INTRODUCTION

Physics is the paradigm of all scientific knowledge. Over the centuries it has evolved to a complexity that has resulted in a separation into various subfields, always connected with one another and very difficult to single out. Freeman Dyson, in his beautiful book 'Infinite in All Directions', distinguishes two aspects of physics and two types of physicists: the unifiers and the diversifiers. The unifiers look for the most general laws of nature, like the universal attraction between masses and electric charges, the laws of motion, relativity principles, the simplest elementary particles, the unification of all forces, symmetry violation and so on. The diversifiers consider the immense variety of natural phenomena, infinite in their extension, try to explain them on the basis of known general principles, and generate new phenomena and devices that do not exist in nature. Even at the beginning of modern science Galileo Galilei, besides studying the laws of motion and laying down the principle of relativity, was interested in the phenomenon of fluorescence and disproved the theories put forward at his time. He was both a unifier and a diversifier. The full explanation of fluorescence had to await the advent of quantum mechanics, as did the explanation of other basic phenomena like electrical conductivity and spectroscopy.

The past century witnessed an explosive expansion in both aspects of physics. Relativity and quantum mechanics were discovered and the greatest of the unifiers, Albert Einstein, became convinced that all reality could be comprehended with a simple set of equations. On the other hand a wide range of complex phenomena was explained and numerous new phenomena were discovered. One of the great diversifiers, John Bardeen, explained superconductivity and invented the transistor.

In physics today we encounter complex phenomena in the behavior of both natural and artificial complex systems, in matter constituted by many particles such as interacting atoms, in crystals, in classical and quantum fluids as well as in semiconductors and nanostructured materials. Furthermore, the complexity of biological matter and biological phenomena are now major areas of study as well as climate prediction on a global scale. All of this has evolved into what we now call "condensed matter physics". This is a more comprehensive term than "solid state physics" from which, when the electronic properties of crystals began to be understood in the thirties, it originated in some way. Condensed matter physics also includes aspects of atomic physics, particularly when the atoms are manipulated, as in Bose–Einstein condensation. It is now the largest part of physics and it is where the greatest number of physicists work. Furthermore, it is enhanced through its connections with technology and industry. In condensed matter physics new phenomena, new devices, and new principles, such as the quantum Hall effect, are constantly emerging. For this reason we think that condensed matter is now the liveliest subfield of physics, and have decided to address it in the present Encyclopedia. Our focus is to provide some definitive articles for graduate students who need a guide through this impenetrable forest, researchers who want a broader view into subjects related to their own, engineers who are interested in emerging and new technologies together with biologists who require a deeper insight into this fascinating and complex field that augments theirs.

In this Encyclopedia we have selected key topics in the field of condensed matter physics, provided historical background to some of the major areas and directed the reader, through detailed references, to further reading resources. Authors were sought from those who have made major contributions and worked actively in the

area of the topic. We are aware that completeness in such an infinite domain is an unattainable dream and have decided to limit our effort to a six-volume work covering only the main aspects of the field, not all of them in comparable depth.

A significant part of the Encyclopedia is devoted to the basic methods of quantum mechanics, as applied to crystals and other condensed matter. Semiconductors in particular are extensively described because of their importance in the modern information highways. Nanostructured materials are included because the ability to produce substances which do not exist in nature offers intriguing opportunities, not least because their properties can be tailored to obtain specific devices like microcavities for light concentration, special lasers, or photonic band gap materials. For the same reasons optical properties are given special attention. We have not, however, neglected foundation aspects of the field (such as mechanical properties) that are basic for all material applications, microscopy which now allows one to see and to manipulate individual atoms, and materials processing which is necessary to produce new devices and components. Attention is also devoted to the ever-expanding role of organic materials, in particular polymers. Specific effort has been made to include biological materials, which after the discovery of DNA and its properties are now being understood in physical terms. Neuroscience is also included, in conjunction with biological phenomena and other areas of the field. Computational physics and mathematical methods are included owing to their expanding role in all of condensed matter physics and their potential in numerous areas of study including applications in the study of proteins and drug design. Many articles deal with the description of specific devices like electron and positron sources, radiation sources, optoelectronic devices, micro and nanoelectronics. Also, articles covering essential techniques such as optical and electron microscopy, a variety of spectroscopes, x-ray and electron scattering and nuclear and electron spin resonance have been included to provide a foundation for the characterization aspect of condensed matter physics.

We are aware of the wealth of topics that have been incompletely treated or left out, but we hope that by concentrating on the foundation and emerging aspects of the infinite extension of condensed matter physics these volumes will be generally useful.

We wish to acknowledge the fruitful collaboration of the members of the scientific editorial board and of the Elsevier editorial staff.

Special thanks are due to Giuseppe Grosso, Giuseppe La Rocca, Keith Bowman, Jurgen Honig, Roberto Colella, Michael McElfresh, Jaap Franse, and Louis Jansen for their generous help.

Acoustics: Physical Principles and Applications to Condensed Matter Physics

J D Maynard, The Pennsylvania State University, University Park, PA, USA

Introduction

For many condensed matter systems, including liquids as well as solids, acoustic measurements provide a crucial probe of important and fundamental physics of the system. In the case of solids, one of the first fundamental properties to be determined would be the atomic structure, defined by the minimum in the free energy with respect to the positions of the atoms. The next fundamental characteristic of interest might be the curvature of the free energy in the vicinity of the minimum, and this would be manifest in the elastic constants for the material. As derivatives of the free energy, elastic constants are closely connected to thermodynamic properties of the material; they can be related to specific heat, Debye temperature, the Gruneisen parameter, and they can be used to check theoretical models. Extensive quantitative connections may be made if the elastic constants are known as functions of temperature and pressure. Acoustic measurements not only probe lattice properties, they are also sensitive probes of the environment in which all interactions take place, and may be used to study electronic and magnetic properties (e.g., through magnetostriction effects). As will be discussed later, acoustic measurements involve tensor quantities, and thus can probe anisotropic properties of crystals. The damping of elastic waves provides information on anharmonicity and on coupling with electrons and other relaxation mechanisms. One of the most important features of acoustic measurements is that they provide a sensitive probe of phase transitions and critical phenomena; important examples, in addition to the obvious example of structural transitions in solids, include the superconducting transition and the superfluid transition. Indeed, one of the most impressive successes in critical phenomena has been the use of acoustics to study the lambda line of liquid helium. For the field of superconductivity, a paper on acoustic attenuation was included as one of the relatively small number of selected reprints on superconductivity published by the American Institute of Physics. Acoustic measurements are among the first performed whenever a material involving novel physics is discovered. Modern acoustic techniques, discussed below, can probe the properties of samples only a few hundred microns in size and nanoscale thin films, and may be utilized in practical applications such as micro-electro-mechanical systems (MEMS). Acoustic measurements provide significant information about condensed matter systems, and their accurate and precise measurement is certainly important.

Acoustics in Solids

For solids, acoustic phenomena reflect the elastic properties of the material. Interest in elasticity dates back to Galileo and other philosophers in the seventeenth century, who were interested in the static equilibrium of bending beams. With the basic physics introduced by Hooke in 1660, the development of the theory of elasticity followed the development of the necessary mathematics, with contributions from Euler, Lagrange, Poisson, Green, etc., and the resulting theory was summarized in the treatise by A E H Love in 1927.

Acoustic and elastic properties of solids are quantified in a set of elastic constants. These constants are like spring constants, relating forces, and displacements, and they may be measured with a static technique, in which a displacement is measured as a linear response to a small applied force. However, it was long ago learned that a better method is to measure an elastic vibration, as found, for example, in a propagating sound wave. Most existing complete sets of elastic constants for materials have been determined by measuring the time of flight of sound pulses. Recently, a relatively new method, resonant ultrasound spectroscopy (RUS), is being used. In the RUS method, rather than measuring sound velocities,

one measures the natural frequencies of elastic vibration for a number of normal modes of a sample, and processes these in a computer, along with the shape and mass of the sample. With a proper configuration, a single measurement yields enough frequencies to determine all of the elastic constants for a material (as many as 21 for a crystal with low symmetry). Samples may be prepared in a wide variety of shapes, including rectangular, spherical, etc., and it is not necessary to orient crystalline samples. A compelling reason for using RUS has to do with the nature of samples of new materials. Whenever a new material is developed, initial single crystal samples are often relatively small, perhaps on the order of a fraction of a millimeter in size. Also, with new developments in nanotechnology and the possibility of applications in the microelectronics industry, there is a great interest in systems which are very small in one or more dimensions, such as thin films and one-dimensional wires. For such small systems, pulse measurements are difficult, if not impossible, but RUS methods may be readily used.

Physical Principles for Acoustics in Solids

To begin a theory for acoustics in solids, one may imagine a spring, extended with some initial tension, and consider two points at positions x, and $x + \mathrm{d}x$. If one applies an additional local tension, or stress, σ, then the spring stretches and the two points are displaced by $\psi(x)$, and $\psi(x + \mathrm{d}x)$ respectively. The separation between the two points will have changed by $\mathrm{d}\psi$, and the fractional change in the separation, defined as the strain, is $\varepsilon \equiv \mathrm{d}\psi/\mathrm{d}x$. Hooke's law for the spring takes the form $\sigma = c\varepsilon$, where c is a one-dimensional elastic constant. For a three-dimensional elastic solid, one may use indices (i, j, etc.) which can take on the values 1, 2, and 3, referring to the x, y, and z coordinate directions, and generalize the strain to

$$\varepsilon_{ij} \equiv \frac{1}{2}\left(\frac{\partial \psi_i}{\partial x_j} + \frac{\partial \psi_j}{\partial x_i}\right) \qquad [1]$$

The symmetric form of ε_{ij} avoids pure rotations, which do not involve stress. The stress is generalized to σ_{ij}, a force per unit area acting on a surface element, where the first index refers to the coordinate direction of a component of the force, and the second index refers to the coordinate direction of the unit normal to the surface element. Hooke's law becomes

$$\sigma_{ij} = c_{ijkl}\varepsilon_{kl} \qquad [2]$$

where c_{ijkl} is the $3 \times 3 \times 3 \times 3$ (81 element) elastic tensor, and where a summation over repeated indices is implied. For a small volume element, the net force in the i-direction is $\partial\sigma_{ij}/\partial x_j$, and Newton's law may be written as

$$\frac{\partial \sigma_{ij}}{\partial x_j} = \rho \frac{\partial^2 \psi_i}{\partial t^2} \qquad [3]$$

where ρ is the mass density.

The symmetric nature of the definitions, and the assumption that the elastic energy must be quadratic in the strains, reduces the number of independent elements of c_{ijkl} from 81 to 21. A basic symmetry has c_{ijkl} invariant if the indices are exchanged in the first pair or second pair of the four subscripts ($c_{jikl} = c_{ijkl}$, etc.); thus a reduced system of indices may be used: $11 \to 1$, $22 \to 2$, $33 \to 3$, $23 \to 4$, $13 \to 5$, $12 \to 6$, so that $c_{ijkl} \to c_{\mu\nu}$. The reduced system is used when tabulating values of elastic constants; however, the full four-index tensor must be used in calculations. Additional symmetries of a particular crystal group will reduce the number of independent elastic constants further below 21; for example, orthorhombic crystals have nine independent elastic constants, cubic crystals have three, and isotropic solids have only two.

Later, the case of an isotropic elastic solid will be useful for the purposes of illustration. In this case, one has $c_{11} = c_{22} = c_{33}$, $c_{44} = c_{55} = c_{66}$, $c_{12} = c_{13} = c_{23} = c_{11} - 2c_{44}$, and all other elements of the elastic tensor are zero. The two independent elastic constants may be taken as c_{11} and c_{44}, but other combinations, such as Young's modulus $Y = c_{44}(3c_{11} - 4c_{44})/(c_{11} - c_{44})$ and the bulk modulus $B = c_{11} - 4c_{44}/3$ are also used. The bulk modulus appears in an important thermodynamic identity involving γ, the ratio of the specific heat at constant pressure c_p to that at constant volume, c_v:

$$\gamma = \frac{c_p}{c_v} = 1 + \frac{T\beta^2 B}{\rho c_p} \qquad [4]$$

Here T is the temperature and β is the thermal expansion coefficient (TEC).

Anharmonic Effects

The basic formulation of acoustics in solids involves the expansion of energy minima about equilibrium to second order, or equivalently, assuming a harmonic potential, quadratic in strain. However, there are a number of effects which require going beyond second order. Some effects are related to exceeding "small displacements" from equilibrium, such as in quantum solids with large zero-point motion, and solids at high temperatures (near melting) where thermal motions are large. Other effects occur in equilibrium at normal or low temperatures; these include thermal

expansion, lattice thermal conductivity, and acoustic dissipation.

The relationship between anharmonic effects and thermal expansion is worth discussing. As temperature is increased, the amplitude of atomic oscillations increases, or equivalently the occupation of higher quantized energy levels increases. If the potential energy was exactly quadratic in displacements, then the center of oscillation, or the expectation value of displacement, would remain the same. With the same average positions for the atoms, the system would not expand with increasing temperature, and the TEC β would be zero. From the thermodynamic identity in eqn [4], one would also have $c_p = c_v$. On the other hand, when potentials are anharmonic, one may have (in the typical case) a stiffer repulsion at short interatomic distances, and weaker attractive forces at larger distances. The result is that at higher energy levels, the "center" position between classical turning points moves to larger distances, and the system thermally expands. This situation is illustrated in **Figure 1**.

Anharmonicity and thermal expansion can also be readily related to nonlinear acoustics in fluids. For fluid acoustics, nonlinear effects are proportional to a dimensionless second order parameter $(\rho/v)(\partial v/\partial \rho)$, where v is the sound speed, and the derivative is at constant entropy. For gases, this parameter is $(\gamma - 1)$, which by the thermodynamic identity in eqn [4], is proportional to the thermal expansion coefficient β. Thus the absence of nonlinear acoustic effects coincides with a vanishing thermal expansion.

That an anharmonic potential results in acoustic dissipation and lattice thermal conductivity may be understood by noting that with a harmonic potential, one gets a linear second-order wave equation, whose wave solutions can superimpose and pass through one another with no effect. An anharmonic potential allows sound waves (lattice vibrations) to interact and scatter from one another, permitting the transfer of energy from an ordered to a disordered form (acoustic dissipation), and allowing a change in distribution functions in passing from one location to another (lattice thermal conductivity).

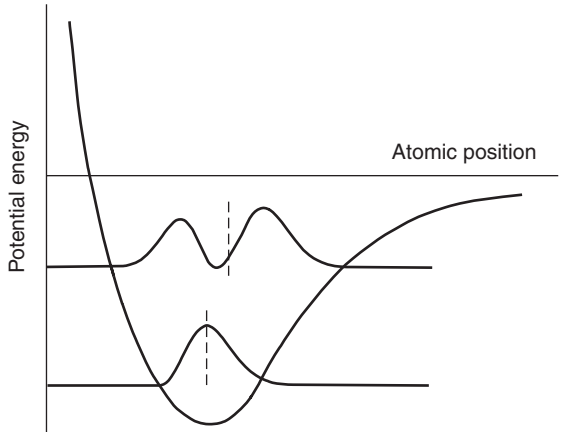

Figure 1 Illustration of the relationship between a nonquadratic potential energy curve (and nonlinear acoustics) and the phenomenon of thermal expansion.

Anharmonic effects may be probed with acoustic experiments by measuring the changes in the elastic constants as the sample is subjected to increasing uniaxial or uniform hydrostatic pressure. The coefficients which relate the changes to the pressure are referred to as "third-order elastic constants." How elastic constants themselves are determined with acoustic measurements is discussed next.

Determining Elastic Properties Experimentally

To determine the nature of sound propagation in solids, one must solve eqns [1] through [3] with some specified boundary conditions. Because of the tensor nature of the equations, the relation between particle displacement and the direction of wave propagation is quite complicated. To tackle the complexity and make a connection between ultrasound measurements and the elastic constants, two approaches may be taken. The first approach, used in conventional pulse ultrasound, is to note that if one had a sample with a large (infinite) plane surface which is perpendicular to one of the principle axes of the elastic tensor, and if a plane wave could be launched from that surface, then the tensor equations would uncouple, and a longitudinal wave or one of two transverse waves could propagate independently. In this case, for each wave, the relationship between the sound velocity and the independent elastic constants is fairly straightforward. While the determination of the principle axes and the relationships between the three sound speeds and the relevant elastic constants may be done analytically, the manipulations are complicated and must be done on a case-by-case basis; there is no elucidating general formula. The simplest case of an isotropic elastic solid will be presented here for purposes of illustration. In this case, Newton's law may be written in terms of the two independent elastic constants, c_{11} and c_{44}:

$$\rho \frac{\mathrm{d}^2 \boldsymbol{\psi}}{\mathrm{d}t^2} = c_{11} \nabla^2 \boldsymbol{\psi} - c_{44} \boldsymbol{\nabla} \times (\boldsymbol{\nabla} \times \boldsymbol{\psi}) \qquad [5]$$

$$= c_{44} \nabla^2 \boldsymbol{\psi} + (c_{11} - c_{44}) \boldsymbol{\nabla} (\boldsymbol{\nabla} \cdot \boldsymbol{\psi}) \qquad [6]$$

where the two equations are related by an identity for the $\boldsymbol{\nabla}$ operator. If one has $\boldsymbol{\nabla} \times \boldsymbol{\psi} = 0$, then the first

equation becomes a simple wave equation for a longitudinal wave with speed $v_l = \sqrt{c_{11}/\rho}$, and if one has $\nabla \cdot \boldsymbol{\psi} = 0$, then the second equation becomes a simple wave equation for transverse waves with speed $v_t = \sqrt{c_{44}/\rho}$.

Although the pulse ultrasound method has been used extensively in the past, it has a number of disadvantages, including problems with transducer ringing, beam diffraction, and side-wall scattering, and the inconvenience that the sample must be recut, repolished, and reattached to a transducer if one wants more than the three elastic constants accessible with one measurement. The second approach to determining elastic constants avoids all of the disadvantages.

The second approach is the one described earlier as RUS, which involves the use of a computer to numerically solve the elastic constants given a set of measured natural frequencies for a solid with a given shape and boundary conditions (usually stress-free conditions). The computer processing involves solving a "forward problem" (finding the natural frequencies in terms of the elastic constants) first and then inverting. Unlike the conventional pulse ultrasound approach, the forward problem does not provide a simple relationship between the modes of vibration and the elastic constants; the displacements in the various modes involve all of the elastic constants in a complicated manner, and a numerical computation is required to sort it all out.

The forward problem may be posed as the minimization of a Lagrangian L given by

$$L = \iiint (\rho\omega^2 \psi_i \psi_i - c_{ijkl}\varepsilon_{ij}\varepsilon_{kl})\, \mathrm{d}V \qquad [7]$$

The minimization is accomplished numerically with a Rayleigh–Ritz method, and the results yield discrete resonance frequencies, $f_n = 2\pi\omega_n$, given the elastic constants, c_{ijkl}. For the RUS technique, what is needed is the inverse. In most cases, there will be more measured frequencies than independent elastic constants; so what is required is to find a set of independent elastic constants which best fits the measured frequencies, usually in a least squares sense. Furthermore, when there are more measured frequencies than independent elastic constants, then other parameters may be varied in order to best fit the measured frequencies. Such parameters may include the shape and dimensions of the sample (although one known length is necessary), and the orientation of the crystallographic axes relative to the faces of the sample. In any case, it is not necessary that crystallographic axes be oriented with respect to faces of a sample, although computations are greatly simplified if they are oriented.

Experimental Methods for Acoustic Measurements in Solids

Acoustic measurements with the pulse method are fairly straightforward; emphasis is on careful bonding of transducers to samples and the use of suitable high-frequency pulse electronics. The RUS method is less well known, and can be briefly described as follows.

In a general RUS measurement, the natural frequencies of a sample with stress-free boundary conditions are determined by measuring the resonance frequencies of the sample when held (lightly, with no bonding agents, at two positions on the sample surface) between two transducers. One transducer acts as a drive to excite vibrations in the sample at a tunable frequency, and the second measures the amplitude (and possibly the phase) of the response of the sample; as the frequency of the drive is swept, a sequence of resonance peaks may be recorded. The positions of the peaks will determine the natural frequencies f_n (and hence the elastic constants), and the quality factors (Q's, given by f_n divided by the full width of a peak at its half-power points) will provide information about the dissipation of elastic energy.

RUS may also be used to measure the properties of thin films on a substrate, to determine the effects of induced strain from lattice mismatch, etc. In this case, the natural frequencies of the substrate alone are measured, then the same sample is again measured with the film in place. From the shifts in the natural frequencies, the properties of the film may be determined.

A simple apparatus for making RUS measurements is illustrated in **Figure 2**. In the illustration, a rectangular parallelepiped sample is supported by transducers at diametrically opposite corners. Corners are used for contact because they provide elastically weak coupling to the transducers, greatly reducing loading, and because the corners are always elastically active (i.e., they are never nodes), and thus can be used to couple to all of the normal modes of vibration.

Acoustics in Fluids

The thermo-hydrodynamic state of a fluid may be specified with five fields, which may be taken as the mass density $\rho(\boldsymbol{r}, t)$, the pressure $p(\boldsymbol{r}, t)$, and the mean flow velocity $\boldsymbol{u}(\boldsymbol{r}, t)$. The five equations needed to determine the five fields are conservation of mass, Newton's law for the motion of the center of mass of a fluid element (three components), and conservation of energy for motion about the center of mass. These

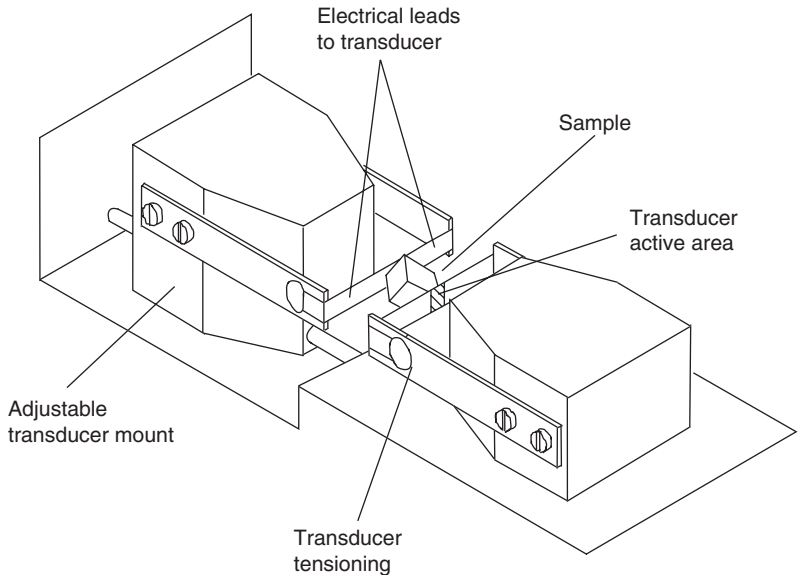

Figure 2 An apparatus for measuring elastic constants and acoustic attenuation with RUS.

equations are respectively:

$$\frac{\partial \rho}{\partial t} + \boldsymbol{\nabla} \cdot (\rho \boldsymbol{u}) = 0 \qquad [8]$$

$$\rho \left[\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u} \cdot \boldsymbol{\nabla} \mathrm{u} \right] = -\boldsymbol{\nabla} p + \eta \nabla^2 \boldsymbol{u} + \left(\frac{1}{3}\eta + \xi \right) \boldsymbol{\nabla} (\boldsymbol{\nabla} \cdot \boldsymbol{u}) \qquad [9]$$

$$T \left[\frac{\partial S}{\partial t} + \boldsymbol{u} \cdot \boldsymbol{\nabla} S \right] = \frac{2\eta}{\rho} \left[e_{ij} - \frac{1}{3} (\boldsymbol{\nabla} \cdot \boldsymbol{u}) \right]^2 + \frac{\xi}{\rho} (\boldsymbol{\nabla} \cdot \boldsymbol{u})^2 + \frac{1}{\rho} \boldsymbol{\nabla} \cdot (\kappa \boldsymbol{\nabla} T) \qquad [10]$$

where S is entropy, $e_{ij} = (\partial u_i / \partial x_j + \partial u_j / \partial x_i)/2$, η and ξ are the shear and bulk viscosity, and κ is the thermal conductivity. The transport terms (involving η, ξ, and κ) give rise to dispersion and dissipation. If these terms are dropped, then the last equation simply gives $S =$ constant, and the first two (for small displacements from equilibrium) are easily combined to give a wave equation with a sound speed given by $(\partial p / \partial \rho)_S$.

Superfluids are modeled as having a superfluid component (in a macroscopic quantum ground state) and a normal-fluid component (a gas of excitations above the ground state). With two fluid components, nine fields are required to specify the state of the system; in addition to the ones for a classical fluid, one also has the mass density and the mean flow velocity for the superfluid component alone. Now the linearized equations admit two sound speeds for the unconstrained fluid, and two more sound speeds when the normal fluid component is held fixed through its viscosity, and the inviscid superfluid component is still free to flow. The four sound modes are (1) a pressure wave with the two components moving together (referred to as "first sound"), (2) a temperature wave with the two components moving in counterflow ("second sound"), (3) a pressure wave with the normal fluid clamped ("fourth sound"), and (4) a temperature wave with the normal fluid clamped ("fifth sound"). An illustration of these modes is presented in **Figure 3**. "Third sound" is a surface wave which propagates on a thin film of superfluid; it is not a fundamental sound mode because its restoring force is not intrinsic to the superfluid, but rather is determined by the substrate on which the superfluid film is formed. With both mechanical and thermal properties represented in the sound modes, the sound speeds, measured as functions of temperature and pressure, may be used to determine all of the thermodynamics of the superfluid.

Applications of Acoustics in Condensed Matter Physics

In areas of condensed matter physics which involve the development of exotic materials, it is often of great value to use acoustics simply to measure and tabulate sound speeds or elastic constants. This is the case for such materials as alloys, composites, porous materials, sintered materials, polymers (plastics, epoxies, elastomers, etc.), cements, piezoelectrics, viscoelastic and non-Newtonian fluids, and fluid mixtures. In some cases, it is of significant benefit to use acoustics to monitor systems which evolve in

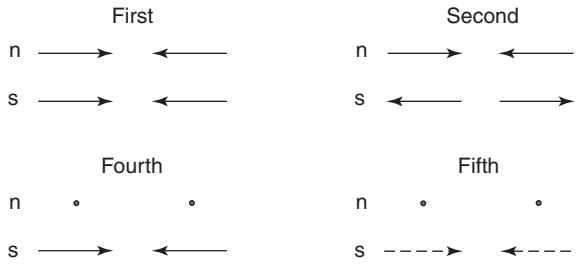

Figure 3 An illustration of the basic sound modes in superfluid helium. The "n" and "s" lines indicate the motion of the normal fluid and superfluid components, respectively. The dots indicate that the normal fluid has been clamped by its viscosity. The dashed lines indicate motion under "pressure release" conditions.

time, as during the curing of epoxy, the hardening of cement, the progress of chemical reactions, etc. Other special condensed matter systems which benefit from basic acoustic measurements are quantum solids, superfluids, quasicrystals, granular media, foams, rocks, etc. High amplitude acoustic fields are used as driving mechanisms in sonochemistry, cavitation studies (including cavitation in quantum fluids), acoustic levitation (facilitating noncontact sample manipulation), and sonoluminescence, in which a collapsing bubble creates such extreme conditions that light may be emitted. Acoustic emission, where signals are generated by the system itself, is important in studies of cracks, fracture, earthquakes, etc.

A particular application of acoustic measurements in solid state physics is the determination of the contribution of lattice acoustic modes to the specific heat, c_{lat}. This is given by

$$c_{\text{lat}} = 9\left(\frac{n}{\rho}\right)k_{\text{B}}\left(\frac{T}{\Theta_{\text{D}}}\right)^3\int_0^{\Theta_{\text{D}}/T}\frac{x^4 e^x dx}{(e^x-1)^2} \qquad [11]$$

where n is the number of lattice sites per unit volume, k_{B} is Boltzmann's constant, and Θ_{D} is the Debye temperature. It is the Debye temperature which may be expressed in terms of acoustic parameters, as follows:

$$\Theta_{\text{D}} = \frac{\hbar}{k_{\text{B}}}\left[\frac{1}{18\pi^2 n}\sum_s\int\frac{d\Omega}{4\pi}\frac{1}{v_s(\hat{k})^3}\right]^{-1/3} \qquad [12]$$

Here the sum in s is over the three different acoustic modes in a particular direction $\hat{k}$, which have sound speeds $v_s(\hat{k})$. For isotropic solids, the average of $1/v_s^3$ is $(1/v_{\text{l}}^3 + 2/v_{\text{t}}^3)$.

As mentioned in the introduction, an important application of acoustics is in the study of phase transitions. Acoustic studies are typically used in conjunction with a model of the transition, for example, a Landau expansion in the case of second-order transitions. In this case the free energy F, including elastic strain energy, may be expressed as a fourth-order equation in some order parameter Ψ:

$$F = \tfrac{1}{2}c_0\varepsilon^2 + \tfrac{1}{2}a_1(T-T_{\text{c}})\Psi^2 + \tfrac{1}{4}a_2\Psi^4 + \tfrac{1}{2}a_3\varepsilon\Psi^2 \qquad [13]$$

where c_0 and ε are some nominal elastic constant and strain (ignoring the tensor nature), T_{c} is the critical temperature, and a_1, a_2, and a_3 are constants. The effective elastic constant is $(\partial^2 F/\partial\varepsilon^2)$. Minimizing the free energy with respect to the order parameter gives the result that the effective elastic constant is c_0 when $T > T_{\text{c}}$, and is $(c_0 - a_3^2/2a_2)$ when $T < T_{\text{c}}$. Thus an experimentally measured jump in an elastic constant at a second-order phase transition gives access to the parameters in a Landau expansion.

An extensive application of RUS has been in geophysics, where the measurement of the thermodynamic properties and anharmonic effects of materials at high temperatures (exceeding twice the Debye temperature) are a high priority. Elastic data can check theoretical models and their extension to high temperature and pressure, where some asymptotic behavior may be convenient for other geophysical calculations and for extrapolations to even higher temperatures. Anharmonic effects are evident in the Gruneisen relation and in the departure of heat capacity from the Law of Dulong and Petit, $c_{\text{lat}} = 3(n/\rho)k_{\text{B}}$.

Acoustic Dissipation

Acoustic dissipation may be discussed with two basic pictures. In one picture, energy in an ordered form in the acoustic field is lost to some disordered form, so that the amplitude of a sound wave decreases with distance x as $e^{-\alpha x}$, where α is the attenuation coefficient. From the functional form $e^{-\alpha x}$, the attenuation coefficient α may be considered as an imaginary part of a complex wave vector, $\tilde{k} = k + i\alpha$. Acoustic dissipation in this picture is typically modeled with a coupling term in a Hamiltonian between phonons and some other system into which energy is lost (electrons, magnetic spins, etc.).

In the second picture, one notes that changes in stress (or strain) are not immediately followed by changes in strain (or stress), and there is a time lag, with a characteristic relaxation time, between energy being stored in kinetic and potential forms. If there were no time lag, then acoustic variations would oscillate back and forth along a single path (typically an isentrope) in the stress–strain plane. If there is a time lag, then the path opens up into a loop, and acoustic energy would be dissipated as "lost work" equal to the nonzero area of the loop. The time lag may be represented with a time dependence $f(t) = (1 - e^{-t/\tau})$, where τ is the characteristic relaxation time from a

sudden change. The time lag is incorporated in the equations of motion with additional time derivatives; however, the equations may be analyzed by Fourier transforming in time, and the result involves the Fourier transform of $f(t)$, proportional to $\hat{f}(\omega)$ given by

$$\hat{f}(\omega) = \frac{1}{1+(\omega\tau)^2} + \mathrm{i}\,\frac{\omega\tau}{1+(\omega\tau)^2} \qquad [14]$$

The real part gives rise to dispersion in sound propagation, and the imaginary part results in attenuation; the effective attenuation coefficient is $\alpha = \alpha_{\max} 2\omega\tau/(1+\omega^2\tau^2)$, where the attenuation peak $\alpha_{\max}$ occurs when $\omega\tau = 1$.

For fluids, the "time lag" derivatives are already in place in eqns [8]–[10]. If the terms containing the transport coefficients η, ξ, and κ are not dropped, and the equations are solved to first order in these coefficients, then solutions will involve a complex wave vector $\tilde{k} = k + \mathrm{i}\alpha$, with the attenuation coefficient α given by

$$\alpha = \frac{\omega^2}{2\rho v^3}\left[\left(\frac{4}{3}\eta + \xi\right) + \frac{\kappa}{\gamma c_v}(\gamma - 1)\right] \qquad [15]$$

For solids, forms of acoustic dissipation which are most readily analyzed with the first picture include electron–phonon scattering and phonon–phonon scattering. The picture for electron–phonon scattering is particularly important for studying Bardeen–Cooper–Schrieffer (BCS) superconductors; as more electrons pair and enter the superconducting state, the phonon interaction gets used up in the pairing interaction, and part of the electron–phonon scattering no longer contributes to acoustic attenuation. Thus, a measured drop in acoustic attenuation tracks the number of paired electrons.

Forms of acoustic dissipation which are most readily analyzed with the second picture include time lags for energy transfer to magnetic spin systems, electric dipole systems, defect and impurity motion (mechanical diffusion or viscosity), other forms of energy storage (thermal diffusion), etc. Models based on the second picture are particularly useful in analyzing acoustic attenuation measurements in glasses, "two-level" systems, impurity doped systems, etc.

The list of mechanisms related to acoustic attenuation just presented is by no means exhaustive. Indeed, the broad range of interacting mechanisms make acoustic attenuation one of the most widespread applications of acoustics in condensed matter physics.

Allotropy and Polymorphism

D R Gaskell, Purdue University, West Lafayette, IN, USA

The thermodynamic origins of allotropy and polymorphism are presented. Allotropy and polymorphism are, respectively, the ability of elements and of chemical compounds to have stable existences in more than one crystal form. The allotropies of iron, carbon, and sulfur, and the polymorphisms of silica and zirconia are discussed.

Introduction

A chemical element exhibits allotropy when it can have a stable existence in more than one crystal form. Polymorphism is the same phenomenon exhibited by a chemical compound. When a range of possible states of existence is available to an element or compound, the stable state is that which has the lowest molar Gibbs free energy at the constant values of pressure and temperature of interest. The molar Gibbs free energy, G, in turn, is determined by the molar enthalpy, H, the molar entropy, S, and the temperature (in kelvins), T, as

$$G = H - TS$$

Low values of G are obtained with low values of H and high values of S. As only changes in enthalpy can be measured by the transfer of thermal energy between a thermodynamic system and a thermostating reservoir, the enthalpy H does not have a definite value and thus, also, G does not. In contrast, S, which is a measure of the thermal and configurational disorder in a thermodynamic system, does have a definite value. Consequently, changes in the molar Gibbs free energy which accompany phase transformations or chemical reactions can be obtained from the corresponding changes in H and S as

$$\Delta G = \Delta H - T\Delta S$$

The molar enthalpy of an element, relative to that of the state in which the atoms are at infinite distances from one another, is the thermal energy transferred to a thermostat when the atoms come together and occupy the sites in a regularly arrayed crystal lattice. The relative enthalpy is then a measure of the bonding energy in the crystal.

The Allotropy of Iron

Iron has two allotropes: a face-centered cubic (f.c.c.) crystal form and a body-centered cubic (b.c.c.) crystal form. In the former, the unit cell has atoms located at each of the eight corners, each one of which contributes one-eighth of an atom to the unit cell. Atoms located at the centers of each of the six faces of the cell, each contribute one-half of an atom to the unit cell, to give a total of four atoms per unit cell. Alternatively, the f.c.c. crystal structure can be considered to consist of planes of close-packed atoms stacked in the sequence ABCABC. The b.c.c. unit cell has atoms located at each of the eight corners of the unit cell and one atom located at the center of the cell, giving two atoms per unit cell.

The variations, with temperature at a constant pressure of 1 atm, of the molar Gibbs free energies of the f.c.c. and b.c.c. allotropes of iron are shown schematically in **Figure 1a**. In **Figure 1a**

$$\left(\frac{\partial G}{\partial T}\right)_P = -S$$

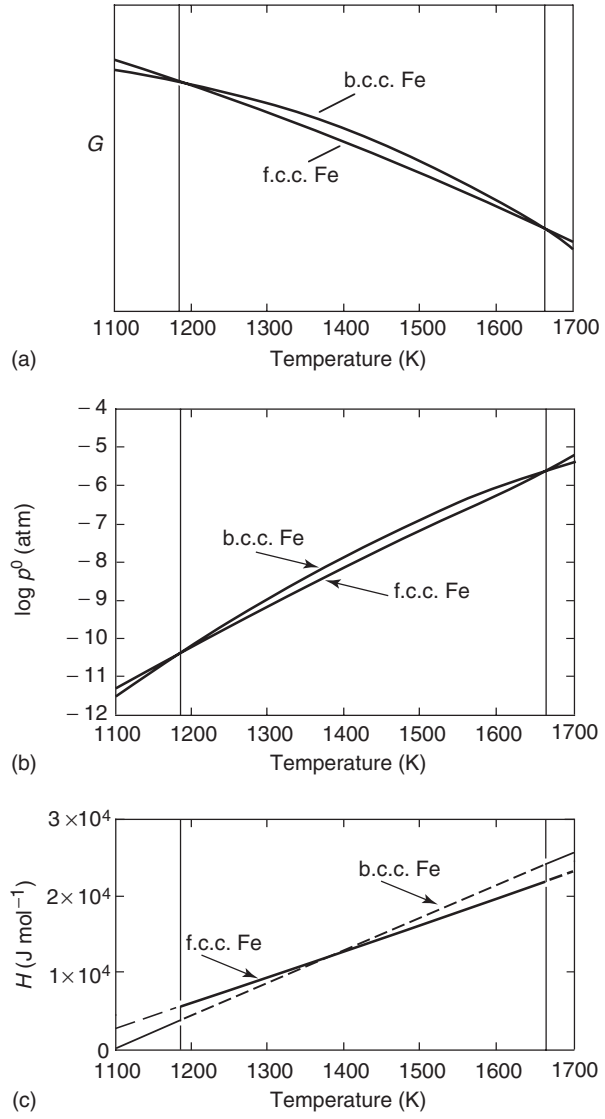

Figure 1 (a) The variations, with temperature, of the molar Gibbs free energies of b.c.c. Fe and f.c.c. Fe (schematic). (b) The variations, with temperature, of the saturated vapor pressures of b.c.c. Fe and f.c.c. Fe. (c) The variations, with temperature, of the relative molar enthalpies of b.c.c. Fe and f.c.c. Fe.

and

$$\left(\frac{\partial^2 G}{\partial T^2}\right)_P = -\frac{c_p}{T}$$

where c_p is the constant pressure molar heat capacity of the phase. This quantity is formally defined as

$$c_p = \left(\frac{\partial H}{\partial T}\right)_P \qquad [1]$$

that is, it is the ratio of the heat absorbed by a mole of substance, at constant pressure, to the consequent increase in temperature.

The shapes of the curves in **Figure 1a** are determined by the constant pressure molar heat capacities and the molar entropy of the two crystal forms. In the temperature range 1100–1700 K, the value of c_p for b.c.c. Fe is 7.9 J K^{-1}, larger than that for f.c.c. Fe and the highly ordered f.c.c. crystal structure has a lower molar entropy than that of the b.c.c. structure. Thus, in **Figure 1**, since the rate of decrease of G with increasing temperature for the b.c.c. Fe is greater than that for the f.c.c. Fe and the second derivative of the line for b.c.c. Fe is greater than that of the f.c.c. line, the lines intersect twice at 1187 and 1664 K. Thus, the b.c.c. form is stable at temperatures lower than 1187 K and at temperatures from 1664 K to the melting temperature of 1809 K. The f.c.c. form is stable in the range of temperature 1187–1664 K. The low-temperature b.c.c. form is referred to as α-Fe, the f.c.c. form is referred to as γ-Fe and the high-temperature b.c.c. form is referred to as δ-Fe. The original assignment of β-Fe to the low-temperature b.c.c. form, between the Curie temperature of 1033 and 1187 K, is no longer used.

Figure 1b shows the variations, with temperature, of the saturated vapor pressures exerted by b.c.c. Fe and f.c.c. Fe in the range of temperature 1100–1700 K. The saturated vapor pressures are related to the difference between the Gibbs free energies of the two crystal forms by

$$\Delta G(\alpha \rightarrow \gamma) = RT \ln \frac{p_\gamma^0}{p_\alpha^0}$$

A negative value of $\Delta G(\alpha \rightarrow \gamma)$ makes the p_γ^0 value lower than the p_α^0 value.

As has been stated, the constant pressure molar heat capacity of b.c.c. Fe is 7.9 J K^{-1} larger than that of f.c.c. Fe. Consequently, from eqn [1], the rate of increase of the molar enthalpy of b.c.c. Fe is greater than that of f.c.c. Fe. The variations, with temperature, of the relative molar enthalpies of the two crystal forms are shown in **Figure 1c**, in which the reference state is chosen as b.c.c. Fe at 1100 K. Increasing the temperature from 1100 to 1187 K causes the molar enthalpy to increase along the b.c.c. Fe line. At 1187 K, the b.c.c. form transforms to the f.c.c. form with the required increase in enthalpy (the latent heat of the transformation). Further heating causes the enthalpy to increase along the f.c.c. Fe line (which intersects with the metastable b.c.c. Fe line at 1397 K) and, at 1664 K, the f.c.c. Fe transforms back to the b.c.c. Fe, again with the required increase in enthalpy.

The combination of the allotropy of iron and Henry Bessemer's patent no. 356, dated 12 February 1856 "On the Manufacture of Malleable Iron and

Steel without Fuel," gave rise to the Industrial Revolution. Carbon, which is the alloying element in plain carbon steel, occupies interstitial sites in the f.c.c. Fe and b.c.c. Fe lattices. The solution of carbon in f.c.c. Fe produces a phase called austenite, and its solution in b.c.c. Fe produces a low-temperature phase called α-ferrite and a high-temperature phase called δ-ferrite. As the interstitial sites in f.c.c. Fe are larger than those in b.c.c. Fe, the solubility of carbon in austenite is larger than in α-ferrite and δ-ferrite. Thus, carbon is an "austenite stabilizer." **Figure 2**, which is the phase diagram for the system Fe-Fe_3C, shows the extent of the austenite phase field which terminates at the eutectoid point (0.78 wt.% C, 723°C). When the temperature of austenite of this composition is decreased to a value lower than 723°C, the austenite undergoes a eutectoid decomposition to produce a structure consisting of alternating layers of ferrite and cementite (the metastable iron carbide, Fe_3C). This structure is called pearlite and the fineness of the structure is determined by the rate of cooling of the eutectoid austenite through the eutectoid temperature. The coarseness of the microstructure increases with decreasing cooling rate. With increasing rate of cooling a limit is reached, beyond which nucleation of the ferrite and the cementite from the austenite is inhibited. The austenite transforms to a metastable body-centered tetragonal phase by means of a diffusionless shear mechanism. This very hard and brittle structure is called martensite and, in it, the shear stresses which cause the brittleness are relieved by tempering at some temperature less than 723°C. The occurrence of allotropy in iron allows the mechanical properties of plain carbon steels to be manipulated by a choice of carbon content and heat treatment. Thus, steels can be produced, which, at one extreme, are soft enough to be plastically deformed to the shape of a paper clip, or, at the other extreme, hard and tough enough to be used as a bearing material.

Nickel, which has the f.c.c. crystal structure, forms substitutional solid solutions with iron and hence stabilizes the f.c.c. structure. Under equilibrium conditions, a γ-Fe,Ni containing 53 wt.% Ni undergoes a eutectoid decomposition to α-Fe and $FeNi_3$ at 345°C. However, as nucleation and growth of α-Fe from γ-Fe,Ni requires significant diffusion by migration of vacant lattice sites, the presence of a few percent Ni in solid solution in the γ-Fe,Ni produces a metastable γ-Fe,Ni phase at room temperature. In contrast, chromium, which has the b.c.c. structure, also forms substitutional solid solutions with iron and thus stabilizes the b.c.c. structure. This causes the formation of a "γ-loop" shown in **Figure 3**. At the minimum temperature of the γ-loop (7 wt.% Cr, 831°C), the γ-Fe and α-Fe,Cr phases have the same composition. In Fe–Cr solid solutions containing less than 12 wt.% Cr, the product of oxidation is the highly defective spinel $FeO \cdot Cr_2O_3$. With Cr contents greater than 12 wt.%, the oxide Cr_2O_3 is the product of oxidation. Thus, a "stainless" steel can be produced by having sufficient Ni in solid solution in Fe to give a single-phased f.c.c. structure at room temperature and by having sufficient Cr in solid solution to produce a protective

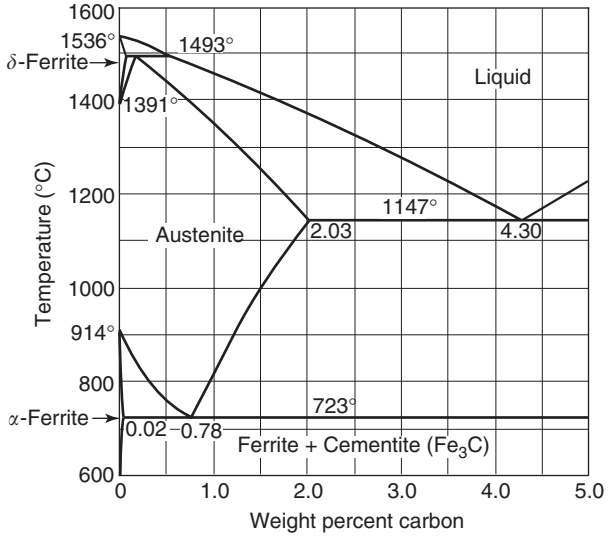

Figure 2 The phase diagram for the system Fe–Fe_3C.

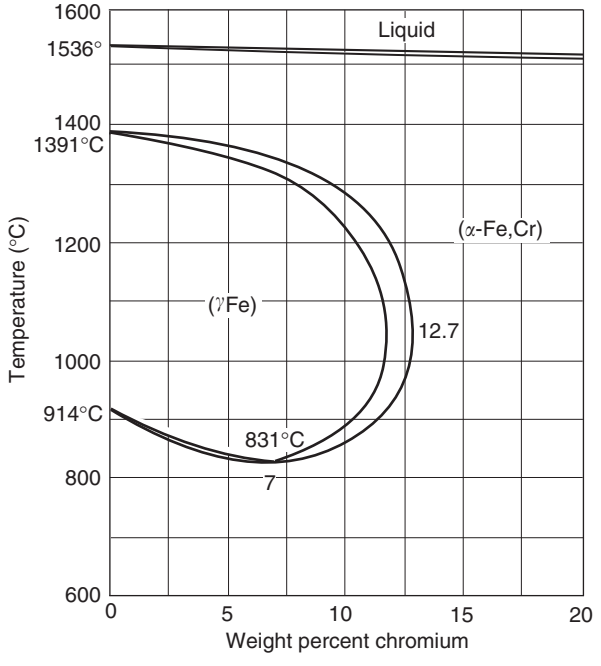

Figure 3 The iron-rich end of the Fe–Cr phase diagram.

coating of Cr_2O_3 on the surface of the alloy. Such an alloy is type 304 stainless steel (or 18-8 stainless steel) which is Fe containing 18 wt.% Cr and 8 wt.% Ni.

The Allotropy of Carbon

Carbon (element number 6), located at the top of group four in the periodic chart of the elements, has the electron configuration $2s^1 2s^2 2p^2$, which would indicate that it has a valence of 2. However, hybridization of the electron orbits of the carbon atom gives rise to the occurrence of the familiar allotropes, diamond, and graphite. In sp^3 hybridization, one of the 2*s* electrons is promoted to the 2*p* orbital and the four electrons in the second shell undergo hybridization to produce four energetically equivalent electrons. The 272 kJ mol^{-1} required to promote the electron from the 2*s* to the 2*p* shell is more than compensated for by the decrease in energy which occurs upon hybridization. The mutual repulsion between the hybrid orbitals causes them to point toward the corners of a tetrahedron, as shown in **Figure 4**. The unit cell for the diamond cubic crystal structure, which is shown in **Figure 5**, can be regarded as being based on the f.c.c. unit cell containing eight subcubes. Carbon atoms occupy the upper-back-left, upper-front-right subcubes, the lower-front-left and lower-back-right subcubes with the bond length being 15.4 nm.The rigidity of the bonds between the atoms makes diamond the hardest material in existence (number 10 on the Moh scale of hardness). It has a high melting temperature, 3800°C, and a large latent heat of melting, 105 kJ mol^{-1} at a pressure of 48 kbar. Also, it has a high index of refraction, 2.417, making it a desirable gem stone. In 1913, the determination of the structure of diamond was one of the early successes of X-ray analysis.

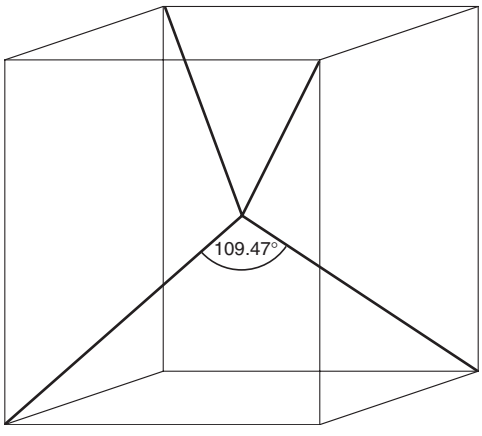

Figure 4 Lines directed to the corners of a tetrahedron.

The crystal structure of graphite is determined by sp^2 hybridization in which a 2*s* electron is promoted to the $2p_z$ orbital and the remaining 2*s* and the $2p_x$ and $2p_y$ orbitals form a trigonal hybrid containing three energetically equivalent orbitals which lie in a plane, forming angles of 120° with their neighboring orbitals. The crystal structure of graphite, which is shown in **Figure 6**, consists of sheets of σ-bonded atoms in the *xy*-plane, arranged in hexagons which are bonded to one another in the *z*-direction by π-bonds formed by overlap of the p_z orbitals. The lengths of the σ-bonds and the π-bonds are, respectively, 14.2 and 34 nm. As the π-bonds are much weaker than the σ-bonds, this property facilitates easy shearing of the sheets of hexagons and makes graphite a good lubricating material.

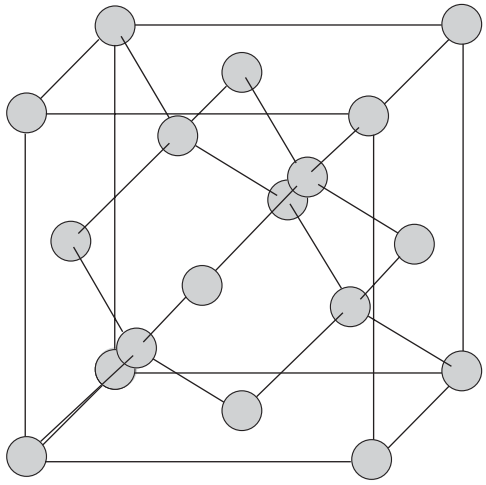

Figure 5 The unit cell for the diamond cubic crystal structure.

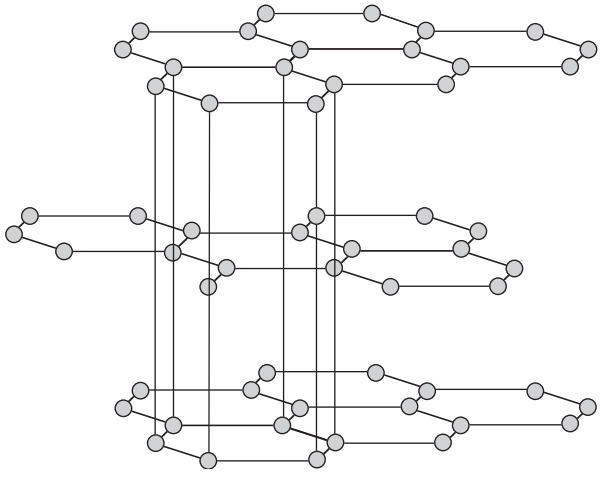

Figure 6 The crystal structure of graphite. The lines join atoms in successive sheets which are aligned vertically.

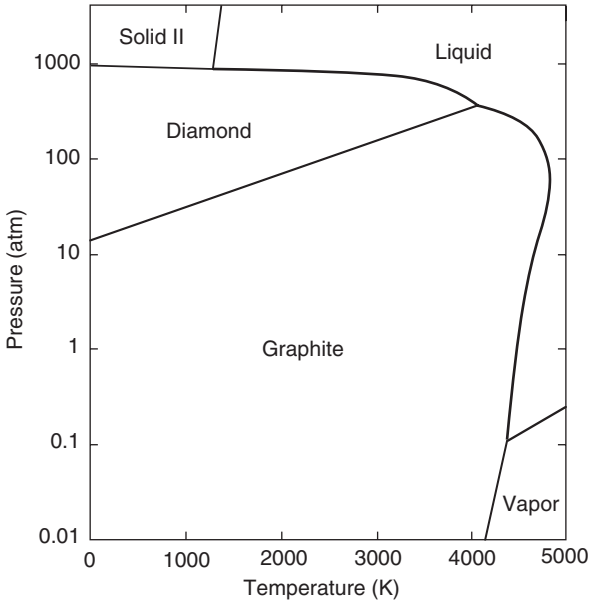

Figure 7 The phase diagram for carbon.

The phase diagram for carbon, presented as **Figure 7**, shows that a third allotrope, solid II, exists at pressures in excess of 1000 atm, and that diamond is metastable at low pressures. Diamonds are formed under conditions of high pressure experienced in clay pipes in the earth's crust. It exists in the metastable state at room temperature and pressure because of the extensive rearrangement of atoms required for the transformation from the diamond structure to the graphite structure. At lower pressures, the melting temperature of graphite increases with increasing pressure, and at higher pressure it decreases with increasing temperature. Thus, at lower pressures, the molar volume of graphite is lower than that of liquid carbon and, at higher pressures, the reverse is the case. At the "nose" of the melting curve, the molar volumes of graphite and liquid have the same value. The densities of diamond and graphite at 298 K and 1 atm pressure are, respectively, 3.515 and 2.2 g cm^{-3}.

The Allotropy of Sulfur

The phase diagram for sulfur, presented as **Figure 8**, shows that sulfur can exist in a rhombic crystal structure and in a monoclinic crystal structure. The unit cell of the rhombic form contains 128 atoms, existing as 16 puckered rings of eight atoms which form S_8 molecules. Sulfur melts to form a translucent liquid, which, when heated above 200°C, transforms to a red, highly viscous form produced by the breaking of the rings and the entanglement of the chains

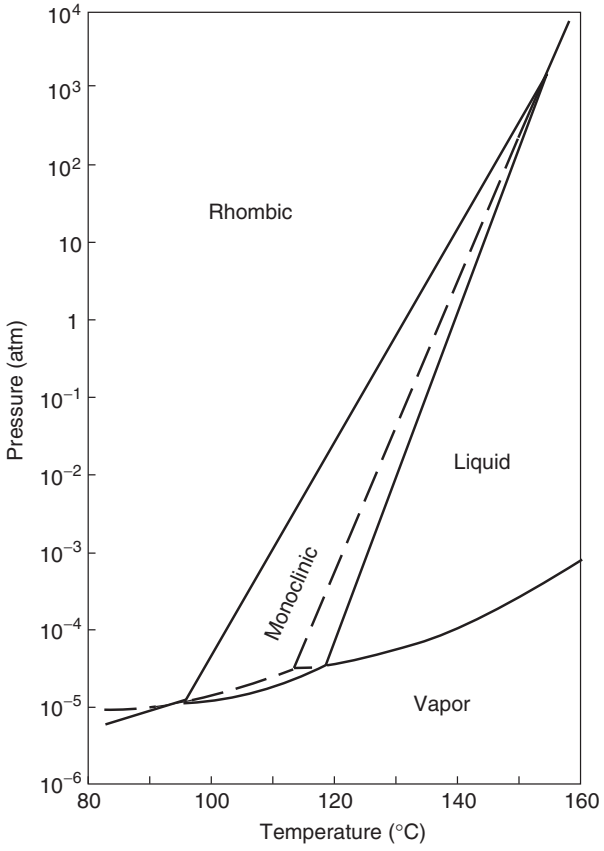

Figure 8 The phase diagram for sulfur.

produced. Amorphous or "plastic" sulfur can be obtained by fast cooling of the crystalline form and this amorphous phase also has a helical structure with eight atoms per spiral. Sulfur is soluble in carbon disulfide and is insoluble in water.

The complexity of rhombic sulfur allows easy supercooling of the monoclinic form and has been used as a means of providing experimental evidence to substantiate Nernst's heat theorem, also known as the third law of thermodynamics. This states that, at 0 K, the entropy of any homogeneous substance, which is in complete internal equilibrium, can be taken as being zero. Summation of the increase in molar entropy of rhombic sulfur when heated from 0 K to the temperature of transformation (38.86 J K^{-1}), the molar entropy of transformation of rhombic to monoclinic sulfur at this temperature (1.09 J K^{-1}), and the change in the molar entropy of monoclinic sulfur when cooled from the transformation temperature to 0 K (−37.8 J K^{-1}) gives the molar transformation of rhombic to monoclinic sulfur at 0 K as 0.15 J K^{-1}. This is less than the experimental error involved and, thus, is taken as an experimental verification of Nernst's heat theorem.

The Polymorphism of Silica

Silicon, occurring below carbon in group 4 in the periodic chart of the elements, undergoes sp^3 hybridization of the 3*s* and 3*p* electrons to produce energetically equivalent electron orbitals, which point to the corners of a tetrahedron. In the crystal structure of silica (SiO_2), the sp^3 orbitals of neighboring silicon atoms form bonds with oxygen atoms, such that each silicon atom is tetrahedrally coordinated by four oxygen atoms and each oxygen atom is bonded to two silicons. The basic building block in the silica structure is thus a tetrahedron, at the center of which is a silicon atom with oxygen atoms located at the four corners. The polymorphism of silica arises from the number of ways in which tetrahedra can be arranged to fill space and one such arrangement is shown in **Figure 9**. The phase diagram for silica, presented as **Figure 10**, shows that, at pressures less than 10^4 atm, the polymorphs are low quartz, high quartz, tridymite, and cristobalite. At pressures between 10^4 and 10^5 atm, silica exists as the polymorph coesite (first described by L Coes, Jr. in 1953) and at pressures higher than 10^5 atm, stishovite is the polymorph. Stishovite differs from the other polymorphs, in that the silicon is in octahedral coordination with oxygen. This polymorph was discovered in meteorites found in Russia by Stishov. It is believed that the high force exerted on the meteorite by contact with the surface of the earth caused the tetrahedral coordination in silica to transform to an octahedral coordination.

The differences in standard free energies of formation, $\Delta(\Delta G^\circ)$, among the various polymorphs of silica, using cristobalite as the reference state, are shown in **Figure 11**. The relatively small differences in the standard free energies among the polymorphs arise because the enthalpies of formation (the –Si–O–Si– bond energies) of the polymorphs and the configurational entropies of packing SiO_4 tetrahedra together are similar.

Figure 11 shows another representation of the polymorphism of silica. The horizontal arrows represent reconstructive transformations, which require bond breaking and complete rearrangement of the SiO_4 tetrahedra. Thus, although the differences in the standard free energies of formation of the polymorphs, shown in **Figure 11**, are small, the high energies of activation for these transformations are such that the high-temperature polymorphs can be undercooled easily. Used extensively in laboratory and medical applications, silica glass is obtained by supercooling liquid silica to form a metastable amorphous phase. The vertical arrows in **Figure 12** represent displacive transformations, which do not involve the breaking of bonds and, consequently, occur at relatively high rates. The sequence of transformations during gradual heating of β-quartz depends on the purity of the quartz. When high-purity quartz

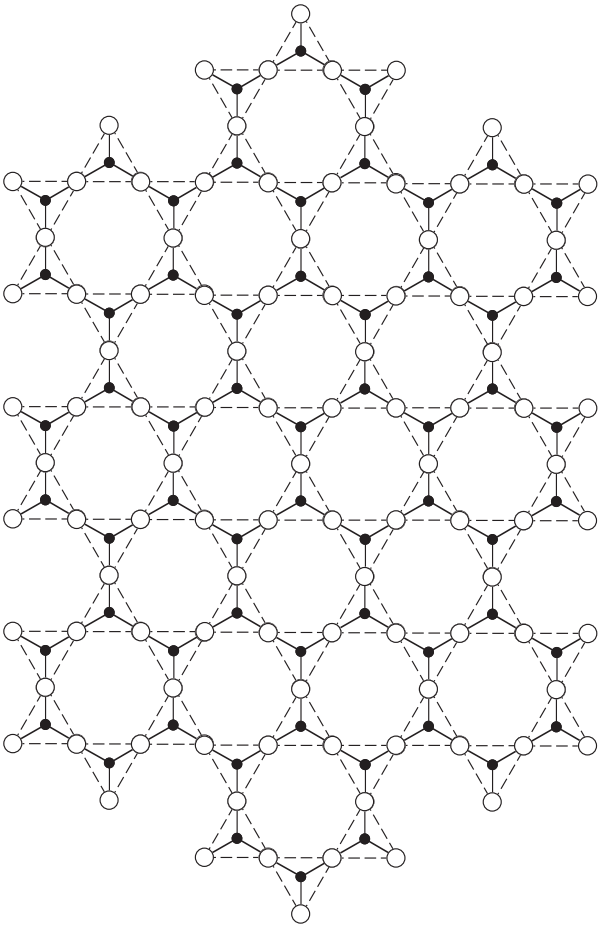

Figure 9 The arrangement of SiO_4 tetrahedra.

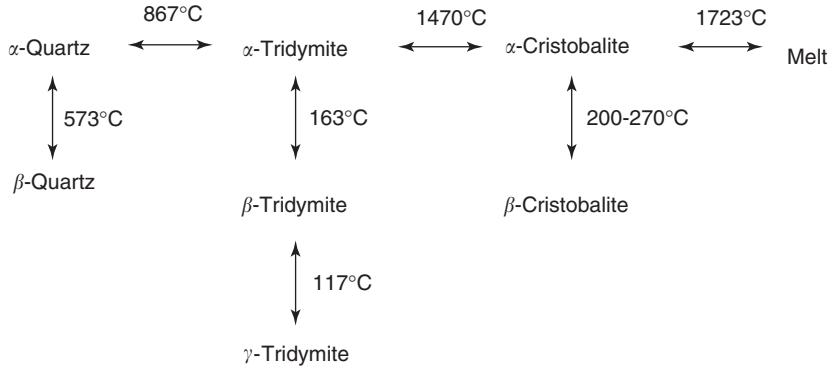

Figure 12 Phase transformations in silica.

($<10^{-2}$ wt.% impurities) is heated, the β-quartz transforms rapidly into α-quartz at 573°C. The α-quartz is stable to ~1025°C, at which temperature it transforms into α-cristobalite. However, if the quartz contains impurities in solid solution, α-quartz transforms to α-tridymite at ~870°C, which, on further heating, transforms into α-cristobalite at 1470°C.

The observation of the influence of impurities and the fact that most of the laboratory studies of phase equilibria in silica were conducted under hydrothermal conditions cast doubt on the validity of the phase relations shown in **Figure 10**. Evidence, which suggests that tridymite is not a stable phase in pure silica, but owes its existence to the presence of impurity ions in the structure, has been provided. This would make tridymite a polytype (same structure, different composition) rather than a polymorph. Two opinions have been expressed on this topic. One suggests the elimination of the tridymite phase and places the temperature of equilibrium between quartz and cristobalite at ~1025°C. The other suggests that a sharp polymorphic transformation exists between stable tridymite (designated "tridymite-S") and stable cristobalite at 1470°C and that quartz and stable tridymite coexist at ~870°C. The latter opinion is in accordance with the "classical" picture shown as **Figure 10**.

The precious mineral opal, which has the formula $SiO_2 \cdot nH_2O$, is a form of silica that is wholly amorphous.

The Polymorphism of Zirconia

Zirconia, ZrO_2, has three polymorphs at atmospheric pressure: a high-temperature cubic structure which exists from 2370°C to the melting temperature of 2680°C, a low-temperature monoclinic structure which exists at temperatures lower than 1174°C,

and an intermediate tetragonal structure which is stable between 1174°C and 2370°C. The high-temperature cubic form has the fluorite, CaF_2, structure shown in **Figure 13**. In this structure, the Zr^{4+} cations occupy the corner and face-centered positions in the f.c.c. lattice and the O^{2-} anions occur at the centers of the eight subcells described in **Figure 5**. The unit cell, thus, contains four Zr^{4+} and eight O^{2-} ions. The intermediate tetragonal form is a slightly deformed fluorite structure, and the low-temperature monoclinic form, which occurs naturally as the mineral baddeleyite, has a structure in which Zr ion is coordinated by seven oxygen ions. This structure is shown in **Figure 14**. The densities and specific volumes of the three polymorphs are listed in **Table 1**.

The 4.6% decrease in density accompanying the tetragonal to monoclinic transformation cannot be sustained and the solid exfoliates by means of a martensite shearing mechanism. The temperature at which this transformation occurs on cooling decreases with decreasing particle size. However, the high-temperature cubic form can be stabilized to room temperature by the substitution, for Zr^{4+}, of appropriately sized cations of valence less than 4. The cations Ca^{2+} and Y^{3+} are used to produce lime-stabilized zirconia (LSZ) and yttria-stabilized zirconia (YSZ). LSZ is considerably less expensive than YSZ. Several versions of the phase diagram for the system ZrO_2–CaO have been proposed and two of them are shown in **Figures 15** and **16**.

Figure 15 shows the existence of the three polymorphs of ZrO_2 and contains the line compound $CaO \cdot 4ZrO_2$, which undergoes incongruent decomposition at 1310°C. **Figure 15** also shows that the

substitution of Ca^{2+} ions for Zr^{4+} in cubic zirconia stabilizes the cubic structure only to 1140°C, at which temperature it undergoes a eutectoid decomposition to tetragonal zirconia and $CaO \cdot 4ZrO_2$. It is known that the substitution of Ca for Zr stabilizes the cubic structure to room temperature, but it is unlikely that supercooled cubic zirconia will maintain a metastable existence at temperatures near 700°C, at which it is used as an oxygen sensing device. On the other hand, **Figure 16** shows the existence of lime-stabilized-cubic zirconia at room temperature, but does not show the existence of cubic zirconia in the pure state. **Figure 17** shows the phase diagram for the system ZrO_2–$YO_{1.5}$, in which it is seen that the substitution of Zr^{3+} ions for Zr^{4+} ions stabilizes the cubic phase at room temperature.

Stabilized cubic zirconia is a practical ceramic material used as the solid-state electrolyte in a cell used for measuring the partial pressure (or thermodynamic activity) of oxygen in a gaseous or liquid medium. Electroneutrality requires that the substitution of a Ca^{2+} ion for a Zr^{4+} ion in cubic zirconia be accompanied by the formation of a vacant site of the oxygen anion sublattice. Hence, x moles of CaO + $(1-x)$ moles of ZrO_2 contain $(x + 2 - 2x) = (2 - x)$ moles of O^{2-} and x moles of vacant sites. Thus, the fraction of vacant sites is $x/(2 - x + x) = 0.5x$. **Figure 16** shows that the percent of vacant oxygen sites in stabilized cubic zirconia can be as high as 12–13%. This high percentage of vacant sites imparts high diffusivity of oxygen in cubic zirconia at elevated temperatures. The working of a lime-stabilized cubic zirconia EMF cell is illustrated in

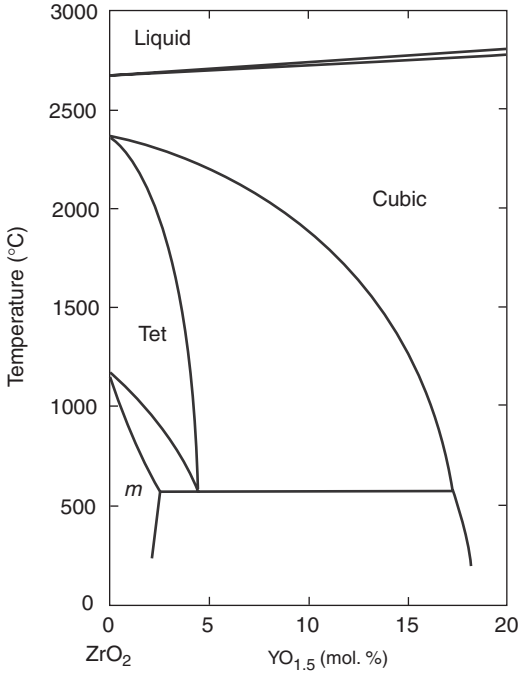

Figure 17 The phase diagram for the system ZrO_2–$YO_{1.5}$.

$$\tfrac{1}{2}O_{2(gas)} + 2e^- \rightarrow O^{2-}$$

and the half-cell reaction at the anode is

$$O^{2-} \rightarrow 2e^- + \tfrac{1}{2}O_{2(gas)}$$

This gives the cell reaction as $O_2(P = P_{high}, T) = O_2(P = P_{low}, T)$ for which

$$\Delta G = RT \ln \frac{P_{low}}{P_{high}}$$

and as

$$\Delta G = -zFE = RT \ln \frac{p_{O_{2(low)}}}{p_{O_{2(high)}}}$$

then

$$E = -\frac{RT}{4F} \ln \frac{P_{O_{2(low)}}}{p_{O_{2(high)}}}$$

where E is the measured EMF of the cell, F is Faraday's constant, and z is the number of electrons transferred by the electrochemical cell reaction. In the use of the oxygen sensor where the value of one of the oxygen pressures is known, measurement of the EMF of the cell and the temperature allows the unknown oxygen pressure to be determined. The oxygen content of liquid steel is measured routinely by immersion of a disposable LSZ cell in the steel bath in the converter.

Stabilized cubic zirconia is also used as an electrolyte in a hydrogen generator, in which water vapor is decomposed to produce hydrogen gas at the cathode and oxygen gas at the anode. Also, it is used in a fuel cell in which electric power is produced by the oxidation of CO or H_2 at the anode and the reduction of oxygen gas at the cathode.

Alloys: Aluminum

E A Starke Jr., University of Virginia, Charlottesville, VA, USA

Introduction

Aluminum is the third most abundant element in the earth's crust but because it is so reactive with other elements it is not found in the native state. Hans Christian Oersted (1777–1851), a Danish physicist and chemist, was successful in isolating aluminum in a pure form in 1835. Sir Humphrey Davy (1778–1829) had previously been unsuccessful at such attempts, but it was Davy who named the element "aluminum," the name used in the US. The rest of the world uses the term "aluminium." Until 1886 a chemical process was used to produce aluminum, which employed crystals of corundum that were chemically converted to aluminum chloride and then reduced with metallic sodium to form salt and metallic aluminum. From 1825 to 1886, aluminum was primarily used for jewelry and as expensive tableware due to the difficulty and cost of extracting it from its ore. During the construction of the Washington Monument, the world's tallest structure of that period, a material was needed to top off the structure and to serve as a lightning rod. A cast aluminum pyramid was produced by William Frishmuth in 1884 and mounted on the top. It was the largest aluminum casting ever produced and was the first architectural application of this metal.

In 1886, Charles Martin Hall (1863–1914) in the US and Paul-Louis Toussaint Héroult (1863–1914) in France simultaneously developed an economical electrochemical method of producing aluminum, which ultimately led to its widespread use throughout the world. Their invention replaced the chemical reduction process and lowered the metal's cost from \$15/pound in 1884 to \$0.50/pound in 1890. The versatility of aluminum has resulted in it replacing many older, more established materials, and it is now consumed, on a volumetric basis, more than all other nonferrous metals combined, including copper, lead, and zinc.

Aluminum is light, ductile, has good electrical and thermal conductivity, and can be made strong by alloying. It has a low density of $2.7\,g\,cm^{-3}$ compared to that of iron ($7.9\,g\,cm^{-3}$) due to its low atomic mass of 27. The ductility and formability of aluminum is due to the high symmetry and thermodyic stability of the face-centered cubic (f.c.c.) lattice and its high stacking-fault energy. In the pure form, aluminum has a low stiffness, E, of 70 GPa compared to 211 GPa for iron, and low tensile strength, 80 MPa, compared to 300 MPa for iron. However, its specific modulus, that is, modulus divided by density, is almost equal to that for iron, titanium, and magnesium. An advantageous chemical property of aluminum is its reactivity with oxygen, which leads to the formation of a dense layer of Al_2O_3 on the surface, which shields the base metal from further environmental interactions.

Pure aluminum is not used commercially because of its low strength, but this property can be improved by alloying elements. A major metallurgical development occurred in 1906 when Alfred Wilm (1869–1937) discovered the process of "age hardening" in aluminum alloys. Wilm was conducting research directed toward improving the strength of aluminum alloys. He knew that steel could be strengthened if the right compositions were cooled fast enough from high temperatures, so following this recipe he heated some alloys of aluminum containing 3.5–5.5 wt.% copper, plus less than 1% magnesium and manganese, to a high temperature and quenched them in water. To his frustration, many of the alloys he tested were softer after quenching than before the heat treatment. However, after a few days he found that their hardness and tensile properties had increased considerably. One of the alloys, designated Duralumin, is still in use today. Much later, in 1919, Merica, Waltenberg, and Scott explained the phenomenon, which is due to nano-sized clustering and precipitation of solute atoms from the supersaturated solid solution. However, these nano-microstructural features are too small to be resolved by optical microscopy and were only inferred by the X-ray diffraction studies of Guinier and Preston in 1938. Direct proof was not obtained until the development of transmission electron microscopy in 1959. Duralumin is probably the first example of a nanostructured material developed by humans.

Aluminum alloys are classified as heat-treatable or non-heat-treatable, depending on whether or not they undergo precipitation (age) hardening. There are also two different product forms of aluminum alloys; wrought alloys that have been worked or deformed after casting and casting alloys, which are used in the "as-cast" condition. Wrought aluminum alloys are normally designated by a four-digit numerical system developed by the Aluminum Association. The nomenclature has now been accepted by most countries and is called the International Alloy Designation System (IADS). The system used for wrought alloys is slightly different from that used for

cast alloys; however, the first digit designates the alloy group and is essentially the same for both wrought and cast alloys. The alloy group is associated with the major alloy addition and the second digit indicates modification of the original alloy or impurity limits. The last two digits identify the specific aluminum alloy. Experimental alloys also use this system, but are indicated as experimental by the prefix X. The 1XXX alloys contain a minimum of 99% aluminum. The major alloying addition in the 2XXX series is copper; it is manganese for 3XXX, silicon for 4XXX, magnesium for 5XXX, magnesium and silicon for 6XXX, zinc for 7XXX, and 8XXX is used for others (tin for casting alloys). A first digit of 9 is not used for wrought alloys but is used for other alloy additions for casting alloys.

The designation system is slightly different for casting alloys although, as mentioned, the first digit still refers to the major alloying element. The second and third digits serve to identify a particular composition. These three digits are followed by a decimal point, which is followed by a zero to indicate a casting. Often, a letter prefix is used to denote either an impurity level or the presence of a secondary alloying element. These letters are assigned in alphabetical sequence starting with A but omitting I, O, Q, and X. X is reserved for experimental alloys. For example, A201.0 has a higher purity than the original 201.0.

The heat-treatment or temper-nomenclature system developed by the Aluminum Association has also been adopted as part of the IADS by most countries. It is used for all forms of wrought and cast aluminum alloys with the exception of ingot. The system is based on the treatments used to develop the various tempers and takes the form of letters added as suffixes to the alloy number. One or more digits following the letter indicate subdivisions of the tempers, when they significantly influence the characteristics of the alloy. Alloys supplied in the as-fabricated or annealed condition are designated with the suffixes F and O, respectively. The letter W designates those supplied in the solution heat-treated condition. Alloys supplied in the strain-hardened condition are designated with the letter H and those in the heat-treated condition with the letter T. Digits following H represent the degree of strain hardening and those following T the type of aging treatment.

Processing of Aluminum Alloys

In fabricating aluminum alloy products, the aluminum alloy composition is made by adding the alloying elements to molten aluminum, usually in the form of a concentrated hardener or master alloy, with the requisite purity. Two types of alloying elements are normally added: those for strength and those to control the grain structures that precipitate as "dispersoids." During solidification of the ingot, some of the alloying elements and impurities may precipitate out of the aluminum, forming coarse "constituent" particles within the ingot. For wrought products, additional precipitation of the alloying elements may occur as the ingot is worked down to the final product form (such as sheet or plate).

The "constituent" particles potentially impair the properties of the final product in several ways. By tying up alloying elements that are added on purpose to develop the desired properties, these elements are not available to impart strength and other beneficial properties to the aluminum alloy. In addition, the constituent particles are more brittle than the surrounding aluminum and, by fracturing under stress, form and promote the growth of cracks and hence impair beneficial mechanical properties. One typical goal of aluminum alloy processing is to reduce the size and amount of the constituent particles in the aluminum alloy product.

Beginning with the as-cast ingot, conventional processing includes a homogenization treatment. This is the stage where dispersoids normally form. For alloys used in the as-cast condition, homogenization may be the final treatment for non-heat-treatable alloys, but for age-hardenable alloys further heat treatments will be required. For wrought alloys, hot working follows the homogenization for ingot breakdown and shape change to the appropriate product form. Since aluminum and its alloys have high stacking-fault energy, sufficient dynamic recovery normally occurs during hot deformation to give rise to a stable polygonized substructure, an example of which is shown in the transmission electron micrograph of **Figure 1**. The grains elongate in the direction of metal flow and do not recrystallize. An example of the grain structure of a hot-worked aluminum-alloy plate is shown in **Figure 2**. The dispersoids, and any constituents and primary phases that may be present, are strung out in the working direction; their spacing increases in the working direction and decreases normal to the working direction. In some cases large constituent phases, if present, are broken up during the working operation. The fine distribution of dispersoids associated with Cr, Mn, or Zr additions delays or prevents static recrystallization and aids in retaining the elongated or "pancake-shaped" grains during subsequent processing. After processing for shape change, non-heat-treatable alloys may then be cold worked and/or annealed to develop the desired strength, and heat-treatable alloys may be solutionized, quenched, in some cases stretched to remove residual stresses developed during quenching or for

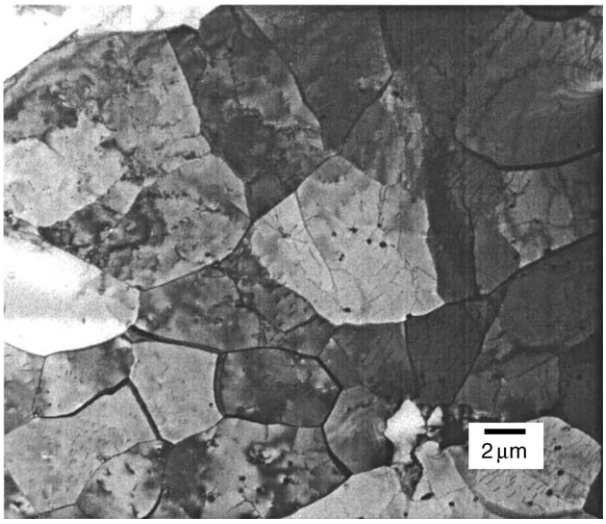

Figure 1 Subgrain structure in a hot-rolled Al–Cu–Mg–Li–Zr alloy.

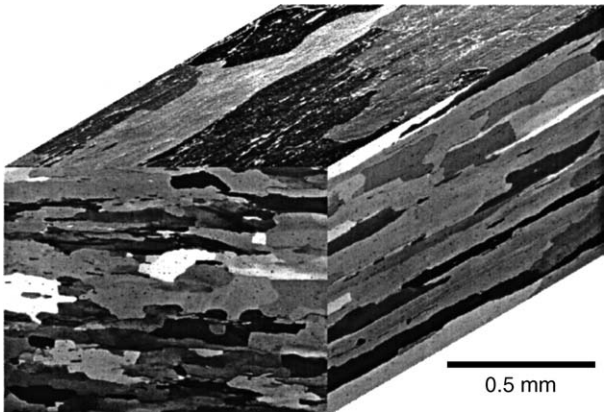

Figure 2 Optical micrograph illustrating the pancake grain structure of a hot-rolled Al–Cu–Mg–Li–Zr alloy.

creating nucleation sites for precipitation, and either naturally aged at room temperature or artificially aged at some moderate temperature. An Al–2.7Cu–1.8Li–0.6Zn–0.3Mg–0.3Mn–0.12Zr alloy naturally aged at room temperature after a rapid quench from the solution heat-treatment temperature is shown in **Figure 3** and the same alloy artificially aged at 150°C for 6 h after a rapid quench from the solution heat-treatment temperature is shown in **Figure 4**.

Alloys that are susceptible to corrosion in moist air may be clad with pure aluminum, which is not susceptible and can offer protection in an aggressive environment, or they may be anodized. Anodizing is a method for producing a very thick, protective oxide film on the surface of aluminum. The anodized film normally contains chemical compounds such as chromates, which are collected from the anodizing bath and render the film more corrosion resistant than films that form naturally in air.

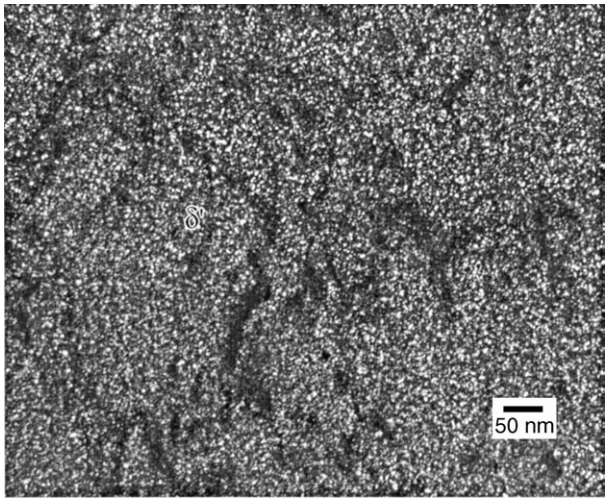

Figure 3 Dark-field TEM micrograph of the matrix precipitation from an Al–2.7Cu–1.8Li–0.6Zn–0.3Mg–0.3Mn–0.12Zr alloy naturally aged for seven days at room temperature after a rapid quench from the solution heat-treatment temperature. The matrix precipitation is dominated by fine δ' (Al_2Li) spheres.

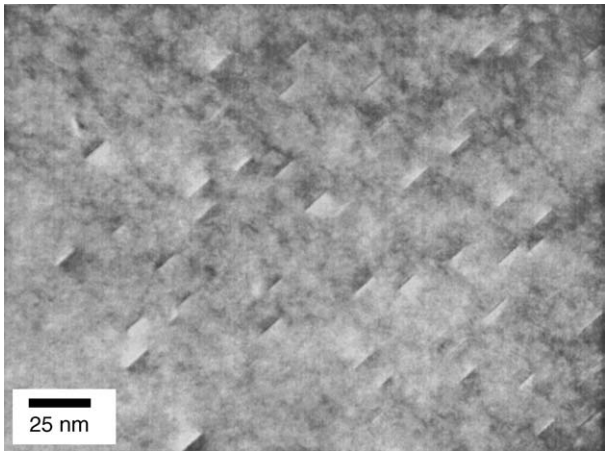

Figure 4 Bright-field TEM micrograph of the matrix precipitation from an Al–2.7Cu–1.8Li–0.6Zn–0.3Mg–0.3Mn–0.12Zr alloy (T6 temper) artificially aged at 150°C for 6 h after a rapid quench from the solution heat-treatment temperature. The matrix precipitation is dominated by fine θ''/θ' (Al_2Cu) plates and δ' spheres (not shown).

Non-Heat-Treatable Alloys

The 1XXX, 3XXX, 5XXX, and some of the 8XXX series alloys are non-heat-treatable. These alloys are primarily strengthened by elements in solid solution and by deformation structures. One of the first non-heat-treatable alloys, other than the 1100 alloy that only contained 0.95 wt.% Fe and Si as impurities, was an alloy containing 1.25 wt.% Mn and 0.12 wt.% Cu, now designated as 3003, that was introduced in 1906, the same year that Wilm discovered age hardening. Alloy 3003 can develop yield

strength up to 400 MPa by special thermomechanical treatments. Magnesium is added to non-heat-treatable alloys for its solid-solution strengthening effect. It also enhances work hardening and makes aluminum more anodic. In general, solid-solution alloys are more resistant to corrosion than two-phase alloys. Al–Mg alloys have a high resistance to corrosion, particularly in seawater and alkaline solutions. However, when magnesium exceeds the solid solubility in binary alloys, it precipitates at grain boundaries as Al_3Mg_2, which is anodic to the matrix and promotes intergranular attack.

Aluminum combines readily with transition metals, Ti, V, Cr, Mn, Fe, Co, Ni, and Zr to form intermetallic phases with little or no solubility in the aluminum matrix. The intermetallics phases increase the strength by enhancing work hardening during working operations, and by refining the grain structure. They increase the work hardening since they are usually incoherent with the matrix, are nondeformable, and must be looped or bypassed by moving dislocations. This increases the dislocation density and blocks the dynamic recovery processes. During hot working, the subgrain structure that is developed can also increase the strength. The smaller (less than 0.6 μm) intermetallic dispersoids aid in the stabilization of the substructure. The intermetallic particles generally do not add a component of the particle strengthening because of their low volume fraction, large size, and interparticle spacing.

It is customary to control both composition and cooling rates in order to prevent large primary phases from forming. For example, commercial Al–Mn alloys most often contain less than 1.25 wt.% Mn, although as much as 1.82 wt.% is soluble in pure aluminum. The 1.25 wt.% limit is imposed because Fe, present in most aluminum alloys as an impurity, decreases the solubility of Mn in aluminum. This increases the probability of forming large primary particles of Al_6Mn, which can have a disastrous effect on ductility.

Silicon is a principal addition to most aluminum casting alloys because it increases the fluidity of the melt. In the solid state, the hard silicon particles are the major contributor to the strength of non-heat-treatable casting alloys. An additional improvement in strength can be obtained by minor additions of Mg or by trace alloy additions, for example, Na that refines the cast structure. The latter also minimizes porosity and increases ductility.

Heat-Treatable Alloys

The 2XXX, 4XXX, 6XXX, 7XXX, and some 8XXX series alloys are considered heat-treatable. These alloys contain elements that decrease in solubility with decreasing temperature, and in concentrations that significantly exceed their equilibrium solid solubility at room and moderately higher temperatures. One of the transition elements Cr, Mn, or Zr, is added to age-hardenable wrought alloys to control the grain structure; however, the grain and deformation structure play only a secondary role in the strengthening of this class of materials.

A normal heat-treatment cycle after deformation processing includes a soak at a high temperature to dissolve the soluble constituent particles and any other precipitates that may be soluble (dispersoids containing the elements Cr, Mn, or Zr have already precipitated at this point). After the aluminum alloy has been held at the solutionizing temperature for a sufficient time, the alloy is rapidly cooled or quenched to prevent precipitation of coarse primary phases and to obtain a solid solution supersaturated with both solute elements and vacancies. The next step involves aging at room temperature (natural aging) or at an intermediate temperature (artificial aging).

Quenching is accompanied by a change in free energy, which increases progressively as the difference between the solutionizing temperature and the quenching temperature increases. The volume free energy change is the driving force for precipitation and is associated with the transfer of solute atoms to a more stable phase. However, when precipitation occurs there are other factors, which increase the free energy, that is, formation of the interface between the matrix and the precipitate requires an increase in the surface free energy, and, if there is a volume change or interfacial strains associated with the precipitate, there is an increase in elastic strain energy. The change in free energy when a precipitate forms, ΔG, is the sum of these free energy changes and can be expressed mathematically as

$$\Delta G = V\Delta G_V + A\gamma + V\Delta G_s \qquad [1]$$

where V is the volume of the new phase; ΔG_V is the free energy decrease due to creation of a volume, V, of the precipitates and is therefore negative; A is the area of the interface between the matrix and the precipitate; γ the energy of the new surface formed; and $V\Delta G_s$ is the increase in elastic strain energy per unit volume of precipitate.

The critical increase in free energy, ΔG^*, required for a nucleus to become an equilibrium or metastable precipitate is known as the activation energy barrier for nucleation and can be expressed as

$$\Delta G^* = (16\pi\gamma^3)/(3[\Delta G_V - \Delta G_s]^2) \qquad [2]$$

The nucleation rate, N, can be expressed as

$$N = C \exp(-Q/kT) \exp(-\Delta G^*/kT) \qquad [3]$$

where C is the number of nucleating sites per unit volume, Q is the activation energy for diffusion, k is the Boltzmann constant, and T the absolute temperature.

There are a number of requirements for an effective age-hardenable alloy. First, there has to be a sufficient volume fraction of the second phase for the desired strength. An examination of aluminum binary diagrams suggests that the most attractive alloying additions would be, in decreasing volume fraction of the second phase, Ag, Mg, Li, Zn, Ga, and Cu. The required volume fraction will depend on the effectiveness of the second phase on impeding dislocation motion, that is, whether it is a "soft" or "hard" phase, and its size and spacing. Second, the aging potential must be adequate and the nucleation of the precipitates should be as close as possible to being homogeneous. This is generally accomplished by the addition of a second alloying element. The addition of the second alloying element may: (1) reduce the solubility of the first element, (2) increase the diffusion rates by trapping vacancies, (3) increase the driving force for nucleation, or (4) reduce the activation energy against nucleation. If the strain term in eqn [1] is large, nucleation may be aided by defects, for example, dislocations. For this type of nucleation, the precipitate distribution depends on the distribution of the defects.

Microstructural Features

Chemical composition and processing control the microstructure and thus the physical, mechanical, and corrosion properties of aluminum alloy products. In general, microstructural features of importance for property control include the following:

1. *Coherency, volume fraction, and distribution of strengthening precipitates*. These form intentionally during aging treatments and unintentionally during quenching. The precipitates normally range in size from 1 to 10 nm.
2. *Size, distribution, and coherency of dispersoid particles*. These form during the ingot preheat or homogenization treatment by precipitation of the transition elements chromium, manganese, or zirconium. They are present by design to control the grain structure and degree of recrystallization. Dispersoids normally range in size from 10 to 200 nm.
3. *Degree of recrystallization*. This is determined by the thermomechanical history. During bulk metal deformation processing at elevated temperatures, the dislocations in aluminum alloy products arrange themselves into a structure of subgrains by the process known as dynamic recovery. As temperature decreases and strain rate increases, the stored energy increases. This increase in stored energy is manifested by an increase in number and consequent decrease in the size of subgrains and an increase in the dislocation density in cell walls. During subsequent heat treatments, the stored energy of deformation may decrease by either static recovery or recrystallization. The final product may be completely unrecrystallized, partially recrystallized, or completely recrystallized.
4. *Grain size and shape*. These are also controlled by thermomechanical history and may be influenced by ingot grain refining practice.
5. *Crystallographic texture*. The deformation process used to produce the product and the thermomechanical history determines this.
6. *Intermetallic constituent particle*. These form by a liquid–solid eutectic reaction during solidification, primarily from impurities, for example, iron and silicon. Because the low solubility of iron in pure aluminum is reduced by alloying elements, constituent particles containing iron are insoluble. The size and size distribution of insoluble constituent particles are controlled by the rate of ingot solidification, the chemical composition, and the extent and nature of bulk deformation. Constituents generally range in size from 1 to 30 μm.
7. Porosity may be a factor in thick plates and, particularly, in castings. Individual pores can range up to and beyond 200 μm.

Aluminum Alloy Design

After Wilm discovered age hardening of the Al–Cu–Mg–Mn alloy through serendipity, traditional aluminum alloy development primarily relied on a trial-and-error philosophy. Most aluminum alloys were developed by simply identifying a given alloying element that led to gains in a certain mechanical property, typically strength, and continuing to add that element until the property began to degrade. The amount of secondary element used would then be the percentage that corresponded with maximum performance. This process would then follow in ternary and higher-order systems in order to optimize a given mechanical property. Often this occurred with little knowledge of the corresponding microstructural components or appropriate thermodynamic understanding, for instance the phase field of operation. Unfortunately, this practice led to the slow insertion of novel alloys into various applications creating a disparity with the design community.

Table 1 Property–microstructure relationships in aluminum alloys

Property	*Desired microstructural feature(s)*	*Function of feature(s)*
Strength	Fine grain size with a uniform dispersion of small, hard particles	Inhibit dislocation motion
Ductility and toughness	Fine structure with clean grain boundaries and no large or shearable precipitates	Encourage plasticity and work hardening, inhibit void formation and growth
Creep resistance	Thermally stable particles within the matrix and on the grain boundaries	Inhibit grain boundary sliding and coarse microstructure
Fatigue crack initiation resistance	Fine grain size with no shearable particles and no surface defects	Prevent strain localization, stress concentrations, and surface slip steps
Fatigue crack propagation resistance	Large grain size with shearable particles and no anodic phases or hydrogen traps	Encourage crack closure, branching, deflection, and slip reversibility
Pitting	No anodic phases	Prevent preferential dissolution of second-phase particles
Stress corrosion cracking and hydrogen embrittlement	Hard particles and no anodic phases or interconnected hydrogen traps	Homogenize slip and prevent crack propagation due to anodic dissolution of phases

More recent aluminum-based alloy development has begun to utilize the knowledge of phase diagrams and the productive interplay between empirical research and theoretical science. Phase diagrams represent the state of an alloy as a function of temperature, pressure, and alloy concentration and can be used for alloy design and process development. There are currently software programs available that use thermodynamic functions for the calculation of phase diagrams. Such calculations reduce the effort required to determine equilibrium conditions in a multicomponent system. Materials design can now be viewed as the best application of available models for the prediction and synthesis of alloys with desired properties. Of course, all theoretical calculations must be verified experimentally, but the experiments should be based on sound theory and not on a trial-and-error approach.

The most general understanding of alloy design must derive itself from the metallurgical paradigm of processing–structure–property relationships. In order to optimize a given property, one must determine the necessary ideal microstructural components, which are dictated by the alloy composition and processing from solidification through final manufacture. Fundamentally, to properly determine the resulting microstructure for a given thermomechanical processing routine, the pertinent literature and equilibrium phase diagrams must be consulted. A summary of various empirical structure–property relationships found in aluminum alloys is summarized in **Table 1**. This table highlights the general structural features desired to optimize a given property.

Applications of Aluminum Alloys

Aluminum alloys are lightweight, resistant to atmospheric corrosion, and have good mechanical properties, which make them a popular material for use in a wide variety of applications. The 1XXX alloys are strain-hardenable, have high formability, corrosion resistance, and good electrical conductivity. They are often used for electrical applications and as foil and strip for packaging. The 2XXX alloys are heat-treatable, and possess excellent combinations of high strength and toughness, but are not resistant to atmospheric corrosion; so, they are usually painted or clad in such exposures. They are primarily used for aircraft and truck body applications. The 3XXX alloys have high formability, corrosion resistance, and can be joined by a variety of methods. They are widely used in cooking utensils, beverage cans, chemical equipment, roofing and siding, and in heat exchangers. The 4XXX alloys are heat-treatable and have good flow characteristics along with medium strength. They are primarily used in forging applications, for example, aircraft pistons and for welding wires. The 5XXX alloys are strain-hardenable and have excellent corrosion resistance, even in salt water, toughness, and weldability along with moderate strength. They find wide application in highway bridges, storage tanks, marine and automotive applications, and pressure vessels. The 6XXX alloys are heat-treatable, have high corrosion resistance, excellent extrudibility, and moderate strength. They are primarily used in building and construction, automotive and marine applications, and recently in aerospace applications. The 7XXX alloys are heat-treatable and can provide the highest strengths of all aluminum alloys. They are primarily used for automotive and aerospace applications. The 8XXX series is used for alloys that contain lesser-used alloying elements such as nickel and lithium. Some are used for electrical conductors and the lithium-containing alloys have found application in the aerospace industry due to lithium's effect in reducing density.

