knowing how crystal imperfections modify the diffraction behavior of the underlying perfect crystal. The dynamical theory of diffraction describes this behavior. The specific contributions of synchrotron radiation (and, briefly, neutrons) are outlined.

Principle of the Topographic Techniques

X-ray topography is an imaging technique for single crystals based on Bragg diffraction. The local variations of the amplitude or direction of the diffracted beam provide information on crystal inhomogeneities such as defects, domains, or phases. This information is often averaged out, and lost, when using usual diffraction methods.

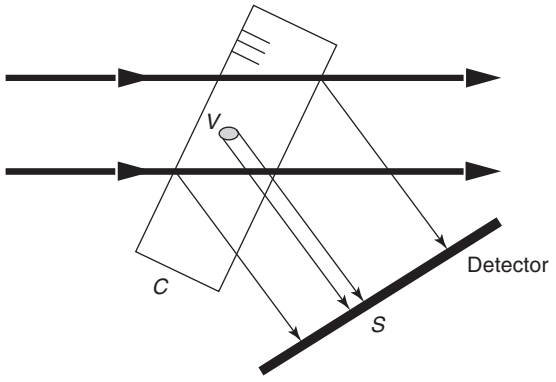

Figure 1 Principle of the topographic methods.

Figure 1 schematically represents the main idea of all the diffraction imaging methods. The single-crystal sample C is set to diffract a fraction of the incoming beam, according to Bragg's law, $2d \sin\theta_B = \lambda$. The diffracted beam is recorded on a position-sensitive detector (usually X-ray films, nuclear plates or, increasingly, CCD cameras equipped with a high-resolution scintillator). If a small volume V within C behaves differently from the matrix, intensity variations ("contrast") can be produced on an area S of the two-dimensional image produced by the diffracted beam. This contrast only occurs if the platelet-shaped crystal displays inhomogeneities.

The inhomogeneities that can be visualized using X-ray diffraction topography include defects such as dislocations (**Figure 2**), twins, domain walls, inclusions, impurity distribution, and macroscopic deformations, such as bending or acoustic waves, present within the single-crystal sample.

Figure 3 is an example of such a topographic image. It shows the image recorded using the 444 reflection from a flux-grown platelet-shaped gallium-substituted yttrium iron garnet crystal ($Y_3Ga_xFe_{5-x}O_{12}$, with $x \sim 1$, Ga–YIG) using the MoKα_1 radiation from a standard X-ray generator.

In addition to a distorted region on the upper corner, associated with the crystal fixation, various features are observable on this topograph: dislocations, growth striations and growth sectors, magnetic domains, dissolution bands, and the initial stage of a crack. These features are observed because they entail a distortion of the crystalline lattice. It is worth giving the typical value of these distortions, which include either a lattice rotation $\delta\theta$, or a lattice parameter variation $\Delta d/d$, or a combination of both. For the growth striations, which are the main observable features, this distortion is in the 10^{-4} range, whereas the variation of magnetostriction associated with the

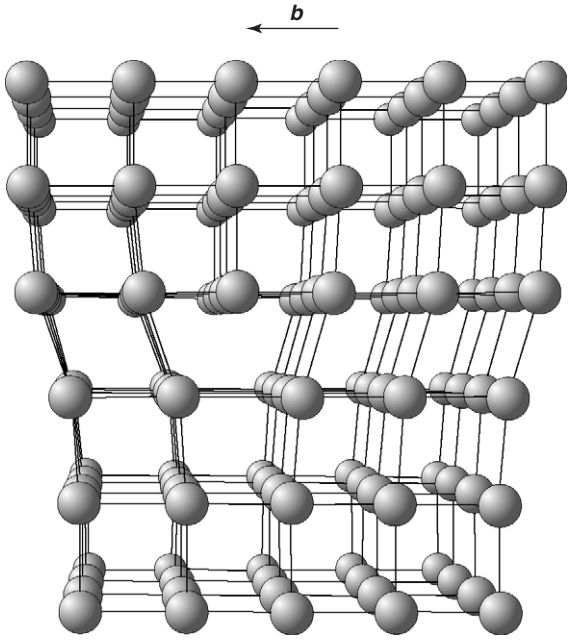

Figure 2 Schematic drawing of a dislocation, characterized by its line direction (the border of the incomplete atomic plane in this case) and the Burgers vector ***b*** (in this case – "edge" dislocation – horizontal and perpendicular to the line direction).