Summary

Aluminum alloys possess a number of very attractive characteristics that, together with their light weight, make them extremely attractive for many applications. Since aluminum comprises 8% of the Earth's crust by weight, the overall reserves are adequate to cope with anticipated demands for the foreseeable future. Cost differentials with respect to competing materials will probably dictate the extent to which aluminum will be used. The cost includes the price of the electrical energy needed for the extraction of the metal from its minerals, and this may be greatly reduced in the future since aluminum can be recycled for many applications. In addition, aluminum often pays off when lifecycle costs, instead of acquisition costs, are considered.

Alloys: Copper

W F Hosford, University of Michigan, Ann Arbor, MI, USA

Copper Production

Copper is among the few metals known to ancient civilizations. Copper, gold, silver, platinum, and meteoric iron are the only metals found in their native state. However ~90% of copper comes from sulfide ores. Most copper ores contain 0.5% Cu or less, iron being the principal metallic impurity. The ores are ground to a fine powder and concentrated (normally by floatation) to 20–25% Cu. This concentrate is melted as a matte of mixed Cu and Fe sulfides containing up to 60% Cu. The matte is oxidized to remove the iron as an oxide and burn off the sulfur. The product is called blister copper which contains 98.5% Cu. Blister copper is fire refined to a tough-pitch (99.5% Cu). It is, often, then electrolytically refined to 99.95% + Cu. Au, Ag, and Pt metals are recovered from slime.

Chile is the single largest producer of copper. The other major producers are US, Indonesia, and Australia as shown in **Figure 1**. Other sources include Zambia, Peru, Canada, Russia, and Mexico. Recycle scrap accounts for ~50% of copper consumed in the US.

Copper has good strength and ductility as well as reasonably good corrosion resistance. The unique features of copper are its color and very high electrical and thermal conductivities.

The physical properties of copper are listed in **Table 1**.

Uses

Figure 2 shows the principal uses of copper. Its excellent electrical conductivity accounts for most of its use, principally as wire. Corrosion resistance, thermal conductivity, formability, and unique color account for almost the rest of the consumption of copper.

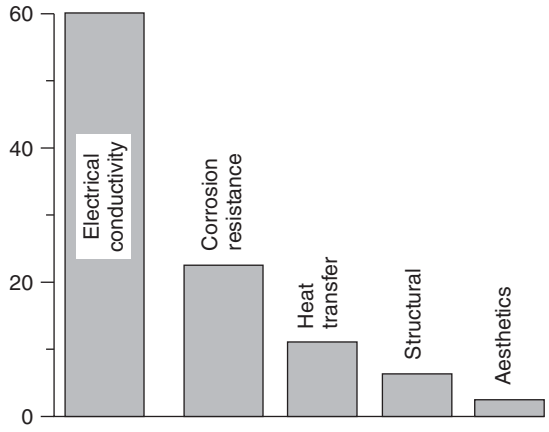

Figure 2 Uses of copper. (Data from ASM (2001) *Copper and Copper Alloys*, *ASM Speciality Handbook*. Materials Park, OH: ASM.)

Table 2 Electrical and thermal conductivities of several metals

Metal	*Electrical resistivity* (nΩ m)	*Electrical conductivity* (% IACS)	*Thermal conductivity* (W m^{-1} K^{-1})
Silver	14.7	108.4	428 (20°C)
Copper	16.73	103.06	398 (27°C)

Platinum	106	16.3	71.1 (0°C)

Data from *Metals Handbook*, 9th edn. vol II. Metals Park, OH: ASM.

Electrical Properties

The International Association of Classification Societies (IACS) standard of conductivity was set up with what was thought to be the conductivity of pure copper as 100%. Later it was found that copper had a higher conductivity than what was originally thought, but the standard was not changed. Pure copper has a conductivity of 104% according to the IACS standard.

Only silver has higher electrical and thermal conductivities than copper. **Table 2** lists the conductivities of various metals. The resistivity increases by 43% between 0°C and 100°C.

All impurities raise the electrical resistivity of copper. At low concentrations, the increase is

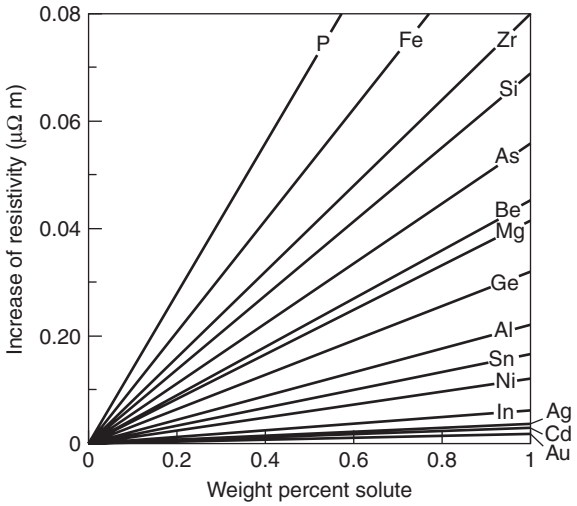

Figure 3 All impurities increase the resistivity of copper. The increase is proportional to the concentration. (Adapted from ASM (2001) *Copper and Copper Alloys. ASM Speciality Handbook*. Materials Park, OH: ASM.)

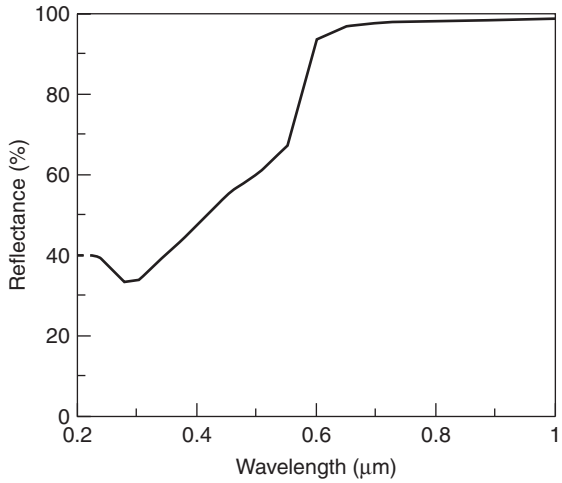

Figure 4 The color of copper is a result of the dependence of reflectivity on wavelength. (Data from ASM (2001) *Copper and Copper Alloys*, *ASM Speciality Handbook*. Materials Park, OH: ASM.)

proportional to the concentration of the impurity. In general, the effect of solutes in raising the resistivity is greater for large differences between the atomic diameter of the solute and that of copper as shown in **Figure 3**. Also solutes of high valency (P, Si, and As) have a greater effect on resistivity than those of low valency such as Ag, Au, and Cd.

Color

Probably the most distinctive property of copper is its color. The reddish hue is a result of how the reflectivity varies with wavelength. The dependence of reflectivity on the wavelength of a polished copper surface is shown in **Figure 4**.

Commercial Grades of Copper

There are several commercial grades of copper. The principal use of oxygen-free copper (C10100) with a minimum of 99.99% Cu is for wire. Fire-refined tough-pitch copper (C2500) is fire-refined copper containing between 0.02% and 0.05% oxygen in the form of Cu_2O and ~0.5% other elements. The copper–oxygen phase diagram is shown in **Figure 5**. There is a eutectic at 0.38% oxygen and 1066°C. **Figure 6** is a typical microstructure of cast tough-pitch copper showing primary copper dendrites surrounded by a copper–copper oxide eutectic.

Often tellurium (~0.5%) or sulfur (~0.5%) is added to copper to promote free machining. Copper is frequently deoxidized with phosphorus. Deoxidation leaves ~0.01% residual phosphorus in solid solution. This lowers the conductivity to below that of oxygen-free copper. Lead is often added to copper and copper alloys to form free machining characteristics. Lead is virtually insoluble in copper as shown by the copper–lead phase diagram (see **Figure 7**). Lead particles appear as a separate phase in the grain boundaries (see **Figure 8**).

Zirconium copper (C15000) contains 0.13–0.20% Zr. It can be heat treated to yield strengths of 400 MPa while retaining a conductivity of 84% IACS. Copper dispersion strengthened by 0.2–0.7% Al_2O_3 retains reasonable strength at temperatures up to 1000°C. It finds applications as electrodes for resistance welding.

Bismuth is a very detrimental impurity. It completely wets the grain boundaries and because it is brittle, its presence renders copper and copper-based alloys brittle. It must be kept $<0.003\%$.

Copper Alloys

Copper is too soft for structural applications. Its strength is markedly increased by alloying. For dilute substitutional solutions (see **Figure 9**), the yield strength increases in proportion to the solute concentration. The rate of this increase is proportional to the 4/3 power of a misfit parameter defined as $\varepsilon = (da/a)/dc$, where da/a is the fractional change in the lattice parameter with concentration c, expressed as an atomic fraction of solutes,

$$\frac{\Delta\tau}{\Delta c} = CG\varepsilon^{4/3} \qquad [1]$$

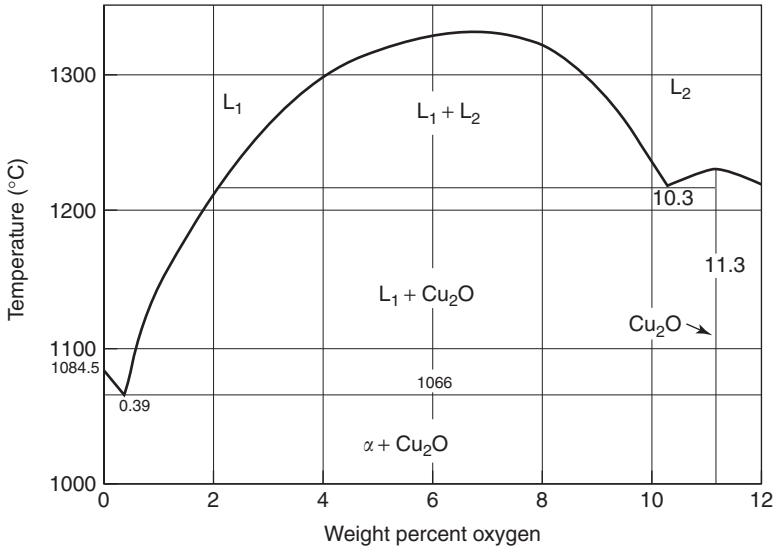

Figure 5 The copper–oxygen phase diagram. (Adapted from (1973) *Metals Handbook*, 8th edn., vol. VIII. Materials Park, OH: ASM.)

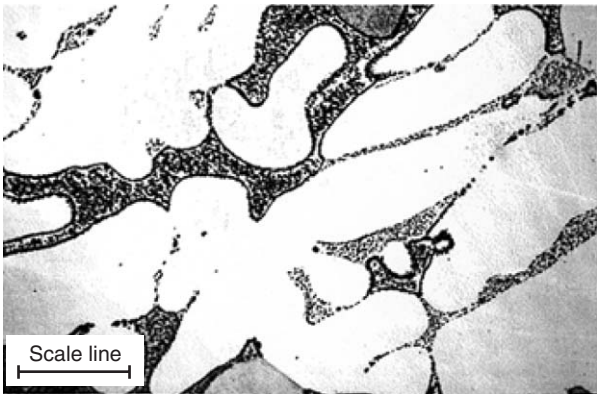

Figure 6 The microstructure of cast toughpitch copper. The scale line is ~125 μm. Note the primary copper dendrites and the Cu–Cu_2O eutectic. (Reproduced with permission of the Copper Development Association Inc.)

where G is the shear modulus of copper and C is a constant. The misfit, ε, is the fractional difference of atomic diameters of copper and solute. **Figure 10** shows the misfits for several solutes. On an atomic basis Sb, Sn, and In are the most potent hardeners.

Although different measurements of the stacking fault energy of pure copper have ranges from 40 to 169 mJ m^{-2}, the best estimate is probably 80 mJ m^{-2}. Zinc, tin, and aluminum form solid solutions that lower the stacking fault energy to <5 mJ m^{-2} at high concentrations as shown in **Figure 11**. The stacking fault energy depends on the ratio of valence electrons to atoms. A lower stacking fault energy leads to more strain hardening. The value of n in the power-law equation,

$$\sigma = K\varepsilon^n \qquad [2]$$

increases from ~0.4 for pure copper to ~0.6 or 0.65 at 35% Zn. The greater strain hardening raises the tensile strength as shown in **Figure 12**.

Finer grain size also increases strength. The grain-size dependence of the yield strength follows the Hall–Petch relation

$$\sigma_Y = \sigma_O + Kd^{-1/2} \qquad [3]$$

Deformation Mechanisms

The slip system in copper, as in all other f.c.c. metals, is $\{1\,1\,1\}\langle 1\,1\,0\rangle$. The critical shear stress for slip is ~3–4 MPa. The extent of work hardening increases as the temperature is lowered below room temperature as indicated in **Figure 13**.

Until the early 1950s, it was believed that mechanical twinning did not occur in copper. However, it is now known that copper can deform by mechanical twinning on $\{1\,1\,1\}$ planes, and in $\langle 11 \gg 2\rangle$ directions, at low temperatures. The critical shear stress for twinning at 4.2 K is ~150 MPa. In copper alloys, twinning depends on the stacking fault energy. The critical resolved-shear stress for twinning is lowered by solid solutions that reduce the stacking fault energy (see **Figure 14**). It is significant that copper is not embrittled at low temperatures and does not fracture by cleavage, because of which copper finds use in cryogenic equipment.

Commercial Alloys

Copper alloys are classified as being either wrought alloys or casting alloys, depending on their usage.

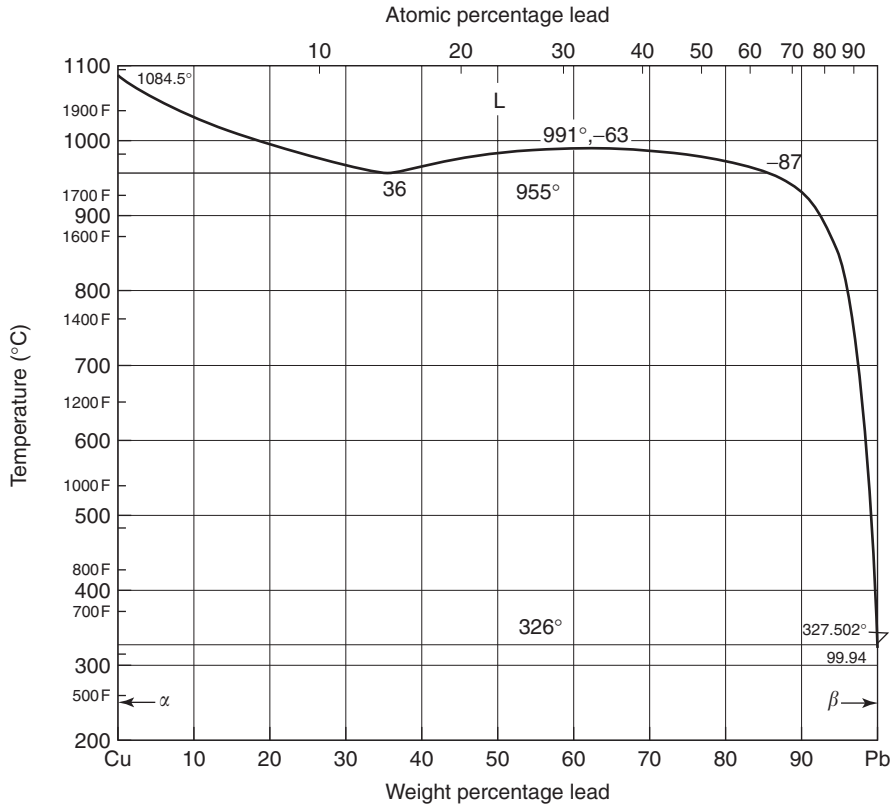

Figure 7 The copper–lead phase diagram. (Data from *Metals Handbook* 8th edn. vol. VIII. p. 296. Materials Park, OH: ASM.)

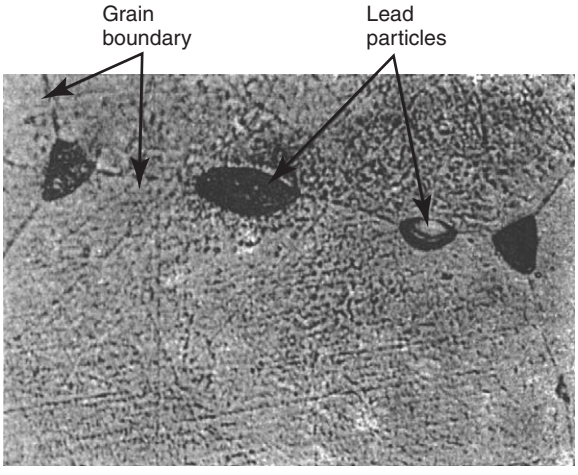

Figure 8 Lead appears as a separate phase in copper alloys. (Adapted from ASM (2001) *Copper and Copper Alloys*, *ASM Specialty Handbook*. Materials Park, OH: ASM.)

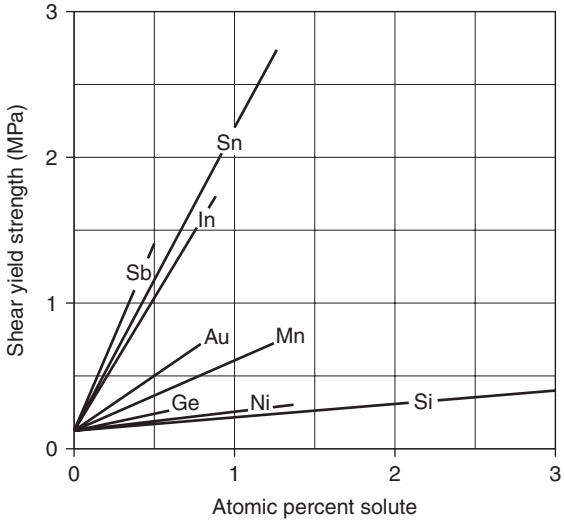

Figure 9 Effect of solute concentration on shear yield strength of dilute copperbase alloys. Note that the strength is proportional to concentration. (Data from Linde JO, Lindell BO, and Stade CH (1950) *Arkiv für Fysik* 2.)

The unified numbering system (UNS) designations for some of the wrought alloys are listed in **Table 3**.

Sheets produced by cold rolling and rods or wire produced by drawing are sold with a temper designation indicating the amount of cold reduction. The system is outlined in **Table 4**.

Brass

Brasses are alloys of copper and zinc. **Figure 15** is the copper–zinc phase diagram. The solubility of zinc in

the f.c.c. lattice of copper is $>35\%$. At nearly equal atomic percentages of copper and zinc, there is a b.c.c. intermetallic phase β, that has a wide range of solubility. At temperatures $<\sim 460^{\circ}C$, β-brass undergoes an ordering reaction to form an ordered b.c.c. phase β' with a B2 (CsCl) structure. Each copper atom is surrounded by eight zinc and eight copper atoms. A eutectoid transformation, $\beta' \rightarrow \alpha + \gamma$ at 250°C has been reported. However, the transformation is rarely, if ever, encountered.

Zinc provides solid solution hardening to copper. Both the yield strength and the tensile strength increase with zinc content, as indicated in **Figures 16** and **17**.

As the lower stacking fault energy increases the exponent n, the uniform elongation also increases in the power-law approximation of the stress–strain curve. Another effect of the lower stacking fault energy is that annealing twins are much more frequent. **Figure 18** compares the annealed microstructure of copper with brass containing 30% Zn. The microstructures of brass containing 40% zinc or more consist of two phases, α and β. The two-phase microstructure of Muntz metal (40% Zn) is shown in **Figure 19**. At 800°C the microstructure is entirely β,

but as the alloy is cooled, α precipitates. The effects of other alloying elements to brass on the solid solubility of zinc can be approximated by "zinc equivalents." A concentration of 1% tin is equivalent to 2% zinc, so tin has a zinc equivalent of 2. **Table 5** lists the zinc equivalents of the common alloying elements. The relative values of the zinc equivalents of the elements can be understood in terms of the number of valence electrons per atom. Silicon and

aluminum have high valencies (4 for silicon and 3 for aluminum) and low atomic masses (28 for silicon and 27 for aluminum), so 1 wt. % causes a large increase of the electron-to-atom ratio. Magnesium, like zinc has a valency of 2, but the atomic mass of magnesium is less than half that of zinc (24 for magnesium vs. 65 for zinc), so 1 wt.%Mg has over twice the effect of 1 wt.%Zn. Tin has a valence of 4, but its atomic mass (119) is roughly twice that of zinc.

Other Alloys

True bronzes are copper–tin alloys. Tin is much less soluble in copper than zinc as shown in the copper–tin phase diagram (see **Figure 20**). The ε phase is very sluggish to form and is rarely encountered. Tin is a potent solid solution strengthener. However, alloys with $>8\%$ Sn are too brittle to be formed mechanically. Because bronzes have a much greater difference of the liquidus and solidus temperatures than brass, they are much easier to cast. Casting alloys often contain up to $\sim 20\%$ Sn. These are used extensively for pipe fittings and bells.

Alloys of copper with aluminum and silicon are called aluminum-bronze and silicon-bronze, even though they contain no tin. Manganese-bronze is a brass with only 1% Sn and 0.1% Mn. Aluminum-bronzes containing up to 7% Al behave much like brass. The phase diagram (see **Figure 21**) shows that a b.c.c. β-phase occurs at $\sim 12\%$ Al.

There is a eutectoid transformation of $\beta \rightarrow \alpha + \gamma_2$ at 565°C and 11.8% Al. **Figure 22** shows the pearlite-like microstructure of alternating platelets of α and γ_2 in an alloy of Cu–11.8% Al after slowly cooling from 800°C. With rapid cooling, the eutectoid transformation is suppressed and the alloy transforms by martensitic shear to a new hexagonal phase β'. **Figure 23** shows the martensitic β' needles in the same alloy after rapid cooling. The martensitic reaction is almost instantaneous. It starts when β is quenched below the M_s temperature and is virtually complete when the temperature is at the M_f. The M_s and M_f temperatures depend on the composition as shown in **Figure 24**. The oxidation resistance of aluminum bronzes is somewhat superior to brass.

Silicon bronzes are more easily cast than brass and have better resistance to oxidation and acid corrosion.

Copper and nickel are completely miscible in both the liquid and solid state as shown in the copper–nickel phase diagram (see **Figure 25**). The low-temperature miscibility gap is rarely encountered.

Nickel imparts improved corrosion and oxidation resistance to copper. Cupronickels containing 20–30% Ni are widely used for heat exchangers.

Alloying copper with 20% Ni causes a loss of the copper's familiar yellow–reddish color. Coinage accounts for $\sim 1\%$ of the consumption of copper. The five-cent pieces ("nickels") in the US and Canada are alloys of 75% copper and 25% nickel. The 10-cent ("dime") and 25-cent ("quarter") pieces are sandwiches of pure copper core clad with 75% copper–25% nickel alloy as shown in **Figure 26**. The Susan B Anthony US dollar is a sandwich of pure copper clad with 77Cu–12 Zn–7 Mn–4 Ni. European coins are

Co	–0.8	Ni	–1.3

either copper-based alloys or combinations of two copper-based alloys. Constantan (45% Ni) has a nearly zero-temperature coefficient of resistivity, hence is useful in instruments.

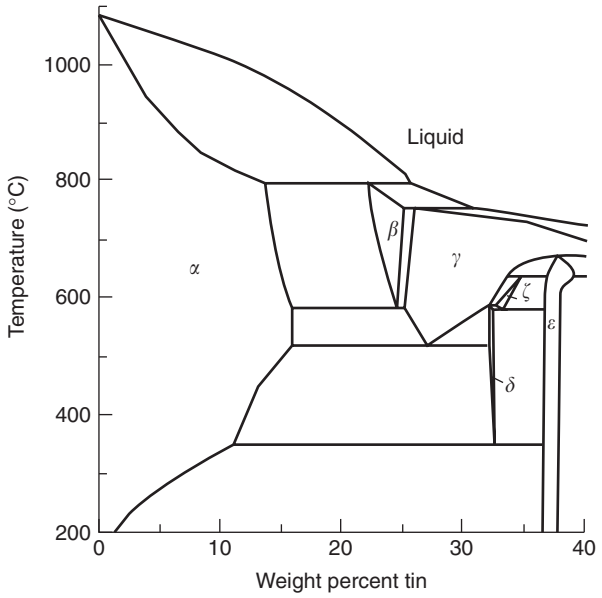

Figure 20 The copper–tin phase diagram. β is a b.c.c. phase. In alloys containing ~20% Sn, formation of the ε-phase is so sluggish that it is seldom encountered. (Adapted from (1973) *Metals Handbook*, 8th edn., vol. VIII. Materials Park, OH: ASM.)

Nickel Silvers

Nickel silvers are ternary alloys containing 12–18% Ni and 17–27% Zn. They have good strength and good corrosion resistance. They are used for springs and corrosion-resistant hardware. Costume jewelry is often made from nickel silver because of its pleasant silvery color.

Beryllium Copper

Copper alloys containing 1.8–2.0% Be and 0.2–0.8% Ni + Co are precipitation-hardenable. The alloy C172000 is solution treated at ~800°C and rapidly cooled. The precipitation is done between

300°C and 400°C. **Figure 27** shows the copper-rich end of the Cu–Be phase diagram. Precipitation hardening produces very high strengths. Even higher strengths can be achieved by cold working after the solution treatment and before precipitation as shown in **Table 6**. The principal drawback is that the toxicity of beryllium is an extreme danger in preparing this alloy.

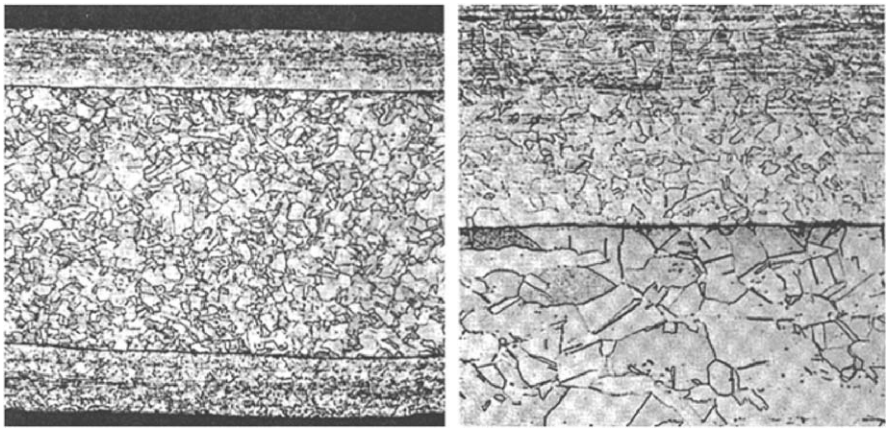

Figure 26 Cross section of a US dime. (Adapted from *Copper and Copper Alloys*, *ASM Speciality Handbook*. Materials Park, OH: ASM.)

Shape Memory Alloys

There are two groups of shape memory alloys: one group consists of Cu–Zn–Al alloys with 10–30% Zn and 5–10% Al. Cu–Al–Ni alloys with 11–14.5% Al and 3–5% Ni form the other group. The recoverable strain for both groups is 4%. The martensitic transformation temperature is $<120^{\circ}$C for the Cu–Zn–Al alloys and $<200^{\circ}$C for the Cu–Al–Ni alloys. The exact temperatures depend on composition. The temperature hysteresis is in the range of 15–25°C.

Deformation Textures

The wire texture of copper consists of 35% $\langle 1\,0\,0 \rangle$ and 65% $\langle 1\,1\,1 \rangle$. The ratio of $\langle 1\,0\,0 \rangle$ to $\langle 1\,1\,1 \rangle$ increases with alloying. The compression texture of copper, like all f.c.c. metals, has $\langle 1\,1\,0 \rangle$ directions parallel to the axis of compression.

Sheet textures are best described by orientation distribution functions (ODF). The rolling texture of copper may consist of two continuous fibers or tubes in the ODF. The major fiber runs between $\{1\,1\,0\}\langle 1\,1\,2 \rangle$ (B) at $\Phi = 45^{\circ}$, $\phi_2 = 90^{\circ}$, $\phi_1 = 35^{\circ}$ through $\{1\,2\,3\}\langle 6\,3\,4 \rangle$ (S) at $\Phi = 37^{\circ}$, $\phi_2 = 63^{\circ}$, $\phi_1 = 59^{\circ}$ to $\{1\,1\,2\}\langle 1\,1\,1 \rangle$ (C) at $\Phi = 35^{\circ}$, $\phi_2 = 45^{\circ}$, $\phi_1 = 90^{\circ}$. A second minor fiber runs between $\{1\,1\,0\}\langle 0\,0\,1 \rangle$ (G) at $\Phi = 45^{\circ}$, $\phi_2 = 90^{\circ}$, $\phi_1 = 0^{\circ}$ and $\{1\,1\,0\}\langle 1\,1\,2 \rangle$ (B) at $\Phi = 45^{\circ}$, $\phi_2 = 90^{\circ}$, $\phi_1 = 35^{\circ}$. The corresponding ODF is shown in **Figure 28** and represented schematically in **Figure 29**. This texture has been characterized as consisting of

27% C, 38% S, 8% B, 18% between S and B, 3% G, and 6% other.

The rolling texture of low stacking fault energy alloys is different. The orientation $\{1\,1\,0\}\langle 1\,1\,2\rangle$ (B) at $\Phi = 45°$, $\phi_2 = 90°$, $\phi_1 = 35°$ is much stronger and the fiber G–B is more prominent. There are two additional fibers. Fiber γ corresponds to orientations having $\{1\,1\,1\}$ aligned parallel to the rolling plane. It extends from $\{1\,1\,1\}\langle 1\,1\,2\rangle$ at $\Phi = 55°$, $\phi_2 = 45°$, $\phi_1 = 0°$ to $\Phi = 55°$, $\phi_2 = 45°$, $\phi_1 = 90°$. Fiber τ consists of orientations with $\langle 1\,1\,0\rangle$ parallel to the transverse direction. For alloys with a stacking fault energy of $\sim 40\,\mathrm{mJ\,m^{-2}}$, there is an additional fiber (τ). **Figure 30** shows the ODF of cold-rolled brass and **Figure 31** is a schematic representation of the

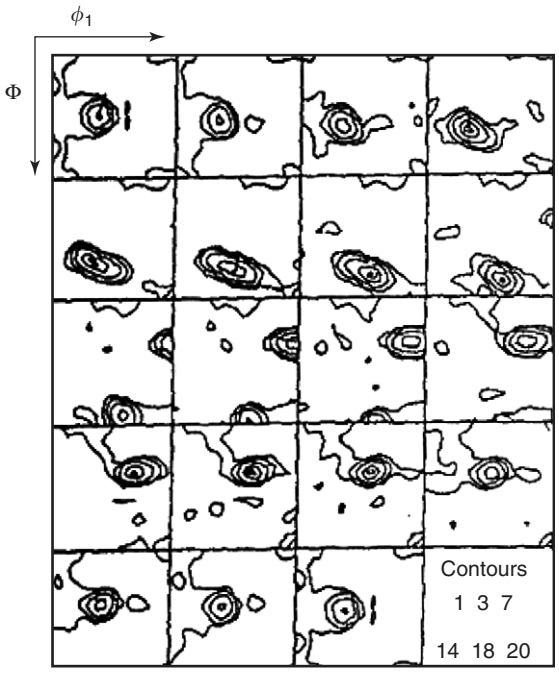

Figure 28 ODF for cold rolled copper. (Adapted from Humphreys FJ and Hatherly M (1996) *Recrystallization and Related Phenomena*. London: Elsevier.)

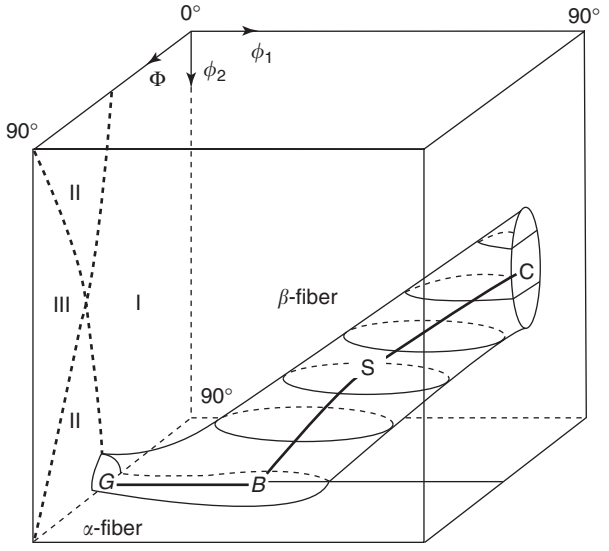

Figure 29 Schematic representation of the ODF shown in **Figure 28**. (Adapted from Humphreys FJ and Hatherly M (1996) *Recrystallization and Related Phenomena.* London: Elsevier.)

fibers. As the amount of deformation increases the α-fiber remains strong, the β-fiber increases, and the C and S components decrease.

Textures are often represented by pole figures. **Figures 32a** and **32b** are the pole figures of copper rolled at room temperature.

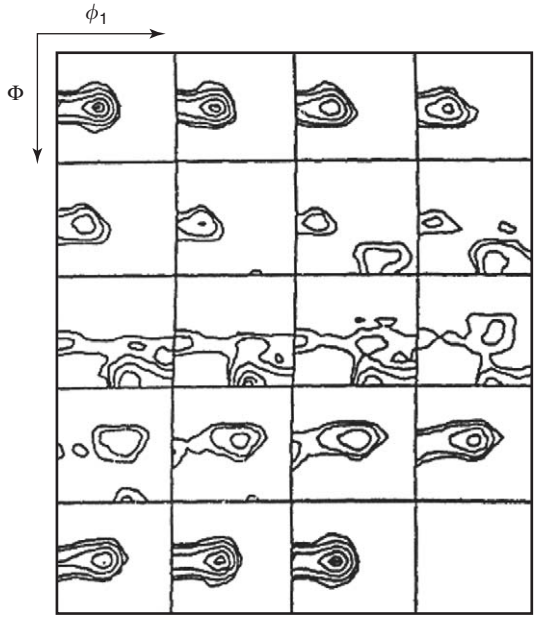

Figure 30 ODF for cold-rolled brass. (Adapted from Humphreys FJ and Hatherly M (1996) *Recrystallization and Related Phenomena*. London: Elsevier.)

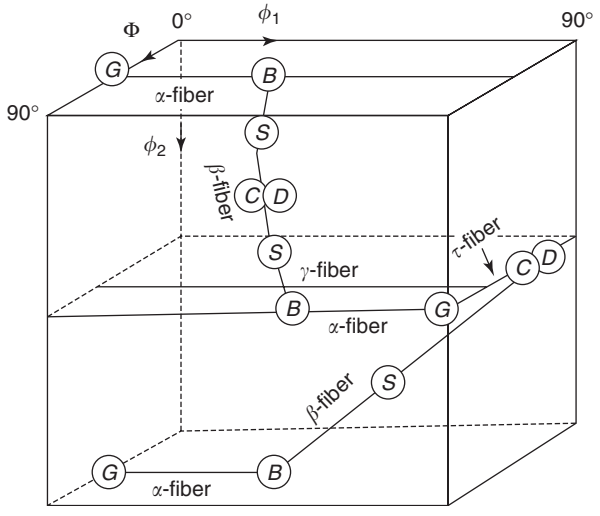

Figure 31 Schematic representation of the ODF in **Figure 30**. (Adapted form Humphreys FJ and Hatherly M (1996) *Recrystallization and Related Phenomena*. London: Elsevier.)

This texture has been described as consisting of ideal components of ~39% {1 2 3}⟨41≫2⟩, ~34% {1 4 6}⟨21≫1⟩, ~14% {1 1 0}⟨1≫12⟩ and ~13% {1 1 2}⟨11≫1⟩. Pole figures for 70:30 brass are shown in **Figures 33a** and **33b.**

The relative amounts of these components change as the temperature of rolling decreases or as the copper is alloyed with zinc or some other element that lowers its stacking fault energy. The transition from copper-type recrystallization texture to the brass-type texture depends on the stacking fault energy of the alloy.

The rolling texture also depends on the rolling temperature. The pole figure of copper rolled at −196°C (see **Figure 34**) is very similar to brass rolled at room temperature. **Figure 35** shows that the texture transition with temperature is gradual.

Recovery

The effects of annealing cold-worked metal are usually divided into three stages: recovery, recrystallization, and grain growth. During recovery, the excess vacancies anneal out and dislocations are rearranged into lower-energy configurations. There are no major changes in hardness or strength. **Figure 36** shows the changes of stored energy and conductivity during recovery and recrystallization of copper.

Recrystallization

During recrystallization after cold work, new strain-free grains are formed. The extent of recrystallization depends on both temperature and time. It is customary to define the recrystallization temperature as the temperature at which 50% of the grains will be recrystallized in a half-hour. For most metals of commercial purity, the recrystallization temperature is between 1/3 and 1/2 of the melting point on an absolute scale. However, the recrystallization temperature depends on purity, the extent of cold work before annealing, and the prior grain size. **Figure 37** shows the kinetics of recrystallization of copper that is 99.999% pure after cold reduction of 98%.

The fact that the recrystallization temperature of 112°C in this case is only 28% of the melting temperature is explained by the extreme purity and very heavy reduction. The time, t, to achieve 50% recrystallization is given by the Arrhenius equation,

$$t = t_0 \exp\left(\frac{Q}{RT}\right) \qquad [4]$$

where Q is the activation energy, R is the gas constant, and T is the temperature. **Figure 38** is an Arrhenius plot of the data in **Figure 37**. The activation energy is 93 kJ mol^{-1}.

According to the Johnson–Mehl–Avrami equation, the fraction, f, of the microstructure recrystallized at any temperature should be given by

$$f = 1 - \exp(-Bt^n) \qquad [5]$$

where the exponent n is the sum of the contributions from nucleation n_n and growth n_g. If the nucleation rate is constant, $n_n = 1$ and if the growth rate is

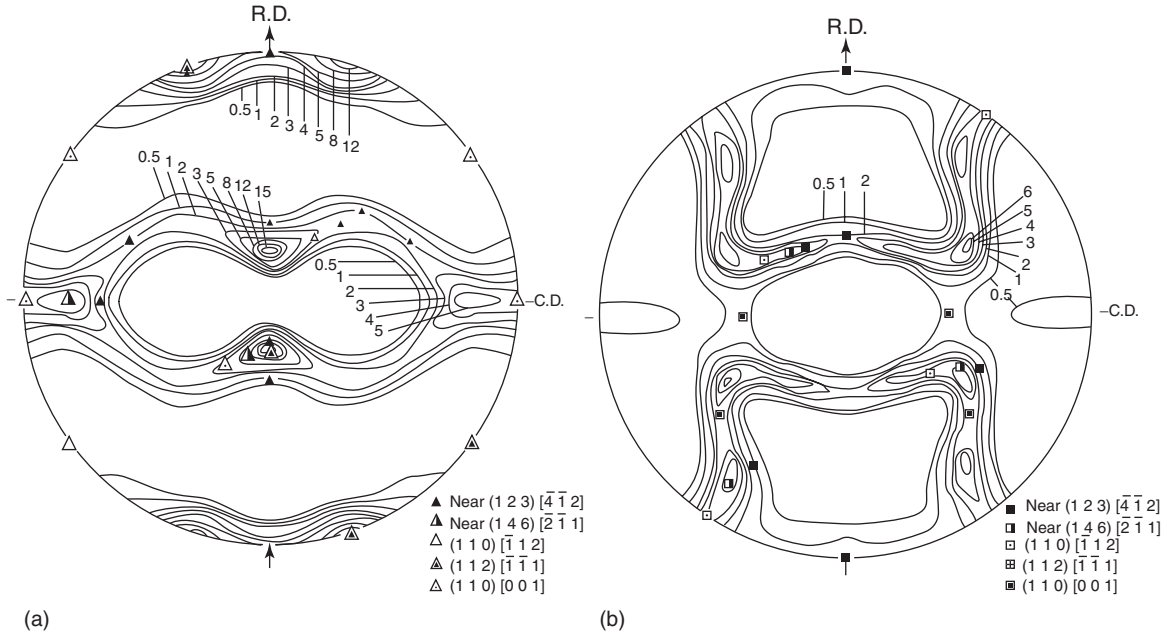

Figure 32 The (1 1 1) and (2 0 0) pole figures of electrolytic copper rolled 96.6% (Adapted from Hu H and Goodman SR (1963) Texture transition in copper. *Trans. Met. Soc. AIME* 227: 627–639.)

constant $n_g = 3$. **Figure 39** is a log–log plot of $\ln(1 - f)$ versus t of the data for **Figure 34** at 135°C. The slope is close to 4, indicating constant nucleation and growth rates.

The effect of the amount of cold work on the recrystallization of brass is illustrated in **Figure 40**.

"Commercially pure" copper recrystallizes at 180°C while zone-refined copper recrystallizes at 80°C. Alloying elements raise the recrystallization temperature as shown in **Figure 41**. The recrystallization temperature also depends on prior grain size as shown in **Figure 42**. With greater amounts of prior

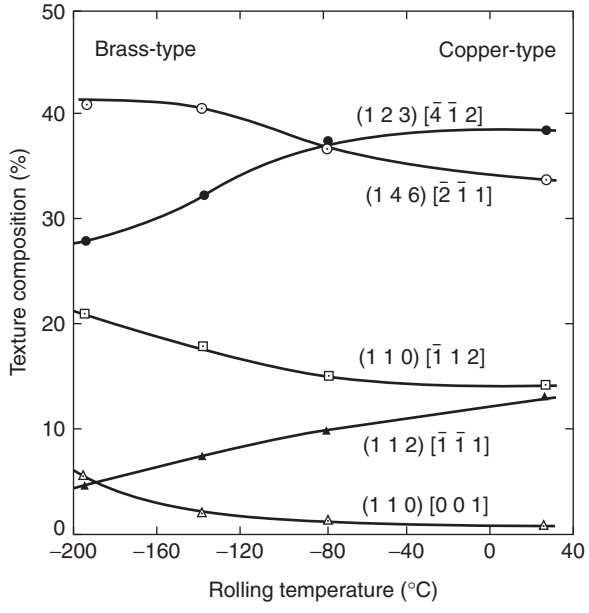

Figure 35 Change texture of cold-rolled copper with temperature. (Adapted from Hu H and Goodman SR (1963) *Trans. AIME* 227.)

cold work, the recrystallization temperature is lowered. (see **Figure 43**).

The grain size resulting from recrystallization depends on the relative rates of nucleation and growth of recrystallized grains. Increasing amounts of cold work before recrystallization decreases the resulting grain size because it increases the nucleation rate more than the growth rate. Solutes in solid solution decrease the recrystallized grain size because they decrease the growth rate by slowing grain-boundary motion. Second-phase particles have the same effect but they may increase the nucleation rate. Finally, the grain size before recrystallization affects the recrystallized grain size. With a finer prior grain size, there are more sites for nucleation, so the resulting grain size is also smaller.

Grain Growth

With continued heating, the larger recrystallized grains grow at the expense of other smaller recrystallized grains, with the result that the grain size

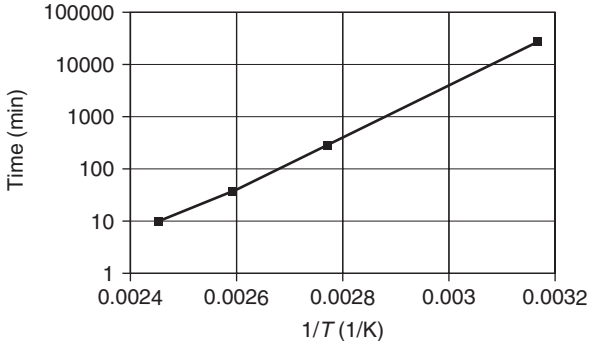

Figure 38 An Arrhenius plot of the time–temperature relation for 50% recrystallization of the copper in **Figure 37**.

increases. The increase of grain size is often characterized by

$$d^{1/n} - d_0^{1/n} = Ct \qquad [6]$$

Simple theory gives the exponent $1/n$ as 1/2, but it is usually much lower. Solutes and second-phase particles have a large effect.

Annealing Textures

ODFs for copper and copper with increasing amounts of zinc are given in **Figure 44**.

The transition from copper-type recrystallization texture to the brass-type texture depends on the stacking fault energy of the alloy. This correlation is shown in **Figure 45**. A marked change occurs at 8% Zn, 3%Al, 2% Ge, or a little over 1% P. The strength of the cube texture is reduced by light rolling reductions, large grain sizes, and low recrystallization temperatures.

Figure 46 is the {1 1 1} pole figure for copper cold rolled 97% at room temperature and recrystallized at 200°C. It consists almost entirely of cube texture and

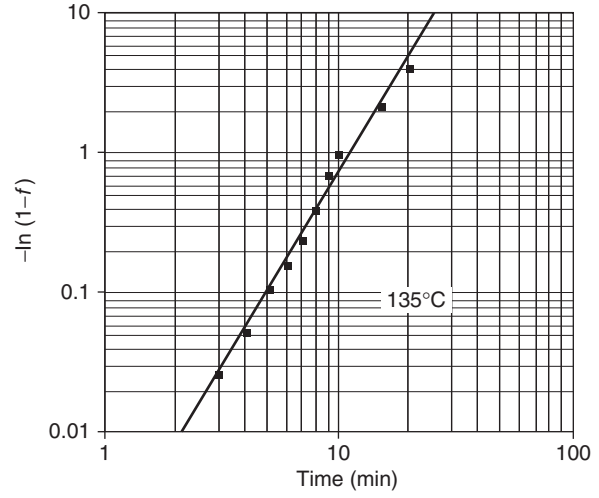

Figure 39 A Johnson–Mehl–Avrami plot of the recrystallization of the copper in **Figure 34** at 135°C. The slope is nearly 4, which indicates that the nucleation rate is constant and there is a constant rate of growth in three dimensions.

Anisotropy

The anisotropy of plastic behavior of sheet material is conventionally documented by the Lankford parameter or *R*-value which is defined by the ratio of

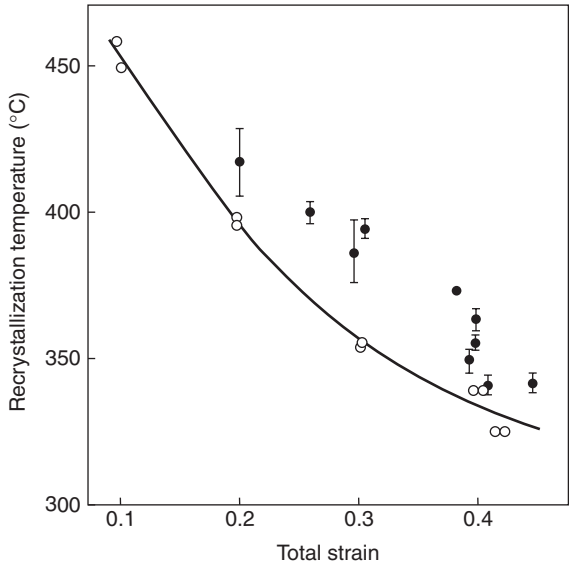

Figure 43 The dependence of the recrystallization temperature on prior strain (○, simple tension, ● compression + tension). (Adapted from Humphreys FJ and Hatherly M (1996) *Recrystallization and Related Phenomena*. London: Elsevier.)

contractile strains during a tension test,

$$R = \frac{\varepsilon_w}{\varepsilon_t} \qquad [7]$$

where w and t denote the width and thickness directions in a tension test. Because R changes with the direction of the tensile axis, it is common to measure the values at 0°, 45°, and 90° to the rolling direction and to define an average $\gg R$ as

$$\gg R = \frac{(R_0 + 2R_{45} + R_{90})}{4} \qquad [8]$$

Like all f.c.c. metals, copper and copper alloys have R-values considerably <1.0. For annealed copper, typically, $R_0 = 0.9$, $R_{45} = 0.4$, $R_{90} = 0.9$, and $\gg R = 0.6$ or 0.7 and for annealed 70:30 brass, typically, $R_0 = 0.9$, $R_{45} = 0.9$, $R_{90} = 0.8$, and $\gg R = 0.9$. The cube texture component lowers R_{45} considerably, while components with {1 1 1} parallel to the sheet raise the R-values.

Forming

Sheet formability benefits from high strain-hardening exponents and high *R*-values. Forming limit diagrams (see **Figure 48**) show the combinations of strains that lead to the formation of localized necks. Minima occur near plane strain, $\varepsilon_2 = 0$. The level of ε_1 at this point depends strongly on the strain-hardening exponent, n in eqn [2]. Cold-worked sheets tend to have lower forming limits. The forming limits tend to rise with sheet thickness. A high strain-rate exponent m, in

$$\sigma = C\varepsilon^m \qquad [9]$$

is also useful in forming. However, it is found to be very low (0.002–0.005) for copper and brass at room temperature.

The compositions and conditions of these sheets are listed in **Table 8**.

The limiting drawing ratio (LDR) for flat bottom cups depends mainly on the *R*-value of the sheet material. Because the *R*-values of copper and brass sheets tend to be <1, the values of LDR tend to fall between 2.1 and 2.2. Formability in sheet forming that involve biaxial stretching depends mainly on the strain-hardening exponent n. Because of this, copper and especially brass have very good stretchability.

Extrusion and Forging

Hot forging temperatures for most copper alloys lie in the range of 600–750°C.

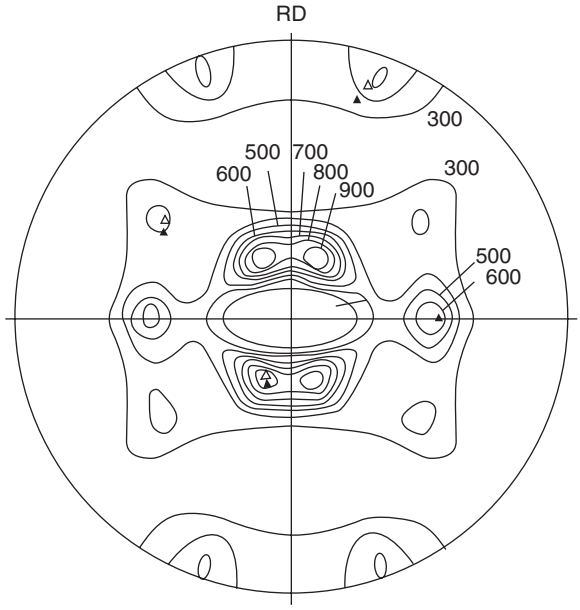

Figure 47 The {1 1 1} pole figure of 70:30 brass cold rolled 97% at room temperature and annealed at 340°C. △ show the ideal (2 2 5)[3 7 4] orientation and the ▲ show the (1 1 3)[2 1 1] orientation. (Adapted from Hu H, Sperry PR, and Beck P (1952) *Trans. Met. Soc. AIME* 194.)

Powder Processing

Parts of copper and copper alloys are sometimes fabricated by conventional powder metallurgy that involves pressing powder to the desired shape and sintering to achieve nearly full density. Porous bearings and filters are made by stopping the sintering before complete densification.

Casting

In general, alloys with a greater separation of liquidus and solidus are regarded as easier to cast. In a fixed thermal gradient, the length of dendrite L, arms is proportional to this temperature difference, ΔT. The liquid-to-solid shrinkage can occur interdendritically. This simplifies risering. Lower liquidus temperatures are also beneficial.

The solubility of hydrogen, like other gases, is much greater in liquid copper than solid copper. **Figure 49** shows the solubility of hydrogen in copper and copper–aluminum alloys. Alloying with aluminum and some other elements decreases the solubility.

As the metal solidifies, dissolved gas is released. For hydrogen,

$$H_2O + 2Cu \rightarrow 2\underline{H} + Cu_2O \qquad [10]$$

This is likely to cause gas porosity. The source of dissolved hydrogen may be from wet scrap or furnace gases.

Corrosion

Many of the applications of copper and copper-based alloys depend on their generally good corrosion resistance. A few specific forms of corrosion are given below. One is pitting corrosion in which the attack is very localized. Pitting attacks cause much more damage than the same amount of metal loss uniformly spread over the corroded surface. A second type of corrosion is dezincification of brasses containing >15% Zn. Both copper and zinc atoms go into solution, but copper then precipitates as a porous plug. **Figure 50** shows the effect of composition on

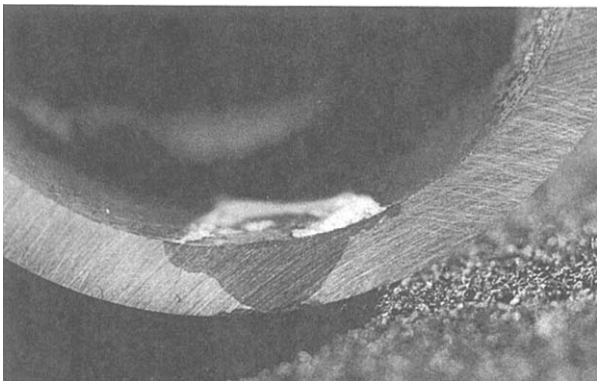

Figure 51 A plug of dezincified metal on a brass pipe. (Adapted from ASM (2001) *Copper and Copper Alloys*, *ASM Specialty Handbook*. Materials Park, OH: ASM.)

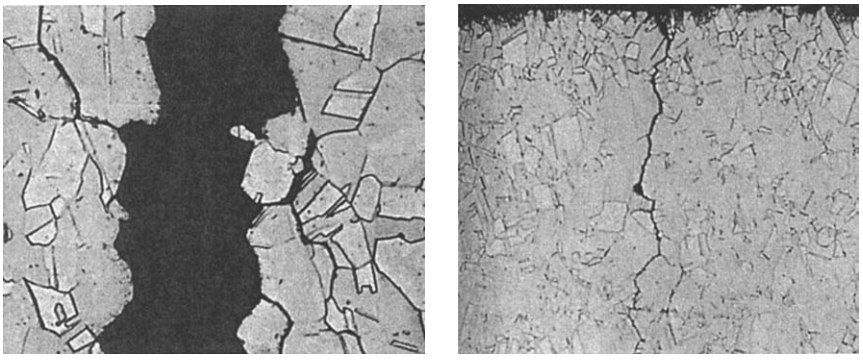

Figure 52 Examples of stress-corrosion cracking in brass. Both condenser tubes of drawn C12200 copper. (Adapted from ASM (2001) *Copper and Copper Alloys*, *ASM Specialty Handbook*. Materials Park, OH: ASM.)

the tendency to pitting and dezincification. An example of dezincification is shown in **Figure 51**.

Brass containing $\geqslant 15\%$ Zn is susceptible to stress corrosion or season cracking. It occurs only when the brass is under tensile stresses and specific environments. For brass, ammonia is the most common agent. **Figure 52** shows examples of stress-corrosion cracking of brass. The propensity to stress corrosion increases with zinc content and temperature as shown in **Figure 53**. Removal of residual stresses by stress-relief anneals is sufficient for many applications. Hydrogen is not a problem for most copper alloys. However, if tough-pitch copper containing Cu_2O is exposed to hydrogen at high temperatures, the reaction is

$$2\underline{H} + Cu_2O \rightarrow H_2O + 2Cu \qquad [11]$$

Such exposure could, for example, occur during torch welding. The formation of H_2O in the form of steam causes embrittlement.

Alloys: Iron

M Ferry, University of New South Wales, Sydney, NSW, Australia

Introduction

Iron alloys are arguably the most important class of engineering materials as a huge number of types can be produced by controlling the type and quantity of alloying elements, casting method, thermal and mechanical processing, etc. Factors contributing to the attractiveness of iron as the principal component of many engineering alloys include: the ability to be produced relatively inexpensively; it has a high melting temperature (1538°C) which allows thermally activated processes over a range of temperatures and it is allotropic thereby allowing its alloys to undergo several useful phase transformations to generate a wide variety of microstructures, and mechanical and physical properties.

Figure 1 presents a subgroup of a much wider range of commercially available iron alloys. The alloys given in this figure contain carbon, are generally classed as steels or cast irons, and are by far the most widely used iron alloys but it is pertinent to note that many others are also important. Depending on alloying additions and the complexity of the various processing stages, microstructures (and properties) of steels and cast irons vary dramatically, and include one or more of the following phases: ferrite, pearlite, bainite (range of structures), austenite, and martensite as well as second-phase dispersions such as cementite, graphite, intermetallic compounds, and precipitates. A detailed treatment of the structure and properties of Fe–C alloys is beyond the scope of this overview but several excellent books are given in the "Further reading" section.

There are a range of essentially carbon-free iron alloys that also generate microstructures with attractive properties. Examples include Fe–Be and FePt that exploit the martensitic reaction to generate shape memory behavior and those alloys that exhibit important physical properties such as Fe–Ni invar alloys with very low thermal expansion coefficients and multicomponent alloys such as (Fe, $Co)_{44}Zr_{7}$-Cu_1B_{15} (HITPERM) and $Nd_2Fe_{14}B$ with exceptional magnetic and magnetomechanical properties. The ability to generate iron alloys with such a large range

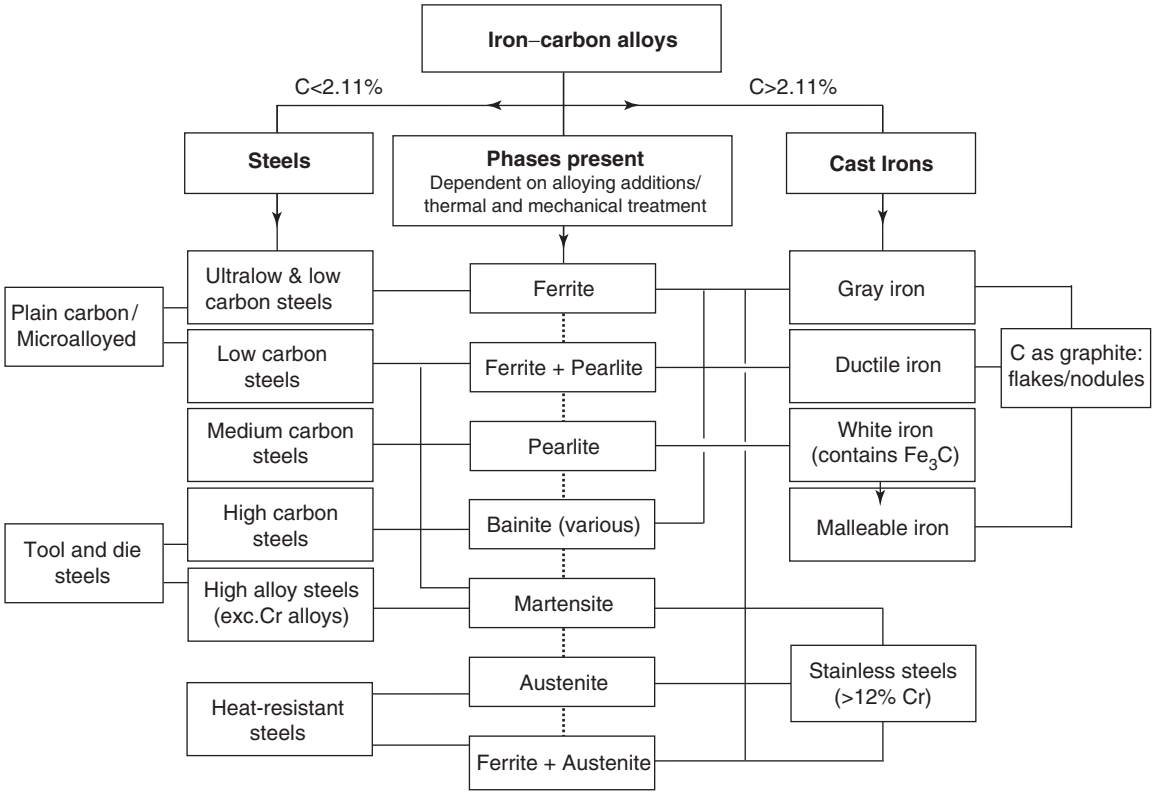

Figure 1 Classification scheme for iron–carbon alloys (range is not exhaustive).

of microstructures and properties has resulted in the use of these materials in an enormous number of applications.

The Production of Iron Alloys

Iron alloy components have been produced from the liquid state for many centuries with mass production of steel commencing in the late nineteenth century. Molten steel was traditionally cast into standing moulds but continuous casting was developed in the 1950s which enabled the production of huge tonnages of steel. Most of the world's steel production is now obtained through this casting route. Following casting, as-cast slabs are thermal and mechanical processed to the desired final shape. In the last few decades, however, near-net-shape casting processes have been developed that are capable of producing near-final-shape products directly from liquid with secondary processing such as hot rolling reduced to an absolute minimum. On a reduced scale, there are various types of novel iron alloys produced in the amorphous, nanocrystalline, and intermetallic form. These materials are either manufactured by conventional casting or by rapid solidification processing, spray deposition, mechanical attrition, and sintering or physical and chemical vapor deposition, etc. Iron alloys produced by these more exotic techniques are generally restricted to specific applications.

Structure and Properties of Iron

The production of pure iron is not possible, but numerous studies have been carried out on the properties of high-purity iron. Iron is situated toward the end of the first transition series in the periodic table with an electron configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^6 4s^2$. Iron lies at the left of the larger atomic species Co, Ni, and Cu which are known to crystallize with a close-packed structure. To the left of iron are the less-filled states of Ti, V, Cr, and Mn which subsequently crystallize with a body-centered cubic (b.c.c.) crystal structure. Iron lies between these groups of elements and, depending on temperature, may exist either as the b.c.c. structure ($1394^\circ C > T_\alpha < 912^\circ C$) or the face-centered cubic (f.c.c.) structure ($912^\circ C < T_\gamma < 1394^\circ C$). The high-temperature b.c.c. structure is not expected under normal circumstances but is a result of magnetic energy effects. The b.c.c. structure exists at standard temperature and pressure, but extreme pressures will generate a hexagonal close-packed (h.c.p.) structure (ε-iron).

An important difference between α-iron and γ-iron is the structure of their dislocations: the Burgers vector of the minimum energy configuration in α-iron is $a/2\langle 1\,1\,1\rangle$ and while dislocations can theoretically dissociate into segments of $a\langle 0\,0\,1\rangle$, the stacking fault energy (SFE) is so high that substantial dissociation has not been observed. In contrast, γ-iron has a relatively low SFE (<80 mJ m^{-2}) and dislocations readily dissociate by the reaction $a/2\langle 0\,1\,1\rangle \rightarrow a/6\ \langle 1\,1\,2\rangle + a/6\langle 2\,1\,1\rangle$, which generates a ribbon of stacking fault. The difference in both crystal structure and SFE of α-iron and γ-iron strongly influences the deformation and annealing behavior of these phases.

Table 1 Approximate diffusivity of various interstitial and substitutional elements in iron

Phase	*Element*	*Activation energy, Q (kJ mol^{-1})*	*Frequency factor, D_o (mm^2 s^{-1})*	*Temperature range (°C)*
α-Iron	Fe	240	200	700–750
	C	80	0.62	700–750
	N	76	0.3	700–750
	Co	226	20	700–790
	Ni	258	970	700–900
γ-Iron	Fe	284	49	900–1050
	C	135	15	900–1050
	Co	364	3000	1050–1250
	Ni	280	77	930–1050
δ-Iron	Fe	239	190	1400–450

Due to the various allotropic transformations in iron ($\delta \leftrightarrow \gamma \leftrightarrow \alpha$), many physical properties, such as specific volume and electrical conductivity, change discontinuously through these critical temperatures. A notable consequence of the f.c.c. $\leftrightarrow$ b.c.c. transformation is the change in magnitude of the self-diffusion coefficient, D, which follows an Arrhenius-type relationship:

$$D = D_o \exp(Q/RT)$$

where D_o is a frequency factor that is virtually independent of absolute temperature (T) and Q is the activation energy for self diffusion. **Table 1** shows the values of D_o and Q for iron and other alloying elements. It is easily shown that the rate of self-diffusion of iron decreases by two orders of magnitude when f.c.c. iron transforms to the more open b.c.c. structure.

Alloying Elements in Iron

A number of elements are added to iron to produce a variety of alloys with a wide range of microstructures and properties (**Figure 1**). Alloying elements have a strong influence on the stable temperature range of b.c.c. and f.c.c. phases. The Wever classification

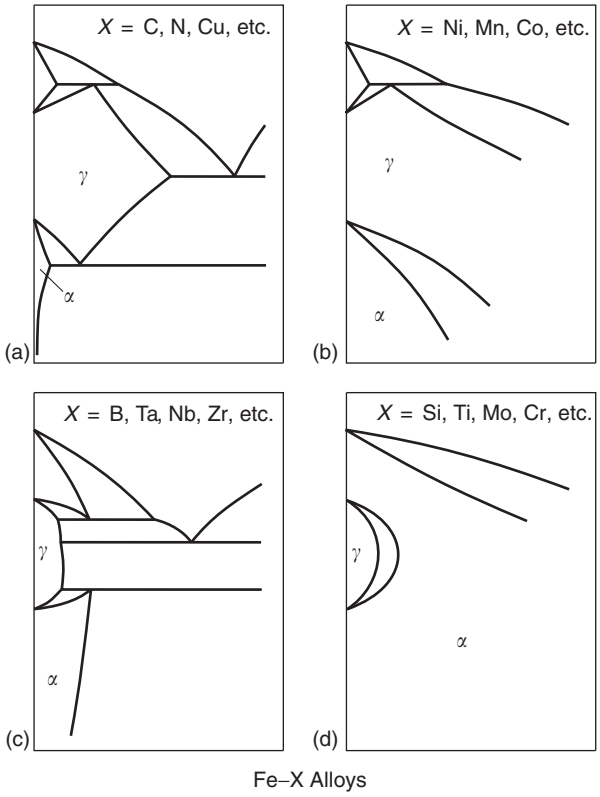

Figure 2 Classification of iron alloy binary phase diagrams: (a) and (b) austenite stabilizers; (c) and (d) ferrite stabilizers.

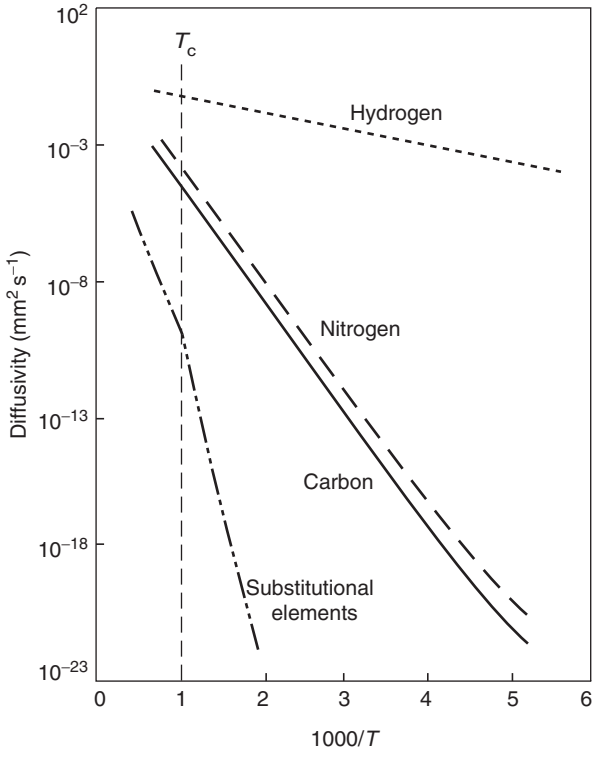

Figure 3 Variation of average diffusivity with temperature for various substitutional and interstitial elements in α-iron.

(**Figure 2**) has shown that most alloying elements fall into four categories with each generating a particular phase diagram. This figure shows that a particular alloying element in iron may either expand the γ-field (austenite stabilizer) or contract this field (ferrite stabilizer). Elements may also form iron-rich compounds that reduce the extent of the γ-field. The overall behavior is a result of the different enthalpies of solution in both the crystal structures of iron which leads to either an increase or decrease of the temperature range in which austenite is stable. Alloying elements can also be grouped into three major classes: those that form interstitial and substitutional solid solutions, and those that are almost completely immiscible with the crystal lattices of iron.

Interstitial Alloys

The elements H, C, N, and O are considerably smaller than Fe and, therefore, tend to occupy interstitial sites in both the lattices of iron. **Figure 2a** shows how the γ-field is stabilized for alloys containing interstitial elements since the f.c.c. lattice provides sites of lower strain energy than does the b.c.c. lattice. These elements have a high rate of diffusion in both the crystal structures of iron, particularly in the less densely packed b.c.c. structure, and are considerably more mobile than substitutional elements (**Figure 3** and **Table 1**). Nevertheless, interstitial elements have low solubility, particularly in α-iron (ferrite), due to the less favorable geometry of the b.c.c. lattice. The solubility of interstitial elements decreases markedly with temperature and obeys a similar relation as diffusivity:

$$C_{\mathrm{Fe-X}}(T) = A \exp(B/T)$$

where A and B are constants and X is either an equilibrium or metastable phase such as graphite, Fe_2B, Fe_3C, and Fe_3N_4 in equilibrium with either ferrite or austenite. **Table 2** gives values of the maximum solubility of various interstitial elements in ferrite and austenite which shows that hydrogen has the highest solubility in ferrite which is demonstrated by a small value of the constant, B (not shown). **Table 2** also shows that the solubility of C and N in both forms of ferrite are considerably lower than in austenite.

In the Fe–C system, graphite does not usually form in either ferrite or austenite due to its high activation energy of nucleation. The cementite phase (Fe_3C) or other less stable carbides tend to form instead. The

Table 2 Solubility of various interstitial elements in iron

Phase	*Element*	*Equilibrium phase*	*Temperature of maximum solubility* (°C)	*Maximum solubility* (at.%)
α-Iron	H	H_2	905	$1-2\times10^{-3}$
	B	Fe_2B	915	<0.02
	C	Fe_3C	727	0.095
	N	Fe_4N	590	0.4
γ-Iron	C	Fe_3C	1148	8.8
	N	Fe_4N	650	10.3
δ-Iron	C	Fe_3C	1495	0.09

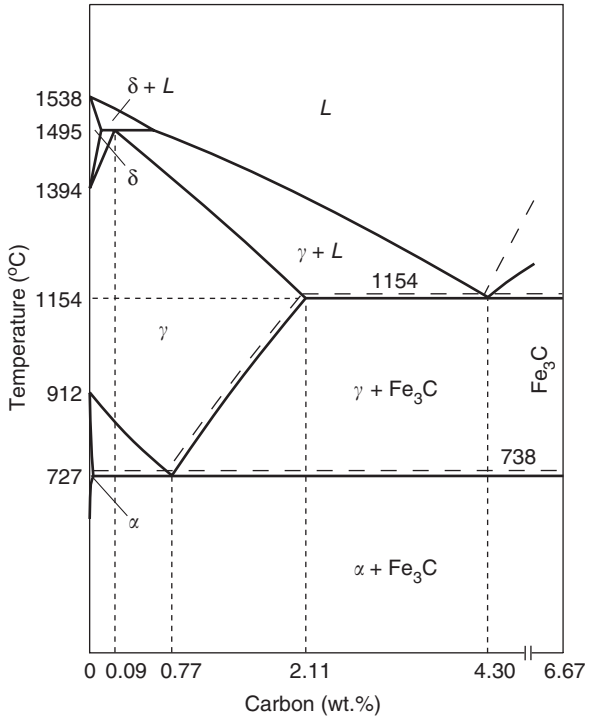

Figure 4 Schematic diagram of the metastable (constitutional) Fe–Fe_3C and the stable (equilibrium) Fe–graphite diagram (dashed) showing important temperatures and compositions.

difference between the equilibrium Fe–graphite and metastable (constitutional) Fe–Fe_3C phase diagram is shown in **Figure 4**, which illustrates the subtle differences in the phase boundaries. Fe–Fe_3C is probably the most important binary system with the following array of characteristics: (1) various types of invariant phase transformations are possible (peritectic, eutectic, and eutectoid) and (2) the solubility of C in α-iron at 727°C is only 0.022 wt.% whereas γ-iron can accommodate 0.77 wt.% C at this temperature. Carbon levels below ~2.11 wt.% are classified as steels while higher carbon alloys are classified as cast iron. Steels are classified further into hypoeutectoid (C < 0.77 wt.%) or hypereutectoid (C > 0.77 wt.%) while cast irons are classified as either hypoeutectic (C < 4.30 wt.%) or hypereutectic.

Substitutional Alloys

There are many substitutional elements that are partially or completely soluble in both the crystal structures of iron. Elements with the largest solubility fall close to Fe in the periodic table: Cr, Ni, Co, Mn, and V. A number of elements, such as Ti, Ca, and K, have almost no solubility in iron. For alloying elements with an f.c.c. or h.c.p. structure, the γ-field is stabilized (**Figures 2a** and **2b**) whereas the γ-field is reduced by elements that form Hume–Rothery phases with Cu, Ag, and Cu (**Figure 2c**) or when iron is alloyed with the b.c.c. transition metals V, Ti, Mo, W, Cr, etc. (**Figure 2d**). For those elements that restrict the γ-field completely, austenite cannot exist which eliminates the possibility of generating several important decomposition products (pearlite, bainite, or martensite). These alloys are non heat-treatable in the sense that phase transformations cannot be exploited to control the microstructure and properties. To achieve the desired mechanical properties such as yield strength, these alloys must either be work hardened (which can also recrystallize to produce a fine grain size) or elements are used to promote solid solution strengthening. The heat-treatable alloys are far more amenable to strengthening over a wide range by controlling the transformation products during austenite decomposition.

Most alloys of iron usually consist of a combination of interstitial and substitutional elements which results in various complex interactions involving atom species. For example, the rate of diffusional transformation is usually controlled by the more sluggish substitutional elements (as shown by the lower diffusivity of these elements, **Figure 3**) which favors the formation of nonequilibrium microstructures following austenite decomposition. In addition, elements can combine to produce enhanced strengthening by the generation of atom complexes (Mn–C, etc.) in the lattice or from the formation of alloy carbides ($[Fe_aX_bY_{c\ldots}]C_j$).

Phase Transformations in Iron Alloys

The allotropic transformations that occur in pure iron can result in a number of important phase transformations in its alloys. As indicated in **Figure 2**, a given concentration of a ferrite stabilizer can eliminate the austenite phase field, whereas an austenite stabilizer will expand this field to allow the alloy to undergo several useful transformations. For

example, **Figure 4** shows that a number of transformations are possible in the Fe–C system. The following brief discussion is devoted mainly to this system as carbon is the most important alloying addition to iron.

During solidification, the peritectic reaction can occur over a certain compositional range. For the peritectic composition (0.09 wt.% C), the following invariant reaction can occur at 1495°C: $L \rightarrow L + \delta \rightarrow \gamma$. In this reaction, liquid + δ-iron transforms isothermally to austenite and has several important consequences during continuous casting of steels.

At higher carbon levels, that is, 0.77 wt.% C, the eutectoid reaction occurs at 727°C: $\gamma \rightarrow \alpha + Fe_3C$. For slow cooling rates, austenite (0.77 wt.% C) decomposes via a diffusional transformation to produce pearlite which is a lamellar structure containing successive layers of ferrite (0.022 wt.% C) and cementite (6.67 wt.% C). With increasing cooling rate, the formation of diffusional products such as pearlite and ferrite is suppressed thereby generating nonequilibrium microstructures ranging from a series of bainitic structures to martensite.

At very high cooling rates, diffusional transformation products do not form since atomic diffusion is necessary for nucleation and growth of these phases. This results in the formation of martensite; a term not restricted to iron-base alloys but used to define the product of a nondiffusional phase transformation both in metals and ceramics. The martensitic transformation has the following important characteristics: each atom retains its original neighbors and there is no interchange among the atoms; the transformation does not involve individual atomic jumps characteristic of diffusion-controlled and interface-controlled transformations; the reaction is diffusionless which means the martensite product has the same composition as the parent phase. In Fe–C alloys, the martensite transformation generates a hard, brittle phase whereas, for essentially carbon-free alloys, the martensite is ductile.

For very low carbon levels (< 0.022 wt.%), Fe–C may undergo a series of precipitation reactions after cooling through the solvus where supersaturated carbon in ferrite decomposes at low temperatures to produce a series of precipitates. This can result in considerable hardening that may or may not be useful depending on the desired application of the alloy.

For carbon levels greater than ~2.11 wt.%, Fe–C undergoes the eutectic reaction: $L \rightarrow \gamma + Fe_3C$. At the eutectic composition (4.3 wt.% C), liquid iron transformations take place at 1147°C to produce austenite and cementite with subsequent cooling to room temperature promoting additional phase changes. It is pertinent to note that alloying additions such as Si promote the formation of graphite rather than cementite (**Figure 1**). Similar to steels, cast irons can generate a wide range of microstructures and properties depending on alloying additions, cooling behavior, etc.

It is clear that the transformation products that form during austenite decomposition in iron-base alloys are expected to be diverse and are influenced by a large number of processing and material-related variables. A particular transformation is achieved by the control of the type and quantity of alloying elements, the cooling rate through the transformation range, and thermomechanical treatments prior to or during transformation, etc. In addition to the classic phase transformations associated with Fe–C, several additional transformations are known to occur in iron alloys. The ability of the alloys of iron to undergo such a diverse range of phase transformations is a major factor contributing to their immense popularity as an engineering material.

Thermomechanical Behavior

An understanding of deformation of ferrite and austenite is extremely important as these phases undergo a significant amount of plastic deformation during thermomechanical processing, the most common method for producing useful final components. During deformation, many microstructural changes occur: the original grains change shape and an internal substructure forms, texture changes take place, precipitation may occur, dynamic recovery (DRV) or dynamic recrystallization (DRX) processes are possible and the constituent particles may fracture and redistribute. The most notable material factors that affect both the deformation microstructure of iron alloys include SFE, crystal structure, initial grain size and shape, and the size, shape, and volume fraction of a second phase.

Cold Deformation

Cold deformation is restricted to low homologous temperatures ($T < 0.5T_m$), where T_m is the absolute melting temperature. During cold deformation of either ferrite or austenite, there is a marked increase in dislocation density resulting in considerable work hardening and grains subdivide in a complex manner to produce a range of features such as a cellular substructure, microbands, deformation twins, deformation bands, and larger-scale heterogeneities such as shear bands. In high SFE b.c.c. α-iron, slip is the principal deformation process and occurs in the close-packed $\langle 1\,1\,1 \rangle$ direction but the slip plane may be any of the planes {1 1 0}, {1 1 2}, or {1 2 3}. In

contrast, γ-iron has a relatively low SFE ($<80\,\mathrm{mJ\,m^{-2}}$) which results in deformation by slip on $\{1\,1\,1\}\langle 0\,1\,1\rangle$ systems as well as by twinning. The different modes of deformation result in differences in the work-hardening rate of these phases as well as in the development of deformation textures.

Hot Deformation

Hot deformation is carried out at $T>0.5T_{\mathrm{m}}$ and is distinguished from cold working by the absence or near absence of strain hardening and lower matrix dislocation content. Deformation becomes more homogeneous with increasing temperature with the frequency of microstructural inhomogeneities such as microbands, transition bands, and shear bands reduced considerably. The driving pressure for softening by recovery and recrystallization (either dynamic or static) is the stored energy of deformation. The process of recovery reduces the internal energy of the metal through mechanisms such as annihilation dislocations and their re-arrangement into low-angle grain boundaries.

The relatively low SFE of austenite does not allow for substantial DRV whereas DRV occurs extensively in ferrite since dislocation climb occurs readily and, for a given temperature, the rate of diffusion of iron atoms in ferrite is $\sim 100x$ greater than in austenite. In ferrite, a significant proportion of the stored energy is released by DRV which reduces the driving force for both dynamic and static recrystallization (SRX). Since the reorganization of dislocations is more difficult in austenite, DRX can occur readily. These differences in the dynamic restoration processes generate two distinctive stress–strain (flow) curves, **Figure 5**. Deformation of austenite results in an increase in flow stress via work hardening but at a critical strain (ε_{c}), there is sufficient stored energy to initiate DRX which tends to eventually decrease the flow stress since the rate of work hardening is offset by the softening caused by recrystallization. In contrast, extensive DRV in ferrite leads to a balance between dislocation generation and annihilation which rapidly results in a steady-state flow stress. There is also insufficient stored energy to dynamically recrystallize this phase. During hot working, successive cycles of DRX in austenite have the capability of refining the grain size whereas grain refinement in ferrite can only be achieved by SRX.

Static Annealing

The principal material factors influencing static annealing in iron alloys include composition, initial grain size, initial texture, and second-phase precipitates. Processing variables are also important and include the mode of deformation, strain, strain rate, and temperature of deformation. In general, both SRX and DRX are initiated by nucleation of strain-free grains at microstructural inhomogeneities such as transition bands, shear bands, and grain boundaries. Cold-deformation of fine-grained ferrite results in nucleation predominantly at prior grain boundaries but a coarse grain size results in substantial shear band nucleation, particularly in those iron alloys containing high levels of interstitial elements.

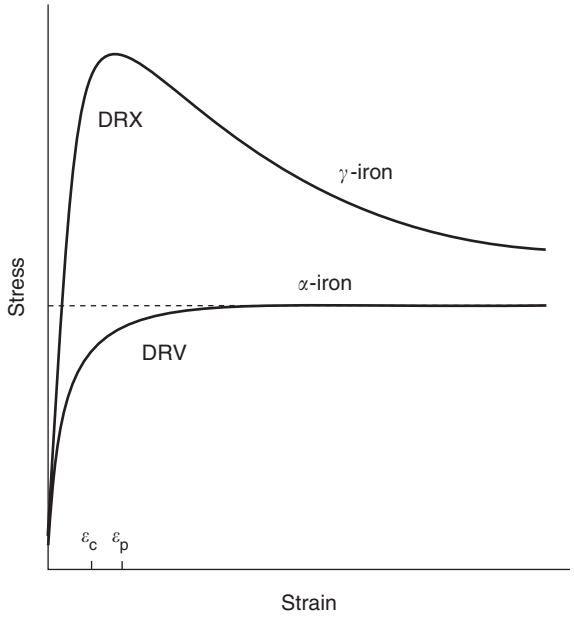

Figure 5 Schematic diagram of typical flow curves associated with the hot deformation of ferrite (α-iron) and austenite (γ-iron).

The most desirable nucleation sites in cold-rolled α-iron are grain boundaries as these nuclei often have orientations where $\langle 1\,1\,1\rangle$ is almost parallel to the normal direction (ND) of the sheet. This is significant since a strong $\langle 1\,1\,1\rangle \| \mathrm{ND}$ texture in cold-rolled and annealed steels results in superior sheet formability. Austenitic alloys recrystallize in a similar manner to ferritic alloys, that is, nucleation occurs mainly at grain boundaries but other microstructural heterogeneities characteristic of deformed austenite also play an important role. Due to the physical processes associated with slip and twinning during cold rolling, austenitic alloys do not produce a high fraction of favorable $\langle 1\,1\,1\rangle \| \mathrm{ND}$ nuclei resulting in reduced formability.

Recent Developments in Iron Alloys

Magnetic Alloys

Iron is ferromagnetic below the Curie temperature and these alloys exhibit a remarkably wide range of

Table 3 Some notable ferromagnetic iron alloys showing typical properties

Material	*Initial relative permeability* (μ_e)	*Hysteresis loss per cycle* ($J\,m^{-3}$)	*Saturation induction* ($Wb\,m^{-2}$)	$(BH)_{max}$ ($kJ\,m^{-3}$)
Soft magnetic alloys				
Commercial iron ingot	1.5×10^2	270	2.14	
Fe-3Si (oriented silicon iron)	1.5×10^3	40–140	2.0	
Fe-45Ni (PERMALLOY 45)	2.7×10^3	120	1.60	
$Fe_{73.5}Si_{13.5}B_9Nb_3Cu_1$ (FINEMET)	5×10^3–2×10^5		1.0–1.2	
$Fe_{88}Zr_7B_4Cu_1$ (NANOPERM)	1×10^4–1×10^5		1.5–1.8	
$Fe_{44}Co_{44}Zr_7B_4Cu_1$ (HITPERM)	2×10^3–3×10^4		1.6–2.1	
Hard magnetic alloys				
Fe-1Mn-0.9C (martensitic)				3.8
Fe-3.5Cr-0.9C-0.3Mn (martensitic)				5.0
Fe-24.5Co-13.5Ni-8Al-2Nb (Alnico-XII)				76.8
$Fe_{60}Pt_{40}$				120
$Nd_2Fe_{14}B$ (oriented)				320–400
$Nd_2Fe_{14}B$ (sintered nanophase)				450

magnetic properties. Magnetic materials are broadly classified into two main groups with either soft or hard magnetic characteristics. Soft magnetic alloys have high permeability, low coercivity, and low hysteresis loss whereas hard magnetic (or permanent) magnetic alloys have a sufficiently large resistance to demagnetizing fields due to their high coercivity, remanence, and energy product.

Table 3 gives some properties of a select range of ferromagnetic alloys which includes some of the more recently developed alloys that possess either an amorphous, or a nanocrystalline phase embedded in an amorphous matrix. These materials are usually produced as ribbons or fibers by rapid solidification techniques and are often followed by a series of heat treatments. Soft magnetic alloys based on these structures are generally complex and contain elements such as Cr, Mo, and Al and varying amounts of metalloids (B, Si, C, and P) that help to form the glassy phase. These alloys have low anisotropy combined with high resistivity (which reduces eddy current losses) and have high permeability and low power losses. The most widely investigated alloys in this new class of soft magnetic materials are $Fe_{73.5}Si_{13.5}B_9Nb_3Cu_1$ (FINEMET), $Fe_{88}Zr_7B_4Cu_1$ (NANOPERM), and $Fe_{44}Co_{44}Zr_7B_4Cu_1$ (HITPERM) which are produced by rapid solidification and crystallization annealing to produce a nanocrystalline structure. Compared with more conventional iron alloys, these materials have very high permeabilities and large inductions (**Figure 6**).

Permanent magnetic iron-base materials include a variety of alloys and intermetallic compounds. The most widely studied materials in recent years are neodymium–iron–boron ($Nd_2Fe_{14}B$) and iron–platinum alloys. For permanent magnets, a parameter

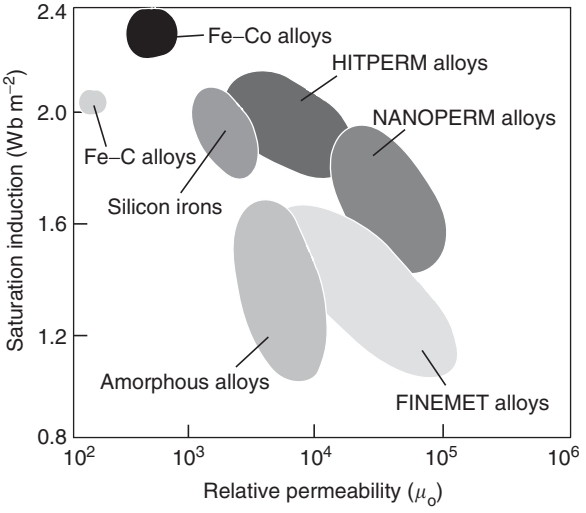

Figure 6 Estimated relationship between permeability and saturation induction for some soft magnetic iron alloys.

that specifies its performance characteristic, that is, its resistance to demagnetization, is the maximum energy product $(BH)_{max}$ where B and H are the magnetic induction and magnetic field strength, respectively. To date, the highest values of $(BH)_{max}$ are obtained in oriented Nd–Fe–B alloys (320–400 $kJ\,m^{-3}$) and sintered fine-grained versions of these alloys ($\sim$450 $kJ\,m^{-3}$).

Shape Memory Alloys

Iron alloys can exploit the martensitic reaction to enable a component to be deformed at one temperature with subsequent recovery of the original shape upon heating. This so-called shape memory effect (SME) is associated with the ability of some martensites to

undergo thermal reversion on reheating which, on a macroscopic scale, corresponds to up to 15% strain recovery. There are various types of SME including pseudoelasticity, one- and two-way shape memory behavior and magnetic field-induced shape memory. Iron-base shape memory alloys are produced either by conventional casting and thermomechanical processing, or mechanical attrition and sintering, or rapid solidification processing. While the various types of shape memory phenomena occur in alloys of the type Fe–Mn–Si–Cr, FeBe, FePt, and Fe–Pd–Pt, they are largely under development and more work is required to explore the potential of shape memory iron alloys.

Intermetallic Compounds

Iron alloys in the form of B2-type ordered intermetallic compounds based on the stoichiometric ratios, FeCo, FeAl, and Fe_3Al, have received considerable attention in high-temperature structural applications due to their low density, high electrical resistivity, high strength at temperature, and excellent resistance to oxidation and corrosion in various aggressive chemical environments. These alloys are either thermomechanically processed in a manner similar to metals or produced by more novel processing routes. While binary iron-base intermetallics are inherently brittle and have low creep resistance, considerable work is being carried out to improve these critical properties both by alloy design and by carefully controlling the various processing stages.

Direct Strip Cast Alloys

There have been substantial developments in the mass production of iron alloys by direct strip casting (DSC) which produces as-cast strip products of a thickness less than 2 mm. Iron alloys currently produced by DSC include carbon and alloy steels, stainless steel, iron–silicon alloys, and cast iron. This casting process often produces a microstructure that is markedly different from the same material produced by conventional casting and thermomechanical processing (TMP). This is a result of the high solidification rates that tend to produce far-from-equilibrium microstructures. By a careful control of casting parameters and alloying additions, as-cast low carbon steel strip can be generated with a final microstructure consisting of one or more of the following phases: martensite, bainite, acicular ferrite, and polygonal ferrite.

Alloys: Magnesium

H Jones, University of Sheffield, Sheffield, UK

Fundamental Characteristics

Magnesium has a density of $1.74\,\mathrm{mg\,m^{-3}}$ at 20°C, melts at 650°C, has a Young's modulus of 45 GPa, and is hexagonal close-packed in crystal structure. Slip at ambient temperatures occurs mainly on the basal plane $(0\,0\,0\,1)\ \langle 1\,1\,\bar{2}\,0\rangle$ with pyramidal and prismatic planes becoming more active with increasing temperature. Deformation of room temperature therefore involves twinning also (initially on $(1\,0\,\bar{1}\,2)\langle 1\,0\,\bar{1}\,2\rangle$), especially when a compressive stress acts parallel to the basal plane.

Pure magnesium, in the absence of moisture, is protected by an adherent thin film of MgO. This MgO reacts with any moisture present to form $Mg(OH)_2$ which breaks down in the pressure of acids which then attack the magnesium. Saltwater is a particularly harsh environment for magnesium, especially when Fe, Ni, or Cu are present as precipitated impurities (**Figure 1**).

There are more than 20 elements with maximum equilibrium solid solubility exceeding 1 at.% in magnesium. Of these, eight are used in commercial magnesium alloys (Al, Zn, Mn, Zr, Li, Ag, Y, Nd) together with Si, Cu, Ca, and Ce. Al and Zn have large effects in reducing the lattice parameters of magnesium, and also raise the critical resolved stress for slip; so potent are solid solution hardeners in magnesium. Al is a less potent precipitation hardener than Zn or Nd, because it precipitates incoherently (e.g., as $Mg_{17}Al_{12}$ at grain boundaries) rather than via Guinier–Preston zones within the grains. The small grain size has a specially marked hardening effect on magnesium (**Figure 2**), approximately double that in aluminum, for example; the small grain size also improves ductility.

Magnesium and its alloys are commonly melted in mild steel crucibles because of their low solubility for iron. The melt surface, however, must be protected by a flux or inert atmosphere. Grain refinement of the cast microstructure can be achieved by treating

with CCl_6 (when Al is present) or with Zr (when it is not) prior to casting. The nucleant is expected to be Al_4C_3, and Zr itself, in the two cases.

Most magnesium alloy components are produced by high-pressure die casting, using hot chamber machines except for the largest castings (up to 10 kg). They can also be sand-cast if certain precautions are taken, for example, to inhibit reaction with the sand and moisture. Ingots are produced by Direct Chill casting, either for remelting or as feedstock for wrought products.

ASTM alloy designations identify the main alloying elements by letters followed by numbers indicating nominal wt.% of each rounded up to a single digit, e.g., AZ91 = Mg–9 wt.%Al–1 wt.%Zn. Letter codes for the main alloying elements are A = Al, C = Cu, E = rare earths, K = Zr, L = Li, M = Mn, Q = Ag, S = Si, W = Y (yttrium), and Z = Zn.

Casting Alloys

AZ91 (9.5Al, 0.5Zn, 0.3Mn, wt.%) is the most common of the Mg–Al-based die casting alloys, achieving ultimate tensile and yield strengths of 215 and 120 MPa, respectively, in the fully heat treated (T6) condition. High-purity versions (maximum 0.004Fe, 0.001Ni, and 0.015Cu and minimum 0.17Mn, wt.%) are available when corrosion resistance is paramount. Reduced Al-contents, such as in AM60 (6Al, 0.3Mn, wt.%) give increased ductility and fracture toughness, when required. Die cast Mg–Al–Zn alloys are susceptible to hot cracking at intermediate Zn contents as shown in **Figure 3**. Improved creep resistance results from added Si (AS21 and AS41: 2 or 4Si, 0.4 or 0.3Mn and 1Si, wt.%) or rare earths (AE42: 4.0Al, 2.5RE, 0.3Mn, wt.%) in which the formation of Mg_2Si and Al_xRE compounds is more effective in pinning grain boundaries than is the relatively soluble $Mg_{17}Al_{12}$. ZE41 (4.2Zn, 1.3RE, 0.7Zr, wt.%) combines precipitation hardening from Zn and Ce with grain refinement by Zr to allow service up to 150°C. EZ33 (2.7Zn, 3.2RE, 0.7Zr, wt.%) and QE22 (2.5Ag, 2.5Nd, 0.7Zr, wt.%) offer creep resistance or high proof strength up to 250°C, again with grain refinement by Zr. WE54 and WE43 (5 or 4.1Y, 3.25 heavy rare earths, 0.5Zr, wt.%) combine high strength at room and elevated temperatures with better corrosion resistance than other high-temperature magnesium-based alloys. The development of a die-castable magnesium-based alloy that has creep resistance comparable with A380 aluminum casting alloy (Al–8.5 Si–3.5Cu–0.5Mn, wt.%) for automotive engine applications is the focus of major R + D activity in Europe, Japan, and the USA currently (**Figure 4**).

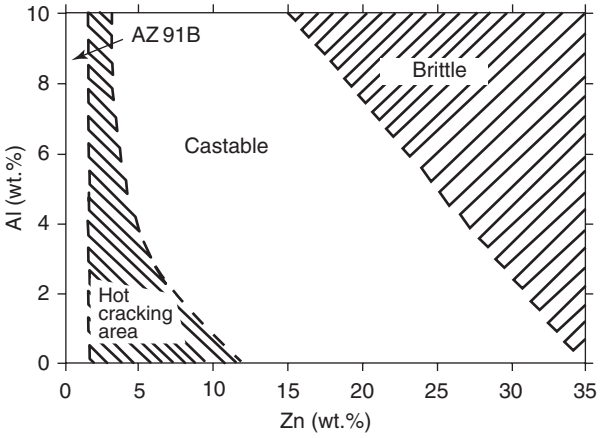

Figure 3 Effect of Al and Zn contents (wt.%) on die castability of Mg–Al–Zn alloys. (Reproduced from Foerster GS (1976) In: *Proceedings of the 33rd Annual Meeting of the International Magnesium Association*, Montreal, pp. 35–39.)

Alloys A to C are developmental Mg–Zn–RE alloys. (Reproduced from Villa Fanjul F, Srimanosaowapak S, Mc Nee KR, Greenwood GW, and Jones H (2003) The effect of Nd substitution for CeMM on creep performance of M–2.5mm–0.35Zn–0.3Mn (MEZ) alloy. *Z. Metallkunde* 44: 25.)

Wrought and Powder Metallurgy Alloys

Working of magnesium is carried out at 300–500°C by extrusion, rolling, or forging. Basal planes and $\langle 1\,0\,\bar{1}\,0 \rangle$ directions tend to orient in the direction of working which can result in proof strengths in compression that are 0.5–0.7 of those in tension. This difference is attributable to the occurrence of twinning more readily under compression, and is reduced at small grain sizes.

AZ31 (3Al, 1Zn, 0.3Mn, wt.%) is the most widely used wrought sheet magnesium-based alloy, comparable in proof and tensile strength with cast AZ91, but with high ductility and being weldable. ZK31

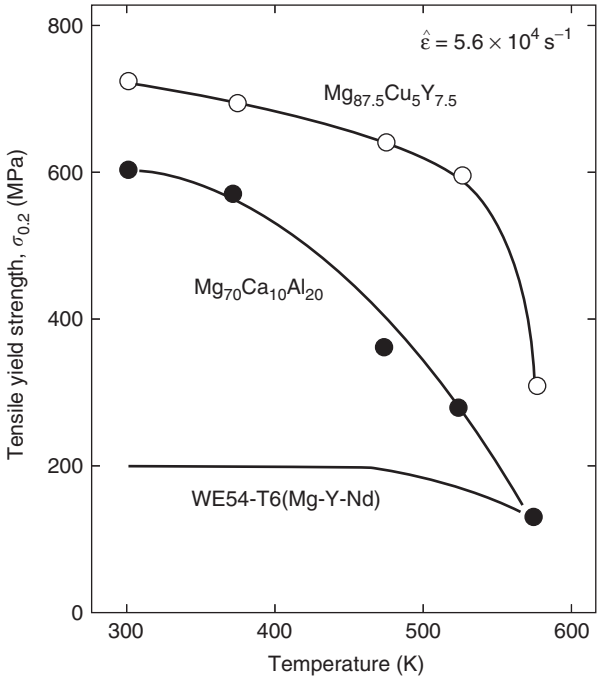

Figure 5 Temperature dependence of tensile yield strength of Mg–5Cu–7.5Y (at.%) and Mg–20Al–10Ca (at.%) rapidly solidified alloy powder extrusions compared with WE54-T6 conventionally processed alloy. ECCM3*, pp. 221–226, with permission from Elsevier.)

(3.0Zn, 0.6Zr, wt.%) is stronger, but at the expense of weldability. LA141 (14Li, 1.2Al, 0.15 minimum Mn, wt.%) has lower strength than either of these but has very low density (1.35 mg m^{-3}) because of the high Li content which confers a duplex hexagonal close-packed/body-centered cubic microstructure. Limitations are poor corrosion resistance and susceptibility to overaging in service which results in excessive creep at relatively low loads. Sheets of all of these alloys can be hot-formed readily at 230–350°C, but cold formability is limited.

AZ61 (6.5Al, 1Zn, 0.3Mn, wt.%) and ZK61 (6Zn, 0.8Zr, wt.%) are examples of extrusion alloys, the latter giving a tensile strength exceeding 300 MPa in the T5 condition, at the expense of weldability. Tensile strengths can be raised to >500 MPa in EA55RS (5Al, 5Zn, 5Nd, wt.%) by rapid solidification processing, which involves planar flow casting to sheet <0.1 mm thick, followed by pulverization and then consolidation by vacuum hot pressing to provide a bulk feedstock for extrusion, forging, or rolling. The very high strengths obtained are mainly attributable to ultrafine grain size (down to 0.3 μm) stabilized by finely dispersed rare-earth aluminides. Strengths as high as 740 MPa have been developed in partially or completely devitrified initially glassy Mg–Cu–Y or Mg–Al–Ca rapidly solidified alloys (**Figure 5**). Some of these compositions exhibit the phenomenon of "bulk metallic glass formation," where section thicknesses of up to several millimeters can be produced in the glassy state directly by chill casting.

Finally, an increased Young's modulus, fatigue, and wear resistance have been achieved in metal matrix composites based on alloys such as AZ91 with ceramic reinforcements (**Figure 6**).

Applications

Figure 7 summarizes the consumption of extracted magnesium in the Western world in 1999. This shows that some 43% was used as an alloying addition to

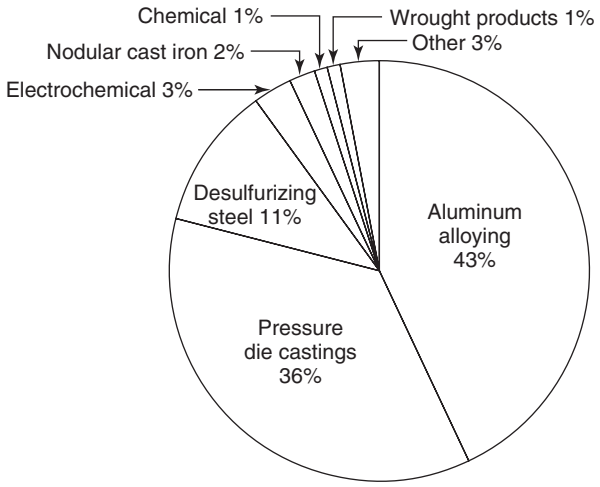

Figure 7 Breakdown of usage of magnesium in the Western world in 1999.

aluminum followed by 36% for magnesium-based alloy die castings, and 13% to desulfurize liquid steel and to nodularize graphitic cast irons, with smaller percentages for electrochemical, chemical, wrought alloy and other purposes. A comparison with the corresponding data for 1991 shows an increase in total shipments from 250 to 380 ktons (kt) (involving a 7% annual growth rate since 1993) due mainly to an increase in demand for magnesium alloy die castings from 38.6 kt (15%) to 133.4 kt (36%), mostly for applications in the automotive industry (driven by weight reduction requirements), but also for components of computers, laptops, cell phones, etc. Typical automotive applications include cylinder head covers, transfer case and transmission housings, seat frames, brake and clutch pedal brackets, steering wheel cores, lock housings, inlet manifolds, cross car beams, and instrument panel substrates. Predictions are that the annual demand for magnesium alloy die castings should exceed 200 kt by the end of 2004. A further growth in general usage of magnesium alloys is likely to depend on (1) expanding the range of alloys with good creep resistance to higher temperatures and even better corrosion resistance, (2) further development of new casting techniques such as thixoforming and squeeze casting, (3) improving the properties of wrought magnesium alloys and their formability, including superplastic forming and diffusion bonding, and (4) continued development of advanced magnesium-based materials, and their metal matrix composites, by such techniques as mechanical alloying, rapid solidification, and other powder technologies.

Alloys: Overview

M Baricco, Università di Torino, Torino, Italy

Introduction

Metallic alloys constitute a fundamental class of engineering materials. Their properties are related to electronic and crystallographic structures, as well as to microstructures. In this article, the fundamental aspects of metallic alloys are described. For details on single classes of metallic alloys, the reader is addressed to specific sections.

Crystal Structures in Metals and Alloys

Chemical Bonds and Crystal Structures

Material properties are related to crystal structure, which depends not only on the chemistry of constituent atoms, but more strongly on the nature of chemical bonds. In fact, the electronic configurations of different atoms determine different kinds of chemical bonds. Though the concept of chemical bond has been developed for molecules, it can also be applied to solid state chemistry. The types of chemical bonds involved in solids may be distinguished as follows: ionic, covalent, metallic, van der Waals, and hydrogen bonds. Metals and alloys are mainly based on

the metallic bond, where valence electrons are delocalized over the whole crystal, even if some contribution from covalent and ionic bonds may be observed in special cases. Alkali metals are purely metallic bonded, whereas metals close to metalloids, such as zinc, have increasing covalent bond contributions.

Geometrical factors also play a crucial role in defining the crystal structure of metals and alloys. Because of the isotropic nature of the metallic bond, the structure of metals may be described in terms of hard-sphere packing. In the case of pure metals, noninterpenetrating equal spheres are interconnected so that the volume is filled as much as possible. Considering a simple layered structure of spheres, hexagonal close-packed (h.c.p.) and face-centred cubic (f.c.c.) crystal structures may be easily built up. On the other hand, considering a slightly lower packing factor, a body-centred cubic (b.c.c.) structure is formed. The crystal structure of metals is often changed on heating (allotropy), as observed in iron, which shows a transition from b.c.c. to f.c.c. at 910°C and a further transition from f.c.c. to b.c.c. at 1400°C before melting at 1539°C. The crystal structures of metals follow the hard-sphere packing as long as pure geometrical factors are concerned. As soon as covalent bonding contributions and electronic effects become important, less dense and more complicated structures are observed, such as in Sn. Similarly, different packing factors are observed in metals with a similar crystal structure. For the same reason, metals showing an h.c.p. structure may have a different ratio between lattice constants (c/a), which turns out to be equal to 1.63 and 1.86 for Mg and Zn, respectively.

In metallic alloys, the constituent elements may be simply mixed in a solid solution or may form an intermediate phase. In the case of alloys, the difference in electronegativity between constituent atoms becomes the main factor in defining the nature of the chemical bond. In the case of a high difference in electronegativity, an ionic contribution to the chemical bond may be observed. As a consequence, rather complicated crystal structures may be formed. Crystallographic parameters relative to various alloys are available in structural databases.

Solid Solutions

Solid solutions may be distinguished as substitutional, when the volume of constituent elements is similar, and interstitial, when a volume difference (size factor) higher than $\sim 15\%$ is observed. A typical example of substitutional solid solution of Zn in Cu is observed in brass, whereas an interstitial solid solution of C in f.c.c. Fe is observed in austenite. Complete solid solubility may be obtained only in alloys when components have the same crystal structure and the size factor is lower than $\sim 8\%$. Au–Ni and Ag–Au–Pt are examples of systems showing complete solid solubility.

Sometimes the distribution of atoms in a solid solution deviates from randomness. When similar atoms group themselves preferentially, a clustering effect is observed. On the other hand, when an atom is preferentially surrounded by different atoms, the solid solution is said to show a short-range ordering.

By means of rapid solidification techniques, the disordered structure of the liquid phase may be retained in the solid, giving a metallic glass. The formation of amorphous alloys is due to the strong undercooling of the liquid, which gives an increase in the viscosity up to the glass transition.

Intermediate Phases

When the limit of solid solubility is exceeded on alloying, a second phase is formed. It may be the primary solid solution of the alloying elements, such as in simple eutectic systems, but more often it appears as an intermediate phase. When only metallic components are present in the system, the intermediate phase is called an intermetallic compound.

The simplest intermediate phase is due to long-range ordering of components in the solid solution (ordered phases). In this case, crystallographic positions are preferentially occupied by a specific element so that an ordering parameter may be defined. Different sublattices constituted by single components may be defined in the structure, as evidenced by diffraction techniques. The ordering parameter changes continuously in a limited temperature range, according to the second-order thermodynamic transition. Ordering of phases is effective in improving mechanical properties and it is fundamental in superalloys.

When the atoms constituting the intermediate phase show a particular value of the valency electron concentration (e/a), electron phases are formed. For instance, 50% of Zn atoms in a Cu matrix give an electron concentration of 1.50, where a b.c.c. β-phase appears. The complex cubic γ-phase and h.c.p. ε-phase are formed for electron concentrations equal to 1.62 and 1.75, respectively. The formation of electron phases is based on the empirical Hume–Rothery's observations, later explained in terms of density of states for valency electrons. Electron phases show a metallic behavior and exist over a range of compositions, such as in brass and bronze.

When the intermetallic phase contains a large number of vacant lattice sites, a defect phase may be

formed in a limited composition range. For instance, in the ordered NiAl phase, the presence of vacancies in the Ni sublattice leads to an increase in the Al-concentration up to ~54%. Vacancy phases play an important role in superalloys.

Very common intermetallic compounds are known as Laves phases. They have a general formula AB_2 and may have a cubic structure ($MgCu_2$) or hexagonal structure ($MgZn_2$ and $MgNi_2$). For the Laves phases, the radii of components have the ratio $r_A/r_B = 1.225$, so that a very high packing density is achieved. Laves phases have recently received attention because of high hydrogen absorption performances, useful in modern batteries.

The interaction of transition metals (M) with small nonmetallic elements (X) generally leads to the formation of interstitial compounds, such as hydrides, borides, nitrides, and carbides. In these compounds, the metal atoms form the matrix and the alloying elements are in interstitial positions. If the ratio between atomic radii r_X/r_M is lower than 0.59, simple compound structures are obtained, where the transition metal forms an f.c.c. or h.c.p. lattice. For cementite (Fe_3C) $r_X/r_M = 0.61$, so that a complex orthorhombic structure is formed. Carbides and nitrides are very useful for strengthening in alloyed steels.

When the components of the intermediate phase have a strong difference in electronegativity, ionic contributions to the chemical bond lead to the formation of valency compounds, which are essentially nonmetallic. They have a fixed stoichiometry and are often formed between transition metals and metalloids. Silicides are an example of such a type of phase.

In recent years, rather complex intermediate phases have been continuously discovered. Frank–Kasper phases show a huge number of atoms in the unary cell. Quasicrystalline phases show a fivefold symmetry, which was considered forbidden according to the classical crystallographic rules.

Phase Stability and Transformations in Metallic Alloys

Thermodynamics and Kinetics of Phase Transformations

Phase stabilities and transformations in metallic alloys are ruled by thermodynamic and kinetic factors. As schematically shown in **Figure 1**, in order to transform a phase (α) into a phase (β), a gain in free energy is necessary. This free energy difference ($\Delta G = G_\beta - G_\alpha$) represents the driving force for the phase transformation. The phase transformation

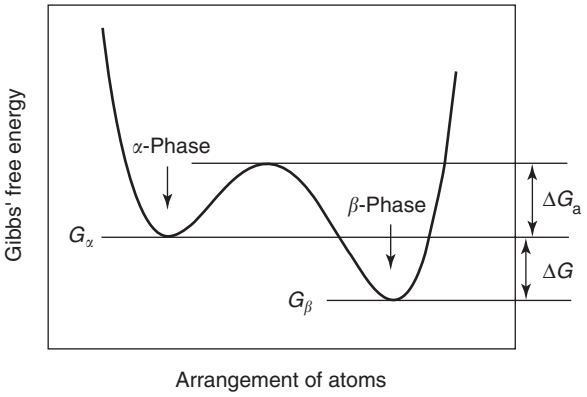

Figure 1 Free energy as a function of the arrangement of atoms in a phase transformation.

becomes possible if the activation barrier (ΔG_a) is overcome and the new phase is formed at a reasonable rate.

The kinetics of a phase transformation is strongly related to the mechanism. In fact, when the crystallography and/or the chemical composition of the two phases are significantly different, a reconstructive transformation occurs and a motion of single atoms is necessary. The whole kinetics of phase transformation may be controlled either by the diffusivity or by interface migration. A typical example is given by perlite formation in eutectoidic steels. On the contrary, a cooperative movement of neighboring atoms occurs in displacive transformations, which are diffusionless and generally very fast, because no activation barrier is present. The formation of martensite in steel by quenching represents an example of such a kind of phase transformation.

The kinetics of phase transformation in metallic alloys is often described in terms of time–temperature–transformation curves (TTT), which are a graphical representation of the time necessary to start and to complete isothermally the phase transformation in a specific temperature range. In the case of cooling treatments, continuous-cooling-transformation curves (CCT) are more appropriate. In order to draw thermal treatments in steels, databases of TTT and CCT diagrams are available. The kinetics of phase transformations may be described in terms of the Avrami equation $y = 1 - \exp(-kt)^m$, where y is the transformed fraction, t is the time, k is a temperature-dependent rate constant, and m is an empirical parameter ranging from 0.5 up to 4, which depends on the type of transformation.

Free Energy and Phase Diagrams

The free-energy of a phase depends on several factors, such as composition, temperature, pressure,

strain, surface, and interfacial energy. In order to define the equilibrium condition for a generic multicomponent system, the free energy of all phases must be known as a function of composition, temperature, and pressure. The thermodynamic equilibrium is reached when the chemical potential of all elements is the same in all phases (common tangent rule). The number of equilibrium phases is defined by the well-known Gibbs' phase rule and the amount of each phase can be calculated according to the lever rule. The description of the equilibrium phases is generally reported as composition–temperature plots, known as phase diagrams.

In the case of a simple binary metallic system, the equilibrium thermodynamics may be estimated by means of suitable models. For instance, the regular solution model considers only solution phases, where the free energy is described by means of an ideal entropy term and a temperature-independent term for the enthalpy of mixing. This term considers the chemical interactions between the constituent elements and it turns out positive in the case of repulsion and negative in the case of attraction. When the enthalpy of mixing becomes zero, the solution is ideal. On the basis of the regular solution model, several binary phase diagrams may be calculated, giving solubility or immiscibility either in the liquid or in the solid phases. Examples of phase diagrams calculated with the regular solution model are reported in **Figure 2**.

As an example, a full miscibility for the liquid and solid phases is shown in Cu–Ni, simple eutectics are observed in Cu–Ag and in Al–Si, and a single peritectic is observed in Ag–Pt. Intermediate phases are shown in the phase diagrams as single lines (line compounds) or as compounds with limited solubility, such as in bronze and brass. The equilibrium conditions for a ternary system may be represented by the Gibbs' triangle, where isothermal sections of the phase diagrams are reported as a function of the composition of components. The method for plotting compositions in a ternary phase diagram is shown in **Figure 3**. For multicomponent systems, only sections of the phase diagram are usually reported (pseudo-binary).

Phase diagrams are generally determined experimentally. Physical properties of alloys with different compositions are followed as a function of temperature, giving an experimental evidence of transition temperatures and equilibrium points. Calorimetric techniques are used for the determination of thermophysical quantities. Modern computing techniques allow the description of the thermodynamics of multicomponent systems of industrial interest. For instance, by means of the CALPHAD (CALculation of

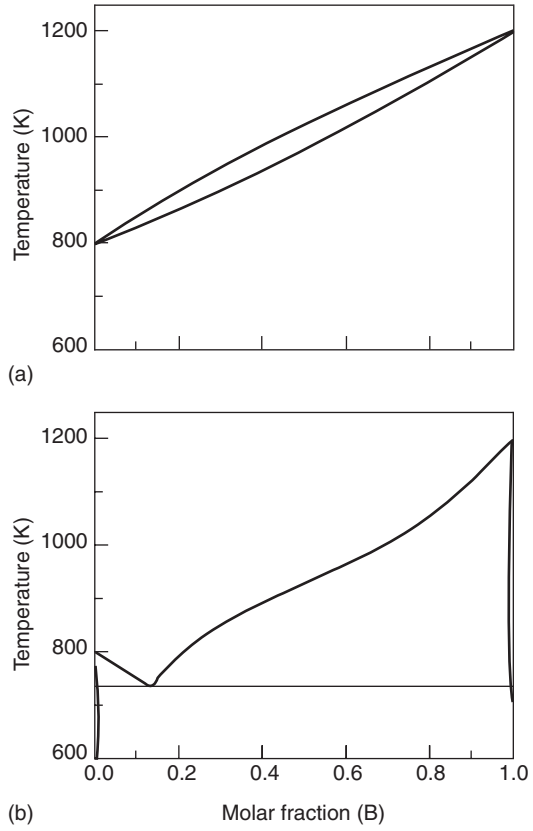

Figure 2 Examples of binary phase diagrams calculated according to the regular solution model. (a) Ideal solution; (b) Interaction parameter equal to $10^4\,J\,mol^{-1}$ and $3 \times 10^4\,J\,mol^{-1}$ for the liquid and solid phases, respectively.

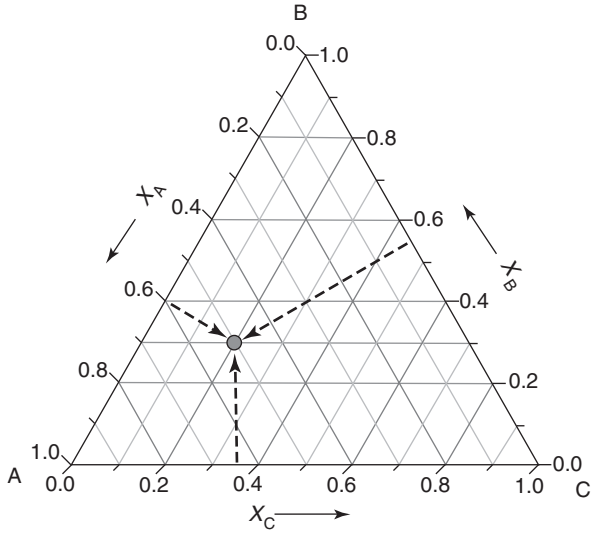

Figure 3 Representation of compositions for ternary alloys. The vertices represent 100% of A, B, or C. The binary systems are represented in the boundaries of the triangle. Ternary alloys are reported in the middle of the triangle. The distances of the points from the boundaries represent the relative proportions of the components indicated in the opposite vertex of the triangle. The point indicated in the figure indicates the composition with 20% of C, 50% of A, and 30% of B ($A_5B_3C_2$).

PHAse Diagrams) method, the free energy of all phases is described as a function of temperature and composition through parameters obtained by an assessment of experimental data. Databases of parameters are available for metallic alloys of industrial interest, allowing the calculation of equilibrium conditions, phase diagrams, and thermodynamic quantities.

Microstructure of Metallic Alloys

Properties of metallic alloys are often related to the microstructure, which depends on phase transformations and mechanical treatments involved in the processing. Examples of microstructures are shown in **Figure 4**.

Reconstructive phase transformations usually proceed by nucleation and growth mechanisms. In the case of a single phase, the grain size determines the grain boundary area, which affects the strength through the Hall–Petch relationship. Grain size is ruled by solidification rate, plastic deformation and recrystallization treatments. Eutectic and eutectoid transformations give a lamellar microstructure. The significant composition difference between the parent and the product phases needs atomic diffusion, so the interlamellar spacing is related to the temperature of the phase transformation. As an example, the temperature of thermal treatments in steels selects the final microstructure, ranging from coarse perlite to fine bainite. Similar fine microstructures may be also obtained by tempering of martensite, previously obtained by quenching. For light alloys, precipitation hardening is related to the microstructure. Metastable phases with interfaces coherent to the matrix may be produced by suitable aging treatments of supersaturated solid solutions obtained by quenching. Similar microstructural effects are observed in spinodal decompositions, where composition fluctuations occur up to the gradient of concentration (uphill diffusion). In recent years, very fine microstructures may be obtained by suitable processing, giving nanostructured alloys. As an example, ball milling of metallic powders, electrodeposition or severe plastic deformation of ingots, may give a grain size down to few tenths of nanometers, leading to improved properties with respect to coarse-grain materials.

Properties of Metallic Alloys

Mechanical Properties

Synthesis and processing of metallic alloys is mainly aimed at mechanical applications. In fact, metallic materials show a very broad range of mechanical properties, which may be often modified by suitable thermomechanical treatments. Basic mechanical properties of metallic alloys are generally determined by standard tensile tests, leading to the classical stress–strain curves shown in **Figure 5**.

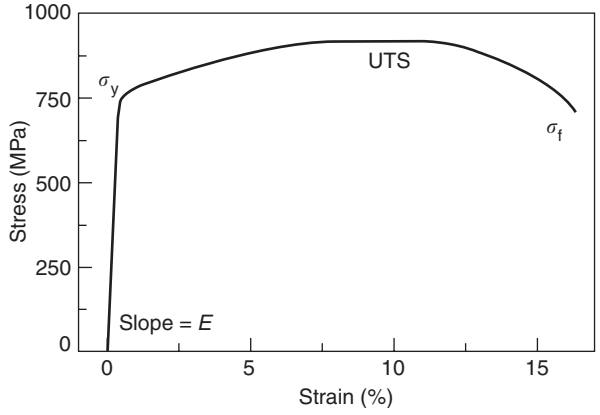

Figure 5 Example of a stress–strain curve for steel (0.4% C, 4% Cr). Basic mechanical parameters are indicated: E, Young modulus; σ_y, yield stress, UTS, ultimate tensile stress, σ_f, fracture stress.

Elastic properties are obtained from the elastic range of tensile tests and they are mainly related to the composition of metallic alloys. The Young modulus (E) ranges from $\sim$40 GPa from Mg-based alloys up to more than 400 GPa for W and Os. The Young modulus for Al-based alloys is $\sim$70 GPa, for Cu-based and Ti-based alloys is $\sim$100 GPa, and for ferrous alloys is $\sim$200 GPa. Metallic alloys have a shear modulus (G) $\sim$3/8 of E and a Poisson ratio (ν) of 0.33. After thermomechanical treatments and changes of the microstructure, the elastic properties remain rather constant, so that they may be considered an intrinsic property of the alloys. The Young modulus of metallic alloys generally decreases as a function of temperature ($dE/dT < 0$). For special applications, such as precision springs, specific compositions have been developed showing $dE/dT \approx 0$ (Elinvar).

The strength and elongation properties may be obtained from the plastic range of the stress–strain curve. The yield stress (σ_y) represents the transition from the elastic to the plastic regime. It depends on the dislocation mobility, so it can be significantly modified by thermomechanical treatments. The strengthening mechanisms in metallic alloys are related to the hindering of dislocation movements. This goal may be obtained by alloying, because the presence of alloying atoms may generate a stress field. In work-hardening processes, the presence of a high-dislocation density leads to an entanglement between crossing dislocations. For precipitation-hardening, widely used in light alloys, the presence of precipitates with interfaces coherent with the matrix produces efficient stress fields against dislocation movements. With the reduction of the grain size, a dislocation pile-up occurs at the grain boundaries and a strengthening in the alloy is observed. For superalloys, a precipitation of the ordered phase may be induced in the disordered matrix, so that dislocations may be blocked at the antiphase boundaries.

Often the yielding point cannot be identified easily, so the stress corresponding to a plastic deformation of 0.2% ($\sigma_{0.2\%y}$) is considered. In the case of annealed low-carbon steels, a nonuniform yield phenomenon may be observed, with the resulting production of Luder's lines at the surface. In this case, an upper-(σ_{uy}) and a lower-(σ_{ly}) yield stress are identified. As long as a uniform plastic deformation acts in the metallic alloys, a hardening effect is observed, according to the general equation $\sigma = K\varepsilon^n$, where σ is the true stress, ε is the true strain, K is the strength coefficient, and n is the strain-hardening exponent. The last parameter measures the rate at which an alloy becomes strengthened as a result of plastic deformation. When the plastic deformation becomes nonuniform, a neck begins to form in the test specimen and an apparent maximum is observed in the nominal stress–strain curve. Necking phenomena are very dangerous for metallic alloys aimed at high-plastic deformation, such as in deep-drawing. Certain metallic materials, under special deformation conditions, behave as superplastic alloys, so they resist necking and show uniform elongations up to 1000 times the normal amount.

Fracture in metallic alloys may be ductile or fragile. In ductile fracture, a significant plastic deformation acts before rupture and a characteristic cup–cone fracture is observed at the surface of the test specimen. Brittle fracture is more dangerous, because it happens suddenly without prior evident plastic deformation. Fracture may be intergranular when it follows the grain boundaries or intragranular when it crosses the interior of the grains. Fracture by cleavage is often observed instead of by shear. A ductile-to-brittle transition may be observed in a limited temperature range by standard impact tests (Charpy type). For instance, for ferritic steels it occurs below room temperature and may be crucial for low-temperature applications, so that austenitic steel is preferred. The tendency for crack propagation is defined by the fracture toughness (K_c). It is obtained from a specific test, where increasing stresses are applied to a pre-cracked specimen. Depending on the mode of loading, different fracture toughness parameters are defined (I, II, and III).

Fracture is generally pictured as consisting of two stages: crack formation and growth. Crack formation may be due to processing or use of the alloy. It generally happens at the surface and it is often related to repeated stresses in the elastic range, a phenomenon known as fatigue. Due to this reason, for

metallic alloys it is necessary to define an endurance limit, which is about one half of the tensile strength: below this value, the alloy can withstand an unlimited number of stress cycles without fracture. Unfortunately, some alloys (e.g., Al-based alloys) do not show this limit, so that the fatigue strength must be defined for a given number of cycles.

Hardness of metallic alloys is determined by specific tests, which are based on the resistance to penetration. A commercial hardness tester forces a small sphere, pyramid, or cone into the body of the alloy by means of an applied load. Hardness numbers may be roughly related to tensile strength. When the applied load is small, the hardness may be determined for single phases evidenced in the microstructure of the alloy. For instance, a resolution down to 200 μm may be obtained by the microhardness Vickers test.

For applications at high temperature, the creep phenomena may occur in metallic alloys. They are due to the occurrence of a plastic strain when the alloy is stressed in the elastic regime. Creep is related to dislocations climbing induced by the high temperature. For moderate stresses, grain boundary sliding may even occur, because of atomic diffusion. Creep may be avoided in superalloys, where precipitates of ordered phases hinder the dislocation movements.

Electrical and Magnetic Properties

Electrical properties of metallic alloys are closely linked to the electronic structure, and the conduction of electrons depends on partially filled bands. According to Mathiessen's rule, the electrical resistivity of alloys increases linearly with temperature near room temperature and above, although the behavior at very low temperature is more complex. Electrical resistivity is strongly enhanced by the presence of foreign atoms in a solid solution in the metal matrix. As an example, the effect of the addition of 0.1 wt.% of different atoms in Cu is shown in **Figure 6**.

It is clear that the effect is strongly dependent on the electronic configuration of the foreign atom. Oxygen has a very big effect and, for the production of copper wires, oxygen-free material is necessary. Cold rolling increases resistivity only slightly and it is often used as a means for strengthening alloys for electrical conductors. Metallic alloys behave as superconductors only at very low temperatures and they have been fully replaced by high-temperature oxide superconductors for practical applications. Thermoelectric effects of metallic alloys are widely used for devices such as thermocouples, thermoresistors, and Peltier junctions.

The magnetic properties of metallic alloys are of fundamental interest and have several industrial

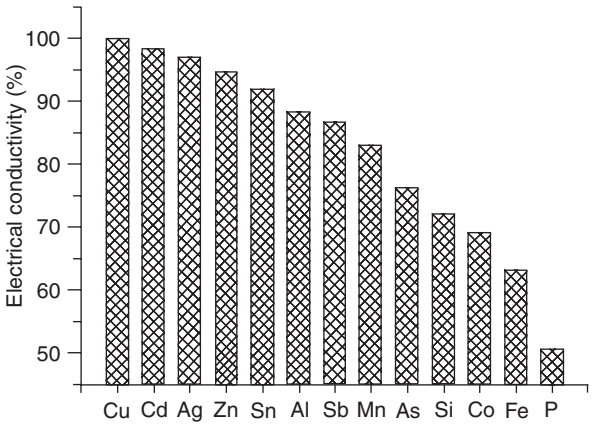

Figure 6 Effect of the addition of 0.1 wt.% of various elements in solid solution on the electrical conductivity of copper.

applications. The primary applications arise in ferromagnetic alloys, based on Fe, Ni, Co, and some rare-earth metals. On the basis of the values of magnetization induced in the material when subjected to a magnetizing field, represented graphically by the hysteresis loop, ferromagnetic metallic alloys are distinguished in soft and hard magnets.

Soft magnetic alloys are characterized by high magnetic permeability, low coercive field, and low core losses. For these materials, a high saturation magnetization is generally desirable. These materials are suitable for electrical motors, transformers, and relays, because of the fast response of magnetization to the applied magnetic field. In Fe, there is a strong relationship between permeability and crystallographic directions, so that the magnetic flux runs better along the (1 0 0) direction (i.e., the edge of the cubic unary cell), giving low-energy losses. For this reason, commercial steel containing 3% Si is processed so that a preferred orientation of grains is obtained (Goss texture). Amorphous alloys show still lower power losses and they find applications in small-sized transformers. Magnetic shields may be obtained using materials with very high magnetic permeability, such as Fe–Ni alloys.

On the contrary, hard magnets have a high coercive field and a high saturation magnetization. A parameter representative of the magnetic energy that can be stored per unit of mass is given by the maximum external energy, $(BH)_{max}$, which is calculated on the demagnetizing portion of the hysteresis loop. These materials are mainly used as permanent magnets, often used to convert electrical energy to mechanical motion (electrical engines) or to convert mechanical motion to electrical energy (microphones). Defects able to hinder the movements of dislocations are usually also able to hinder the movement of magnetic domains, increasing the

magnetic hardness of the material. So, high carbon and alloyed steels are often used as permanent magnets. In recent years, new metallic alloys, characterized by a strong magnetic anisotropy in the unary cell, have been developed. These materials contain rare earths as alloying element, such as in $SmCo_5$ and in $Fe_{14}Nd_2B$.

Chemical Properties

Metallic alloys are not chemically stable. In fact, metallurgical processes devoted to the production of metals from their oxides are often counter-balanced by corrosion and oxidation, which progressively transform the metallic alloys in more stable compounds. Corrosion is a wet phenomenon, which is possible only in the presence of humidity. The corrosion resistance of metallic alloys is generally related to the properties of parent elements, according to the electromotive series. A control of the microstructure of the alloys may change the mechanism of corrosion, which should not be localized but uniformly distributed on the whole surface. In several cases, the addition of elements prone to passivity (Cr, Al) is used to increase the corrosion resistance of alloys, such as in the case of stainless steel. Corrosion might be also avoided by deposition of thin layers of a metal on the surface of the alloy, such as in zinc coating and tinning of steel. Oxidation is a high-temperature process, due to the reaction of the metallic alloy with the atmosphere. At the very beginning of the reaction, a thin layer of the oxide is formed at the surface. If the volume of the oxide is at least as great as the volume of the metal from which it formed, the oxide is protective and oxidation proceeds slowly. On the contrary, if the volume of oxide is less than this amount, the layer is not continuous and it is less effective in preventing the access of oxygen to the alloy surface, so that the reaction rate becomes high. Often the simultaneous formation of two or more oxide layers is observed, such as in steel, where a variable amount of FeO, Fe_3O_4, and Fe_2O_3 layers are formed at different temperatures.

Materials Selection

For specific applications, it is a combination of material properties (material index) that characterizes the performance. Properties of alloys are available in databases, so that merit indices, combined with Ashby's charts, allow optimization of the material selection process.

Alloys: Titanium

T R Bieler, R M Trevino, and L Zeng,
Michigan State University, East Lansing, MI, USA

Introduction

Titanium and titanium alloys offer a unique combination of physical and mechanical properties that makes titanium an excellent choice for applications that require high strength at temperatures below 550°C, good stiffness (104–133 GPa), toughness, and corrosion resistance. Another desirable characteristic of titanium is its relatively low density of 4.54 g cm^{-3}, which is between iron (7.87 g cm^{-3}) and aluminum (2.70 g cm^{-3}). The high specific strength along with good corrosion resistance makes titanium an enabling material in the aerospace industry (e.g., airframe components, rotors, and compression blades in jet engines), and it is important in the growing biomedical engineering field due to its biocompatibility with living tissues. Titanium alloys have historically been too expensive for the auto industry, but titanium alloys have been recently used for exhaust systems, valves, and springs (its high-yield strength and moderate modulus value gives titanium alloys tremendous elastic resilience). Titanium aluminide intermetallic alloys are likely to become important in the future, due to their lower density and superior high-temperature capabilities.

Titanium ranks ninth as the most plentiful elements, and is the fourth most abundant structural metal in the Earth's crust exceeded only by aluminum, iron, and magnesium. Despite this abundance, the difficulty in processing titanium makes it expensive (~$50/kg for Ti, compared to $4/kg for Al and $1/kg for Fe); yet it is a strategic metal due to which its corrosion resistance and specific strength outweigh its high cost. The cost is likely to drop in the next decade, as new processing methods that reduce the energy requirements and allow continuous processing are scaled up.

The crystallography is considered first, to establish how phase transformations between low- and high-temperature crystal structures occur. From this, the rationale and the complexity surrounding alloying and processing strategies can be appreciated. Finally, a few problematic issues associated with titanium alloys are noted.

Crystallographic Structure of Phases in Titanium Alloys

Titanium exists in two allotropic crystal forms, α, which is a hexagonal structure with a *c*/*a* ratio of ~1.59 (slightly squashed compared to the close packed ratio of 1.63), and β, which has the body-centered cubic (b.c.c.) crystal structure. In pure titanium, the α-phase is stable up to the β transus temperature (β_T), 883°C. The α-phase is transformed upon heating above 883°C to the b.c.c. β-phase. The idealized orientation relationship between α (thin lines) and β (dashed lines) is illustrated in **Figure 1**. However, the actual lattice spacings for α and β do not match perfectly. **Figure 2** shows how the atomic positions of these phases are related to each other based on a common origin using lattice constants from a Ti–6Al–4 V alloy. With heating, the $\alpha \rightarrow \beta$ transformation requires lattice strains of ~10% expansion along $[2\,\bar{1}\,\bar{1}\,0]_\alpha$ to become a $[1\,0\,0]_\beta$ direction, ~10% contraction along the $[0\,1\,\bar{1}\,0]_\alpha$ to become $[0\,1\,\bar{1}]_\beta$, and ~1% contraction along $[0\,0\,0\,1]_\alpha$ that becomes $[0\,1\,\bar{1}]_\beta$. Due to this imperfect geometrical relationship, one of the two $\langle 1\,1\,1 \rangle_\beta$ directions in the {1 1 0} plane will be rotated ~5° to align itself with one of the $\langle \bar{2}\,1\,1\,0 \rangle_\alpha$ directions, leading to six possible variants of β from one α orientation, as shown in **Figure 3a**. This means that two β variants can be misoriented from another by ~10°. Thus, β variants arising from one parent α crystal can be misoriented from each other by ~10°, 50°, 60°, or 70° rotation about a $\langle 0\,1\,1 \rangle_\beta$ axis (a prior $\langle 0\,0\,0\,1 \rangle_\alpha$ axis).

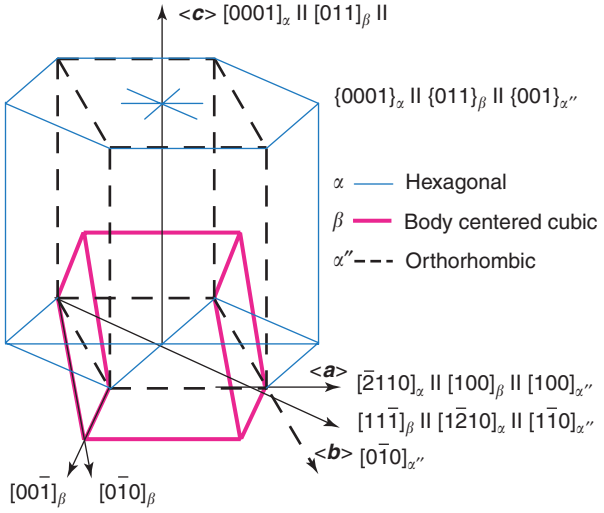

Figure 1 Idealized orientation relationship between α, β, and α″ crystal structures.

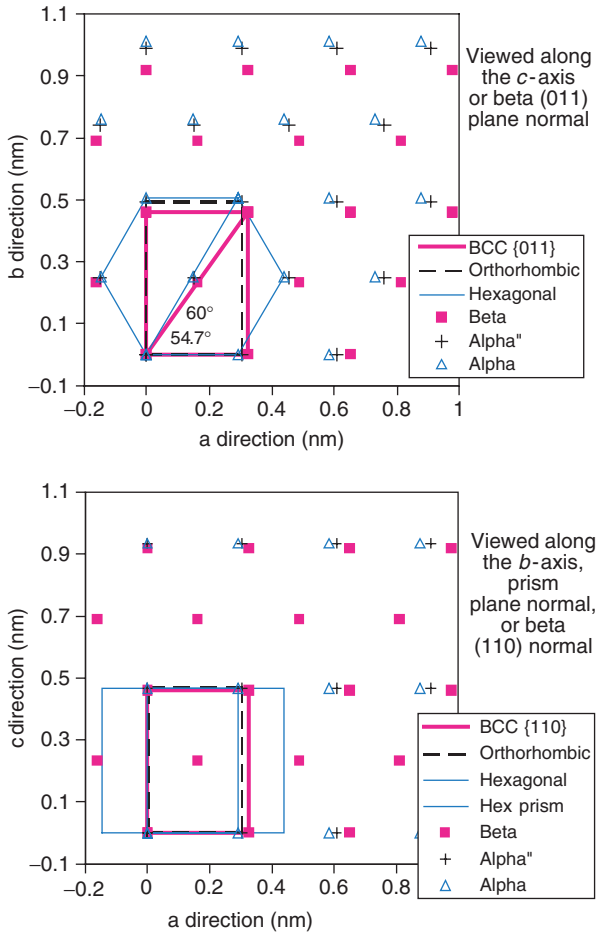

Figure 2 Atomic lattice positions of the α, β, and α'' crystal structures.

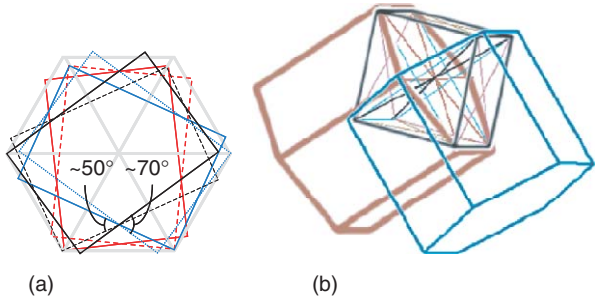

Figure 3 (a) Possible β {0 1 1} plane orientations based upon parent α during $\alpha \rightarrow \beta$ transformation, and (b) two possible α orientations based upon parent β during $\beta \rightarrow \alpha$ transformation.

With the reverse $\beta \rightarrow \alpha$ transformation upon cooling, a $\langle -2\,1\,1\,0 \rangle_\alpha$ vector can align with one of the two $\langle 1\,1\,1 \rangle_\beta$ directions on each of the six {1 1 0} planes in the β-phase. Since the angles between $\{1\,1\,0\}_\beta$ planes are either 60° or 90°, the c-axes of daughter α can point in as many as six directions, and each direction has two variants that are rotated $\sim 10°$ about the c-axis. An example of a 90° misorientation from the same parent β crystal is shown in **Figure 3b**.

Although there are 12 variants of the α orientation possible for each parent β orientation, most prior β grains will only choose a few of the 12 α variants during the α–β transformation process. Recent research has shown that the preferred transformation variants are those that have higher populations of dislocations present on $\{1\,1\,0\}_\beta$ planes. Therefore, it is possible to control the transformation process by controlling the dislocation density in the β-phase. The dislocation density depends on dislocation generation (plastic deformation) and annihilation (recovery) processes that are sensitive to prior deformation history, heating rates, and time at temperature. The understanding of what controls variant selection is just emerging, and it is likely to be exploited profitably in the coming decade to allow the manufacturing processes to be designed to achieve optimized properties for a given application.

In addition to α-and β-phases, there are a number of subtle variations, including α' and α'' martensites that may form during quenching, and ordered phases such as α_2- and ω-phases. With quenching, there is no opportunity for diffusional segregation of alloying elements; so the resulting hexagonal supersaturated α' has lattice constants slightly different from equilibrium α. The α''-phase has an orthorhombic crystal structure, which is outlined in bold lines in **Figure 1**. This crystal structure is between the α and the β crystal lattice (**Figure 2**). The α_2-phase (Ti_3Al) is an ordered version of the hexagonal lattice with Al atoms spaced regularly on the hexagonal lattice, which increases the resistance to dislocation motion. There has been much interest in ordered orthorhombic intermetallic Ti–Al–Nb alloys in the past decade. The ω-phase is a different hexagonal ordered-crystal structure that could form in prior β-regions after long-term aging or in α-regions after stress-induced transformation from $\alpha \rightarrow \omega$. Ordered phases resist dislocation motion, which can increase the strength, but the continuous ω-phase is known to reduce the ductility and facilitate crack nucleation.

Figure 2 shows that the atomic arrangement of the α-, α''-, and β-phases are very similar; but small differences in atomic position lead to different crystal structures that have significantly different properties. Thus, phase boundaries in Ti alloys are typically coherent or semi-coherent. These phase boundaries are quite easily observed in polished and etched microstructures, often giving the impression of a fine grain size, but it is important to realize that the domains of similar orientations are often much

larger than they appear, and these "invisible" mesotextural features can account for early dwell fatigue crack nucleation.

Unlike steels, the martensitic transformations in titanium result in small volume changes and modest shears, but the paradigm of using martensitic transformations in steels to manipulate microstructures and properties is also used in titanium alloys, though the details are completely different (e.g., α'' is softer than α). Ordered intermetallic alloys based on Ti_3Al and TiAl can also be manipulated with similar strategies as those used in titanium alloys, but again, the details differ. The technology of titanium alloys is highly dependent on the ability to control the phase transformation from the β- to the α-phase using strategic alloying and heat treatment history, which gives titanium alloys flexible and designable properties similar to that possible with steels.

Effects of Crystal Orientations on Mechanical Properties

The hexagonal crystal structure has considerable elastic and plastic anisotropy, which are strongly affected by processing history. Young's modulus is highest (143 GPa) along the *c*-axis, and lowest (104 GPa) in any direction in the basal plane. Titanium deforms with eight slip and twinning systems are illustrated in **Figure 4**. Each of these systems require different critical resolved shear stresses to operate, making the plastic deformation process much more complicated than cubic metals. Prism slip in $\langle a \rangle$ directions is the easiest, leading to plastic deformation that leaves the crystal dimension along the *c*-axis and the *c*-axis orientation unchanged. The next easiest slip system is basal slip in $\langle a \rangle$ directions, which also does not change the dimension of the crystal along the *c*-axis, but it causes crystal rotation about a prism plane normal axis. It is possible to have $\langle a \rangle$ slip on pyramidal planes as well.

To change the crystal dimension along the *c*-axis, twinning or $\langle c+a \rangle$ slip on pyramidal planes is required, but the critical resolved stress for $\langle c+a \rangle$ slip is high, so twinning systems are usually more easily activated. Consequently, Ti crystals are intrinsically hard when stressed along the *c*-axis. Furthermore, the relative strengths of these deformation systems change with temperature, for example, twinning does not occur at elevated temperatures. Consequently, the distribution of crystal orientations can have a large impact on both elastic and plastic properties. Even pure titanium behaves like a composite material; depending on the crystal orientation with respect to the resolved shear stresses, any crystal can be either hard or soft. In **Figure 5**, shades of gray represent the Taylor factor (proportional to the plastic flow stress of the crystal) in a rolled plate deformed in uniaxial tension.

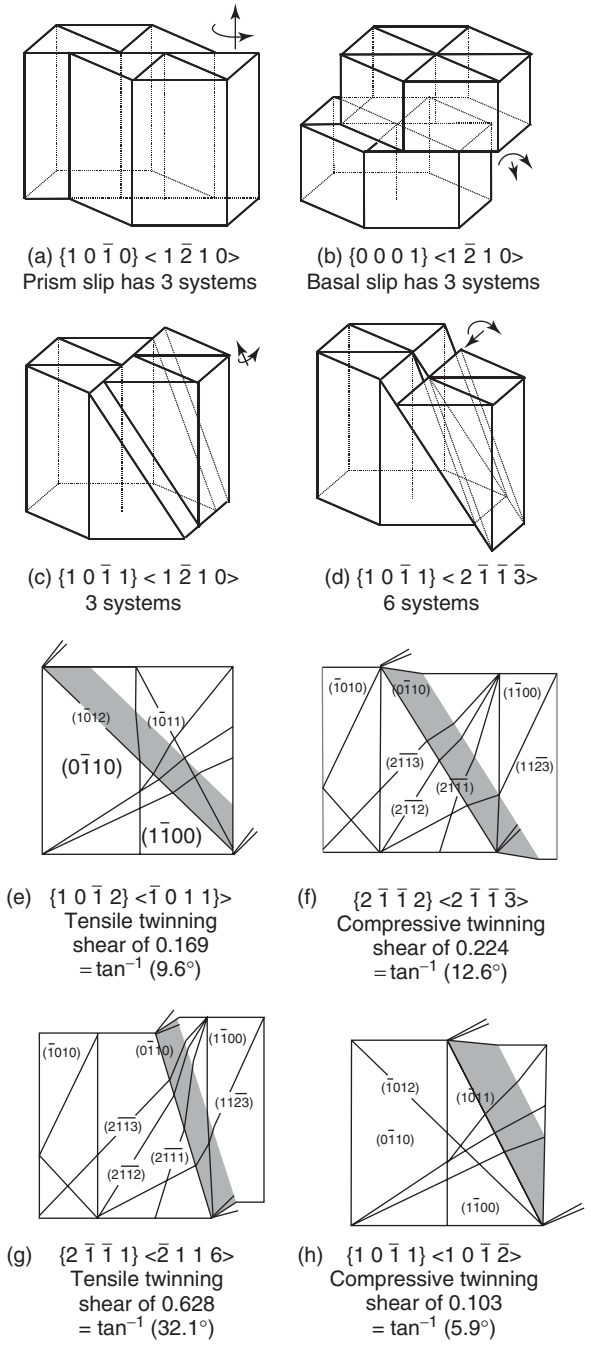

Figure 4 (a) Prism slip, (b) basal slip in the $\langle a \rangle$ direction, (c) $\langle a \rangle$ slip, (d) $\langle c+a \rangle$ slip on pyramidal planes, and (e–h) twinning systems; all types have 6 systems. Only $\langle c+a \rangle$ slip or twinning causes a change in crystal dimension in the *c* direction. Arrows illustrate axis of crystal rotation due to slip; only prism slip does not change the orientation of the *c*-axis.

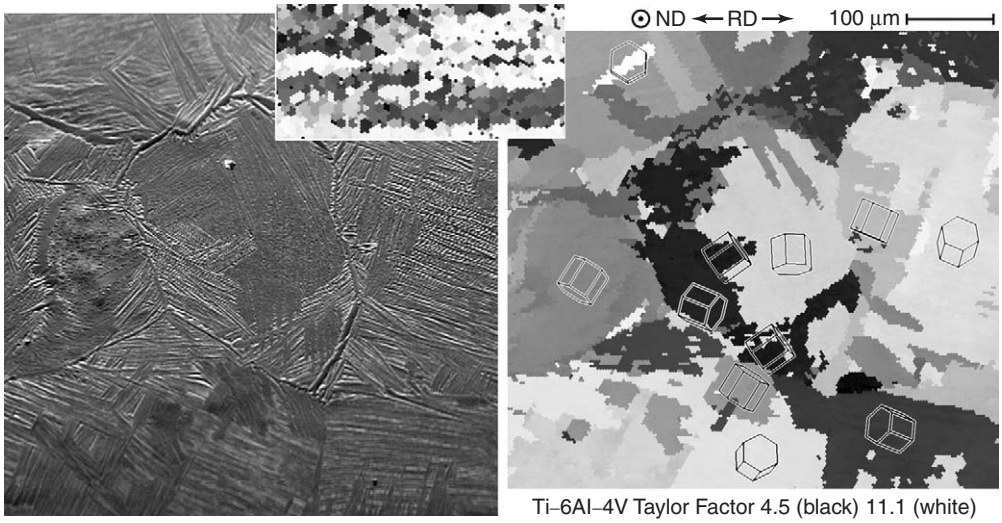

Figure 5 Rolled plate (rolling direction and plate normal are indicated) SEM and Orientation Imaging Microscopy Taylor factor maps before (inset) and after annealing above β transus, followed by controlled slow cooling. Taylor factor was computed based upon uniaxial deformation in the rolling direction with CRSS ratios of 0.7:1:3 for prism:basal:pyramidal $\langle c+a \rangle$ slip. (Images obtained at the Air Force Research Laboratory, WPAFB, OH.)

The Classification of Titanium Alloys

Titanium alloys are classified according to the phases present within their microstructure. Alloys consisting of mainly α-phase are called α-alloys, but if small amounts of β-phase are present, the alloy is classified as a near-α alloy. Alloys consisting of a mixture of both α- and β-phases are termed α–β alloys. Finally, titanium alloys that have the majority of β-phase at room temperature are called β-alloys. **Figure 6** shows the effects that several important alloying elements have on the phase diagram, indicating that the equilibrium between α, $\alpha+\beta$, and β phase fields (α and β transus lines) are highly sensitive to alloy composition. Aluminum is one of the most important alloying elements because it is a potent solid–solution strengthener and it reduces the density, so it is found in virtually all titanium alloys. Ti_3Al (α_2) forms with more than 6 wt.% Al, which can strengthen, but also embrittle the alloy. Molybdenum and vanadium are the two most popular β-stabilizing additives, which also provide strengthening of the β-phase. Tin and zirconium are the only two alloying elements used which have neither an α-stabilizing nor β-stabilizing effect on the crystal structure (**Figure 6a**), but both provide solid–solution strengthening to the α-phase; also, Sn is known to improve weldability. All other elements either stabilize the α- or β-phase, as summarized in **Table 1**.

The aluminum equivalent and molybdenum equivalent equations (in wt.%) are used to describe the degree of stability of the α- and β-phases, and to define what class an alloy is in. Oxygen and nitrogen are potent α-stabilizers, and iron is the most potent β-stabilizer:

$$Al_{equiv} = \%Al + \tfrac{1}{3}(\%Sn) + \tfrac{1}{6}(\%Zr) + 10(\%O)$$

$$Mo_{equiv} = \%Mo + 0.67(\%V) + 2.9(\%Fe) + 1.6(\%Cr) - \%Al$$

$$O_{equiv} = \%O + 2(\%N) + 0.67(\%C)$$

Commercially Pure Titanium; 99–99.5% Ti

Commercially pure (CP) titanium is considered an α-alloy, because the α-phase is the only phase present. Oxygen is the main alloying element that determines the grade and strength of the alloy (**Figures 6b** and **7**). CP titanium has lower strength than other alloys, but it is the alloy of choice for applications requiring corrosion resistance, and it has better elevated temperature creep resistance, and is less expensive than the other titanium alloys. **Figure 7** shows how the strength and hardness increase with interstitial element concentration. Since oxygen is the main alloying element in CP titanium, the O_{equiv} describes the strengthening effect of the interstitial elements O, N, and C. Each 0.1% O_{equiv} increases the strength of unalloyed titanium by $\sim$120.5 MPa.

Near α and α Titanium Alloys; $Al_{equiv} < 8$ and $Mo_{equiv} < 1$

Alpha titanium alloys are primarily used in the chemical and processes engineering industry. These applications require excellent corrosion resistance and ductility. Aluminum is the most important alloying element in order to stabilize α-phase, add

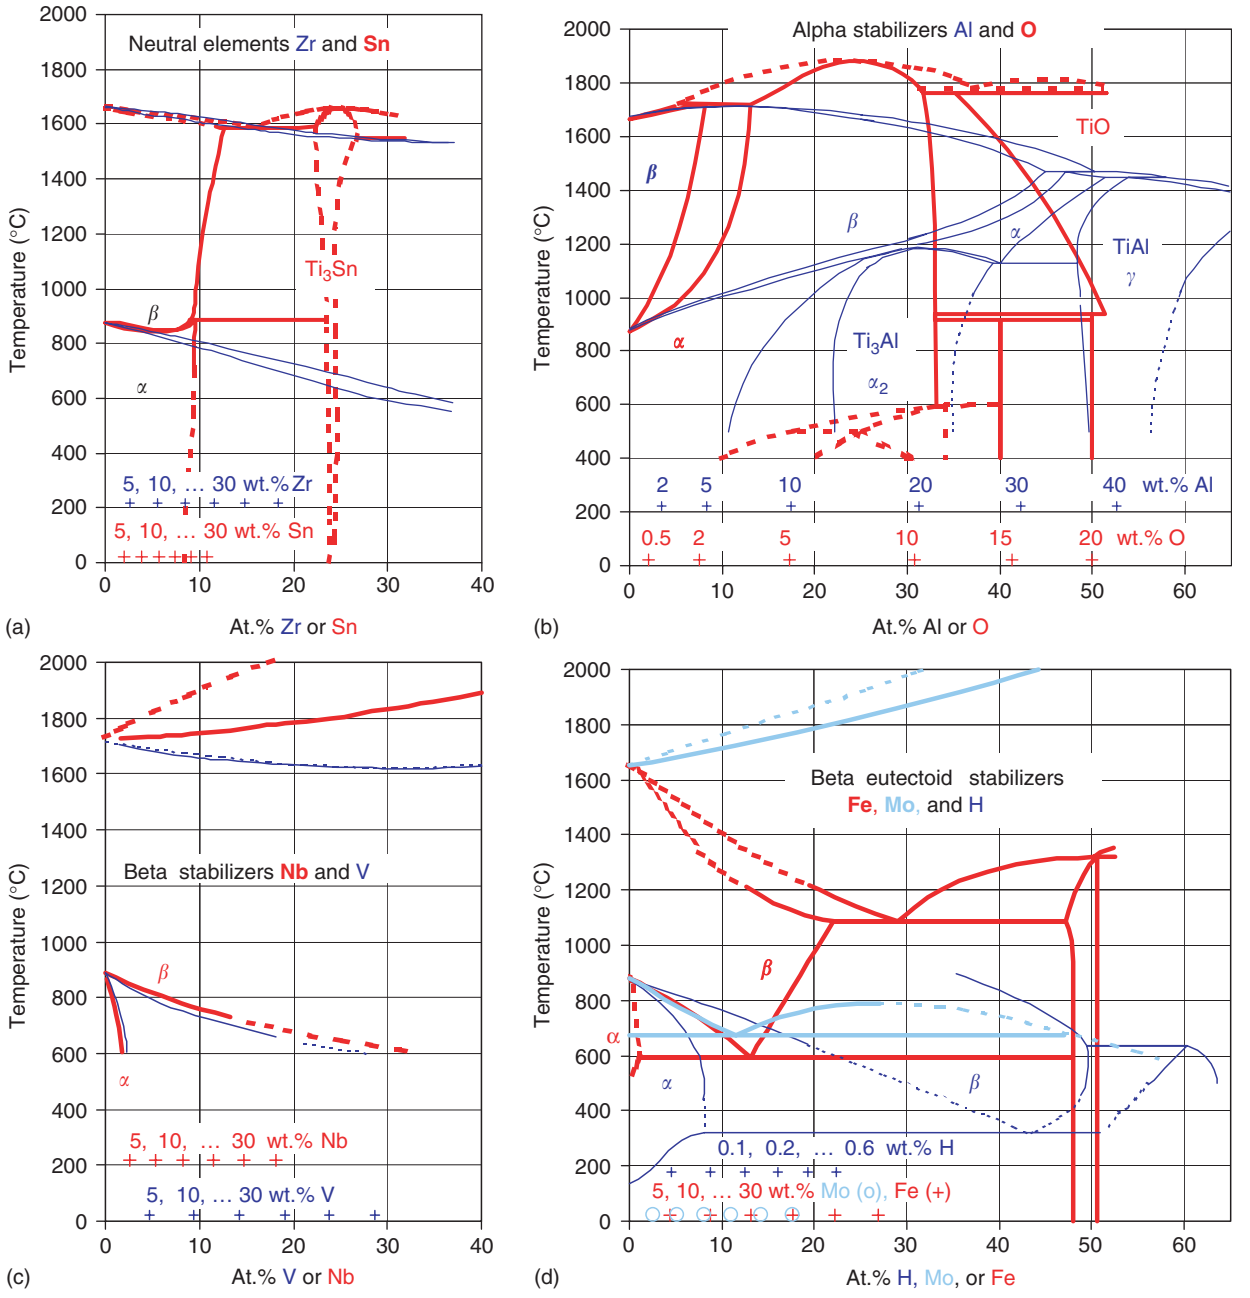

Figure 6 Exemplary phase diagrams for elements that have (a) neutral, (b) α stablizing, (c) β stabilizing, and (d) β eutectoid stablizing effects. (Adapted from Smithells Metals Reference Book, 7th edn., 1992, London: Butterworth. McCullough C, Valencia JJ, Levi CG, and Mehrabian R (1989) Phase equilibria and solidification in Ti–Al alloys. *Acta Metallurgica* 37(5): 1321–1336, for update of Ti–Al system.)

strength, and lower the density (**Figure 6b**, **Table 2**). Ti–5Al–2.5Sn is the most commonly used α alloy, and like most α alloys it cannot be age-hardened, but it does has excellent weldability.

Near-α Titanium Alloys; $6 < Al_{equiv} < 10$ and $Mo_{equiv} < 2$

Near-α alloys are ideal for high temperature applications ~500–550°C, where its excellent creep resistance can be combined with higher strength due to a small amount of dispersed β-phase. Small amounts of molybdenum and vanadium are added to retain some β-phase at room temperature. Ti–8Al–1Mo–1V is the most commonly used near-α alloy, however the high aluminum content can cause stress corrosion cracking (SCC) problems; therefore, most alloys used today are limited to 6 wt.% Al to avoid SCC problems. This alloy has good weldability, but a limited degree of hardenability due to a small amount of β-phase.

Table 1 Effects of alloying elements

Alloying element	*Range* (wt.%)	*Effect on structure and properties*
Aluminum, Al	2–7	α-Stabilizer, solid solution strengthener, reduces density, improves oxidation resistance
Carbon, C	0.05–0.1	α-Stabilizer, interstitial element
Chromium, Cr	2–12	β-Eutectoid stabilizer
Cobalt, Co		β-Eutectoid stabilizer
Copper, Cu	2–6	β-Eutectoid stabilizer, improves weldability, α and β strengthener
Hydrogen, H	0.008–0.02	β-Eutectoid stabilizer, interstitial element
Iron, Fe		β-Eutectoid stabilizer
Manganese, Mn		β-Eutectoid stabilizer
Molybdenum, Mo	2–20	β-Isomorphous stabilizer, moderate solid solution strengthener of β phase
Nickel, Ni		β-Eutectoid stabilizer
Niobium, Nb		β-Isomorphous stabilizer, known to improve oxidation behavior of Ti alloys, moderate solid solution strengthener of β phase
Nitrogen, N	0.015–0.07	α-Stabilizer, interstitial element
Oxygen, O	0.1–0.4	α-Stabilizer, interstitial element, strengthens α phase
Silicon, Si	0.05–1	β-Eutectoid stabilizer, Si atoms tend to segregate at dislocations and thus effectively prevent dislocation climb, improving creep resistance, also strengthens α phase
Tantilum, Ta		β-Isomorphous stabilizer
Tin, Sn	2–6	Neutral stabilizer, improves weldability, solid solution strengthener of α phase
Vanadium, V	2–20	β-Isomorphous stabilizer, moderate solid solution strengthener of β phase
Zirconium, Zr	2–8	Neutral stabilizer, solid solution strengthener of α phase, Zr also tends to homogenize fine silicide precipitates

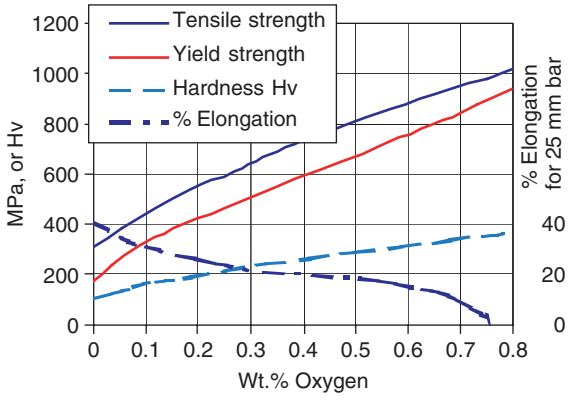

Figure 7 Effect of oxygen on strength and elongation in CP titanium. (Adapted from Jaffee RI (1958) The physical metallurgy of titanium alloys. *Progress in Metal Physics* 7:109.)

α–β Titanium Alloys; $5 < Al_{equiv} < 10$ and $2 < Mo_{equiv} < 8$

The α–β alloy Ti–6Al–4V is the most popular of all titanium alloys, representing more than 50% of the titanium market (**Figures 6b** and **6c**). The α–β alloys can be solution heat-treated, quenched, and aged to medium-/high-strength levels and have good formability, but the creep resistance and weldability are lower than the α and near-α alloys, primarily due to the presence of the β-phase, which has a much higher diffusivity and more slip systems.

β Titanium Alloys; $Al_{equiv} < 6$ and $Mo_{equiv} = 15$–30 (Metastable β), > 30 (Stable β)

The β titanium alloys are heat treatable, to achieve the highest strength levels of the five types of titanium alloys (**Figures 6c** and **6d**). The high strength arises from precipitation of very fine α-phase during an aging heat treatment. The b.c.c. crystal structure also gives good formability properties prior to heat treatment. Beta titanium alloys contain large amounts of alloying elements such as Mo, Cr, V, and Fe which are needed to stabilize the β-phase. The high degree of alloying elements makes β alloys the densest of the five alloy types (**Table 2**).

Tables 2–4 provide further details, using normal font to identify CP, italics to identify near-α and α alloys, bold italics to identify α–β alloys, and bold to identify β alloys. **Table 2** is sorted by density to illustrate the influence of alloying. **Table 5** describes weldability issues, and **Tables 3** and **4** describe heat treating methodologies, which are discussed next.

Table 4 Heat treating of α–β alloys

Heat treatment designation	*Heat treatment cycle*	*Microstructure*
Duplex anneal	Solution treat at 50–75°C below $T(\beta)$, air cool and age for 2–8 h at 540–675°C	Primary α, plus Widmanstätten α–β regions
Solution treat and age	Solution treat at ~40°C below $T(\beta)$, water quench(a) and age for 2–8 h at 535–675°C	Primary α, plus tempered α' or a β–α mixture
Beta anneal	Solution treat at ~15°C above $T(\beta)$, air cool and stabilize at 650–760°C	Widmanstätten α–β colony microstructure
Beta quench	Solution treat at ~15°C above $T(\beta)$, water quench and temper at 650–760°C for 2 h	Tempered α'
Recrystallization anneal	925°C for 4 h, cool at 50°C h^{-1} to 760°C, air cool	Equiaxed α with β at grain-boundary triple points
Mill anneal	α–β Hot work plus anneal at 705°C for 30 min to several hours and air cool	Incompletely recrystallized α with a small volume fraction of small β particles

In more heavily β-stabilized alloys such as Ti–6Al–2Sn–4Zr–6Mo or Ti–6Al–6V–2Sn, solution treatment is followed by air cooling. Subsequent aging causes precipitation of α-phase to form an α–β mixture.

Table 5 Welding of titanium alloys

Alloy type	*Condition*	*Description*
Unalloyed titanium	Annealed	Welding of cold-worked alloys anneals the HAZ and negates any strength produced by cold working
Alpha titanium alloys	Annealed	Ti–5Al–2.5Sn, Ti–6Al–2Sn–4Zr–2Mo, Ti–5Al–5Sn–2Zr–2Mo, Ti–6Al–2Nb–1Ta–1Mo, and Ti–8Al–1Mo–1V are always welded in annealed condition
Alpha–beta titanium alloys	Annealed or solution-treated and partially aged	Low weld ductility of most α–β alloys is caused by phase transformation in the weld zone or HAZ
Metastable beta titanium alloys	Annealed or solution heat treated	In as-welded condition, welds are low in strength but ductile; to obtain full strength the alloys are welded in annealed condition, the weld is cold worked by shot peening or planishing, and the weldament is then solution treated and aged
Weld type	*Thickness range*	*Description*
Gas–tungsten arc weld (GTAW)	Base metal up to 2.5 mm, for thicker base metal filler metal is required	
Gas–metal arc weld (GMAW)	More than 3 mm to greater than 13 mm	Applied using pulse current or spray mode and is less costly than GTAW
Plasma arc welding (PAW)	Plate up to 13 mm, filler metal may be used	Faster than GTAW and can be used on thicker sections
Electron-beam welding (EBW)	Plates 6 mm to more than 76 mm	Used in aircraft and aerospace industry for producing high quality welds; performed in high vacuum atmosphere therefore low contamination of weldament
Laser-beam welding (LBW)	Base metal usually cannot exceed 13 mm	
Friction welding (FRW)		Useful for joining tube, pipe, or rods
Resistance welding (RW)		Used to join titanium sheet by spot welds or continuous seam welds, also used to weld titanium sheet to dissimilar metals
Fluxes	N/A	Fluxes cannot be used because they combine with titanium to form brittleness and may reduce corrosion resistance

Heat Treating of Titanium Alloys

Titanium and titanium alloys are heat treated for a number of reasons: to reduce residual stresses from the many different fabrication processes (stress relieving), to obtain optimum combinations of ductility, machinability, and dimensional stability (annealing), to increase strength (solution treating and aging in α–β and β alloys), and finally to optimize specific properties such as fracture toughness, fatigue strength, and high-temperature creep resistance. In general, a heat treatment is used to rearrange phase–volume fractions, phase boundaries in strategic ways. A quench from high temperature is commonly used to provide a thermodynamic driving force for nanoscale rearrangement at lower aging temperatures. More recently, benefits of rapid heating into the β-phase field to obtain desirable microstructures have been described. Standard practice is identified in **Tables 3** and **4**, and the preferred phase for alloying elements is in **Table 1**. However, alloy element local concentration is highly dependent on the history of the phase volume fraction and locations of phase boundaries in space and hence, on all prior heat treating and working history. For this reason, the same heat treatment on materials with different prior history can cause considerable variability in resulting properties.

Unalloyed α titanium alloys can be stress relieved and annealed, but cannot be heat treated to increase their strength. When the heat treatment of titanium alloys involves heating to temperatures near the β transus, it is important that T_β is known for each specific alloy. **Table 3** illustrates how the β transus temperature (β_T) depends on alloy composition.

Stress Relieving

Stress relieving (SR) is used to remove residual stresses from prior fabrication steps, or even prior heat treatments. Unbalanced residual stresses can result in part distortion, and cause problems in those alloys susceptible to hydrogen embrittlement. SR can result in aging of all alloy types, α can be aged by α_2 precipitates, and if metastable β is present, α precipitation that provides strengthening can occur. For α and α–β alloys, the SR temperature will be in the range of 480–815°C, and if these alloys were β-annealed, more rearrangement of phase boundaries is needed and the SR temperature should be increased by $\sim$55°C. When stress-relieving β alloys, care must be taken to avoid interfering with the final age-hardening treatment. If a β alloy has not been heat treated, the SR temperature should be substantially below the β_T to prevent preferred α precipitation in grain boundaries (which embrittles the material). If the β alloy is in its final age-hardened condition, the SR temperature should be at or below the aging temperature to prevent strength reduction.

Annealing

Annealing is similar to SR but usually done at higher temperatures. The annealing of titanium and titanium alloys serves primarily to increase fracture toughness, room temperature ductility, dimensional stability, and high-temperature creep resistance. This is often the final heat treatment for α and α–β alloys, as it yields a good balance of properties. Care must be taken when using β alloys in the annealed condition in service temperatures up to 400°C, which could result in embrittlement, and service temperatures in the range of 400–600°C could age-harden the β alloy, resulting in a strength increase at the expense of ductility. Alpha and α–β alloys are typically annealed in the temperature range of 700–900°C, while β alloys are normally annealed in the temperature range of 690–815°C.

There are four commonly used annealing treatments, mill annealing (MA), duplex annealing (DA), recrystallization annealing (RA), and β annealing (BA). MA is a general-purpose heat treatment given to all mill products, but it is not a full anneal and the material may retain effects of prior working processes. DA is used for α and α–β alloys; it involves an initial anneal high in the α/β-phase field to generate significant fractions of both α and β with small grain/phase sizes near 10 μm, followed by an MA to provide thermal stability in the prior β regions. DA improves creep resistance and fracture toughness (resistance to crack nucleation) of the material. An RA is done at a temperature high enough in α/β-phase field to ensure recrystallization. It is then slowly cooled to form a high-volume fraction of equiaxed α with islands of retained β at triple points, and some interfacial β at α/α boundaries. RA provides high-damage tolerance properties (fracture toughness, crack growth resistance) that are crucial for fracture critical applications. Finally, BA is done at temperatures above the β_T, leading to a large grain size followed by a subsequent MA (**Figure 5** shows how a BA converted a small grain size DA microstructure into large prior β grains that were transformed into several α variants during slow cooling). For α and α–β alloys, BA maximizes the damage tolerance properties, since resistance to crack propagation is best when there are fewer grain boundaries.

Solution Treating

Solution treating (ST) is used to transform a desired amount of α- to β-phase in near α and α–β alloys, by

heating the material to a temperature near β_T and then cooling strategically to produce a higher ratio of β-phase in a desired morphology. Beta alloys are normally solution treated above the β_T (700–815°C), while α and α–β alloys are normally solution treated slightly below the β_T (850–1000°C) (**Table 3**). For most β alloys, the object of ST is to retain 100% β-phase upon quenching, so that upon subsequent aging, decomposition of the metastable β-phase occurs to generate second-phase precipitates that provide high strength.

Quenching

The rate of cooling from the ST temperature strongly affects the strength of the material. Slow cooling rates allow diffusion to occur, resulting in decomposition of the β-phase and may prevent effective strengthening during the aging process. Also the quench delay, which is the time from which the material is removed from the furnace and subsequently placed into the quenching media, can affect properties. Longer quench delays can lower strength; this reduced strength is ascribed to the formation of coarse acicular α prior to immersion in quenchant. Alpha–beta alloys are typically quenched in water, a 5% brine solution, or a caustic soda solution because the rate is sufficient to retain the β-phase obtained by ST. For highly β-stabilized alloys and small sections, an air or fan cooling may be adequate.

Aging

Aging is the final heat treatment step needed in order to achieve high-strength levels. Aging causes the decomposition of the supersaturated β-phase retained upon quenching, through α-precipitation within the β-matrix. Martensites also decompose in a manner that sharpens interfaces or boundaries that provide strengthening. The aging temperature controls the size and volume fraction of the α-precipitates, and determines the final strength of the material. Aging at or near the annealing temperature results in overaging, which is desirable if good toughness and dimensional stability are needed with only a modest increase in strength. For α and α–β alloys, aging is usually done in the temperature range of 480–605°C, and β alloys are typically aged in the temperature range of 425–595°C.

Suggested heat treatments for various titanium alloys are listed in **Tables 3** and **4**. It is also important to note that not all heat treatments are applicable to all titanium alloys, because some alloys are designed for specific purposes, for example, Ti–5Al–2Sn–2Zr–4Mo–4Cr (Ti-17) and Ti–6Al–2Sn–4Zr–6Mo are designed for strength in heavy sections, Ti–5Al–2.5Sn and Ti–2.5Cu, for weldability, Ti–6Al–2Sn–4Zr–2Mo and Ti–6Al–5Zr–0.5Mo–0.2Si, for creep resistance.

Welding of Titanium Alloys

Table 5 provides relevant details for welding titanium alloys. Unalloyed titanium and α alloys are weldable. These alloys are typically welded in the annealed condition, and have good weldability because they are insensitive to heat treatments. Alpha–beta alloys and weakly β-stabilized alloys are also weldable, but should be welded in the annealed or solution-treated conditions prior to aging heat treatments. Most β alloys can be welded in annealed or solution-treated condition, but subsequent aging can cause the weld to become brittle. Most strongly β-stabilized alloys are embrittled by welding, since it is not possible to quench a weld (without quenching, second phases precipitate preferentially on grain boundaries).

Challenging and Problematic Issues with Titanium Alloys

Although titanium alloys have many desirable characteristics, they have problematic areas as well. These include their affinity to oxygen, hydrogen pickup, susceptibility to certain types of chemical attack, and damage generation arising from the elastic and plastic anisotropy of the hexagonal crystal structure.

Heat treating can cause contamination due to oxidation that causes an oxygen-rich brittle layer on the metal surface called "α case." Unless surface hardening is needed for wear resistance, this α case must be mechanically or chemically removed before the part can be put into service. Another concern is embrittlement due to very low levels of hydrogen, nitrogen, and carbon absorption at virtually every fabrication stage from casting to heat treating. Due to its great affinity to oxygen, alumina (Al_2O_3) cannot be used to machine titanium alloys, so WC tools (typically C-2 grades) are used for turning and face milling, while high-carbide, high-speed steels are appropriate for drilling, tapping, and end milling.

Though CP titanium is highly corrosion resistant, SCC is more likely with increasing alloy content, and in environments with red fuming nitric acid, N_2O_4, HF, methonal, HCl, and seawater. The susceptibility depends greatly on alloy elements, crystal orientation and misorientations at grain boundaries, and the details of microstructural evolution.

Due to its hexagonal crystal structure, slip in the $\langle a \rangle$ direction is much more facile than other

directions, so heterogeneous deformation and shear banding is common. Combinations of working and heat treatment can generate highly preferred crystal orientations, so between the coherent phase boundaries with transformation shears, and the anisotropy of the thermal expansion coefficient (which is 20% higher in the $\langle c \rangle$ than $\langle a \rangle$ directions) substantial residual stresses are common even after a stress relief anneal. Though titanium alloys can be processed for excellent high-temperature creep resistance, room-temperature creep occurs in some microstructures and alloys, and hence dimensional stability can be a problem. To fully optimize material property design for particular applications, control of texture and microstructure with innovative processing strategies requires predictive understanding of the rules for variant selection during the $\alpha \rightarrow \beta \rightarrow \alpha$ transformations, which are not yet well established.

Ballistic Transport

M Dragoman, National Institute for Research and Development in Microtechnology (IMT), Bucharest, Romania
D Dragoman, University of Bucharest, Bucharest, Romania

Introduction

The transport of charged carriers depends greatly on the scale of the sample. At the macroscopic scale, in bulk semiconductors with dimensions larger than 1 mm, conduction electrons move randomly due to the high scattering rates with impurities and phonons. An applied electric field induces a diffusive electron transport described by the stochastic Boltzmann equation. At the microscopic scale of atoms and molecules, which is of the order of $\text{Å} = 10^{-10}$ m, the particles evolve according to the laws of atomic and molecular physics. At the intermediate, mesoscopic scale, distinct features in the particle transport appear, which include the emergence of the ballistic transport regime characterized by the coherent, wavelike behavior of charged particles over length scales much larger than the dimension of molecules and much smaller than macroscopic dimensions. Ballistic transport is defined as the collisionless transport regime, valid when the dimensions of the sample are smaller than the mean free path L_{fp} and the phase relaxation length L_{ph}. The mean free path is a measure of the distance between successive electron collisions with impurities or phonons that destroy the initial electron momentum. L_{fp} is about tens of nanometers in polycrystalline metallic films and about tens of micrometers in high-mobility semiconductors at low temperatures ($T < 4$ K); the latter materials are thus more likely to exhibit ballistic transport. The phase relaxation length is the distance after which the coherence (the phase memory) of electrons is lost. Phase memory is lost in time-reversal breaking processes such as electron–electron collisions, dynamic scattering processes, or scattering by impurities with internal degrees of freedom (spin) that change in the process; any static spin-independent scattering does not affect phase relaxation. L_{ph} is of the same order of magnitude as L_{fp} in high-mobility semiconductors.

Experimental conditions for ballistic transport observation have become achievable only in the last decades due to impressive developments in semiconductor technology, especially in advanced epitaxial growth and lithography techniques. It has thus become possible to fabricate band-engineered semiconductor heterostructures called quantum wells, quantum wires, and quantum dots that confine, respectively, the electron motion in one, two, and three dimensions. The electron density in such structures can be controlled through electric potentials applied on surface gates. Coherent propagation of electron waves, electron tunneling, and Coulomb blockade are examples of specific phenomena associated with ballistic transport. These phenomena have found hosts of applications in the design of new devices such as resonant tunneling devices and the single-electron transistor, the ballistic transport regime being indispensable for high-frequency electronic and optoelectronic devices. Not only electrons but also holes and even quasiparticles, such as phonons, experience ballistic transport regime under the same conditions as those defined above, but with the corresponding mean free path and phase relaxation length parameters.

Energy Subbands and Density of States in Ballistic Transport

Ballistic transport occurs when, at most, only a few elastic scattering processes take place, such that electron motion is characterized in this regime by a constant energy E, and can be described by a time-independent Schrödinger equation for the envelope electron wave function Ψ, which varies slowly over the dimensions of the unit cell:

$$-\frac{\hbar^2}{2}\{m^{\alpha}\nabla[m^{\beta}\nabla(m^{\alpha}\Psi)]\} + V\Psi = E\Psi$$

where α and β are material-related parameters for which $2\alpha + \beta = -1$, m is the electron effective mass that incorporates the effect of the periodic lattice

potential on electron motion, and V is the potential energy. This scalar equation is valid when coupling between different electron bands is negligible. Ballistic transport has been mainly evidenced in AlGaAs semiconductor compounds for which $\alpha = 0$ and $\beta = -1$. The potential energy V includes the conduction band discontinuities in heterojunctions (which is the dominant component in the low doping and the low free carriers case), the electrostatic potential due to ionized donors and acceptors (which is determined from a self-consistent solution of the coupled Schrödinger and Poisson equations), and the self-consistent Hartree and exchange potentials due to free carriers.

The solution of the Schrödinger equation requires proper boundary conditions. The constraints on electron motion present in any ballistic structure impose the appearance of discrete energy levels along the direction of the constraint and a resulting discontinuity in the density of states. For example, in a quantum well the conduction electrons are free to move along the x and y directions, and are confined by potential barriers along z in a region of width L_z. For abrupt infinite-height barriers, the electron wave function $\Psi(x,y,z) = \sqrt{2/L_z}\sin(k_z z)\sqrt{1/L_x L_y}\exp(\mathrm{i}k_x x)\exp(\mathrm{i}k_y y)$, obtained from the Schrödinger equation for $V = 0$, with L_x and L_y the sample dimensions along x and y, must satisfy the boundary conditions $\Psi(x,y,0) = \Psi(x,y,L_z) = 0$. These induce a discrete spectrum $k_z = p\pi/L_z$ for the momentum component along z, with p an integer, and an energy dispersion relation of the form

$$E(k_x,k_y,k_z) = E_c + \frac{\hbar^2}{2m}\left(\frac{p\pi}{L_z}\right)^2 + \frac{\hbar^2}{2m}(k_x^2+k_y^2) = E_{s,p} + \frac{\hbar^2}{2m}(k_x^2+k_y^2)$$

where E_c denotes the bottom of the conduction band and $E_{s,p}$ is the cut-off energy of the subband or transverse mode labeled by p. The energy spacing between discrete p levels increases as L_z decreases, that is, as electrons become more confined. Although periodic boundary conditions imposed on x and y also require the quantization of k_x, k_y according to $k_x = q(2\pi/L_x)$, $k_y = r(2\pi/L_y)$, with q and r integer values, the energy spectrum remains quasicontinuous in the $k_x - k_y$ plane, since $L_x, L_y \gg L_z$. The quantization of the wave vector components along x and y mainly influences the density of states by assigning to an individual state an area $(2\pi/L_x)\times(2\pi/L_y)$ in the $k_x - k_y$ plane. Then, the total number of spin-degenerate states with a wave number less than k (or with an energy less than E, for $E > E_{s,p}$), which occupy in the $k_x - k_y$ plane an area $\pi k^2 = \pi(k_x^2 + k_y^2)$, is $N_{tot}(k) = k^2(L_x L_y)/2\pi$ (or $N_{tot}(E) = m(L_x L_y)(E - E_{s,p})/\pi\hbar^2$). The density of states per unit area $S = L_x L_y$, and per unit energy in the pth subband is thus

$$\rho_{2D,p}(E) = \frac{1}{S}\frac{\mathrm{d}N_{tot}(E)}{\mathrm{d}E} = \frac{m}{\pi\hbar^2}\,\vartheta(E - E_{s,p})$$

with ϑ the unit step function, the total density of states $\rho_{2D}(E) = \sum_p \rho_{2D,p}$ represented in **Figure 1a** being discontinuous, unlike in bulk semiconductors where no size constriction is imposed upon the electron motion.

The equilibrium electron density per unit area is given by

$$n = \int_0^\infty \sum_p \rho_{2D,p}(E) f(E)\mathrm{d}E = k_B T\frac{m}{\pi\hbar^2}\sum_p \ln[1 + \mathrm{e}^{(E_F - E_{s,p})/k_B T)}]$$

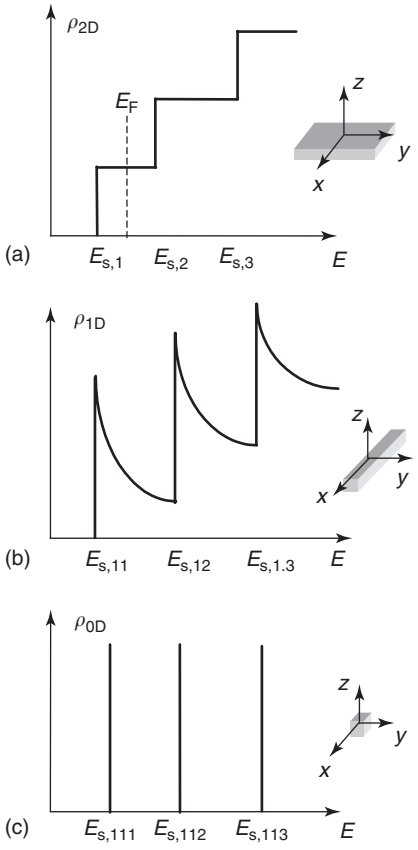

Figure 1 Density of states in (a) quantum wells, (b) quantum wires, and (c) quantum dots. The Fermi energy position in (a) corresponds to 2DEG systems.

the energy levels being occupied by electrons according to the Fermi–Dirac distribution function

$$f(E) = \frac{1}{1 + \exp[(E - E_F)/k_B T]}$$

At low temperatures or in the degenerate limit, when $k_B T \ll E_F$, the Fermi–Dirac distribution function becomes proportional to $\vartheta(E_F - E)$, and all electron subbands are filled up to the Fermi energy and are empty above it. In this case, all electrons that participate in transport have energies close to E_F, unlike in the diffusive transport regime in which electrons have a widespread energy distribution. The number of subbands $M(E)$ occupied at low temperatures by electrons with energy E is obtained by counting the number of transverse modes with cutoff energies smaller than E.

In a similar manner, if the electron motion is constrained by infinite-height potentials along two directions, y and z, the boundary conditions imposed on the electron wave function $\Psi(x, y, z) = 2/\sqrt{L_y L_z}\,\sin(k_y L_y)\sin(k_z L_z)\sqrt{1/L_x}\,\exp(\mathrm{i}k_x x)$ require that $k_y = p\pi/L_y$, $k_z = q\pi/L_z$, with p, q integers. In such a one-dimensional ballistic quantum wire, the electrons are free to move only along x, the energy dispersion relation being

$$E(k_x, k_y, k_z) = E_c + \frac{\hbar^2}{2m}\left(\frac{p\pi}{L_y}\right)^2 + \frac{\hbar^2}{2m}\left(\frac{q\pi}{L_z}\right)^2 + \frac{\hbar^2 k_x^2}{2m} = E_{s,pq} + \frac{\hbar^2 k_x^2}{2m}$$

The total number of states with a wave vector component along x less than k_x, which occupy an "area" in the k_x plane equal to $2k_x$, is now $N_{tot}(k_x) = 2 \times 2k_x/(2\pi/L_x)$, where the first factor 2 accounts for spin degeneracy. The density of states in the k_x plane per unit length, $\rho_{1D}(k_x) = L_x^{-1}\mathrm{d}N_{tot}/\mathrm{d}k_x$, is constant and equal to $2/\pi$, half of this value representing the contribution of states for which k_x is positive, and half representing the contribution of states with negative k_x values. $\rho_{1D}(k_x)$ corresponds to a total energy-dependent density of states $\rho_{1D}(E_c) = (1/\pi)(2m/\hbar^2)^{1/2}\sum_{p,q}(E - E_{s,pq})^{-1/2}$, which is represented in **Figure 1b**.

In quantum dots the electron motion is confined along all directions, and the energy spectrum

$$E(k_x, k_y, k_z) = E_c + \frac{\hbar^2}{2m}\left(\frac{p\pi}{L_x}\right)^2 + \frac{\hbar^2}{2m}\left(\frac{q\pi}{L_y}\right)^2 + \frac{\hbar^2}{2m}\left(\frac{r\pi}{L_z}\right)^2 = E_{s,pqr}$$

is discrete, as in atoms or molecules. Quantum dots, with density of states $\rho_{0D} \propto \delta(E - E_{s,pqr})$ (see **Figure 1c**), can thus be considered as artificial atoms.

Two-Dimensional Electron Gas

If, as in **Figure 1a**, the position of the Fermi level in a quantum well is between the first and the second energy subband, the electron density per unit area, $n = (m/\pi\hbar^2)(E_F - E_{s,1})$, is related to the Fermi wave number k_F through $k_F = \sqrt{2\pi n}$. The Fermi wave number is determined by the kinetic energy of electrons: $E_{kin} = E_F - E_{s,1} = \hbar^2 k_F^2/2m$. The electrons form, in this case, a two-dimensional electron gas (2DEG), which has a metallic behavior since E_F is inside the conduction band.

Two-dimensional electron gas systems form, for example, at the interface between intrinsic GaAs and n-doped AlGaAs layers in modulation-doped GaAs/AlGaAs heterojunctions, the spatial separation of dopant atoms in AlGaAs from the free electrons that form an inversion layer on the GaAs side of the interface assuring extremely low scattering rates. The electron density in this 2DEG can be changed by modifying the electron kinetic energy via negative electrostatic voltages applied on Schottky surface gates situated in close proximity to the 2DEG; the bias depletes the 2DEG underneath the gate, and laterally from the geometric edge of the gate until no free electrons are left, a case in which a barrier for electrons is created. The coherence of the electron wave function in ballistic structures together with the possibility of manipulating the electron wave number allows the implementation of electron counterparts of both geometrical optical systems and interference devices. **Figures 2a–2d** show an electron prism, a refractive lens, an electron beam splitter, and an interferometer, respectively. As in the classical electromagnetic theory, the refraction at an interface between two 2DEG systems with electron densities n_1 and n_2 occurs according to Snell's law for ballistic electrons: $\sin\theta_1/\sin\theta_2 = (n_2/n_1)^{1/2}$, with θ_i the angle in region i with the normal to the interface. The electron wave function is partly reflected and partly transmitted at the interface. Narrow constrictions in the 2DEG created by the black depletion gates in **Figure 2** act as electron sources with a wide angular spectrum, the gray electrodes in **Figure 2** representing partially depleting gates that refract electron waves.

The analogy between electron propagation in ballistic conductors and electromagnetic wave propagation is based on the formal analogy between the time-independent Schrödinger equation for the electron wave function and the Helmholtz equation

$$\nabla^2 F + k^2 F = 0$$

satisfied by the electromagnetic field component F (electric field, magnetic field, or vector potential).

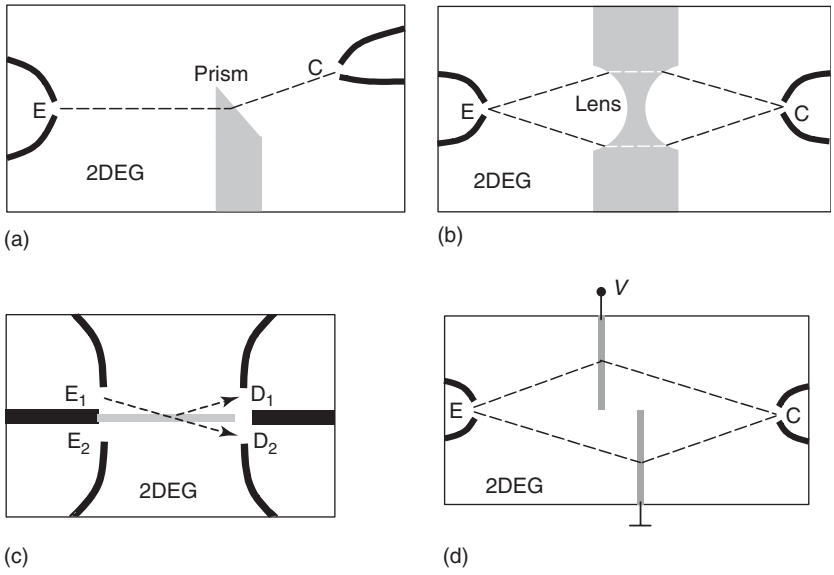

Figure 2 Schematic representation of (a) an electron prism, (b) a refractive electron lens, (c) a beam splitter, and (d) an interferometer. The electrons are emitted from the narrow orifice E and are collected by the collector C. Dashed lines represent electron trajectories.

The vectorial character of the latter implies that the eventual quantitative analogies between electron and light parameters (energy, effective mass, potential energy and frequency, electric permittivity, magnetic permeability, respectively) depend on which electromagnetic field component is compared to the scalar electron wave function. Different sets of analogous parameters between the electron wave function and the electromagnetic field are derived if, besides the evident similarity between the equation satisfied by $m^{\alpha}\Psi$ and $\boldsymbol{F}$ if k is replaced by $[2m(E-V)]^{1/2}/\hbar$, additional different boundary conditions for different field components $\boldsymbol{F}$ are considered.

Resistance of a Ballistic Conductor

A net electron transfer across a ballistic conductor sandwiched between two contacts that act as electron reservoirs is possible, when an external bias V is applied between the contacts. The bias drives the electron system in the ballistic conductor away from equilibrium such that no common Fermi energy exists; instead, one can define a spatially varying local quasi-Fermi level that takes the values E_{Fl} and E_{Fr} in the left and right contacts, respectively. The net current can then be easily calculated if the contacts are reflectionless, that is, if the electrons can enter them from the conductor without suffering reflections. If $E_{\mathrm{Fl}} > E_{\mathrm{Fr}}$, such that for a small applied bias $E_{\mathrm{Fl}} - E_{\mathrm{Fr}} = eV$, only electrons that flow from filled states on the left to empty states on the right contribute to the net current. At zero temperature, there is current flow only in the electron energy range $E_{\mathrm{Fr}} < E < E_{\mathrm{Fl}}$, the contribution to the current of electrons in each occupied subband being additive if the ballistic conductor has a constant cross section; in this case, there is no scattering of electrons from one subband (transverse mode) to another. The net current flow in one subband due to the extra density of electrons in the left contact, $\delta n = (\mathrm{d}n/\mathrm{d}E)eV$, is $I = ev\delta n$, where $v = \hbar^{-1}(\mathrm{d}E/\mathrm{d}k)$ is the electron velocity along the current flow direction. Then $I = (e^2/\hbar)V(\mathrm{d}n/\mathrm{d}E)(\mathrm{d}E/\mathrm{d}k)$, or $I = (2e^2/h)V$ for a one-dimensional conductor for which $\mathrm{d}n = N_{\mathrm{tot}}(k)(\mathrm{d}k/\mathrm{d}E)\mathrm{d}E$, with $N_{\mathrm{tot}}(k) = 1/\pi$ for electrons flowing in the direction of the applied bias. The total current can be expressed as $I = (2e^2/h)MV$, if the number of transverse modes $M(E)$ is constant over the energy range $E_{\mathrm{Fr}} < E < E_{\mathrm{Fl}}$, the ballistic conductor having a conductance $G_{\mathrm{c}} = I/V = 2e^2M/h$ or, equivalently, a resistance

$$R_{\mathrm{c}} = 1/G_{\mathrm{c}} = \frac{h}{2e^2M} \cong \frac{12.9\,\mathrm{k\Omega}}{M}$$

In the collisionless propagating regime, the resistance can only be caused by the mismatch between the finite number of transverse modes that are allowed to propagate in the ballistic conductor and the infinite number of transverse modes carried by contacts. The resistance is called contact resistance because this mismatch appears at the conductor/contact interface. R_{c} decreases with the number of transverse modes (energy subbands) in the ballistic conductor.