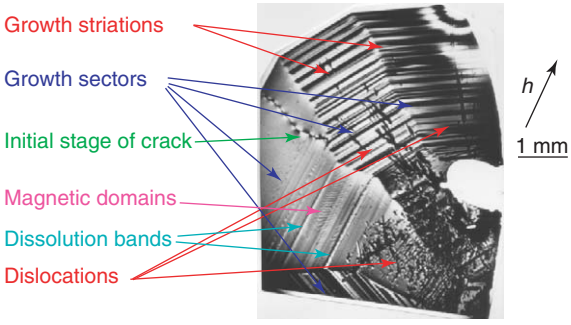

Figure 3 Topograph of a flux-grown Ga–YIG crystal.

magnetic domains, as well as the distortion between growth sectors, are in the 10^{-6} range. The distortion associated with dislocations is a function of the distance to the core; at the level of the image border, it is in the 10^{-5} range. Large contrast on the image can, therefore, correspond to rather weak distortions, showing that these techniques are very sensitive.

Some Results of Dynamical Theory

A few results of the dynamical theory, necessary to understand the contrast mechanisms, are given below. The discussion is restricted to symmetrical transmission geometry as shown in **Figure 1**.

In the case of a monochromatic plane wave beam, and a perfect crystal set in Bragg diffraction position (**Figure 1**), two "wavefields" propagate within the crystal if the direction of the incident beam propagation vector lies within an angle ω_b around the exact Bragg position (ω_b the intrinsic width of the diffraction curve, often called the Darwin width, being of the order of 10^{-5}–10^{-6} rad):

$$\omega_b = (2\lambda^2 C_p |F_b| r_0)/(\pi V_c \sin 2\theta_B) \qquad [1]$$

where C_p is the polarization factor ($C_\pi = \cos 2\theta_B$ for π polarization, i.e., for the electric field vector $\boldsymbol{E}$ in the scattering plane, and $C_\sigma = 1$ for σ polarization, i.e., for $\boldsymbol{E}$ perpendicular to this plane), r_0 is the "classical electron radius" (2.8×10^{-15} m), V_c is the unit cell volume, and F_b is the structure factor corresponding to the Bragg reflection used. A wavefield corresponds to the superposition of one diffracted and one forward-diffracted wave, coupled because the perfect crystal is set for Bragg diffraction. These waves decouple outside the crystal, producing two beams, parallel to the incident and diffracted directions, respectively (**Figure 4**).

In the case of a monochromatic spherical wave, wavefields propagate and interfere within the whole "Borrmann" fan or Borrmann triangle ABC (**Figure 4**). The characteristic coupling length between wavefields is Λ_0 (extinction length, or Pendellösung period), which corresponds, in the case considered, to the distance necessary for most of the energy participating in the diffraction process to move from the transmitted to the diffracted direction, or vice versa:

$$\Lambda_0 = (\pi V_c \cos\theta_B)/(\lambda C_p |F_b| r_0) \qquad [2]$$

Typical values of Λ_0 are in the 1–100 μm range.

If the crystal is rotated in a monochromatic beam, or if the beam is polychromatic, the diffracted power is a function of this "variable" (angle, or wavelength), leading to the integrated reflectivity ρ, defined as the area under the diffraction curve. **Figure 5** shows ρ for a nonabsorbing perfect crystal, as a function of t/Λ_0, t being the thickness of the platelet-shaped crystal, for both the transmission ("Laue") and reflection ("Bragg") cases. These curves show that

- ρ is proportional to t for $t \ll \Lambda_0$ ("kinematical" limit of the dynamical theory);
- ρ is nearly constant for $t \gg \Lambda_0$, the saturation value being proportional to $|F_b|$; and
- ρ displays an oscillatory behavior in the Laue case (the image produced by a low-absorption wedge-shaped crystal will, therefore, exhibit "equal thickness" fringes associated with the maxima and minima of the curve, and to the varying