Unlike the conductance $G = \sigma S/L$ in bulk materials, where σ is the conductivity of the material, L the

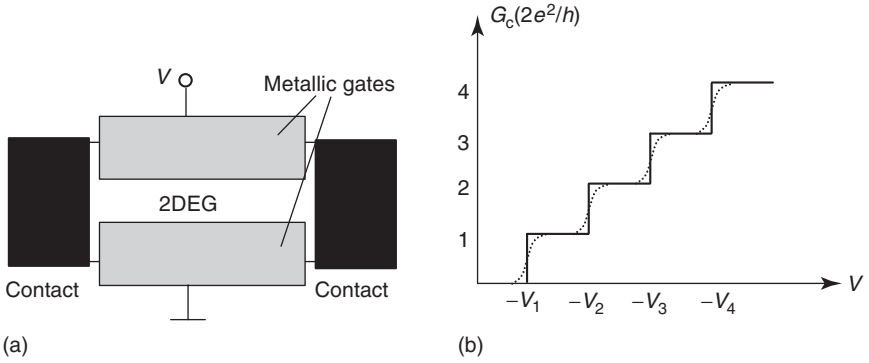

Figure 3 (a) Constriction with variable width in a 2DEG and (b) the conductance dependence on the gate voltage at zero temperature (solid line) and finite temperatures (dotted line).

length of the sample, and S its cross section, the conductance of ballistic structures does not depend on the length of the conductor. (Note that an unjustified extension of the domain of validity of the conductance formula in bulk materials would imply that in ballistic conductors, G becomes extremely large as L decreases.) In ballistic conductors, G_c depends however on S (the width of the one-dimensional conductor), since the number of transverse modes occupied by electrons propagating with the Fermi wave number can be estimated from $M = \mathrm{Int}[k_F S/\pi]$, where Int denotes the integer value. This dependence can be evidenced by measuring G_c of a ballistic conductor delimited from a 2DEG by a pair of metallic gates (**Figure 3a**), the conductor width depending on the negative voltage $-V_M$ applied on the gates. A step-like increase of the conductance with $2e^2/h$, as shown in **Figure 3b**, is observed at low temperatures and/or for confined electrons with large spacings between the energy levels each time M increases by one. This discontinuity is otherwise "smoothed" by a thermal motion.

Landauer Formula

The formula derived above for the conductance of ballistic structures assumed implicitly that electrons injected by the left contact are transmitted with unit probability to the right contact. This is not always the case. In particular, a partial (nonunity) transmission of electrons from one contact to the other occurs if the ballistic conductor is composed of several parts that differ in their width or potential energy. The conductance, in this case, can be easily calculated if the conductor with a transmission probability T is connected to two large reflectionless contacts by ballistic leads each of which have M transverse modes. In the model presented in **Figure 4**, T is the average probability that an electron injected in lead 1 is transmitted to lead 2, the conductance measured between the contacts at zero-temperature being given by the Landauer formula

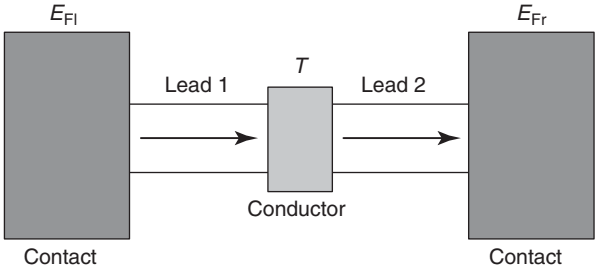

Figure 4 Model of a ballistic conductor with transmission probability T between the contacts.

$$G = \frac{2e^2}{h} MT$$

This expression can be viewed as a mesoscopic version of the Einstein relation $\sigma = e^2 \rho D$, if the conductivity σ is replaced by G, the density of states ρ is replaced by M, and the diffusion constant D is replaced by T. The total resistance $R = h/(2e^2MT)$ measured between the contacts is the sum between the contact resistance $R_c = h/(2e^2M)$ and the resistance of the "scatterer" element with transmission T, $R_s = h(1-T)/(2e^2MT)$, that would be measured between the two leads.

This identification allows the calculation of the resistance of multiple scatterers with transmission probabilities T_i connected in series as $R_s = \sum_i R_{si}$, with $R_{si} = h(1-T_i)/(2e^2MT_i)$, or the calculation of the total transmission probability as $(1-T)/T = \sum_i (1-T_i)/T_i$. This addition law, which can alternatively be obtained by adding the contribution of successive partial transmitted waves, is an expression of the coherent nature of the electron wave function in ballistic conductors.

At finite temperatures, when the Fermi–Dirac distribution is no longer step-like, electron transport through multiple energy channels takes place in the energy range $E_{Fr} - \Delta E < E < E_{Fl} + \Delta E$, where ΔE is of the order of a few $k_B T$. Since both the number of transverse modes M and the transmission probability T generally depend on E, the net current flow between the left and right contacts in the absence of inelastic scattering is

$$I = \frac{2e}{h} \int M(E) T(E) [f_l(E) - f_r(E)] \mathrm{d}E$$

where $f_l(E)$ and $f_r(E)$ are the Fermi–Dirac quasi-distribution functions in the left and right contacts.

Büttiker Formula

The expression for the net current flow or for the conductance of a ballistic structure can be generalized to account for the existence of several contacts or terminals. This is the case, for example, of four-terminal measurements (see **Figure 5**), where two additional terminals are used to measure the voltage drop along a conductor besides the two terminals through which the current flows. Modeling the additional floating or zero-external current terminals as scatterers characterized by transmission probabilities, the current through the pth terminal at zero-temperature is determined by the Büttiker formula

$$I_p = \frac{2e^2}{h} \sum_q [\bar{T}_{qp} V_p - \bar{T}_{pq} V_q] = \sum_q [G_{qp} V_p - G_{pq} V_q]$$

where $G_{pq} = (2e^2/h)\bar{T}_{pq}$ is the conductance associated to the electron transfer from terminal q with a quasi-Fermi energy level $E_{Fq} = eV_q$ to terminal p with a quasi-Fermi energy level $E_{Fp} = eV_p$. $\bar{T}_{pq}$ is, in general, the product between the number of modes M and the transmission probability per mode T_{pq} at the Fermi energy. The requirement that the net current flow is zero at equilibrium implies that $\sum_q G_{qp} = \sum_q G_{pq}$.

At finite temperatures, the net current flow through the pth terminal is given by

$$I_p = \frac{2e}{h} \int \sum_q [\bar{T}_{qp}(E) f_p(E) - \bar{T}_{pq}(E) f_q(E)] \mathrm{d}E$$

Transmission Probability Calculation

Ballistic electron transport is determined by the transmission probability between the leads that connect the conductor to several contacts. There are many methods to calculate the transmission probability: the scattering matrix formalism, the Green's function approach, the Kubo formalism, or the transfer Hamiltonian formalism. The most widespread for its ease of application is the matrix formalism which, in its simplest case, relies on approximating the spatially varying potential profile, electron effective mass, and/or dimensions of the conductor as a succession of regions in which this variation is step-like.

The application of the matrix method to ballistic conductors with a constant cross section is simplified by the absence of electron scattering from one transverse mode to another. Then, for a one-dimensional conductor composed of several regions with different but constant potential and electron effective mass, the solution of the Schrödinger equation in the ith region, $\Psi_i(x) = A_i \exp(\mathrm{i}k_i x) + B_i \exp(-\mathrm{i}k_i x)$, can be expressed as a superposition of forward- and backward-propagating waves in the x direction with wave number $k_i = \hbar^{-1}\sqrt{2m_i(E - V_i)}$ (see **Figure 6**). Inside each layer the wave function and its x-derivative must be continuous, whereas boundary conditions impose the continuity of the wave function and $\nabla\Psi \cdot \hat{x}/m^{\alpha+1}$ at the interface between two

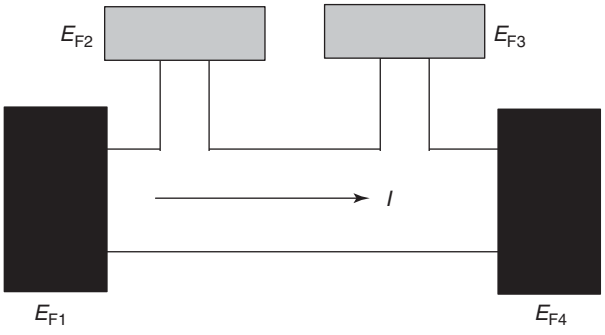

Figure 5 Four-terminal configuration: the current flows between the first and the fourth terminal, the second and third being used to measure the voltage drop along the conductor.

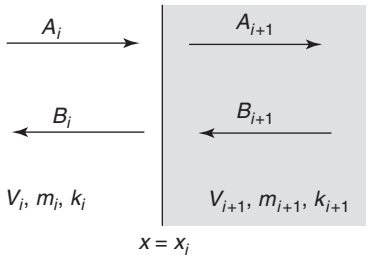

Figure 6 Electron wave function forward- and backward-propagating components at an interface between layers i and $i + 1$ with different characteristics.

layers, where $\hat{x}$ is the unit vector (the versor) along the x direction.

The matrix that expresses the electron wave function form at different x values depends on which parameters are related. For example, when $\alpha = 0$, a transfer matrix at the interface between the layers i and $i+1$ situated at $x = x_i$ can be defined as

$$\begin{pmatrix} A_i \exp(\mathrm{i}k_i x_i) \\ B_i \exp(-\mathrm{i}k_i x_i) \end{pmatrix} = \frac{1}{2}\begin{pmatrix} (1+v_{i+1}/v_i) & (1-v_{i+1}/v_i) \\ (1-v_{i+1}/v_i) & (1+v_{i+1}/v_i) \end{pmatrix} \times \begin{pmatrix} A_{i+1} \exp(\mathrm{i}k_{i+1} x_i) \\ B_{i+1} \exp(-\mathrm{i}k_{i+1} x_i) \end{pmatrix}$$

where $v_i = \hbar k_i / m_i$ is the electron velocity in the ith layer, whereas at free propagation across the ith layer, between planes $x = x_{i-1}$ and $x = x_i$ the transfer matrix is diagonal, with elements $\exp[\mathrm{i}k_i(x_i - x_{i-1})]$ and $\exp[-\mathrm{i}k_i(x_i - x_{i-1})]$. The total transfer matrix with elements M_{pq}, $p, q = 1, 2$ is obtained by multiplying the corresponding matrices at each interface and across each layer, and the transmission probability across the whole structure, from the first to the last, Nth layer is $T = v_N |A_N|^2 / (v_1 |A_1|^2) = v_N / (v_1 |M_{11}|^2)$.

The matrix that relates the outgoing field amplitudes $B_i \exp(-\mathrm{i}k_i x_i)$, $A_{i+1} \exp(\mathrm{i}k_{i+1} x_i)$ to the incoming field amplitudes $A_i \exp(\mathrm{i}k_i x_i)$, $B_{i+1} \exp(-\mathrm{i}k_{i+1} x_i)$ on either side of an interface is called the scattering matrix. For free propagation across the ith layer the scattering matrix is antidiagonal, with elements $\exp[-\mathrm{i}k_i(x_i - x_{i-1})]$ and $\exp[\mathrm{i}k_i(x_i - x_{i-1})]$. In terms of the scattering matrix elements S_{pq}, $p, q = 1, 2$ of a succession of N regions, the total transmission probability can be expressed as $T = v_N |S_{21}|^2 / v_1$. In general, the elements of the scattering matrix are $S_{11} = r$, $S_{12} = t'$, $S_{21} = t$, $S_{22} = r'$, with r, t, r', t' the reflection and transmission amplitudes of the structure from left to right and right to left, respectively.

For a ballistic conductor with a variable cross section, there is scattering between transverse modes, which is not caused by collisions but by the transverse mode matching imposed by the electron wave function continuity. The difference from the former case is that not only do the electron wave numbers k_i in the adjacent regions differ, but so do the number of transverse modes M_i. More precisely, the electron wave function propagating along x has in the ith layer the expression $\Psi_i(x, y, z) = \sum_{k=1}^{M_i} [A_{ik} \exp(\mathrm{i}k_i x) + B_{ik} \exp(-\mathrm{i}k_i x)] \phi_{ik}(y, z)$, where $\phi_{ik}(y, z)$ is the transverse part of the kth mode in the ith layer. The transmission probability has a more complicated expression, but is also obtained by imposing the boundary conditions at each interface between different layers.

Electron Tunneling

The matrix formulation is valid for either real or imaginary values of the wave numbers k_i. An imaginary wave number in at least one region i implies that the electron energy is smaller than the potential energy value in this region, so that electrons are forbidden to enter the ith region from a classical point of view. Such a region acts as a barrier for electron propagation. The propagation of ballistic electrons in regions with imaginary wave numbers can be paralleled with an evanescent propagation of electromagnetic waves. As for evanescent electromagnetic waves, the electron wave function decays exponentially inside the region with imaginary k_i and therefore, the transmission probability through this region vanishes unless its dimension along the propagation direction is smaller than the distance over which the electron wave function decays to zero. Thus, the transmission probability can still be significant for thin barriers; electrons can pass through classically forbidden regions, a phenomenon known as electron tunneling. Tunneling can also occur through a succession of barriers for electrons separated by quantum wells, that is, by regions with real wave numbers. In ballistic structures, quantum tunneling is a coherent phenomenon and thus generates, in this case, constructive or destructive interference between partially reflected and transmitted waves. Then, resonances, which correspond to high-transmission probability values, can appear similarly to the occurrence of high intensity values in light diffraction due to interference between coherent light beams.

Coulomb Blockade

In quantum dots, more than in any other confined structure, a Coulomb interaction between tightly confined electrons leads to a high sensitivity of electronic states on the number of particles in the dot and to the appearance of specific phenomena such as the Coulomb blockade, which reflect the discrete nature of the electron charge. A Coulomb blockade has been observed in semiconductor quantum dots and small metallic clusters coupled to metallic leads through tunneling barriers. It consists in the opening of a gap in the energy spectrum at the Fermi energy when an electron is transferred at low temperatures from the reservoir into the dot or cluster (generically, island). This gap, caused by charge rearrangement and observed when the associated potential change is greater than the thermal energy $k_B T$, leads to the inhibition of further electron tunneling until this charging energy is compensated by an applied bias.

A quantitative description of the Coulomb blockade is simpler in metallic clusters, where size quantization effects are absent because the ballistic transport conditions are not met; in semiconductor quantum dots, the Coulomb blockade coexists with the quantization of energy levels. In either case, the Coulomb blockade can be understood in terms of a macroscopic capacitance associated with the system, if the electrons that tunnel through either junction relax in the dot. Modeling the thin tunnel junctions as a parallel combination of a tunneling resistance R_i and a capacitance C_i, $i = 1, 2$, as in **Figure 7**, a voltage source between the leads performs the work $W_s = eV(C_1 n_2 + C_2 n_1)/C$ to transfer n_2 charges through junction 2, and n_1 charges through junction 1. Here, V is the applied voltage and $C = C_1 + C_2$ is the capacitance of the island. The electrostatic energy stored in the capacitors is $E_s = (n_1 e)^2/2C_1 + (n_2 e)^2/2C_2 = [C_1 C_2 V^2 + (ne)^2]/2C$, with $n = n_1 - n_2$ the excess electrons accumulated on the island. Then, the change in the total energy $E(n_1, n_2) = E_s - W_s$ when a single particle tunnels through junction 1 is $\Delta E_1^{\pm} = E(n_1, n_2) - E(n_1 \pm 1, n_2) = (e/C)[-e/2 \mp (en + VC_2)]$, whereas the change in energy when a particle tunnels through the second junction is $\Delta E_2^{\pm} = E(n_1, n_2) - E(n_1, n_2 \pm 1) = (e/C)[-e/2 \pm (en - VC_1)]$. The system evolves at zero temperature only when $\Delta E_{1,2}^{\pm} > 0$, a condition which can only be satisfied for $n = 0$ if the voltage exceeds a threshold. Tunneling cannot occur below this threshold, and thus no current flows through the island because the Coulomb gap e^2/C that opens symmetric around the Fermi level at $V = 0$ and $C_1 = C_2 = C/2$ prevents tunneling, no states being available for electrons to tunnel into from the leads and no empty states existing for electrons in the island to tunnel out. This Coulomb blockade is a consequence of the additional Coulomb energy $e^2/2C$ that must be expended by an electron to tunnel in or out of the island, the Coulomb gap resembling the energy gap in semiconductors.

If a bias is applied now such that $V > e/C$, an electron can tunnel in the island from one lead, the Fermi energy in the island raises by e^2/C, and further tunneling is prohibited by the appearance of a new energy gap unless the voltage increases to $V > 3e/2C$ or the extra electron in the island tunnels out through the other junction, a case in which the island reverses to the $n = 0$ state. These correlated tunneling processes into and out of the island produce a net current flow. The I–V characteristic has a staircase-like behavior if the capacitances or the tunneling resistances of the two junctions are very dissimilar. The charging effects can be observed if $e^2/C \gg k_B T$ and $R_{1,2} \gg h/e^2$.

Nomenclature

C	capacitance
k_x, k_y, k_z	wave vector components along x, y, z
k_F	Fermi wave number
e	electron charge
E	electron energy
E_c	bottom of the conduction band
E_{kin}	kinetic energy of electrons
E_F	Fermi energy
E_{Fl}, E_{Fr}	quasi-Fermi levels in the left and right contacts
E_s	electrostatic energy

$E_{s,p}$	cut-off energy of the subband or transverse mode labeled by p
$\boldsymbol{F}$	electromagnetic field component
$f(E)$	Fermi–Dirac distribution function
$f_l(E)$, $f_r(E)$	Fermi–Dirac distribution functions in the left and right contact
G_c	conductance of a ballistic conductor
G_{pq}	ballistic conductance associated to the electron transfer from terminal q with a quasi-Fermi energy level E_{Fq} to terminal p with a quasi-Fermi energy level E_{Fp}
I	current
K_B	Boltzmann constant
L_{fp}	mean free path
L_{ph}	phase relaxation length
L_x, L_y, L_z	dimensions of the free space propagation region along x, y, z
m	electron effective mass
$M(E)$	number of subbands occupied by electrons with energy E
M_{pq}	transfer matrix elements
n	electron density per unit area
$N_{tot}(k)$, $N_{tot}(E)$	total number of spin-degenerate states with a wave number less than k, or with an energy less than E
r, r'	reflection amplitudes from left to right and right to left
R	resistance
R_c	contact resistance
S_{pq}	scattering matrix elements
t, t'	transmission amplitudes from left to right and right to left
T	temperature; also electron transmission probability
v	electron velocity
V	potential energy; also applied voltage
W_s	work
$\rho_{2D,p}$	density of states per unit area $S = L_xL_y$
$\rho_{1D}(k_x)$	density of states in the k_x plane per unit length
ρ_{0D}	density of states in quantum dots
ϑ	unit step function
θ	angle of propagation
$\Psi(x,y,z)$	envelope electron wave function

Bioelectronics

E Katz, The Hebrew University of Jerusalem, Jerusalem, Israel

Introduction

Bioelectronics is a rapidly progressing interdisciplinary research field that aims to integrate biomolecules and electronic elements, for example, electrodes, field effect transistors, or piezoelectric crystals, into functional systems. Surface engineering of biomaterials, such as enzymes, antigen–antibodies, or deoxyribonucleic acids (DNA), on the electronic supports controls the electrical properties of the biomaterial–transducer interface and enables the electronic transduction of biocatalyzed transformations and biorecognition events on the transducers. Bioelectronic sensing devices, biofuel elements, and biotemplated circuitries have been developed recently.

Bioelectronic Systems Based on Biocatalytic Redox Enzymes

Natural redox enzymes catalyzing oxidative or reductive transformations of organic molecules operate upon an electron transfer between the enzyme active center and the respective substrate molecules. For example, the enzyme glucose oxidase (GOx), which catalyzes oxidation of glucose, includes the active center (also called cofactor) flavin adenine dinucleotide (FAD) that accepts electrons from the substrate glucose and donates them to the natural acceptor O_2. If the enzyme is immobilized on a conductive support and an efficient electron transfer between them is provided, the electron transfer from the enzyme active center could be directed to the conductive support instead of the natural acceptor, thus producing an electronic signal. However, most of the redox enzymes deny direct electrical contact with electrodes. The electron-transfer theory developed by R Marcus implies that the rate constant of the electron transfer between an electron acceptor and a donor pair is given as follows, eqn [1]:

$$k_{et} \propto \frac{\exp[-\beta(d-d_0)] \cdot \exp(-\Delta G^0 + \lambda)^2}{4RT\lambda} \qquad [1]$$

In eqn [1], d and d_0 are the actual distance and the van der Waals distance, respectively, that separate the donor–acceptor pair; ΔG^0 and λ correspond to the free-energy change and the reorganization energy accompanying the electron-transfer process, respectively; and β is the electronic coupling constant.

Thus, theory predicts that the electron transfer rate constant between the donor and acceptor sites exponentially decreases upon increase of the distance separating the couple. As the enzyme active center and the conductive support may be considered as a donor–acceptor pair, the embodiment of the active centers in the protein matrices spatially insulates the active centers and blocks the electrical contact between the redox enzymes and conductive supports. The understanding of the fundamental limitations for the electrical contacting of the redox enzymes with electrodes enables the development of synthetic methods to electrically wire redox enzymes and electronic transducers. Realizing that the lack of electrical contact between redox enzymes and the electrodes originates from the distance separating the donor–acceptor couple, one may suggest that the shortening of the electron-transfer distances by intermediate electron relay units may facilitate the electron transport between the active centers and the electrode (**Figure 1**).

The electrical contacting of redox enzymes that defy direct electrical communication with electrodes can be established by using charge carriers as intermediates between the enzyme active center and the electrode. These artificial electron donor or acceptor molecules (in the case of reductive or oxidative enzymes, respectively), usually referred to as electron-transfer mediators, can be accepted by many redox enzymes in place of their natural oxidants or reductants. The redox enzymes were incorporated into polymer matrices consisting of electron-transfer mediator units (e.g., Os-complexes (**1**)) (**Figure 2a**), or the redox mediator molecules (e.g., ferrocene derivatives (**2**)) were covalently tethered to the enzyme molecules (**Figure 2b**) to provide electron transport between the active centers of the enzymes and electrodes. Although redox enzymes anchored to electrodes by these means

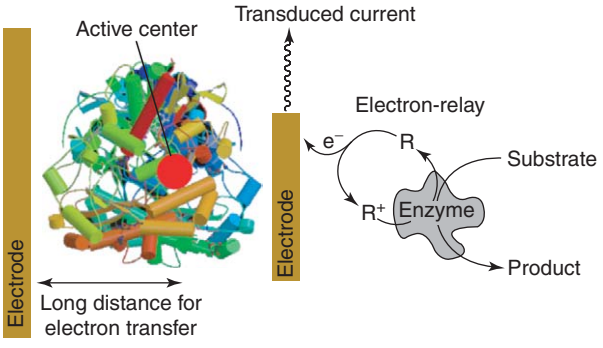

Figure 1 Spatially isolated redox active centers of enzymes could be electrically contacted on electrode surfaces with the use of electron relay molecules.

reveal electrical contact with the conductive support, the experimental electron transfer turnover rates are far lower than those observed for the enzymes with the natural donor or acceptor substrates. This was attributed to the random, nonoptimized, positioning of the relay units relative to the redox centers of the respective enzymes, that themselves lack a structural orientation in the integrated enzyme–electrode system. Thus, for optimal electrical communication between the redox centers of the enzymes and the electrodes, it is essential to develop means to align all enzyme molecules on the electrode in a configuration so that the redox centers are as close as possible to the electrode surface, and to place an appropriate electron relay unit between the redox center and the electrode support. The architecture of electrically contacted enzymes in an aligned configuration was accomplished by a surface-reconstitution method. The surface-confined cofactor unit (FAD, (**3**)) was incorporated into the GOx enzyme molecule instead of the natural cofactor, thus allowing the enzyme alignment on the electrode surface in a form of a stable complex. An electron-transfer mediator (e.g., pyrroloquinolino quinone (PQQ), (**4**)) located between the FAD-cofactor and the electrode surface provides efficient electron transfer from the enzyme FAD active center to the electrode (**Figure 3a**). Bioelectrocatalyzed oxidation of glucose to gluconic acid by the surface-reconstituted GOx enzyme results in the generation of an electronic signal in the electrode. Similarly, nicotine adenine dinucleotide (NAD^+)-dependent enzymes, for example, lactate dehydrogenase (LDH), were associated with a surface-confined NAD^+-cofactor (**5**) linked to the electrode surface via a catalyst molecule (PQQ) providing its fast electrochemical oxidation (**Figure 3b**). Since the NAD^+-cofactor is weakly bound to the respective enzymes, the enzyme molecules after formation of the surface-confined complex were additionally cross-linked to stabilize the biocatalytic interface. Bioelectrocatalyzed oxidation of lactate to pyruvate by the surface-integrated LDH enzyme results in the generation of an electronic signal in the electrode. Therefore, an efficient electron transport from the enzyme active centers (e.g., FAD or NAD^+) via the intermediate relay units (e.g., PQQ) to the conductive support was achieved, thus providing electronic signals generated by the biocatalytic systems. It should be noted that the relay units are chemically reduced and oxidized upon the electron-mediating process that could introduce some limitations to the rate of the process.

Application of conductive nanosized objects, such as metal nanoparticles or carbon nanotubes, for

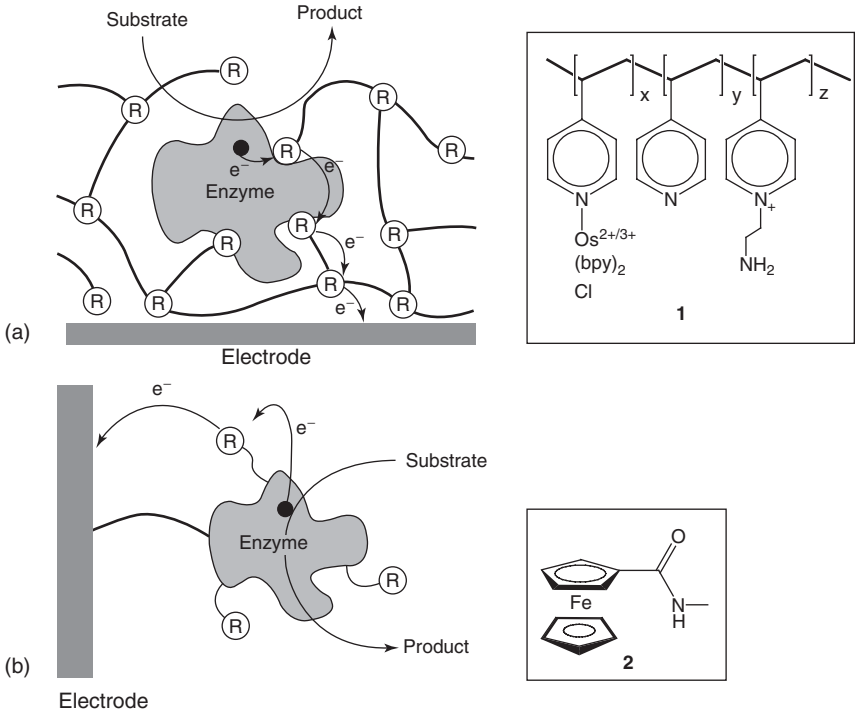

Figure 2 Redox enzymes electrically contacted on the electrode by means of: (a) the redox polymer (**1**) surrounding the enzyme molecules and (b) the redox mediator (e.g., ferrocene, **2**) tethered covalently to the enzyme molecules.

wiring of redox enzymes allowed the effective electron transfer between the enzyme active centers and the conductive supports using metal-like conductivity instead of the chemical redox-mediating process. Gold (Au) nanoparticles or single-walled carbon nanotubes (SWCNTs) were functionalized with the FAD-cofactor units and assembled on electrodes. Reconstitution of GOx enzyme molecules on the functionalized interfaces resulted in the biocatalytic interfaces, where the enzyme active centers are electrically wired to the conductive support via the Au nanoparticles (**Figure 4a**) or SWCNTs (**Figure 4b**). The nanosize of the wires allowed a short distance between them and the FAD cofactor, thus providing effective electron transfer, whereas the conductivity of the Au nanoparticles and SWCNTs provided the efficient electron transport to the macroconductive support.

The electric current provided by the enzyme–electrode systems depends on the rate of the biocatalytic reactions and could be proportional to the concentration of the substrate, if the entire process is limited by the substrate diffusion to the biocatalytic interface. Thus, the generated electronic signal could be used to design amperometric biosensors. For example, the GOx enzyme electrically contacted via an Au nanoparticle generates the current proportional to the glucose concentration in a certain concentration range.

The electrically wired redox enzymes could generate electrical power sufficient for construction of biofuel cells. The biofuel cells are primary sources of electrical energy extracted from organic materials using electrochemical processes catalyzed by biological substances (e.g., redox enzymes). They include two enzyme–biocatalytic electrodes: the first electrode (anode) provides oxidation of the organic substrate by an enzyme (e.g., oxidation of glucose by GOx), thus injecting electrons into the external electrical circuit, whereas the second electrode (cathode) is used to withdraw electrons from the circuit and transfer them to a chemical acceptor (e.g., O_2). The tailoring of efficient electron transfer at the enzyme-modified electrodes could enable specific biocatalytic transformations that compete kinetically with any chemical reaction of the electrodes or of the biocatalysts with interfering substrates (e.g., substrate transport from the counter compartment, oxygen). This would enable the design of noncompartmentalized biofuel cells, where the biocatalytic anode and cathode are immersed in the same phase with no separating membrane. In a working example, an anode consisting of GOx reconstituted onto a PQQ–FAD monolayer for the biocatalyzed oxidation of glucose was coupled to a cathode composed of an aligned cytochrome *c*/cytochrome oxidase (Cyt *c*/COx) couple that catalyzes

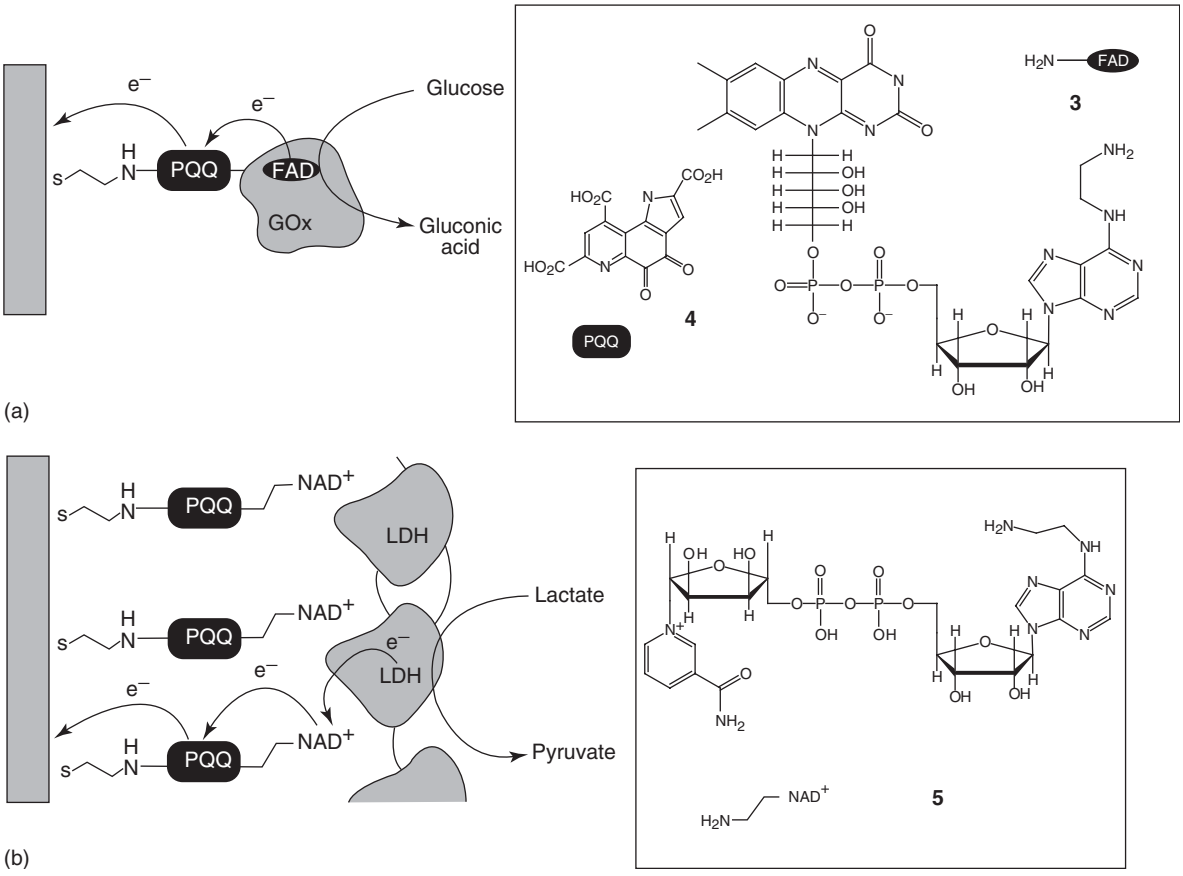

Figure 3 Redox enzymes electrically contacted on the electrode by means of: (a) reconstitution of the GOx on the electrode surface functionalized with the FAD (**3**)-cofactor and PQQ (**4**)-mediator; and (b) integration of LDH with the NAD^+ (**5**)-cofactor and the PQQ-mediator.

the reduction of O_2 to water (**Figure 5**). Since the reconstituted GOx provides extremely efficient biocatalyzed oxidation of glucose that is unaffected by oxygen, the anode can operate in the presence of oxygen. Thus, the biofuel cell uses O_2 as an oxidizer and glucose as a fuel without the need for compartmentalization. The glucose–O_2 biofuel cell element, or similar cells, might act as implanted self-fueled electrical energy generation devices in living organisms providing power for other bioelectronic elements.

Redox enzymes could be integrated with a gate of a field-effect transistor. An ion-selective field-effect transistor (ISFET) operates with a gate open to a chemical system, which provides electrical signals governing the current between source and drain electrodes. This signal is a potential change generated by chemical means on the gate. The redox enzymes associated with the ISFETs gate could reduce or oxidize co-immobilized electron relay units, thus providing the potential change on the gate further amplified by the respective change of the source–drain current (**Figure 6**). The amplified electronic signal is dependent on the rate of the biocatalytic reaction provided by the enzyme and proportional to the enzyme–substrate concentration, thus allowing potentiometric biosensors. Nano-sized bio-ISFETs were constructed with a single SWCNT operating as a gate modified with a few biomolecules (e.g., redox enzymes) providing a signal further electronically amplified by the source–drain current.

Bioelectronic Systems Based on Protein or DNA Biorecognition Systems

Biomolecules could provide very specific recognition processes resulting in the formation of complexes between them. For instance, biological immunosystems protecting organisms from foreign species are based on affinity complex formation between antibodies (recognition proteins produced by the organism) and antigens (foreign target molecules).

Biological genetic information is saved in deoxyribonucleic acid (DNA) molecules producing complexes with complementary DNA molecules. Association of a biorecognition element such as antigen (or antibody) or a DNA molecule with an electronic transducer allows electronic transduction of the affinity complex formation with the respective complementary biomolecule. The bioaffinity complex formation in a thin film near the conductive or semiconductive surface of the electronic transducer yields a chemically modified film on the surface that alters its interfacial properties. Blocking the electrode surface with bulky biomolecules upon immunorecognition between antigens and antibodies (**Figure 7a**), or formation of the charged interface upon hybridization of negatively charged DNA molecules (**Figure 7b**), perturbs the double-charged layer existing at the electrode–electrolyte interface resulting in the increase of its thickness, δ_{dl}, and in the insulation of the electrode surface with respect to redox labels added to the solution. This results in the capacitance change and electron-transfer resistance change at the interface, respectively, that could be read out by impedance spectroscopy. Two main approaches were used to increase these interfacial changes in order to amplify the electronic signal generated upon the biorecognition events: (1) secondary binding of bulky units (proteins, functionalized liposomes, or nanoparticles) complementary to the primarily biorecognition complex formed on the interface (**Figure 8a**), and (2) labeling the biorecognition elements with biocatalytic entities which provide a cascade of reactions on the surface, for example, resulting in the precipitation of an insoluble material on the sensing surface (**Figure 8b**). Both the amplifying processes are triggered by the primary

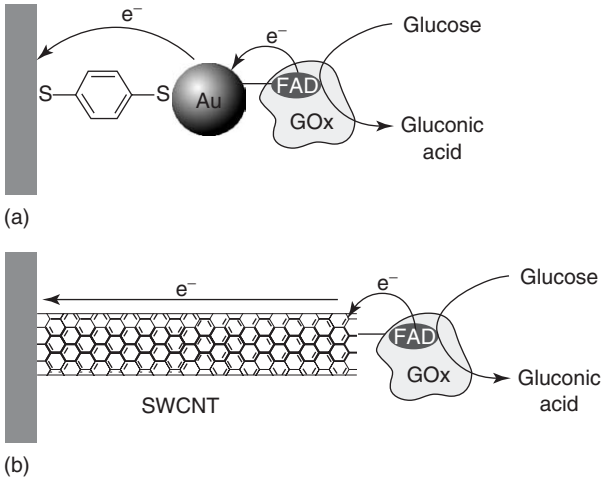

Figure 4 Redox enzymes electrically contacted on the electrode by means of: (a) reconstitution of the GOx on the electrode surface functionalized with the FAD-cofactor and an Au-nanoparticles plugging into the enzyme; and (b) reconstitution of the GOx on the electrode surface functionalized with the FAD-cofactors covalently linked to conductive SWCNTs assembled on an Au electrode surface.

recognition event and cannot proceed in the absence of the antigen–antibody or DNA–complementary DNA complex at the surface. Combination of high specificity and sensitivity provided by the primary biorecognition process and the secondary biocatalytic amplification, respectively, with the electronic transduction of the biochemical signal allows bioelectronic immunosensing and DNA sensing.

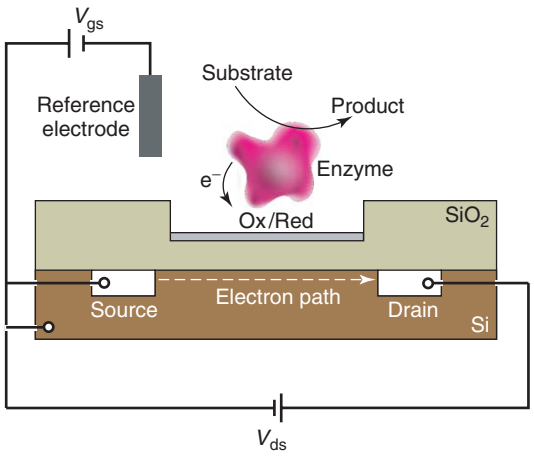

Figure 6 Redox-enzyme integrated with a gate of a field-effect transistor (V_{gs} – gate-source voltage; V_{ds} – drain-source voltage; Ox/Red – a redox-relay associated with the redox-enzyme).

Single-base DNA mismatches analysis, which is important for the analysis of genetic disorders, could exemplify the bioelectronic DNA sensing. The process is exemplified by the identification of the DNA mutant (**6**), in which the T-base in the normal gene (**6a**) is substituted with the G-base (**Figure 9**). A thiolated DNA primer (**7**) complementary to the analyzed gene up to one base before the mutation site is assembled as the sensing interface on an Au electrode. The normal gene (**6a**), as well as the mutant (**6**), associate with the sensing interface to generate the double-stranded DNA configuration. Reaction of the resulting interface with biotinylated-deoxycytosine triphosphate (dCTP) base in the presence of a polymerase enzyme results in the coupling of the biotinylated-tagged-base only to the layer which includes the mutant site. Subsequent association of the avidin-alkaline phosphatase (AlkPh)

biocatalytic conjugate, which stimulates the oxidative hydrolysis of 5-bromo-4-chloro-3-indoyl phosphate (**8**) to the insoluble indigo product (**9**), provides a route for the amplified transduction of the existence of the mutation site in (**6a**). Faradaic impedance spectroscopy was used as an electronic means to transduce the biochemical signal.

Another approach to the bioelectronic sensing of the recognition events uses incorporation of redox active species into the bioaffinity complex generated on a conductive transducer surface. Redox molecules, which are able to exchange electrons with the electrode support, are used as labels upon hybridization of complementary DNA molecules (**Figure 10a**), or upon biocatalytic replication of a long DNA sequence (**Figure 10b**). For example, the amplified amperometric transduction of DNA sensing with a bioelectronic system was demonstrated by the generation of a redox active DNA strand complementary to the analyzed DNA, which activates a secondary bioelectrocatalytic process (**Figure 10b**). The complex generated between the 7249-base M13 phage viral

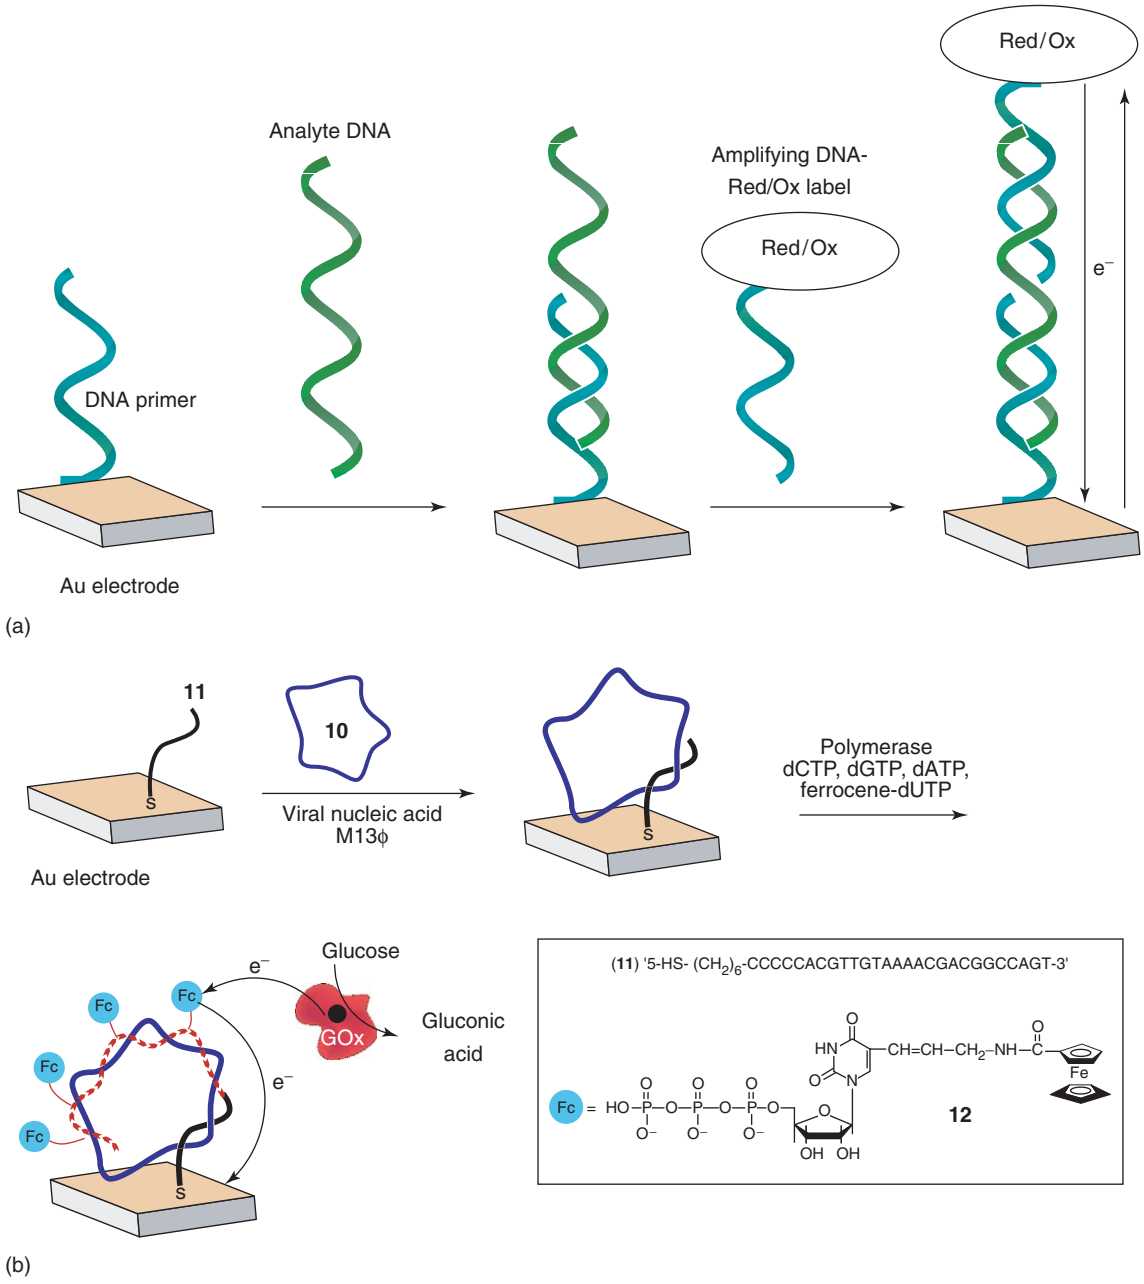

Figure 10 Labeling DNA molecules with redox units for amperometric read-out of the DNA reactions on the transducer interface. (a) Hybridization of complementary DNA molecules and (b) biocatalytic replication of DNA.

DNA (**10**) and a 27-base primer (**11**) associated with an Au electrode was replicated in the presence of a polymerase enzyme and a mixture of nucleotides that includes ferrocene-modified deoxyuridine triphosphate (dUTP) (**12**). The resulting ferrocene-labeled DNA replica was then coupled to GOx and, upon electrochemical oxidation of the ferrocene units, the GOx-biocatalyzed oxidation of glucose was activated. Because the enzyme exhibits a high turnover rate, the electrical output from this process represents an amplified electrical signal of the primary recognition event between the M13 phage viral DNA and the sensing nucleic acid associated with the electrode.

Metal nanoparticle labels linked to the biorecognition components (e.g., DNA molecules) were electrochemically oxidized, thus generating the electronic signal reporting on the formation of a bioaffinity complex on the sensing interface. Catalytic features of metal nanoparticles that enable the electroless deposition of metals on the nanoparticle clusters allow the enlargement of the particles, thus providing further amplification of the read-out signal.

Switchable and Tunable Bioelectronic Systems

Bioelectrocatalytic and biorecognition assemblies on electronic transducer interfaces that can be internally "tuned" or turned on and off during their operation are highly desirable. The use of such interfaces could allow the construction of variable output biofuel cells or variable range biosensors. Various physical input signals such as light, magnetic field, or electrical potential applied on the bioelectronic interfaces have been used to switch and tune bioelectronic transduction of the generated chemical signals.

For instance, photoswitchable biomaterials open a route to optobioelectronic systems. Photoisomerizable molecules undergo reversible structural changes when exposed to specific energies of light. Their two states often differ considerably, for instance, in their charge, polarization, or shape. If an enzyme molecule is functionalized with photoisomerizable groups, then the local environment of that enzyme will depend on the state of those groups. As the conformation of the enzyme is very sensitive to its environment, the shape and therefore the activity of the enzyme may be controlled by photonic input. To optimize the photoswitchable bioelectrocatalytic features of redox enzymes, the site-specific functionalization or mutation of the active-site microenvironment is essential. This has been accomplished, for example, by the reconstitution of GOx with a photoisomerizable FAD-cofactor. Nitrospiropyran carboxylic acid was covalently coupled to N^6-(2-aminoethyl)-FAD to yield a photoisomerizable nitrospiropyran-FAD cofactor (**13**). The native FAD cofactor was extracted from GOx and the modified FAD cofactor (**13**) was reconstituted into the apoglucose oxidase (apo-GOx) (**Figure 11a**). This reconstituted enzyme includes a photoisomerizable unit directly attached to the redox center of the enzyme, and hence the enzyme is predisposed for optimized photoswitchable bioelectrocatalytic properties. The photoisomerizable enzyme was assembled on an Au-electrode as outlined in **Figure 11b**. The bioelectrocatalytic interface was reversibly switched "off" and "on" by light signals resulting in photoisomerization of the molecular unit bound to the FAD cofactor between spiropyran (**13**) and merocyanine (**14**) isomeric states, respectively. The electron transport between the photoisomerizable enzyme cofactor and the electrode surface was achieved with the use of a diffusional electron-transfer mediator (e.g., ferrocene monocarboxylic acid (**15**)).

The distance between surface-confined redox proteins and the bioelectronic transducer surface could be controlled by an applied electrical potential. Biasing the electrode surface at potentials more positive than a zero-charge potential results in the positive charging of the surface, thus repelling positively charged protein molecules (e.g., cytochrome *c*). The longer distance, which is allowed by a long flexible molecular spacer, results in a slow kinetics of the electron transfer between the electrode and the protein redox active center. Opposite biasing yielding a negative electrode surface results in a short distance upon electrostatic attraction of the positively charged protein, thus providing a short electron-transfer distance and the fast electron exchange (**Figure 12**).

The magnetic control of bioelectrocatalysis is a novel concept of bioelectronics. **Figure 13** outlines the method to control by an external magnetic field the bioelectrocatalytic oxidative functions of a redox enzyme, for example, GOx. Magnetic particles (e.g., Fe_3O_4) functionalized with a relay unit, R (e.g., a ferrocene unit), are used to electrically contact the redox enzyme (e.g., GOx) and the electrode. Positioning of a magnet below the electrode attracts the functionalized-magnetic particles to the electrode. This enables the oxidation of the relay unit by the conductive support, and subsequently activates the bioelectrocatalyzed oxidation of the substrate (e.g., glucose) by the oxidized relay associated with the magnetic particles. Transfer of the external magnet to an upper position lifts the functionalized-magnetic particles upward, and removes them from the electrode support. This prevents the oxidation of

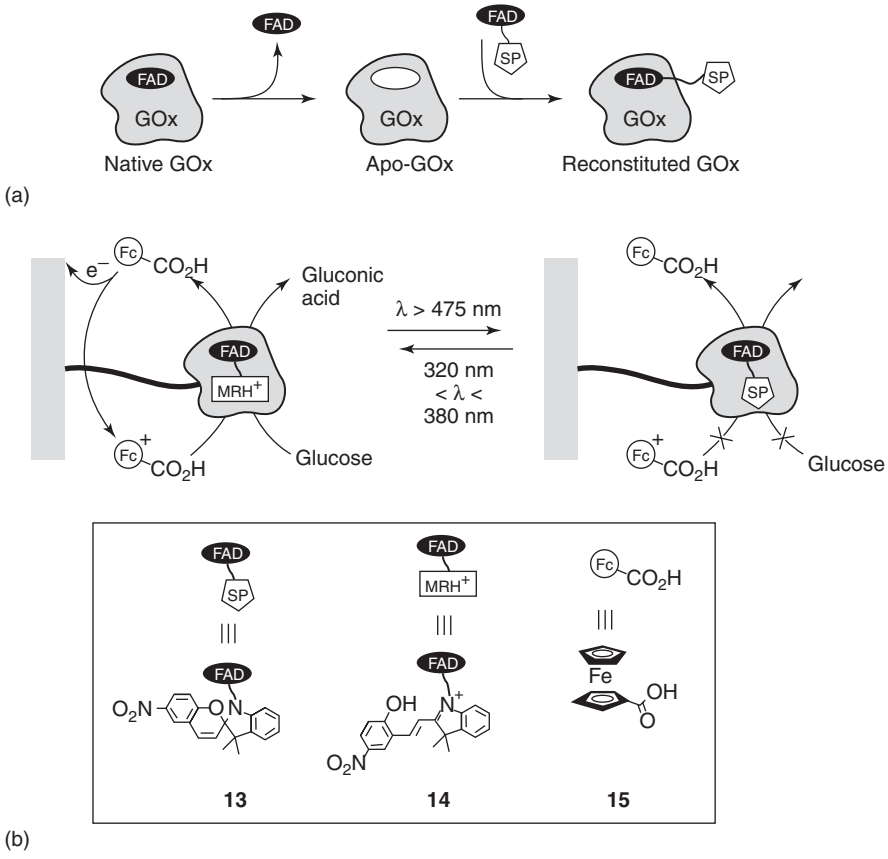

Figure 11 (a) Implanting of a photoisomerizable FAD derivative into apo-GOx to yield a photoisomerizable enzyme. (b) Switching "on" and "off" the photoisomerizable enzyme by light signals.

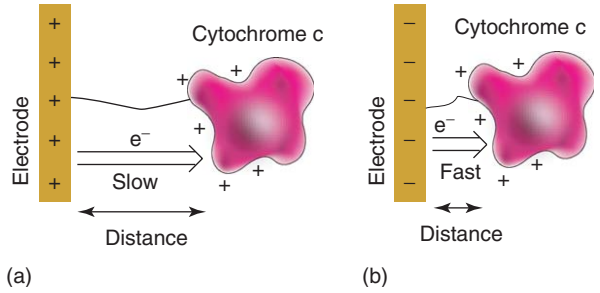

Figure 12 Potential-induced changes of the protein-surface distance resulting in the alteration of the electron transfer kinetics.

the relay units and the bioelectrocatalyzed oxidation of the substrate is switched off. By alternate positioning of the external magnet below and above the electrode surface, the bioelectrocatalyzed oxidation of the substrate is reversibly switched between "on" and "off" states, respectively. The magnetic control of a bioelectrocatalytic reduction process can be similarly controlled by the use of relay-functionalized magnetic particles that are reduced at the electrode support.

An important advance in the magnetic control of electrocatalytic and bioelectrocatalytic transformations was accomplished by magnetic attraction of the magnetic particles to the electrode support followed by the rotation of the magnetic particles on the electrode by means of an external rotating magnet. The rotation of the redox-functionalized magnetic particles turns them into circularly rotating microelectrodes. As a result, the redox-activated bioelectrocatalytic process mediated by the functional particles is controlled by convection rather than diffusion of the substrate to the microelectrodes. Accordingly, enhanced amperometric responses of the particle-mediated bioelectrocatalytic processes are anticipated, and the resulting currents should be controlled by the rotation speed of the particles. **Figure 14** depicts the amplified amperometric analysis of glucose by the rotation of ferrocene (**16**)-functionalized magnetic particles on the electrode support. The rotating magnetic particles are functionalized with an electron-transfer mediator, and the interaction with GOx and glucose is convection controlled. The bioelectrocatalysis in the presence of rotating magnetic particles can be used to enhance biosensing events and to yield the amplified electronic signal.

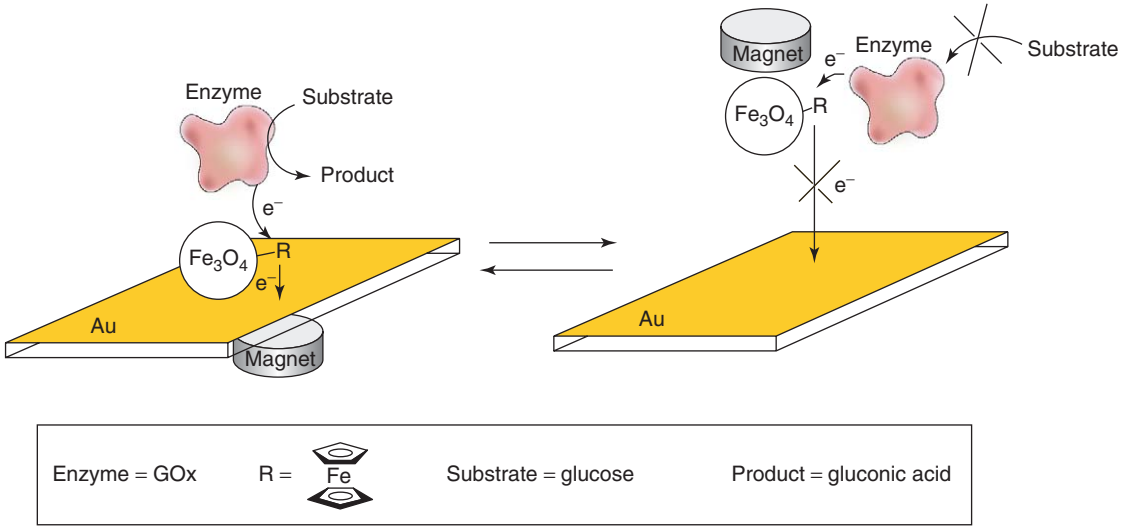

Figure 13 Magneto-switched bioelectrocatalyzed oxidation of glucose in the presence of electron relay-functionalized magnetic particles.

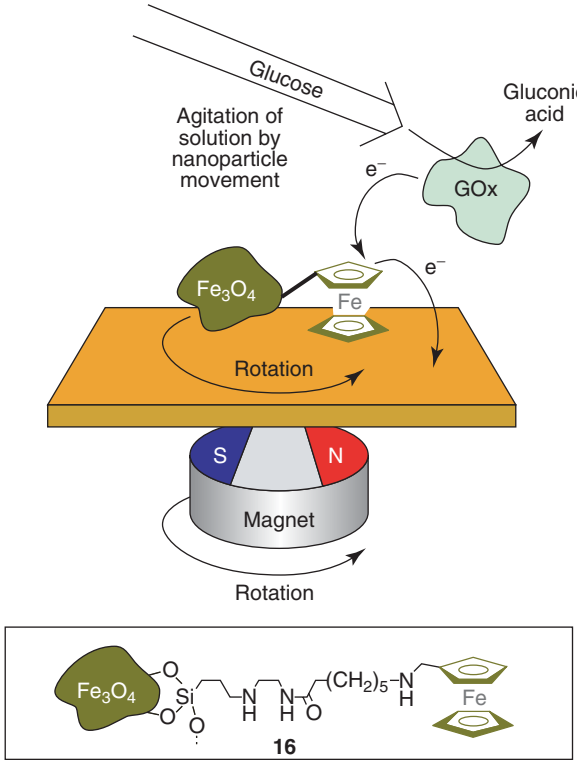

Figure 14 Bioelectrocatalytic oxidation of glucose in the presence of GOx and ferrocene-functionalized magnetic particles enhanced upon circular rotation of the particles by means of an external rotating magnet.

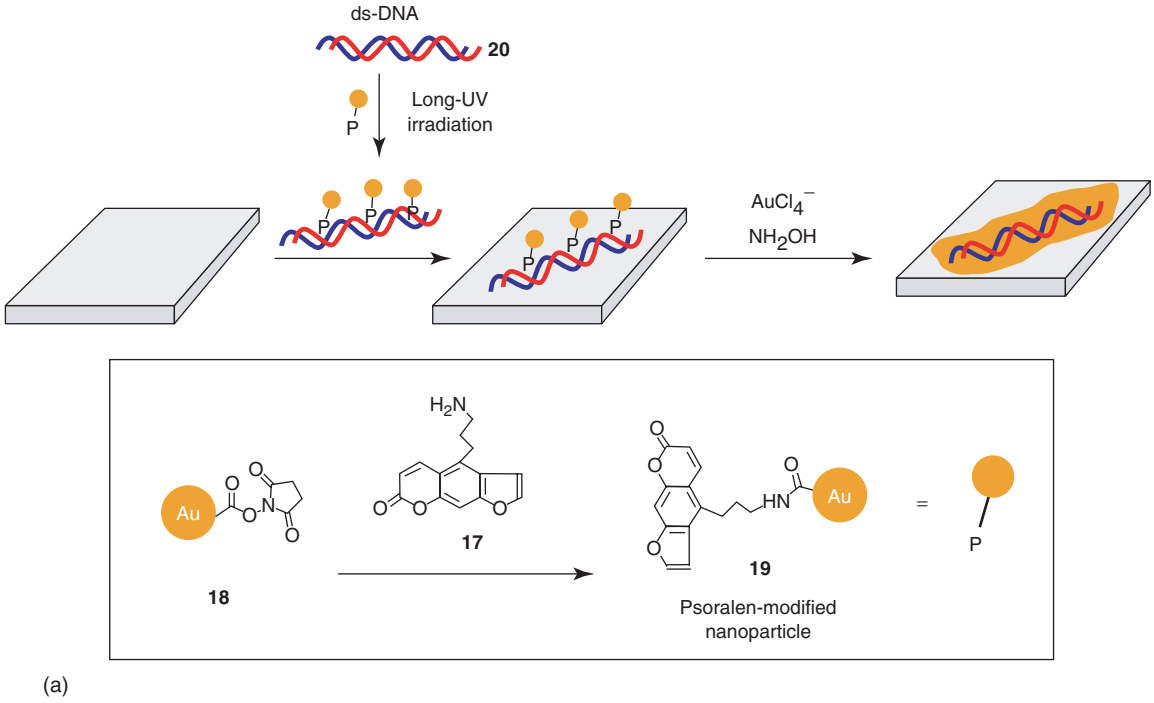
Biomaterial-Based Nanocircuitry for Bioelectronic Systems

The miniaturization of objects by lithographic methods reaches its theoretical limits. It is generally accepted that different miniaturization methods need to be developed in order to overcome this barrier. While the lithographic methods use "top" to "down" miniaturization of patterns, the alternative approach of the "bottom-up" construction of objects has been suggested as a means to overcome the lithographic limitations. That is, the construction of objects on molecular or supramolecular templates could generate nanometer-size features. Nanowires are considered as building blocks for self-assembling logic and memory circuits in future bionanoelectronic devices.

Different biomaterials, for example, proteins and nucleic acids, may act as important building blocks for functional bionanocircuitry, and eventually may provide bionano-elements for the construction of nanodevices. Biological templates have been used to direct the nucleation, deposition, and assembly of inorganic micro- and nanostructures. Among the different biomaterials, DNA is of specific interest as a template for the construction of nanocircuitries. Several arguments support the use of DNA as a future building block of nanostructures: (1) Nucleic acids of pre-designed lengths, base-orderings, and shapes can be synthesized, and complex structures generated by self-assembly methods. (2) Nature provides us with an arsenal of biocatalysts that can manipulate DNA. These enzymes may be considered as tools for shaping the desired DNA and eventually for the generation of nanocircuitry. For example, ligase ligates nucleic acid, endonucleases affect the specific scission of nucleic acids, telomerase elongates single-stranded nucleic acids by telomer units, and polymerase replicates DNA. These biocatalysts represent "cut" and "paste" tools for the formation



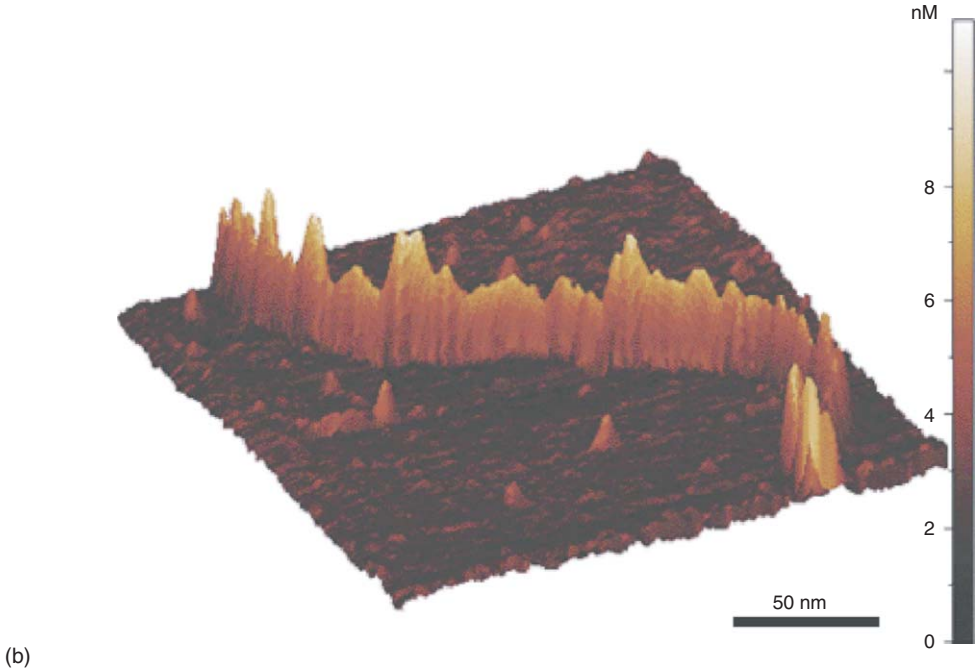


Figure 15 (a) Assembly of an Au-nanoparticle wire in the polyA/polyT template. (b) AFM image of an Au-nanoparticle wire in the polyA/polyT template. (Adapted from Patolsky F, Weizmann Y, Lioubashevski O, and Willner I (2002) Au-nanoparticle nanowires based on DNA and polylysine templates. *Angewandte Chemie International Edition* 41: 2323–2327, with permission.)

of DNA templates and by the application of the replication biocatalyst, the design of future "factories" of nanowires may be envisaged. (3) The intercalation of molecular components into DNA and the binding of cationic species, for example, metal ions to the phosphate units of nucleic acids allows the assembly of chemically active functional complexes. (4) Different proteins bind specifically to certain nucleic acid sequences. This allows the addressable assembly of complex DNA–protein structures. Such protein–DNA complexes may either act as addressable domains other than the DNA for the selective deposition of metals, or alternatively, may act as temporary shielding domains that protect the DNA

from metal deposition. Such insulated domains may then be used for the deposition of other metals or semiconductors, thus enabling the fabrication of patterned complex structures.

With the vision that DNA may act as a template for the generation of nanocircuitry, attempts were made to explore the possibility of organizing DNA-crosslinked semiconductor nanoparticles and DNA-based metal nanoparticle nanowires on surfaces. Since nanoparticles are loaded on the DNA template with gaps between them, the conductivity of metallic nanoparticle aggregates on a DNA template can be enhanced upon the chemical deposition of another metal (e.g., Ag deposition on Au aggregates) filling the gaps and forming a continuous conductive nanowire. The binding of the primary metallic clusters to the template DNA for the subsequent catalytic deposition of wires on the DNA frame may be accomplished by several means: (1) The reduction of metal ions linked to the phosphate groups to metallic seeds linked to the DNA. (2) The use of metal or semiconductor nanoparticles functionalized with intercalator units. Intercalation of the molecular components into double-stranded DNA leads to the association of the nanoparticle to the DNA template. (3) The synthesis of DNA with functional tethers that enable the covalent attachment of the metal or semiconductor nanoparticles to the DNA. (4) The synthesis of single-stranded DNA that includes constant repeat units (e.g., telomers) and the hybridization of metal or semiconductor nanoparticles functionalized with short nucleic acids, that are complementary to the single-stranded DNA repeat units.

Figure 15a exemplifies the method for assembling the Au-nanoparticles on the DNA template using Au-nanoparticles functionalized with an intercalator. The amino-functionalized psoralen (**17**) is reacted with the Au_{55}-nanocluster (diameter 1.3 nm) that includes a single *N*-hydroxysuccinimide active ester functionality (**18**), to yield the psoralen-functionalized Au_{55}-nanoparticle (**19**). As psoralen acts as a specific intercalator for A–T base pairs, the functionalized Au_{55}-nanoparticles were reacted with the pA/pT-ds-DNA (**20**). Subsequently, the assembly was irradiated with UV light to induce the $2\pi + 2\pi$ cycloaddition reaction between the psoralen units and the thymine base sites of DNA. This latter process fixes covalently the Au_{55}-nanoparticles to the DNA matrix. **Figure 15b** depicts the AFM image of the resulting nanoparticle wire. A $\sim$600–700 nm long nanoparticle wire is formed. Its width corresponds to $\sim$3.5–8 nm and it is controlled by the width of the DNA template. The height of the wire is $\sim$3–4 nm, consistent with the fact that the Au-nanoparticles intercalate into the DNA on opposite sides of the double-stranded DNA template. The continuous appearance of the Au-nanoparticle wire is due to the dimensions of the scanning AFM-tip, and in reality, most of the particles are not in intimate contact one with another. The possibility to arrange the Au-nanoparticles on the DNA template allows further catalytic enlargement of the particles by an electroless deposition process (e.g., reaction of $AuCl_4^-$ with NH_2OH) to yield continuous conductive nanowires.

Practical applications of the nanowires require their electrical contacting with macro- or microelectrodes. Toward this goal, a single nanowire produced on a DNA template bridging two microsize electrodes was constructed. Two microelectrodes facing each other (12–16 μm separation) were functionalized with 12-base oligonucleotides that were then bridged with a 16 μm long λ-DNA (**Figure 16**). The resulting phosphate units of the DNA bridge were loaded with Ag^+ ions by ion exchange, which were then reduced to Ag metal by hydroquinone. The small Ag aggregates produced along the DNA backbone were then used as catalysts for further reductive deposition of silver, eventually leading to the formation of an Ag nanowire. This micrometer-sized element had a typical width of 100 nm and a granular morphology (as determined by AFM).

The use of biomaterials as templates for the generation of nanostructures and nanocircuitry in the presence of nanoparticles is in an early phase of development. The viability of the concept has been proven, and nanowires of controlled shapes and electronic functions have been generated by the incorporation of nanoparticles on template biomaterials. The biggest challenges are ahead however, and exciting systems are envisaged for the future. Besides the interesting nano-architectures that may be generated, fundamental problems, such as probing charge transport phenomena in such nanoparticle-biomaterial

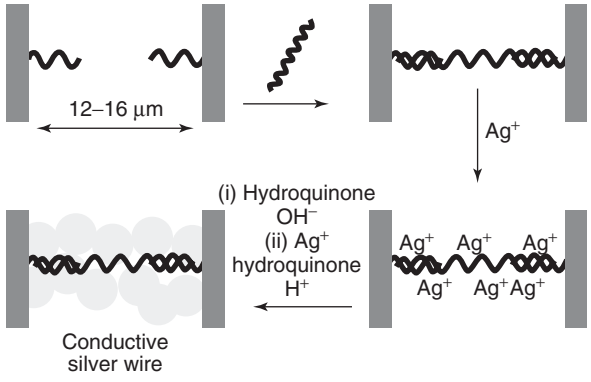

Figure 16 The construction of a wire bridging two microelectrodes by the deposition of nanoparticles on a bridging DNA strand, followed by silver deposition.

systems, may be highlighted. Nonetheless, the organization of nanoparticle architectures on biomaterial templates involves relatively simple motifs that do not make full use of the biomaterial's catalytic functions. The replication of nanoparticle-labeled DNA, and specifically the tailoring of polymerase chain reaction (PCR) for the formation of nanoparticle wires, represents a novel approach to design biological machines for the synthesis of nanoparticle wires and circuitry.

Conclusions

Three facets of bioelectronics – biomaterial-based electronic sensors, biofuel cells, and biomaterial-based electronic circuitry – continue to progress rapidly in research, and some of its applications have been developed commercially. Other topics, such as hybrid systems of neural network and electronic elements, biomaterial-based computers, and biomaterial-based micromachinery devices represent other opportunities in bioelectronics that show promise for future applications. Despite this outlook, however, challenges in bioelectronics remain, including the development of implantable fuel cells, biomaterial-based micromachines (e.g., prosthetic units), and the fabrication of functional electronic circuitry. Recent advances in nanotechnology, the availability of quantum-size nanoparticles and nanotubes of unique electronic and catalytic properties, and nanoscopic tools for manipulating surfaces could open nanobioelectronics as a new research field. The electronic detection of biorecognition events of single molecules, the optical or electronic read-out of biological processes by functional nanoparticles, the high-throughput analysis of numerous genes or protein functions on dense sensing arrays, the construction of biomaterial-based electronic devices of nanodimensions, and the tailoring of ultrasmall self-powered devices for the controlled release of therapeutic drugs may be possible as well.

Biological Structures

R M Ottenbrite and R Javan, Virginia Commonwealth University, Richmond, VA, USA

Polymers

Polymers are materials composed of molecules linked to one another in a linear or branched manner as multiple repeat units. Applications of biomedical polymer structures include: sutures, maxillofacial implants, dental constructs, joint replacements, cardiovascular devices, artificially engineered tissues, and drug-delivery and gene-transvection systems.

In order to understand biomedical polymer structures, one should have some knowledge of the physical properties that are essential for their function in a biological system. To accomplish specific biorelated tasks, the materials used must meet many physical and biological requirements. These include biocompatible and nontoxic, degradable or nondegradable, water soluble or insoluble, hard or soft, rigid or flexible, hydrophobic or hydrophilic, and bioactive or bioinactive materials. To help with the reading of this article some concepts such as biocompatibility, characterization, biodegradation, and applications such as biological scaffolds, hydrogels, polymeric drugs, and drug-delivery systems are addressed.

Biocompatibility

Biocompatibility refers to the ability of a material to perform with an appropriate host response in a specific application and incorporates blood and tissue compatibility. When a material is characterized for a bioapplication, mechanical properties, such as stress–strain relationships, surface properties, such as wettability, in addition to chemical and biological properties, are thoroughly evaluated.

Biodegradation

Biodegradation is the chemical breakdown of materials by the action of living organisms leading to changes in physical properties. There are other definitions of polymer degradation; however, they all involve a chemical breakdown in an aqueous environment caused by hydrolysis (reactions with water) and/or enzymes. Biodegradable polymers were first used surgically as sutures, staples, implants, and temporary devices. With current developments being made in drug-delivery systems, tissue engineering, and scaffolds for regenerative organs, there is a growing need for new biodegradable materials. The majority of the products presently in use are composed of poly(lactic acid), poly(glycolic acid), poly (ε-caprolactone), their copolymers and composites. In addition to these polymers, several other important degradable polymer systems are available and many more are currently being developed (**Figure 1**).

Biological Scaffold

Biological scaffold is an artificial support system to replace, temporarily or permanently, a biological structure. Sutures, bone-fixation devices (bone nails, screws, or plates), and vascular grafts are early examples of such support devices. The degradable scaffold implant provides temporary mechanical support until the natural tissue has developed and regained its strength. As the tissue assumes integrity, the scaffold material should concomitantly slowly degrade.

Adjusting the rate of degradation to the regeneration process of the surrounding tissue presents one of the major challenges in the design of a temporary scaffold. For temporary scaffolding to function effectively, a gradual stress transfer should occur. As the natural tissue develops, the degradable implant should gradually weaken so that regenerated tissue can resume its function. For example, when a bone is shattered, usually a metal pin is inserted or a metal

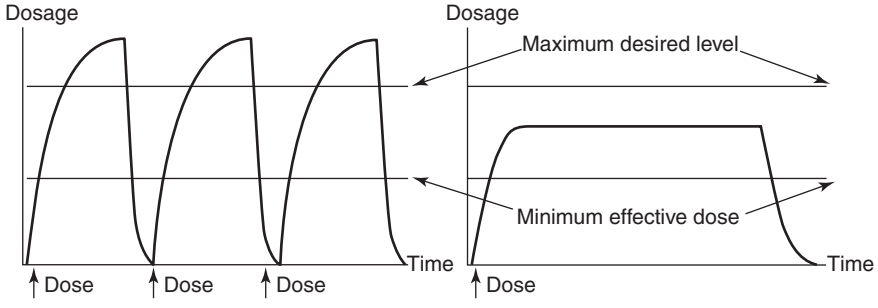

Figure 1 Ordinary drug delivery (left) and delivery using degradable polymer systems (right).

plate fixed to the bone in order to stabilize the injury. These supply support and alignment during the healing process. However, the pin or the plate must be surgically removed after ossification is complete. While these supports are in place, the bone to be mended has been stress free. After the pin or plate is removed, the regenerated bone is too weak to support normal activity until the bone regenerates sufficiently to assume the normal stress loads. The major advantage of biodegradable supports is that as the osteocytes proliferate, the polymer degrades and is absorbed while stress is gradually transferred from the scaffold to the bone. Consequently, the bone adjusts to the increasing stress as it mends. This significantly reduces rehabilitation time and eliminates a second surgical process to remove the support.

Tissue Engineering

Tissue engineering is a new frontier in bioscaffolding and is defined as "the application of engineering principles to create devices for the restoration, modification, and assembly of functional tissues from native or synthetic sources." The goal is to regenerate tissue, bone, or organs that have been disabled or weakened by disease or injury. The tissue scaffold has to be nontoxic and biodegradable as well as possess the right three-dimensional structure to support cell differentiation. The mechanical properties of the scaffold and the surrounding environment have to be in harmony during the process. To enhance cell proliferation, slow release of supportive bioactive recipients, such as specific enzymes, can be included in the scaffold which are then released as the scaffold degrades.

Polymeric Drugs and Drug-Delivery Systems

These systems constitute an important technology that has been developing over the last 30 years. Currently, polymeric drug delivery is a 35 billion dollar market and will continue to grow 5% per year for the next ten years. Many drugs are rapidly cleared from the circulatory system through the kidneys or taken up by the liver or spleen and, therefore, exhibit very little efficacy. Other difficulties that are associated with drug assimilation are due to low solubility, random distribution, and toxicity. Polymers are very versatile and, therefore, offer novel approaches so that systems can be tailored for an intended application and long-term delivery times (days, weeks, months, and even years). Polymeric drug-delivery systems are prepared in a variety of sizes and shapes, such as films, fibers, disks, slabs, pellets, rods, and monolithic forms. The development of new polymer methodology is critically important as new drug therapies, such as peptide, protein, and DNA type drugs, are being developed (**Figure 1**).

Polymeric drugs are drugs that are physiologically active polymers. In nature, these are proteins (enzymes) and polysaccharides (heparin). However, other than synthetic mimetics, there are few man-made polymers that are biologically active. Among these are the polyanionic and polycationic polyelectrolytes. Polyanions stimulate the immune system and have shown anticancer and antiviral activity (HIV and hoof and mouth disease). Polycations have antimicrobial activity and are currently being investigated as gene-delivery adjuvants.

Active agents can be attached to a polymer backbone and are known as drug-conjugates. Polymer–drug conjugates enhance circulation time (due to increased size) as well as increase solubility which enables transport in the circulatory system. However, conjugation usually inactivates the drug. Therefore, polymeric prodrugs were developed. Prodrugs are conjugate systems that have a drug attached to a polymer by a degradable linkage so that the drug can be released by hydrolysis or enzyme activity. Furthermore, polymer conjugate systems can be modified with solubilizing and targeting groups. This system has been successfully used for delivering anticancer drugs, such as daunarubacin.

Implantable drug-delivery systems involve incorporating drugs into a biodegradable polymer matrix. Using this technology, desirable dosages can be released over a prolonged period of time at an intermittent or constant rate. This achieves effective therapies and prevents under- or overdosing the patient. Biodegradable polymers that are most commonly used are poly(glycolic acids), poly(lactic acids), polyurethanes, and poly(ortho esters) with commercial names such as Decapeptyl®, Lupron Depot®, and Sandostatin LAR®. Degradation may occur through bulk hydrolysis in which the polymer degrades in a fairly uniform manner throughout the matrix. For some degradable polymers, mostly polyanhydrides and poly(ortho esters), degradation and erosion occurs only at the surface of the polymer which provides a release rate that is proportional to the surface area of the drug-delivery system.

With advancements in pharmaceutical sciences, it has been recognized that constant release is not necessarily the optimum method for delivering drugs. As a result, externally modulated or self-regulating drug-delivery systems, using biomedical polymer structures, are being engineered to respond to environmental stimuli, pH, temperature, or pressure. The glucose-sensitive insulin-release system is an example of this application; in this device, high glucose concentrations induce matrix disintegration

with polymer dissociation from the surface, leading to the release of insulin.

Hydrogels

Hydrogels are water-insoluble, three-dimensional networks formed by cross-linking a hydrophilic polymer. These networks absorb large quantities of water to form a gel. Natural hydrogels, such as acacia, agar, carrageen, and alginates, have been known for centuries and are used in food and personal products.

Research to develop synthetic hydrogels started in the 1970s and dramatically increased in the 1990s due to the recognition of the many potential applications that these constructs could have in medicine, agriculture, and industry. This work has led to the synthesis of many new hydrogels and a better understanding of the physicochemical properties involved. When a hydrogel is in the swollen state, the three-dimensional compartment holding the solvent is called a cell or pore. As the gel dries, it becomes concomitantly smaller in size and finally collapses to the solid state called a sol (thus the term sol–gel). The overall chemical structure remains the same during these processes. The three-dimensional cell structure is achieved through cross-linking linear polymer chains either chemically (by covalent bonding) or physically (by hydrogen bonding, ionic, or hydrophobic interactions). Since noncovalent bonds are reversible, physical gels have sol–gel reversibility. The extent of swellability depends on the hydrophilic nature of the polymer and the cross-linking density. Smaller cells (higher cross-link density) provide more stable hydrogels and appear to be more solid-like. Methods for preparing hydrogels include irradiative cross-linking using electron beams, gamma rays, X-rays, or UV light, and chemical reactions using di- or multifunctional cross-linking agents (**Figure 2**).

Most hydrogels have good mechanical stability, good refractive index, and oxygen permeability. Consequently, one of the early biomedical applications of hydrogels was for soft contact lenses. The most widely used hydrogel for bioapplications is cross-linked poly(hydroxyethyl methacrylate) (PHEMA). This structure provides a water content similar to that of living tissue and was one of the first materials used for soft contact lenses. This hydrogel is inert to biodegradation, permeable to metabolites, not absorbed by the body, endures heat sterilization, and can be fabricated into different shapes and forms. However, problems with protein deposits are still an issue. Hydrogels are now used for artificial tendons and muscles, wound-healing bioadhesives, artificial kidney membranes, artificial skin, and maxillofacial reconstruction materials.

Hydrogels have also been made with poly(*N*-vinyl-2-pyrrolidone), poly(methacrylic acid), and poly (methyl methacrylate-co-maleic anhydride), which are used in similar biomedical applications. For example, polyacrylamides are synthetic long-chain polymers designed to attract positively or negatively charged materials and are widely used in gel electrophoresis. In gel extraction processes, an acid is added to shrink the hydrogel, and conversely, a base is added to swell it (**Figure 3**).

Biodegradable hydrogels have emerged as an important class of biomaterials for controlled drug delivery. The release rate of an excipient is determined by drug and polymer properties, such as the swellability, degradability, porosity, permeability, and hydrophilicity of the hydrogels.

Smart (or intelligent) polymer-structured hydrogels are being developed for several biomedical applications. A unique aspect about these hydrogels is that their swelling ratio (swollen volume divided by dried volume) can be engineered to change abruptly with a slight external aberration. Hydrogel materials can undergo continuous or discontinuous changes in swelling in response to environmental stimuli, such as changes in pH, temperature, ionic strength, pressure, and light. These stimuli–response properties are advantageous in many potential bioapplications. For example, timed control release of insulin has been achieved with "smart" pH-sensitive hydrogels. This phenomenon is known as on-demand release of insulin in response to increased levels of glucose. Thermosensitive hydrogels, such as poly(*N*-isopropylacrylamide) and poly(*N*-vinyl caprolactam), have also been engineered for controlled drug delivery, where hydrophobic interactions respond to small changes in temperature

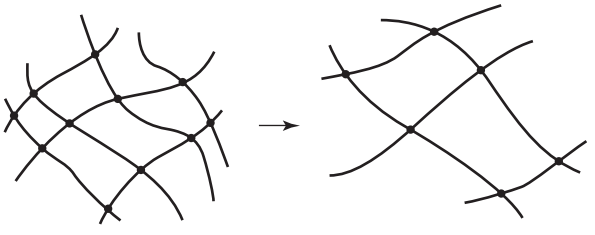

Figure 2 Network of cross-linking polymer chains in hydrogels (left) that swell after water absorption (right).

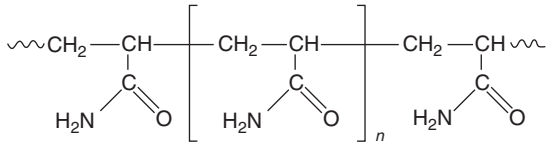

Figure 3 Polyacrylamide.

that can vary drug release rates. "Smart" hydrogels are being used extensively for robotics where responses to numerous and different stimuli are important features. Reversible contraction and expansion are essential in the development of advanced robotics with electrically driven muscle-like actuators. The transformation of electrochemical stimuli into mechanical work is being used for such artificial muscle responses.

Hybrid hydrogel systems are composed of at least two distinct classes of macromolecules. These are of particular interest because it is possible to combine and superimpose the component macromolecule properties into the hydrogels. Theoretically, it is possible to manipulate the DNA sequence and generate unlimited varieties of protein products with optimum structures and properties. For example, hybrid hydrogels have been prepared, using synthetic polymers and biological macromolecules, as engineered proteins and DNA-based biomaterials.

Microporous and macroporous hydrogels are being made with pore sizes in the 10–100 nm and 100 nm–10 μm range, respectively. These hydrogels are designed to swell within minutes regardless of the size of the matrix. In these cases, the pore size is an important property of a hydrogel. Now superporous hydrogels, a new type of hydrogel, with supersize pores are being developed. These pore sizes are larger than 100 μm and can reach millimeter range. Their fast swelling kinetics, in addition to super-absorbent properties, allow these superporous hydrogels to be used in special biomedical applications, such as long-term oral drug delivery, due to their ability to achieve high gastric retention times. Superporous hydrogels and their composites are also being engineered for artificial pancreas, cornea, skin, and joint cartilage. They are being used as cell growth substrates in tissue engineering scaffolding, burn dressings, soft tissue substitutes, and as surgical pads to control bleeding.

Hyaluronic Acid

Hyaluronic acid (HA, Hyaluronan®) is a naturally occurring, biocompatible, and biodegradable linear polysaccharide. It is composed of unbranched repeating disaccharide units of glucuronic acid and *N*-acetyl glucosamine linked by *β*-(1-3) and *β*-(1-4) glycosidic bonds. HA is present in all soft tissues of higher organisms but is in very high concentration in the synovial fluid and vitreous humor of the eye. It can be extracted from various sources of animal tissues, such as the umbilical cord, skin, and rooster combs.

Hyaluronic acid is used in many medical applications, such as promoting cell mobility and differentiation in wound healing, viscosupplementation and viscosurgery, ophthalmic surgery, and in cosmetic applications. Despite its highly attractive rheological properties, unmodified HA has a short residence time and poor mechanical properties. However, HA can be chemically modified to prolong degradation time and improve mechanical stability *in vivo*. Recently, it has been formed as a thin film that can be used for tissue separation. HA-based films or sponges have been made for implants loaded with therapeutic agents for delayed release and prolonged activity.

Chitosan

Chitosan, poly(*β*-(1-4)-D-glucosamine), is a water-soluble product obtained by *N*-deacetylation of chitin (**Figure 4**). Chitin is a naturally occurring polysaccharide and second to polysaccharides as the most abundant natural polymer. It is mainly isolated from crustaceans, such as crab and shrimp, but is also found in fungi and the hard shells of insects. The physical properties of chitosan are related to the number and the distribution of *N*-acetyl groups. The primary amino group at the 2-position forms quaternary groups in water that become soluble at $pH < 8.5$.

Chitosan has superior biocompatible and biodegradable properties and is used in biomedical applications such as wound dressings. It was first used for burn bandages because it maintains good hydration, allows toxins and metabolites to be transported away from the injury, and promotes healing. In wound healing, chitosan facilitates the formation of granulation tissue with angiogenesis. It induces fibroblasts to release interleukin-8, which is involved in the migration and proliferation of fibroblasts and vascular endothelial cells. However, chitosan's surface-induced clot-forming potential has limited its application in blood contact situations. Although chitosan itself has a hemostatic function, its derivatives, such as, *N*-hexanoyl and *N*-octanoyl chitosan, have antithrombogenic activity. The antimicrobial and wound-healing properties along with an excellent film capability make chitosan suitable for ocular lens bandages.

Although water soluble, chitosan can be formed in different shapes such as nanoparticles, microspheres,

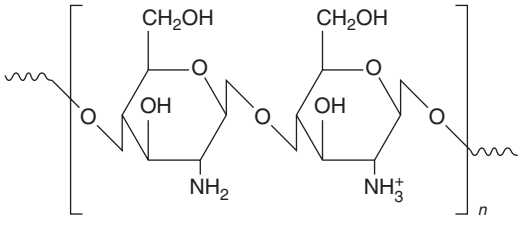

Figure 4 Chitosan [poly(*β*-(1-4)-D-glucosamine)].

membranes, sponges, rods, beads, and solutions. Consequently, the porous spongy chitosan matrices are excellent biomaterials for tissue engineering, especially artificial skin. When replacing skin, it is important that the substitute material completely adheres, wets, and conforms to the wound surface so as to prevent small air pockets where bacteria can proliferate. In addition, antibiotics and growth factors can be incorporated into the basic matrix.

The chitosan microspheres were found to be a very favorable form for parenteral controlled drug-delivery systems requiring low-acting drug delivery to the systemic circulation, as well as for active or passive targeting to the treatment sites. Several types of active reagents, such as DNA, Cyclosporine A, and insulin, have been encapsulated in chitosan nanoparticles. Chitosan membranes have good mechanical properties and are being evaluated for transdermal drug delivery.

With new biotechnology techniques, peptide analogs that are resistant to enzyme degradation have been prepared for oral drug delivery. However, their hydrophilicity and molecular size present problems with respect to absorption through tight junctions of the intestinal epithelium. Due to chitosan's mucoadhesive characteristics, it has the ability to partially open tight junctions and enhance the penetration of macromolecules across membranes, such as the intestinal barrier. Consequently, chitosan and its derivatives have been found to be very effective for oral peptide delivery systems.

Currently, chitosans are being investigated as nonviral gene-delivery vectors. However, when loaded with DNA at physiological and alkaline pH, they are insoluble. This originally presented a problem, but trimethyl quaternization has increased the soluble range of this system.

Polyhydroxyalkanoates

Polyhydroxyalkanoates (PHA)s are natural polyesters that are produced and stored by a wide variety of microorganisms. *Pseudomonades* are the most commonly known microorganism that produces and uses PHA as an intracellular energy reserve. When *Pseudomonades* are stressed under conditions of excess carbon substrates and limited essential nutrients, PHA is formed and stored as nodules that can be up to 90% of the organism's dry weight. Polyhydroxybutyrates (PHB) and polyhydroxyvalerates (PHV) comprise the majority of the bacterial polyesters produced in nature (**Figure 5**). These natural polyesters provide an important source of highly pure 3-D-hydroxybutanoic acid and 3-D-hydroxypentanoic acid, respectively. PHB has been developed as biocompatible

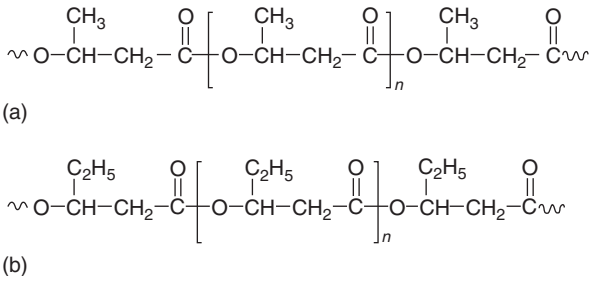

Figure 5 (a) Poly(hydroxybutyrate) and (b) poly(hydroxyvalerate).

and biodegradable materials based on properties such as low toxicity and degradation to 3-D-hydroxybutyric acid, which is a normal constituent in human blood. In addition, industries now have the technology to melt-process PHB materials into a variety of shapes and forms. These thermoplastic biopolymers can be produced as rigid brittle plastics, flexible materials, or strong elastomeric fibers.

Pure PHB or PHV are highly crystalline and brittle; however, their copolymers and composites provide materials that have more desirable properties such as enhanced rates of degradation and more flexibility. Consequently, PHAs have been developed for medical applications, such as sutures, artificial skin, drug delivery, and paramedical disposables. Currently, polyhydroxybutyrates are being investigated for bone-implants and bone-related treatments. It has been found that transected nerves heal and restore their function after being wrapped in thin PHB films.

These unique natural polyesters have not yet reached their full biomedical potential due to some biocompatibility issues. For example, on contact with blood, PHA induces platelet adhesion and subsequent thrombi formation. However, new composites are being developed, by combining PHB with poly(ethylene glycol) to form "natural–synthetic hybrid" block copolymers, that exhibit enhanced blood-compatibility as well as inherent bone-compatibility.

Aliphatic Polyesters

Aliphatic polyesters are derived from naturally occurring compounds, such as lactide (LA), glycolide (GL), and ε-caprolactone (CL). These represent an important class of biocompatible and biodegradable materials. Initially, the main application of these materials was for reabsorbable sutures. L-lactic and L-glycolic acids, commonly found in animal systems and in low concentrations, are nontoxic and readily absorbed by the host. However, pure poly(L-lactic acid) and pure poly(L-glycolic acid) are highly crystalline; consequently, they do not have good material properties, such as flexibility or degradability

(**Figure 6**). On the other hand, PLLA and PLGA copolymers and composites (mixtures) are amorphous and provide desirable properties such as tenacity, flexibility, and facile degradability. In addition, PLA/PGA copolymers can be "tailor-made" to meet the requirements of specific applications. Currently, these copolymers are being widely utilized as temporary scaffolds for the regeneration of tissues and as carriers to deliver bioactive molecules.

Poly(ε-caprolactone) (PCL) has a low melting point, high solubility, and an exceptional ability to form blends. Biodegradable PCL staples for wound closure are in clinical use in Europe. Studies have shown that ε-caprolactone and its copolymers are tissue-compatible and nontoxic. Semicrystalline PCL has good drug permeability and a very slow degradation rate. The requirements for optimal controlled drug release or mechanical properties for engineered tissue can be achieved through copolymering PCL with other monomers. When PCL is combined with amorphous PLA/PGA copolymers that have poor drug permeability, a much higher degradation rate is obtained.

These aliphatic polyester polymers usually degrade by hydrolysis, and to a lesser extent, by enzymatic processes in animal systems. Consequently, these materials have rapidly gained recognition in the area of tissue engineering. Here, cells and extracellular matrix components can be implanted into the porous scaffolds to make pseudo-anatomical shapes. Although approved by FDA, specific applications, biocompatibility, sterilization, and storage issues need further improvement.

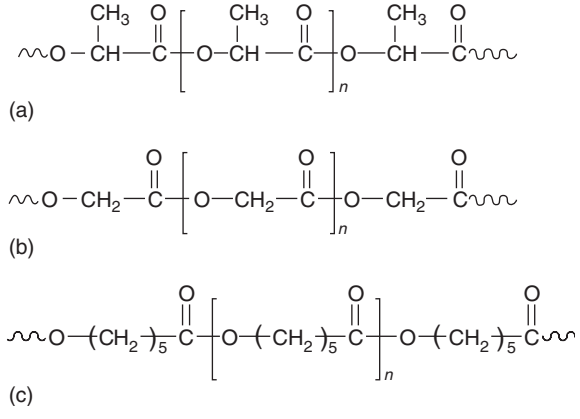

Figure 6 (a) Poly(lactic acid), (b) poly(glycolic acid), and (c) poly(caprolactone).

Current developments involve applications for bone, cartilage, and vessel engineering and for mechanically dynamic sites. Recently, unique biodegradable copolymer nanofibrous scaffolds were produced by electrospinning. The diameter of the fibers was approximately 500 nm with an aligned topography that mimics the orientation of cells and fibrils found in a native artery. This process provides an almost ideal tissue-engineering scaffold, especially for blood vessel engineering due to the nanometer-scale dimension that physically resembles the natural material but has the advantage of biodegradability.

Poly(ortho-esters)

Poly(ortho-esters) are unique polymeric structures that undergo degradation more rapidly than the aliphatic polyesters. In an aqueous environment, they undergo surface erosion and are able to release drugs at a constant rate. However, the degradation is not uniform and the acid that is released catalyzes a localized breakdown and causes the formation of local erosion forming large void areas. By varying the acidity and the amounts of neutralizing excipients incorporated into the polymer, the erosion rate can be controlled. Delivery systems are being produced for short-term applications such as oral 12–24 h applications, intermediate ophthalmic products lasting 1–7 days, and subdermal implants that last as long as one year or more.

Polyanhydride

Polyanhydride polymers are synthesized by dehydrating dicarboxylic acid functional monomers to form corresponding polyanhydride linkages (**Figure 7**). The anhydride groups in the polymer chain are very moisture sensitive and on contact with water rapidly hydrolyze to form carboxylic acid groups. Because of the hydrolytic instability of this linkage, these materials were developed as sutures, drug carriers, bioabsorbable prostheses, and vascular grafts. In general, they show some degree of crystallinity and most are soluble in common organic solvents. The decomposition rate decreases as the aromatic content and hydrophobicity of the polymer backbone is increased.