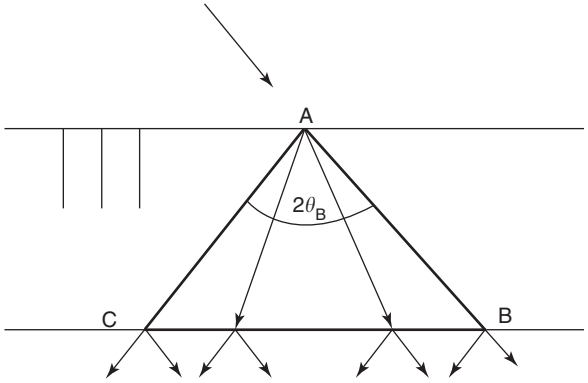

Figure 4 Propagation of wavefields within the "Borrmann" triangle ABC in the case of a perfect crystal.

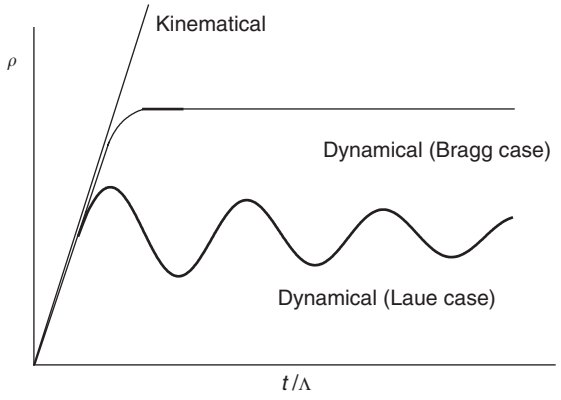

Figure 5 Reflecting power ρ of a nonabsorbing perfect crystal as a function of the reduced thickness t/Λ_0 for the transmission ("Laue") and reflection ("Bragg") cases. The kinematical approximation limit is also shown.

thickness of the crystal). Its saturation value, for $t \gg \Lambda_0$, is half of the one corresponding to the Bragg case.

Effect of Imperfections: Contrast Mechanisms

For a nonabsorbing plate-shaped crystal illuminated by a parallel and polychromatic beam (a good approximation for the simplest and presently the most usual topographic technique, white beam synchrotron radiation topography), within a very simplified approach, the direction and intensity of the locally diffracted intensity depends upon

- the structure factor F_h;
- the angle θ formed by the considered lattice planes, and the incident beam; and
- Y, a parameter that incorporates the modifications introduced by the crystal inhomogeneities on the perfect-crystal dynamical theory results.

The beams diffracted by two neighboring regions I and II of the sample produce contrast on the topograph if

1. $(F_h)_I \neq (F_h)_{II}$, where the differences can either reside in the modulus or the phase or the structure factor. This structure factor contrast is the main contrast mechanism in neutron diffraction topography of magnetic domains, the magnetic structure factor often being different for the various domains (**Figure 6**);
2. $\theta_I \neq \theta_{II}$, that is, regions I and II are misoriented – subgrains, domains, etc. – one with respect to the other: this is orientation contrast; **Figure 7** shows, for instance, white or black thick lines, corresponding to the separation, or superposition, of the images of subgrains;
3. $Y_I \neq Y_{II}$, the two regions display extinction contrast.

Imperfections modify the perfect-crystal behavior described by the dynamical theory. They can hide the interference fringes, or lead to locally enhanced or reduced diffracted intensity, depending on the absorption conditions. New images can occur through the decoupling of a wavefield and the creation of new wavefields at a defect.

In the low-absorption case, the predominant contrast mechanism is the so-called direct-image process. Assume again (**Figure 1**) that a polychromatic, extended beam impinges on a crystal such that a small crystal volume V contains a defect (inclusion, dislocation, etc.) associated with a distortion field, which decreases with growing distance from the defect core. A wavelength range $\Delta\lambda/\lambda = \omega_h/(\tan\theta_B)$ $(\sim 10^{-4})$ participates in diffraction by the "perfect" matrix crystal, whereas regions around the defect are at the Bragg position for components of the incoming beam which are outside this spectral range. The defect thus leads to additional diffracted intensity on the detector.