Well-defined and predictable degradation rates depend on the polymer composition and the size and shape of the implant. A unique feature of polyanhydrides is their ability to undergo uniform surface

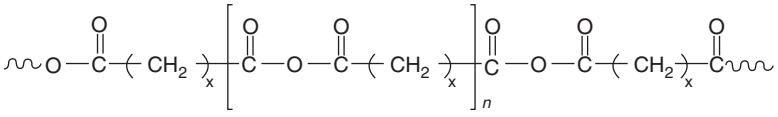

Figure 7 Polyanhydride.

erosion without additional additives to inhibit pitting and cavity formation. This increases performance predictability and decreases the presence of extraneous substances; both properties are highly desirable in controlled-release drug delivery, which is the most current application of this polymer system. Current investigations are under way to use polyanhydrides for controlled delivery of osteogenic proteins and insulin. Polyanhydrides and their degradation products have been shown to be neither mutagenic nor cytotoxic and were FDA approved in 1996 for local delivery of chemotherapeutics to brain tumors.

Polyphosphazenes

Polyphosphazenes are unique polymers with an inorganic backbone structure consisting of nitrogen–phosphorous bonds (**Figure 8**). By changing the side groups on the phosphorous, researchers can easily modify the bulk and surface properties of polyphosphazenes. The side groups can be amino, alkyl, aryl, alkoxy, aryloxy, inorganic, or organometallic units.

If both side groups on the repeat unit are identical, the polyphosphazene is homogeneous; if they are different, then the polyphosphazene is heterogeneous. Due to the facile modification of the polyphosphazene side chains, interesting new materials have been generated in order to develop inert biocompatible materials for use in cardiovascular and other biomedical devices as well as biological membranes and coatings. Currently, these polymers are being investigated as gene and drug-delivery systems. Several bioactive agents, such as, steroids, local anesthetics, catecholamines, and heparin, have been attached to the polyphosphazene side groups are being evaluated as a delivery system.

Nondegradable Polymers

Nondegradable polymers are materials that are not degraded in a biological environment. These materials are used in devices that are implanted for permanent use, such as joint prostheses, maxillofacial implants, and heart valves. Many of these materials are made by polymerization of vinyl groups ($-CH=CH_2$). These polymer structures include methyl methacrylate, polypropylene, and polyethylene and cyanoacrylates. Some are polyesters such as Dacron®. Other polymer materials include polyurethanes, silicones, and poly(ethylene oxide).

Polycyanoacrylates

Polycyanoacrylates are better known as "super glues" as they adhere to many different materials, such as metal, glass, wood, and tissue (**Figure 9**). Strong bonds are formed at room temperature in an aqueous environment without the need of adding a catalyst. The monomers polymerize very rapidly in the presence of weak bases such as water (moisture) or amino compounds. The higher alkyl cyanoacrylates, such as *n*-butyl cyanoacrylate, are more hydrophobic and, therefore, spread more rapidly on surfaces, polymerize more rapidly and degrade slower than methyl cyanoacrylate. In the body, these materials achieve hemostasis rapidly and bond to wet tissues strongly. Consequently, they are useful as bioadhesives.

However, due to adverse tissue response and production of tumors in laboratory animals, cyanoacrylates have not been approved for routine clinical applications. The current applications include surface wound dressing in dental surgery and ophthalmic surgical adhesives where monomers are applied directly to the tissue and almost instantaneously polymerize with strong adherence to the tissue. They are also being investigated as adhesives to stop bleeding of gastric varices – abnormally dilated and lengthened vessels. As the cyanoacrylate is injected into the varix, it forms a polymer plug that occludes the aperture in the vessel, which is eventually expelled into the lumen of the stomach. Cyanoacrylates have also been investigated as potential drug-delivery matrices. However, they have a tendency to induce significant inflammatory response at the implant site.

Polyurethanes

Polyurethanes are unique materials that offer the elasticity of rubber combined with the toughness and durability of metal (**Figure 10**). They are more commonly known as wood finishes that are more durable than varnish. For medical use, they can be manufactured as very strong and resilient products with good flexible and electrometric properties. Applications including artificial heart diaphragms, ventricular

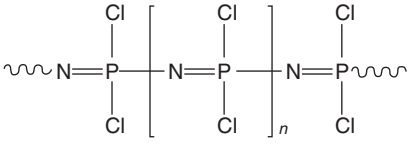

Figure 8 Polyphosphazene.

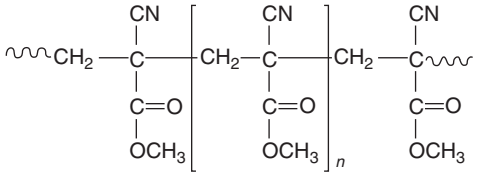

Figure 9 Polycyanoacrylate.

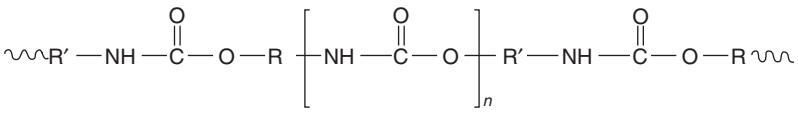

Figure 10 Polyurethane.

assist bladders, vascular grafts, mammary prostheses, and pacemaker leads.

Copolymers of urethane with monomers, such as esters, ethers, and ureas provide a wide range of mechanical properties that are suitable for tissue engineering and regenerative medicine. Polyurethanes have exceptional elasticity and flexibility that are extremely important qualities for soft tissue engineering and scaffolds. Porous, biodegradable, electrometric polyurethane scaffolds combined with the patient's own bone marrow have successfully facilitated bone regeneration. Studies show that polyurethane scaffolds induce crystalline calcium phosphate deposition similar to that formed in bone structure. When used in plastic and orthopedic reconstructive surgery, tissue ingrowth occurs with low acute inflammation. However, after several months these implants begin to show degradation. Poly(ether urethanes), however, are resistant to hydrolysis and are much less biodegradable.

Poly(methyl methacrylate)

Poly(methyl methacrylate) (PMMA) is an amorphous, transparent, and hydrophobic thermoplastic polymer that is very hard and stiff but brittle and notch-sensitive (**Figure 11**). PMMA, commonly known as "safety glass," is an "acrylate" with brand names such as Plexiglas, Diakon, and Lucite. Based on its strength, hardness, and adhesive qualities it is used in dentures, dental crowns, and caps.

It has excellent light transmittance and good abrasion and UV resistance, but poor low temperature, fatigue, and solvent resistance. It is, however, very biocompatible and was the original material used for hard contact lenses and intraocular lenses. Soft contact lenses evolved by substituting a $–CH_2–CH_2OH$ group for the alkyl methyl ester group which was engineered to form a hydrophilic hydrogel lens and other biorelated products.

Methyl methacrylate (PMMA) is used extensively as a medical adhesive. It is used as bone cement to secure prostheses, such as hip replacements and dental crowns. In orthopedic surgery, PMMA cement is injected into the collapsed vertebra to reconstruct back injuries. Although this procedure does not re-expend the collapsed vertebra, it seems to alleviate pain by reinforcing and stabilizing the fracture. PMMA is used extensively in maxillofacial augmentation to

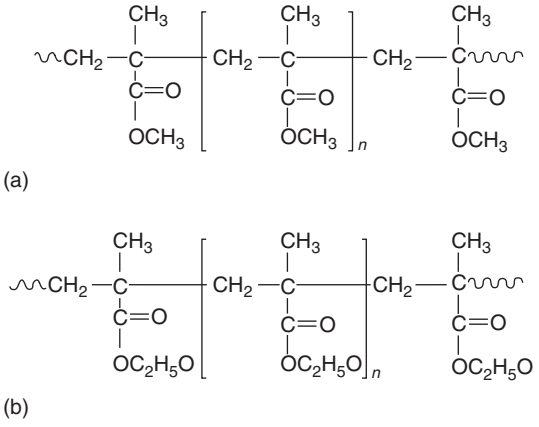

Figure 11 (a) Poly(methyl methacrylate) and (b) poly(hydroxyethyl methacrylate).

improve the skin contours and reduce depressions in the skin due to scars, injury, or lines. When applied in cosmetic surgery, PMMA is used as a suspension of polymer beads in a vehicle, such as bovine collagen (Artecoll®), hyaluronic acid (MetaCrill®), or other biocolloidal suspension.

Silicone

Silicone materials consist of repeating units of inorganic $–SiO_2–$ as the backbone structure, with methyl or other functional groups as –Si– side groups (**Figure 12**). These materials are biocompatible, very stable, nontoxic, and insoluble in body fluids. For medical applications, dimethylsiloxane is polymerized to form a silicone gel. Cross-linking the dimethylsiloxane polymer chains leads to the formation of silicone rubber-like elastomers.

High-viscosity silicone rubbers are used as tissue expanders. The more common applications of this material have been for maxillofacial, breast, chest, and calf augmentation. They are currently being evaluated for joint replacement and tendon reconstruction. Although silicone is considered biologically inert, it can elicit a mild foreign body reaction followed by tissue encapsulation. The use of silicone gels became controversial due to the concerns regarding monomer migration and toxicity as well as (unproven) human adjuvant diseases. These uncertainties lead to a limitation of the use of silicone gel implants by the FDA in 1992. Currently, silicone gel implants are being reevaluated and are

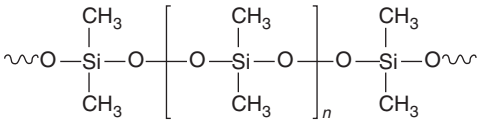

Figure 12 Silicone.

available only under specific guidelines for breast reconstruction.

Poly(ethylene oxide)

Poly(ethylene oxide) (PEO) is also known as poly(ethylene glycol) or (PEG) and is one of the few polymers that is approved by the FDA for clinical use (**Figure 13**). PEG compounds are nontoxic and nonimmunogenic as well as soluble both in water and polar solvents. In the pharmaceutical industry, the use of many drugs has been prevented or limited due to delivery and solubility problems. Getting a drug to target is a difficult task and failure to do so can produce serious toxic effects. Currently, the attachment of PEG to various drugs (also known as "PEGylation") is widely employed to enhance drug solubility and efficacy. PEGylation technology consists of linking PEG to a bioactive component. The resulting bioconjugate, when administered intravenously, is stable in the blood with enhanced drug delivery. The method of attachment may be with a permanent or a biodegradable linkage depending on the specific application. The solubility of the bioconjugate can be tailored since it is dependent upon the lipophilicity of the drug and the length of the PEG. Usually, the molecular weight of the PEG molecules used is between 200 and 20 000, and their shape can be either linear or branched. The *in vivo* half-life of PEG-bioconjugates in plasma is prolonged due to the larger molecular size of the PEG-conjugate, which diminishes the rate of renal excretion and distribution in the tissues.

In addition, PEG-bioconjugates can decrease antigenicity by masking the immune recognition of antigenic sites. This is known as a "stealth" component of the PEG-bioconjugates since they are not recognized by the immune system as a foreign material. Consequently, PEGulated drugs have become very important in the design of new pharmaceuticals due to the fact that they enhance bioavailability by increasing drug solubility, as well as increasing residence time in the body by increasing the size of the conjugate drug and so decreasing kidney elimination.

Pluronics®

Pluronics® represent an important class of biomedical polymers (**Figure 14**). They are unique materials

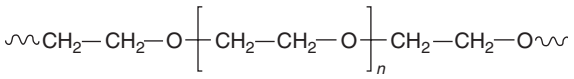

Figure 13 Poly(ethylene glycol).

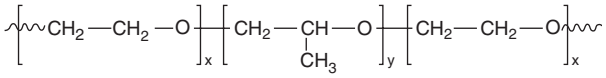

Figure 14 Pluronics $(PEO)_x$–$(PPO)_y$–$(PEO)_x$.

composed of triblock PEO–PPO–PEO copolymers of poly(ethylene oxide) (PEO) and poly(propylene oxide) (PPO). The pluronic PEO block is hydrophilic and water soluble while the PPO block is hydrophobic and water insoluble. In an aqueous environment, these block copolymers self-assemble into micelles with a hydrophobic PPO center core and a hydrophilic PEO outer shell that interfaces with water. Since these micelles are amphiphilic, they are able to accommodate lipophilic molecules in the central hydrophobic core area. Consequently, pluronic micelles are effectively used as drug carriers because their assemblies can act as passive drug containers. These assemblies deliver drugs into subcellular compartments by slowly releasing hydrophilic–hydrophobic encapsulated excipients into physiological fluids.

Pluronic micelles have many advantageous properties that include a relatively low *in vivo* toxicity and an appropriate size that restricts renal excretion. They provide the opportunity to deliver drugs from micelles in a spacial and temporal controlled manner with enhanced intracellular uptake via fluid-phase endocytosis rather than a passive diffusion. When drugs are encapsulated as pluronic micelles, their intracellular uptake by normal cells or drug-sensitive tumor cells is usually substantially reduced. This shielding effect is an advantage as it diminishes drug interaction with healthy tissues. Site-specific release of pluronic-encapsulated drugs can be activated under the influence of ultrasound with an enhanced penetration and retention effect that provides selective accumulation of the encapsulated drugs in solid tumor cells. The latter factor is important for overcoming drug resistance, which is a significant problem in cancer chemotherapy. In addition to sensitizing tumor anticancer agents and maximizing therapeutic outcomes, pluronic block copolymers also effect gene expression at the transcript level. The aggregation state of these micelle systems can be controlled by choosing the appropriate pluronic size and PPO/PEO block-length ratio. For example, pluronic P-105, which is often used in biosystems, has a molecular weight of 6500 and PEO/PPO repeat unit blocks of 37 and 56, respectively.

Summary

In summary, the application of biomedical polymer structures has become one of the most interesting and rapidly growing areas in polymer science with an annual economic growth of 5%. Based on current research results, conventional commodity polymers, such as poly(methylmethacrylate), polystyrene, polyethylene, and polypropylene, are being replaced with novel, high-performance materials. The design and synthesis of these exceptional polymer systems are providing new and more effective ways to enhance biocompatibility along with unique and efficacious bioapplications.

Biomedical Materials

J R Jones and L L Hench, Imperial College, London, UK

The Need for Biomedical Materials

Improving healthcare and technology are increasing life expectancy but as one ages the body parts cannot maintain their function. Tissues such as bone and cartilage are needed to support the aging body even though the cells that produce them become less active with age. The heart, kidneys, and liver have to operate for much longer than ever before. This entry discusses how biomedical materials and biophysics techniques are being used in the development of regenerative medicine procedures. The aim of regenerative medicine is to regenerate diseased and damaged tissue to its original state and function.

Bone Defects

Bone is a natural composite of collagen (polymer) and bone mineral (ceramic). Collagen is a triple helix of protein chains, a complex structure that has high tensile and flexural strength and provides a framework for the bone. Bone mineral is a crystalline calcium phosphate ceramic (hydroxyapaptite (HA), $Ca_{10}(PO_4)_6(OH)_2$) that provides stiffness and the high compressive strength of the bone. The two most important types of bone are cortical and cancellous bone. Cortical bone is a dense structure with high mechanical strength and is also known as compact bone. Cancellous or trabecular bone is an internal porous supporting structure present in the ends of long bones such as the femur or within the confines of the cortical bone in short bones. The trabecular bone is a network of struts (trabeculae) enclosing large voids (macropores) with 55–70% interconnected porosity.

The mechanism for natural bone generation/regeneration in the body is the secretion of extracellular matrix by osteogenic cells (osteoblasts), which have developed (differentiated) from stem cells. The extracellular matrix is collagen type I, which mineralizes to form bone mineral, creating a composite of orientated collagen fibrils and apatite. The bone is remodeled in response to its local loading environment by the body. Osteoclasts are cells that resorb old bone and bone that is not required (i.e., not under any load), while osteoblasts lay down new bone.

Osteoporosis is a disease where bone resorption occurs faster than new bone is produced, causing the trabeculae to become thinner which leads to a reduction in total bone density and strength. The disease eventually leads to fracture of bones especially in the hip, wrist, knee, and spine. At present, when osteoporotic fracture occurs in knees and hips, joint replacement is often required. Millions of orthopedic prostheses made of bioinert materials have been implanted, an example of which is the Charnley total hip replacement, which is heralded as one of the most successful surgical inventions.

Long-term monitoring of 20 000 Charnley joints has revealed that it has a survivability of 76% after 25 years implantation, that is, 24% of hip operations required revision surgery. Improved metal alloys, special polymers, and medical-grade ceramics are the basis for this success, which has enhanced the quality of life for millions of patients. Reasons for failure tend to be aseptic loosening of the femoral stem, where bone resorption occurred due to a mismatch in the Young's modulus of the bone and the metal stem. Many modifications and variations of the Charnley joint have been developed over the years, including coating the metal stem with a synthetic HA layer that can bond to the bone mineral in the bone; however, survivability studies are so far only medium term and have shown similar results to that of the Charnley prosthesis.

A New Direction

All present day orthopedic implants lack three of the most critical characteristics of living tissues: (1) the ability to self-repair; (2) the ability to maintain a blood supply; and (3) the ability to modify their structure and properties in response to environmental factors such as mechanical load. All implants have a limited lifespan and as life expectancy is continually increasing, it is proposed that a shift in emphasis from "replacement" of tissues to "regeneration" of tissues is required to satisfy this growing need for very long-term orthopedic repair.

One way to restore diseased or damaged tissue to its original state and function would be the successful engineering of the replacement tissue in the laboratory. In a typical tissue engineering application, cells would be harvested from the patient (i.e., osteogenic cells in the case of bone) and seeded on a synthetic scaffold that acts as a guide and stimulus for tissue growth in three dimensions creating a tissue engineering construct or living biocomposite. The biocomposite would then be implanted back into the patient. Over time, the synthetic scaffold should be resorbed into the body as nontoxic degradation products at the same rate that the cells produce their own extracellular matrix.

In this article, the development of scaffold technology is discussed, focusing primarily on porous glass scaffolds that bond to bone and the growth of bone and cartilage in the laboratory on such scaffolds. The biophysics techniques that are now being used to monitor cell behavior as the cells grow are also discussed.

Biomedical Materials

Any material that is implanted into the body should be biocompatible, that is, not cytotoxic (not toxic to cells). There are three classes of noncytotoxic materials; bioinert, bioactive, and bioresorbable. No material is completely inert on implantation, but the only response to the implantation of bioinert materials is encapsulation of the implant by the fibrous tissue. Examples of bioinert materials are medical-grade alumina, stainless steels, and high-density polyethylene that are used in the total hip replacements.

Resorbable materials are those that dissolve on contact with body fluids and the dissolution products can be secreted via the kidneys. The most common biomedical resorbable materials are polymers that degrade by chain scission such as polyglycolic (PGA) and polylactic acids (PLLA) and their co-polymers, which are commonly used as sutures.

Bioactive Materials

Bioactive materials stimulate a biological response from the body such as bonding to tissue. Bone is a natural composite of bone mineral (HA) and collagen and other proteins. Therefore, synthetic HA (with $Ca/P = 1.667$) and other calcium phosphate ceramics, including coral, have gained much attention as a bone mineral substitute.

There are two classes of bioactive materials; class B bioactive materials bond to hard tissue (bone) and stimulate bone growth along the surface of the bioactive material (osteoconduction). Examples of class B bioactive materials are synthetic HA and tricalcium phosphate ceramics. Synthetic HA has been used in

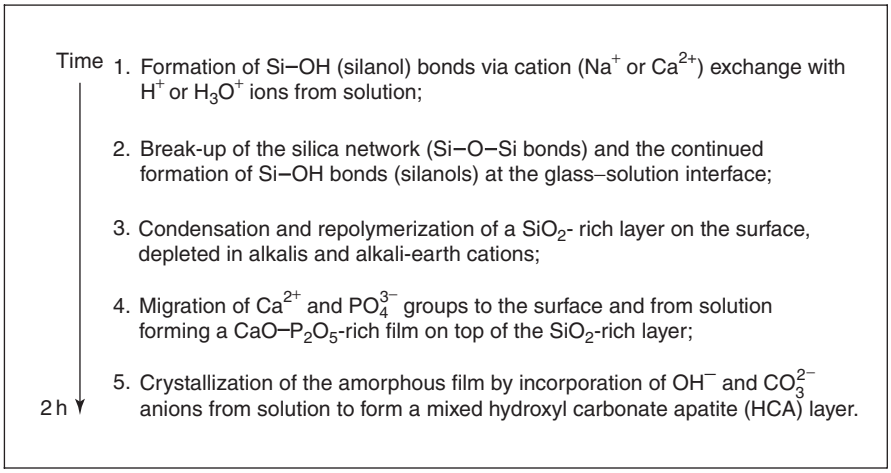

Figure 1 Mechanism of formation of the HCA layer on the surface of bioactive glasses in solution.

several clinical applications such as a bone defect filler and is used to coat the stainless steel or titanium alloy shaft of the total hip prosthesis so that it bonds to the thigh bone (femur). Tricalcium phosphate (β-TCP, with Ca/P = 1.5) is an osteoconductive material that is also resorbable in the body. β-TCP is usually used in conjunction with synthetic HA to improve the resorbability of HA in applications such as the filling of bone defects left by cysts, sinus floor augmentation, and bone cements.

Class A bioactive materials not only bond to bone and are osteoconductive but they are also osteoproductive, that is, they stimulate the growth of new bone on the material away from the bone/implant interface and can bond to soft tissue such as gingival (gum) and cartilage. Examples of class A bioactive materials are bioactive glasses. A certain composition of melt-derived bioactive glass (46.1% SiO_2, 24.4% Na_2O, 26.9% CaO, and 2.6% P_2O_5, in mol), called Bioglass® is used in the clinic as a treatment for periodontal disease (Perioglas®) and as a bone-filling material (Novabone®). Bioglass® implants have also been used to replace damaged middle ear bones, restoring hearing to thousands of patients.

The mechanism of bone bonding to bioactive materials is thought to be due to the formation of an HA layer on the surface of the materials after immersion in body fluid. This layer is similar to the apatite layer in bone and therefore a strong bond can form. The layer forms quickest on class A bioactive materials. The mechanism of formation of the HA layer on bioactive glasses is shown in **Figure 1**. Stage 1 involves release of cations. Stage 2 is the break up of the silica-based glass network. These two stages are dissolution processes; therefore, these glasses are not only bioactive but are also resorbable in the body. β-TCP ceramics are also resorbable.

Figure 2 shows suggested mechanisms for osteoproduction, where new bone grows on bioactive glasses away from the glass–host bone interface. The sequence follows on from the events in **Figure 1** but concentrates on the effects of the glass on the cells within the bone and bone marrow, however it does not fully explain osteoproduction. Recent findings by Professor Dame Julia Polak's team at the Tissue Engineering and Regenerative Medicine Centre at Imperial College, London, have shown that the dissolution products of bioactive glasses up-regulate seven families of genes that regulate osteogenesis and the production of growth factors.

Composites

To overcome the low toughness of HA, a polyethylene–HA composite was developed by Professor William Bonfield and colleagues at the University of London. It is clinically available under the name HAPEX™ and has been used as middle ear implants and orbital floor replacements. The polymer provides toughness strength and the HA increases the compressive strength and provides bioactivity so that implants are not encapsulated by scar tissues. The composite is class B bioactive and is easily shaped with a scalpel by the surgeon and so is now routinely used to replace the bones of the middle ear.

Scaffolds for Bone Repair

The Criteria for an Ideal Scaffold

To be able to regenerate the trabecular bone, a construct is required that will mimic the structure and mechanical properties of the trabecular bone and stimulate new bone growth in the shape dictated by the scaffold. Therefore, the scaffold should have a

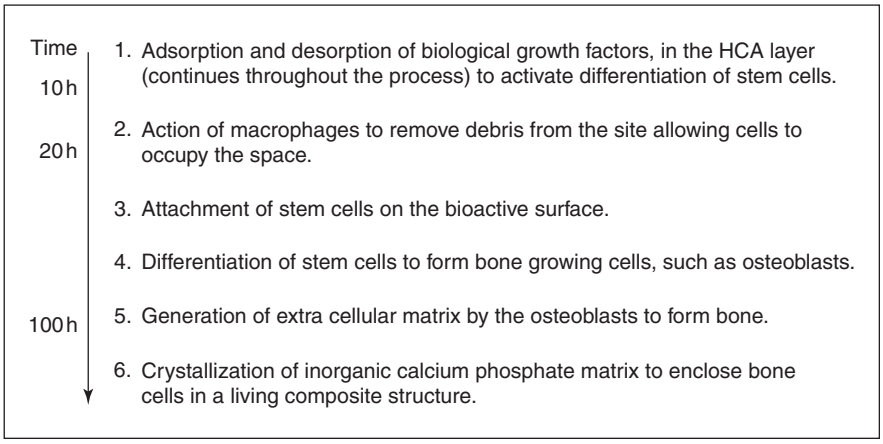

Figure 2 Suggested mechanism of cellular interactions between cells and bioactive glasses after implantation, after the formation of the HCA layer.

structure that acts as a template for tissue growth in three dimensions. The template must be an interconnected macroporous network containing pores with diameters in excess of 100 μm to promote cell migration, tissue ingrowth and vascularization, and nutrient delivery to the center of the regenerating tissue on implantation. The scaffold material should be able to bond to the host bone without the formation of scar tissue, that is, it should be made from an osteoconductive material. If the bone is to be restored to its original state, the scaffold should be resorbable so that eventually there is no trace of the scaffold's presence. The degradation rate of the scaffold must be controllable so that it can be tailored to match the rate of bone growth. The dissolution products would ideally influence the genes in the bone generating stem cells to stimulate efficient cell differentiation and proliferation. Importantly, the mechanical properties of the scaffold should match that of the host bone and not decrease too rapidly during degradation so that bone regeneration occurs at load-bearing sites.

If the scaffold is to be mass produced so that surgeons can use it in the clinic, it must be made from a processing technique that can produce irregular shapes to match that of the defect in the bone of the patient. It must have the potential to be producible to the required ISO (International Standards Organization) or FDA (Food and Drug Administration) standards and be easily sterilized.

The need for implant materials to pass the FDA standards may be necessary for the safety of patients, but it places a large financial obstacle in the path of new scaffold developments. Many researchers use materials that have already been passed by the FDA so that they are sure their scaffold will be safe for use in the clinic. They are unwilling to risk using materials that have not undergone FDA testing because of the time and financial commitment required for fulfilling the extensive tests.

Polymer Scaffolds

Resorbable polymeric scaffolds have been developed with porous structures similar to the trabecular bone. There are three reasons why much effort has been put into using polymers as scaffolds. First, polymers are easy to process in the shape of a 3D scaffold with a pore morphology suitable for a tissue engineering application with techniques such as phase separation, gas foaming, freeze drying, combined solvent leaching and extrusion, and computer-controlled rapid prototyping techniques. Polymer fibers can be woven together using textile processing techniques.

Second, polymers can have high tensile properties and high toughness. The mechanical properties of polymers can be controlled very easily by changing the molecular weight (chain length) of the polymer. Third, bioresorbable polymers have been successfully used as dissolving sutures for many years. Therefore, these degradable polymers, such as the esters PGA and PLLA, have passed FDA regulations and can be implanted into the body.

There are however some problems with using biodegradable polymers as scaffolds for bone regeneration. First, while a degradable scaffold is desired, sutures dissolve within 2 weeks of implantation, which is too rapid for bone regeneration applications.

Second, although resorbable polymers can be made with high tensile strength and toughness and their mechanical properties can be matched with collagen, their Young's modulus is much lower than that of bone, therefore these polymers cannot be used in load-bearing sites where they undergo compressive forces.

A third problem is that the mechanical strength of polymers decreases rapidly as they degrade. High tensile strength polymers have long chains (high molecular weight), which entangle with each other. As a tensile force is applied to the entangled chains, the chains begin to unravel until they become straight. The maximum tensile strength of polymers is reached when the chains are fully extended. Therefore, for a polymer to be tough, it must have a molecular weight over the entanglement value. The mechanism for degradation of biodegradable polymers is chain scission. The polymers undergo hydrolysis and the chains are cut in two. The average molecular weight of the polymer is therefore approximately halved with every chain scission event. The mechanical properties of the polymer are proportionate to the square root of the molecular weight and therefore decrease very rapidly as the polymer degrades. Biodegradable polymers have also been found to produce an inflammatory response due to the acidic by-products of the degradation.

Bioactive Ceramic Scaffolds

Ceramics are crystalline materials and tend to have high compressive strength and Young's modulus but low toughness, that is, they are brittle materials. Alumina and synthetic HA are ceramics that are most commonly used in biomedical applications. Alumina is a bioinert ceramic that is very hard and resistant to wear. It is therefore commonly used as a replacement to the ball of the femur in total hip replacement. Bioactive ceramics that have been used as bone regeneration materials are synthetic HA and β-TCA. Synthetic HA has been used most regularly because of its similarity to bone mineral; it has a similar structure and Young's modulus. β-TCP is similar to bone mineral in that they are both calcium phosphate ceramics, however β-TCP is resorbable.

In a porous form, HA and β-TCP ceramics can be colonized by bone tissue. A problem with introducing pores into a ceramic is that the compressive strength of the material decreases dramatically. The strength of the scaffold depends on the thickness and strength of the struts or pore walls. Generally, for the brittle compression of a foam

$$\sigma_{cr} \propto \rho_r^{3/2} \quad [1]$$

where σ_{cr} is the critical strength of the pore walls and ρ_r is the relative density, expressed as

$$\rho_r = \rho_b/\rho_s \quad [2]$$

where ρ_b is the bulk density of the scaffold and ρ_s is the skeletal (true) density of the material.

The simplest way to generate porous scaffolds from ceramics such as HA, is to sinter particles, preferably spheres of equal size. The scaffolds can then be pressed using cold isostatic pressing. As the sintering temperature increases, the pore diameter decreases, and mechanical properties increase as the packing of the spheres increases. Mechanical properties can be increased further by hot isostatic pressing (HIPing). High mechanical strengths can be achieved but the pore diameter is not high enough. Porosity can be increased by adding fillers such as sucrose, gelatine, and polymethyl methacrylate (PMMA) microbeads to the powder slurry, which burnout on sintering. However, this technique decreases the compressive strength to below that of the trabecular bone.

The majority of methods that are used to produce polymer foams cannot be applied to ceramic systems. However, a popular method for producing highly porous ceramics is to produce a polyurethane foam template that can be immersed in ceramic slurries under vacuum to allow the slurry to penetrate into the pores of the foam. The organic components are burnt out and the ceramic foams sintered (1350°C) producing a scaffold with interconnected pore diameters of up to 300 μm.

The ceramic slurries can also be foamed to obtain pores in the range of 20 μm up to 1–2 mm. The incorporation of bubbles is achieved by injection of gases through the fluid medium, mechanical agitation, blowing agents, evaporation of compounds, or by evolution of gas by *in situ* chemical reaction. A surfactant is generally used to stabilize bubbles formed in the liquid phase by reducing the surface tension of the gas–liquid interface. Surfactants are macromolecules composed of two parts, one hydrophobic and one hydrophilic. Owing to this configuration, surfactants tend to adsorb onto gas–liquid interfaces with the hydrophobic part being expelled from the solvent and a hydrophilic part remaining in contact with the liquid. This behavior lowers the surface tension of the gas–liquid interfaces, making the foam films thermodynamically stable, which would otherwise collapse in the absence of the surfactant.

The gel-casting method has been the most successful method used to produce macroporous bioactive HA ceramics with interconnected pores of greater than 100 μm in diameter. Suspensions of HA particles and organic monomers are foamed by agitation with the addition of a surfactant under a nitrogen atmosphere. *In situ* polymerization (cross-linking) of the monomers, which is initiated by a catalyst, creates a 3D polymeric network (gel). The porous gels are sintered to provide mechanical strength and to burnout the organic solvents. HA foams have been made with

compressive strengths in excess of 10 MPa, which is similar to that of trabecular bone. When the foams were implanted into the tibia of rabbits, bone partially filled the pores after 8 weeks and there was no inflammatory response. The compressive strength of the scaffolds that were colonized by bone trebled.

Hydrated silicon ($SiOH_4$) has been found to be a major contributor to the mineralization of bone and gene activation, which has lead to the substitution of silica (SiO_2) for calcia (CaO) into synthetic HA. *In vivo* results showed that bone ingrowth in silica-substituted HA granules was significantly greater than that into phase pure HA granules.

The disadvantages of an HA scaffold over a bioactive glass scaffold with similar morphology are that HA resorbs only very slowly, the dissolution products do not stimulate the genes in the osteogenic cells and HA is only osteoconductive as it generates bone at a slower rate than bioactive glasses. HA is still a bone replacement material rather than a regenerative material.

Bioactive Glass Scaffolds

Theoretically, gel-casting could be applied to melt-derived bioactive glass powders. However, bioactive glasses undergo surface reactions on contact with solutions to produce an HCA surface layer and it is desirable to have control over the reaction before a scaffold is ready for clinical use.

Sacrificial porogens and foaming agents have also been used to create melt-derived bioactive glass (Bioglass®) scaffolds. Large pores with diameters in the region of 200–300 μm were created but the total porosity was just 21% and there were large distances between pores, so this process failed to mimic the interconnectivity of the trabecular bone.

The most successful method for the production of bioactive glass scaffolds of similar structure to trabecular bone mineral is the foaming of sol–gel derived bioactive glasses. The sol–gel process involves polymer reactions of the glass precursors in a solution (sol). The sol is a solution of silica species that forms a gel by cross-linking together into a silica network. Sol–gel derived bioactive glasses tend to be more bioactive and resorb quicker than melt-derived glasses of similar compositions. The compositions of gel-glasses can also contain fewer components while maintaining bioactivity. This is due to them having a textural nano-sized porosity that is inherent to the sol–gel process, which provides a specific surface area of 150–600 $m^2 g^{-1}$, which is two orders of magnitude higher than melt-derived glasses. Along this surface there are many silanol groups that act as nucleation sites for HCA layer formation (**Figure 1**).

During the foaming process, air is entrapped in the sol under vigorous agitation as viscosity increases and the silica (–Si–O–Si–) network forms. A surfactant is added to stabilize the bubbles at short times. As the porous foam becomes a gel, the bubbles are permanently stabilized. The gel is then subjected to controlled thermal processes of aging (60°C) to strengthen it, drying (130°C), and thermal stabilization/sintering to remove organic species from the surface of the material (500–800°C). Bioactive glass foam scaffolds can contain macropores up to 600 μm in diameter, connected by pore windows with modal diameters in excess of 100 μm and compressive strengths up to 2.5 MPa. **Figure 3** shows a scanning electron microscopy (SEM) micrograph of a pore network of a typical bioactive glass foam. *In vitro* cell studies using primary human osteoblasts have shown the foams stimulate formation and mineralization of bone nodules within 2 weeks of culture (**Figure 4**). **Figure 4** shows osteoblasts that have attached to the concave surface of the pore. The cells have proliferated, coating the pore in an organic layer, and have released extracellular matrix, which has mineralized to form bone mineral. *In vivo* studies have shown that foam scaffolds implanted on rabbit crania stimulated new bone growth at a similar rate to that of the melt-derived bioactive glass powder available commercially.

Spectroscopy and Biophotonics

Vibrational spectroscopy is one of the most common techniques to study the surface reactions of bioactive materials. It is nondestructive, rapid, and can be used to analyze small areas of a sample surface. The two most commonly used vibrational spectroscopy

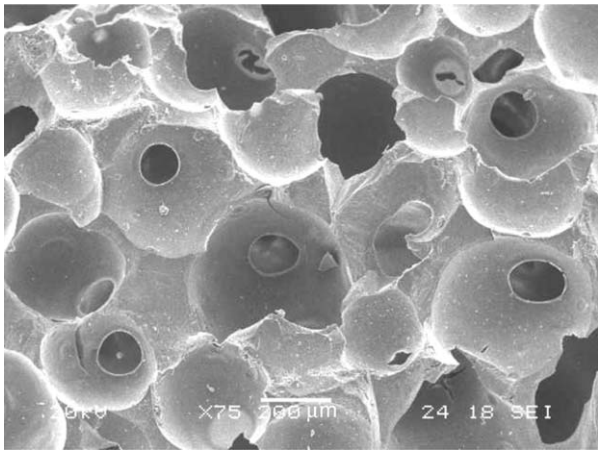

Figure 3 Scanning electron micrograph of a bioactive glass foam scaffold.

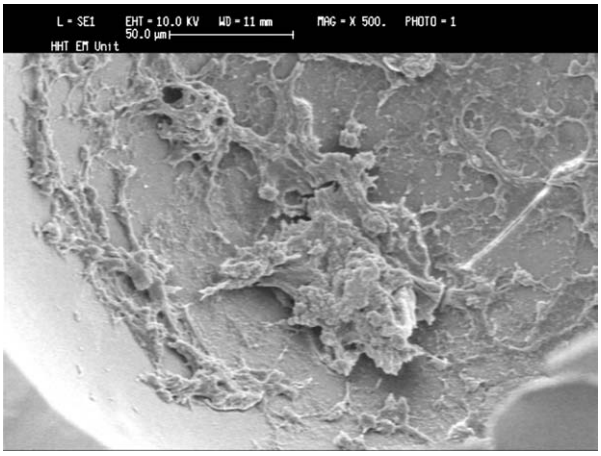

Figure 4 Scanning electron micrograph bone cells and mineralized bone extracellular matrix in a pore of a bioactive glass foam scaffold. (Courtesy of J Gough.)

techniques are Fourier transform infrared spectroscopy (FTIR) and Raman spectroscopy.

Fourier Transform Infrared Spectroscopy

FTIR spectra have been used to determine the rate of formation of the HCA layer on bioactive glasses and the technique is used as a quality assurance (QA) test for bioactivity. FTIR spectra of the glass surface area usually taken after a glass sample has been reacted in simulated body fluid (SBF) and dried. The crystalline HCA layer is characterized by the P–O bending vibration bands at 560 and 604 cm^{-1} (infrared wave number). Stretching and bending vibration bands for the amorphous silica network are also present in the spectra. The relative intensity of the bands can be used to monitor growth of the layer as a function of time. **Figure 5** shows FTIR spectra of three forms of the sol–gel derived bioactive glasses of the 58S composition (60 mol.% SiO_2, 36 mol.% CaO, 4 mol.% P_2O_5) that were soaked in SBF for 2 h. The spectra show that the HCA layer thickness was thicker for the powders and foams with respect to the monolith. Although FTIR can be used for the characterization of dried materials after soaking or after implantation and removal, *in situ* measurements are hindered by the strong adsorption of water in the infrared region.

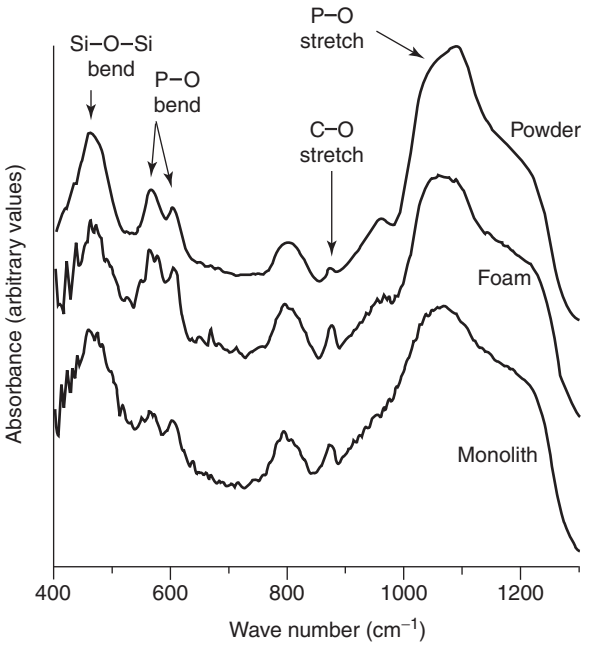

Figure 5 FTIR spectra for 58S glass powder, foam, and monolith after 2 h immersion in SBF at 37°C and 175 rpm agitation.

Bio-Raman Spectroscopy and Biophotonics

Raman spectra are fingerprints of the chemical composition of the material. Raman spectra are obtained by collecting electromagnetic radiation that has been scattered by molecules (Raman effect). The spectral shifts depend on the vibrational frequencies of the molecules. The low Raman signal and low Raman scattering of water, and the combination of Raman spectroscopy with optical microscopy (water immersion objectives) has allowed noninvasive *in situ* monitoring of cells in cell culture. This technique is called micro-Raman spectroscopy. The optical objective provides high spatial resolution and is used to locate the cell or part of the cell, such as the cytoplasm or the nucleus, from which a spectrum will be collected. A laser is then fired at the identified area and the scattered photons are collected by a detector.

Low scattering efficiency of the cells makes the measurement of Raman shifts difficult. Raman signals can be enhanced using UV lasers; however, high-powered lasers can denature the cells and change cell phenotype. Decreasing the laser power decreases the Raman signal, but reduces the risk of changes to the cell. A laser wavelength of 785 nm has been found to produce optimal *in situ* spectra of living cells. A single spectrum obtained from the nucleus of a cell can contain information about the protein and DNA content of the cell. **Figure 6** shows a Raman spectrum of a cultured lung cell containing vibrational bands corresponding to DNA (A, G, T, C adenine, guanine, thymine, cytosine), BK: backbone, RP: ribose-phosphate and the proteins phenylalanine (Phe) and tyrosine (Tyr). Raman spectroscopy using 785 nm lasers can be used to monitor the biochemical changes taking place in a cell. During cell death, for example, the degradation of proteins, DNA breakdown, and the formation of lipid vesicles can be detected in real time.

Cells cultured on bioactive materials can also be monitored by *in situ* Raman spectroscopy. A

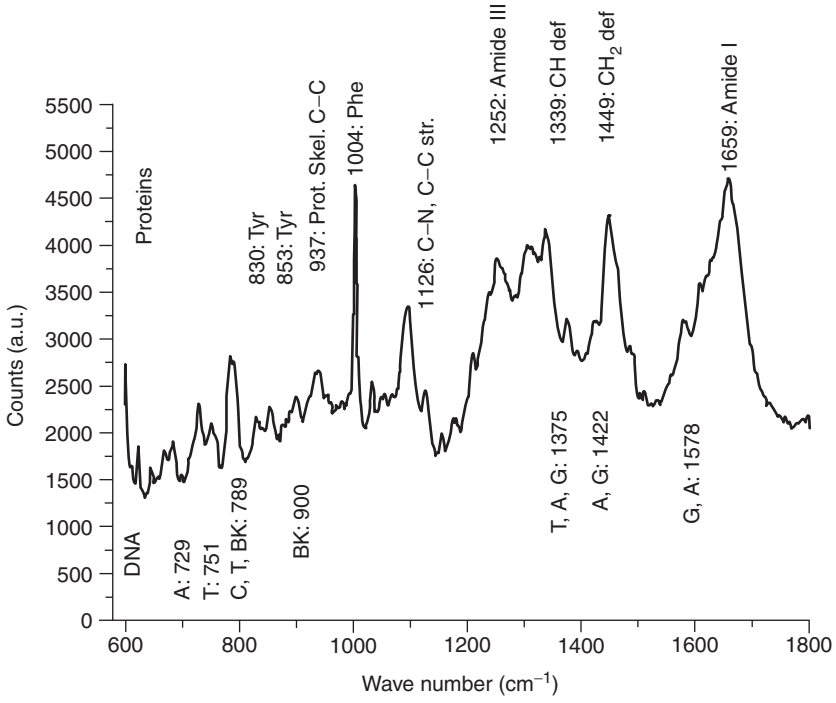

Figure 6 Raman spectrum of a cultured living lung cell. (Courtesy of I Notingher.)

background spectrum for the unreacted material can be subtracted from the spectrum of a cell on the material. The resultant spectrum will then also contain vibrational bands corresponding to the formation of any calcium phosphate layer on the surface of the bioactive material as a function of time.

Raman spectroscopy may hold the key for the *in situ* monitoring of bone cells growing on scaffolds. When acquisition techniques and interpretation of the spectra are perfected, the micro-Raman spectrometers can be linked to bioreactors and the effect of flow rates, growth factors, and dissolution products on cell behavior can be monitored in real time.

Summary

Numerous materials have been developed to replace living tissues. They are bioinert (stainless steel, alumina), bioresorbable (polyglycolic acid), or bioactive (synthetic HA and bioactive glasses). New biocomposites have been made that combine bioinert and bioactive properties. The latest generation of materials are used in combination with cells. Many techniques have been employed to produce porous scaffolds. The scaffold that most closely matches the criteria for an ideal scaffold and that most closely mimics the structure of the trabecular bone is the bioactive glass foam. However, these scaffolds do not yet have the mechanical properties to be directly implanted into load-bearing sites. Ideally, a bioactive glass/polymer foam composite would be developed with improved toughness. The properties of a scaffold must be optimized with respect to the cell response to the scaffold. Biophotonics techniques such as Raman spectroscopy have the potential to be able to monitor cell activity and intracellular processes of living cells in real time noninvasively.

Biomembranes

F Bordi and C Cametti, Università degli Studi di Roma "La Sapienza," Rome, Italy

Introduction

A biomembrane can be considered as a barrier of highly selective permeability that allows and regulates the traffic of a myriad of different molecular species between the interior of the cell and its surrounding environment (as, e.g., in a plasmatic membrane), or between different compartments within the same cell (e.g., in the membrane of the different organelles). Its basic structure is formed by a bilayer of amphiphilic molecules, the most common of which are three different classes of lipids (glycerolipids, sterols, and sphingolipids). On the extracellular side, this bilayer couples to a glycocalix, a carbohydrate network composed of oligosaccharides believed to be responsible for cell–cell recognition and adhesion. On the intracellular side, the bilayer couples to the cytoskeleton, that contributes to the mechanical properties of the overall composite structure.

The main functions exerted by a biomembrane can be summarized as follows: (1) the membrane is a selective filter which controls the transport and the permeation of ions, molecular aggregates, and even large particles between the extracellular medium and the cytosol; (2) the membrane is the site for energy producing processes and for hormone signal transduction; (3) the membrane acts as receptor for extracellular signals and mediates the communications between intra- and extra-cellular media; and (4) the membrane can perform mechanical tasks as in cellular motion or in eso- or endo-cytosis processes.

These demanding tasks are fulfilled thanks to a very complex, yet in principle, surprisingly simple, basic structure based on two-layered sheets of lipid molecules held together by a delicate balance between hydrophobic and hydrophilic interactions (**Figure 1**). The first important fact is that this is a self-assembling structure. The balance between a favorable interaction of the hydrophilic polar heads of the lipids with the aqueous solvent and the unfavorable hydrophobic interactions of their aliphatic chains, represents the driving force to the spontaneous formation in an organized closed structure. Due to hydrophobic/hydrophilic interactions, the lipid molecules arrange themselves into two-faced leaflets (the double layer) with the hydrophobic

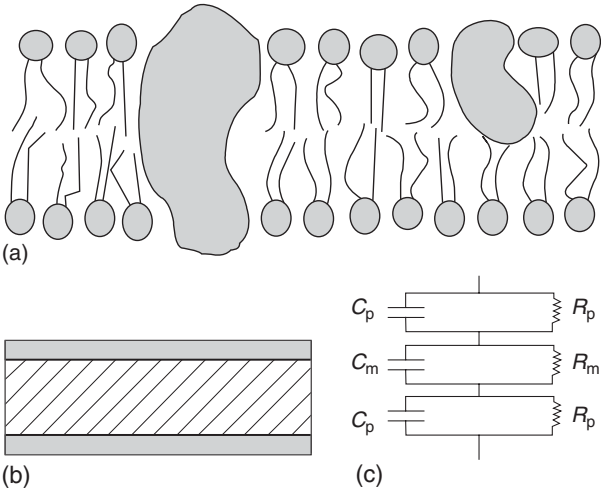

Figure 1 A sketch of a biological cell membrane as seen by a chemist ((a) a lipid bilayer with membrane proteins) and by a physicist ((b) a hydrophobic layer covered by a hydrophylic interface). (c) The passive equivalent circuit of a plasmatic membrane. C_p, R_p and C_m, R_m represent the capacitance and resistance per unit surface of the hydrophilic and hydrophobic regions, respectively.

moiety in the inside and "polar heads" on the outside, representing the interface with the aqueous environment. The presence of lipids of different shapes (different volume ratios of the hydrophobic/hydrophilic moieties) in the two leaflets stabilizes the radius of curvature of the double layer.

The second important aspect is that, being mainly stabilized by "structure-solvent" effects, without strong "links" between different molecules, the bilayer is a highly dynamic structure, where lipids (and proteins) can flex, rotate, and diffuse laterally, as in a "two-dimensional" fluid. The lipid distribution results from a continuous inward and outward movement between the two monolayers, the lipid asymmetry being maintained by specific mechanisms that counterbalance the concentration-driven transbilayer permeation (**Figure 2**). The lipid bilayer has often been considered, in the past, as a passive structure and only recently, more attention is being directed towards its implications in a variety of membrane biological functions.

Due to its peculiar structure, the overall shape of the membrane during the biological functionality can be easily changed, for example, during pseudopodia movement or eso-/endo-cytosis processes. In endocytosis, in particular, after a region of the membrane has surrounded the particle to be introduced within the cell, it detaches from the rest, forming a vacuum that can move within the cytoplasm. The whole process is reversed in eso-cytosis, when a substance has to be expelled from the cell. These processes well illustrate the "modularity" of the membrane structure, that can easily lose or acquire parts to accomplish particular tasks.

Among the enormous variety of possible lipids, only a few classes are used to build up a biomembrane. Lipids that exert a predominantly structural role can be grouped into three categories: sterols (e.g., cholesterol), phospholipids (e.g., phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), sphingomyelin (SPHM)), and sphingolipids (cerebrosides, glycolipids). Lipids with a predominantly functional role are: phosphatidylinositol, phosphatidic acid, and many types of gangliosides.

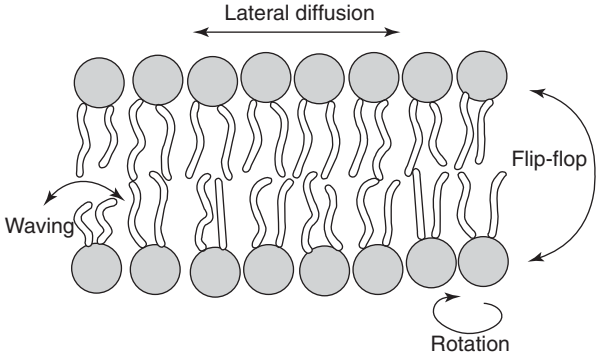

Figure 2 Movements of phospholipids in bilayers. The lipid distribution results from lateral diffusion, flip-flop, waving and rotation movements between the two leaflets of the membrane.

The lipid composition of different cell types shows great differences and within the same cell, the plasma membrane, the nuclear envelope, mitochondria, and other membranous organelles and structures have different lipid compositions. Depending on the cell type, proteins constitute 20–80% of the membrane mass. Nevertheless, by comparing the average molecular weight of lipid molecules (in the range 700–1000 Da) and the typical molecular weight of a protein (in the range of the order of tens of thousands Da), lipids are the more abundant components in terms of molar concentration.

Membrane proteins are usually divided into two classes, "intrinsic" and "extrinsic" ones. This differentiation is mainly based on the greater or lesser difficulty in separating the fraction of the protein of the two classes from the other membrane components by organic solvent extraction. However, intrinsic proteins are generally considered more deeply embedded into the nonpolar environment (the interior of the lipid double layer), while extrinsic proteins are assumed more "at the surface" or even simply adsorbed at the double-layer interface. However, most intrinsic proteins possess specific sites that are exposed to the aqueous environment on one, or on both the sides of the membrane.

The thickness of a lipid bilayer can be estimated in the range of 4–6 nm. However, in estimating the thickness of a real biological membrane, the fact that proteins and many lipids (glycolipids) bear groups that extend into the aqueous medium, has to be taken into account. This region (glycocalix), at the outer surface of the plasmatic membrane, is typically 10–100 Å thick.

Membranes of cells and organelles are sometimes corrugated and folded or show protrusions of different shape and size. For example, the needle-like protrusions of the plasmatic membrane of some cells (microvilli) typically measure 50–200 nm in diameter and may extend for several hundreds of nanometers and even more.

Functional Cell Membrane Domains and Influence of the Cytoskeleton on the Organization of the Cell Membrane

One intriguing issue in membrane biophysics is the presence within the plasma membrane of lipid

microdomains, termed rafts, which are believed to be essential for its complex activity. Although the present view of structural organization of a biological membrane is still deeply indebted to the fluid-mosaic model proposed by Singer and Nicholson in 1972, consisting of a fluid-lipid bilayer where lipids and proteins are more or less randomly distributed, recently a considerable amount of experimental work suggests that biomembranes are not laterally homogeneous, but floating domains with distinct lipid and protein composition. However, it is not yet completely understood what the mechanism at the molecular level is, that determines the composition of these domains and what their precise functional roles are. Moreover, in addition to the random motion predicted by the fluid mosaic model, a variety of lateral transport modes exist for several membrane proteins.

Microdomains have been detected in certain lipid mixtures, for example, PC and cholesterol, that exhibit coexisting liquid phases under definite conditions of temperature, lateral pressure, and composition. In this case, the size of membrane domains ranges from several hundred lipid diameters (100–200 nm) to one micrometer.

The biological membrane system where the existence of lateral domains has been now evidenced with certainty, is the plasma membrane of mammalian cells. In living cells, raft domains appear to be very small and probably heterogeneous. This may explain why they have escaped direct visualization by microscopical techniques. Indirect evidence for small rafts was obtained using single-particle tracking of the thermal position fluctuation, showing that raft-associated membrane proteins are stably associated to a small cholesterol-dependent lipid assembly of ~ 50 nm in diameter.

In this case, domains are lipid and protein supramolecular complexes which include, for example, multimers of receptor molecules or receptor and effector molecules that are thought to be the first trigger for the cellular reactions that follow ligand binding. Moreover, there are specialized membrane domains, such as synapses, caveolae, and cell–cell and cell–substrate adhesion structures, where specific proteins and lipids are assembled together to carry out specific functions.

The domain distribution does not cover the whole membrane area, and domains (rafts) are in dynamic equilibrium with more homogeneous and fluid membrane regions. These domains are thought to form because they represent the energetically most favorable packing of the membrane components. However, these rafts should be considered as being "soft" structures that, despite a high degree of local order, do not have a long-range order.

Where the fluid-mosaic model fails is in the assumption of a uniform protein distribution within the double layer. Limiting ourselves to the transport within the membrane, a great deal of evidence has now been accumulated, showing that a variety of 'intra-membrane' movement modes exist for membrane proteins. In addition to the simple Brownian diffusion assumed by the fluid-mosaic model, membrane proteins also appear in a stationary phase and experience different diffusion modes: directed diffusion, confined diffusion (the particle can diffuse freely but within a restricted area), diffusion in a harmonic potential well (this is, e.g., the diffusion mode experienced by a protein bound elastically to the cytoskeleton).

In particular, single-particle tracking techniques, together with a careful theoretical and statistical analysis of the particle tracks, have shown that the plasma membrane is compartmentalized with regard to lateral diffusion of transmembrane proteins although, in many cases, inter-compartmental hopping diffusion is observed.

The relationship of lipid rafts to the zones detected by single-particle tracking, where proteins do not experience free diffusion (transient confinement zones (TCZs)) is still controversial. The membrane lipid composition and, in particular, the abundance of cholesterol appears to have an effect on TCZ abundance. However, experimental evidence, the observed 'hopping' between different zones, in particular, indicates that trapping cannot simply be ascribed to particles encountering a much more viscous region, and suggests that some types of barriers are involved.

To account for the presence of these barriers, two models have been already proposed. These models, of course, do not exclude each other and some combinations of them occur. In the first model, which has been given the suggestive title of "membrane-skeleton fence model," the membrane skeleton provides the barrier to the free diffusion of membrane proteins. The idea is that the space between the membrane and the cytoskeleton is too small to allow the cytoplasmic portion of any membrane protein to pass. The membrane compartment would hence ensue from a steric hindrance, and would be different for proteins that extend differently into the cytoplasm. The hopping diffusion between adjacent compartments should result from the combination of two favorable conditions. As a result of the dynamic properties of the cytoskeleton, the distance between the membrane and the skeleton may fluctuate (the membrane skeleton probably dissociates and reassociates from the membrane in a dynamic equilibrium). In this way, the membrane protein molecules that have sufficient kinetic energy and that approach the compartment boundaries will be able to cross the

barrier. This model has received strong support from experiments on red blood cells. It has been observed that an impaired cytoskeleton (as it is found in erythrocytes of patients affected by different forms of hereditary hemolytic anemia) causes an enhancement of the lateral diffusion of "band 3" protein, a typical transmembrane protein of erythrocyte membrane, while its rotational diffusion remains practically unaffected.

In the second model, TCZs would be delimited by the presence at their boundaries of a high concentration of "obstacles." The protein confinement within a small zone should result from a repeated bouncing of the protein between the obstacles, in a sort of "pinball effect." The obstacles could be membrane proteins directly linked to the cytoskeletal network. This mechanism may justify the transient confinement of proteins that are known not to have parts in the protrusion into the cytoplasm and that, for this reason, cannot directly interact with the cytoskeleton.

Also, the directed diffusion of membrane protein has been ascribed to two different mechanisms. Analogous to contractile movements that allow cell locomotion, the first mechanism involves the concerted action of a number of molecular motors to move entire regions of the cortical cytoskeleton and, with it, patches of cross-linked membrane proteins.

Moreover, a protein can in principle undergo directed diffusion exploiting the skeleton fence mechanism again, with elements of the cytoskeleton tracing a sort of corridor underneath the membrane, within which the protein can freely diffuse.

Membrane Electrostatics

Biological membranes carry a great number of polar or ionized groups. The net charge is usually negative, because most of the membrane proteins and all charged natural lipids have their isoelectric point below neutral pH (in human blood, e.g., physiological pH must be maintained within narrow limits ~ 7.4). The charge density is not usually very high, typically less than $0.05\,\mathrm{C\,m^{-2}}$ (corresponding to about 1 elementary charge on a surface of $250\,\text{Å}^2$) and much lesser than the charge density in artificial lipid double layer, where the surface charge density can reach values as high as $0.25\,\mathrm{C\,m^{-2}}$ (1 elementary charge per $50\,\text{Å}^2$).

From an electrical point of view, a biomembrane can be considered as an extremely thin ($\sim 50\,$Å) hydrophobic isolating interface between two conducting phases. The passive electrical behavior of a membrane can be described as an R–C element network, whose specific capacity C_s is given by $C_s = \varepsilon_0\varepsilon_s/d$ and the specific conductance G_s by $G_s = \sigma_s/d$, where ε_s and σ_s are the membrane permittivity and the membrane conductivity, d the membrane thickness, and ε_0 the dielectric constant of free space. For a normal cell membrane, different experimental procedures yield $C_s \simeq 1\ \mu\mathrm{F\,cm^{-2}}$ and $G_s \simeq 1\ \Omega^{-1}\,\mathrm{cm^{-2}}$ that, assuming a membrane thickness $d \approx 80\,$Å allows one to evaluate the membrane permittivity and the electrical conductivity to be of the order of $\varepsilon_s \simeq 5$ and $\sigma_s \simeq 10^{-4}\ \Omega^{-1}\,\mathrm{cm^{-1}}$.

Fixed surface charges give rise to an electrostatic surface potential that, in turn, results in the formation of a diffuse electrical double layer. An accumulation of charged species near the membrane surface influences the transmembrane transport mechanisms. The conformation and function of many molecules is generally affected by electrostatic fields. As a consequence, the membrane charged surface acts as a catalytic site and, besides the transmembrane transport, the changes in the surface charge can also influence recognition and other biochemical reactions that take place at its surface.

Using as an obligatory starting point the Poisson–Boltzmann equation with the exponential space charge density expanded to the first order in the electrostatic potential, the electrostatic potential Φ, and consequently the space charge density ρ, in the simplified case of a 1 : 1 valent electrolyte solution, can be calculated as a function of the distance from the membrane surface (assumed as an infinite plane) from the expression (Gouy–Chapman theory)

$$\Phi(x) = \frac{2k_BT}{e}\ln\frac{1+\gamma e^{-kx}}{1-\gamma e^{-kx}} \qquad [1]$$

Here, γ is a constant that depends on the electrostatic potential calculated at the surface Φ_0

$$\gamma = \tanh\left(\frac{e\Phi_0}{4k_BT}\right) \qquad [2]$$

and k is the Debye constant

$$k = \left(\frac{2\rho_\infty e^2}{k_BT\varepsilon_0\varepsilon_r}\right)^{1/2} \qquad [3]$$

that depends on the ionic force of the solution. k_BT is the thermal energy.

In eqn [3], ρ_∞ is the electrolyte concentration far away from the surface. The Debye length can be considered approximately as the thickness of the diffuse double layer at the membrane surface. Equation [1] combined with the boundary condition $d\Phi/dx|_{x=0} = -\sigma/\varepsilon_0\varepsilon_r$ gives the following relation, connecting the potential Φ_0 and the surface charge

density σ

$$\sigma = \sqrt{8\rho_{\infty}\varepsilon_0\varepsilon_r k_B T}\,\sinh\left(\frac{e\Phi_0}{2k_B T}\right) \qquad [4]$$

It must be considered that, in the case of biological membranes, the charge cannot be considered, not even approximately, homogeneously distributed on a flat surface. Charges are, in part, borne by the groups attached to the lipid head groups and to the surface proteins that extend into the solution, forming the glycocalix. The thickness of this zone is often comparable with the electrical double-layer thickness obtained from eqn [3]. Consequently, the charge should be considered distributed tri-dimensionally within a layer at the membrane surface, and not with a bi-dimensional distribution. Besides all the approximations of the model, this is another reason for taking the values calculated in the framework of the Gouy–Chapman theory with some warning. Models based on Bogolyubov–Born–Yvon–Green or Ornstein–Zernike equations, together with a suitable closure relation, give a better description of double-layer behavior and characteristics, but at the cost of a more complicated formalism. In the understanding of the electrokinetic phenomena that take place at the membrane surface, the Gouy–Chapman theory often gives helpful hints as a working model, provided that the higher-order effects, mainly arising from ion–ion interactions and from the nonuniform, tri-dimensional charge distribution, are negligible.

Across many biological membranes exists an electrostatic transmembrane potential also, $\Delta\Phi$, that is, a difference in the electrostatic potential between the two surfaces of the membrane.

Different ion-surface affinities lead to the formation of a nonuniform layer of ions more or less intimately associated with the membrane surface. This affinity can be different in the two surfaces of the membrane and contribute to the transmembrane potential.

Another contribution stems from the "dipole potential" that arises from the dipole moment of the membrane constituents, in particular from the headgroups of (zwitterionic/charged) lipids, the carbonyl groups of their hydrocarbon chains, and from the interfacially bound water layers.

However, when the electrolyte composition at the two membrane sides is different, the main contribution to the transmembrane potential comes from the Nernst diffusion potential. To the first approximation, Nernst potential is proportional to the logarithm of the ratio of the concentrations on the two sides of the membrane, according to

$$\Delta\Phi_N = \frac{k_B T}{ze}\ln\left(\frac{c_1}{c_2}\right) \qquad [5]$$

Such a transmembrane potential is found in almost all living cells.

The efficiency of the membrane as a barrier to the passage of charged molecules is mainly due to the high energy cost of transferring a charge from the aqueous environment into the apolar core of the membrane. Membrane pores or the formation of ion-carrier complexes can reduce this energy requirement dramatically. The membrane surface electrostatics plays a role in transmembrane transport by affecting the interfacial ion concentration and by increasing the probability of a pore or an ion-carrier complex formation.

Experimental Techniques

A large variety of experimental methods for the study of the biomembrane structure and dynamics have been developed, the most important of which are nuclear magnetic resonance (NMR), electron spin resonance (EPR), patch clamp, and Langmuir–Blodgett technique, single-particle tracking, radiowave dielectric spectroscopy, and many more. A brief survey on the applicability to the membrane of each of them follows.

Single-Particle Tracking

In "single-particle tracking," the membrane molecular species whose diffusion has to be investigated is marked by specifically bound colloidal gold particles or by fluorescent molecules. The concentration of these probes is kept very low, in such a way that only few of them appear within the field of an optical microscope, equipped with a digital camera. From a statistical study of deviations from a purely diffusive Brownian motion, information on membrane structure and particle–particle interactions can be obtained. In a different approach, known as "fluorescence correlation spectroscopy," the analysis of the motion of individual molecules is replaced by the analysis of the time-averaged fluctuations of the fluorescence signal, deriving from a very small volume, at the membrane surface. The requirement of selecting the signal from a volume small enough to make fluctuations observable is fulfilled by using a confocal optical microscope. In this way, an "open" volume optically selected $\sim 10^{-15}$ l, in which molecules can freely go in and out, can be investigated.

Patch Clamp

Electrical currents flowing through the cell membrane can be measured by means of a particular technique known as "patch clamp" developed in the early 1970s by B Sakmann and E Neher, who for their research in this field obtained the Nobel Prize in

physiology in 1991. A microelectrode of suitable size can be obtained by rapidly pulling a glass capillary with an inner diameter of one millimeter or less in size, intensely heated in the middle (a specially designed "puller" has been devised to this scope). The capillary ultimately breaks into two hollow spikes at the tip, with a diameter of a fraction of a micrometer. The rim of the hole on the tip is then polished and smoothed with a microforge. These "micropipettes" are filled with a suitable electrolyte. The micropipette is then implanted through the membrane into the cell. Two metal electrodes, one within the micropipette and the other in the bathing solution around the cell, connected to a picoamperometer, allow the measurement of the electrical current flowing through the membrane. In appropriate configurations, the current through the membrane of the whole cell or through "patches" cut from the cell membrane can be measured. In the last case, it is possible to measure the current flowing through an individual protein channel. With this technique, the protein channels responsible for the selective transport of different ions and charged molecules have been identified and their properties studied thoroughly, discovering, for example, that many of them are controlled by the voltage difference across the membrane (voltage-gated channels). Two different electrical arrangements are usually employed. In the "current-clamp" technique, the current is kept constant and the voltage recorded. In "voltage-clamp," conversely, the voltage is kept constant and the current is the measured signal. Voltage-clamp results are more suitable for very low-current intensities and in studies on voltage-gated channels, where the voltage level is used to control the opening and closing of the channel.

Langmuir–Blodgett Film

A suitable model of a biological membrane is represented by a lipid monolayer, where the nature and the packing of the lipid molecules, the composition of the subphase, and the temperature can be chosen without any limitation. The main characteristics of these systems consist in their homogeneity, stability, and planar geometry, with lipid molecules undergoing a well-defined orientation, providing a bi-dimensional system.

Langmuir monolayers are produced by dissolving at the air–water interface, a known amount of the amphiphile under investigation in a Langmuir trough. After volatile solvent evaporation, the monolayer extension is compressed by two movable barriers and monitored with the surface-pressure area isotherms, that is, a plot of the change of the surface pressure as a function of the area available to each molecule at the aqueous interface. The lowering of the surface tension at the interface caused by the presence of the amphiphile is given by $\Pi = \gamma^0 - \gamma$, where γ^0 and γ are the surface tension in the presence and in the absence of the amphiphile. Π is a measure of the surface pressure needed to prevent the film from spreading. At very low pressure, Π obeys a two-dimensional equivalent ideal gas law

$$\Pi A = k_B T \qquad [6]$$

where A is the area occupied by each molecule and $k_B T$ the thermal energy.

These monolayers undergo a surface potential due to the group dipole moments of the film-forming molecules. By considering the monolayer as a parallel plate condenser, comprising a sheet of uniformly distributed dipoles, the surface potential ΔV is given by

$$\Delta V = \frac{4\pi N_0 \mu_n}{\varepsilon_r A} \qquad [7]$$

where N_0/A represents the array of N_0 dipoles by area A and μ_n the normal component of the dipole moment per molecule. The potential of a monolayer-free subphase is taken as reference. The measurement of the surface potential can be carried out by the ionizing electrode method or the vibrating plate method. In the first case, the ionization of the air above the film, induced by an α-emitter, allows the potential difference between two electrodes, above and below the aqueous subphase, to be measured. In the latter, the vibrating electrode of one of the plates of a condenser generates an alternating signal that can be measured using a high-gain amplifier.

NMR and EPR Spectroscopies

A good picture of the characteristics of lipids and protein motion in membranes can be derived from both EPR and NMR techniques. In EPR, the study of the conformational flexibility of the membrane involves the use of spin labels containing an unpaired electron available to observe transition between different energy levels induced by the presence of the external magnetic field. Spin labels of different structures have been used to probe the behavior of lipid hydrocarbon chains in the membrane.

NMR spectroscopy can provide information about the structure and dynamics of membrane proteins at a molecular level and, in particular, the molecular arrangement in the bilayer. For example, because of the anisotropy nature of the bilayer, the order parameter, related to the quadrupole splitting arising in a ^{2}H-NMR spectrum, measured at different positions

in the alkyl chain, offers a detailed picture of the molecular bilayer arrangement. During the past decade, considerable advances in both NMR and computational methodologies have taken place, opening up the possibility of investigating structural and dynamic properties of systems that may not be suitable for crystallography. NMR can reveal dynamic information about regions of macromolecular structure, and conformation or structural changes that occur as a result of ligand binding. For example, by the ^{31}P-NMR method, the fraction of the phospholipid molecules at the outer leaflet of the bilayer can be determined. Moreover, dynamical parameters such as rotational and translational diffusion coefficients, the rate of conformational changes, the activity of membrane embedded proteins up to interactions between membranes and other macromolecules can be appropriately investigated.

Radiowave Dielectric Spectroscopy Technique

Dielectric spectroscopy in the radiowave frequency range furnishes a valuable method to investigate the electrical properties of a biological cell membrane, both concerning the structural properties (charge and dipole moment distribution) described by the permittivity, and the dynamical properties (ionic transport across the membrane) described by the electrical conductivity. The method takes advantage from the fact that, due to the different electrical parameters associated with the intracellular medium (the cytosol), the extracellular medium and the membrane, a well-defined dielectric dispersion appears, generally centered $\sim$1–10 MHz. The analysis of this dispersion, both on the basis of specific dielectric models of a biological cell suspension and on the basis of a phenomenological approach, results in the evaluation of some characteristic parameters, particularly the permittivity and the electrical conductivity of the cell membrane, which describe the structural and functional behavior of the membrane. This method, that, from an experimental point of view requires the measurement of the electrical impedance of the sample under investigation, has been applied to a variety of biological cell suspensions and the parameters associated with the cell membrane have been determined.

Biomolecules, Scanning Probe Microscopy of

C Ascoli, CNR-Istituto Processi Chimico Fisici, Pisa, Italy

Introduction

The relevance of microscopy for science, and in particular for biology, has always been clear. In the famous talk of Feymann, given at Caltech for the annual meeting of the American Physical Society in 1959, the requirement of a better microscope for biologists was strongly underlined. The possibility of high-resolution probe microscopy was also clear for the physicists. The use of local probes to illuminate and/or to detect light in a near-field configuration was first proposed in 1928 by Synge, who later suggested the use of piezoelectric actuators. The actual possibility of measuring subatomic movements or distances by piezoelectric actuators was experimentally proved in 1971 by measuring the evanescent light on the surface of a prism placed in the condition of total reflection.

Scanning tunneling microscopy (STM), was first realized in 1982 and, subsequently, many different types of scanning probe microscopy (SPM) techniques followed, which are now used extensively. Clearly, the widespread development of SPMs was made possible by the easy use of personal computers.

The general structure of each SPM is similar: a thin local probe, placed close to the sample (at a distance of the order of the resolution), scans the sample and a quantity that depends on an interaction between the probe and the sample is measured. It is then reported in a plot $f(x,y)$ in a color scale or with a three-dimensional (3D) perspective. Virtually each kind of interaction between the protruding tip of the probe and the sample can originate a

particular SPM, but the key for high resolution is always the steep dependence of the measured quantity on the tip–sample distance. A steep dependence, with space constant of the order of 1 Å or less, as for STM, implies that at short distances the predominant interaction is between the most protruding atoms on the two sides, and then atomic resolution is possible. The most relevant SPM techniques, in particular for the biological systems, are discussed briefly below.

STM is based on the quantum tunnel effect. In quantum mechanics, electrons are described by a wave function. The Schrödinger equation implies that the wave function is not zero beyond a potential barrier even if the electron energy is lower than the barrier itself. Thus, in quantum physics, particles have a nonvanishing probability to be found beyond a potential barrier, in a region forbidden by classical physics: this is known as the tunneling effect. In STM, a sharp conducting tip (the probe) and a conducting sample are separated by an insulator (e.g., a vacuum gap). By the tunneling effect, electrons have some probability of passing from the tip to the conducting sample. When a difference of potential (typically between 1 mV and 1 V) is applied between the tip and the sample, a tunnel current (typically between 0.1 and 10 nA) runs through the insulator for working distances of the order of angstroms. **Figure 1** shows schematically how to get images by measuring the tunneling current: piezoactuators move the sample in the *xy* plane and the tunneling current, measured and stored in a computer, changes according to the underlying surface.

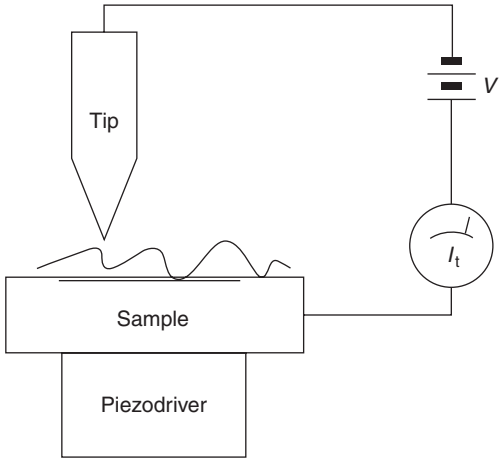

Figure 1 Scheme of STM. The tunneling current I_t flows from the tip to the sample because of the applied bias potential V. The piezodriver moves the sample forward and backward along the x direction; at the end of each line, it makes a step in y. The measured current I_t changes according to the tip–sample distance and gives tunneling current maps of the surface.

Atomic force microscopy (AFM) was developed some years later by Binnig, Quate, and Gerber. AFM is based on mechanical interactions: a small flexible cantilever, with a tip on the sample side, is carried in contact with the sample and makes a regular scanning of the surface. While doing so, the cantilever deflection changes according to the surface profile. The measured deflections (or other equivalent signals) give information on the sample topography and on other local features. An AFM essentially works as old phonographs did, but the difference in scale implies a fundamental difference. For instance, the meaning of "contact," which is clear on a macroscopic scale, is rather undefined on the atomic or nanometer scale. This holds for each SPM, and in order to get a better understanding of what is possible to measure, it is required to consider, in some detail, the interaction between the probe and the sample.

AFM can easily work in water solution, namely, in the normal conditions for biological molecules. Under appropriate conditions, STM can also work in liquids.

Another SPM technique, which necessarily works in ionic solution, is scanning ion conductance microscope (SICM). It was initially proposed by Hansma and co-workers, and it is based on the idea of using, as a scanning probe, a pipette-shaped microelectrode of the type employed by electrophysiologists for intracellular recording (the radius of the tip is of the order of hundreds of nanometers). The current flowing in such a probe is limited when the electrode is in the proximity of a nonconducting (or only partially conducting) object, typically the membrane of a cell. After some years of latency, this kind of microscopy is now applied successfully to living cells, with very interesting results. Two points have been of crucial importance for the development of SICM. One is the use of a small modulation of the tip–sample distance; the other is the coupling with classical electrophysiological experiments. The use of a position modulation allows for a better stabilization of the tip–sample distance (particularly critical at cellular scales). Combining this technique with other microscopies or with electrophysiological recordings, it is possible to observe the time evolution of submicrometric cellular structures and the localization of specific ion channels on the cell surface.

The scanning near-field optical microscopy (SNOM; also called NSOM, PSTM, and by some other names, according to different experimental configurations), the first one conceptually proposed, uses various kinds of proximal probes. By using proximal probes to collect light, or as sources of local lighting, it is possible to overcome the half-wavelength limit of the classical optical microscopy (Abbe or Rayleigh criterion). In fact, the Rayleigh criterion

is not a stringent theoretical limit. It takes into account only the propagating components of the electromagnetic field, which are commonly called "far-field components" and are those involved in traditional optical devices. However, light diffracted, refracted, or reflected by small objects contains more information than its propagating part; for instance, very close to a narrow slit, the light intensity obviously mimics the slit profile. The working distance and the probe used are very important for the resolution. Frequently, tapered optical fibers with a metal coating opened on the tip and suitably modified AFM cantilevers are employed. Moreover, apertureless probes (gold nanoparticles, quantum dots down to single molecules) are also in use now. Spatial resolutions up to a few tenths of nanometers have been reached. SNOM is also used experimentally to obtain nanolithography; its specificity in biological systems is connected with its capability to detect fluorescence of single molecules with spatial resolution.

The AFM Microscopy

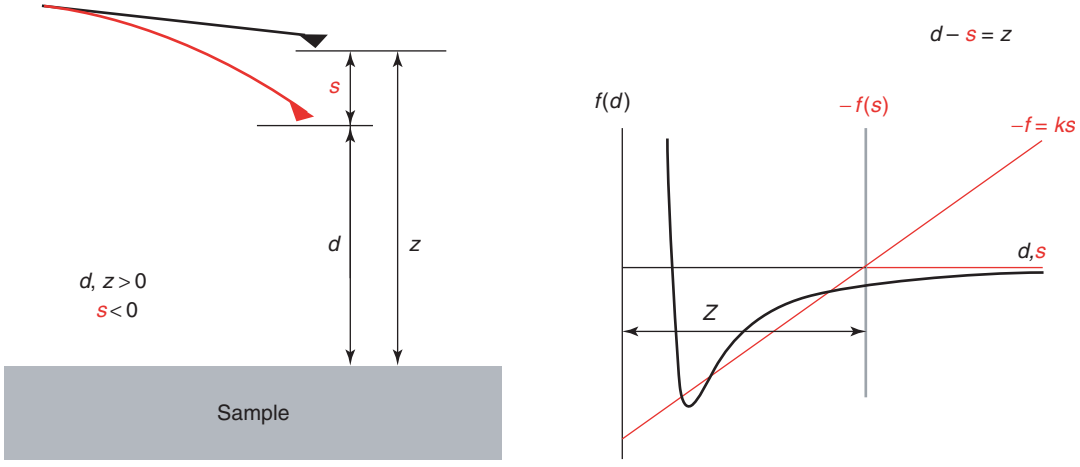
AFM can be considered as an extension of the sense of touch, in all its aspects. Through fingers one is able to perceive the relieves on a surface, to evaluate if it is smooth or rough, compliant or stiff, and how sticky it is. Accordingly, by an AFM it is possible to measure topographic relieves, the local elasticity and plasticity of a body, the friction between the sample and the tip and their adhesion, etc; but all this is now on a nanometer scale and sometimes on an atomic scale.

With regard to the atomic resolution available with AFM, it should be noted that most of the older data show atomic lattices with no well-defined atomic-scale local defects, while STM data clearly show the presence of defects at the atomic level. A partial answer to this issue is that a typical radius of curvature of the tip ranges 5–50 nm, while typical lattice constants are of the order of a few angstroms, so that in the tip there are a number of atoms that interact simultaneously with the sample surface. This number increases when a strong force is applied, because of the deformation of the tip. The force acting on the tip is the composition of the forces due to each single interacting atom. The periodicity of the lattice can be detected, because during the scanning the force due to each interacting atom on the tip has the lattice periodicity. So the tip vertical displacements reproduce the lattice period and not the profile of single atoms. However, it has been proved that, working at distances where repulsive and attractive forces balance, the interaction of the most protruding atom is enhanced. In this case, true atomic resolution has been achieved by AFM, revealing atomic-scale defects.

Forces between Tip and Substrate

Interactions between single atoms obey the Lennard-Jones (LJ) potential. The LJ potential is characterized by two terms: the attractive one, due to the van der Waals forces, acts on a relatively long range, while the repulsive term becomes most important at short distances. For AFM tip–substrate interaction, it is to be taken into account that the number of significantly interacting atoms varies with the distance. Far from the sample, many atoms on the tip and on the surface are in a significantly equivalent situation and contribute equally to the attractive force, while, as the tip approaches the sample, only the most protruding atoms on the two surfaces are relevant in the interaction. This implies that at a short distance, the main contribution comes from the repulsive force between the two nearest atoms on the two sides, while at greater distances the resulting attractive force is due to the integration on many atoms. Therefore, an LJ-like potential, with increased attractive forces, is expected to hold and actually is able to account for the basic features of experimental force–distance curves. **Figures 2** and **3** outline a graphical method to obtain the force–distance curves from an LJ-like potential. Let z be the distance (controlled by the piezodriver) between the resting position of the tip and the sample, d the actual tip–sample distance, and s the deflection of the cantilever. Which deflection and distance are realized for a given z can be determined by assuming that the elastic force of the cantilever (shown in red in **Figure 2**) balances the LJ-like force. Depending on the value of the cantilever elastic constant k, the intersection between $f = -ks$ and the LJ force can have more than one solution, as shown in **Figure 2**, where two stable solutions and an intermediate unstable solution occur. This determines two typical discontinuities in the experimental $F(z)$ force–distance curves, as shown in **Figure 3**. The "jump to contact" occurs during the approach when the attractive force suddenly pushes the cantilever down. The "jump off contact" occurs while retracting the tip from the sample. After the "jump to contact," the tip and the sample move together (for an ideally rigid sample) and this region of FD curves is called contact line. The tip–sample adhesion force is measured by the "jump off contact" height and, as discussed above, can be simply due to the unstable equilibrium between the LJ force and the elasticity of the cantilever. However, adhesion is due also to different chemical or physical reasons. For instance, the adhesion in air is very high for the meniscus formed because of the water adsorbed on the surfaces.

Actually, real force–distance curves give much more information than that predicted from the schematic



z Distance between sample and cantilever resting position

d Tip–sample distance

s Cantilever deflection

Figure 2 (a) Schematic representation of cantilever and sample relative position. The sign of *s* is assumed negative when the cantilever is deflected down (attractive force), so $z = d - s$. (b) Lennard-Jones force (black curve) and cantilever elastic force (red curve with the vertical axis inverted) are reported as functions of *d*. The elastic force, given by $f_{elastic} = -ks = kz - kd$, is zero for *d* equal to *z*, that is controlled by the piezodriver. The cantilever deflection is obtained by the balancing of Lennard-Jones and elastic forces, and is given by the ordinate of the intersection of the two graphs, where $f_{LJ} = -f_{elastic}$. Three possible solutions occur in the graph above. Multiple solutions disappear for the cantilever with *k* greater of the maximum slope of LJ force.

discussion above. By suitably choosing and preparing the cantilever, tip, and sample, the aspecific adhesion does not mask other interactions, and it becomes possible to measure forces between molecular partners (specific adhesion) or unfolding of proteins. In biological systems, the measurement of the force required for unfolding and the force responsible for chemical bonds involved in biological functions is very stimulating, as will be discussed below in some detail.

Nevertheless, AFM was originally considered mainly as a microscopy, namely as a tool to get images. The different ways to get and to handle AFM images are discussed next.

AFM Scheme and Operating Modes

The most-used scheme for detecting the deflection of an AFM cantilever is schematized in **Figure 4**: a Gaussian laser beam is focused on the back of the cantilever and the reflected light is collected by a four-quadrant photodetector, so the displacement of the laser spot gives a signal proportional to the cantilever deflection or torsion, and hence to the interacting force. In particular, with a properly mounted detector, the deflection signal is given by

$$I_D = (I_1 + I_2) - (I_3 + I_4)$$

with $I_{1,2}$ the upper-quadrants signal and $I_{3,4}$ the lower-quadrants signal, while

$$I_T = (I_1 + I_4) - (I_2 + I_3)$$

gives a measure of the torsion of the cantilever, proportional to the friction the tip encounters while scanning the sample.

The signal-to-noise ratio depends basically on the photodetector shot-noise, whose spectral density is given by

$$i_N = \sqrt{2eI\Delta f}$$

where *e* is the charge of the electron, *I* is the generated photocurrent proportional to the laser intensity, Δf is the detection band. The important elements in determining the sensitivity of this detection method are the dimensions of the light spot reflected by the cantilever, which are due to the diffraction induced by the cantilever on the beam.

In analogy with STM and other SPMs, AFM could operate either at constant height or at constant force (**Figure 5**). In the constant-height mode, the piezodriver moves the sample in the *xy* plane maintaining it at a constant *z* and the cantilever deflections are acquired. It is possible to employ this mode only on very flat surfaces, since steep steps can

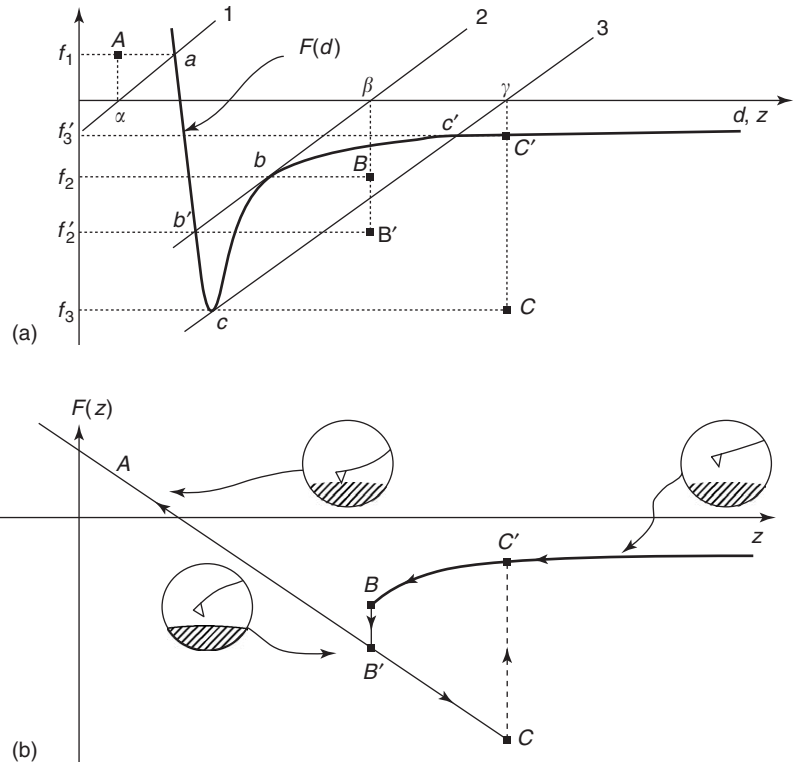


Figure 3 Graphical method to obtain experimental force–distance curves from the Lennard-Jones force F_{LJ}. In (a), lines 1, 2, and 3 represent the elastic force for three different values (α, β, γ) of the height z. The intersection of these lines with F_{LJ} determines the value of the cantilever deflection s. A single solution is possible for line 1 (intersection a), two solutions for lines 2 and 3 (intersection points b and b' and c and c'). Lines between 2 and 3 (not drawn) have three intersections with F_{LJ}. While the tip approaches the sample, the solution moves from c' to b (the corresponding forces can be read on the vertical axis following the dashed lines and range from $f_{3'}$ to f_2); further, approaching the tip and sample, the solution will jump from b to b'. During the withdrawal, a bigger jump will occur from c and c'. (b) Force vs. distance curve during the cantilever approach to and retract from the sample, obtained from the graphs in (a). In the insets, a representation of the cantilever deflection is shown for different positions. (Adapted from Cappella B, Baschieri P, Frediani C, Miccoli P, and Ascoli C (1997) Force-distance curves by AFM. *IEEE Engineering in Medicine and Biology* 58–65.)

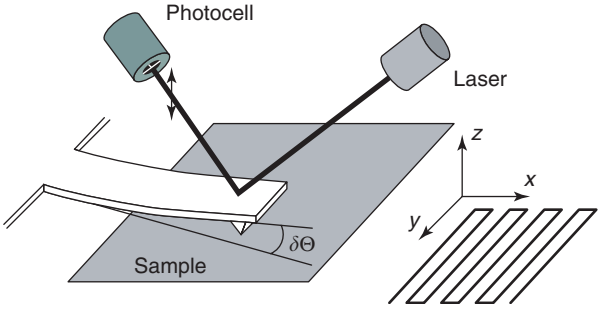

Figure 4 Left – Poggendorf detection method. A laser beam focused on the free end of the cantilever deflection is reflected on a four-quadrant photocell. When the cantilever deflects an angle $\delta\Theta$, the balance between the upper and lower quadrants of the position-sensitive photodetector changes proportionally to $\delta\Theta$. The cantilever deflection can be stabilized by a feedback which moves the sample holder on the z axis. Right – an illustration of the raster scanning of the surface.

cause breaking of the tip or damage of the sample. The use of the constant-force mode is more common. In this mode, the cantilever deflection is maintained constant via a feedback controlling the height z of the piezodriver. This mode decreases the imaging speed because of the limited response time of the feedback loop.

In the constant-force mode, it is usual to acquire the height signal (i.e., the z signal) as well as the so-called error signal. In fact, although the tip deflection is stabilized by the feedback, small deflections of the cantilever occur (they are the error signal). The error signal behaves as the derivative of the height signal along the scanning line and it is useful to enhance the borders of small objects and to highlight periodic patterns, when they are not immediately visible on the topographic images. The error-signal images are like the sample surface lighted by a lateral source.

The height signal is a direct measurement of the sample topography, which, however, depends on the applied force via the local elastoplastic properties of the surface. Generally, AFM images are represented as color-scale 2D images. When represented in

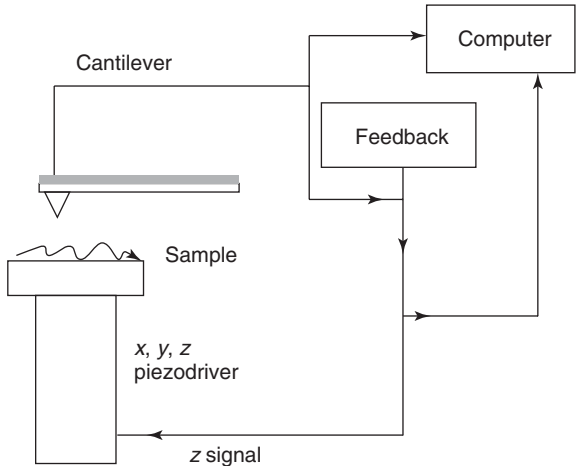

Figure 5 Scheme of an AFM setup. The deflection is used as input for a feedback loop that stabilizes it at a preset value. The output of the feedback controls the voltage that moves the piezodriver in the *z* direction. Both cantilever deflection and feedback output are sampled and stored by the computer.

perspective (3D images), it is easier to appreciate details that are lost in the flat rendering.

During scanning, the cantilever is deflected, but lateral forces, which depend mainly on the tip–sample friction, also twist it. The measurement of the cantilever torsion makes it possible to obtain friction maps, which give an information qualitatively different from the topographic one. Friction maps have been one of the first steps in the direction of obtaining chemical or the so-called spectroscopic information in AFM microscopy. A deep discussion on the tribology at a nanoscopic level is due to Bhushan and others (see the "Further reading" section).

When working in contact, as described above, the friction force can damage soft samples. A possibility of reducing friction forces is achieved in the "tapping" mode. In this mode, the cantilever is maintained in oscillation orthogonal to the sample at a frequency close to its resonant frequency. When approaching the sample, the oscillation, measured via a photodetector, is progressively limited by the sample contact. A feedback loop keeps the oscillation amplitude constant by adjusting the sample height *z*.

Since the tip touches the sample for a very limited time, there is basically no friction and the risk of damaging the tip or sample is greatly reduced compared to the contact mode. Furthermore, beyond the height information obtained from the feedback, in AC mode it is possible to use the phase signal. In fact, the oscillation phase varies during the scan compared to that of the drive signal, and this phase difference is determined by the local elastoplastic properties of the investigated sample. Thus, the phase image contains information on the sample composition.

Sample Preparation

A key step to get good images by AFM is sample immobilization. Graphite and mica and other inorganic materials can be simply glued to the support, but cells or cell fragments or large molecules, such as DNA, require specific preparation of the support to be firmly attached. Glass and mica are the most-used supports. Mica must be freshly cleaved and glass must be cleaned from contaminants, mainly hydrocarbons (e.g., with a detergent or via exposure to UV light). There are many methods for getting the biological samples firmly attached to the support and are based on the knowledge of their interactions with the surface and with the solution where they are suspended. Various ways to firmly anchor the sample to the support are:

- the glass surface may be chemically modified, as in the case of silanized glass, to cause covalent bonding between support and sample;
- coating the support with poly-L-lysine (the support surface becomes positively charged and cell plasma membranes, usually negatively charged, adsorb on it); and
- adjusting the pH and valence of the electrolyte solution can ensure the attachment.

The last of the above methods is possible due to the fact that biological macromolecules are usually charged, and their charge and isoelectric point depends on pH. The same is true for the support surface. Charged surfaces induce counter-ions around them and thus the formation of electrical double layers. A chemical–physical theory of colloidal stability (DLVO theory, developed by Derjaguin–Landau and Verwey–Overbeek) may be applied in order to determine the buffer conditions necessary to obtain a net attractive force as the result of the van der Waals attraction and double-layer repulsion. In conclusion, sample adhesion may be ensured by adjusting the pH and the electrolyte concentration, and by selecting the appropriate electrolyte valence.

A good buffer for sample adsorption is not necessarily good for sample imaging (the force at which the tip and sample are in contact depends on the buffer) and it is very common to perform sample adsorption in a buffer, then rinse it gently and carry out imaging in a different buffer. Once firmly attached to the support, the sample usually stays there even after the buffer has changed.

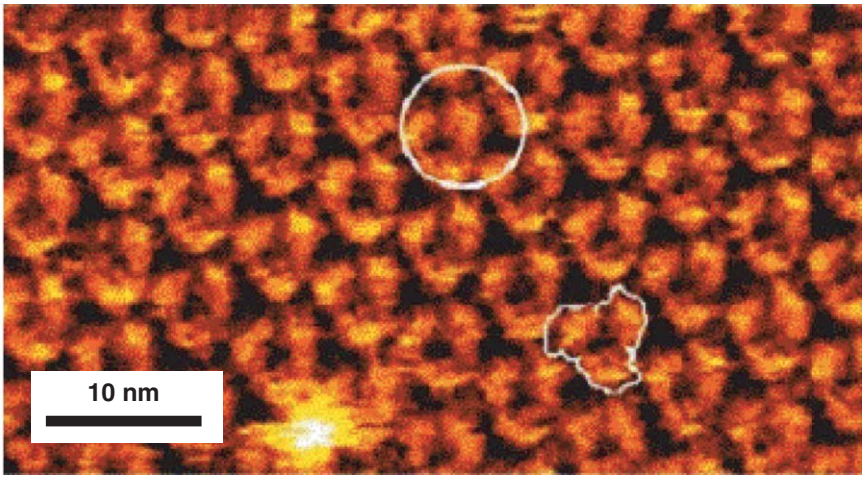
When using FD curves to study specific interactions between molecular partners (antigen–antibody, receptor and its ligand), the preparation of a sample includes suitable functionalization of the sample and tip. Once the stylus has been functionalized with one

of the partners, for instance, via silanization of the surface and subsequent adhesion of proteins, it can be approached to the sample (already functionalized with the other partner) to induce a chemical bond between the two. In this way, protein–protein interaction forces have been studied. Usually, suitable spacers are also interposed between the support and the molecules to be studied, so that the specific detachment on the FD curve occurs far enough from the nonspecific adhesion. Often chemical modifications of the terminal groups in the investigated proteins are required to obtain a suitable preparation.