The regions that produce the direct image of a given defect are some distance away from the core of the defect. This distance depends not only on the nature of the defect, but also on the diffraction process itself. The lattice distortion acts on diffraction through an angle, the effective misorientation $\delta\theta$, which reflects the change in the departure from the Bragg angle that is associated with the existence of the defect:

$$\delta\theta(r) = -(\lambda/\sin 2\theta_B)\partial(\boldsymbol{h} \times \boldsymbol{u}(\boldsymbol{r}))/\partial(s_h) \qquad [3]$$

where $\boldsymbol{h}$ is the undistorted reciprocal lattice vector, $\boldsymbol{u}(\boldsymbol{r})$ is the displacement vector, and $\partial/\partial(s_h)$ is the

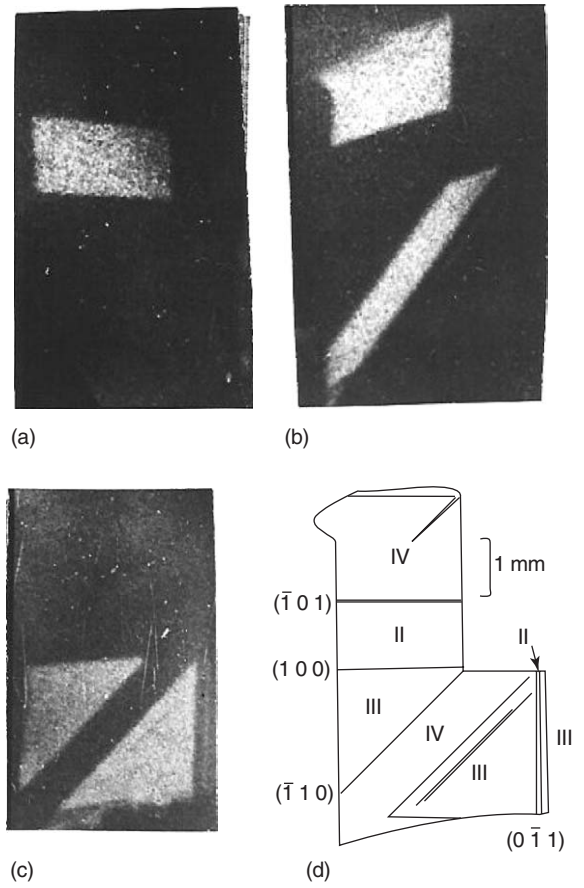

Figure 6 The observation, by neutron diffraction topography of antiferromagnetic domains in NiO is an example of "structure factor contrast." These domains are characterized by their propagation vector, which lies along one of the four equivalent 1 1 1 directions; each type of domain has a nonzero magnetic structure factor for the Bragg reflection corresponding to its propagation vector, and zero for the other three magnetic reflections: (a) 1,1, – 1, (b) – 1,1,1, (c) – 1,1, – 1, and (d) drawing of the domain configuration – type I is missing in the investigated crystal. These images were recorded – exposure times ~10 h – using a ^{157}Gd screen acting as n-β converter and X-ray film; "white" means more illuminated.

Figure 7 White beam topograph of an Fe–3%Si crystal, $E \approx 25$ keV, showing orientation contrast associated with subgrains. A fir-tree magnetic domain pattern is also visible.

differentiation along the reflected beam direction. It was shown that the width of the direct image corresponds to the contribution of regions such that $\delta\theta$ is of the order of ω_b. This can be understood when considering that the regions where the distortion is $< \omega_b$ are within the diffraction range of the perfect crystal, and that those where the distortion is $\gg \omega_b$ have a negligible contribution for the considered Bragg diffraction spot. This leads to "intrinsic" image widths, for an edge dislocation such as the one schematized in **Figure 2**, $\sim \Lambda_0 |\boldsymbol{b} \cdot \boldsymbol{h}|/4$ ranging in the 1–100 μm scale, and therefore implies a limitation on the density of defects that can be resolved on a topograph ($\sim 10^4$–$10^5\,\mathrm{cm}^{-2}$ for dislocations).

This also implies that direct images are only seen in crystals that are thick enough. Indeed, the dynamical theory predicts a width ω_b for thin ($t < \Lambda_0/\pi$) crystals inversely proportional to the thickness. If the crystal is thin, only very distorted regions with a strongly reduced volume – and consequently reduced diffracted intensity – can contribute to the direct image, which cannot therefore be observable.

The effective misorientation $\delta\theta$ allows, in addition, determining on which reflections a given defect can produce an image. Equation [3] shows that $\delta\theta = 0$ if $\boldsymbol{u}$ is perpendicular to $\boldsymbol{h}$. The defect is not visible on the corresponding topographs. A dislocation, for instance, is usually not visible when $\boldsymbol{h} \cdot \boldsymbol{b} = 0$, $\boldsymbol{b}$ being the Burgers vector. The invisibility criteria are powerful ways of characterizing the defects.

The effective misorientation can also be written as a function of the local variation in the rotation $\delta\varphi$ of the concerned lattice planes and the local relative variation in the lattice parameter, $\Delta d/d$, as

$$\delta\theta = -(\Delta d/d)\tan\theta_B \pm \delta\varphi \qquad [4]$$

When taking absorption into account, the situation can change drastically. Direct images do not occur in the high-absorption case ($\mu t > 10$), and are replaced by dips in the intensity corresponding to the disruption of a dynamical-theory-related effect, the anomalous transmission (also called the Borrmann effect). Both types of images ("additional" intensity and "dips") are simultaneously present on the topographs, as well as interference fringes ("dynamical" and "intermediary" images) for samples with intermediate absorption ($\mu t \sim 2-5$).

Diffraction Topographic Techniques

As already discussed, Bragg diffraction imaging may be used either in transmission or in reflection. In addition, the beam can be extended or restricted, and the image can be an integrated or a nonintegrated one.

Figure 1 shows an extended, divergent, and/or nonmonochromatic beam illuminating the whole sample, or a large area. This results in an image which can, to a first approximation corresponding to the predominance of the direct images, be considered as the projection of the defect distribution along the diffracted beam direction. The incident beam can also be restricted to a small width (typically 10–20 μm) in the scattering plane. In the same first approximation, this produces an image of those defects intercepted by the blade-shaped incident beam, hence the name "section" topograph.

A better definition of the extended/restricted beam distinction is based on the width of the Borrmann triangle, $w_B = 2t \sin\theta_B$ in the symmetrical Laue case, t being the crystal thickness. The extended beam, or projection topograph, situation corresponds to the case where the width w of the incoming beam in the scattering plane is such that $w \gg w_B$. The restricted beam, or section topograph, case corresponds to $w \ll w_B$.

In the section topography, the position of the direct images within the image can be used to extract the depth of the related defects in the crystal, one edge of the image corresponding to the entrance face of the sample, the other to the exit surface. In very good crystals, with small or moderate absorption, the same interference effect that leads to the oscillations shown in **Figure 5**, produces interference fringes, called Kato's fringes. These fringes are very sensitive to crystal distortion, and their modification is one of the first indications of a departure from the perfect-crystal situation (see **Figure 11**).

The use of a polychromatic beam with a sufficiently wide bandwidth often offers advantages. Several reflections are recorded simultaneously, which is very helpful when characterizing defects or phenomena, and misoriented regions within a sample diffract at once, each region finding a wavelength λ that satisfies the local Bragg condition. This "white beam" version of diffraction topography is identical to the well-known Laue technique, except that the incident beam is broad. Each Bragg spot is now a topograph. This is an integrated wave diffraction image, because it results from the superposition of contributions from a range of wavelengths. It is mainly sensitive to the variations of lattice plane orientation $\delta\varphi$, which produce a change in the diffracted beam direction, and not to $\Delta d/d$. "White beam" topography is widely used at synchrotron radiation facilities. The exposure time is often of the order of a fraction of a second, and it is possible to follow the evolution of any one of the Bragg spots in "real time," using a CCD camera equipped with a scintillator.