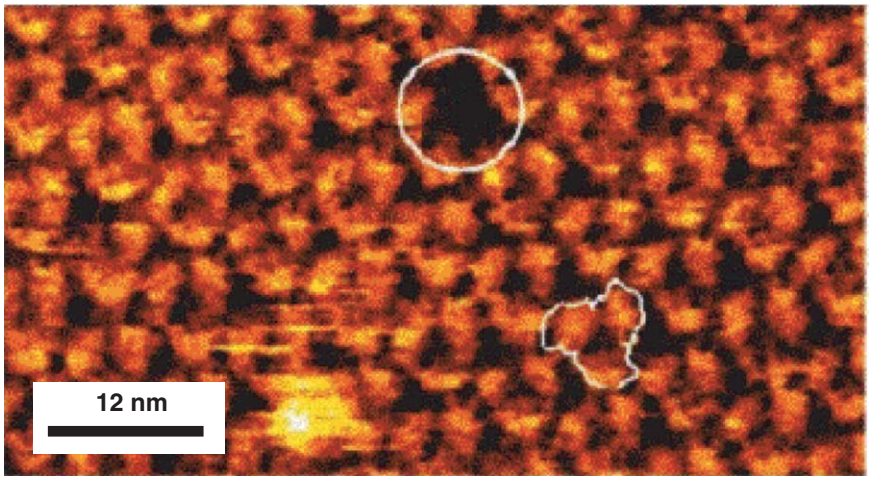
Some Results

It is difficult to give, in a short space, a review of the vast results obtained by SPM in biological systems. Below are reported just a few examples of what is possible to obtain, which are also illustrative of the methods used to extract information from the raw data.

Figure 6 shows a high-resolution image of bacteriorhodopsin (BR) in purple membranes extracted from *Halobacterium salinarum*. BR molecules, in their native membrane, are assembled into trimers, arranged to form a trigonal bidimensional crystal lattice. When the cantilever tip is gently pressed on a molecule, in some cases, the molecule adsorbs on the tip, so once the latter is retracted it extracts a single BR molecule from the membrane. The comparison of the two panels of **Figure 6** shows the empty place of the missing molecule. This figure is illustrative not only of the molecular resolution achieved by AFM on



(a)



(b)

Figure 6 (a) High-resolution AFM images of the cytoplasmic side of purple membranes extracted from *Halobacterium salinarum*. The 2D crystal lattice of bacteriorhodopsin molecules and the organization in trimers are clearly visible. A trimer is contoured for clarity. The length of the white bar is 10 nm. The same area has been imaged twice, before and after stretching the molecules that were adsorbed on the tip. (b) The missing molecule was extracted by the tip during the withdrawal. (Adapted from Oesterhelt F, Oesterhelt D, Pfeiffer M, Engel A, Gaub HE, *et al.* (2000) Unfolding pathways of individual bacteriorhodopsins. *Science* 288: 143–146.)

soft samples but also of its possible use as nanomanipulator. This is one of the directions in which AFM development is focused.

Figure 7 reports a beautiful example of imaging conformational changes at molecular resolution. On the right-hand side of the figure, the scanning in the *y*-direction was stopped and the same molecules were sampled in subsequent scans, showing the dynamical association and dissociation of GroEL–GroES complexes.

More information on the formation and the breaking of molecular bonds or the folding and unfolding

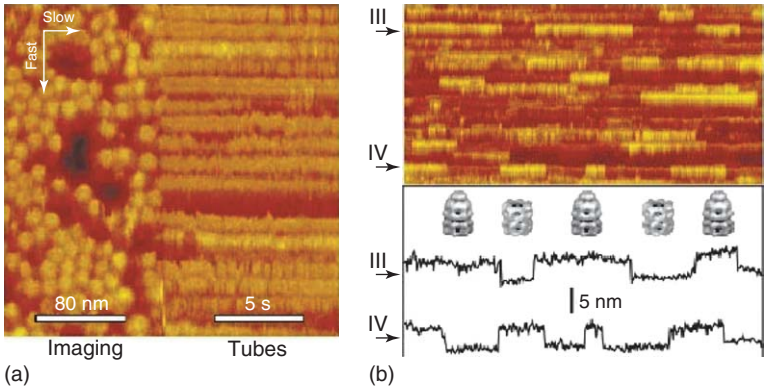


Figure 7 (a) Topography of GroEL proteins adsorbed on mica. The *x* axis, in this case, is in the vertical direction (indicated by the arrow of the fast scan direction). At half the way, the scanning along the *y* direction (the horizontal one in this case, indicated by the arrow of the slow scan direction) was disabled and the scan was repeated on the same line of proteins, generating the protein "tubes" of the right-hand part of the image. The tubes are the evolution over time of the height of the proteins along that line, monitored with a temporal resolution of 100 ms. (b) GroES (144 nM) and ATP (2.5 nM) are added to the buffer solution and the tubes are imaged. Under these conditions, the association and dissociation of GroEL–GroES complexes is possible, in fact, large repeated variations in height along the length of many tubes are observed. The height profile of the tubes indicated with III and IV are reported below. They show a stepping of the height between two levels that differ for 3.6 ± 1 nm. This height difference is consistent with that of GroEL and GroEl–GroES complex seen by X-ray crystallography, confirming that the observed phenomenon is the association and dissociation process. (Adapted from Viani MB, Pietrasanta LI, Thompson JB, Chand A, Gebeshuber IC, *et al.* (2000) Probing protein–protein interactions in real time. *Nature Structural Biology* 7(8): 644–647.)

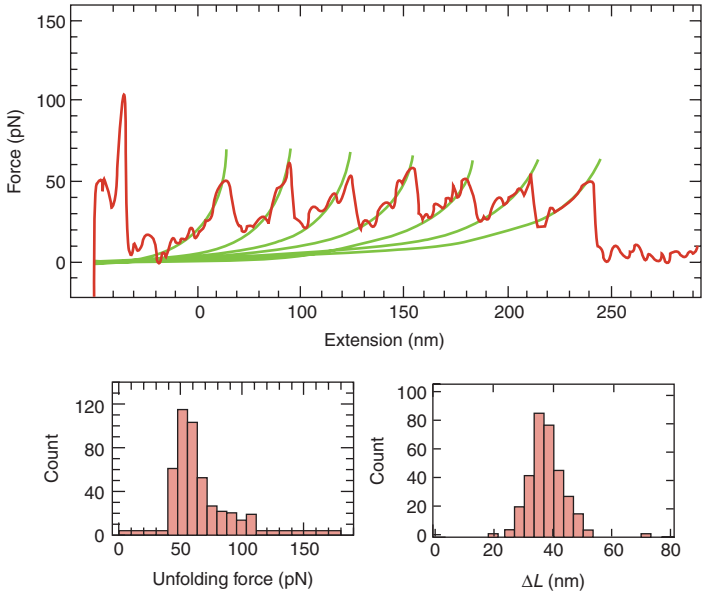

Figure 8 Unfolding of T4 lysozyme in a polymer. Successive unfolding of different units are recorded. The fitting curves are obtained by the WLC model. The two histograms show the distribution of the forces at which unfolding occur and the variation in length obtained by the fitting. (Adapted from Yang G, Cecconi C, Baase WA, Vetter IR, Breyer WA, *et al.* (2000) Solid-state synthesis and mechanical unfolding of polymers of T4 lysozyme. *Proceedings of the National Academy of Sciences of the USA* 97: 139–144.)

of polymers can be obtained by AFM by using the force–distance curves. An alternative technique, very suitable for studying force–distance curves, is that of optical tweezers. **Figure 8** is an example of studying by AFM, the unfolding process in a globular polymer. The figure shows the results as force–extension curves; in this kind of representation, the measured deflection is reported as a function of the actual tip–sample distance given by $d = z - s$ (see **Figure 2**). The dependence of the measured force on the elongation maps the potential of the folding–unfolding process and can be fitted by appropriate models, which come from theoretical studies of polymer dynamics. The reference book for polymer modeling appeared in 1969 and is due to Flory, who won the Nobel prize for chemistry in 1975. Models like freely jointed chain (FJC) or worm-like chain (WLC), and others can be used to fit force–extension curves, and this allows one to determine parameters as the contour length of the polymer or its permanence length.

The other kind of information that can be obtained from results such as those of **Figure 8** is the amplitude of the jumps due to the sudden occurrence of unfolding, that is, the estimated value of the force at which unfolding occurs. These values are somewhat variable, as shown from their histogram reported in the insets of **Figure 8**. This is not a mere effect of the noise that affects the measurements, but is partially due to the stochastic nature of the unfolding process. This is better visible in **Figure 9**, which was obtained by stretching the biotin–streptavidin bond; in this case, the measurements were made at several different velocities of the z-scanning, and the histograms of the measured strengths of the bond depend on this velocity. The peak of the histogram shifts on the right, and the histogram width increases with the velocity on the z-axis.

To understand why the measured strength depends on the rate of force variation, it is important to consider that the lifetime of a bond due to weak noncovalent interactions depends, in the most trivial case, on a potential barrier that separates the two conformations; the height of the barrier is the difference ΔG of the free energy between the bound state

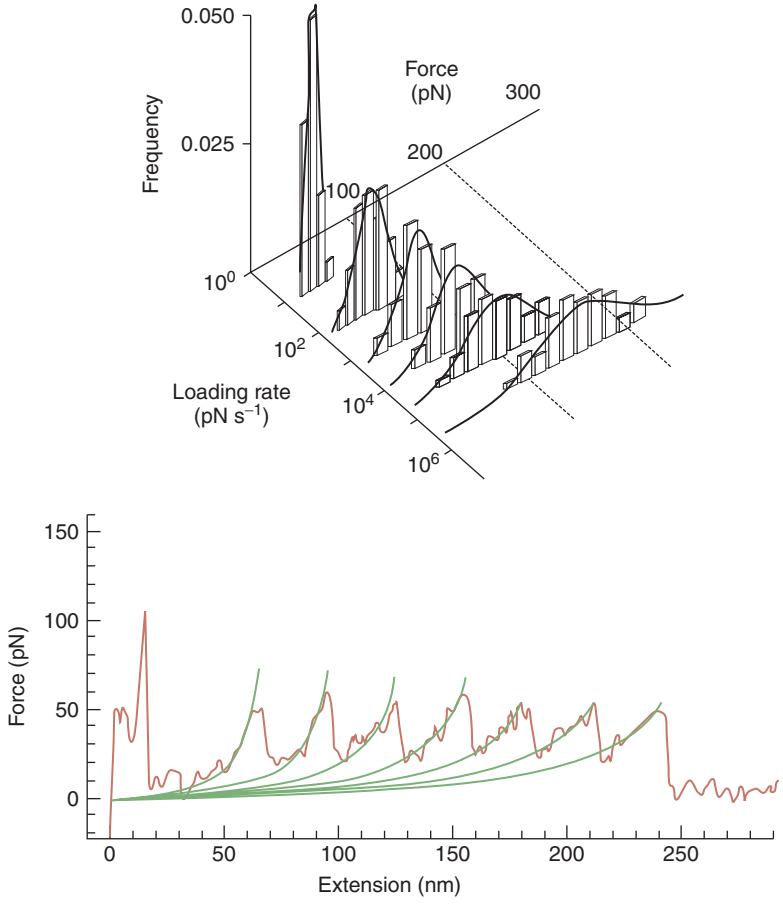

Figure 9 Histogram of biotin–strepavidin bond strength. The histogram peak shifts to right and the histogram width increases with increase in loading rate. (Adapted from Merkel R, Nassoy P, Leung A, Ritchie K, and Evans E (1999) Energy landscapes of receptor-ligand bonds explored with dynamic force spectroscopy. *Nature* 397: 50–53.)

and the transition state. Spontaneous breaking of the bond at temperature T occurs with a probability that depends exponentially on the ratio between ΔG and the thermal energy $k_B T$. Under stretching, the potential profile is modified, the energy landscape is tilted by force so that the height of the barrier decreases and the transition becomes more likely. Complex macromolecular bonds involve many interactions that create a series of barriers. However, for each barrier the probability of breaking in a short interval dt is an exponential function of the applied force, which varies as the stretching proceeds. At a given value, f, of the stretching force, the probability of breaking in a short interval dt is constant; say, $p(f)dt$. The process is Poissonian and the probability $P(t)$ to wait for a time t before the breaking depends exponentially on t:

$$P(t) = \frac{1}{p(f)}\, e^{-p(f)t}$$

Most of the breakings occur in time intervals, shorter than $3/p(f)$. If the stretching force varies quickly in this timescale, breaking will occur at higher values of the force. The process being an inhomogeneous Poisson process, $P(t)$ is given by

$$P(t) = \frac{\exp\left[-\int_0^t p(f(t))\, dt\right]}{\exp\left[-\int_0^\infty p(f(t))\, dt\right]}$$

Experiments are possible where the vertical sweep stops at a preset value of the deflection, keeping the force constant until the conformation change. If the process under study is reversible, these experiments allow one to determine the histogram of the waiting times and then $p(f)$. It is clear from the discussion above that the interpretation of results is much more direct in experiments made at constant stretching force, while the results obtained by retracting the tip without a control on the applied force do not allow a straightforward evaluation of $p(f)$. Some experiments at constant force have been reported recently, and it is to be expected that stretching at constant force will be a rule in the future.

Quantum Mechanics Reigns at Low Temperature

At room temperature, the dynamic behavior of a gas is governed by the laws of classical mechanics. In fact, the thermal de Broglie wavelength

$$\lambda_T = \sqrt{\frac{2\pi\hbar^2}{m k_B T}} \qquad [1]$$

which gives the smearing of the position of the atoms, due to the Heisenberg uncertainty principle ($\hbar$ is the Planck constant divided by 2π, k_B is the Boltzmann constant, m is the atomic mass, and T is the temperature of the gas), is much smaller than the average spacing between atoms, which then behave

as classical objects. As the gas is cooled, however, the smearing increases and the wave functions of adjacent atoms overlap, causing the atoms to lose their identity. If the overlap is large, the effects of quantum mechanics cannot be ignored.

When quantum effects become important, it is crucial to distinguish between Bose and Fermi statistics. Bosons are particles with even total spin and their many-body wave function is symmetric with respect to the exchange of two particles. As a consequence, bosons like to occupy the same state. Conversely, fermions (particles with odd spin) are described by an anti-symmetric wave function and cannot occupy the same state due to the Pauli exclusion principle. At very low temperatures, bosons and fermions behave quite differently (see **Figure 1**), giving rise to distinct dynamic and thermodynamic behaviors.

Bosons are known to undergo a phase transition below a critical temperature T_c. This transition is characterized by the macroscopic occupation of a single particle state and is called Bose–Einstein condensation (BEC). A unique peculiarity of the transition is that it can occur even in the absence of interactions, being driven by genuine quantum statistical effects.

A Einstein predicted the occurrence of this transition in 1925, on the basis of a paper of the Indian physicist S N Bose (1924), devoted to the statistical description of the quanta of light. For a long time, Einstein's predictions had no practical impact and only after the discovery of superfluidity in liquid helium (1938), the phenomenon of BEC became the object of theoretical investigation again with the pioneering works by London, Bogoliubov, Landau, Lifshitz, Penrose, Onsager, and Feynman.

At low enough temperatures, all interacting systems, with the exception of helium, undergo a phase transition to the solid phase. This behavior is illustrated in **Figure 2**, where a typical pressure–temperature phase diagram is shown. In the figure, the pressure–temperature line characterizing the BEC phase transition of an ideal gas is also drawn. Above this line, a dilute gas would be Bose–Einstein condensed. However, this configuration is unstable since thermodynamic equilibrium would correspond to the crystal phase for such values of pressure and temperature. This shows that BEC can be actually achieved only in conditions of metastability, and that the density of the gas should be small enough to suppress the collisional processes (three-body collisions) responsible for bringing the system into the thermodynamically stable solid phase. In practice, typical densities reached in the BEC phase are 10^{13}–$10^{15}\,\mathrm{cm}^{-3}$, so that the predicted values of T_c are extremely low (a few microkelvin or even less). This explains why BEC was experimentally realized in atomic gases only 70 years after Einstein's historical paper.

The realization of BEC in atomic gases was achieved for the first time in 1995 and was recognized with the Nobel prize in 2001. This achievement is the result of extraordinary efforts made in atomic physics during the 1990s, through the development of advanced techniques of cooling and trapping atoms, which were recognized with the award of the Nobel prize in 1997. At present BEC has been achieved in

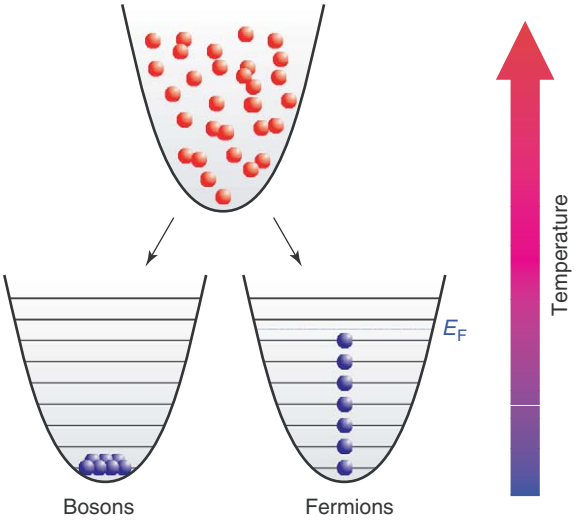

Figure 1 Schematics of the level occupancy for a harmonically trapped gas at ultralow temperature. The ground state of the many-body system is completely determined by the quantum statistics. The bosons (even spin particles) all occupy the same single-particle ground state, forming a Bose–Einstein condensate. The fermions (odd spin particles), obeying the Pauli exclusion principle, pile up until they reach the Fermi energy E_F.

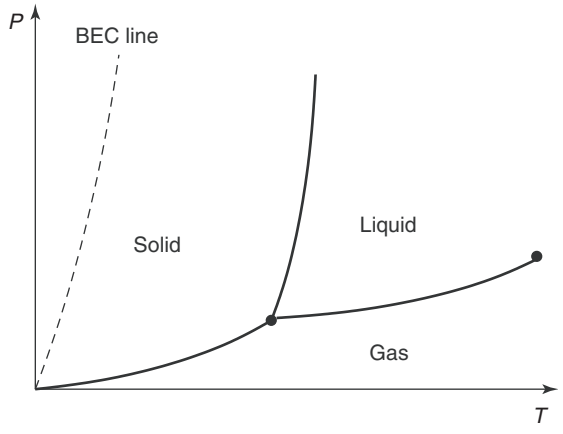

Figure 2 A typical pressure–temperature phase diagram. The dashed line corresponds to the BEC phase transition for an ideal gas.

How to Reach BEC in Dilute Atomic Gases

The first experimental studies on BEC were focused on spin-polarized hydrogen that was considered the most natural candidate because of its light mass. For this purpose, cryogenic and evaporative cooling techniques were developed since the early 1970s. However, BEC was first realized in alkali atoms despite their relatively high masses, because of their suitability to be cooled with laser techniques. In a typical setup, the strategy to achieve BEC of alkali gases consists of the following steps: (1) laser cooling of the atoms, (2) magnetic trapping, and (3) evaporative cooling.

The first cooling stage is performed in a magneto-optical trap (MOT) that consists of the combination of counterpropagating laser beams and a magnetic field gradient. The physical mechanism at the basis of the cooling process is the transfer of momentum between photons and atoms. The laser beams are red-detuned with respect to an atomic transition, in such a way that the resulting effect is a viscous force slowing the motion of atoms. In addition, the presence of the magnetic field gradient allows one to spatially confine the atoms in a region of a few cm^3. In the case of rubidium, one can typically trap $\sim 10^9$ atoms with a temperature of $\sim 10\,\mu$K (inferred from the velocity distribution of the atoms).

The density and temperature achievable in a MOT are far from the values required for BEC (the fundamental limit for laser cooling is the recoil temperature, i.e., the kinetic energy gained by an atom after absorption of one photon, $\sim 400\,$nK for rubidium). The next stage consists in transferring the atoms from the MOT to a magnetostatic trap, where higher densities and lower temperatures can be achieved. An example of a typical coil configuration is shown in **Figure 4**. The current flowing in the coils produces a magnetic field that has a minimum in the center of the trap, and is, in good approximation, harmonic around this point. Due to their magnetic moment, atoms in a low-field seeking Zeeman state are trapped in the center of the trap.

The final cooling stage is the so-called evaporative cooling that is performed by selectively removing the hottest atoms from the magnetic trap. RF transitions are used to excite the atoms located at the border of the trap (the ones with the highest energy) to untrapped states. This process is successful only if the energy of the RF cut is lowered slowly enough in such a way that the remaining atoms have time to collide and thermalize to lower temperatures. At the end of this process, if the density of the sample is high enough, the phase transition to a Bose–Einstein condensate can take place (typical values for rubidium are $n \sim 10^{14}\,\text{cm}^{-3}$ and $T \sim 100\,$nK). BEC, in a trap, occurs both in momentum and coordinate space, with the atomic density distribution reflecting the shape of the trapping potential (cigar-shaped for the trap in **Figure 4**).

All these stages are performed in a ultra-high-vacuum environment (background pressure $\sim 10^{-12}\,$torr), in order to ensure a perfect thermal isolation and a long lifetime of the trapped atomic samples against collisions with the background gas.

Imaging the New Macroscopic Quantum State

Images of the ultracold atomic sample are achieved by shining a nearly resonant laser beam. The absorption of light by the atoms creates a shadow that is recorded by a CCD camera. The typical size of a condensate is of the order of a few micrometers and a very high resolving power is hence necessary for *in situ* imaging. More frequently, images are taken by switching the trap off and allowing the gas to expand to larger sizes. Typical images obtained after expansion are shown in **Figure 5**. From these images one extracts relevant information on the physical properties of the system. At temperatures higher than T_c, the sample expands ballistically and quickly reaches an isotropic distribution, well described by a Maxwellian. From this distribution one extracts the temperature of the gas. At the onset of the BEC transition, the shape of the cloud is characterized by a pronounced increase of the density in the center. At lower temperatures, the density takes a characteristic bimodal shape (**Figure 5**): the noncondensed atoms determine the wing of the distribution, still given by a Maxwellian form, while the condensed atoms give rise to a narrow central peak which becomes more and more pronounced as the temperature is lowered. The shape of the central peak is no longer a Maxwellian, but is given by an inverted parabola as predicted by the Gross–Pitaevskii theory, and exhibits a typical nonisotropic expansion. The diagnostic of the images also provides the number N of atoms in the sample.

In the presence of harmonic confinement, the theory predicts both the value of the critical temperature T_c and the fraction of condensed atoms for $T \leqslant T_c$. For an ideal gas trapped by a harmonic potential, one finds

$$k_B T_c = 0.94 \hbar \omega_0 N^{1/3} \qquad [2]$$

and

$$\frac{N_0}{N} = 1 - \left(\frac{T}{T_c}\right)^3 \qquad [3]$$

where ω_0 is the geometric average of the trapping frequencies and N_0 is the number of atoms in the condensate. A typical theory–experiment comparison is shown in **Figure 6**, where the value of T_c is a few hundreds of nanokelvin. Despite the relatively small number of atoms used in this experiment ($\sim 10^4$), the evidence for the phase transition is very clear. The good agreement with the predictions of the ideal gas model indicates that the effects of the interactions on the condensate fraction as well as on the value of T_c are small. This is the consequence of the extreme diluteness of the trapped gas.

In the following sections, some of the major achievements obtained in these years on these ultracold gases will be discussed. These include the study of their coherence and superfluid properties, as well as the novel features exhibited in the presence of a

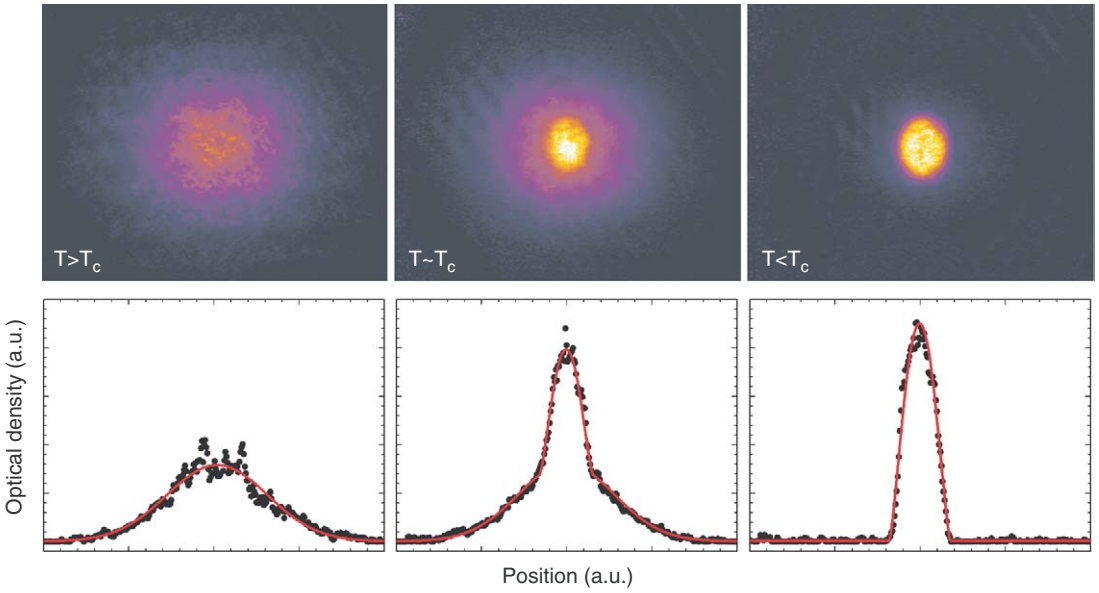

Figure 5 (Top) Absorption images of an expanded atomic cloud varying the temperature T across the BEC transition at T_c. From left to right, the images show a thermal cloud, a partially condensed cloud, and a pure BEC. (Bottom) Horizontal cross section of the density distribution. The lines are fits of the experimental points with a Gaussian, a bimodal distribution and an inverted parabola, respectively.

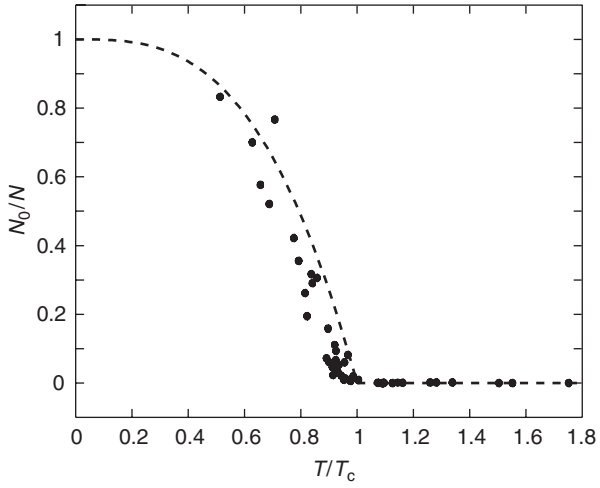

Figure 6 Condensate fraction N_0/N as a function of T/T_c. Circles are experimental results from JILA (1996), while the dashed line is the theoretical prediction of eqns [2] and [3].

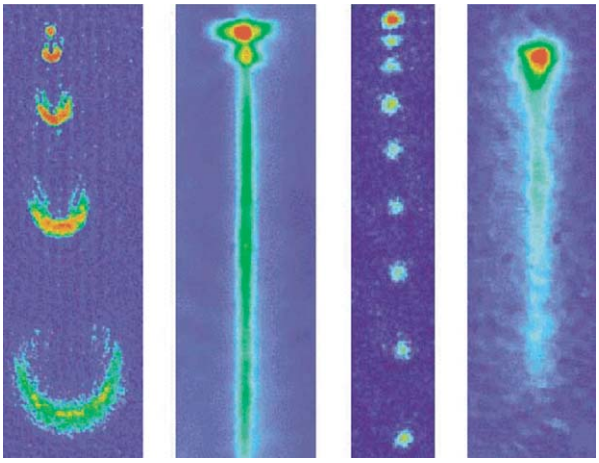

Figure 7 A collection of atom lasers, obtained outcoupling coherent atoms from a Bose–Einstein condensate with different methods. The first two lasers have been achieved using pulsed or cw RFs in order to induce transitions toward untrapped states. The third one has been obtained taking advantage of the tunneling induced by gravity in a vertical lattice. The fourth laser has been obtained using optical Raman transitions.

periodic potential. A short discussion on recent results with ultracold Fermi gases is also presented.

Coherence and Superfluidity

Bose–Einstein condensates are characterized by a complex order parameter (the so-called wave function of the condensate)

$$\Phi = \sqrt{n_0}\mathrm{e}^{\mathrm{i}S} \qquad [4]$$

The modulus is fixed by the condensate density n_0 which, in dilute gases and at temperatures much smaller than T_c, in practice, coincides with the density of the gas. The phase S of the order parameter is at the origin of important properties of the system, both concerning coherence and superfluid effects.

Coherence phenomena make the physics of these systems similar to the one of a laser, if one replaces photons with atoms. Bright sources of atoms, the so-called atom lasers, can be obtained outcoupling the atoms from the condensate (see **Figure 7**) that is the analog of the laser cavity in which coherent photons are stored. This has been accomplished with different methods (RF transitions, Raman pulses, gravity-induced tunneling) that have allowed one to create cw and pulsed sources of coherent atoms.

Another example of this analogy is revealed by the interference phenomena observed with Bose–Einstein condensates. **Figure 8** shows the interference fringes produced by two separate condensates overlapping after expansion. This experiment, which first demonstrated the coherence of the condensed state, is the analog of the most famous double-slit experiment with light.

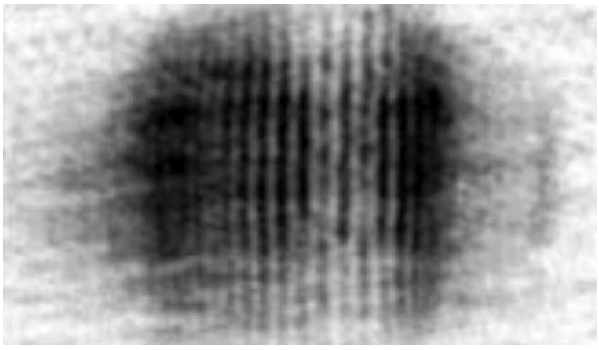

Figure 8 Density profile of two condensates overlapping after expansion. In the central region one clearly sees interference fringes, similar to the ones observed in optics in the famous Young experiment. This image has been recorded in the first experiment in which interference of matter waves has been observed (MIT 1996).

Differently from photons, atoms are interacting particles. In the mean field approach, interactions give rise to important nonlinear phenomena. A beautiful analogy with nonlinear optics is provided by the experiments on four wave mixing (see **Figure 9**), in which three matter waves, interacting through nonlinearities, can produce a fourth matter wave. This can only be achieved if phase-matching conditions (energy and momentum conservation) are satisfied. While in the case of light, nonlinearities are a property of the medium in which the mixing process takes place, in the case of atoms nonlinearities are an intrinsic property of the mixing waves and are due to

the elastic s-wave collisions between the atoms forming the matter wave. Interactions in Bose–Einstein condensed gases are in most cases repulsive. Profiting from the occurrence of resonant states between two interacting atoms, it is now possible to tune the value and even the sign of the scattering length by simply applying an external magnetic field. When the scattering length becomes negative, the nonlinearities in the Gross–Pitaevskii equation are responsible for solitonic solutions (bright solitons) which propagate without dispersion in 1D configurations. The existence of bright solitons has been confirmed in a recent series of experiments.

Another spectacular consequence of the phase of the order parameter is related to superfluidity. In fact, the gradient of the phase S is proportional to the superfluid velocity:

$$\boldsymbol{v}_s = \frac{\hbar}{m}\nabla S \qquad [5]$$

Before 1995, superfluid phenomena had been observed only in dense liquids, such as ^{4}He. The possibility of extending such investigations to dilute gases has opened new challenging perspectives for a better understanding of the microscopic origin of superfluidity and its relationship to the phenomenon of BEC. Among the various manifestations of superfluidity, it is worth mentioning the rich variety of collective oscillations exhibited by these confined systems, which have been the object of intense theoretical and experimental work in the last few years. **Figure 10** shows the shape oscillation of a Bose–Einstein condensate. From these images one can extract the frequency of the collective oscillation with high precision. The dynamic behavior of the condensate is well described by the hydrodynamic equations of superfluids, which predict values for collective frequencies in excellent agreement with the experiment.

An even more spectacular prediction of superfluidity concerns the rotational properties of Bose–Einstein condensates. Superfluids cannot rotate like classical objects because of the irrotationality constraint imposed by eqn [5]. A striking consequence is that angular momentum can be carried only by quantized vortices. If the confining trap rotates slowly, vortices cannot be formed because they are energetically unfavorable and the sample does not carry any angular momentum. However, when the angular velocity increases, quantized vortices are formed (see **Figure 11**). Eventually, at high angular velocities, one can generate a vortex lattice of regular geometrical shape.

Another important manifestation of superfluidity is given by the Josephson oscillations characterized by the coherent tunneling of atoms through the barriers generated by an external potential (see the next section).

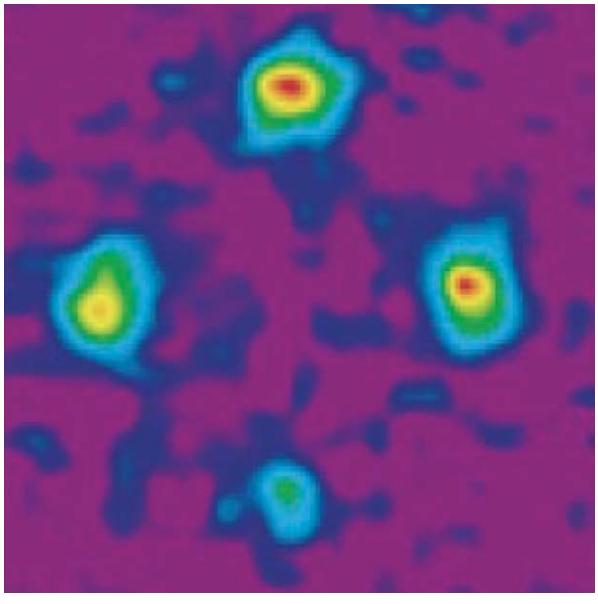

Figure 9 Four wave mixing with matter waves (NIST 1998). In this absorption image, taken after a time of flight, each peak represents a matter wave with different momentum. The three most intense peaks (up, left, right) are created by splitting a Bose–Einstein condensate with laser light. The fourth smaller peak (down) is the result of the mixing process caused by the nonlinear interaction between the three initial waves.

BEC in Periodic Potentials

Ultracold atoms can also be trapped with nonresonant laser light taking advantage of the interaction with the induced dipole moment. Differently

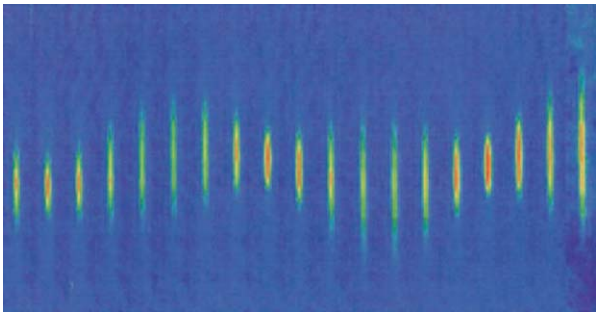

Figure 10 Collective excitations of a Bose–Einstein condensate (MIT, 1998). The excitations were produced by modulating the magnetic field used to trap the condensate and then letting the cloud evolve freely. The field of view in the vertical direction is about 600 μm and the time step is 5 ms per frame. The measured frequency of these collective excitations is a clear signature of the BEC superfluidity.

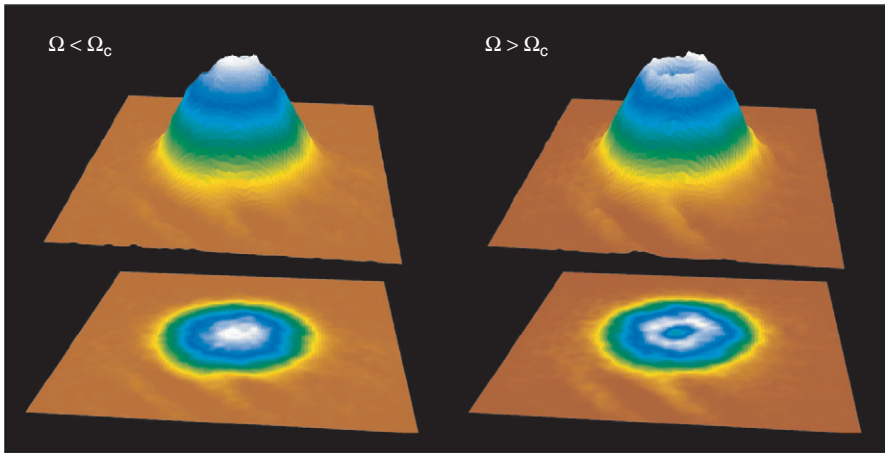

Figure 11 Formation of vortices in a Bose–Einstein condensate (ENS, Paris, 1999). The images refer to a BEC confined in a trap rotating at angular velocity Ω. Above a critical velocity Ω_c, a vortex forms in the condensate, as can be seen by the reduction of density in correspondence of the center.

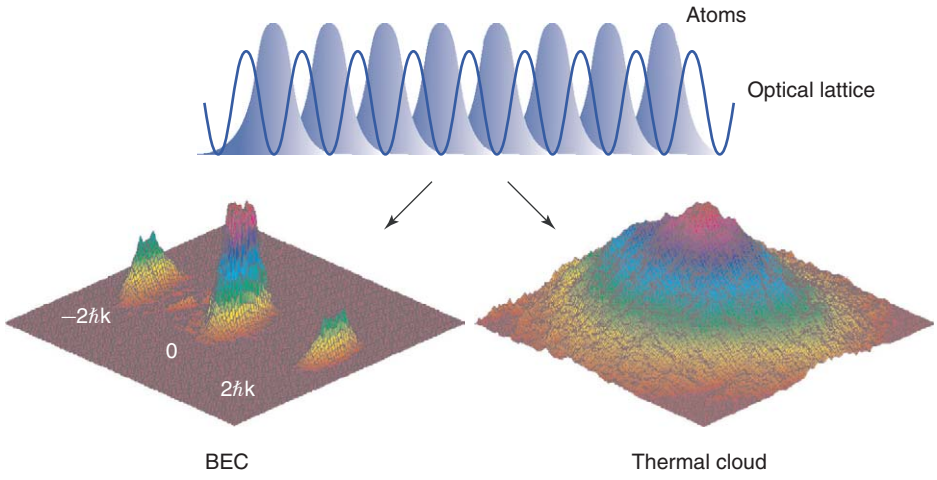

Figure 12 Expansion of a Bose–Einstein condensate from an optical lattice (LENS, Florence, 2001). The atoms are trapped in a periodic potential generated with laser light and then released from this trap. The figure on the left, showing the density distribution after expansion, exhibits resolved peaks originated from the interference of the condensates initially located at the lattice sites. The observed structure, signature of the long-range coherence of the system, cannot be observed with a thermal incoherent sample (figure on the right). This effect is analogous to the diffraction of light by a matter grating.

from magnetic trapping, this allows one to trap atoms of any spin state and to produce new geometrical configurations. In particular, working with counterpropagating laser beams, it is possible to generate periodic potentials, the so-called optical lattices. These optical configurations give rise to the possibility of producing new crystals where the ordered atomic structure is ensured by the laser light.

Arrays of condensates can be produced with an optical lattice high enough to trap the atoms in the lattice sites (see **Figure 12**). The density distribution of the atoms released from this optical trap shows well-resolved peaks originated by the quantum interference of the condensates initially located at the lattice sites and overlapping during the expansion. This feature, which is a signature of the long-range coherence of the system, cannot be observed in a thermal sample, which instead presents a broader unstructured distribution. This is analogous to the diffraction of light from a matter grating, where the role of matter and light is interchanged.

A condensate in a periodic potential is also an ideal tool to study the key phenomena of solid-state physics related to the Bloch description. In particular, it is possible to point out directly the typical band structure and related transport properties in the ideal situation of a perfect crystal, avoiding the presence of phonons or defects, typical of solid-state configurations (**Figure 13**).

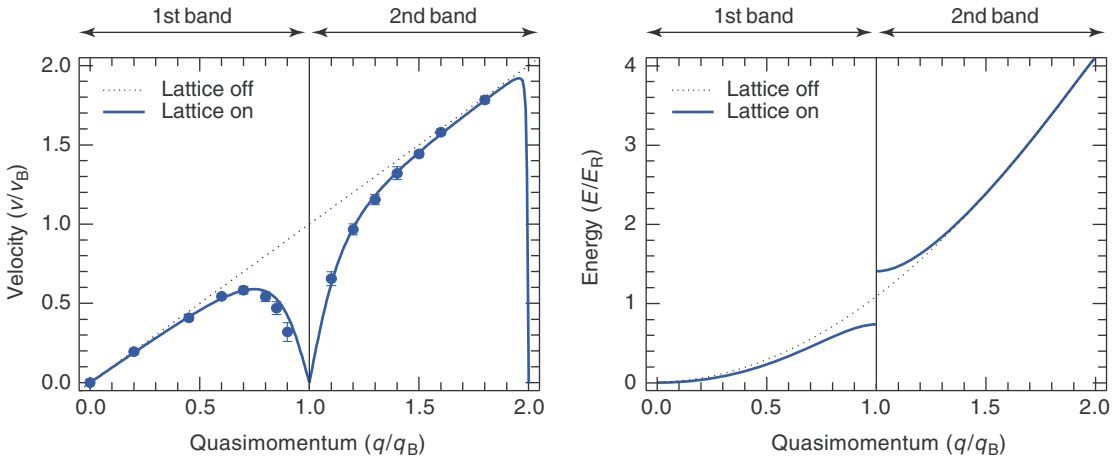

Figure 13 A BEC in an optical lattice is the ideal system for studying problem of solid-state physics. By directly observing the propagation of the matter wave packet in a periodic potential, one can measure the energy band spectrum.

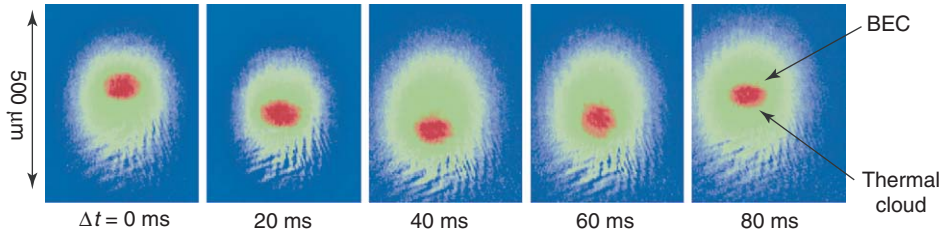

Figure 14 A partially condensed cloud is oscillating in the harmonic trap in the presence of an optical lattice (along the vertical direction, in figure). While the thermal cloud center of mass is stuck in the initial position, the condensed part moves through the periodic potential because of the coherent tunneling between the lattice sites, analogous to the Josephson effect (LENS, Florence, 2001).

An interesting possibility provided by these periodic potentials is the study of Josephson-like oscillations in the superfluid phase. These oscillations are characterized by a coherent tunneling of the gas through the optical barriers. Experimentally, one can easily excite center-of-mass oscillations of the gas confined in the combined potential created with a harmonic trap and an optical lattice. **Figure 14** shows that only the condensed component is able to tunnel coherently, while the thermal component is localized. Theoretically, one can predict the frequency of the oscillation, which turns out to be in good agreement with the experiment.

A spectacular achievement with these new configurations is the possibility of studying the transition from a superfluid to a Mott insulator phase (**Figure 15**). By increasing the intensity of the laser (and hence the height of the barriers generated by the 3D optical lattice), one reduces the tunneling rate between neighboring sites, thereby favoring the localization effects. At some point, the coherence of the sample is lost and the system exhibits an insulating phase. **Figure 15** shows the experimental evidence for this transition, which is proven by the disappearance of the interference peaks in the density profile imaged after expansion.

Fermions

Differently from the case of bosons, an ideal Fermi gas does not exhibit a phase transition at low temperature. The system, however, is still characterized by important quantum phenomena originating from the Pauli exclusion principle. This is well illustrated in **Figure 1**, where one sees that at very low temperatures the gas exhibits single occupancy of the particle states up to a maximum energy, called Fermi energy.

The experimental procedure to reach ultracold regimes in Fermi gases cannot be the same as in the case of bosons. Indeed, in a Fermi gas of a single spin species, collisions are suppressed at low temperature by the antisymmetrization requirement. This causes the absence of thermalization processes which are crucial for the mechanism of evaporative cooling to be efficient. This difficulty has been overcome by working with two spin species, which can interact also at low temperature. Alternatively, one can use

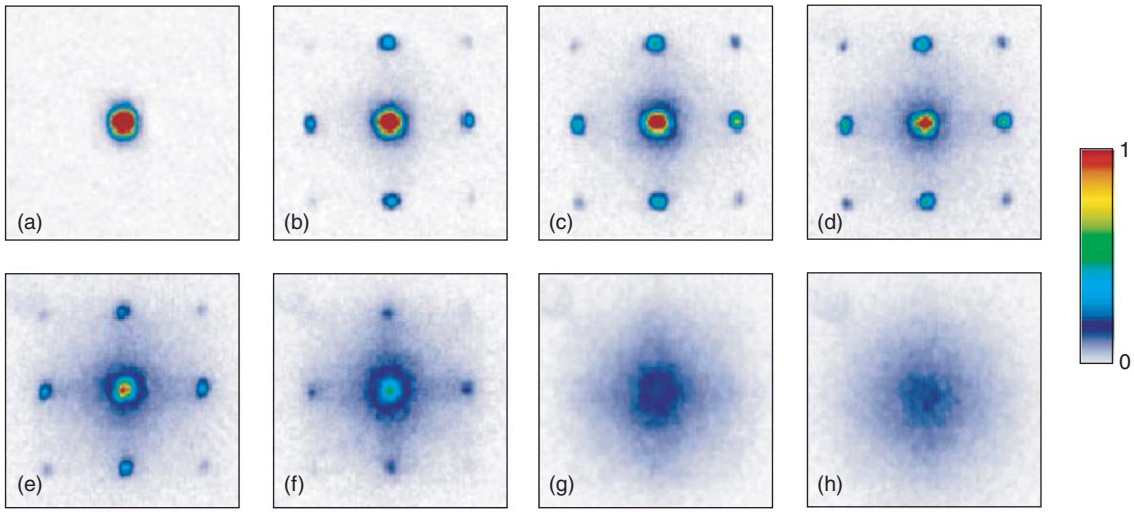

Figure 15 BECs in 3D optical lattices have allowed the observation of the quantum phase transition from a superfluid to a Mott insulator. In the latter phase (achieved for the first time in Munich in 2001) a number Fock states are created at the lattice sites when the tunneling between the optical barriers is lower than a critical value. Consequently, phase fluctuations increase and the long-range coherence typical of the superfluid phase is lost. This is evidenced by the disappearance of the interference pattern in expansion when the lattice height is increased (from a to h).

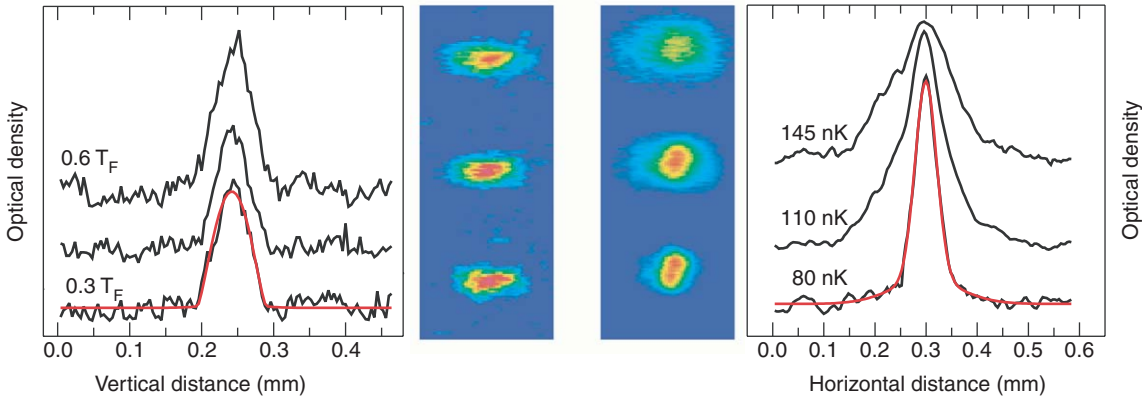

Figure 16 Sympathetic cooling of fermionic ^{40}K with bosonic ^{87}Rb (LENS, Florence). The bosons are directly cooled with standard evaporative cooling techniques and the fermions thermalize sympathetically at lower temperatures via collisions with the bosons. The figure shows the simultaneous onset of Fermi degeneracy for ^{40}K (left), and of Bose–Einstein condensation for ^{87}Rb (right). The absorption images are taken for decreasing temperatures (from top to bottom) and the graphs show the cross sections of the density distribution after expansion.

mixtures of fermions and bosons. Bosons are cooled down with traditional techniques and fermions then thermalize sympathetically. **Figure 16** shows this second type of approach, achieved with potassium and rubidium.

The absence of interactions of polarized fermions in a gas, on the one hand, complicates the cooling procedure and, on the other hand, can provide important advantages. In fact, noninteracting degenerate Fermi gases exhibit peculiar features which have been the object of recent investigations. An example is given by the occurrence of undamped Bloch oscillations in the presence of periodic potentials, which are very promising for future precision measurements (see **Figure 17**). Also, the achievement of efficient registers for quantum computation might be strongly favored by the use of ultracold noninteracting Fermi gases.

On the other side, the possibility of trapping fermions in different spin states is opening new perspectives related to the physics of interacting systems. In particular, recent experimental efforts have been aimed at realizing superfluid configurations. For dilute gases interacting with attractive scattering

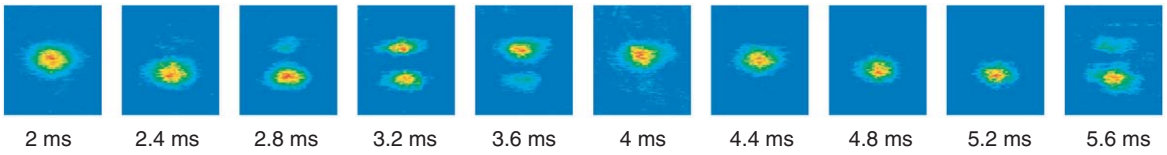

Figure 17 Bloch oscillations of ultracold fermions trapped in a vertical optical lattice, as observed in a recent experiment at LENS, Florence (2004). The images show the momentum distribution of the fermionic cloud moving under the action of gravity. Measuring the frequency of the oscillation allows an accurate determination of the local gravity acceleration g, and can be, in principle, used for high precision measurements of forces on a short distance scale.

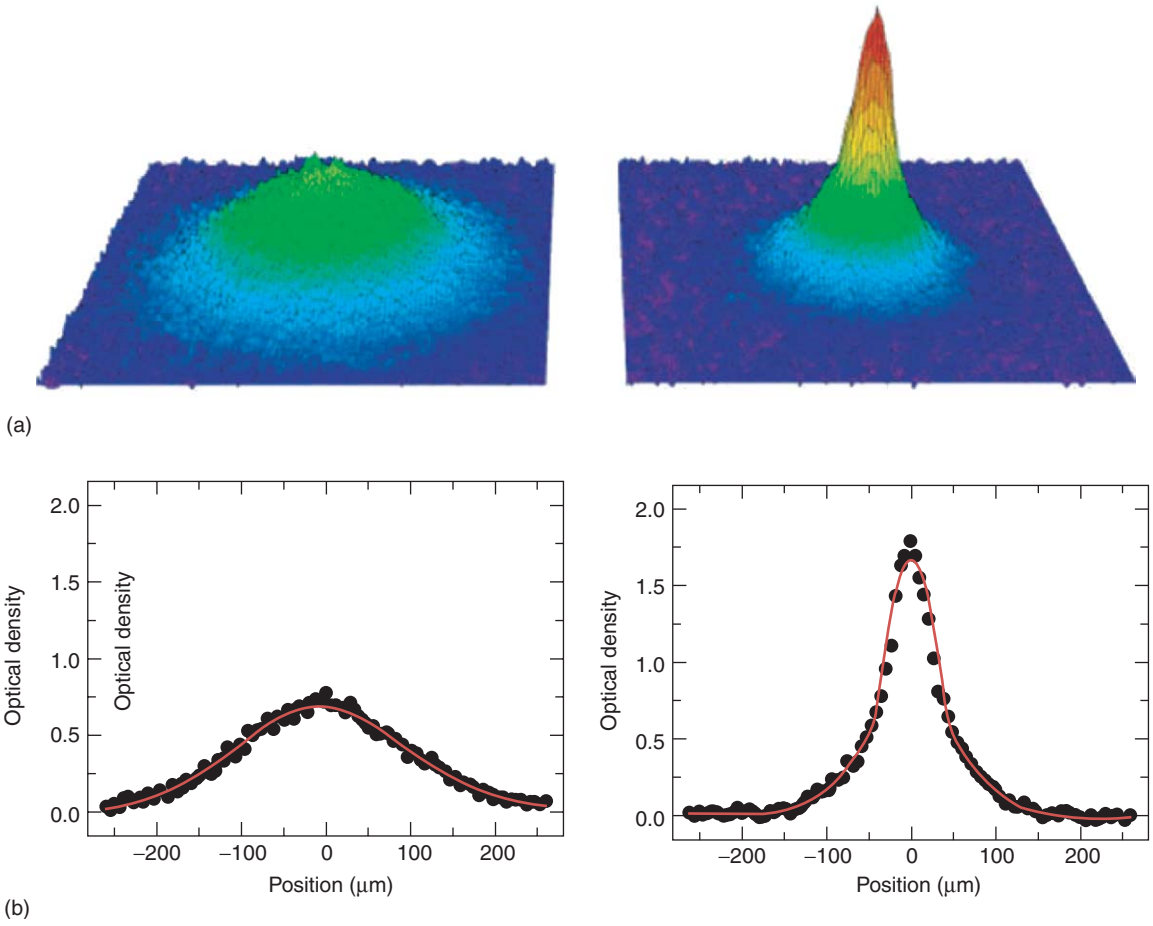

Figure 18 BEC of $^{40}K_2$ molecules (JILA, 2003). The (bosonic) dimers are produced starting with quantum degenerate ^{40}K fermions in two spin states and sweeping the value of an applied magnetic field across a resonance. (a) Absorption images of the molecular density distribution after expansion. When the initial temperature of the fermionic cloud is lowered across a critical value (from left to right), a narrow peak appears in the momentum distribution. (b) Cross section and fit with a bimodal distribution. The change in the density profile is a signature that a BEC of molecules has formed.

length, the superfluid phase is described by the traditional BCS theory, first developed to describe the phenomenon of superconductivity. If the scattering length of fermions in two spin states becomes large or positive, new scenarios take place. Such configurations can now be achieved experimentally by tuning the scattering length in the vicinity of a resonance. In particular, this technique has proved quite successful in the efficient production of ultracold molecules in a gas of atoms interacting with positive scattering length. Since these molecules have a bosonic nature, being composed of an even number of fermions, they can undergo a phase transition to BEC, similar to the one exhibited by a gas of bosonic atoms.

Molecular BEC has been already realized starting from Li and K fermionic atoms (see **Figure 18**). At present, significant efforts are being made to study the BEC–BCS crossover, which occurs by varying continuously the scattering length through the application of an external magnetic field. In particular at resonance, where the scattering length becomes much larger than the average distance between atoms, the system exhibits new challenging features which cannot be simply described using the theory of weakly interacting gases and requires the use of more advanced many-body approaches.

Introduction

Carbon is a remarkable element that shows a variety of stable structures, ranging from three-dimensional (3D) diamond to 2D graphite and 1D carbyne. The different forms of carbon are the consequence of two important characteristics of its electronic $1s^2 2s^2 2p^2$ configuration. First, carbon may form different hybridizations, called sp^n, between its $2s$ orbital and n of its $2p$ orbitals ($1 \leqslant n \leqslant 3$). Next, the C–C distance is small enough to allow for a large π bonding between those $2p$ orbitals of neighboring atoms that are not hybridized with the $2s$ orbital (when $n < 3$). These two properties together give many structural flexibilities, thanks to which the chemistry of carbon is so rich. Already with pure carbon, different structures can be realized, which have very different electronic properties. These structures derive from the three allotropic crystalline forms of carbon listed in **Table 1**.

Hybrid Orbitals

When two carbon atoms are brought close together to form a C_2 molecule, the electrons move in an effective potential that has cylindrical symmetry around the line joining the two nuclei. A molecular wave function may be totally invariant under a rotation by an angle φ about this axis, thus forming a σ state, or it may transform like $\cos(m\varphi)$, thus forming a π state ($m = 1$), a δ state ($m = 2$), etc. The ground state of the C_2 molecule is a σ state. Its expression can be written as a linear combination of atomic orbitals (LCAO) restricted to the $2s$ and $2p_z$ valence orbitals, which have full rotational symmetry about the molecular axis chosen as the z direction. In addition, the wave function of the ground state is even with respect to the inversion about the molecule center. This means $\psi_{\sigma_g} = (\Phi_{A+} + \Phi_{B-})/\sqrt{2}$, where $\Phi_{A+} = \alpha\phi_{A_s} + \beta\phi_{A_z}$ and $\Phi_{B-} = \alpha\phi_{B_s} - \beta\phi_{B_z}$. In that expression, ϕ_s and ϕ_z are the $2s$ and $2p_z$ orbitals located on one C atom, either at location A or B. Φ_{A+} and Φ_{B-} are linear combinations of these orbitals, called sp^1 hybrids (see **Figure 1a**). They are symmetric to each other with respect to the inversion center. The numerical coefficients α and β are determined by solving a secular LCAO equation.

In a C_2 molecule, two electrons occupy the σ_g ground state (see **Figure 1b**) and form a strong σ bond. Two electrons occupy the next σ state, which is a nonbonding state with wave function $\psi_{\sigma_u} = (\Phi_{A-} - \Phi_{B+})/\sqrt{2}$. It is a combination of sp^1 hybrids on A and B sites that point opposite to the other atom. These hybrid orbitals are ready to overlap with an H atom each, such as in the acetylene C_2H_2 molecule, or with other C atoms such as in carbyne, which is a 1D carbon structure (pure carbyne should be fully sp^1-hybridized). The last four electrons of the C_2 molecule occupy the doubly degenerate π_u bonding state (see **Figure 1b**) obtained by combining

the $2p_x$ orbitals and the $2p_y$ orbitals. These electrons form two π bonds.

Other hybridizations of the 2*s* and 2*p* valence orbitals may be formed. The most symmetric combinations correspond to the sp^2 and sp^3 hybrids illustrated in **Figure 2**. In the first case, each carbon atom forms three sp^2 hybrids, by mixing the 2*s* orbital with $2p_x$ and $2p_y$ orbitals. In graphene and graphite, the sp^2 hybrid orbitals have maxima of probability density along three directions at 120° in the *xy* plane. They form σ bonds with neighboring atoms. sp^3 hybrids are combinations of all valence orbitals. In diamond, each atom forms four such hybrids along four directions at 109° in space with tetrahedral symmetry.

Diamond

When carbon atoms are brought together to form a solid, their 2*s* and 2*p* levels broaden and form energy bands. The formation of these bands is illustrated in **Figure 3** for the case of diamond. At large interatomic distance, the bands are narrow and conserve most of the 2*s* and 2*p* characters of the individual atoms. When the distance decreases, the width of the bands increases and their *s* and *p* characters start to mix. At some distance, there is a crossing between the bottom of the band that originates from the 2*p* level, and the top of the band that originates from the 2*s* level. From now on, one may consider that the electronic states result from the σ overlapping of sp^3 hybrid orbitals. By reducing the interatomic distance further, a gap opens between σ bands that have acquired bonding and antibonding characters, respectively. There are four hybrid orbitals per atom,

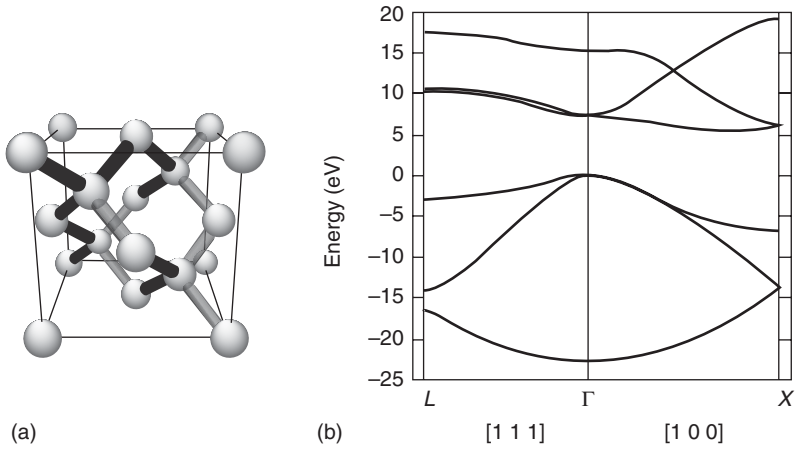

Figure 4 (a) Cubic diamond crystal structure, (b) Band structure of diamond along high-symmetry lines calculated with the all-electron GW approximation. (Courtesy of M Alouani.)

giving rise to two states in each of the bonding and antibonding bands. Each band may therefore accommodate four electrons, due to spin degeneracy. Since there are four electrons per atom, the bonding band is full, the antibonding band is empty, and the system is a semiconductor. The so-called hybridization gap that separates the bonding and antibonding σ bands increases with decreasing distance. Interestingly enough, this picture remains qualitatively correct for the tetrahedral *sp* semiconductors that adopt the same diamond structure. From the decreasing interatomic distance in going from Ge to Si to C, one may understand the increase of their band gap. The picture also remains qualitatively correct for tetrahedral amorphous carbon.

For a crystalline material, the most complete description of the electronic states is provided by its band structure. A theoretical band structure of diamond is shown in **Figure 4b** for Bloch vectors parallel to a principal diagonal of the cubic cell (ΓL line) and parallel to an edge of the cubic cell (ΓX line). The valence band extends from -22.6 to 0 eV. The width of the hybridization gap at the Γ point is 7.4 eV. There are four branches in the valence band, the two atoms per unit cell of diamond (**Figure 4a**) bringing two bonding σ states each. The symmetry of the wave function along the ΓL and ΓX lines is high enough to allow for a twofold degeneracy of the top valence branch and the bottom conduction branch. The computed minimum band gap is 5.6 eV. It is an indirect gap, corresponding to a transition between the Γ point and the minimum of the bottom conduction branch along ΓX. The gap is so large that diamond does not absorb any visible radiation. Pure diamond is transparent, as a consequence. Diamond can be doped with boron and other elements, and can reach relatively high *p*-type or *n*-type conductivity. The σ bonds in diamond are very strong. As a result, diamond is the hardest material known. Its Young modulus for uniaxial strain applied along a fourfold symmetry axis is 1.05 GPa.

Graphite

Graphite can exist in different phases according to the stacking of its layers, each of which is a single carbon sheet with a honeycomb structure called graphene. The most common crystalline form of graphite, discovered by J D Bernal in 1924, has the ABABAB… stacking illustrated in **Figure 5a**. The σ states of graphite are formed by overlapping sp^2 hybrid orbitals oriented along the C–C bonds in each layer. Qualitatively, the picture of **Figure 3** still applies to these σ states. In Bernal graphite, there are four atoms per unit cell (two per layer), each of them builds three σ states, of which half have a bonding character. In the band structure of **Figure 5c**, the bonding σ states contribute $1.5 \times 4 = 6$ branches between -20.1 and -3.4 eV. Since there is very little σ interaction between two successive atomic planes of graphite, the σ branches are nearly twofold degenerate. The antibonding σ^* states lie above $+3.7$ eV, the hybridization gap is 7.1 eV. Unlike the case of diamond, this gap is bridged by the π states that originate from the $2p_z$ orbitals, perpendicular to the atomic layers. These orbitals form two bonding bands and two antibonding bands. They appear as two pairs of branches split by the interlayer coupling, which is much more efficient with the out-of-plane $2p_z$ orbitals than with the in-plane sp^2 hybrids. The bonding π and antibonding π^* branches have an appreciable dispersion, ~ 8 eV, which means a high degree of delocalization of the electrons originating from the $2p_z$ orbitals. The π and π^* branches cross

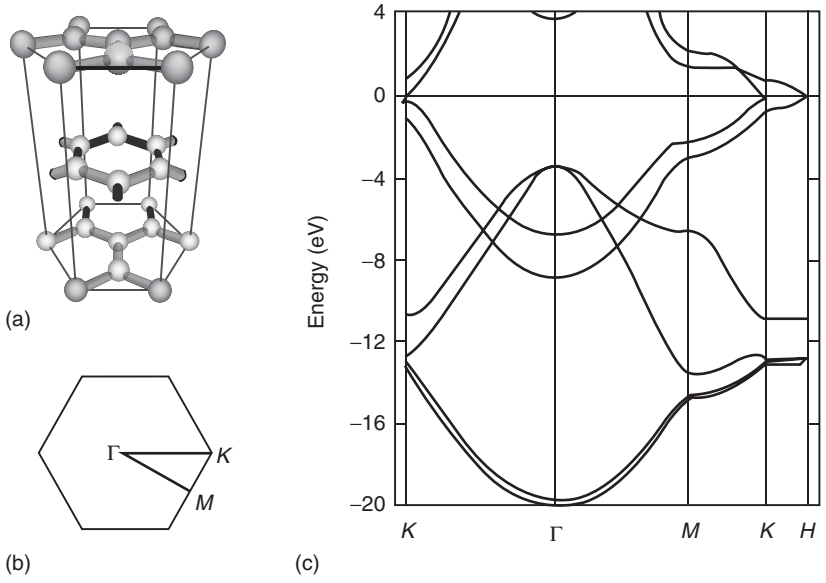

Figure 5 (a) Graphite crystal structure, (b) high-symmetry points in the basal plane of the first Brillouin zone of graphite, and (c) band structure of graphite calculated with the local-density approximation and the pseudopotential approach. (Courtesy of J C Charlier.)

each other for Bloch vectors very close to the *KH* line, which corresponds to an edge of the hexagonal prism defining the first Brillouin zone of graphite. There is a small overlap of $\sim 30\,\text{meV}$ between the π and π^* bands, and the Fermi level is located in this region. This means that graphite is a semimetal. It is a poor electrical conductor (room temperature resistivity of crystalline samples $\rho_{||} \approx 10^{-6}\,\Omega\text{m}$) because the number of charge carriers (electrons and holes) is small.

The high cohesive energy of graphite (see **Table 1**) comes almost exclusively from the strong σ interactions between the sp^2 hybrids and the less strong π interactions between the $2p_z$ orbitals. The atomic layers bind together by weak van der Waals forces. If the distance between the atomic layers of graphite is allowed to increase, each pair of branches, whose degeneracy was lifted off by the interlayer coupling in the graphite band structure, will degenerate into a single branch. The resulting band structure is that of graphene. In graphene, there is one π branch and one π^* branch. These branches cross at the corner K of the hexagonal first-Brillouin zone defined in **Figure 5b**. The Fermi level coincides with the crossing energy, and graphene is a zero-gap semiconductor.

Nanotubes

Carbon nanotubes are cylindrical forms of graphite. A single-wall nanotube (SWNT) is composed of one graphene sheet rolled up on a cylinder. The circumference of the nanotube is a translation vector of graphene, wrapped around in such a way that its two ends coincide. This vector has the form $\boldsymbol{C} = n\boldsymbol{a}_1 + m\boldsymbol{a}_2$, where n and m are two integer numbers (the wrapping indices of the nanotube), $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ being two Bravais vectors of graphene. As in graphite, the electronic structure of a nanotube close to the Fermi energy is dominated by π and π^* states. An SWNT can be metallic or semiconducting, depending on its wrapping indices. When the radius is not too small, the rule is that the (n, m) nanotube is a metal if $n - m$ is a multiple of three, otherwise it is a semiconductor, the gap of which is inversely proportional to its diameter d. This rule derives from the condition that the Bloch vector $\boldsymbol{k}_K$ of the K point (see **Figure 5**), where the π and π^* branches of graphene meet, satisfies cyclic boundary conditions around the circumference: $\boldsymbol{C} \cdot \boldsymbol{k}_K = l2\pi$, with l an integer. In fact, only the armchair (n, n) nanotubes are metallic, the nanotubes with $n - m$ a nonzero multiple of three have a small gap that scales like $1/d^2$ (see **Table 2**). The density of states of two nanotubes, a metal and a semiconductor, are shown in **Figure 6**. In the band structure of a metallic nanotube, two branches derived from the π and π^* branches of graphene meet at the Fermi level (see **Figure 6**). These branches, with nearly linear dispersion, give rise to a plateau of density of states around the Fermi level. Each band crossing the Fermi level contributes one quantum $2e^2/h$ to the conductance of the nanotube when it is connected to two macroscopic electrodes. This means that the minimum resistance of a metallic SWNT is $h/4e^2 = 6.45\,\text{k}\Omega$. Below room temperature, the intrinsic resistance of an isolated nanotube increases upon cooling. This unconventional behavior for a metallic system may be the signature of electron

Table 2 Electronic properties of the single-wall (n, m) nanotube

$n-m \neq \mathcal{M}(3)$	$n-m=\mathcal{M}(3)\neq 0$	$n-m=0$

d is the diameter, $\theta = \tan^{-1}[\sqrt{3}m/(2n+m)]$ is the chiral angle, $d_{CC} = 0.142\,\text{nm}$, E_g is the bandgap of the semiconducting tubes, $c_g \approx 3.1\,\text{eV}$, $n(E_F)$ is the density of states per atom at the Fermi level for the metallic tubes, and $\gamma_0 = 2.9\,\text{eV}$ is the π-electron interaction.

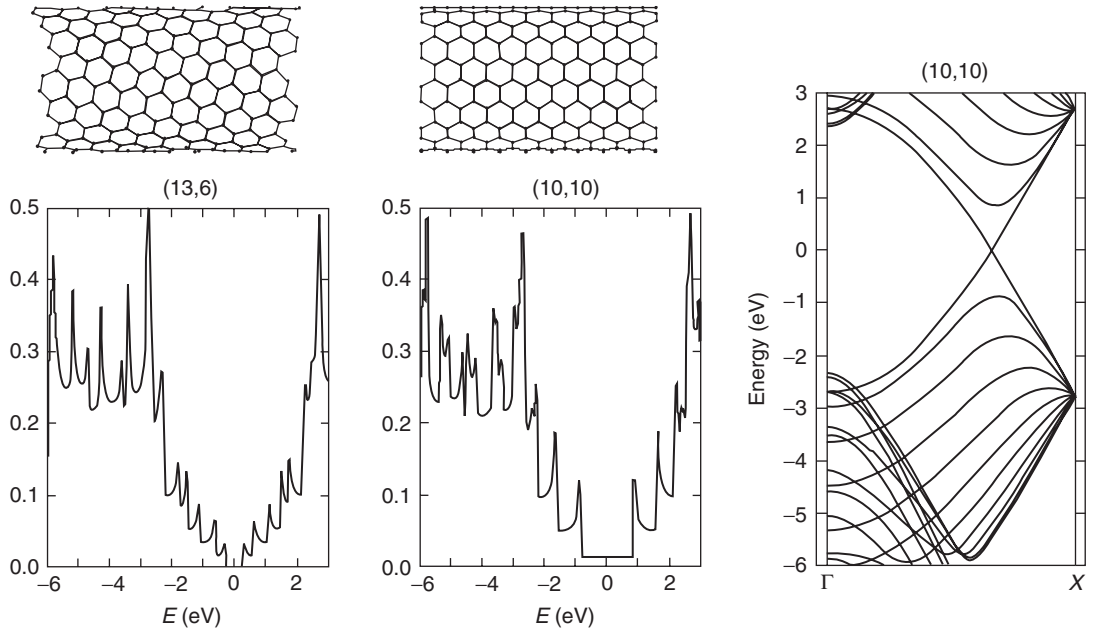

Figure 6 Tight-binding $\sigma + \pi$ electron density of states of the semiconducting (13,6) chiral nanotube and the metallic armchair (10,10) nanotube. The atomic structures of these two nanotubes are illustrated on the top. The band structure of (10,10) is shown in the right-hand side panel, van Hove singularities in the density of states occur at energies where an energy branch has a maximum or a minimum. The Fermi level is at zero energy.

correlation effects (Luttinger liquid), or it may indicate an increase of elastic backscattering cross section of the electrons by defects due to quantum interferences.

SWNTs most often pack together on a triangular lattice, in the form of bundles of 10–200 tubes. The van der Waals attraction between the tubes has small effects on the electronic density of states of the individual components. Multi-wall carbon nanotubes are composed of several single-wall tubes arranged coaxially, with interlayer distance $\sim 0.34\,\text{nm}$. The electronic structure of large multi-wall nanotubes is similar to that of graphite; roughly speaking, they behave like a semimetal. In principle, about one third of the coaxial layers are metallic, the remaining being semiconducting. Experiments reveal that, under high potential bias, each tubular layer of a multi-wall nanotube can transport a current $\sim 20\,\mu\text{A}$ before breaking, which corresponds to a very large current density.

A remarkable characteristic of the SWNTs, directly linked to their 1D periodicity, is the presence of spikes in the density of states (see **Figure 6**), called van Hove singularities. These spikes form real fingerprints of the nanotube structure. They can be probed by optical absorption, resonant Raman spectroscopy, electron-energy-loss spectroscopy (EELS), and scanning tunneling spectroscopy. An example of optical absorption spectrum of bundles of SWNTs with 1.3 nm average diameter is shown in **Figure 7a**. The peaks ~ 0.7 and 1.3 eV are due to transitions between the first pair (E_{11}^S) and the second pair (E_{22}^S) of van Hove singularities that border the gap of the semiconducting nanotubes. The absorption peak $\sim 1.9\,\text{eV}$ is due to interband transitions (E_{11}^M) across the plateau of density of states of the metallic nanotubes (see **Figure 6**). As in all sp^2 carbon systems, collective electron excitations from occupied π to unoccupied π^* bands of a nanotube form the so-called π plasmon, which can be probed by EELS. Momentum-dependent EELS experiments performed in transmission on SWNTs show the π-plasmon peak located at 5.2 eV when the electrons are collected in a

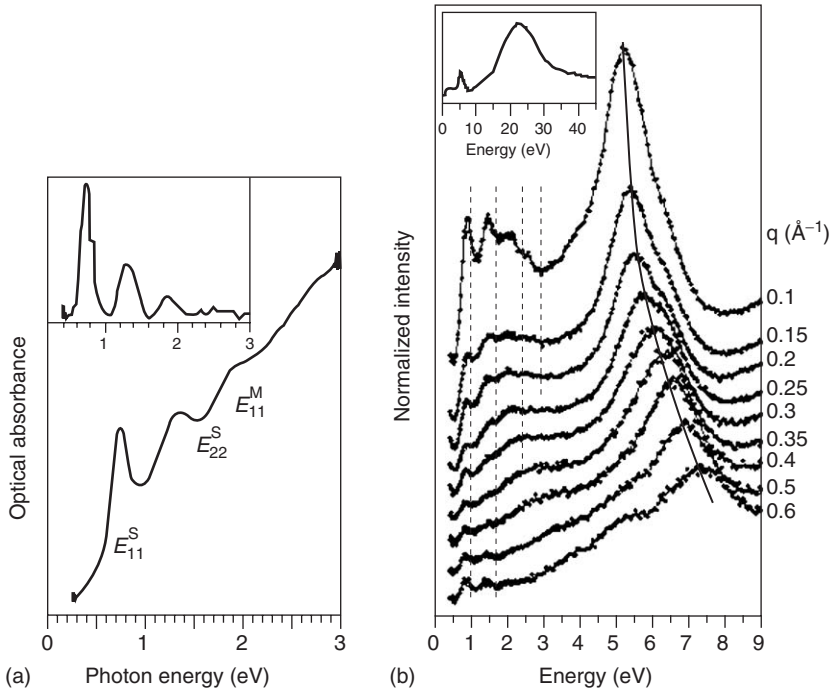

Figure 7 (a) Optical absorption spectrum of bundles of SWNTs, with interband transition peaks superimposed on the wing of the broad π-plasmon absorption band. The same spectrum after removal of the plasmon background is shown in the inset. (b) Electron-energy loss spectrum of purified, nonaligned bundles of single-wall carbon nanotubes as a function of momentum transfer q. The inset shows the loss spectrum in a wider energy range for $q = 0.15\,\text{Å}^{-1}$.

direction close to the incident direction (see **Figure 7b**). In this geometry, the wave vector q transferred from the electrons to the plasmon excitation is small. By increasing the detection angle of the spectrometer with respect to the incident direction, q increases, which produces an upward shift of the π-plasmon. The observed plasmon dispersion indicates dispersive bands of delocalized π electrons, as in graphite. At low energy, there are a few, well-resolved loss peaks, whose positions do not vary with q, and which are due to the interband transitions E_{11}^{S}, E_{22}^{S}, and E_{11}^{M}. In the inset of **Figure 7b**, the loss spectrum for $q = 0.15\,\text{Å}^{-1}$ is shown, the π plasmon is near 5 eV and the $\sigma + \pi$ plasmon, due to collective excitations of all the valence electrons, is near 23 eV.

Fullerites

Fullerites are solids realized by close packing of fullerene molecules, among which are C_{60}, C_{70}, C_{76}, C_{78}, and C_{84}. The cohesion of these crystals is assured by van de Waals interactions between the C clusters. In the C_{60} molecule, which is the most abundant fullerene, the atoms are located on a sphere of 0.7 nm diameter. They are positioned at the vertices of 12 pentagons, the edges of which have a length of 0.145 nm, slightly longer than the 30 bonds (0.140 nm) shared by the hexagons that connect the pentagons together. Due to curvature, the hybridization of the σ bonds in fullerene is not exactly sp^2. Nevertheless, one still may refer to $2p$ orbitals locally normal to the molecular shape surface, that will form π states, and $sp^{2+\varepsilon}$ hybrids, which point along the C–C bonds and will build σ states. The electronic states of the molecule have dominant π or σ characters, with some mixing of both characters due to the strong curvature of the molecule. All together, there are 60 π states, of which 30 are occupied. Similarly, there are 90 σ occupied states. Due to the icosahedral symmetry of the molecule, most of the electronic levels are degenerate. The highest occupied molecular orbital (HOMO) of C_{60} has h_u symmetry (fivefold degeneracy), and the lowest unoccupied molecular orbital (LUMO) has t_{1u} symmetry (threefold degeneracy). The HOMO–LUMO separation is 2 eV. The states near the HOMO–LUMO gap have a dominant π character. Because both the HOMO and LUMO wave functions are antisymmetric with respect to the inversion center of the molecule, the HOMO–LUMO transition is dipole forbidden. The lowest measured optical transition of the C_{60} molecule is ~ 3 eV.

Due to its lower symmetry, the C_{70} molecule has eight different bonds, whose length varies between 0.137 and 0.147 nm. The one-electron states of C_{70} are singly or doubly degenerate, the HOMO–LUMO separation is 1.8 eV. Like all molecules, the fullerenes

are highly-correlated electronic systems. An effective Coulomb energy U can be estimated by $U = I - A - \Delta$, where I is the ionization energy, A is the electron affinity, and Δ is the HOMO–LUMO separation. From the data of **Table 3**, one obtains $U \approx 2.8$ eV, which is a bare value for an isolated fullerene. It can be reduced by 1 eV in the solid state due to screening effects. In the solid, the electronic levels of the individual fullerene molecules are only weakly broadened by intermolecular coupling; they form bands with little dispersion, typically 0.5 eV. The C_{60} crystal (**Figure 8b**) is a semiconductor with a 2.2 eV band gap. The distribution of the occupied states in C_{60} fullerite is clearly revealed by photoemission spectroscopy (**Figure 8b**), whereas the unoccupied states can be probed by inverse photoemission and also by EELS (**Figure 8c**).

The fullerenes can be doped by intercalation (see the next section, "Intercalation compounds"), by incorporation of atoms in the cage (endohedral doping, e.g., Gd@C_{82}, Sc_2@C_{84}), and by atomic substitution (heterofullerenes, such as $C_{59}N$). X-ray photoemission provides valuable information on the electronic structure of these compounds. Inversely, various fullerenes and endohedral metallo-fullerenes can be encapsulated inside single-walled carbon nanotubes.

Table 3 Electronic properties of fullerene molecules

	C_{60}	C_{70}
Symmetry	I_h	D_{5h}
HOMO degeneracy	5	1 + 2*
LUMO degeneracy	3	1 + 2*
HOMO–LUMO gap (eV)	2.0	1.8
Ionization energy (eV)	7.5	7.3
Electron affinity (eV)	2.7	2.8

*Nearly degenerate states

In these remarkable structures, called carbon peapods, the encapsulated molecules form 1D chains. The fullerenes in a peapod can be more densely packed than in bulk fullerite. Their electronic levels form bands, which hybridize partly with the electronic states of the host nanotube.

Intercalation Compounds

Graphite intercalation compounds (GIC) are composed of planes of intercalant atoms or small molecules separated by a few graphitic sheets, in a sequence that repeats periodically along the *c*-axis as in a superlattice. The number of graphitic layers stacked between two successive intercalant planes is called the stage of the GIC. The intercalants can be electron donors (such as alkali metals) or electron acceptors (such as iodine). Depending on the intercalants used and their concentration, a huge class of GICs can be realized with tailored electronic properties, ranging from metals ($\rho_{||} \approx 10^{-8}\ \Omega$m) to insulators.

Similar to graphite, bundles of single-wall carbon nanotubes can be doped by intercalating either electron acceptors (*p*-type doping) or donors (*n*-type doping) between, and sometimes, inside the tubes. In all cases, there is a charge transfer, a noticeable modification of the optical response of the nanotubes, and a strong reduction of the electrical resistance of the bundles. The Fermi level of the nanotube can be shifted by more than 1 eV by electron or hole doping. In the case of alkali intercalation, for instance, the Fermi level moves up across the conduction bands of the nanotubes. As a consequence, the lowest optical transitions E_{11}^S, E_{22}^S, and E_{11}^M, are progressively suppressed as their final states become occupied. The corresponding resonant behavior of the Raman cross section disappears at the same occasion.

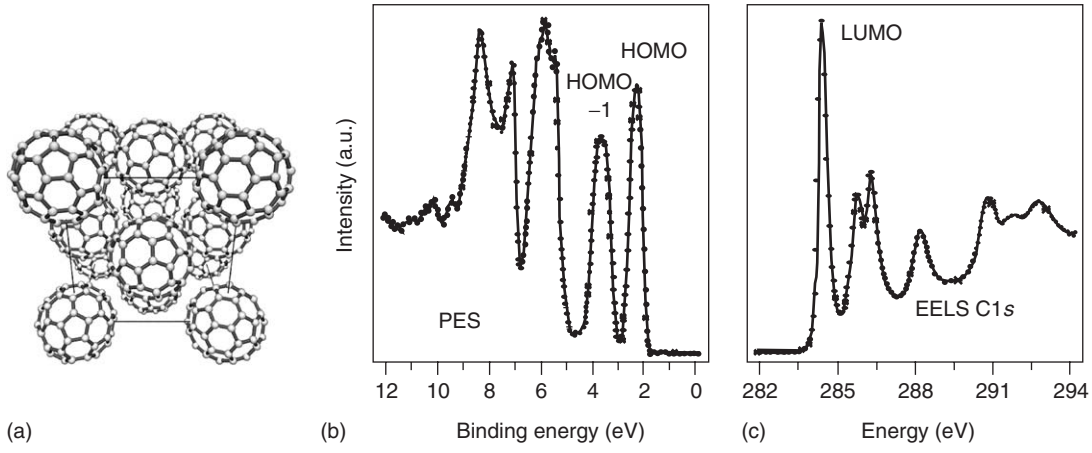

Figure 8 (a) Conventional cubic cell of the C_{60} fullerite, (b) Room temperature photoemission spectrum, and (c) C1*s* excitation EELS spectrum of C_{60} thin film, revealing the distribution of occupied and unoccupied electronic states, respectively.

The fullerites can be doped by intercalation of atoms and small molecules in the octahedral and tetragonal cavities of their crystal lattice. Since the electron affinity of the fullerene molecules is high, they easily accept electrons from the intercalants. In the case of C_{60}, the phase diagram of the A_xC_{60} compounds, with A an alkali metal, is remarkably rich. The x electrons given by the ionized alkali atoms fill in the t_{1u} LUMO-derived band, which may accommodate six electrons. This simple rigid band-structure picture predicts that all the A_xC_{60} compounds should be metallic except for $x = 0$ and 6. In fact, there are strong electron correlation effects in fullerites, as mentioned above, which invalidate this model, and only A_3C_{60} is metallic. Remarkably enough, most of the compounds having that composition are superconductors. The critical temperature T_c increases with increasing the ionic radius of the intercalant: 19 K in K_3C_{60}, 30 K in Rb_3C_{60}, and 32 K in $RbCs_2C_{60}$. The raising of T_c is due to the narrowing of the LUMO-derived band and the resulting increase of density of states at the Fermi energy.

Disordered Carbons

Carbon may form different partially disordered solids depending on the preparation technique used and experimental conditions. All these disordered forms of carbon have considerable technological interest. They belong to two structural families: turbostratic carbons, which derive from graphite (stack of graphene layers, now with orientational disorder in their sequence), and amorphous carbons, which mix variable proportions of sp^2 and sp^3 units in a nonperiodic arrangement. Carbon black is a turbostratic carbon obtained by combustion of carbon-rich precursors under oxygen depleted conditions; its texture can be viewed as a folded version of the graphite network. Glassy carbon, also a turbostratic carbon, with a density ranging from 1 to 1.5 g cm^{-3}, is formed by vacuum pyrolysis of polymerized organic resins; it is built up from nanosized graphene stacks that enclose 1–5 nm sized pores. Graphite-like amorphous carbon is produced by sputtering or evaporation; its density varies between 1.8 and 2.27 g cm^{-3} (density of graphite). Diamond-like amorphous carbon, obtained in general by C atom or ion deposition, has a density intermediate between graphite and diamond (3.52 g cm^{-3}).

The amorphous carbons form a wide range of structures intermediate between the two extreme allotropic forms, diamond and graphite. The density of a carbon sample can be determined from the position of its $\sigma + \pi$ plasmon measured in EELS, by the formula $\omega_p = \sqrt{ne^2/\varepsilon_0 m^*}$, where n is the valence-electron density, directly related to the atomic density, ε_0 is the dielectric permittivity, and m^* is the electron effective mass ($\approx 0.87\, m_e$). The bonding type of a nonhydrogenated, disordered carbon can be characterized by measuring the ratio between sp^3 and sp^2 hybridization states, though there may be a small proportion of sp^1 states as well. EELS and C1s photoelectron spectroscopy give access to the sp^3/sp^2 fraction. Experiments indicate that the sp^3/sp^2 ratio increases linearly with the atomic density of the sample.

When the sp^2 and sp^3 sites are intermixed at the atomic scale, the electronic structure of amorphous carbon near the Fermi level is dominated by π and π^* states, arising from the sp^2 sites, and to a much lesser extent, by disorder-induced σ-band tails due to both sp^2 and sp^3 sites. When the sp^3/sp^2 ratio is large, as in most diamond-like carbons, one speaks of tetrahedral amorphous carbon. This material is hard, electrically insulating, and transparent. The minority sp^2 sites tend to form small clusters; they control the band gap, which can be reduced by a factor of 2 or more with respect to crystalline diamond. In sp^2-rich systems, the sp^3 sites can be randomly and uniformly distributed among the atoms, leading to a non-graphitic disordered structure. The electrical conductivity of such a sample is small and exhibits a semiconducting behavior. By heat treatment, and concomitant migration of the sp^3 defects, graphite-like amorphous carbon is obtained. It can be viewed as a random assembly of nanometer-sized turbostratic entities, partly embedded in a matrix of four-fold atoms. The electronic structure and the

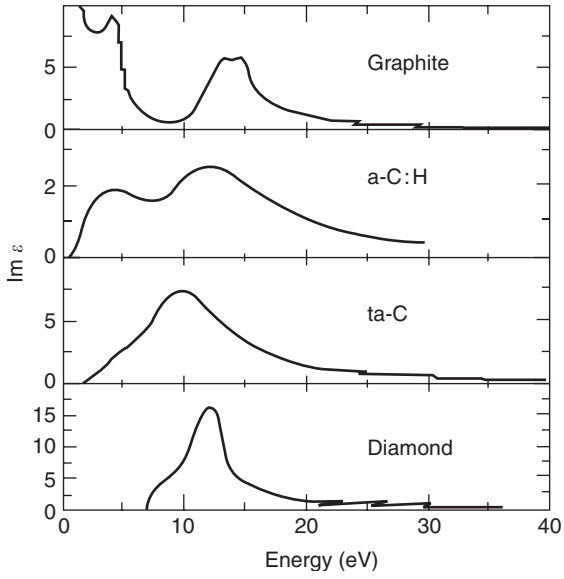

Figure 9 Plot of the imaginary part of graphite, graphitic amorphous carbon, tetrahedral amorphous carbon, and diamond vs. energy.

conductivity, then, depend critically on the size distribution of the turbostratic entities and on their degree of disorder.

To illustrate how the electronic states of amorphous carbons may interpolate between those of graphite and diamond, **Figure 9** shows the imaginary part of the dielectric function of graphite, together with a graphitic-like amorphous carbon which contains some hydrogen (a-C:H), a tetragonal amorphous carbon (ta-C), and diamond. The peaks in these spectra reflect excitations of the π and σ valence states. In graphite, one sees the presence of $\pi \rightarrow \pi^*$ transitions ($\sim 4\,\text{eV}$) and $\sigma \rightarrow \sigma^*$ transitions ($\sim 14\,\text{eV}$). In a-C:H, the $\pi \rightarrow \pi^*$ transitions are slightly reduced (consistent with a small fraction of sp^3 sites), in ta-C, they are strongly reduced (consistent with a large sp^3/sp^2 ratio), and in diamond, they are absent.

Catalysts: Combinatorial Catalysis

A Hagemeyer and A Volpe Jr., Symyx Technologies, Inc., Santa Clara, CA, USA

Introduction to Combinatorial Heterogeneous Catalysis

The use of combinatorial and high-throughput methodologies to accelerate the research and development process in heterogeneous catalysis is increasing at a rapid pace in both industrial and academic laboratories. For industry, the key drivers include the need to reduce the time-to-market for new and optimized catalysts and processes, increased probability of success due to the ability to perform far greater numbers of experiments than in the past, better intellectual property protection made possible by the thoroughness with which a given technical area can be explored, shorter/more projects possible per unit time, the benefits of "early failure," and the increased organizational efficiency resulting from improved data storage, access, analysis, and sharing. Similar advantages have already been addressed by the pharmaceutical industry, where long development times and high research costs have forced the development of high-throughput approaches to accelerate the drug discovery process.

Traditional methods for the discovery of new heterogeneous catalysts are not very efficient because discovery protocols are primarily trial-and-error processes. The ability to predict the required catalyst composition, structure, and formulation for a given chemical transformation is low and, for complex multicomponent catalysts, almost nonexistent. In addition, there are many variables that affect a catalyst, including not only the elemental composition but also metal precursor types used, wet synthesis variables, method of post-treatment such as calcination conditions, presence and type/shape of catalyst support, and operating conditions such as temperature, pressure space velocity, and reactant gas composition. These variables are too numerous to adequately explore using conventional methods, especially in discovery programs, but also in catalyst optimization work where there may be fewer variables but where catalyst complexity (catalysts are often multicomponent systems) is high.

The high-throughput experimental process in heterogeneous catalysis involves the software assisted design of diverse, high-density assemblies or arrays of potential catalytic materials (known as "libraries"), and high-throughput synthesis, characterization, and screening techniques that are characterized by using robotics and advanced software. The integrated synthesis and screening of a plurality of catalysts in library format has been recognized as an essential factor. Equipment miniaturization and integrated data management systems are also key

aspects of successful workflows. The development and implementation of these methods requires the involvement of unconventional engineering and software resources not commonly available at chemical, refining, and petrochemical companies where heterogeneous catalysis is practiced. High-throughput research is optimally performed by interdisciplinary teams typically made up of chemists, engineers, and programmers.

Work beginning in the mid-1990s, led by Symyx, has significantly advanced the field of high-throughput experimentation and initiated the many efforts that are currently underway. The number of experiments that can now be performed using state-of-the-art high-throughput workflows can be an order of magnitude or more higher than was possible only a few years ago using conventional research. For example, a high-throughput program can yield 50 000 experiments per year compared to 500–1000 experiments using traditional methods. This article describes the current state-of-the-art synthesis and screening techniques for high-throughput experimentation in heterogeneous catalysis with a focus on technology developed over the last 2–3 years. For focus, this discussion is being limited to gas–solid systems. Earlier work has been extensively reviewed.

The Hierarchical Workflow in Heterogeneous Catalysis

The research and scale-up phases leading to commercialization are shown in **Figure 1**. The high-throughput workflow can be divided into primary, secondary, and, in some cases, tertiary screening. Primary screening approaches are typically very high throughput qualitative or semiquantitative screens performed on small samples often using unconventional reactor designs, and are most often focused on discovery. The objective during this phase is to broadly screen a large and diverse set of material types that may perform the desired catalytic reaction. Discoveries, termed "hits," are then taken to the secondary screen and, importantly, compositional space that is not useful is discarded. Although it is critical that primary screening results correlate with the real catalytic process, this can usually be accomplished by screening for qualitative trends and using relative performance rankings generated by using a simplified analog of the real process parameter. The primary screen must be designed to minimize both false positives and especially false negatives. Primary screening removes the key bottleneck in the R&D process.

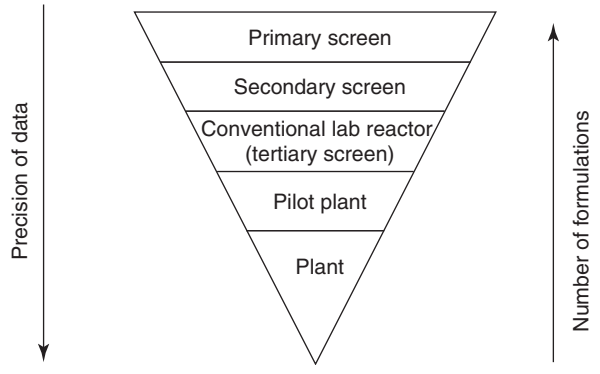

Figure 1 Stages in catalyst discovery, scale-up, and commercialization.

Secondary screening is used for confirmation and optimization of primary hits. In contrast to the primary screen, the catalyst form, reactor, and process analytics are designed to closely represent those of the real bench-scale material and reaction. The data quality and precision should be equivalent to that of a standard laboratory reactor since the goal is to observe small improvements in performance as a function of catalyst modification. Optimized hits, termed "leads," are taken to the tertiary screening phase to generate commercial development candidates. If necessary, tertiary screening can be performed using conventional fixed-bed microreactors with full reactant and product detection and full mass balance, and in some cases is also parallelized. Secondary synthesis and screening technology has, in many cases, evolved to the point where the quality of the data obtained is equivalent to that obtained using conventional laboratory technologies. Accordingly, in some instances, pilot plant studies can proceed directly from secondary screening, without tertiary screening.

A generalized set of high-throughput workflows used in heterogeneous catalysis is depicted in **Figure 2**. The cycle of library design, synthesis, screening, and data analysis is illustrated. Software tools and databasing of synthesis and performance data are key factors.