The incident beam on the sample can also be monochromatized. This "monochromatic wave" nevertheless displays a range of wavelengths ($\Delta\lambda/\lambda$) as well as an angular divergence ω. Let ω_c be the diffraction width of the crystal (which reduces to ω_b in the case of a "perfect" crystal). If the divergence ω (and/or $(\Delta\lambda/\lambda)\tan\theta_B$) $> \omega_c$, the image is still an integrated wave topograph.

If ω (and $(\Delta\lambda/\lambda)\tan\theta_B$) $\ll \omega_b$, the technique is called plane wave topography. It is not only suited to detect weak deformations (10^{-6}–10^{-8} range), but also to obtain images of defects such as dislocations (see **Figure 9**) with much more details than in the case of direct images. Its use allows a quantitative analysis, because the local diffracted intensity is closely related to the effective misorientation $\delta\theta$. An example of the use of "plane wave" topography is shown in **Figure 8**: the seed of the investigated quartz crystal and the various growth sectors exhibit different impurity contents, which result in small variations of the lattice parameter (in the 10^{-5}–10^{-7} range).

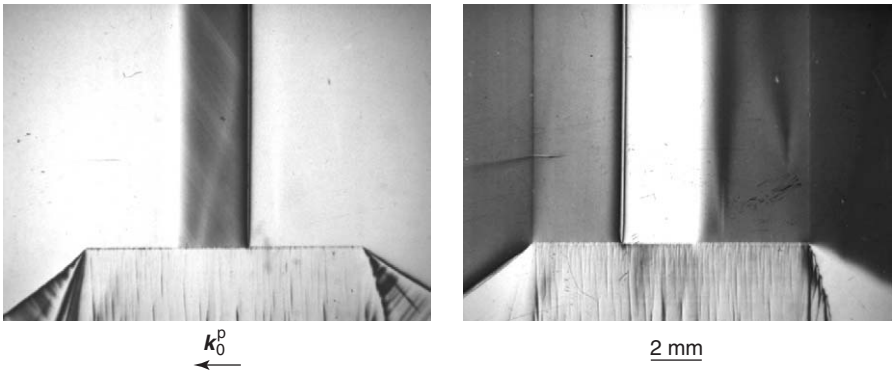

Figure 8 Bragg case plane wave topographs of a quartz plate with nonhomogeneous distributions of impurity atoms in different growth sectors and in the seed plate (rectangle in the middle part), $40\bar{4}0$ reflection, $E = 8.04778$ keV, $\boldsymbol{k}_0^p$ is the projection of the wave vector of the incident wave on the crystal surface; the topographs were recorded at ~40% of the maximum intensity on the low-angle side (left image) and ~20% of the maximum intensity on the high-angle side (right image) of the rocking curve.

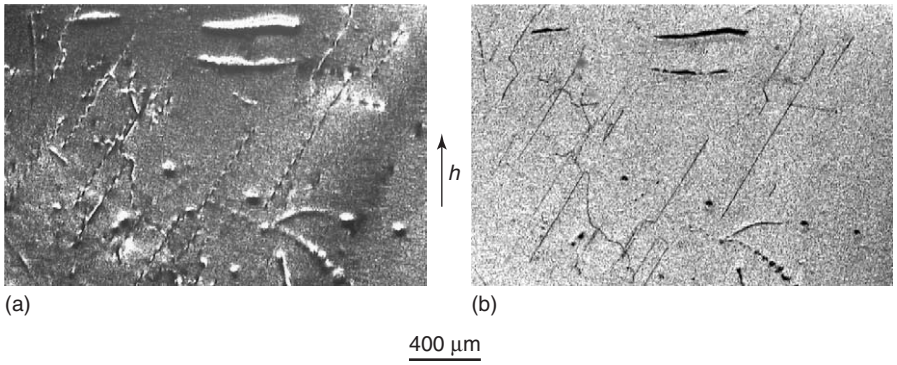

Figure 9 1 1 1 topographs of a Ge crystal recorded using the beam (35 keV) produced by an Si 1 1 1 monochromator: (a) top of the rocking curve, and (b) on the high-angle tail of the rocking curve ("weak beam" image).

If an image is recorded at an angular position very far away (typically a few ω_c) from the center of the diffraction curve, the main contribution to Bragg diffraction originates from the distorted regions, and not from the perfect-crystal matrix. This allows reducing the "intrinsic" width of the images and is known, by analogy with electron microscopy, as weak beam topography (**Figure 9**).

Synchrotron Radiation Topography: Real-Time Investigations and Coherence-Related Effects

Synchrotron radiation is now widely used for X-ray imaging. The typical exposure time to record a synchrotron radiation topograph is a fraction of a second. It is therefore possible to investigate evolving phenomena such as the movements of defects, boundaries during first-order phase transitions, or domains. Specific sample environments (cryostat, furnace, electric or magnetic field, strain, etc.) are added for each particular experiment. Image subtraction can help emphasize changes with respect to a reference state.

It is possible to investigate quicker phenomena if they are periodic, through stroboscopic imaging. Choppers located on the beam path and synchronized with periodic magnetic or electric fields were used to investigate phenomena such as the motion of magnetic domains or the evolution of conduction channels, in the 10^{-2}–10^{-3} s range. Stroboscopic experiments on bulk or surface acoustic waves, in the 10^{-8}–10^{-9} s range, were performed using the pulsed structure of the synchrotron radiation source itself (**Figure 10**).

The small source sizes and the large source-to-sample distances, which are now common features of modern synchrotron radiation facilities, lead to highly coherent X-ray beams, which can be used for diffraction topography. In this case surface inhomogeneities, or porosities, can be imaged in the diffracted beam even when they do not produce a strain field through their Fresnel diffraction image. Recording images at various sample-to-detector distances allow retrieving the phase jump involved in these images. The use of Bragg diffraction imaging with a coherent beam can even, in special cases, produce structural information at the atomic level, even though the spatial resolution of the images is on a much larger scale of micrometers. For instance, diffraction topographs of ferroelectric crystals, using a coherent beam, give access to a very elusive microstructural piece of information: how ferroelectric domains are connected across the domain wall and, in particular, how they match at the atomic level.

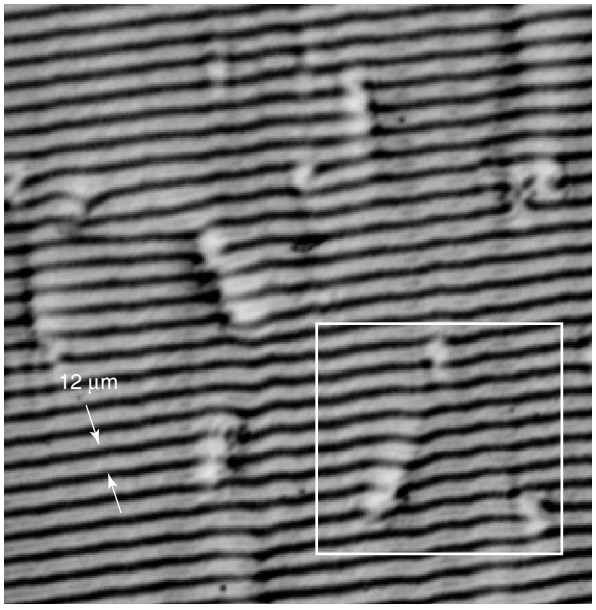

Figure 10 Stroboscopic topograph showing the propagation of surface acoustic waves – 12 μm wavelength – in an $LiNbO_3$ crystal. Wave front distortions caused by the interaction of the waves with dislocations are visible. One dislocation region is framed. (Courtesy of E Zolotoyabko.)