High-Throughput Synthesis Technologies

For primary screening, catalyst libraries can be efficiently prepared and tested on two-dimensional substrates. Symyx has described the automated preparation of 16×16 catalyst arrays of approximately 1 mg each on 4 in quartz wafers (**Figure 3**). To prepare these libraries, precursor solutions are first premixed in microtiter plates and then volumetrically transferred to quartz or glass catalyst substrates using automated liquid handling robots, either in a rapid serial or parallel manner. For impregnation synthesis, catalyst supports are predispensed onto the

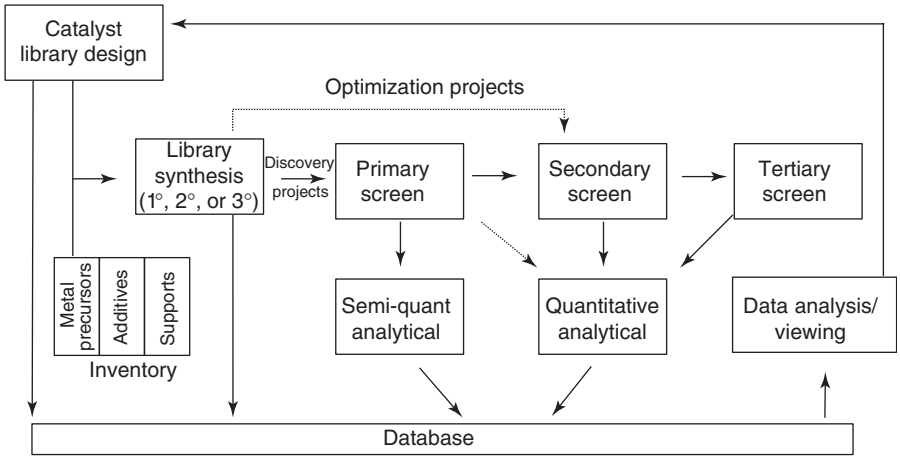

Figure 2 High-throughput catalyst discovery workflow.

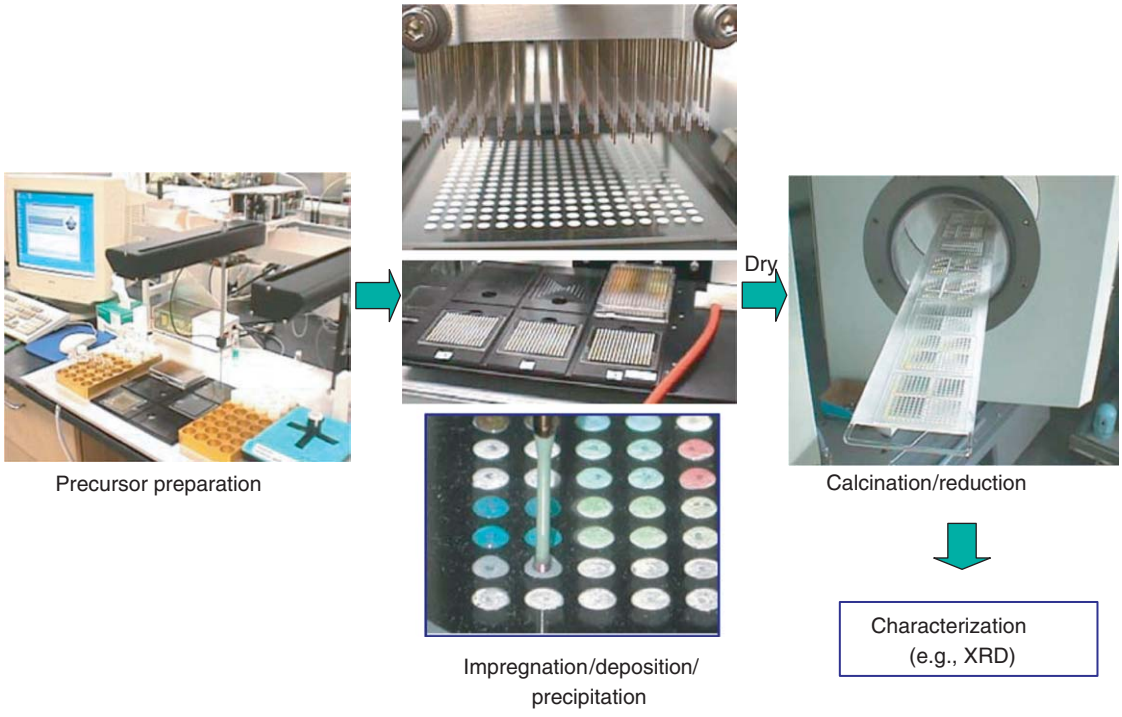

Figure 3 Example of a primary synthesis workflow. Catalysts can be prepared by impregnation, deposition/evaporation, or precipitation.

wafers as slurries resulting in an array of thick film support spots. After drying, the premixed catalyst precursor solutions are added using advanced, often fully parallel, liquid-dispensing techniques allowing precise addition of appropriate liquid volumes (this is very important for incipient wetness impregnation, for example). After drying, the wafers are calcined/reduced to form the final catalyst oxides, metals, etc., and then tested for catalytic activity in primary screening reactors. **Figure 3** shows hardware components for impregnation synthesis, including the liquid handling robot, parallel liquid transfer (impregnation) tool, and post-treatment furnace. This method produces catalysts using preparative methods that closely resemble those used on much larger scales, and can also be used for precipitation and solvent evaporation synthesis.

Apart from parallel synthesis, methods of pooled synthesis have also been reported for primary screening. In one recent proof-of-concept example that is

an alternative to spatially addressable libraries, Mallouk *et al.* have described the synthesis of split-pool material libraries consisting of noble metals on gamma alumina beads. With this technique, the support beads are placed in small vials and impregnated with several combinations of many metal precursor solutions. After drying and thermal treatment, the beads are mixed together and then split again into separate vials. This process is repeated several times to generate a library. The theoretical number of different bead compositions is given by $N\ (\mathrm{nm}) = (n+m-2)!/(n-m)!(m-1)!$, where n is the number of components and m is the number of split-pool operations. The use of fluorescent dyes and micro-X-ray fluorescence as tags for post-synthesis bead identification is proposed. Although this method makes it possible to prepare large libraries in a simple manner, a rapid method of analyzing the individual bead compositions still needs to be developed. Conceivably, some type of single-bead reactor could be used for the screening step. The use of continuous films (as opposed to discrete spots or grids) is another approach for fast parallel synthesis of compositionally diverse flat libraries, prepared, for example, by physical vapor deposition techniques.

Larger amounts of bulk catalysts (up to approximately 1 g) are usually prepared for secondary screening because the testing reactors are generally fixed-bed units. Synthesis methods utilize partially or fully automated procedures that are similar to larger-scale conventional preparations. For example, an impregnation synthesis workflow for secondary screening in use at Symyx consists of several stations for precursor preparation, support dispensing, impregnation, catalyst washing, and thermal post-treatment. The metal precursor solution mixtures from the experimental design are prepared in an array of vials from a set of stock solutions. The supports are pre-sized, either by pressing, crushing, and support powders, or by crushing and sieving larger-scale commercial supports such as extrudates or spheres. These supports are dispensed into an array of vials using a powder-handling robot prior to impregnation. Obtaining good liquid–solid contacting during the impregnation is important for obtaining a uniform catalyst. An effective way to achieve this is by mechanically fluidizing the supports while adding the precursor solutions. After drying and sometimes calcination, the catalysts may be washed with water or another solvent to remove undesirable components and thermally treated under the appropriate gas flow conditions for oxidation, reduction, sulfidation, etc. Inspection of catalyst particles by optical microscopy as well as SEM/EDS is often used to investigate catalyst distribution within the support particles. Precipitation and solvent evaporation workflows to synthesize bulk catalysts are also available.

In the zeolite area, high-throughput hydrothermal secondary synthesis workflows have also been reported. For example, the preparation of new, open-framework zinc phosphate compounds has been recently reported by Xu *et al.* using a multi-well autoclave and automated XRD analysis using a GADDS microdiffractometer for characterization. The authors demonstrate the utility of a crystallization reactor containing 64 Teflon chambers at the 800 µl scale. Reagent dispensing and mixing as well as product separation and characterization are automated. Several other multi-autoclaves for the synthesis of molecular sieves can be found in the literature.

Some of the challenges in these secondary synthesis workflows, especially when making unsupported catalysts, are rapidly and reproducibly sizing the catalyst particles properly for the secondary reactor-bed dimensions, and performing solids processing steps such as grinding, which are often important synthetic variables. Processing steps such as parallel pressing, grinding/crushing, and sieving of catalysts are beginning to be addressed.

High-Throughput Screening Technologies

The focus of high-throughput heterogeneous catalysis over the past few years has been on the development of new reactors. Designs range from scaled-down traditional laboratory reactors sharing some common components such as feed systems and detectors to fully parallel units allowing the evaluation of hundreds of catalysts simultaneously. Several analytical techniques for the high-throughput screening of catalysts have recently been proposed or demonstrated. These include gas and liquid chromatography, thin layer chromatography, resonance-enhanced multiphoton ionization, time-resolved and differential IR thermography, scanning mass spectrometry, photoacoustic analysis, gas sensors, and colorimetry/fluorescence. While GC, IR thermography, and fluorescence or colored-dye assays have been some of the most commonly used methods, especially in early work, new techniques have emerged to identify active catalysts in an array. The need for fast screening of libraries together with the complexity involved in parallel or rapid serial detection of the reactants, products, and side products make it difficult for any single screening method to offer a general solution to the problem. It is important, therefore, to develop screening technologies and methods suitable to the detection requirements of the reaction(s) of interest. In many cases, it is essential to have a combination of screening tools available for screening

under different conditions and to adequately characterize the product streams.

Symyx researchers have recently described a primary screening reactor system based on a microfabricated fluidic flow distribution and equalization device, a 256-element catalyst array, and optical detection methodology allowing fully parallel reaction and detection (**Figure 4**). Microreactors are formed by connecting ("sandwiching") together the catalyst wafer and a gas distribution wafer. Each of the 256 individual reactant streams contacts a 2 mm diameter $\times$ 0.2 mm deep well containing $\sim$1 mg of catalyst, and then flow simultaneously out of the reactors and through a temperature gradient to a cooled absorbent plate/wafer where the products of interest are trapped by absorption or chemical reaction. After sufficient amounts of products have accumulated, the absorbent array is removed from the reactor and sprayed with a dye solution in a separate spray station. A dye is chosen that selectively interacts with the reaction product(s) of interest to cause a change in the absorption spectrum, or the enhancement or bleaching of fluorescence. The developed absorbent array is then imaged by a CCD camera, and the intensities are integrated and the data are stored. Standard catalysts and control spots are present on every wafer to allow normalization and to check the performance of the known standard. This reactor system has recently been used to screen catalysts for the partial oxidation of ethane to acetic acid and the ammoxidation of propane to acrylonitrile, and the results are reported in the literature. A continuous flow parallel 49-channel reactor using a manifold of capillaries as connectors to an analytical device containing filter paper impregnated with an organic dye for the colorimetric assay has been reported by Schuth and demonstrated for NOx abatement.

A fast serial scanning mass spectrometer either independently or in combination with a photothermal deflection detector has been reported for the primary screening of heterogeneous catalyst libraries. Local heating and local sampling of catalyst spots prevents cross talk and interference between neighboring spots. In the case where the products can be identified without overlapping signals, mass spectrometry alone is applicable. In cases where the MS signals overlap, the mass spectrometer is used in conjunction with the additional detection system. For example, the sensitivity of the PTD detector to ethylene is below 0.1 ppm. Related work in this area has been described by the groups of Maier and Senkan, whose scanning MS devices are characterized by common heating of a wafer-formatted array of wells or metal-impregnated shaped beads in parallel channels, respectively.

Willson, and subsequently Maier, independently also describe a parallel method for screening catalyst libraries by differential IR thermography. IR thermography measures the heat evolved due to catalytic activity in exothermic reactions. In Maier's protocol, the image of the IR radiation emitted by the catalyst was used to obtain information on the surface

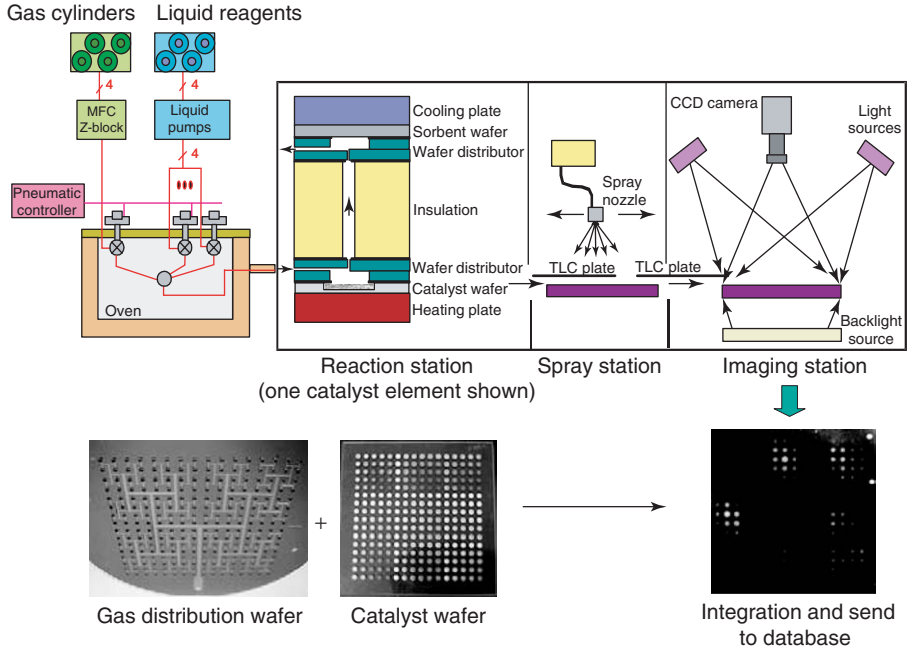

Figure 4 Primary screening reactor for evaluating 256 catalysts in parallel.

temperature and hence the catalyst activity. The IR images of a catalyst library in a reaction block were obtained using an IR camera with a PtSi array detector. The method was demonstrated using a number of examples. In one example, mixed oxides were prepared as amorphous microporous materials (AMMs) by sol–gel. The compositions of the AMM-mixed oxides consisted of a small percentage of a transition metal oxide in silica or titania. The catalysts were prepared *in situ* in the wells of a reaction block. The library was used to study the hydrogenation of cyclohexene as well as the oxidation of isooctane and toluene in air. The mixed oxides with catalytic activity could be seen in the thermographic image of the catalyst library during reaction.

Another interesting method for screening catalysts reported by Smotkin *et al*. utilizes a composite membrane system made up of a semipermeable polymer onto which is overlaid a porous carbon paper on which a catalyst library has been deposited. Detection is by mass spectrometry and the catalysts are locally heated by a CO_2 laser. The membrane separates the catalyst reaction chamber and the vacuum of a QMS. Products flow through the membrane to the mass spectrometer. Note that a loss of detection sensitivity may be a limitation if library density were to be increased over the 12 catalysts currently used.

Secondary screening is normally carried out in parallel fixed-bed reactors sized for catalyst loadings between 15 and 500 mg. **Figure 5** depicts a 48-channel reactor system with sets of eight reactor wells (channels) contained in six individual modules. The effluents of six reactors are analyzed in parallel. Reactant feeds are generated by vaporizing liquid flows from HPLC pumps, high-pressure syringe pumps, and mixing this vapor with gas components metered through mass flow controllers. The reaction feed is divided equally between the 48 channels using flow restrictors such as silica capillaries. The capillaries feed into the inlets of the reactor modules. Each of the eight reaction product streams leaving a reactor module are fed into a stream selection valve where one of the eight effluents is selected and sent to a GC for on-line analysis. The remaining channels are combined and sent through a back-pressure controller to waste.

A key aspect of running a high-throughput reactor successfully is to ensure high system reliability and data integrity. For the above system, for example, after the catalysts are loaded into the reactor and the modules are sealed, a leak check is performed. If a leak is detected, additional valving is used to isolate the location of the leak for repair. After a leak check has been successfully completed, a flow rate check is performed through each of the 48 channels to ensure that the flows are within specifications. Once these checks are completed successfully, the reaction gasses are mixed and stabilized. Reaction temperatures are then set and must reach the set point or the run is stopped. Each analytical selection valve has a bypass input to allow the feed to be directly analyzed on each GC. This allows analytical measurements to be normalized to the reactant feed compositions and allows tracking of any feed compositional changes. During screening, parameters such as temperatures, pressures, and flow rates are monitored and recorded. At the end of a run, the flow rates are measured again to ensure that all flows are still within range. All data are stored in a database for future reference.

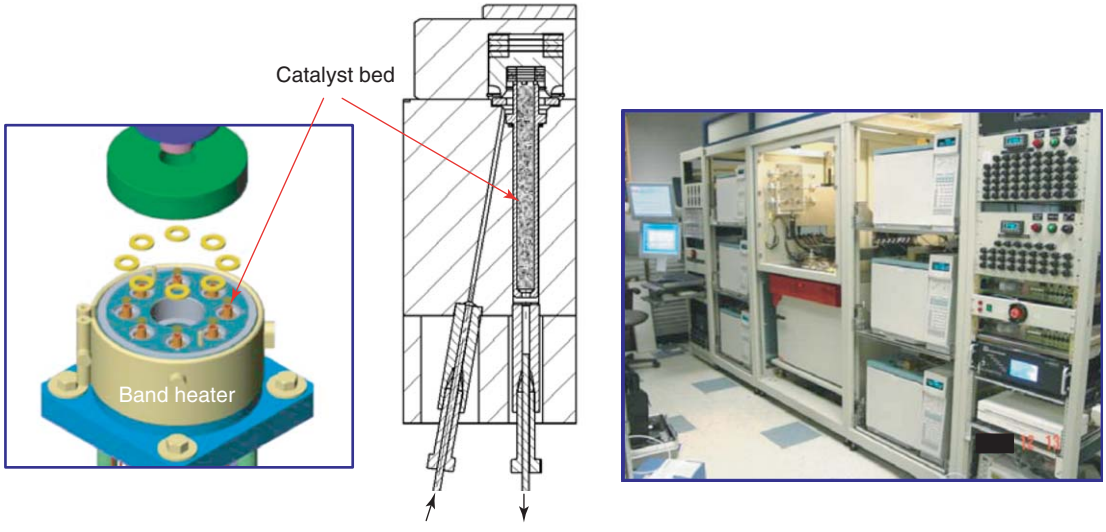

Figure 5 48-Channel fixed-bed reactor for secondary screening in use at Symyx Technologies.

Researchers at IMM, Mainz, have developed a modular parallel 48-channel primary-/secondary-screening reactor. It consists of a gas distribution module, a catalyst titer plate/reaction module, an insulation module to separate hot and cool sections of the reactor, and a multiport valve module to deliver products to a GC. The catalysts are prepared by sputtering or by impregnating catalyst precursor solutions onto a predispensed support on the titer plate. The catalytic combustion of methane was used as a demonstration reaction.

An interesting high-temperature, high-pressure 16-channel secondary screening reactor that utilizes a fast-response stainless-steel photo-etched fluidic switching valve plate that has no moving parts and can operate at temperatures above those of conventional valves has been described by researchers from University of Sheffield. The valve is operated serially, directing one stream to an FTIR detector and 15 streams to a vent line. It is designed to minimize dead volume between the reactor and detector, which consists of a low-volume commercial IR light pipe. The reactor has been used for the evaluation of catalysts for the hydrogenation of CO to ethanol, with quantification of products in ~ 2 min. A 49-channel parallel flow reactor for use at pressures of up to 5 MPa has been developed by Schuth's group and applied to the high-pressure methanol synthesis over Cu/ZnO catalysts.

High-Throughput Characterization Techniques

It is often of interest to characterize properties of catalysts synthesized by various high-throughput methods, especially in the secondary screening phase. Currently, a mix of conventional techniques and high-throughput methods are in use. The current trend is to adapt conventional single-channel characterization tools with movable x–y stages or auto samplers to increase throughput by automated serial analysis of catalyst libraries. Pore volume, acid site density, and metal surface area can be obtained by gas adsorption; however, there have been few, if any, reports of high-throughout methods for these analyses, although auto samplers are often used. Particle-size distribution via light scattering, morphology via SEM or TEM, phase and structure by XRD, and elemental composition via EDS and XRF have been implemented for use on arrays of catalysts.

Applications

This section lists examples of the application of high-throughput methods to heterogeneously catalyzed chemistries. Combinatorial catalysis is ideally suited for the discovery of novel noble metal and mixed metal oxide catalyst formulations for total combustion/VOC removal, emissions control from stationary and mobile sources (NOx abatement, CO oxidation, automotive three-way catalysis) due to the uncomplicated feeds and product mixes that often allows truly parallel detection and very high sample throughputs in primary screening. Furthermore, combinatorial methods are advantageously applicable to multicomponent catalysts (mixed metal oxides, alloys) for selective oxidation, hydrogenation, and dehydrogenation. The demand for higher selectivities and efficiencies in refining has triggered the search for new zeolite structures by parallel hydrothermal synthesis. Additionally, improved fast analytical techniques are making it increasingly possible to perform high-throughput experimentation on complex real plant feeds, especially in the secondary screening phase.

Published examples of extended and comprehensive gas-phase combinatorial screening programs include ethane oxidative dehydrogenation leading to the discovery of novel Ni–Nb–Ta catalysts (Symyx), combustion catalysis due to the demand for better low-temperature activity (Maier) in exhaust gas and air cleaning, automotive emission, stoves, and explosion prevention sensors, the water gas shift reaction aiming at high activity nonpyrophoric catalysts for fuel processors in future fuel cell driven vehicles (Symyx, Mirodatos), preferential CO oxidation in excess hydrogen (Mirodatos, Wolf), propylene oxidation over supported metals (Senkan), isobutane oxidation over mixed metal oxides (Maier), low-temperature light paraffin isomerization catalysts (Corma), methanol synthesis catalysts (Schuth), ethylbenzene oxidative dehydrogenation (Degussa), HCN synthesis over supported noble metals (Baerns, Degussa), new anode and cathode formulations for PEM fuel cells (Symyx, Mallouk, Johnson Matthey), and diesel tailpipe emissions control (HTE).

Future Trends in Combinatorial Catalysis

Combinatorial methods are allowing the exploration of very large and diverse compositional, structural, and process spaces, much of which would otherwise go unexplored, but from which new and unexpected discoveries often arise. The result is an increasing probability of discovering new catalytic materials, facilitated catalyst and process optimization, and the availability of large amounts of information to aid the chemist in the development of new heterogeneous catalysts.

Looking forward, it is clear that the field of combinatorial heterogeneous catalysis will continue to advance and be applied at an ever-increasing rate.

Areas in which advances are needed and are being pursued include: acceleration of scale-up activities using commercial-sized catalysts (e.g., large commercial-size pellets with control over active catalyst distribution in the support), performing process optimization in high-throughput reactors, development of new equipment that can handle harsher reaction feeds and conditions, including high temperature, pressure, corrosive and heavy feeds, improved and faster analytical methods for analyzing reaction products from screening (including analyzing complicated real plant feeds) and for faster/better characterizing catalyst materials, and further miniaturization and automation.

Catalysts: Materials

A Hagemeyer and A Volpe Jr., Symyx Technologies, Inc., Santa Clara, CA, USA

Definition of Catalysis

A "catalyst" is defined as a compound that increases the rate of a chemical reaction, but which is itself not consumed or changed by the reaction. A catalyst does not, however, affect the thermodynamics of a reaction or the equilibrium composition of the reaction components.

The Importance of Catalysis

Catalysis is very important and widely applied in the chemical and pharmaceutical industries, in refining, and in environmental protection. A large number of catalysts and catalyst types are utilized commercially, including heterogeneous catalysts (porous solids), homogeneous catalysts (dissolved in liquid reaction mixture), and biological catalysts (as enzymes). Catalytic processes include single-phase homogeneous liquid, two-phase heterogeneous liquid–solid and gas–solid (the most prevalent), and three-phase heterogeneous liquid–solid–gas, implemented using a

variety of reactor types. Catalyst activity, selectivity, chemical and mechanical stability, lifetime, and form determine the economics and capital cost of each process. Control factors to tune catalyst properties are bulk chemical composition, surface composition, stability of active phases, active site distribution, texture (i.e., surface area and porosity), and mass and heat transport. The method of preparation is also crucial to final catalyst performance.

Catalytic processes are superior to noncatalytic synthetic routes mainly because of energy, raw material savings, and selectivity enhancements. Advantages of heterogeneous catalysis compared to homogeneous catalysis include easy separation of the catalyst and reaction products, minimized reactor corrosion, and larger ranges of possible reaction conditions, which is important when the equilibrium limits the reaction to extreme conditions. Typical heterogeneous catalysts comprise metals or metal oxides and inorganic microporous materials such as zeolites. This article focuses on heterogeneous catalysis in the vapor phase.

Applications of Catalysis in Chemical Processes

Thermodynamics frequently limits the concentration of the desired product(s) of a reaction, and conditions (temperature, pressure, space velocity, and reactant composition) must be optimized to maximize the equilibrium concentration of those products. The next step is to develop a catalyst to increase the reaction rate since it is frequently too slow to be practical. It might seem that the optimal catalyst should produce the highest possible reaction rate; however, this is not always the case since such a catalyst might exhibit mass and energy transfer limitations and could be unstable under feasible reaction conditions.

The catalyst and the reactor form an integrated unit. Common reactor types (and associated catalyst formulations) are fixed beds (shaped millimeter-sized bodies), fluidized beds (50–150 μm diameter fluidizable particles), stirred tank reactors (slurried powders), and trickle beds (for three-phase reactions). Reactor operation can be continuous, semicontinuous, or batch, with adiabatic or isothermal temperature control. Consideration of mass and energy balance from the macroscopic catalyst bed scale down to the active center is needed to address the complexity of heterogeneous catalysis (**Figure 1**).

Status of Catalysis Research and Catalyst Discovery

Current approaches used for the understanding and rational design of catalysts include various types of spectroscopy on catalysts and catalyst models, acquisition of kinetic data for catalytic reactions, quantum-chemical and thermodynamic calculations for the elementary steps and molecules involved in a reaction, and microkinetic modeling.

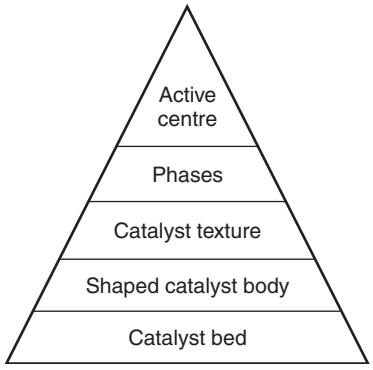

Figure 1 Heat and mass balances can be formulated on five different macroscopic and microscopic scales.

Although catalysis has been used in industry for more than 150 years, the experimental techniques for investigating catalysis at the atomic level did not become routine until about 25 years ago, and the computational techniques have not yet become routine. For this reason, the field has been largely an empirical one. Recently, high throughput methodologies for catalyst discovery and optimization (particularly for complex multicomponent systems where theory is lacking) have emerged and are rapidly expanding.

Kinetic Considerations

The slow step in a reaction mechanism is known as the "rate-limiting step" since it determines the rate of the overall reaction. The rate-limiting step can usually be described as an energy barrier the system must cross. The rate constant has the temperature dependence:

$$k = A \exp(-E_A/RT)$$

where A is the pre-exponential factor and E_A is the activation energy. The activation energy can be determined graphically from experimental determination of the rate constant as a function of reaction temperature through an Arrhenius plot. A catalyst provides an energetically easier reaction pathway to transform reactants into products that is characterized by a lower activation energy (**Figure 2**).

The kinetics of a catalytic reaction is usually measured in a reactor under relevant process conditions and often power law equations such as $r = k\, C_A^n\, C_B^m \ldots$ that are used to model the macrokinetics (n, m are reaction orders for A and B).

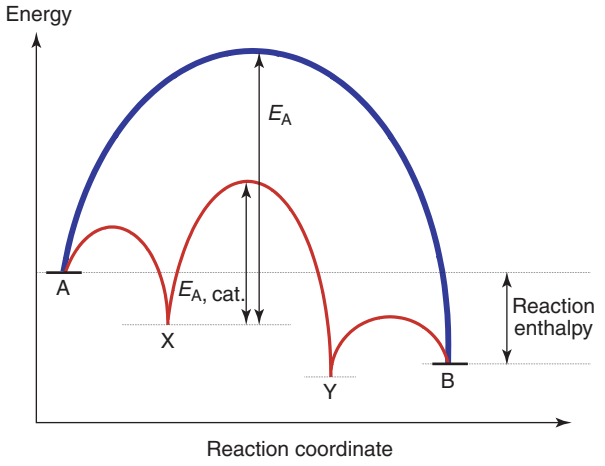

Figure 2 Simplified free energy diagram (red curve – with catalyst; blue curve – without catalyst) for the reaction A→B showing lowering of the activation energy through the use of a catalyst (not the intermediate adsorbed species X and Y).

Aspects of Adsorption

Mass transport and adsorption are important aspects of catalysis. Mass transport exists between the fluid phase (gas, liquid) and catalyst particles, and within a catalyst particle. It is important to determine the influence of mass transport on the catalytic reaction rate and product selectivity. The first step in a catalytic event is adsorption of reactant(s) onto a catalyst surface, followed by chemical reaction(s) at the surface and eventually desorption of products into the fluid phase. There are two main classes of adsorption: physisorption and chemisorption. In physisorption the attractive force is a weak van der Waals interaction with an adsorption energy of $\sim$5–10 kJ mol^{-1} and the chemical bonds in the adsorbing molecules remain intact. Multiple layers of adsorbed molecules are possible. In chemisorption the adsorption energy is comparable to that of a chemical bond, and the molecule may adsorb intact or it may dissociate. Chemisorption energies are $\sim$30–70 kJ mol^{-1} for molecules and 100–400 kJ mol^{-1} for atoms.

The number of adsorption sites on a catalyst is constant and the competition for those sites has important consequences for the macroscopic kinetics and thus catalysis. This is the reason for treating the surface sites as if they were a reactant in the reaction equations. Measurements of adsorption isotherms are used to characterize catalyst porosities and surfaces, to model the reaction kinetics, and help in understanding reaction mechanisms. An isotherm is the coverage considered as a function of temperature and pressure, $\theta(T, p)$. The Brunauer–Emmett–Teller (BET adsorption isotherm for multi-layer physisorption is used in the determination of catalyst surface areas and porosities. Let the surface area be given by

$$\mathrm{SA} = \frac{V_\mathrm{m}}{22414} A_\mathrm{m} N$$

with SA = surface area, V_m = monolayer volume (cc STP), 22414 = molar volume of ideal gas (cc STP), A_m = adsorbate molecular cross-sectional area, N = Avogadro's number. The BET model is applied to isotherm data from $P/P_0 = 0.05 - 0.35$ as fallows:

$$\frac{P/P_0}{V_\mathrm{ads}(1 - P/P_0)} = \frac{1}{V_\mathrm{m} C} + \frac{(C-1)}{V_\mathrm{m} C} \frac{P}{P_0}$$

and from the linear relationship, $V_\mathrm{m} = 1/(\mathrm{slope} + \mathrm{intercept})$ and $C = \mathrm{slope/intercept} + 1$ (the C value is related to the heat of adsorption). The Langmuir adsorption isotherm, on the other hand describes adsorption for single-layer chemisorption, i.e., when the adsorbate forms a monolayer with sites having the same adsorption energy. The Langmuir calculation is applicable only to microporous samples:

$$\frac{P/P_0}{V_\mathrm{ads}} = \frac{1}{V_\mathrm{m} B} + \frac{P/P_0}{V_\mathrm{m}}$$

and from the linear relationship (typically for $P/P_0 < 0.05$), $V_\mathrm{m} = 1/\mathrm{slope}$.

Catalysis

In a catalytic reaction, active sites react and are regenerated and reused in a cyclic manner. The catalyst activity depends on "the number of active sites" and "the turnover frequency." The reaction mechanism consists of many different steps each of which may be of a different type. For example, the Langmuir–Hinshelwood mechanism consists of the following sequence of steps: (1) adsorption from the gasphase, (2) dissociation of molecules at the surface, (3) reactions between adsorbed molecules, and (4) desorption to the gas phase. The Eley–Rideal mechanism covers another important class of reactions and consists of: (1) adsorption from the gas phase, (2) dissociation of molecules at the surface, (3) reactions between gas and adsorbed molecules, and (4) desorption to the gas phase. The Mars–van Krevelen mechanism is often observed for selective oxidations over reducible metal oxide catalysts when lattice oxygen from the oxide is inserted into the hydrocarbon reactant and the lattice defect is subsequently reoxidized by reaction with gaseous oxygen. The oxidation of the hydrocarbon is thus mediated by the catalyst which is the direct oxidizing agent proviing nucleophilic lattice oxygen that is often

more selective than molecular or chemisorbed oxygen species.

The Principle of Sabatier

When different metals are used to catalyze the same reaction, it has been found that the rate of reaction correlates well with the location of the metal on the periodic table. A plot of the rate versus adsorption results in a volcano curve (see **Figure 3b**). This relationship is known as the "Principle of Sabatier." Catalytic activity is highest for the catalyst on which the reactants are most weakly chemisorbed but on which there is still good surface coverage. For this case an increase in adsorption strength causes the adsorbed molecules to be less reactive and a decrease leads to lower activity because the surface is not being fully utilized. In general, the activation energy for the catalyzed dissociation of diatomic molecules decreases when moving left from the noble metals in the periodic table. For CO, for example, the antibonding $2\pi^*$ states are partially filled when chemisorbed and they fill further during dissociation. The antibonding molecular states must be close to the Fermi level of the metal, and when the metal has *d*-states close to the Fermi level, as in the transition metals, there is a strong covalent interaction between the antibonding states and the metal *d*-states. For the early transition metals with low *d* filling, the antibonding metal–C orbital is almost empty due to strong donation resulting in a stronger metal–CO bond, negative adsorption enthalpy, and dissociation (e.g., Fischer Tropsch metals Fe, Co, and Ru), whereas for the late transition metals and noble metals with high *d* filling, the antibonding metal–C orbital is almost full due to strong back-donation resulting in weaker metal–CO bond, positive adsorption enthalpy, and no dissociation (e.g., WGS and methanol synthesis metals: Cu, Pt; see **Figure 3**).

Microkinetic Modeling

The detailed microscopic description of a chemical reaction in terms of the motion of the individual atoms taking part in the event is known as the "reaction dynamics." The link between the microscopic description of the reaction dynamics and the macroscopic kinetics that can be measured in a catalytic reactor is the microkinetic model. Such a model for a given reaction begins with binding energies and

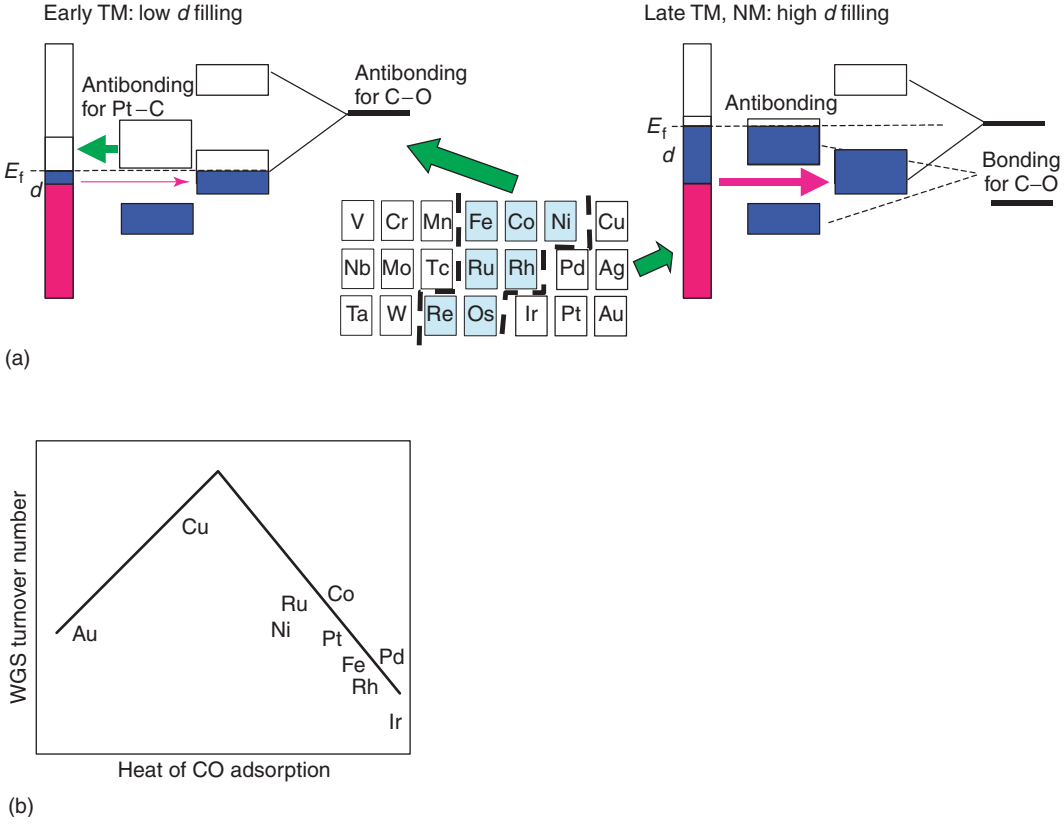

Figure 3 (a) Reactivity trends on alloys for CO dissociation. (b) Volcano curve.

reaction rate constants deduced from surface science experiments on well-defined single-crystal surfaces, and relate these to the macroscopic kinetics of the reaction. The aim is to identify the basic parameters of the reactants and the surface that determine the reaction dynamics (activation barriers, etc.) and relate them to factors determining the catalytic activity. The models are useful for understanding variations in the catalytic activity from one system to another. The stability of the intermediates and the activation barriers are among the input parameters for the microkinetic model, and it is straightforward to calculate the effects of changes in stability for some or all the intermediates.

Catalyst Properties, Shapes, and Preparation

Catalysts for continuous-flow fixed-bed processes have to be shaped to allow the fluid reactant stream to freely pass through the packed bed with an acceptable pressure drop and come into contact with a surface area as large as possible. Catalyst bodies of various sizes, shapes, and geometries have been developed for different applications, e.g., pellets, cylinders, rings, spheres, and monoliths (**Figure 4**). The shape determines the void fraction, packing density, and mechanical strength. The fluid mechanics, flow characteristics and pressure drop, and diffusion restrictions are influenced by the shape and size of the catalyst bodies. Small bodies are often easier to manufacture but suffer from higher pressure drop.

Catalyst pellets used in commercial fixed-bed reactors range in diameter from 1.5 to10 mm. Typical ring sizes are 6–20 mm. Extrudates are 1–5 mm in diameter and 10–30 mm long. Pellets can have several channels and are usually 20–40 mm in diameter and 10–20 mm long (compared to a ring, the use of several smaller channels gives improved mechanical strength with good mass- and heat-transport). Monoliths are used for high gas flow rates or dust (fly ash, soot) containing gas feeds. For the control of emissions in power plant exhaust gas steams, for instance, typical honeycombs are sized 150 mm in edge and 1 m in length, with ~1000 channels per monolith. A stack consists of two to three layers of several hundred honeycombs each. Solid catalysts can be entirely composed of the catalytically active material (bulk catalysts) or supported on porous carriers to improve the mechanical stability or finely distribute the active material thereby creating a large number of active sites.

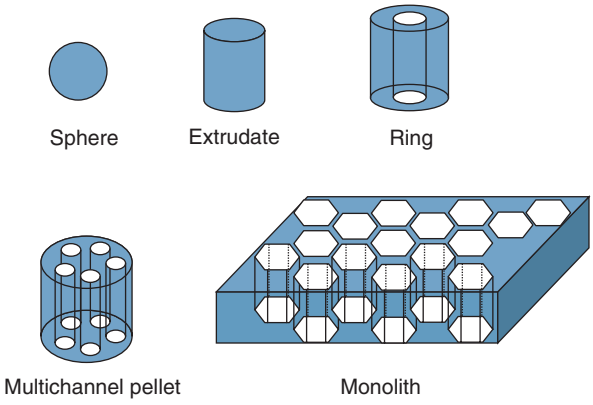

Figure 4 Shaped catalyst bodies.

High activity and selectivity, long-term stability (lifetime), resistance to poisons, tolerance to deviations from operating conditions such as temperature excursions (hot spots), good mechanical strength, and lack of toxic or hazardous ingredients – make high demands on technical catalysts. A variety of synthetic tools are available for the preparation of catalysts, and the performance often more strongly depends on the details of the synthetic route rather than the final composition.

Precipitation (Bulk Catalysts)

Catalysts are precipitated by mixing one solution with another solution or a suspension to form an insoluble compound. Typical precipitation agents are acids or bases to induce a pH change to a metal salt solution. The precipitate is filtered, washed, dried, calcined, and crushed to a fine powder. A binder is added and the powder is tableted. The catalyst may also be shaped before calcination by extruding the filter cake. Typical binders are graphite or stearic acid. Common catalysts prepared by precipitation include alumina-supported Cu–Zn for methanol synthesis and the water gas shift reaction.

Fusion (Bulk, Premolten Alloys, and Metal Oxides)

Catalysts based on metals and metal oxides may be prepared by fusion, crushing, and screening. The finished catalyst consists of irregular pieces of a narrow range of sizes. Fusion is only possible for catalysts that are conductors at high temperatures. During the preparative process, the catalyst powder is placed in an electro-furnace and heated by passing a large current through graphite electrodes. At the start of the cycle, solid catalyst is added to the furnace and the electrodes are lowered. The voltage is fixed and the current is regulated through the height of the electrodes. The molten mass is stirred by the electromagnetic fields generated by the current flowing between the electrodes. At the end of the process, the

electrodes are raised and the molten catalyst is poured out.

The catalyst has no porosity before reduction. The pore system is created when the metal oxide is reduced during the activation of the catalyst (the catalyst may also be supplied in prereduced form). The prereduced catalyst is first completely reduced then passivated by gentle oxidation to allow it to be transported and loaded safely. Common catalysts prepared by fusion include alloy catalysts (e.g., Pt–Rh gauze for ammonia oxidation) and oxides (e.g., Fe oxide for ammonia synthesis or Fischer–Tropsch synthesis), and fused V_2O_5–$K_2S_2O_7$ for sulfuric acid synthesis.

Impregnation (Supported Catalysts)

Impregnated catalysts are prepared by impregnating (e.g., spraying) a solution of a metal salt or mixture onto pellets of a porous support. The metal loading in the finished catalyst is typically 1–5% but can be as low as 0.1%. When liquid is slowly added to a porous solid powder, the liquid is first absorbed in the pores and the powder flows as if it is dry. When the pores are filled, the outer surface of the granules suddenly becomes wet, the granules tend to stick together, and the powder forms lumps instead of flowing freely. Incipient wetness is the point when the pores are filled, but the outer surface of the granules is dry, and can easily be determined by shaking or stirring the powder. Following impregnation to incipient wetness, the pellets are dried and calcined to transform the metal into an insoluble form. The metal salt can be deposited homogeneously through the pellet or most of the metal may be deposited near the outside of the pellet. The distribution of the metal is controlled through the interaction of the metal solution(s) with the support, e.g., through varying the metal counterion, through control of pH, or through addition of chelating agents to the impregnation liquid. The impregnation method (wet versus dry, fast, and slow) and drying conditions can also affect distribution. Typical distributions include eggshell, egg white, and egg yolk. Shell catalysts are often used for selective oxidations to overcome pore diffusion limitations and suppress consecutive over-oxidation reactions, whereas egg-white catalysts are used in refining to protect the inner catalyst layer from feed poisons.

Compared to other catalyst preparation methods, impregnation offers several advantages. For example, the pellets may be shaped before the metal is added; the filtering and washing of the catalysts are not necessary; low metal loadings are easily achieved; and control over the distribution of the metal in pellets is possible. There are also some disadvantages. For example, high metal loadings are not possible without multiple impregnation steps, and an impregnation solution may not be available.

Common catalysts prepared by impregnation include carbon-supported Pt and Pd for hydrogenations, ceria-zirconia supported Pt–Rh for the three-way catalytic converter, and titania-supported V_2O_5 for NO_x abatement.

Evaporative Methods

Wet mixing of (soluble or insoluble) metal precursors in water or organic solvents and subsequent removal of the solvent by evaporation, freeze drying, or spray drying may be used for the production of mixed multimetal oxide catalysts. Often, preformed catalyst powders are slurried and spray dried once again to produce a fluffy and compactable powder for subsequent shaping by extrusion or tablet pressing.

Catalyst Supports

Many heterogeneous catalysts used in industries consist of very small metal particles on a support. Since the catalysis occurs at the surface of the metal particles, the catalysts are prepared so as to expose a large metal area, typically 10–100 $m^2 g^{-1}$of catalyst. The function of the support is primarily to increase and stabilize the area of the metal particles. The size of the metal particles may be reported as the total area of the metal surface, as the diameter of the metal particles (commonly 3–15 nm), and as the so-called metal dispersion (defined as the fraction of all metal atoms that are present at the metal particle surface, commonly from 20 up to $\sim$80%).

A support contains pores having irregular shapes. These pores fall into two size ranges. Macropores have diameters of 100 nm or more and are formed from cracks/spaces between crystallites. Micropores have diameters of 1 nm or less and are due to the "roughness" of the solid surface itself, or the structure of the crystal lattice.

Common and commercially available porous supports are refractory ceramic materials (synthetic such as silica, alumina, titania, zirconia, ceria, magnesia, and niobia, or naturally occurring such as clays, pumice, kieselguhr, and bentonite) and carbon carriers. Their properties are specified by composition, phase, crystallinity, surface area, porosity, packing density, crush strength, and shape. Supports are also used for metal oxide catalysts.

Hydrothermal Synthesis (Zeolites)

Typically, Si and Al precursors together with an organic structure-directing agent are heated up to 200°C under autogeneous pressure in autoclaves for up to several days to synthesize crystalline microporous

zeolites or other molecular sieves such as aluminophosphates. These materials have well-defined pore structures (pore diameters ranging from ~3 to 8 Å) as compared to the broad pore size distributions found in traditional carrier materials. As catalysts, they may contain metal in the pore. Applications of zeolites as supports, solid acids, or shape selective catalysis are common. Zeolites are widely used in refining and petrochemicals, e.g., ultrastabilized Y zeolite for fluid catalytic cracking and ZSM-5 for xylene isomerization.

Raney Metals

Highly porous metal sponges can be made in aqueous solutions by dissolution of aluminum alloys using a strong base. The metal sponges are typically used for hydrogenation in laboratory synthesis. Raney nickel is made by dissolving an (Al, Ni)-alloy containing 50% Ni in 20% NaOH in water. The surface area is 80–100 $m^2 g^{-1}$. The most commonly used Raney metals are Ni, Co, Cu, and Fe.

Colloids

Metal colloids can be prepared by chemical reduction of metal salts in solution using CO, hydroxylamine, oxalic acid, formaldehyde, citric acid, or sodium citrate, or by electro-reduction in the presence of stabilizing salts, ligands, or polymers. Reaction can be carried out directly in colloidal solution or carriers can be impregnated with these preformed nanoparticles.

Catalyst Characterization

Catalysts are characterized for chemical composition, atomic order (crystallinity), phase identification and distribution, porosity, and to identify deactivation mechanisms. Commonly applied techniques include inductively coupled plasma, X-ray fluorescence, physi-/chemisorption measurements (BET, Hg porosimetry, various titration techniques), electron microscopy (SEM, TEM), Auger spectroscopy, X-ray photoelectron spectroscopy, atomic force microscopy, secondary ion mass spectrometry, X-ray absorption, and X-ray diffraction. These methods gather information from different microscopic scales and are complementary.

Catalyst Deactivation

A number of different processes that contribute to the loss of catalyst activity with time on stream are described below. This problem is most often dealt with commercially by slowly increasing the catalyst temperature over time to maintain constant activity/productivity. When it is no longer possible to achieve the necessary performance, the catalyst is replaced.

Sintering

For supported metal catalysts, the active component is present on the catalyst in the form of small particles which are inherently unstable. A catalyst slowly loses activity due to growth of these particles (favored by the resulting decrease in surface energy) and the resulting loss of surface area. There are two mechanisms for sintering: atoms may detach from one particle and move to another (Ostwald ripening), or crystallites may move along the support surface and coalesce. Sintering depends on the nature of the metal, the support, the strength of the metal–support interaction, the gases present, temperature, pressure, and time. Catalyst sintering is irreversible.

Structure Decomposition or Structure Collapse

Crystalline catalysts such as zeolites and multi-metal oxides can deactivate due to destruction of the crystalline phase or lattice structure. Another problem can be loss of elements from the catalyst (or volatile compounds such as Mo, Re, etc.). This can be solved in some cases by the slow addition of the volatile element to the catalyst bed. In the case of attrition losses (e.g., for fluid catalytic cracking (FCC) zeolite catalysts), it is necessary to add in new catalyst slowly over time to the riser.

Fouling and Poisoning

Catalytic activity may also be lost due to the formation of carbon ("coking") or due to the deposition of impurities or of dust or other particulates in the reactant stream onto the catalyst surface. The formation of carbon in many cases is reversible. For example, the catalyst can be taken off line and the carbon removed by oxidation ("catalyst regeneration").

Examples of fouling by particulates occur in removal of NO_x from industrial flue gases or in catalytic converters used in automobiles. In these cases, the catalyst is manufactured in a shape that allows the particulates to pass through the reactor with minimum accumulation (e.g., a catalyst was coated onto a ceramic monolith). A serious problem with catalyst dust may occur if the catalyst bed is improperly loaded, if there is a problem with excessive vibration in the reactor, or if physically weak catalysts are used. In these cases, dust may be formed by attrition, leading to dust accumulation in the reactor or elsewhere in the process impeding or blocking the gas flow. The highly reactive catalyst dust presents a serious safety hazard since it can cause an explosion when pipes or heat exchangers are opened for maintenance.

Examples of poisons that can be present in feeds include metallic impurities such as V, Na, and Ni in FCC processes, metallo-organics in desulfurization

processes, and thiophenic sulfur compounds in various refining processes such as reforming. These poisons react with the catalyst and reduce or destroy its activity. It is often necessary to remove the poisons with a guard bed or dedicated upstream catalytic process (as is done with hydrodesulfurization, for example). Sometimes, the impurity is completely absorbed in the first few percent of the catalyst bed due to its strong interaction with the catalyst.

Future Trends in Heterogeneous Catalysis

Commercial catalysts are used in refining (e.g., alkylation, dimerization, disproportionation, isomerization, catalytic cracking, FCC, hydroprocessing (e.g., hydrotreating, hydrodesulfurization, hydrocracking), hydrogen production, reforming), chemical catalysis (e.g., aromatics production, monomer synthesis, polymerization, organic synthesis, cyclic and acyclic intermediates, medical, flavors and perfumes, rubber processing, plasticizers, surface active agents, agricultural, using oxidation, hydrogenation, dehydrogenation, phase transfer catalysis), biocatalysis, and environmental applications (automobile and industrial pollution control). There are numerous references available covering these applications in detail.

Competitive pressures of a mature industry, the trend toward simpler and less capital intensive processes, access to cheaper feedstocks, and the desire for more environmentally benign processes drives the development of new, high-performance catalysts in the future. New approaches to the discovery of potentially new catalytic materials, including innovative preparation methods and combinatorial/high-throughput catalysis, are having an impact and pushing catalyst development forward. Increased molecular understanding of the mechanism of catalytic transformations based on *in situ* catalyst characterization is also having an impact.

Ceramic Materials

K P Constant, Iowa State University, Ames, IA, USA

Introduction

Although some of the earliest artifacts from ancient civilizations bear witness to man's long history of utilization of ceramic materials, presently ceramic science is advancing at an unprecedented pace. Ceramics remained an art (often with closely guarded secrets) for a major part of recorded history, and has become the science it is only in the past century. With the pressures of increasingly demanding high-tech applications, whether smaller, larger, hotter, tougher, cleaner, brighter, or smarter, ceramics are often the material of choice.

State-of-the-art characterization techniques allow one to achieve a new level of understanding of atomic-scale processes and capability for manipulation of atomic structure. In effect, ceramics can often be built atom-by-atom, layer-by-layer.

That said, what are ceramics? The definition is becoming increasingly more difficult to articulate. For a significant fraction of society, the definition relates to the art of making and decorating pottery, or other items of "baked" clay. However, from the viewpoint of the scientist or engineer, ceramics are often defined by the chemistry, behavior, or processing methods used to create them. For example, a definition might be: an artifact made of hard, brittle, electrically insulating material produced from nonmetallic minerals by firing at high temperatures. This definition specifies the chemistry, properties, and processing. While this definition is accurate for a large fraction of ceramics, it is not all-inclusive, and examples of ceramics that do not conform to one or more parts of this definition are becoming increasingly common. There are examples of ceramics (some discussed here), which are not brittle and electrically insulating, are not made from nonmetallic minerals, or not fired at high temperatures. In fact, ceramic superconductors are among the most conductive materials known. An acceptable, but not complete definition might be a refractory, inorganic, and nonmetallic material. Even this attempt at description is flawed as the boundaries between biology and ceramics blur.

The field of ceramics (and all materials) is often represented as the four corners of a tetrahedron-labeled structure, properties, processing, and performance. In this article, the state of the art of ceramic science and engineering is presented through discussion of properties, novel processing, and general trends, with examples of the applications that have driven these advancements. The structure and performance are addressed within the context of both the properties and processing of these advanced ceramics.

Properties

Ceramics have long been associated with characteristic properties such as high hardness, high stiffness, resistance to high temperatures, and chemical inertness, but today's ceramics stretch conventional applications of ceramics beyond, what in the past were considered, their fundamental limitations. A huge body of work has been generated since the 1990s, some of which are highlighted here with examples in which mechanical, electrical, and optical properties are critical. Although not represented in the examples below, ceramics are also often used in thermal and magnetic applications in which there are many examples of exciting and novel advances.

Mechanical/Structural

Ceramics are often used where high hardness is required but are usually limited by their lack of toughness. A number of innovations have improved upon this mechanical deficiency including those demonstrated in the development of transparent ceramics for ballistic protection, defense against artillery shells, bullets, and shrapnel in warfare. Toughness can also be improved by the use of hard coatings on tough substrates. Although carbide coatings have long been used for grinding and cutting tools, even harder diamond coatings are becoming increasingly popular. Because the processing techniques required are the most novel aspect of that field, thin film diamond coatings are discussed in the section, "Processing."

Transparent ceramics for ballistic protection One of the most aggressive mechanical applications of ceramics is that of armor. With increasing attention paid to terrorist threats, there is escalating interest in the development of armored vehicles. The chief requirement of armor is that of the ability to sustain repeated impact, but in this application, armor has two other significant constraints. In many instances, it must be transparent and should also be relatively lightweight. As shown in **Table 1**, the ceramic must be optically transparent, and if sensors or guidance systems are used, may also need to be transparent in the infrared or ultraviolet spectra. Although a variety of polymers have been used in many applications, they are not suitable for applications that require optical transparency from the ultraviolet through the mid-infrared (IR) wavelengths. Such applications not only include military applications

Table 1 Wavelength transparency requirements for ceramic armor

Wavelength	*Electromagnetic spectrum*	*Applications*
10–400 nm	Ultraviolet	Sensor windows and radomes
400–700 nm	Visible light	Face shields, windows, windshields for vehicles, Blast shields
700–400 000 nm	Infrared	Sensor windows and radomes

such as forward-looking IR windows, missile domes, underwater sensors, transparent armor, and personnel protection, but also have commercial promise for supermarket scanner windows, scratchproof lenses, lighting applications, and semiconductor wafer carriers. A tough, lightweight, transparent ceramic material has been developed through the US Air Force Research Laboratory working with Raytheon Electronic Systems. This polycrystalline aluminum oxynitride, known commercially as ALON, is optically transparent, has low density, high strength, and high durability. Processing techniques for fabricating sintered corundum are being developed for applications where impact resistance is not critical. A technique that has been shown to be successful involves liquid shaping of sintered and hot isostatically pressed Al_2O_3 ceramics.

Electrical

Ceramics have long been used in the electronics industry as passive devices such as capacitors and insulators, and continue to be critical in those functions; however, in a variety of other electrical applications, ceramics have become increasingly important including sensors (gas and chemical), conductive oxides (mixed conductors), and high-power/high-temperature electronic materials.

Fuel cells The exponential growth of portable electronic devices, cellular phones, PDAs, pagers, computers, etc., provides a strong motivation for the development of fuel cells and high-energy-density batteries. Fuel cells can provide clean energy for a variety of portable energy needs. Ceramic materials play a large role in the development of commercially viable products. Solid oxide, proton exchange membranes, and direct methanol fuel cells, lithium-ion batteries, oxide-ion electrolytes, proton conductors, and mixed ionic/electronic conductors are all ceramic-based technologies. Solid oxide fuel cells (SOFC) are electrochemical energy conversion devices based on ion-conducting oxide electrolytes and are used in a broad spectrum of power-generation applications from small lightweight compact devices to large SOFC/turbine hybrid systems. The cells are solid-state devices operating at high temperatures. Because of this, there is great design flexibility (no liquid management is required as in other "batteries"). There are a variety of designs and geometries currently under investigation. The most common electrolyte materials include yttria (Y_2O_3) stabilized zirconia (ZrO_2), often called 8YSZ, as it contains 8% yttria. This ceramic is ion conducting in both oxidizing and reducing environments. The most common anode material is a cermet (ceramic–metal composite) composed of Ni and 8YSZ. Nickel provides the electronic conductivity and catalytic activity while the 8YSZ supports the Ni particles and improves the anode thermal expansion match. The most common cathode material is a strontium-doped lanthanum manganite (Sr-doped $LaMnO_3$) – called LSM. The interconnect material is usually doped $LaCrO_3$ or a metal that is stable in both oxidizing and reducing environments; however, metal interconnects require lower operating temperatures. The cost of these fuel cells is still a limiting factor in terms of broad applications and ways to reduce the costs are being aggressively sought, including reducing operating temperatures to allow the use of metallic interconnects and increasing the power density. Much effort has focused on the techniques to make dense ceramic coatings using the techniques of the semiconductor industry including chemical vapor deposition (CVD), electrochemical vapor deposition (EVD), physical vapor deposition (PVD), and screen printing as well as more traditional techniques such as sol–gel, tape casting, slurry casting, and centrifugal casting. The former techniques often have film quality and performance advantages, but also have low deposition rates (they are slow) and are costly. The latter techniques are efficient and economical but often result in lower-quality films.

Optical

Although glass has long been used as an optical material, more recently in fibers for communication and laser surgery, ceramics are gaining importance in a variety of optical applications, including wireless technologies, microwave dielectrics, luminescent materials, and nonlinear optical materials. One such emerging field is that of photonic bandgap materials.

Photonic bandgap materials Photonic materials are those in which light is manipulated in novel ways. It is a critically important technology that has wide-ranging potential in a variety of applications, including lasers, catalysis, and optical computing. The field of "photonics" refers to light emitting materials, optical waveguides, nonlinear optical materials, and photonic bandgap materials among others. Most of these applications make use of glasses and dielectric materials. In the specific case of photonic bandgap materials, a high dielectric constant is required. The unique properties of photonic crystals, which allow or inhibit propagation of certain frequencies in all directions, have spurred a flurry of activity in the development of these periodic dielectric structures.

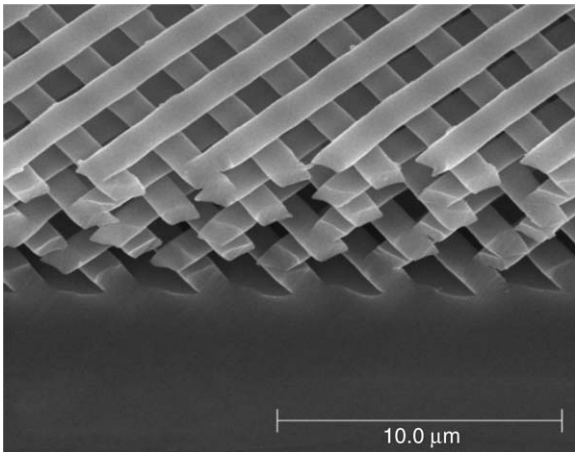

Figure 1 An eight-layer polymer template used to mold a ceramic titania bandgap crystal. (K Constant, unpublished work.)

One method of creating these structures is through a process called microtransfer molding, where a sacrificial polymer template is created which represents the inverse of the desired structure. The creation of this template is a multiple-step process, but requires relatively simple technology, and is quick and economical. A master mold containing parallel bars is created using standard photolithographic techniques. A flexible reproduction (or mold) is created from polydimethylsiloxane (PDMS) by pouring the prepolymer over the master (**Figure 1**). The channels of this mold are then filled with a polymer that is cured and then transferred to a substrate. This process is repeated, rotating the bars perpendicular to the previous layer and aligning them over the channel of the layer, two layers down. A titania ceramic precursor is then infiltrated into the polymer structure and allowed to gel. The gel is converted to a ceramic (TiO_2) and the polymer is removed through heat treatment. The result is a ceramic structure with a configuration that resembles the diamond cubic structure and has a photonic bandgap. If the structure is built with a periodicity $\sim$400–700 nm, a photonic bandgap at optical frequencies will be present. Currently, 1 μm periodicity has been achieved and work toward smaller structures is ongoing.

Processing

The processing of advanced ceramics can be divided into two general classes with respect to the starting material – those that involve powders (powder processing) obtained by a variety of methods, and those that do not. In this section, recent advances in each method are presented through a specific example of each.

3D Rapid Prototyping

A recent advance in the forming stage of ceramic processing is that of 3D rapid prototyping. There are a variety of techniques that fall into this general category. The concept is to translate a 3D computer-generated design (CAD model) to a physical structure without the traditional step of making a mold in which to shape the product or the time and cost associated with machining a ceramic to desired dimensions. These methods can often make very complex geometries in a variety of shapes, sizes, surface finishes, and materials compositions. Most of these techniques rely on cutting 2D "slices" from the 3D model and building them one on top of the other. These techniques usually begin with a bed of fine ceramic powder. Some techniques deposit a binder into specific areas of the powder to "select" that which will remain after the entire shape is formed.

Other techniques use a laser or directed light to cure a polymer component added to the ceramic powder for that purpose. Layer upon layer of powder is added to the bed, each layer representing a subsequent 2D slice of the desired product. Regardless of the technique, the result is that some ceramic powder is held in place as part of the shape to be made, while the remainder can be shaken out of the part. The powder is then further consolidated through heat treatment and sintering to form a monolithic ceramic part. These techniques have a variety of applications including those that are obvious such as prototyping parts for testing before investing in tooling for mass production, as well as the less obvious, such as one-of-a-kind designs, for example, prosthetic devices for biomedical uses.

One blend of rapid-prototyping and biomimetics recently reported is that of computer tomography (CT) assisted artificial bone design. (Biomimetics is discussed in further detail in a later section.) In this work, a 3D image of natural bone is acquired using CT, and used to create a duplicate by rapid prototyping. Currently, the resulting bone-structured ceramic is being used to study osteogenesis (the building of bone), but it could be envisioned that it could be used to fabricate a replacement for missing or diseased bone. Another approach to rapid prototyping and its role in the fabrication of MEMS is discussed later.

Thin Film Techniques

A variety of thin film techniques have emerged from the semiconductor industry, many involving ceramic materials such as oxides, nitrides, and carbides. Most of them rely on liquid or gas phase precursors and sophisticated control of chemistry, temperature, and

pressures. These techniques often result in the growth of thin films of chemistries and morphologies not achievable in bulk form through traditional powder processing in similar temperature or pressure regimes (or sometimes in any temperature or pressure regime). One example of such techniques is presented here: CVD (chemical vapor deposition) of diamond thin films.

Thin film diamond coatings Diamonds are truly an extreme material, having several properties that can only be described in superlatives: the hardest, the stiffest, the highest thermal conductor, highest sound propagation velocity, etc. Additionally, diamonds are very resistant to chemical corrosion, are biologically compatible, are optically transparent over a huge range of frequencies, and are excellent electrical insulators. However, their scarcity and availability only in single-crystal form have prevented widespread xploitation of most of these properties. With the exception of industrial diamonds created for cutting and grinding, the use of synthetic diamonds has been very limited. Rather than attempting to recreate nature's approach to diamond making (extreme temperatures and pressures), an alternative method has been discovered which has two significant advantages over nature's approach – easier processing resulting in a more convenient form. This method, which induces diamond growth by adding carbon atoms one-at-a-time to a template, can be achieved without high temperature and pressure, and results in a thin film coating rather than isolated single crystals. Although this idea was conceived several decades ago (in the 1950s), it was not until the mid-1980s that good-quality films were grown. The concept, while relatively simple, presents numerous engineering challenges. At the heart of the technique is CVD. In this technique, a gas-phase chemical reaction occurs above a solid surface (often called a substrate as it forms the mechanical support for the resulting film). For the case of diamond films, a method of activating the gas-phase carbon-containing precursors is required. These include a hot filament or electrical discharge, or a combustion flame.

The most common method of diamond thin film growth uses methane, CH_4, as a precursor gas. The gas concentration (usually diluted with H_2) and temperature of the substrate must be controlled to suppress the deposition of graphite or amorphous carbon. The method used is normally tailored to the desired application. For example, hot-filament techniques, which use a refractory metal (such as tungsten or tantalum), can be used to make good-quality diamond films for mechanical application, but they are not suitable for electronic applications because they contain metallic impurities from the filament that degrade the electrical properties.

Although requiring more expensive equipment than hot-filament growth, microwave plasma CVD reactors are currently the most widely used technique for diamond growth as they produce high-quality, chemically pure films. The substrate requirements for this process are significant. Among them, the substrate must be able to withstand the thermal and chemical conditions of the reactor, which precludes a large number of materials including all polymers, most metals, and many electronic materials. Also, because diamond has such a low thermal expansion coefficient, α, it is susceptible to delamination or flaking off a substrate which contracts more on cooling from the reaction temperature (usually about 700°C, so a substrate with a low α is required). In addition, the substrate must be able to form a carbide to some extent, as it has been suggested that the diamond films actually grow off an initial carbide interfacial layer. Currently, silicon wafers are the most commonly used substrate material.

The chemical and physical processes which occur during thin-film growth are complex, but a very simplified model can be described by the schematic in **Figure 2**. Not all reactions result in diamond; the process is slow and requires very careful control of both the chemical and physical conditions of the system. Much effort has been expended to understand the gas-phase chemistry of this system, and progress continues to date, resulting in improved, more efficient methods and higher-quality thin films.

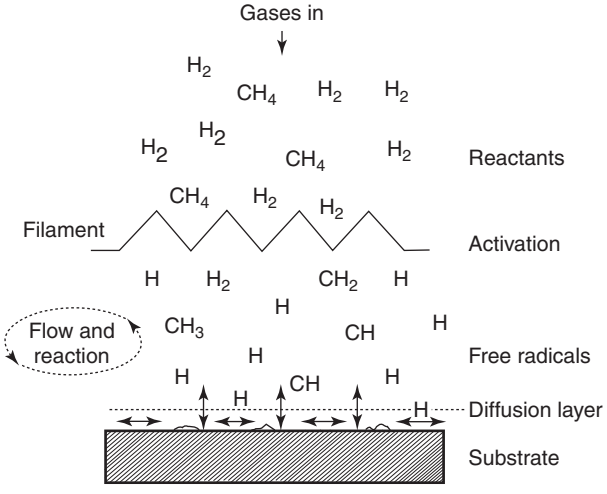

Figure 2 Schematic of the physical and chemical processes occurring during diamond CVD. (Reproduced with permission from May PW (2000) *Philosophical Transactions of the Royal Society of London. Series A* 358: 473–495; © Royal Society.)

The widespread application of diamond thin films is still limited by economic restrictions, but they are beginning to be used for cutting tools, thermal management where rapid heat dissipation is required, IR windows, and electronic devices. Recently, work has been reported which uses diamond thin films as an ideal substrate for integrating microelectronics with biological sensing functions. More on this topic is discussed in the section, "Trends in ceramic materials."

Ceramics and the Environment

Increasingly strict legislative controls and escalating public concern for the local and global environment have affected most manufacturers of goods, including those of ceramics as is testified to by the recent creation of ISO 14000 – the international standards organization that is focused on certifying manufacturers and organizations in environmental management systems.

The environmental impact of any class of materials can be considered to have many aspects including: the source of raw materials, the energy and by-products associated with all stages of manufacture, and the disposal of the product when it is no longer useful. Likewise, ceramics can also be considered in terms of their use in remediation of the environmental impact of energy production. There has been increased awareness of each of these aspects in the manufacture of ceramics as well as in other materials. One such environmental application of ceramics has already been discussed in SOFC for clean energy storage solutions. With respect to energy production, research continues in the area of coal gas cleanup – that is in the development of ceramic sorbents for use in integrated coal gasification combined cycle (IGCC) systems that burn coal for the production of electricity. These calcia-based sorbents have been designed not only to remove sulfur from the gas used to drive the turbines but also to be regenerable – so that the sorbent itself does not create an environmental burden as a waste product. In this work, natural lime is encased in a ceramic shell that provides structural integrity as well as a porous coating for gas flow (**Figure 3**).

Eco-ceramics Environmentally friendly ceramics usually refer to those that undergo processing using environmentally benign solvents or resulting in harmless by-products. NASA recently reported the development of a method to make a SiC ceramic using wood as the preform to supply both the structure and the carbon for the process. In this technique, wood is pyrolyzed to form a carbon structure that is then infiltrated with silicon or a silicon alloy. The result is a SiC-based ceramic with a microstructure imposed by the original wood and a shape that duplicates that of the pyrolyzed form. The structure (and therefore, properties) is tailorable by the choice of wood and can be further adjusted by laminating wood layers in various arrangements. This technique has been used to produce porous and nonporous structures of various compositions based on SiC. This technique could be considered akin to biomimicry, which is discussed in the next section.

Trends in Ceramic Materials

The most notable general trends in ceramics are those of the entire materials industry, and perhaps science and engineering as a whole. The first includes an ever-aggressive shrinking scale of our technological devices – requiring a more complete understanding of how material properties vary for very thin films and small grains (sometimes composed of fewer than 100 atoms). The second includes a renewed interest and focus on biological systems, which can serve as inspiration for the structure, as manufacturing aids, or even as end-users of ceramic materials. Third, a renewed commitment to national security and aggressive pursuit of technologies to support these efforts have resulted in increased attention on sensors that can detect any number of chemical and biological hazards quickly, effectively, and efficiently. Previous examples of properties and processing have already exposed these trends. The ceramic armor already discussed, photonic bandgap materials, and sensors for detection of biological agents, and micromechanical devices all have potential use in national security functions.

Nanotechnology/MEMS

As the scale of electronic devices shrinks, so has the scale of both the starting materials and the components of such devices. The trend toward nanoscale control has impacted ceramics as it has most fields of engineering and science. In a like manner, mechanical devices have continued to shrink to smaller and smaller dimensions, resulting in what is termed micro-electromechanical systems (MEMS). Ceramics are particularly well suited for MEMS applications in biological and chemical sensing systems (they tend to be chemically inert, even at high-temperatures and severe environments). The advantages they bring to full-scale mechanical devices (e.g., engines) are also present at the microscale. Low density and high-temperature capability make ceramics an attractive choice for high-speed devices, such as nanoturbines.

Ceramic MEMS have been made by microcasting a liquid ceramic precursor (e.g., polysilazanes) in a mold produced from photoresist by conventional lithographic methods (**Figure 4**). The resulting form is then pyrolyzed to convert to a Si–C–N amorphous ceramic. A second method of producing MEMS involves photopolymerization, a technique becoming increasingly widespread in the rapid prototyping industry. The technique involves adding a photoinitiator to a liquid ceramic precursor that will promote polymerization upon exposure to light of a specific wavelength. Shapes are constructed by exposing a layer of the precursor through a mask that has the desired shape. 3D structures are made by successive exposure to another layer, which has either the same, or a different geometry depending upon the desired result. Exposure can also be accomplished through the "writing" of a directed laser beam. The exposed material polymerizes, and solidifies, allowing the remaining unexposed liquid to be washed away. In this way, a 3D structure can be created. The resolution achievable by such efforts is related to several factors both of the chemistry of the precursor and photoinitiator and the physical characteristics of the mask or direct-write system. A similar approach to direct writing of structures is found in computer-controlled ink-jet printing of ceramic parts that is limited only by the length scale of the droplet. This technique relies on a colloidal, gel-based ink that forms a self-supporting structure. This technique, called robocasting has produced features as small as 100 μm, and has been made out of silica, alumina, lead-zirconate-titanate, and hydroxyapatite.

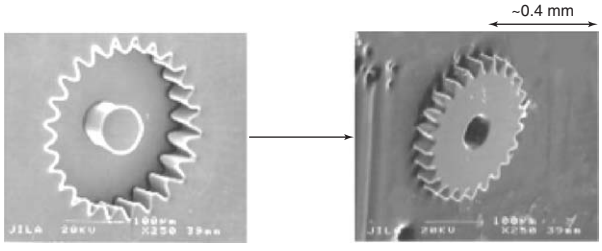

Figure 4 Left: a photoresist mold about 200 μm across. Right: The fired ceramic gear. (Reprinted with permission from The American Ceramic Society; © 2001.)

Bioceramics

Perhaps one of the most transformational trends in ceramics is that of bioceramics. Biology can take a variety of roles in the development of advanced ceramics from serving as the inspiration (or more directly, the template) for novel structures to providing the motivation for the development of materials to be used in biomedical applications. Biomimicry is really nothing new – ancient people observed animals to learn the best methods to stalk prey, to identify safe foods to eat, and to predict weather changes, but until the tools to examine nature at the microscopic (and now, atomic) level were developed, few efforts were made to copy nature at these length scales. Today, however, many scientists and engineers are again carefully studying natural materials striving to glean their secrets. Examples include the study of fracture toughness and interfacial design of the fiber-matrix ceramic composite that constitutes sea-urchin teeth and the self-assembled opal structure used as a template for photonic bandgap materials. Ceramics for biomedical applications have also become increasingly important in improving the quality of life for many of the world's aging. Ceramics can be bioinert (such as alumina or zirconia) or bioactive (including hydroxyapatite, and bioactive glass and glass ceramics). Ceramics have been used or are being developed for use in replacement joints for hips and knees, replacements for diseased or damaged bone, and reconstruction of teeth and jawbones. Ceramic and carbon coatings are also used in a variety of biomedical devices including prosthetic heart valves. The bonding between hard and soft tissue is being studied to improve such applications. Ceramics are also being used for controlled drug delivery. For example, therapeutic treatment of cancer has been achieved using glass beads doped with radioactive isotopes. In addition, in the drug-delivery arena, rapid prototyping, or 3D printing techniques have been used to fabricate specialized drug-delivery devices. These ceramics are functionally graded structures that can yield complex release profiles in which there is control time, dosage, and even the chemistry of the drug.

Biosensors

Diamond, because of its electrical and chemical properties, is a good candidate for integrated sensing materials, and recently, selective biological modification and adsorption has been achieved. In this work, DNA oligonucleotides were covalently bonded to nanocrystalline diamond thin films resulting in an extremely stable, highly selective platform for subsequent surface hybridization processes. This integration of DNA and other biological materials with microelectronics has broad-ranging implications for the development of completely integrated bioelectronic sensing systems.

Concluding Remarks

While these examples testify to the extent and breadth of the research and development in advanced ceramics, there remains much to be understood and accomplished. The ever-expanding variety of analytical tools will provide the technology to further probe the structure and properties of ceramic materials, often at the nanoscale. The blurring of lines between ceramics, biology, and other fields of engineering will most certainly persist requiring that tomorrow's ceramists be cognizant of a broad range of fields and have command of a variety of analytical tools and techniques. While evolving, ceramics will continue to have a large role in the shaping of our society.

Ceramics, History of

I Yasui, University of Tokyo, Tokyo, Japan

Introduction

A ceramic is defined as a nonmetallic inorganic solid, but in a narrow sense it is a massive solid obtained by the heat treatment process of inorganic powders.

Ceramics have a long history. One of the first materials used by humans was a stone implement. Obsidian in composition, such a material can be classified as being glassy. Similarly, porcelain and earthenware also have a long history. The same can be said of glass too; human beings produced glassy solids in 3000 BC. Ceramic powder was also used as an adhesive at the time of the construction of the pyramids.

Ceramics are classified, from the viewpoint of structure, as: (1) single crystal, (2) sintering object, (3) glass, and (4) powder.

1. The technology to produce single crystals artificially is difficult; moreover, it is not suitable for mass production. Commercial ceramic products in the form of single crystals are, therefore, rather new historically. At present, some of the single crystals such as a quartz oscillation unit and an optical crystal are of much importance, because it is impossible to obtain the desired properties by using materials other than single crystals.
2. Sintered bodies are obtained by a forming process where starting powders are pressurized and the massive solid is obtained by subsequent heat treatment. Although earthenware was the origin of this technique, ceramics with various functionalities were developed.
3. Glass is a material obtained through a melting state by heating starting raw powders at a high enough temperature. Since the composition of common glasses was similar to that of earth, it was made artificially as early as in 3000 BC. However, these early glasses were not transparent. Although glass as a transparent material was developed later, it was only in the twentieth century that the technology of manufacturing sheets of glass with larger area became available.
4. Powders have been used from the BC period by grinding natural ores. The history of pigments also goes back a long way. Powder today means such materials as can be used in making high-performance sintered ceramic bodies. Original materials for ceramics were natural minerals, especially silicates. Clay, which is a natural silica mineral and very suitable for the production of porcelains, was the primary raw material for a long time. It is, therefore, understandable that the industry which used clay emerged first. The ceramic industry showed a marked progress after materials other than silicates came into use. Alumina is the first example and titanium oxide as a dielectric followed in industrial use. These simple oxides offered an easy control of the properties of their powders, suggesting that substances with easy handling became raw materials for practical use.

Silicate industries have also undergone constant development. The wall thickness of ordinary china used for tableware is ~ 1 mm; $\sim 50\,\mu$m thick silicate ceramics are manufactured in large quantities as catalyst carriers for cars (in the absence of this technology, automobiles would perhaps be contributing to air pollution at levels even higher than they do now).

As a next step, complex oxides constituted the mainstream of the practical use of ceramics. The first generation of complex oxide ceramics are barium titanates and ferrites. These substances came to be used, due to a great deal of development in the management of purity, fine-tuning of composition, surface modification, etc. For example, the control of grain boundaries is one of the most important parameters that determines the total characteristics of a ceramic material. New types of ceramic heaters, which are capable of self-control of temperature with a composition of barium titanates, were developed and used. These are characterized by controlled grain boundaries and the so-called positive temperature coefficient (PTC).

Most industrial applications of ceramics exploit the characteristics of the substrates on the one hand and the electronic or ionic properties of their constituents on the other.

Nowadays, the most useful example of functional ceramics are lead zirconium titanates (PZTs). For instance, cellular phone designs are materialized by using these piezoelectric ceramics. Barium titanates and ferrites, sometimes called electronic ceramics, are extensively used in the electronics industry. This is because the electronic properties play a crucial role in determining the function of these ceramics.

Simultaneously, materials using the ionic properties of ceramics have also emerged and are used practically. The purification of the exhaust gas of a car is attained due to the use of zirconium oxide ceramics as an oxygen sensor, thus utilizing the ionic conductivity of oxide ions. It is called a solid electrolyte because the substance has conductivity due to an ionic motion within a solid. One of the notable examples is beta alumina, which is now used as an electrolyte for an Na–S battery, a large-sized rechargeable battery for load leveling of electric power.

A compositional survey of the possible properties of oxides containing two or three metals has already been conducted. Although additive agents are used to promote sintering or optimization of properties, compounds which principally contain more than four kinds of metals are seldom examined. In this unexplored area, a new category of ceramic materials has emerged, that is, superconducting ceramics.

It is to be noted that the most important characteristic of ceramics is their tolerance to high temperature. For many years, oxides have been used as refractory materials. It is quite clear that "refraction" supports the basic technology in the metal-refining industry. By extending the function of an oxide as a high-temperature material to the extreme, its application in the area of energy production etc., can be expected. However, it was not oxides, but nitrides and carbides, which attracted attention as such materials in the 1980s. As a result, a ceramic turbocharger was developed for automobiles. Although non-water-cooled engines made from ceramics were proposed to be used, this has not yet been realized.

The glass industry at present is very large in scale. This is one of the several reasons for natural silica to be the major raw material in the industry. An example of the application of glass, which uses transparency to its extreme, is the optical fiber. An optical fiber is made from very high purity silica although it includes a very small quantity of additives to control the contour of refractivity.

The composition of the often used glasses resembles that of sheet glass or bottles. The insulated film used in semiconductor devices is also glassy. Although only glassy material with a simple composition can be used in device processes, one can expect new compositions to find future applications.

Cement is a material which has been used in large quantities for a long time. Of course, it is also a product of the silicate industries. The use of a material in such large quantities is bound to pose a problem of depletion of resources, sooner or later.

History of Development of Ceramics

In the preceding section, an outline of ceramics was given from the historical point of view. The present section selects some ceramics as examples to consider the development process in more detail.

Large-Sized Insulator and Ceramic Carrier

The largest ceramic (1.2 m $\varnothing \times 12$ m length) ever made was the insulator for 1000 kV power transmission. In consideration of it being corrosion-proof and earthquake-resistant, it had a special form of a bamboo hat and was made of large-sized porcelain with a thick wall.

The catalyst system was established as a primary means of automobile exhaust gas purification. Although started in the form of pellets, the monolithic honeycomb-type catalyst carrier was developed in 1976. This type of catalyst opened up the possibility of stricter emission control of automobiles.

Cordierite, with a composition of $2MgO \cdot Al_2O_3 \cdot 5SiO_2$, was used because of excellent heat resistance due to a low expansion coefficient. In the initial stage, the number of cells was $\sim$200/square inches (1 inch = 2.54 cm) but later reached 900 square inches, and the wall thickness decreased from 12 mil (1 mil = 0.0254 mm) to 2 mil.

Alumina (Aluminum Oxide) and Substrate Material

Some aluminum oxides have been used for many years as refractory materials. Examples range from highly pure alumina crucibles to low-purity alumina pipes or plates for low-heat-resistance applications. Their application as an insulator for spark plugs was developed in 1931, and alumina started being used in automobile and electronics industries.

The decisive extensive use of ceramic materials in electronic industries occurs in the form of substrate materials used as a part of large-scale integrated circuits. Alumina substrates for electronic circuits cover a wide range of products, such as those made by the thick-film process, the thin-film process, and multilayer-type circuit boards. Alumina powders with purity higher than 99.5%, with 0.2% of magnesium oxide as additives, are generally used to give a flat and smooth surface, which is excellent for use as substrates.

The multilayer aluminum circuit board was first developed by IBM for the CPU used in the 308 X series mainframe computers. The CPU was $90 \times 90\,mm^2$ in size and the number of layers was 33. It was evaluated that this circuit board had superior properties both in the delay time of signal propagation and heat dissipation. Silver, gold, copper, etc., were used as conductive materials for wiring.

Because of the success of the alumina circuit board for the CPU, other substrate materials with higher heat dissipation capability, such as in the AlN and SiC boards, were investigated. Since AlN and SiC have simple crystal structures, both materials have excellent thermal conductivity, provided the grain boundaries are controlled. Since AlN is an insulator, it is only necessary to control the grain boundaries to obtain a high heat conduction, but since SiC has electronic conductivity, it is inevitable to control the grain boundaries so that it is electrically insulating. It was found that the addition of BeO as a sintering agent changed ceramics to insulating substrates.

Although ceramic substrates for large-scale integrated circuits were excellent in performance, the production cost was a prohibitive factor for use of this product. The semiconductor packaging process was changed, and it was found that even plastic could be used as a substrate. If ceramic substrates continue to be used in the electronics industries, they will be limited to high-performance type of products, such as single crystals or diamond.

Development of Ceramic Capacitors

Natural materials such as mica have historically been used in capacitors for a long time. Electrolyte capacitors use an aluminum oxide thin film as a dielectric. Several other oxides have been used as capacitor materials for many years.

It is well-known that barium titanate has a high dielectric constant (several 1000 or more). This ceramic was independently developed and studied in USA, Japan, and the Soviet Union. The abnormalities of the dielectric constant of barium titanate were discovered by Wainer and Salomon in 1942, which was an important breakthrough in the application of ceramics after World War II. Subsequently, Vul and co-workers, von Hippel, and Ogawa and Waku studied the ferroelectric properties of barium titanate.

However, from the point of its practical use, it is important to note that it took a remarkably long time from the discovery of barium titanate as a substance to its development as a ceramic capacitor. It was actually in the 1990s that the ceramic capacitor with a multilayer-type structure using barium titanate came to be loaded into almost all electric devices. This is because it took time to develop the process of manufacturing multilayer ceramic capacitors on a large scale. A process using the doctor blade method is first used to form thick films, and it is necessary to carry out the lamination of films. The technical developments, other than that of a ceramic layer, were also important. The development of conductive layers using nickel for an internal electrode was also a key factor in the development of the technology.

History of Piezoelectric Ceramics

The piezoelectric effect was discovered by Jack and Pierre Curie in 1880. Materials that display the piezoelectric effect need to be in the form of single crystals. Therefore, in order to use this effect for practical purposes, single crystals of appropriate materials were produced industrially. In Japan, Toyo Communication Equipment industrialized the production of quartz by the hydrothermal method in 1959.

Other materials were also studied for use as piezoelectric ceramics. Since it was reported by Bell Laboratories in 1963 that the thin film of CdS worked as a piezoelectric transducer, development of piezoelectric thin films and thick films started. The development of the thick-film process and materials that were more suitable for mass production attracted much attention. PZT, that is, Pb (Zr, Ti) O_3, discovered in the late 1950s, became the primary candidate for practical applications. A phase transition occurs when the Zr/Ti ratio is 53/47. In the vicinity of the phase boundary with this composition, the dielectric constant and the piezoelectric constant become the maximum.

In order to make a piezoelectric body of this composition, materials with random orientation cannot be used. Therefore, polarization processing was indispensable during sintering and the related process itself had to be developed. A number of sheets must be laminated as a layer, especially in the case of an actuator; thus, the manufacturing technology acquires key importance.

In Europe, a restriction in the use of lead in electronic products will be in effect from the year 2006. PZT, of course, contains lead. It does not necessarily mean that this material will be prohibited from use in Europe soon, but it is also possible, that if a new material for replacement is developed, PZT will then be forbidden. Therefore, development of piezoelectric materials which do not contain lead is now in severe competition.

Ion Conductivity Ceramics

It has been known for many years that glass and other ceramics show an alkali ion conduction. For example, a group of substances called beta alumina, containing Na as a component (in spite of being known as alumina), have been known as Na ionic conductors for many years. Their crystal structures were analyzed in the 1950s.

The Na–S battery, which uses beta alumina as an electrolyte, was proposed as a large-sized rechargeable battery for load leveling after the oil crisis of the 1970s. The Na–S battery attained the level of practical use at last by a joint development of NGK Insulators and the Tokyo Electric Power Co., (the delivery track record in 2002 was set at 5000 kW).

Although historically, ZrO_2 has been used due to its very high chemical durability at very high temperature, it was already known at the end of the nineteenth century that ZrO_2, with the addition of CaO or Y_2O_3, has oxygen ion conductivity. This material attracted attention after its use as an oxygen sensor for automobile exhaust gas purification was proposed. As an oxygen sensor, ZrO_2 plays the role of a solid electrolyte similar to that in fuel cells. A solid electrolyte-type fuel cell, on the other hand, has not yet reached a stage where it can be used in practical applications.

Development of Ceramic Sensors

It must be noted that a ceramic material used as a chemical sensor brings about an improvement in the performance of various electrical appliances. The range of home electrical appliances which were originally apparatuses that could only detect temperature, now also include appliances (such as air conditioners, microwave ovens, or refrigerators) which can detect humidity, carbon dioxide, infrared radiation, etc. This development has been required from the viewpoint of increasing energy efficiency in relation to global warming and other environmental issues. In addition, detection of flammable gas, such as hydrogen, methane, and a liquefied petroleum gas, is indispensable because of concerns of safety. A gas sensor that made use of SnO_2 was developed. The principle of a gas sensor itself is rather conventional. The ZrO_2 sensor already mentioned is the so-called concentration cell type, and the principle is also classic.

The SnO_2-type gas sensor utilizes the characteristics of compounds as semiconductors, along with the capability of gas adsorption. It has, therefore, been an important target in its development as to how the most suitable textures and microstructures could be formed in ceramics to enhance the properties of adsorption of thick-film materials.

There are several ways for a modified usage of ion-conducting ceramics to detect a certain gas. One is to use ion-conducting ceramics together with the auxiliary electrode, which consists of the conduction ion and detection gas components. For example, in the case of the carbon dioxide sensor using beta alumina, $NaCO_3$ (containing Na^+, the conduction ion of beta alumina) and the carbon dioxide of the detection gas will be used as the auxiliary electrode. Many approaches for development range between such theoretical understanding and the practical design of a sensor (see section “Further reading”).

Ferrite Materials and Magnetic Recording

A ferrite, which is a magnetic oxide body, was invented by Takei and Kato in the 1930s. Ferrites are widely used as a core material for a transformer or magnetic heads. The oxide permanent magnet was also invented during almost the same period, and after that, it has been used as a low-cost permanent magnet material. Iron oxide ceramic powder is used as a magnetic recording material in videotapes such as VHS. A record system may change to a perpendicular type and oxide powder may be used again, although currently metallic materials are used for the purpose of high-density recording.

Ceramic Turbocharger and Ceramic Turbine

Silicon nitride and silicon carbide, which are the main components of nonoxide ceramics, are artificial compounds. Since these compounds have a strong covalent bond in nature, till 1960 it was accepted that they could not be sintered.

The first oil shock pushed the development of efficient energy devices, and the use of ceramic materials, which can be employed at much higher

temperatures, was pursued. It was proposed in the 1980s that nonoxide ceramics could be used as parts of a gas turbine. The ceramic gas turbine project (CGT) was actually undertaken from 1988 to 1999 in Japan. A CGT with 300 kW power for co-generation and a 100 kW CGT for automobile use were developed. However, it has not reached the stage of commercial production, mainly because of production costs.

Ceramic turbocharger turbine blades made of silicon nitride are an example of a practical application of a nonoxide. Ironically, the material originally developed for raising energy efficiency was used in the automobile industry, which aimed at producing fuel-inefficient cars. However, the ripple effect was large. Nonoxide ceramics now have several applications, which are growing steadily.

Superconducting Ceramic Materials

In 1986, an oxide superconductor of the lanthanum–barium–copper system was first announced by Bednorz and Muller of the IBM Zurich Research Institute and its critical temperature T_c was 35 K, which exceeded the historical T_c 23 K of the NbGe. The Y–Ba–Cu system oxide was discovered in the following year and the critical temperature exceeded 77 K, which is the temperature of liquid nitrogen. Then, various new compound oxides, such as the Hg system, the TI system, and the Bi system, were announced.

A F Hebard and others have reported that the powder of C_{60} with doped potassium (K_3 C_{60}) shows a superconducting nature at a critical temperature of $T_c = 18$ K, and the same thin film of K_3 C_{60} shows the superconducting nature at a critical temperature of $T_c = 16$ K. MgB_2 has recently been reported to become superconducting at 39 K (for further details, see section "Further reading"). Thus, superconductivity is serving as a frontier of the science of new compounds in the ceramics system.

Optical Fibers

In 1964, Nishizawa succeeded in developing graded-index-type optical fibers for communications.

In 1966, Kao found that if heavy metals contained in glass were removed, the absorption loss of light in glass decreased dramatically. This epoch-making discovery was the key to utilizing an optical fiber and one that enabled the material development of low-loss fibers. Kao also had the foresight of proposing the structure of today's optical fibers consisting of a clad with a low refractive index and a core with a high a refractive index glass.

Following the basic work of Nishizawa and Kao, Corning Inc. succeeded in making low-loss (20 $dB\,km^{-1}$) fibers. Subsequently, the basic technology of the present-day information technology grew through a stiff competition in the development of optical fibers.

Conclusion

Ceramics are practically useful materials. From their discovery, through application development and testing (the so-called seed-driven route), ceramics have come a long way. However, new materials with superior properties continue to be desired in a variety of application areas. Given the limitations of the global environment, exploring new ceramic materials is a real challenge for further sustainability.

Composites: Carbon Matrix

B Rand, University of Leeds, Leeds, UK

Introduction

Carbon matrix composites (or carbon–carbon composites) are advanced composites in which carbon fibers are used to reinforce a carbon matrix. Both the fibers and matrices may encompass a vast range of crystallinity and the composites themselves may be constructed from a variety of different fiber architectures and volume fractions such that this class of composites may display a huge diversity of properties. These are the most refractory of all composites (in nonoxidizing conditions), exhibiting exceptional dimensional stability in extremes of temperature, high toughness and mechanical reliability, specific thermal conductivity many times that of copper, and remarkable wear resistance at high temperatures and speeds. These properties lead to such applications as:

- furnace parts, rocket nozzles, fusion reactor linings,
- construction materials for space applications,
- components in electronic packaging,
- thermal management,
- aircraft and formula one brake linings, and
- first wall linings in fusion reactors.

The origin of these properties lies in the intrinsic properties of the graphite crystal, since the various carbon forms that are developed in the composites display structures and properties that resemble those of graphite to different degrees.

Graphite Properties

The structure of graphite is well known, comprising graphene layers stacked in *abab* (hexagonal) or, rarely, *abcabc* (rhombohedral) sequence. The carbon atoms in the graphite crystal are sp^2 hybridized, forming three strong covalent bonds within the graphene layer whilst the layers are held together by van der Waals type interaction. Thus, the crystal displays the strongest and the weakest bonding possible in its two principal crystallographic directions, resulting in the most extreme anisotropy in physical and chemical properties. The principal physical properties are listed in **Table 1**. The strong "in-plane" bonding results in a Young modulus greater than 1000 GPa and a thermal expansion coefficient that is negative at room temperature and becomes slightly positive above $\sim 150^{\circ}$C. Although there is an electronic contribution at low temperatures, thermal transport is largely by a phonon mechanism above room temperature and reaches values comparable with those of diamond in the "*a*" direction. Delocalization of the π electrons makes graphite a semimetal with a small-band overlap. The "*a*"-axis electrical resistivity is 0.4–0.8 $\mu\Omega$ m at room temperature. In the "*c*"-direction most of the properties are significantly lower, as shown in the table, but the "*c*"-axis thermal expansion coefficient is large due to the weak bonding in this direction. The development of engineering carbon and graphite materials requires careful control of this anisotropy (**Figure 1**).