Simulations of X-Ray Topographs

The information provided by the topographs allows a detailed quantitative analysis. This is performed through simulations. The simulation process requires introducing a deformation field with free parameters that will be refined by comparing the simulated image to the experimental one. Depending on how rapidly the distortions (expressed by the effective misorientation $\delta\theta r$) change locally within the crystal, this may be done using diffraction theories with various complexities. In the case of **Figure 8**, the Bragg-case plane wave topographs of a quartz plate with nonhomogeneous distributions of impurity atoms, the local application of the dynamical theory for perfect crystals already provides very good results. In this case, the diffracted intensity can be approximated by the simple formula $I_h = I_M R_N(\theta_A - \delta\theta)$, where R_N is the rocking curve of the setup, I_M is a normalization factor, and θ_A is the Bragg angle in a crystal part assumed as the perfect reference one. This means that the contrast depends on the position of the "working point," which is determined, through the parameter $\delta\theta(\boldsymbol{r})$, by the local Bragg angle on the perfect reference–rocking curve. For faster varying deformations (**Figure 11**), a geometric-optical approximation may be chosen. The most general case requires a wave-optical approach, which is necessary to calculate, for instance, the contrast of a dislocation. The algorithms give very good results for the plane wave case.

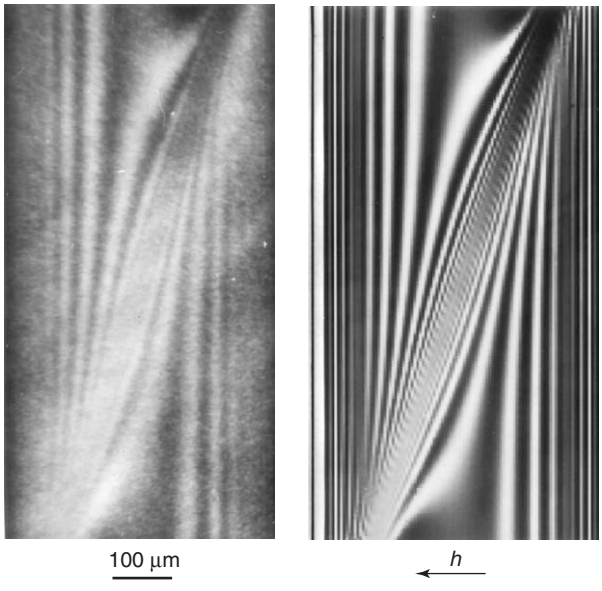

Figure 11 Measured (left) and calculated (right) 422 section topographs of a 565 μm thick silicon crystal with the edge of a 150 nm silicon oxide film, $E = 17.48$ keV.

Conclusion

X-ray diffraction topography is an invaluable tool to characterize single crystals and investigate many-crystal physics phenomena (creation of defects, domains, phase transitions, vibrations, etc.), whereas neutron topography remains a unique tool for the investigation of magnetic crystals, and more specially the antiferromagnetic ones. The scope of X-ray topography, when coupled with synchrotron radiation, extended to unexpected topics through the use of coherent beams or by *in situ* experiments, where the material, in an adequate sample environment device, is imaged while an external parameter (temperature, stress, etc.) is changed. Some of the applications, of course, require a better spatial resolution. A possibility of overcoming this limitation is to use an X-ray lens to magnify the image before the detector. Promising attempts are being made using parabolic compound refractive lenses, asymmetrically cut crystals, or bent mirrors (Kirkpatrick–Baez setup).

Nomenclature

$\boldsymbol{b}$	Burgers vector of a dislocation (m)
C_p	polarization factor (X-ray diffraction)
$F_{\boldsymbol{h}}$	structure factor associated with the reciprocal vector $\boldsymbol{h}$
r_0	classical electron radius (2.8×10^{-15} m)
$\boldsymbol{u}(\boldsymbol{r})$	displacement vector (m)
V_c	volume of the unit cell (m^3)
$\delta\theta(\boldsymbol{r})$	effective misorientation (rad)
θ_B	Bragg angle (rad)
λ	wavelength (m)
Λ_0	extinction distance (dynamical theory) (m)
$\omega_{\boldsymbol{h}}$	intrinsic width of the diffraction curve (dynamical theory) (rad)