Carbon Fibers and Matrices – Structures and Properties

All synthetic carbon forms are produced by the thermal degradation in an inert atmosphere of organic precursors, gas, solid, or liquid (carbonization). The structure of the resultant carbon is determined by the nature of the precursor and the thermal history. The essential structural units are defective graphene layers, limited usually to nanometer dimensions, and stacked imperfectly with no regular stacking sequence, **Figure 2**. The precursors fall into two fairly well-defined groups depending upon whether they develop into synthetic graphite with the hexagonal *abab* stacking of graphite when heat treated to temperatures $\sim 3000^{\circ}$C. Those which do are graphitizing carbons whilst those which show relatively little

Table 1 Major physical properties of crystalline graphite

Property		*"a"-axis*	*"c"-axis*
Density (kgm^{-3})	2.265×10^3		
Young modulus (GPa)		1060 ± 20	36.5 ± 1
Shear modulus (GPa)		4.5 ± 0.5	
Thermal conductivity (Wm^{-1}K^{-1})		>2000	<10
Electrical resistivity ($\mu\Omega$ m)		0.4–0.8	>100
Coefficient of thermal expansion (K^{-1})		$\sim -1 \times 10^{-6}$ at room temperature	25.6×10^{-6} at room temperature

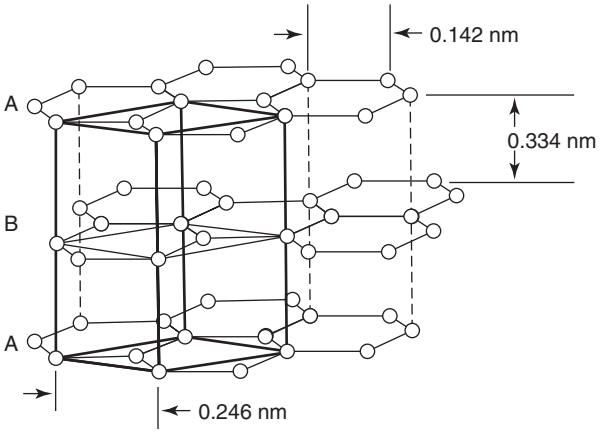

Figure 1 The structure of an ideal crystalline graphite.

structural development following such drastic thermal stimulus are the nongraphitizing carbons. Carbon fibers from rayon and from polyacrylonitrile (PAN) fall into the latter group (even though in the commercial world they are frequently and incorrectly referred to as graphite fibers), whilst those from mesophase pitch and hydrocarbon gases are of the graphitizing variety. In low-temperature carbons, the defective graphene layers may contain vacancies, and have five- and seven-membered rings which bend the layers in different directions. Hence it is not possible for the layers to stack in any regular array and the interlayer spacing, d_{002} is significantly greater than that in graphite. Only very broad 001 and *hk* X-ray diffraction lines are observed. A line-broadening analysis, using the Scherrer equation, enables X-ray coherence lengths in the "*a*" and "*c*" directions (L_a and L_c) to be identified from the 002 and 10 diffraction peaks. These are initially of the order of 1–2 nm, but during graphitization they increase progressively with heat treatment temperature (HTT) up to about 50–100 nm, when the additional *hkl* lines appear, indicating that a 3D structure has been formed. Simultaneously, there is steady decrease in d_{002} to the value for graphite.

X-ray diffraction gives no information about the spatial distribution of these coherently diffracting regions. High-resolution transmission electron microscopy (HRTEM), **Figure 3**, shows that they may be randomly arranged as in the nongraphitizing carbons or show extensive regions of preferred orientation in the graphitizing materials.

Matrix Carbons

The most common matrix material is chemically deposited from hydrocarbon vapors, CVD. When the deposition takes place in the interstices of the fiber preform onto the surfaces of the fibers, it is known as chemical vapor infiltration (CVI). The structure of the deposit is very dependent upon the deposition conditions, temperature, partial pressure, and residence time. Various different microstructures are possible which are classified as isotropic, laminar, rough laminar, and surface nucleated. Infiltration conditions must be carefully controlled not only to deposit the desired microstructure for the particular application, but also to ensure a uniform deposition throughout the fiber architecture and avoid preferential deposition on the surface of the fiber preform. This requires a careful balance between the rate of deposition and of vapor transport into the porous fiber preform. The infiltration process is slow and the manufacture of large items may take several weeks. It may also be necessary to machine the outer surface intermittently to remove the surface deposit which seals off the interior. The product is graphitizable. For aircraft brake linings, the preferred microstructure is the rough laminar variety which seems to give the optimum combination of thermomechanical properties and wear resistance. Since the deposition takes place onto the fiber surfaces, the graphene layers show a preferred orientation with the fibers, **Figures 4** and **5**.

Alternative matrix sources are pitches and thermosetting polymeric resins. Pitches are complex mixtures of polynuclear aromatic molecules, many having aliphatic side chains. They are thermoplastic and can have low viscosities at temperatures ~100–150°C above the glass transition temperature, T_g. Heat treatment increases the average molecular weight by evaporating volatile species, resulting in a gradual shift in the T_g to higher temperatures and

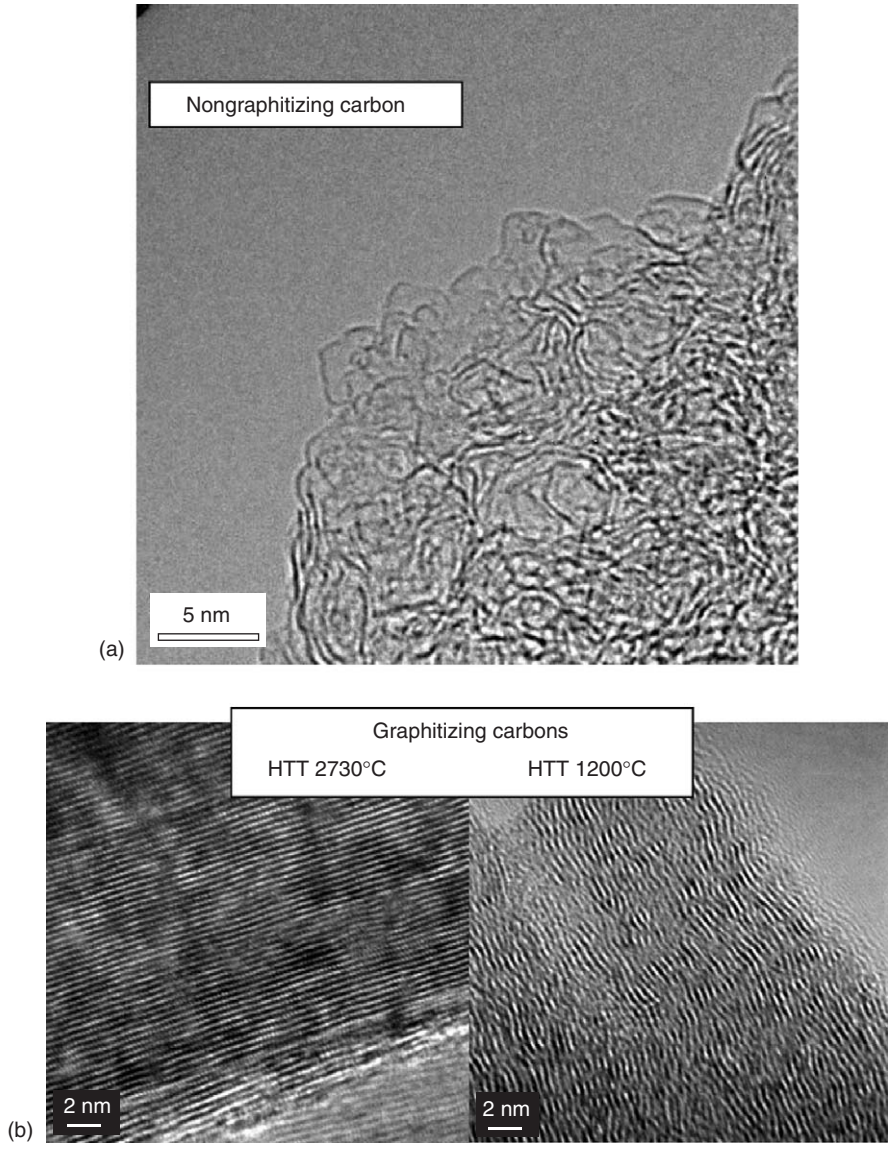

Figure 3 High-resolution transmission electron micrographs showing 002 lattice fringes for (a) a nongraphitizing carbon and (b) graphitizing carbons at two different heat treatment temperatures.

ultimately the solidification of the material to a carbon product. Intermediate in this process is a key step in which the disk-like molecules stack up to form a nematic discotic liquid crystalline phase, the carbonaceous mesophase. This is the basis of the graphitizability of the subsequent carbon, the basic long-range preferred orientation of lamellar structure being determined at the solidification stage of this transient phase.

Phenolic resins are the most common thermoplastic precursors, although polymers with higher carbon yields, such as poly-paraphenylenes have also been used. The resins are thermally cross-linked prior to carbonization. This prevents any liquid crystal formation and the materials do not graphitize. Normally, only minor microstructural changes take place after heat treatment to 3000°C. However, both the pitch and resin precursors may bond to the carbon fibers during the fabrication heat treatment and form an aligned interphase at the fiber–matrix interface. Thus, all three matrix precursors tend to give matrix oriented with the fibers, although in the case of the pitch and resin matrices, this may only extend a few micrometers out from the surface. **Figure 6** shows optical micrographs of typical examples.

Carbon Fibers

The main form of carbon fiber used is from PAN. A wide range of properties are available, depending

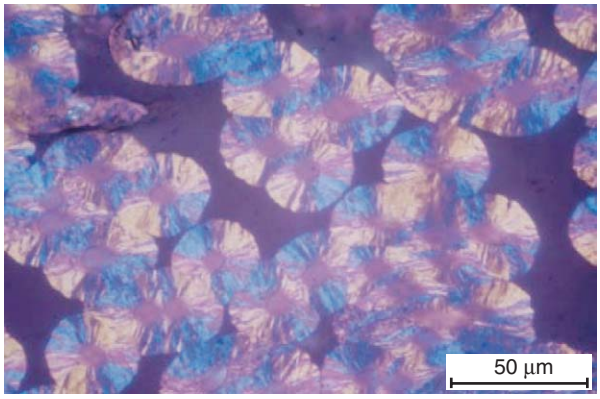

Figure 4 Polarized light optical micrograph of CVD carbon deposited onto the surfaces of carbon fibers within a carbon–carbon composite (crossed polars). The yellow and blue interference colors denote regions where the layers are oriented at 90° to each other. In this instance the layers are oriented parallel to the fiber surfaces.

mostly upon the degree of preferred orientation of the graphene layers along the fiber axis and the perfection of those layers, controlled by the final HTT. Young moduli up to ~500 GPa are possible with strengths in the range 2–7 GPa. **Table 2** lists typical data. Fibers are also spun from mesophase pitch and these are highly graphitizable displaying much higher extents of preferred orientation of the planes along the fiber axis and consequently higher moduli, which may approach that of the perfect graphene layer itself. These fibers also show very high thermal and electrical conductivities. Although in all cases the graphene layers are aligned predominantly along the fiber axis, transversely they may show various textures, whilst still maintaining the high stiffness. This effect is most strongly displayed in the range of mesophase pitch-based fibers, **Figure 7**, where the texture is largely controlled by the conditions in the spin capillary. Indeed even ribbon-shaped fibers have been produced with significant orientation of the graphene planes perpendicular to the plane of the ribbon as well as parallel to the ribbon long axis. The strengths of all carbon fibers are dominated by process-induced defects, flaws, the dimensions of which control the strength in accordance with the Griffith fracture criteria. The fiber microstructure has a secondary effect.

An early form of carbon fibers was produced from rayon in the US. This form is not so widely used worldwide, but still finds some defense applications in the US. Its demise is largely due to the fact that the PAN process is cheaper, whilst that for rayon required a stretching operation at graphitization temperatures to develop the high elastic moduli, by aligning the layers with the fiber axis. These fibers tend to have a "dog-bone" transverse shape and can therefore be recognized readily easily in micrographs.

Carbon fibers may also be produced from hydrocarbon vapors by a catalytic route; their dimensions and structure may vary considerably with the process conditions from filaments of micron diameter down to carbon nanotubes. Some of these materials are highly graphitizable and display excellent properties, but as yet are not used in the fabrication of C–C composites to any significant degree.

Plain weave 5D woven structure

Figure 8 Schematic representation of one typical weave structure and a 5D multidirectional weave.

Fiber Architectures

Composites may be unidirectional, 1D, angle ply laminates, woven cloths, or more complicated 3-, 4-, or multi-directional woven structures, designed to deliver more or less isotropic properties. Pierced, "needled" laminated plies or cloths may be used to give improved properties in the "*z*"-direction, whilst the "in-plane" isotropy will depend upon the cloth weave or lamination sequence of angled 1D plies. General purpose applications rely on laminates of various types and the expensive multi-D structures are mainly used in sophisticated and demanding aerospace and defense applications. High-pressure infiltration and carbonization of pitch and resin precursors may be required to densify these more complicated structures. **Figure 8** shows examples of some of these structures, schematically. Angle ply laminates are commonly used in the fabrication of aircraft and formula one car brake disks, comprising not only unidirectional layers, but also random staple-fiber regions of significantly lower fiber fraction. These staple layers assist in the transport of the pyrolytic vapor into the preform.

Fabrication

Figure 9 shows typical fabrication routes for all precursor types. The fiber preform is densified by infiltration of liquid pitch or resin or by CVI. In some cases, the preform may be rigidized with resin first. In the CVI process, it is difficult to completely fill all the internal porosity since the entrances to large pores

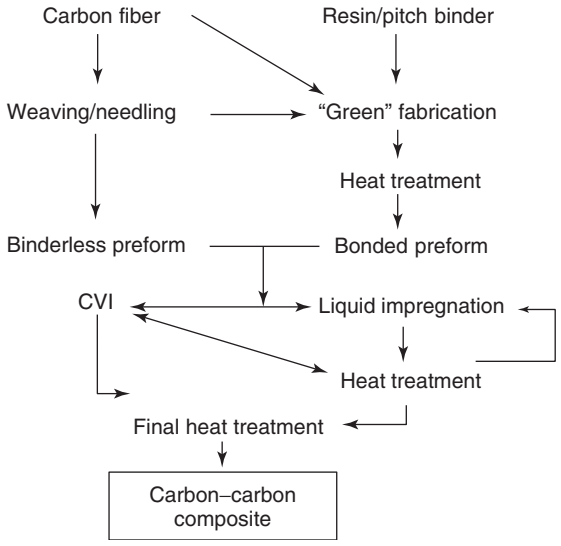

Figure 9 Generalized fabrication routes for carbon–carbon composites.

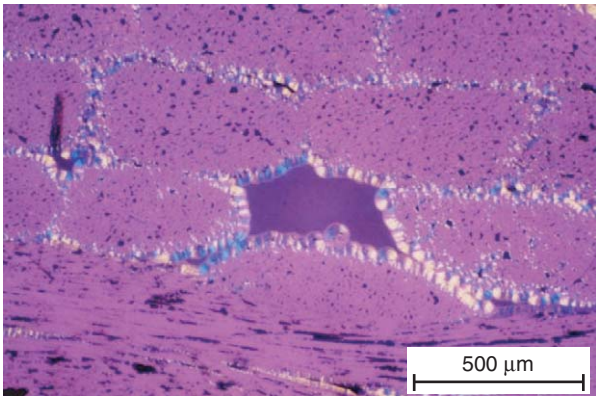

Figure 10 Polarized light optical micrograph of CVI densified C–C composite showing the tendency for the deposition of carbon to take place on the surface of bundles and not to completely penetrate the interstices within the bundle.

may be blocked by the pyrolytic deposit, **Figure 10**, and the process is slow. In the liquid infiltration route, the resins and pitches have only 50–80% carbon yields due to the loss of volatiles. Also, the density of the carbon–graphite product is significantly less than that of the precursor organic, resulting in volumetric yields that are even lower. Consequently, repeated infiltrations and re-carbonization steps are required to reduce porosity. Since graphitization of the matrix increases its density, it may even be necessary for the most advanced composites to be re-impregnated after this step and then re-graphitized, resulting in very expensive products.

Various combinations of precursors and impregnation stages may be adopted and this can result in materials with varieties of carbon structures within the matrix and in the fibers. The most extreme fabrication routes are adopted for aerospace and defense applications. For more commercial applications, such as aircraft brake disks, there are vigorous programs currently underway to develop more rapid fabrication routes.

Composite Microstructure

C–C composites are complex materials. They display structural features at many different dimensional scales all of which contribute to the observed physical properties. **Figure 11** shows some examples of various internal microstructures. At the nanoscale, there are the different degrees of structural organization in the various carbon forms (fiber, pitch, resin, or CVD-derived matrix) that may be present as well as the possibility of nanoscale porosity (especially within the carbon matrix derived from thermosetting resins). At the microscale, there is the distribution of anisotropic regions within the matrix, the fibers, and at the fiber–matrix interfaces, as well as porosity and microcracks. At the millimetric scale there are the fiber bundles (which vary in dimensions according to the fiber type and manufacturer), the laminae, large pores which have not been filled by matrix and cracks formed by shrinkage of bundles during carbonization.

Lamellar cracks develop on cooling from the fabrication temperature to relieve thermal stresses arising from the anisotropic thermal contraction of the components of the microstructure. A thermal expansion mismatch, leading to such microcracking, may exist

- at fiber–matrix interfaces within fiber bundles,
- at interfaces between carbon forms from different precursors,
- between regions of different preferred orientation within the matrix,
- between laminae in 2D materials, and
- between differently oriented bundles in multi-D composites.

Thus, cracks and voids are an integral part of the composite structure and must be taken into account in the interpretation of all physical and chemical properties. The matrix carbon increases its true density on heat treatment up to graphitization temperatures leading to contraction which also is largely in the "*c*"-direction; thus this mechanism is also a source of microcracking. However, whilst those fissures arising from the anisotropic thermal contraction may close on reheating, those from the

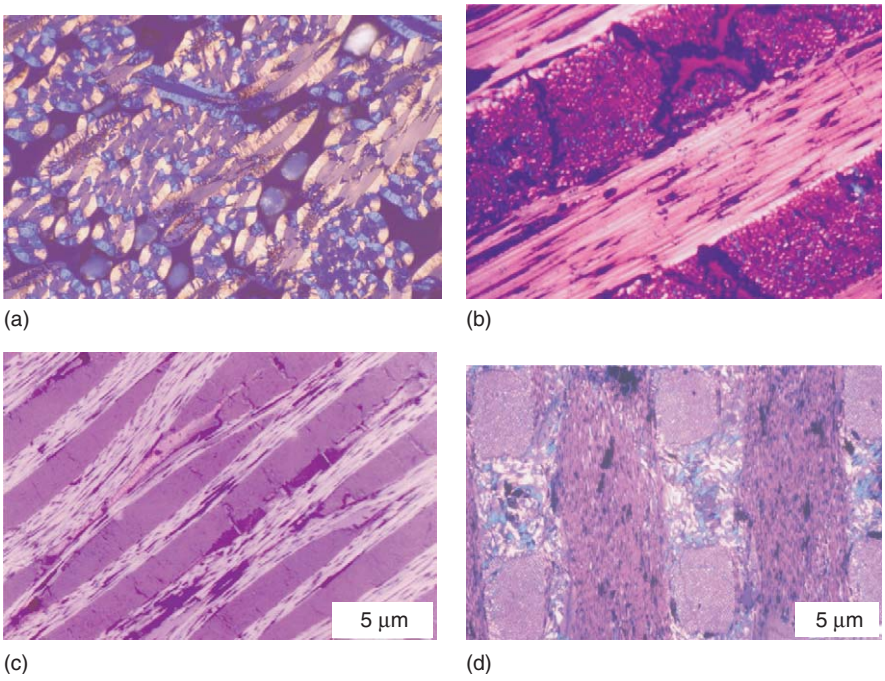

Figure 11 Optical micrographs (polarized light) showing microstructures of various types of C–C composite. (a) CVD carbon around fibers in a random fiber architecture. (b) Section of a 0/90 laminate showing shrinkage cracks in the transverse ply, partially filled with resin-based carbon. Note how the carbon in the crack has shrunk as well, displaying the shape of the surrounding pore. (c) Section through a woven cloth composite showing shrinkage cracks in the transverse bundles. (d) Section through a 3D orthogonal composite. The matrix pocket that exists between the *X*, *Y*, and *Z* bundles is in the case partially filled with pitch-based carbon matrix.

densification process will not. **Figure 11c** shows a typical example of transverse cracks in a woven cloth due to the differential shrinkage during carbonization of fiber bundles oriented perpendicular to each other and **Figure 12** is a schematic representation of the microcracks in an orthogonal 3D composite.

Physical Properties

The most dominant feature controlling the physical properties is the fiber architecture and type. The mechanical property in any principal direction is determined by the volume fraction of fibers oriented in that direction. This decreases as the directionality increases in multi-D lay-ups. **Tables 3** and **4** give approximate values for different types of material.

Mechanical Properties

Young Modulus

The Young modulus varies widely according to the composition and structure of the composite, see **Table 3**. Unidirectional materials may show values as high as 800 GPa after graphitization when the highly graphitizing MP fibers are used. Since both pitch and CVD matrices are highly graphitizable and also orient with the fiber, they may both contribute significantly to the observed Young modulus value, provided that the degree of filling of the fiber preform is high, **Figure 13**. One problem in modeling the mechanical properties of C–C composites is that it is not usually possible to obtain experimental data on the basic properties of the matrix material, because its structure is controlled by the fabrication conditions and the interaction with fibers. Simple mixture rules do not always work, because the level of microcracking and the residual porosity in incompletely densified composites may limit the load transfer between the fiber and the matrix as illustrated in **Figure 13**. For laminates and multi-D composites, the values in specific directions are more or less as expected from the fiber orientations and volume fractions. **Table 3** gives some typical values.

Strength and Fracture Behavior

C–C composites are examples of brittle matrix composites. Bulk carbon and graphite materials are porous and of generally low strength, elastic modulus, and fracture toughness. Therefore, in contrast to ceramic matrix composites, for which the matrix is intrinsically strong and where the fibers are used mainly to modify the mode of fracture and induce damage tolerance and mechanical reliability, in C–C the fibers do act to stiffen and reinforce as well as to

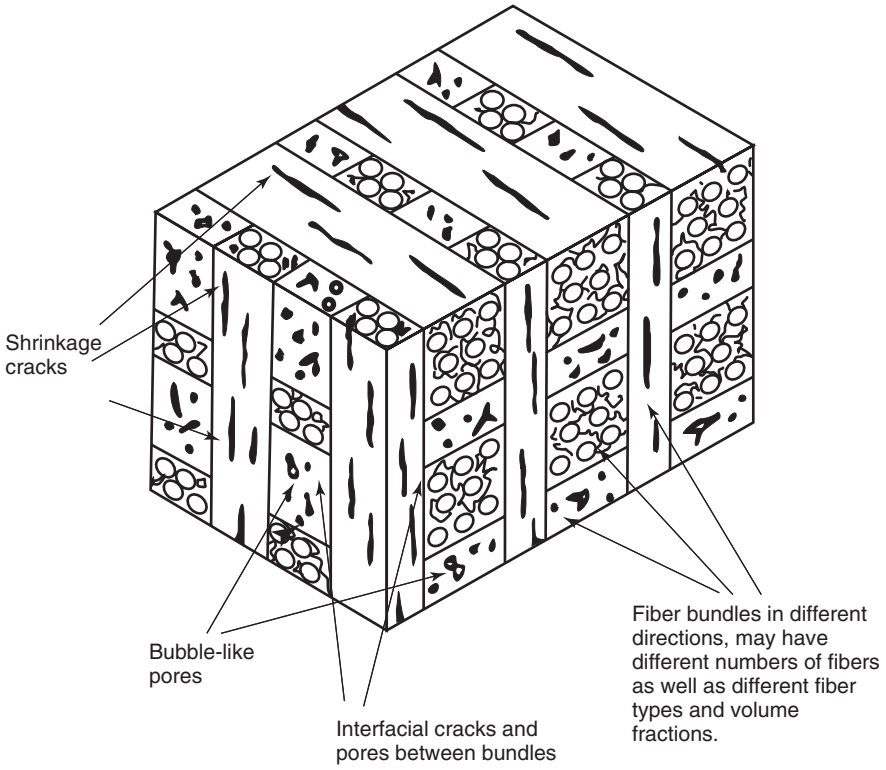

Figure 12 Schematic representation of the structure of a 3D orthogonal C–C composite depicting microcracks in fiber bundles and at bundle–bundle interfaces, pores and variable bundle dimensions, and character.

toughen the matrix. In common with other brittle matrix composites, the strength of the fiber–matrix bond is critical. The lower strain to failure of the matrix leads to the generation of cracks within this phase which, if the fiber–matrix bonding is strong, may propagate through the fiber, leading to brittle fracture at the matrix failure strain. However, if debonding can take place at the fiber–matrix interface, the cracks may be deflected along the fiber axis allowing the fibers to bridge the crack leading to classical multiple matrix cracking. In 1D composites, when this cracking is saturated with approximately equally spaced cracks, the elastic modulus should approximate to $v_f E_f$ and failure should occur at the failure strain of the fibers, leading to full utilization of the fiber strength. **Figure 14** shows stress–strain plots for 1D composites with weak and strong fiber–matrix bonding, illustrating this behavior. The crack bridging and fiber pull-out lead to high work of fracture and excellent damage tolerance. However, weak bonding at the fiber–matrix interface also reduces the intralaminar shear strength in 1D materials. The fiber–matrix bond strength with pitch and resin-derived matrices arise from the interaction of the precursor with the complexes on the fiber surfaces, which depend on the previous treatments given to the fibers by their manufacturers to control fiber–resin interactions. In the absence of such complexes, the bonding is very weak or even absent. The fiber–matrix bonding is also influenced by the heat-treatment. Graphitization increases the solid density of the matrix and fiber, if it has not experienced that temperature regime in its production. This introduces internal stresses and shrinkages which tend to debond the fiber from its matrix. This occurs with all matrix types. Graphitization tends to "polygonize" the oriented matrix sheath around the fiber and also shrink the fiber radius, so debonding the interface, **Figure 15**. Thus, a material that displays brittle fracture after carbonization in the range 1000–1600°C may show multiple matrix cracking and damage tolerance after graphitization. **Figure 14** shows these effects for a 1D material in tensile loading. In flexural testing, any weak interfaces may promote shear failure at stresses significantly lower than the tensile fracture stress unless very large span to depth ratios are adopted.

The behavior of 2D laminates and of multi-D structures may also be influenced by the interfacial region, but other factors come into play. Typical strength values for composites of different architecture are shown in **Table 3**. The 3D and multi-D materials generally show low strength values in specific directions because of the lower fiber volume fraction.

Table 3 Typical mechanical of various types of carbon–carbon composite

Composite type	*Fiber volume fraction in measurement direction*	*Tensile modulus* (GPa)	*Tensile strength* (MPa)	*Tensile strain at failure* (%)	*Flexural modulus* (GPa)	*Flexural strength* (MPa)	*Compressive strength* (MPa)	*Shear strength* (MPa)	*Fracture energy* ($kJ\,m^{-1}$)	*Poisson's ratio*

[a] High values obtained with graphitized pitch based fibers and matrix.

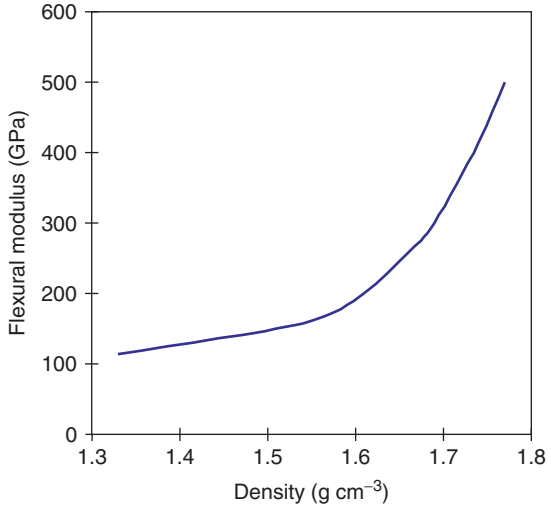

Figure 13 Example of the effect on the elastic modulus of successively densifying a 1D composite by a series of reimpregnation and recarbonization steps using pitch. The final composite would be graphitized. As the pore space between fibers is progressively filled, the load transfer to the fibers is dramatically improved. These data would be typical of a 50–60% volume of PAN-based fibers which after graphitization would display a Young modulus of ~450 GPa. Note that the composite modulus exceeds this value showing that the pitch-based matrix oriented around the fibers develops a Young modulus in excess of that of the fibers.

In directions with minimal fiber fraction, for example, at 45° to an orthogonal direction in orthogonal 3D composites, the fracture stress is similar to the values for normal un-reinforced porous graphites. Multi-D composites tend to show a very gradual type of failure mode (sometimes called "pseudoplastic"), indicating high damage tolerance, **Figures 16** and **17**. This is probably due to the many cracks and interfaces present that may deflect the main crack and provide a variety of crack-bridging elements (fibers and fiber bundles) that make a major contribution to the fracture energy. In woven cloth laminate structures, the presence of needled tows may enhance the strength and elastic modulus in the "*z*"-direction but this may be at the expense of some disruption of the "in-plane" fiber arrangement resulting in a small decrease in the "in-plane" properties. Similarly, the weave pattern can influence the "in-plane" properties due to the crimping effect of the criss-crossing fiber tows. The various bundles in the multi-D composites may be of different sizes or contain different fibers, enabling the composite to be designed to withstand the anticipated stresses in various directions to be experienced in the specific application.

Effect of Temperature on Mechanical Properties

The Young moduli and the fracture stress of most carbon–graphite materials are remarkable in that they increase with measurement temperature. The effect is attributed to the re-expansion into the microcracks created by thermal expansion mismatch, which lowers the porosity and increases the Young modulus and strength. These effects are present in C fiber–C matrix composites to a significant degree. Thus, C–C composites in nonoxidizing conditions are the strongest materials at very high temperatures when the strengths of other materials are drastically reduced. **Figure 18** shows a comparison, whilst **Figure 19** shows schematically how the fracture behavior of 3D orthogonal material may be drastically altered at extreme temperatures.

Creep and Fatigue

It is because of the strong covalent bonding that the mechanical properties do not degrade significantly

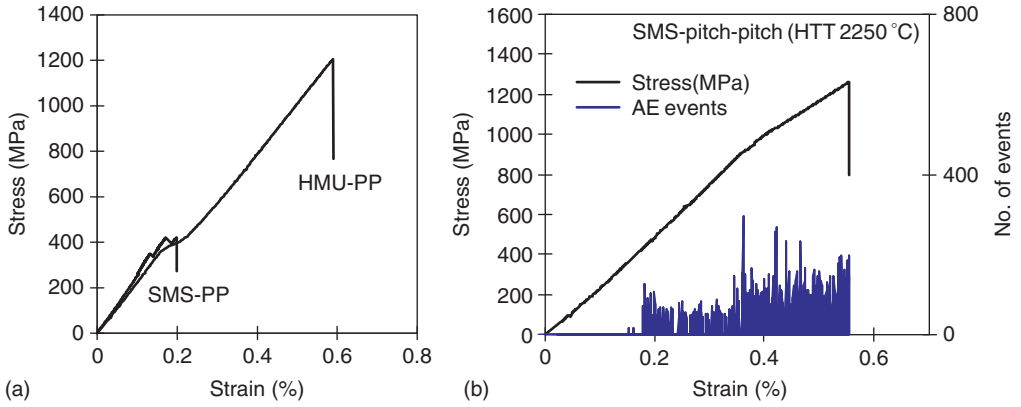

Figure 14 Tensile behavior of 1D carbon composites. (a) A surface-treated intermediate modulus PAN-based fiber (SMS-PP) composite is compared with one of the similar fiber volume fractions using high modulus carbon fibers. The former has an active surface whilst the latter has an inert, largely basal, surface. In both cases, the matrix is derived from pitch and the carbonization temperature is in the region of 1000°C. The fracture is catastrophic at the failure strain of the resin for the surface-treated fiber composite, due to a strong interfacial bond, whilst in the latter case multiple matrix fracture occurs around the same value of strain and the ultimate fracture stress is determined by the fibers, giving strength greater than 1 GPa. (b) The behavior of the surface-treated fiber composite is displayed after graphitization. The matrix has now pulled away from the fiber weakening the interface and dramatically increasing the strength and the strain at ultimate failure. During this heat treatment the Young modulus of the fiber increases as well. (b) Also shows the acoustic emission accompanying the test, indicating some subcritical events prior to fracture.

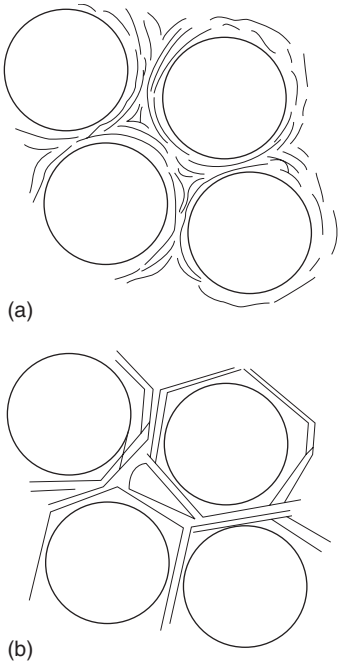

Figure 15 Schematic representation of the preferred orientation of graphene layers with fiber surface in C–C composites. (a) Carbonized matrix and (b) after graphitization.

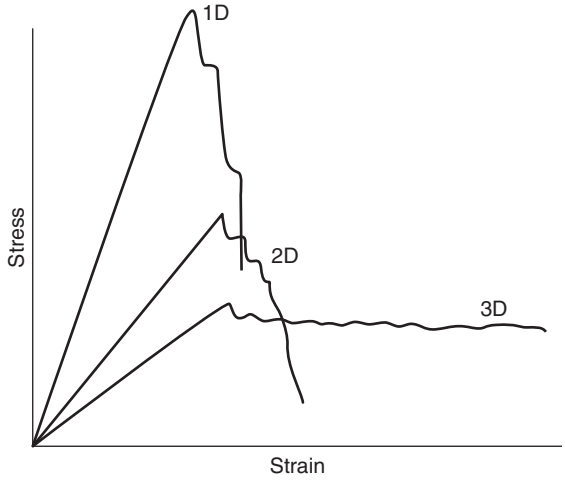

Figure 16 Schematic representation of the different general stress–strain behavior of C–C composites of different fiber architecture.

until very high temperatures are achieved. Thus, the creep resistance of C–C composites is very high, there being virtually no creep below ~2000°C, but above this region the creep rate becomes finite and shows a steady increase as the temperature rises to 3000°C.

The fatigue resistance of C–C composites is also good. Studies in flexure and in torsion have shown that the opening and closing of slit-like fissures (pores) in the structure is a significant feature. At stresses greater than about 1/3 the fracture stress, microcracks are formed and internal damage to the matrix can lead to the loss of small particles, a so-called "dusting out" process.

Friction and Wear

The tribological properties are critical in the major commercial application of C–C composites, in aircraft brake linings. The friction coefficient increases with temperature to a value as high as 0.6 at the

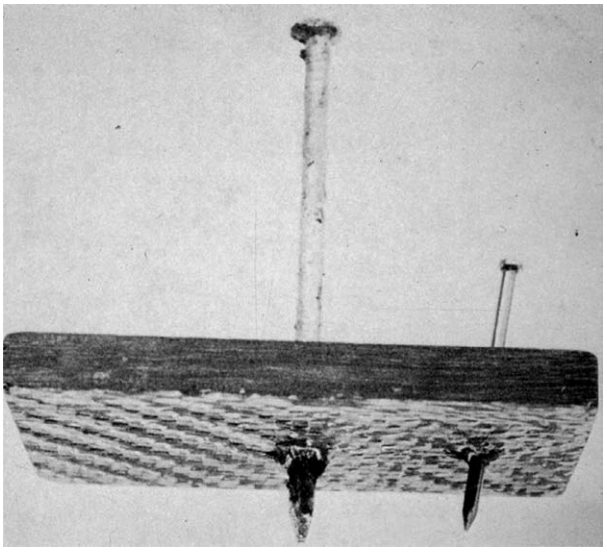

Figure 17 Nails driven through a C–C composite, illustrating the general toughness (damage tolerance) of this material.

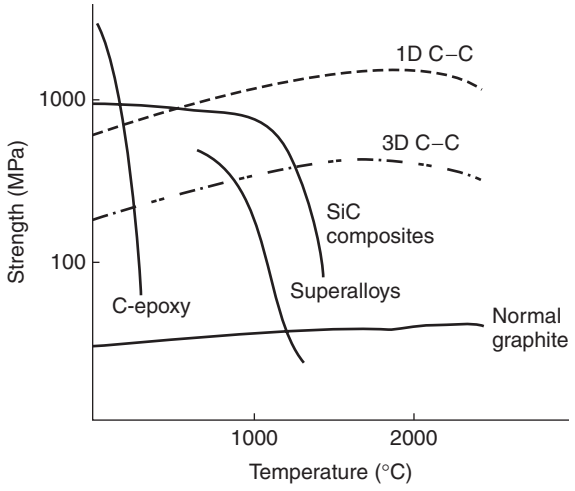

Figure 18 Comparison of the temperature dependence of strength of C–C composites with other advanced materials.

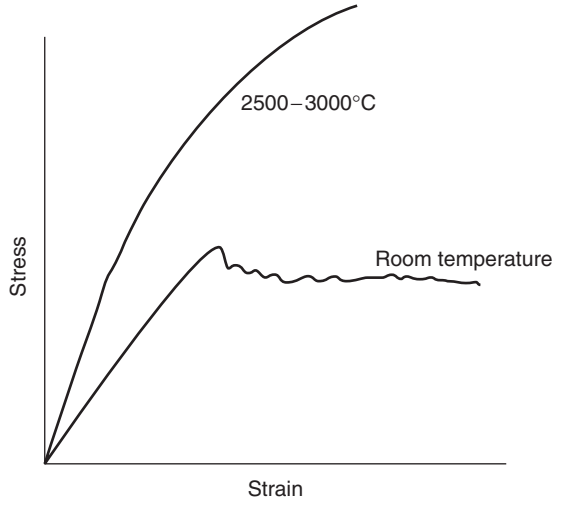

Figure 19 Schematic representation of the effect of temperature on the stress–strain behavior of a 3D orthogonal C–C composite.

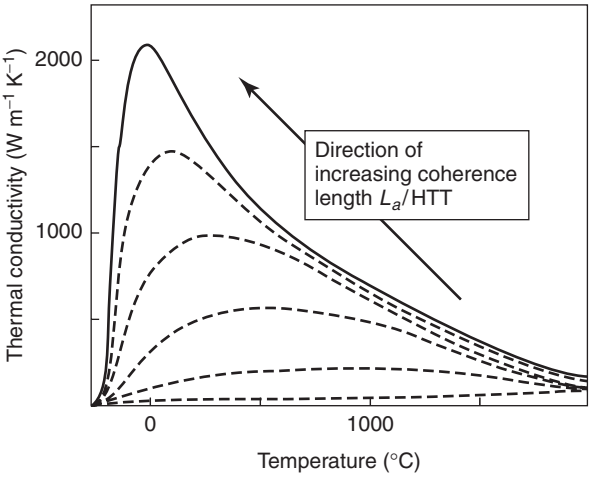

Figure 20 General trend of thermal conductivity with temperature for carbon–graphite materials of different order (extent of graphitization).

same time as the wear resistance increases. The key factor is the structure of the film of wear debris at the interface which may take on different structures in different wear regimes, that is, low temperature, during taxi-ing or high temperatures during landing and aborted take off.

Thermal and Electrical Properties

Thermal Expansion

Carbon–carbon composites are extremely dimensionally stable over very wide temperature ranges. The thermal expansion in fiber directions is controlled by the values of the fibers themselves, which for high-modulus fibers and fibers that have been heat-treated to graphitizing temperatures during the composite processing is initially negative rising to a small positive value above 150°C. The result is that over a temperature range of 2800°C, the linear expansion is only $\sim$0.7%. This value prevails more or less within the plane of laminates and in fiber directions in multi-D composites. In transverse directions, the situation is more complicated, the expansion coefficient being determined by the extent to which the large "*c*-axis" expansion of the graphite crystal is accommodated in microcracks, and the orientation of the lamellar regions and the associated cracks to the direction of measurement. Some typical values are listed in **Table 4**.

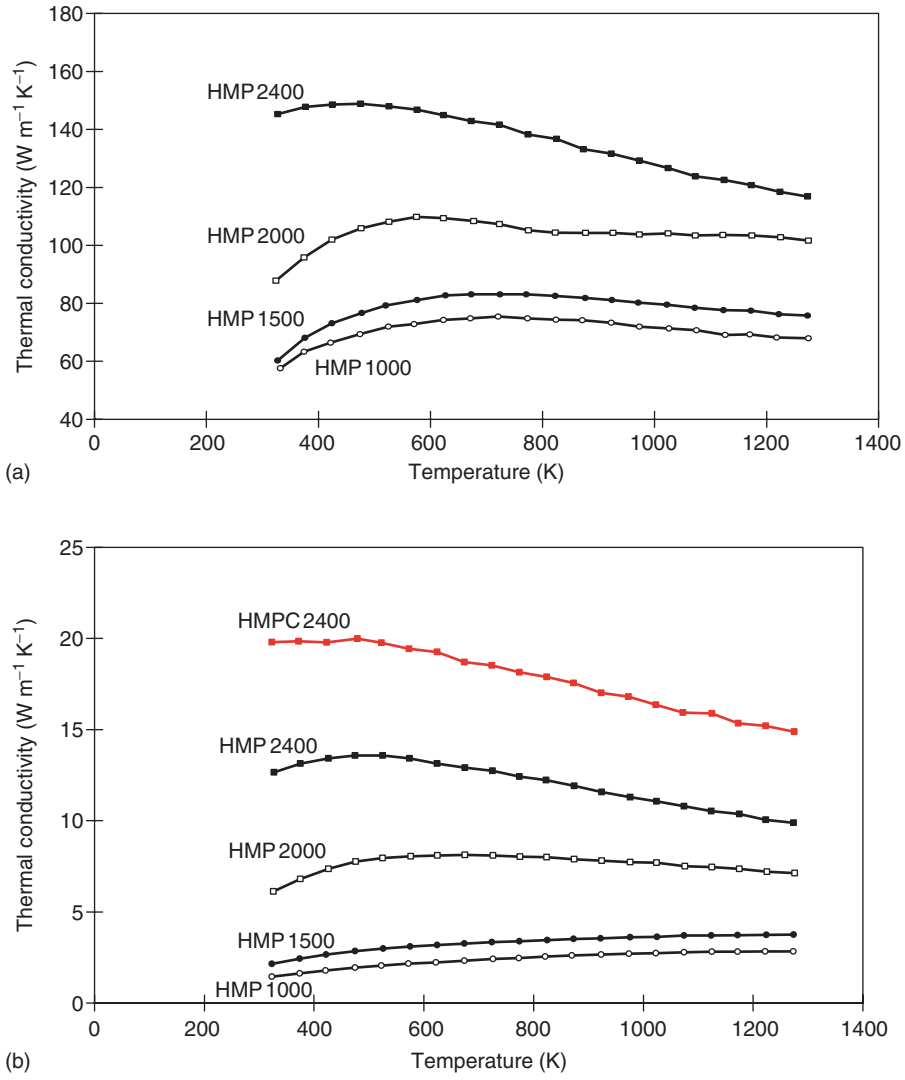

Figure 21 Thermal conductivity data for 1D model laminates measured (a) in the longitudinal and (b) in the transverse directions. The composites all comprise high modulus PAN-based carbon fibers with a pitch-based matrix, heat treated to temperatures in the range 1000–2400°C.

Thermal and Electrical Conductivity

Thermal and electrical conductivity both increase with the degree of order of the graphene layers and also with the extent of preferred orientation of the layers with respect to the thermal or potential gradient. Both parameters increase with the *a*-axis coherence length, L_a. The thermal transport in graphite is dominated by lattice vibrations (phonons). Only near 0 K is the electronic contribution to heat conduction significant. The thermal conductivity is highly temperature and structure dependent. Phonon–phonon interaction (Umklapp scattering) and scattering at boundaries between ordered regions are the principal processes controlling the conductivity at elevated temperatures and the relative effects of these two mechanisms depends on the coherence length, L_a. When L_a is large (graphitized materials), the phonon scattering mechanism is dominant, but when it is small, as in nongraphitizable carbons and materials heat treated only to modest temperatures, the Umklapp mechanism is significant only when the phonon mean free path becomes smaller than the coherence length, that is, at high temperatures. The result is that thermal conductivity–temperature curves for carbons of varying structural perfection show maxima at different temperatures, the value of the maximum increasing with the degree of graphitization, **Figure 20**. The maximum for graphite and highly graphitized fibers and matrices is below room temperature, but for poorly graphitized materials it may be as high as 500–1000°C. At very high

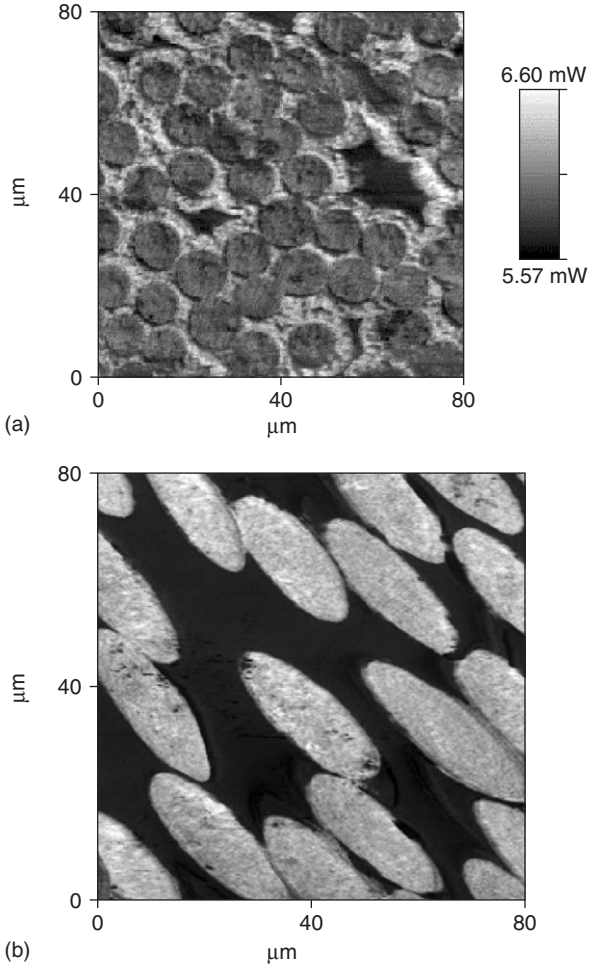

Figure 22 Thermal micrograph of transverse sections of (a) a PAN fiber-based composite with a CVD matrix and (b) a high thermal conductivity mesophase pitch-based fiber composite with a resin-derived matrix. The brightness reflects the relative thermal conductivity, which in (a) is greatest in the graphitizable matrix, but in (b) is greatest in the graphitized fiber.

temperatures, the curves tend to come together resulting in very little difference in thermal transport of different forms of carbon in this region. **Table 4** lists thermal conductivities of various types of composites and **Figure 21** shows data for a graphitized series of 1D laminates, showing the increase in thermal conductivity as the matrix is progressively improved in order. PAN-based carbon fibers are nongraphitizing and display limited thermal conductivities even for the high-modulus forms that have been heat treated to near 3000°C. Thus, pitch- and CVD-derived matrices, after graphitization, may have significantly higher conductivities than PAN-based fibers. Graphitized MP fibers, on the other hand, have high conductivities. **Figure 22** illustrates these trends. When mesophase pitch-based fibers are combined with these two types of matrix and graphitized, then extremely high thermal conductivities may be obtained.

The electrical conductivity of composites will generally vary in the same way as thermal conductivities. An empirical relationship between the two properties has been developed for carbon fibers. It is possible that a similar relationship may prevail for 1D materials, in the fiber direction. This arises because both properties vary with structure in the same way.

Thermal Shock

The combination of low expansion coefficient with high thermal conductivity, high strength at elevated temperatures and very high work of fracture result in exceptional thermal shock resistance of C–C composites, a critical factor in refractory applications, such as furnace parts, first wall materials in fusion reactors, rocket nozzles, and shielding (e.g., shuttle nose cone and leading edges of wing tips).

Oxidation

Because of the oxidation of graphite, that is prevalent above $\sim 500^{\circ}C$, the exceptional properties can only be achieved at high temperatures in inert atmospheres or for limited periods of time in oxidizing ones. There have been many attempts to protect carbon against oxidation. The main approaches are:

- incorporation of various glassy phases in the pore structure to reduce oxygen transport to the internal structure,
- inclusion of carbide-forming elements during fabrication. The carbides oxidize to protective oxides,
- coating the outer surface with refractory carbides. Thermal expansion mismatch may lead to cracking of the layer on cooling, but the internal glassy phases are designed to help seal these cracks on reheating.

Concluding Remarks

The properties of C–C composites can vary over a vast range due to the variety of carbon structures that may be engineered within the fibers and the carbon matrices, and the variety of fiber architectures that exist. The carbon structures may change dramatically during thermal processing. This variation enables materials to be designed with properties that may approach those intrinsic to the graphite crystal in 1D materials which are highly anisotropic, or may have almost isotropic properties in multi-D materials with properties in specific directions that reflect the

amount of fiber so oriented. The materials may be the most refractory and dimensionally stable of all in inert atmospheres or for limited periods in oxidizing ones. The technology is fairly mature, the most active field currently being to reduce processing costs and time, and to develop C–C–SiC composites with improved wear for terrestrial braking systems.

Composites: Overview

C H Zweben, Devon, PA, USA

Introduction

A composite material is two or more materials bonded together. This definition distinguishes composite materials (composites) from materials such as alloys. The most important composites consist of matrices reinforced with various types of fibers, whiskers, or particles. Using composites technology, it is possible to design new, multifunctional materials with unique properties and combinations of properties that cannot be obtained with any monolithic material.

Many widely used materials are composites, but not generally recognized as such. For example, tungsten carbide cutting tools are actually composites consisting of tungsten carbide particles bound together with a cobalt matrix, rather than monolithic tungsten carbide. The reason for using the composite is that it has a much higher fracture-toughness than monolithic tungsten carbide, a brittle ceramic.

Composites are material systems. Their properties depend on those of the constituents (reinforcement and matrix), reinforcement coating, if any, and the process by which they are made. All of these have pronounced effects, and altering any of these can greatly affect their properties.

The development of composites and the related design and manufacturing technologies is one of the most important advances in the history of materials. Composites are widely used, and are enabling materials in many applications. For example, Voyager, which was in effect an all-composite aircraft, was the first to fly around the world without refueling. However, it is emphasized that modern composites technology is only about five decades old. In the history of materials, this is hardly the blink of an eye.

Composite materials are considered primarily as structural materials. However, there are numerous examples of applications for which nonmechanical properties, such as thermal, electrical, magnetic, and

piezoelectric, are of primary interest. Important applications based on nonmechanical properties include glass–fiber-reinforced polymer printed circuit boards, magnetic particle-reinforced polymer audio and video recording tape, and ceramic particle-reinforced polymer sensors.

Another unique characteristic of composites is that many are made with processes that have advantages over those used for monolithic materials. To cite one example, manufacturing methods for fiber-reinforced polymers allow fabrication of aircraft structures having shapes that are aerodynamically superior to those made from metals. Another illustration is the magnetic particle-reinforced polymer permanent magnets that can easily be made into complex shapes by processes such as injection molding.

Composites are usually categorized by the type of material used for the matrix. The primary classes are polymer matrix composites (PMCs), metal matrix composites (MMCs), intermetallic matrix composites (IMCs), ceramic matrix composites (CMCs), and carbon matrix composites (CAMCs). The last category, CAMCs, includes carbon–carbon composites (CCCs), which consist of carbon matrices reinforced with carbon fibers. Currently, PMCs are the most widely used.

It is worth noting that biological structural materials occurring in nature are typically composites. Common examples are wood, bamboo, bone, teeth, and shell. Further, use of artificial composite materials is not new. Bricks made from straw-reinforced mud were employed in biblical times. This material has also been widely used in the American Southwest for centuries, where it is known as adobe. In current terminology, it would be described as an organic fiber-reinforced ceramic matrix composite.

As discussed earlier, there are many types of composites. This article concentrates on those that are used primarily because of their mechanical and thermal properties.

Table 1 Types of composite materials

Ceramic	X	X	X	X
Carbon	X	X	X	X

Overview of Composite Materials and Applications

For the purposes of this article, solid materials are divided into four categories: polymers, metals, ceramics, and carbon. Carbon as a separate class is considered because of its many unique forms and characteristics. There are reinforcements and matrix materials in all four categories of solids. This results in the potential for a limitless number of new material systems having unique properties that cannot be obtained with any single monolithic material. Composites consisting of all possible combinations of matrix materials and reinforcements have been produced (see **Table 1**).

For decades, CCCs were the only significant type of CAMCs. However, there are now other types of composites utilizing a carbon matrix. Notable among these is silicon carbide fiber-reinforced carbon, which is being used in military aircraft gas turbine engine components.

Table 2 shows the radical differences in the characteristics of the four classes of matrix materials used in composites. This is reflected in the properties of the resulting composites.

Composites are now important commercial and aerospace materials. Currently, PMCs are the most widely used. MMCs are employed in a significant and increasing number of commercial and aerospace applications, such as automobile engines, electronic packaging, cutting tools, circuit breakers, contact pads, high-speed and precision machinery, and aircraft structures. CCCs are used in high temperature, lightly loaded applications, such as aircraft brakes, rocket nozzles, glass processing equipment, and heat

Table 2 Properties of selected matrix materials

treatment furnaces. The space shuttle "Orbiter" has CCC leading edges. Although CMCs are not as widely used at present, there are notable production and developmental applications that are indicative of their potential.

Composites technology makes possible the use of an entire class of solid materials, for example, ceramics, in applications for which monolithic versions are unsuited because of their great strength scatter and poor resistance to mechanical and thermal shock. Further, some manufacturing processes for CAMCs are well adapted to the fabrication of large, complex structures. This allows consolidation of parts, which can reduce the manufacturing costs.

In addition to their excellent structural properties, composites have unique physical properties that are of great interest in applications such as thermal management and packaging of microelectronic, optoelectronic, and microelectromechanical (MEMS) devices. For example, carbon fibers with thermal conductivities much greater than that of copper are now commercially available. These reinforcements are being used in polymer, metal, and carbon matrices to create composites with high thermal conductivities that are being used in applications for which thermal management is important. Discontinuous versions of these fibers are also being incorporated in thermoplastic injection molding compounds, improving their thermal conductivity by as much as two orders of magnitude or more. This greatly expands the range of products for which injection-molded polymers can be used. In addition, there are an increasing number of composites reinforced with diamond particles, which impart very high thermal conductivities and low coefficients of thermal expansion (CTEs). Thermal management materials are covered in a separate section later.

Composites are now used in a wide and increasing range of important commercial and aerospace applications, including

- internal combustion engines;
- machine components;
- thermal management;
- electronic, optoelectronic, and MEMS packaging;
- automobile, train, ship, spacecraft, launch vehicle, and aircraft structures;
- aircraft and commercial gas turbine engines;
- mechanical components, such as brakes, drive shafts, and flywheels;
- tanks and pressure vessels;
- dimensionally stable components;
- process industries equipment requiring resistance to high-temperature corrosion, oxidation, and wear;
- offshore and onshore oil exploration and production;
- sports and leisure equipment;
- biomedical devices;
- civil engineering structures;
- instrument structures; and
- antennas.

Over the years, increasing production volumes have helped to reduce material prices, increasing their attractiveness in cost-sensitive applications.

As mentioned earlier, composites technology is in its infancy. It is anticipated that new and greatly improved materials are likely to emerge. It is also expected that new concepts will emerge, such as "smart materials" that incorporate greater functionality, including the integration of electronics, sensors, and actuators.

Reinforcements

The main types of reinforcements used in composite materials include continuous (cont.) fibers, discontinuous (disc.) fibers, whiskers (elongated single crystals), particles (including flakes), and numerous forms of fibrous architectures produced by textile technology, such as fabrics and braids. In addition, there is an increasing interest in composites reinforced with various types of nanoparticles, such as carbon nanotubes, graphite nanoplatelets, and silica (clay) nanoparticles.

As mentioned earlier, use of natural fiber-reinforcement is far from a new idea. However, in recent years there has been considerable work on composites reinforced with a variety of naturally occurring fibrous materials, including wood fiber, kenaf, hemp, flax, jute, sisal, banana leaf, china reed, and rice hulls. Matrices include thermoplastic and thermoset polymers and Portland cement. A number of material systems have been used in production applications, such as construction and automobile parts.

Increasingly, designers are using hybrid composites that combine different types of reinforcements and reinforcement forms to achieve greater efficiency and reduce cost. For example, fabrics and unidirectional tapes are often used together in structural components. In addition, carbon fibers are combined with glass or aramid to improve impact resistance. Laminates combining composites and metals, such as "Glare," which consists of layers of aluminum and glass fiber-reinforced epoxy, are being used in aircraft structures to improve fatigue resistance. There are also examples of composites reinforced with combinations of fibers and particles.

The great importance of composites and the revolutionary improvements in properties they offer

Table 3 Properties of key reinforcing fibers

Fiber	*Density* ($g\,cm^{-3}$)	*Axial modulus* (GPa)	*Axial tensile strength* (MPa)	*Axial CTE* ($10^{-6}\,K^{-1}$)	*Axial thermal conductivity* ($W\,m^{-1}\,K^{-1}$)
E-glass	2.6	70	2000	5	0.9

High density polyethylene	0.97	172	3000		
High-modulus PBO	1.58	270	5800	−6.0	

are derived to a great extent from the development of synthetic fibers with unprecedented properties. The key synthetic fibers are made from glass, carbon (sometimes called graphite), ceramics, and high-modulus organics, such as aramids. Most fibers are produced in the form of multifilament bundles called strands or ends in untwisted forms, and yarns when twisted. Some fibers are produced as monofilaments, which generally have much larger diameters than strand filaments. **Table 3** presents typical properties of key fibers, which are discussed in the following subsections.

Fiber strength requires some discussion. Most of the key fibrous reinforcements are made of brittle ceramics or carbon. It is well known that the strengths of monolithic ceramics decrease with increasing material volume because of the increasing probability of finding strength-limiting flaws. This is called size effect. As a result of size effect, fiber strength typically decreases monotonically with increasing guage length and diameter. Flaw sensitivity also results in considerable strength scatter at a fixed test length. Consequently, there is no single value that characterizes fiber strength. This is also true of key organic reinforcements, such as aramid fibers. Consequently, the values presented in **Table 3** should be considered as approximate values, and are useful primarily for comparative purposes. It is to be noted that because unsupported fibers buckle under very low stresses, it is very difficult to measure their inherent compression strength, and these properties are almost never reported. Instead, composite compression strength is measured directly.

Glass Fibers

Glass fibers are used primarily to reinforce polymers. The leading types of glass fibers are E-glass, high-strength (HS)-glass, and corrosion resistant (CR)-glass. E-glass fibers, the first major synthetic composite reinforcement, was originally developed for electrical insulation applications (that is the origin of the "E"). E-glass fibers are, by many orders of magnitude, the most widely used of all fibrous reinforcements. The primary reasons for this are their low cost and early development compared to other fibers. Glass fibers are produced as multifilament bundles. Filament diameters range from 3 to 20 μm. **Table 3** presents the representative properties of E- and HS-glass fibers.

E-glass fibers have relatively low elastic moduli when compared to other reinforcements. In addition, E-glass fibers are susceptible to creep and creep (stress) rupture. HS-glass is stiffer and stronger than E-glass, and has better resistance to fatigue and creep.

The thermal and electrical conductivities of glass fibers are low, and glass fiber-reinforced PMCs are often used as thermal and electrical insulators. The CTE of glass fibers is also low when compared to most metals.

Carbon (Graphite) Fibers

Carbon fibers, often called graphite fibers in the US, are used to reinforce polymer-, metal-, ceramic-, and carbon matrices. There are dozens of commercial carbon fibers, with a wide range of strengths and moduli. As a class of reinforcement, carbon fibers are

characterized by high stiffness and strength and low density and CTE. Fibers with nominal tensile moduli as high as 895 GPa and with tensile strengths of 7000 MPa are commercially available. Carbon fibers have excellent resistance to creep, stress rupture, fatigue, and corrosive environments, although they oxidize at high temperatures. Some types of carbon fibers also have extremely high thermal conductivities – many times that of copper. This characteristic is of considerable interest in electronic packaging and other applications, where temperature control is important. Carbon fibers are workhorse reinforcements in high-performance aerospace and commercial PMCs and some CMCs. Of course, as the name suggests, carbon fibers are also reinforcements in carbon–carbon composites.

Most carbon fibers are highly anisotropic. Axial modulus, tension and compression strength, and thermal conductivity are typically much greater than the corresponding properties in the radial direction. Carbon fibers generally have small, negative axial CTEs (which means that they get shorter when heated) and positive radial CTEs. Diameters of common reinforcing fibers, which are produced in the form of multifilament bundles, range from 4 to 10 μm. Carbon fiber stress–strain curves tend to be nonlinear. The modulus increases with increasing tensile strain, and decreases with increasing compressive strain.

The three key precursor materials for carbon fibers are polyacrylonitrile (PAN), petroleum pitch, and coal tar pitch. Rayon-based fibers, once the primary CCC reinforcement, are far less common in new applications. Another type of carbon fiber, referred to as "vapor grown" by its manufacturer is made by a chemical vapor deposition (CVD) process. Some of the latter have exhibited axial thermal conductivities as high as 2000 $W\,m^{-1}\,K^{-1}$, five times that of copper.

Carbon fibers made from PAN are the most widely used. There are dozens available in the market. Fiber axial moduli range from ~235–590 GPa. They generally provide composites with excellent tensile and compressive strengths, although strength properties tend to drop off as the modulus increases. Fibers having nominal tensile strengths, as high as 7 Gpa, are available. **Table 3** presents properties of three types of PAN-based carbon fibers and two types of pitch-based carbon fibers. The PAN-based fibers are standard modulus (SM), ultrahigh strength (UHS), and ultrahigh modulus (UHM). SM PAN fibers are the most widely used type of carbon fiber reinforcement. They are one of the first types commercialized, and tend to be the least expensive. UHS PAN carbon fibers are the strongest type of another widely used class of carbon fiber called intermediate modulus (IM), because of the fact that their axial modulus falls between those of SM and UHM carbon fibers. IM fibers are also widely used in aircraft and other aerospace structural applications. PAN fibers have relatively low thermal axial and transverse thermal conductivities.

A key advantage of pitch-based fibers is that they can be produced with much higher axial moduli and thermal conductivities than those made from PAN precursors. For example, UHM pitch fibers with nominal moduli as high as 895 GPa are available. In addition, some pitch fibers, designated as ultrahigh thermal conductivity (UHK), have extremely high axial thermal conductivities. For example, there are commercial UHK fibers with a nominal axial thermal conductivity of 1100 $W\,m^{-1}\,K^{-1}$, almost three times that of copper. However, composites made from pitch-based carbon fibers are generally somewhat weaker in tension and shear, and much weaker in compression than those using PAN-based reinforcements.

As mentioned earlier, carbon fibers display nonlinear stress–strain behavior, making the method of calculating the modulus critical. Various tangent and secant definitions are used throughout the industry, resulting in confusion in reported properties. The moduli presented in **Table 3** are based on tangents to the stress–strain curves at the origin.

Boron Fibers

Boron fibers are primarily used to reinforce PMCs and, to a lesser extent, MMCs. Boron fibers are produced as monofilaments (single filaments) by CVD of boron on a tungsten wire or carbon filament, the former being the most widely used. They have relatively large diameters (100–140 μm) compared to most other reinforcements. **Table 3** presents representative properties of boron fibers having a tungsten core and diameter of 140 μm. The ratio of overall fiber diameter to that of the tungsten core influences effective fiber properties. For example, fiber specific gravity is 2.57 for 100 μm fibers and 2.49 for 140 μm fibers. Because boron fibers are more expensive than many types of carbon fibers, their use is much more restricted.

Fibers Based on Silicon Carbide

Silicon carbide-based fibers are primarily used to reinforce metals and ceramics. There are a number of commercial fibers based on silicon carbide, one of which, a monofilament, is produced by CVD of high-purity silicon carbide on a carbon monofilament core. Some versions use a carbon-rich surface layer that serves as a reaction barrier in MMCs and CMCs.

There are a number of muitifilament silicon carbide-based fibers made by pyrolysis of polymers. Some of these contain varying amounts of silicon, carbon, oxygen, titanium, nitrogen, zirconium, and hydrogen. **Table 3** presents properties of selected silicon carbide-based fibers.

Fibers Based on Alumina

Alumina-based fibers are primarily used to reinforce metals and ceramics. As for silicon carbide-based fibers, they have a number of different chemical formulations. The primary constituents, in addition to alumina, are boria, silica, and zirconia. **Table 3** presents properties of high-purity alumina fibers.

Aramid Fibers

Aramid, or aromatic polyamide fibers are high-modulus organic reinforcements, primarily used in PMCs and for ballistic protection. There are a number of commercial aramid fibers produced by several manufacturers. As for other reinforcements, they are proprietary materials with differing properties. **Table 3** presents properties of one widely used aramid fiber, "Kevlar 49." As for carbon fibers, aramid fibers have nonlinear stress–strain curves.

High-Density Polyethylene Fibers

High-density polyethylene fibers are primarily used to reinforce polymers and for ballistic protection. **Table 3** presents properties of one such type. The properties of high-density polyethylene tend to decrease significantly with increasing temperature, and they are susceptible to creep deformation (time-dependent deformation under constant stress), even at low temperatures.

PBO Fibers

Many polymeric fibers have been developed over the years. One that appears to be making successful inroads is poly-*p*-phenylenebenzobisoxazole (PBO). There are two versions, regular and high modulus (HM). **Table 3** presents properties of the latter, which has the highest modulus of any commercial organic fiber. Applications of this type include aerospace components, sports equipment, and audio speaker cones.

Characteristics and Properties of Composite Materials

Composites are strongly heterogeneous materials. That is, the properties of a composite material vary considerably from point to point in the material. For example, the properties of a point located in the matrix are typically much different from one in the reinforcement phase. Most monolithic polymers, ceramics, metallic alloys, and intermetallic compounds are usually considered as homogeneous materials, to a first approximation.

Many artificial composites, especially those reinforced with fibers, are anisotropic, which means that their properties vary with direction (the properties of isotropic materials are the same in every direction). They share this characteristic with a widely used natural fibrous composite, wood. As for wood, when structures made from artificial fibrous composites are required to carry loads in more than one direction, they are typically used in a laminated form known as plywood. It is to be noted that the strength properties of some metals also vary with direction. This is typically related to manufacturing processes, such as rolling. In addition, all single crystals are anisotropic.

With the exception of MMCs, composites do not display plastic behavior as monolithic metals do, which makes composites more sensitive to stress concentrations. However, the absence of plastic deformation does not mean that composites should be considered brittle like monolithic ceramics. The heterogeneous nature of composites results in complex failure mechanisms that impart an effective toughness.

Fiber-reinforced materials have been found to produce durable and reliable structural components in countless applications. For example, PMCs have been used in production boats, electrical equipment, and solid rocket motors since the 1950s, and extensively in aircraft since the early 1970s. Technology has progressed to the point where the entire empennages (tail sections) of commercial aircraft are made of carbon–epoxy. Passenger planes under development are scheduled to have virtually all-composite structures, including wings and fuselages.

There are a large and increasing number of materials that fall in each of the four types of composites, which makes generalization difficult. However, as a class of materials, composites tend to have the following characteristics: tailorable mechanical and physical properties, high strength, high modulus, low density, low CTE, excellent resistance to fatigue, creep, creep rupture, corrosion, and wear. Composites are available with tailorable thermal and electrical conductivities that range from very low to very high.

As for monolithic materials, each of the four classes of composites has its own particular attributes. For example, CMCs tend to have particularly good resistance to corrosion, oxidation, and wear, along with high-temperature capability.

The outstanding mechanical properties of composite materials has been a key reason for their

extensive use in structures. However, composites also have important physical properties, especially low, tailorable CTE and high thermal conductivity, resulting in the use of an increasing number of applications. Key examples are electronic packaging and thermal management, as discussed later.

Many composites, such as PMCs reinforced with carbon and aramid fibers, and silicon carbide particle-reinforced aluminum, have low CTEs, which are advantageous in applications requiring dimensional stability. Examples include spacecraft structures, instrument structures, optical benches, and optoelectronic packaging. By appropriate selection of reinforcements and matrix materials, it is possible to produce composites with near-zero CTEs.

CTE tailorability provides a way to minimize thermal stresses and distortions that often arise when dissimilar materials are joined. For example, the CTE of silicon carbide particle-reinforced aluminum depends on particle content. By varying the amount of reinforcement, it is possible to match the CTEs of a variety of key engineering materials, such as steel, titanium, and alumina (aluminum oxide). This characteristic of composites has particular value in electronic packaging, because thermal stresses can cause failure of ceramic substrates, semiconductors, and solder joints.

There are a large and increasing number of thermally conductive PMCs, MMCs, and CAMCs. One of the most important types of reinforcements for these materials is pitch fibers. As discussed earlier, PAN-based fibers have relatively low thermal conductivities. However, pitch-based fibers with thermal conductivities more than twice that of copper are commercially available. These UHK reinforcements also have very high stiffnesses and low densities. As pointed out earlier, fibers made by CVD exhibit thermal conductivities as high as $2000\,\mathrm{W\,m^{-1}\,K^{-1}}$, about five times that of copper. Fibers made from another form of carbon, diamond, also have the potential for thermal conductivities in this range. PMCs and CCCs reinforced with UHK carbon fibers are being used in a wide range of applications, including spacecraft radiators, battery sleeves, electronic packaging, and motor enclosures. MMCs reinforced with diamond particles have reported thermal conductivities as high as $1200\,\mathrm{W\,m^{-1}\,K^{-1}}$, three times that of copper. The latter materials are of great interest in electronic and optoelectronic packaging.

Overview of Mechanical and Physical Properties

As discussed earlier, initially, the excellent mechanical properties of composites were the main reason for their use. Today, however, there are an increasing number of applications for which the unique and tailorable physical properties of composites are key considerations. For example, the extremely high thermal conductivity and tailorable CTEs of some composite material systems are leading to their increased use in electronic packaging. Similarly, the extremely high stiffness, near-zero CTE, and low density of carbon fiber-reinforced polymers have made these composites the materials of choice in a variety of applications, including spacecraft structures, antennas, and optomechanical system components such as telescope metering structures and optical benches.

As stated before, composites are complex, heterogeneous, and often anisotropic material systems. Their properties are affected by many variables, including, *in situ* constituent properties such as reinforcement form, volume fraction, and geometry; properties of the interphase, the region where the reinforcement and matrix are joined (also called the interface); and void content. The process by which the composite is made affects many of these variables. Composites containing the same matrix material and reinforcements, when combined by different processes, may have very different properties.

It is important to keep several other important things in mind when considering composite properties. First, most composites are proprietary material systems made by proprietary processes. There are few industry or government standards for composites and reinforcements, as there are for many structural metals. However, this limitation also applies to many monolithic ceramics and polymers, which are widely used engineering materials. Despite their inherently proprietary nature, there are some widely used composite materials made by a number of manufacturers which have similar properties. Notable examples are standard-modulus- and intermediate-modulus carbon fiber-reinforced epoxy.

Another critical issue is that properties are sensitive to the test methods by which they are measured, and there are many different test methods used throughout the industry. Further, test results are very sensitive to the skill of the technician performing them. As a consequence of these factors, it is very common to find significant differences in the reported properties of what is nominally the same composite material. Because of these considerations, the properties of composite materials in this article should be considered as approximate values. As for all materials, composite properties depend on temperature.

There is often a great deal of confusion among those unfamiliar with composites, about the effect of reinforcement form. The properties of composites

are very sensitive to reinforcement form, reinforcement volume fraction, and internal reinforcement geometry.

It is important to keep in mind that a key problem with disc. fiber–reinforcement is the difficulty to control fiber orientation. For example, material flow during processing can significantly align fibers in some regions. This affects all mechanical and physical properties, including modulus, strength, CTE, thermal conductivity, etc. This has been a frequent source of failures.

Traditional fabric reinforcements have fibers oriented at 0° and 90°. For the sake of completeness, it is noted that triaxial fabrics, which have fibers at 0°, +60°, and −60°, are now commercially available. Composites using a single layer of this type of reinforcement are approximately quasi-isotropic, which means that they have the same inplane elastic (but not strength) properties in every direction. Their thermal conductivity and CTEs are also approximately isotropic in the plane of the fabric. "Perfect" fabrics would have exactly isotropic thermal properties.

Overview of Manufacturing Processes

Manufacturing processes for some composites have significant advantages over those used for monolithic metals and ceramics. For example, fiber-reinforced polymers and ceramics can be fabricated in large, complex shapes that would be difficult or impossible to make with other materials. The ability to fabricate complex shapes allows consolidation of parts, which reduces machining and assembly costs. For example, one-piece PMC grill opening panels are widely used in automobiles, replacing as many as 12 metal parts that have to be joined by welding or bolting.

Some processes allow fabrication of parts in their final shape (net shape) or close to their final shape (near-net shape), which can also reduce manufacturing costs. The relative ease with which smooth shapes can be made is a significant factor in the use of composites in boats, aircraft, and other applications for which fluid dynamic and aerodynamic considerations are important. The manufacturing methods for the key composites are discussed in the respective sections.

Polymer Matrix Composites

PMCs are the most efficient structural materials that have ever been developed for moderate-temperature applications. As a result, they are now used as baseline materials in numerous applications, including aircraft, spacecraft, boats, solid-fuel launch vehicles, industrial equipment, and sports equipment. At present, thermosetting polymers are the key matrix materials for structural applications, but use of thermoplastics is gradually increasing.

The high thermal conductivities of some PMCs have led to their increasing use in applications such as spacecraft structures and electronic packaging components, such as printed circuit boards, heat sinks, heat spreaders, and heat sinks used to cool microprocessors. The addition of disc. thermally conductive carbon fibers and ceramic particles to thermoplastics significantly increases thermal conductivity, opening the door for the use of injection molded parts in an increasing number of applications, such as heat sinks and motor covers.

Polymers have low-stiffness and are relatively weak, viscoelastic materials with low thermal conductivities and high CTE. In order to obtain materials with mechanical properties that are acceptable for structural applications, it is necessary to reinforce them with cont. or disc. fibers. The addition of ceramic or metallic particles to polymers results in materials that have an increased modulus. However, as a rule, strength typically does not increase significantly, and may actually decrease.

There are many particle-reinforced polymers used in electronic packaging, primarily because of their physical properties. For these applications, ceramic particles, such as alumina, aluminum nitride, boron nitride, and even diamond are added to obtain electrically insulating materials with higher thermal conductivities and lower CTEs than those of the base polymer. Metallic particles such as silver, copper, and aluminum are added to create materials that are both electrically and thermally conductive. These materials have replaced solders in some applications. Magnetic composites are made by incorporating ferrous or magnetic ceramic particles in various polymers.

As stated earlier, for a wide range of applications, composites reinforced with cont. fibers are the most efficient structural materials at low to moderate temperatures. Consequently, the focus is on them. **Table 4** presents room temperature mechanical properties of unidirectional polymer matrix composites reinforced with key fibers: E-glass, aramid, boron, SM PAN carbon, IM PAN carbon, UHM PAN carbon, UHM pitch carbon, and UHK pitch carbon. The fiber volume fraction is 60%, which is a typical value.

The properties presented in **Table 4** are representative of what can be obtained with a well-made PMC employing an epoxy matrix. Epoxies are widely used, provide good mechanical properties, and can be considered as a reference matrix material. Properties of composites using other resins may differ from these.

The properties of PMCs, especially strength, depend strongly on temperature. The temperature dependence of polymer properties differs considerably. This is also true for different epoxy formulations, which have various glass transition temperatures.

The properties shown in **Table 4** are axial, transverse and shear moduli, Poisson's ratio, tensile and compressive strengths in the axial and transverse directions, and inplane shear strength. The Poisson's ratio presented is called the major Poisson's ratio. It is defined as the ratio of the magnitude of transverse strain to the axial strain when the composite is loaded in the axial direction. It is to be noted that transverse moduli and strengths are much lower than corresponding axial values. Unidirectional composites share this characteristic with wood, which is stronger and stiffer along the grain than perpendicular to it.

Elastic moduli are based on tangents to the stress–strain curves at the origin. Using this definition, tensile and compressive moduli are usually very similar. However, this is not the case for moduli which are computed using various secants. These typically produce compression moduli that are significantly lower than tensile moduli because the stress–strain curves are nonlinear.

Due to the low transverse strengths of unidirectional laminates, they are rarely used in structural applications. The design engineer selects laminates with layers in several directions to meet requirements for strength, stiffness, buckling, etc. There are an infinite number of laminate geometries that can be selected. For comparative purposes, it is useful to consider quasi-isotropic laminates, which have the same elastic properties in all directions in the plane of the fibers. It is to be noted that through-thickness properties of quasi-isotropic laminates are somewhat similar to the transverse properties of unidirectional composites.

Laminates have quasi-isotropic elastic properties when they have the same percentage of layers every $180^\circ/n$, where $n \geqslant 3$. The most common quasi-isotropic laminates have layers that repeat every 60°, 45°, or 30°. It is to be noted, however, that strength properties in the plane are not isotropic for these laminates, although they tend to become more uniform as the angle of repetition becomes smaller. Laminates have quasi-isotropic CTEs and CTEs, when they have the same percentage of layers in every $180^\circ/m$, where $m \geqslant 2$. For example, laminates with equal numbers of layers at 0° and 90° have quasi-isotropic thermal properties.

Table 5 presents the mechanical properties of quasi-isotropic laminates having equal numbers of layers at 0°, $+45^\circ$, -45° and 90°. The elastic moduli of all quasi-isotropic laminates are the same for a given material. It is worth noting that the moduli and strengths are much lower than the axial properties of unidirectional laminates made of the same material. In many applications, laminate geometry is such that the maximum axial modulus and tensile and compressive strengths fall somewhere between axial unidirectional and quasi-isotropic values.

Table 6 presents physical properties of selected unidirectional composite materials having a typical fiber volume fraction of 60%. The densities of all of the materials are considerably lower than that of aluminum, while some are lower than that of magnesium. This reflects the low densities of both fibers and matrix materials. The low densities of most polymers give PMCs a significant advantage over most MMCs and CMCs at low-to-moderate temperatures, all other things being equal.

As **Table 6** shows, all of the composites have relatively low axial CTEs. This results from the combination of low fiber axial CTE, high fiber stiffness, and low matrix stiffness. The CTE of most polymers is very high. It is noteworthy that the axial CTEs of PMCs reinforced with aramid fibers and some carbon fibers are negative. This means that, contrary to the general behavior of most monolithic materials, they contract in the axial direction, when heated.

The transverse CTEs of the composites are all positive, and their magnitudes are much larger than the magnitudes of the corresponding axial CTEs. This results from the high CTE of the matrix and a Poisson effect caused by a constraint of the matrix in the axial direction and lack of constraint in the transverse direction. The transverse CTE of aramid composites is particularly high, in part, because the fibers have a relatively high, positive radial CTE.

It is to be noted that PMCs also undergo dimensional changes due to moisture absorption and desorption. These changes are usually described by coefficients of moisture expansion, which are analogous to CTEs. This subject is beyond the scope of the current article.

The axial thermal conductivities of composites reinforced with glass, aramid, boron, and a number of the carbon fibers are relatively low. In fact, E-glass and aramid PMCs are often used as thermal insulators. As **Table 6** shows, most PMCs have low thermal conductivities in the transverse direction as a result of the low thermal conductivities of the matrices and the fibers in the radial direction. Through-thickness conductivities of laminates tend to be similar to the transverse thermal conductivities of unidirectional composites.

Table 7 presents the inplane thermal conductivities and CTEs of quasi-isotropic laminates made from

the same materials as in **Table 6**. Here again, a fiber volume fraction of 60% is assumed.

It is to be noted that the CTEs of the quasi-isotropic composites are higher than the axial values of the corresponding unidirectional composites. However, the CTEs of quasi-isotropic composites reinforced with aramid and carbon fibers are still very small. By appropriate selection of fiber, matrix, and fiber volume fraction, it is possible to obtain quasi-isotropic materials with CTEs very close to zero. The through-thickness CTEs of these laminates are positive and relatively large. However, this is not a significant issue for most applications. One exception is optical mirrors, for which through-thickness CTE is an important issue.

The inplane thermal conductivity of quasi-isotropic laminates reinforced with UHM pitch carbon fibers is similar to that of aluminum alloys, while UHK pitch carbon fibers provide laminates with a conductivity over 50% higher. Both materials have densities ~35% lower than that of aluminum.

As mentioned earlier, through-thickness thermal conductivities of laminates tend to be similar to the transverse thermal conductivities of unidirectional composites, which are relatively low. If laminate thickness is small, this may not be a severe limitation. However, low through-thickness thermal conductivity can be a significant issue for thick laminates and for very high thermal loads. Through-thickness conductivity can be increased by addition of thermally conductive reinforcements, such as disc. carbon fibers, and ceramic particles, such as boron nitride or carbon nanotubes. Fiber-reinforced thermoset PMCs are made by a wide variety of processes, many of which are highly automated, including hand lay-up, filament winding, tape placement, fiber placement, and various types of resin transfer molding.

A significant recent advance in PMC technology is the development of injection moldable carbon fiber-reinforced thermoplastics with much higher thermal conductivities than those available in the past. Unreinforced polymers have thermal conductivities $\sim 0.2\,W\,m^{-1}\,K^{-1}$. A number of commercially available PMCs consisting of thermoplastic matrices reinforced with disc. carbon fibers have reported thermal conductivities ranging from $2\,W\,m^{-1}\,K^{-1}$ to as high as $100\,W\,m^{-1}\,K^{-1}$. Matrices include PPS, nylon 6, polycarbonate, and liquid crystal polymers. These composites are also electrically conductive. Electrically insulating PMCs reinforced with thermally conductive disc. ceramic particles, such as boron nitride, have reported thermal conductivities of up to $15\,W\,m^{-1}\,K^{-1}$.

Metal Matrix Composites

MMCs consist of metals reinforced with a variety of ceramic fibers, carbon fibers, whiskers, and particles. There are wide ranges of materials that fall in this category. An important example cited earlier is a material consisting of tungsten carbide particles embedded in a cobalt matrix, which is used extensively in cutting tools and dies. This composite (often referred to as cermet, cemented carbide or simply, but incorrectly as "tungsten carbide") has much better fracture toughness than monolithic tungsten carbide, which is a brittle ceramic material.

Another interesting MMC, tungsten carbide particle-reinforced silver, is a key circuit breaker contact pad material. Here, the composite provides good electrical conductivity and much greater hardness and wear resistance than monolithic silver, which is too soft to be used in this application. Ferrous alloys reinforced with titanium carbide particles have been used for many years in numerous aerospace and commercial production applications, including dies, engine valves, and aircraft fuel pumps. Compared to the monolithic base metals, they offer better wear resistance, higher stiffness, and lower density.

MMCs are also used in automobile engine blocks. In one design, the cylinder walls of an aluminum engine block are reinforced with a combination of disc. aluminum oxide (alumina) and carbon fibers, enabling elimination of cast iron cylinder liners. MMCs have also been used in high-speed electronics manufacturing equipment and in the equipment used for production of microprocessor chips, such as photolithography tables. Other applications include diesel engine pistons, aircraft structures, exit-guide vanes of aircraft engine fan, actuators, and automobile and train brake rotors.

The most important uses for MMCs is in electronic packaging and thermal management. For example, silicon carbide particle-reinforced aluminum, often called Al–SiC in the electronics industry, is being used in high volume production parts, such as microprocessor lids and power modules for hybrid electric vehicles. Other MMCs used in packaging are carbon fiber-reinforced aluminum, beryllium oxide (beryllia) particle-reinforced beryllium and silicon–aluminum. Here, the advantages are high stiffness, high thermal conductivity and low density, and CTE. Two traditional packaging materials, copper–tungsten and copper–molybdenum, are also MMCs. The CTEs of all of these composites can be tailored by varying the ratio of the two constituents. Another major advantage of the newer composites is that they have relatively low densities.

Monolithic metallic alloys are among the most widely used structural materials. By reinforcing them with cont. fibers, disc. fibers, whiskers, and particles, new materials are created with enhanced or modified properties, such as higher strength and stiffness, better wear resistance, and lower CTE. In some cases, the improvements are dramatic.

The greatest increases in strength and modulus are achieved with cont. fibers, at least in the direction parallel to the fibers, called the axial or longitudinal direction. As for PMCs, transverse properties are dominated by the properties of the matrix and interface. However, because the metal matrices are in themselves structural materials, transverse strength properties are frequently great enough to permit use of unidirectional MMCs in some structural applications. This is usually not possible for PMCs. The boron fiber-reinforced aluminum struts used on space shuttle "Orbiter" are a good example. Other key MMCs reinforced with cont. fibers include silicon carbide-reinforced titanium and carbon fiber-reinforced aluminum. The key particle-reinforced MMCs, include titanium carbide-reinforced steel, aluminum reinforced with silicon carbide and alumina particles, titanium carbide particle-reinforced titanium, and titanium boride-reinforced titanium.

Aluminum reinforced with silicon carbide particles is arguably the most important of the newer types of structural MMCs. The low cost of the aluminum matrix and silicon carbide particles makes these composites particularly interesting. There is a wide range of materials falling into this category. They are made by a variety of processes. Properties depend on the type of particle, particle volume fraction, matrix alloy, and the process used to make them. **Table 8** presents representative composite properties for three particle volume fractions, 25%, 55%, and 70%. Properties of common steel, aluminum, and titanium alloys are shown for comparison.

It is seen that as particle volume fraction increases, modulus and yield strength increase, and fracture toughness, tensile ultimate strain, and CTE of particle-reinforced composites decrease. Particulate reinforcement also improves the elevated temperature strength properties and, perhaps surprisingly, the fatigue resistance. The ability to tailor CTE by varying particle volume fraction is a key attribute of these materials.

There are a variety of processes to make silicon carbide particle-reinforced aluminum, including powder metallurgy, stir casting, and pressure and pressureless infiltration. The last two, as well as remelt casting can make net shape or near-net shape parts. Fiber-reinforced MMCs are made by a variety of processes, including pressure infiltration and diffusion bonding.

Table 8 Properties of silicon carbide particle-reinforced aluminum, aluminum, titanium and steel

Property	*Aluminum 6061-T6*	*Titanium 6Al-4V*	*Steel 4340*	*Composite particle volume fraction* (%)		
				25	*55*	*70*

Carbon Matrix Composites

CAMCs consist of a carbon matrix reinforced with any combination of fibers, whiskers, or particles. For many years, the only significant CAMCs were CCCs, in which the reinforcements are disc. or cont. carbon fibers. In the last few years, a new proprietary carbon matrix material system has been developed which has a silicon carbide fiber-reinforcement. This material is now being used for engine flaps on a military aircraft engine. One of the key reported advantages of this new material is that it has a higher CTE than CCCs, reducing the tendency of protective ceramic coatings to crack. The focus of this section is on CCCs.

CCCs are used in a variety of applications, including electronic packaging, spacecraft radiator panels, rocket nozzles, reentry vehicle nose tips, the space shuttle "Orbiter" leading edges and nose cap, aircraft brakes, heat treating furnaces, and glass making equipment.

As for PMCs, there are many different CCC materials having widely different mechanical and physical properties. The primary advantages of CCCs are: (1) high strength compared to competing materials at very high temperatures, (2) high stiffness, (3) ablation resistance, (4) high thermal conductivity (some systems), (5) low CTEs, (6) low density, and (7) absence of outgassing. In addition, CCCs are less brittle than monolithic carbon.

The primary disadvantages are: (1) Susceptibility to oxidation at temperatures above $\sim$37–500°C (700–930°F), (2) low interlaminar (through-thickness) tensile and shear strengths for materials with 2D reinforcement, (3) microcracking at low stresses in some directions for 3D composites, and (4) high cost of many systems. Because of the low interlaminar strength properties of CCCs, many applications, particularly those with thick walls, often use 3D reinforcement.

As mentioned earlier, one of the most significant limitations of CCCs is oxidation. Addition of oxidation inhibitors to the matrix and protective coatings raises the threshold substantially. In inert atmospheres, CCCs retain their properties to temperatures as high as 2400°C (4300°F).

The combination of high thermal conductivity and low density makes CCCs attractive candidates for thermal management and electronic packaging. In addition, CCCs have very low CTEs, leading to their use as thermal doublers with carbon fiber-reinforced PMC structures. The unique combination of properties possessed by CCCs, combined with a lack of outgassing, also makes them attractive for optical systems.

Two leading types of processes are used to make CAMCs. The first type is the chemical vapor infiltration (CVI) which is a process in which gaseous chemicals are reacted or decomposed, depositing a solid material on a fibrous preform. In the case of CAMCs, hydrocarbon gases such as methane and propane are broken down, and the material deposited is the carbon matrix. The second type of process involves infiltration of a preform with polymers or pitches, which is then converted to carbon by pyrolysis, (heating in an inert atmosphere). After pyrolysis, the composite is sometimes heated to high temperatures to graphitize the matrix. To minimize porosity, the process is repeated until a satisfactory density is achieved. This is called densification. Common matrix precursors are phenolic and furan resins, and pitches derived from coal tar and petroleum.

Ceramic Matrix Composites

As a class of materials, monolithic ceramics are characterized by high stiffness and hardness, resistance to wear, corrosion and oxidation, and high-temperature operational capability. However, they also have serious deficiencies, which have severely limited their use in applications that are subjected to significant tensile stresses.

A fundamental problem is that ceramics have very low fracture-toughnesses, which makes them very sensitive to the presence of small flaws. This results in

great strength scatter and poor resistance to thermal and mechanical shock. Civil engineers recognized this deficiency long ago, and do not use ceramic materials such as stone and concrete to carry tensile loads. In the latter, this function has been relegated to reinforcing bars or prestressing cables made of steel or, more recently, PMCs. An important exception has been in lightly loaded structures where dispersed reinforcing fibers of asbestos, steel, glass, and carbon allow modest tensile stresses to be supported.

CMCs can be thought of as an improved form of CAMCs in which the carbon matrix is replaced with ceramics that are stronger and much more resistant to oxidation. CMCs employ a variety of reinforcements including cont. fibers, disc. fibers, whiskers, and particles. Cont. fibers provide the best properties. There are many different types of CMCs, which are at various stages of development. As discussed earlier, straw-reinforced mud is an ancient CMC, as is concrete, which consists of a cement matrix reinforced with stone and sand.

The key advantage of CMCs is that, when properly designed and manufactured, they have many of the advantages of monolithic ceramics, such as much lower density than high-temperature metals, but with greater durability. That is, CMCs have higher effective fracture-toughnesses, so that they are less susceptible to failure when subjected to mechanical and thermal shock. As a consequence, it is possible to consider CMCs for applications where they are subjected to moderate tensile loads. However, CMCs are the most complex of all types of composites, and CMC technology is less developed than that of PMCs, MMCs and CAMCs.

CMCs are being used in a number of commercial production applications. One of the most successful is silicon carbide whisker-reinforced alumina cutting tool inserts, which have greater fracture-toughness, and are, therefore, more durable than monolithic alumina. Another application is silicon carbide whisker-reinforced aluminum nitride crucibles, which are used for casting molten aluminum. In this application, the key advantage of the CMC over monolithic ceramics is thermal shock resistance. Silicon carbide particle-reinforced alumina is being used in slurry pumps because of its good durability and wear resistance. In this application, the process makes it possible to fabricate reliable, complex parts that would be hard to make out of monolithic ceramics. Other high-temperature CMC applications include coal-fired power plant candle filters used for particulate removal, natural gas burner elements, and U-tubes. In addition, there are a wide variety of candidate applications including stationary gas turbine combustor liners and shrouds, abradable rim seals, reverberatory screens, particle separators, tube shields, recuperators, turbine tip shoes, pipe hangers, heat treating furnace fans, hot gas filters, and natural gas burner elements.

Aerospace applications of ceramic matrix composites to date have been limited. Perhaps, the most significant are fighter aircraft engine flaps. There are two types, both using silicon carbide matrices. One is reinforced with carbon fibers, and the other a multifilament silicon carbide fiber. Another application is a missile diverter thruster made of carbon fiber-reinforced silicon carbide. Again, the process used to make this part is CVI. The space shuttle "Orbiter" thermal protection system (TPS) makes extensive use of tiles composed of a 3D network of disc. oxide fibers with silicate surface layers. While there is no continuous matrix for most of the tile, the surface region is a form of CMC. In a sense, this can be considered as a type of functionally graded material.

The addition of cont. fibers to a ceramic matrix can significantly change failure modes. Monolithic ceramics have linear stress–strain curves, and fail catastrophically at low strain levels. However, well-designed and fabricated CMCs display nonlinear stress–strain behavior with much more area under the curve, indicating that more energy is absorbed during failure, and that the material has a less catastrophic failure mode.

Reinforcements that have been used for CMCs include cont. fibers, disc. fibers, whiskers, and particles. Key cont. fibers used in CMCs include carbon, silicon carbide-based, alumina-based, alumina-boria-silica, quartz, and alkali-resistant glass. Steel wires are also used. Disc. CMC fibers are primarily silica-based. Silicon carbide is the key whisker reinforcement. Particulate reinforcements include silicon carbide, zirconium carbide, hafnium carbide, hafnium diboride, and zirconium diboride.

A large number of ceramics have been considered for matrix materials, including alumina, glass, glass-ceramic, mullite (aluminum silicate), cordierite (magnesium aluminosilicate), yttrium alumina garnet (YAG), barium aluminosilicate (BAS), barium magnesium aluminosilicate (BMAS), calcium aluminosilicate (CAS), barium and strontium aluminosilicate (BSAS, or celsian), "Blackglas" (silicon oxycarbide or Si–O–C), silicon nitride, silicon carbide, silicon nitride-bonded silicon carbide, silicon carbide and silicon, hafnium carbide, tantalum carbide, zirconium carbide, hafnium diboride, zirconium diboride, and molybdenum disilicide.

The most mature CMCs consist of silicon carbide matrices reinforced with silicon carbide-based fibers (SiC–SiC) and silicon carbide reinforced with carbon fibers (C–SiC).

As for other classes of composite materials, there are many processes that can be used to make CMCs. Key considerations in process selection are porosity and reactions between reinforcements, reinforcement coatings, and matrices. The most important processes for making CMCs at this time are CVI, melt infiltration, preceramic polymer infiltration and pyrolysis (PIP), slurry infiltration, sol-gel, hot pressing, and hot isostatic pressing. In addition, there are a number of reaction based processes, which include reaction bonding and direct metal oxidation ("Dimox").

Thermal Management Materials

One of the most significant new areas for composites is in thermal management. There are many engineering uses of these materials, but perhaps, the most important is in the packaging of microelectronics, optoelectronics, and MEMS. Packaging provides support and protection to semiconductors and ceramics, which typically have low CTEs, and removes heat by conduction. The material requirements for these applications are high thermal conductivity, low CTE to minimize thermal stresses, and low density to minimize weight. Composites offer advantages in all the three areas.

Table 9 presents properties of traditional packaging materials, including thermal conductivity, CTE, density, and specific thermal conductivity, which is defined as the ratio of density to specific gravity. Specific thermal conductivity is a useful figure of merit where both thermal conductivity and weight are important. It is seen that, aside from CVD diamond (diamond produced by chemical vapor deposition), the maximum thermal conductivity is for copper, which has a high CTE. All materials with low CTEs have thermal conductivities that are no better than that of aluminum. In addition, all of them have relatively high densities. These are all significant deficiencies. Increasing heat fluxes has resulted in a need for improved materials.

Table 10 shows properties of some of the increasing number of new monolithic and composite packaging materials that have been developed in response to the universally recognized, thermal management problems. A number of these materials are being used in production applications. Reinforcements include cont. and disc. thermally conductive carbon fibers, and a variety of particles, including diamond, silicon carbide, and beryllia. Monolithic materials, all of which are carbonaceous, include carbon foam, natural graphite, and highly oriented pyrolytic graphite (HOPG). It is seen that these materials offer great advantages over traditional packaging materials.

The Future of Composite Materials

Composites are now baseline materials in countless applications. However, the technology, which is only several decades old, is still in its infancy. In the future, significant improvements in properties of existing fibers, matrices and processes, and development of new composites are likely to be seen. So far, composites have been used primarily for their excellent mechanical properties, environmental resistance, and durability. This is likely to continue. In addition, an increasing use in applications for which nonmechanical properties, such as thermal conductivity and CTE are important is foreseen. Among these are packaging of microelectronics, optoelectronics, and MEMS. These are extremely large and growing markets.

Development is under way on multifunctional and smart composites, which incorporate electronics,

sensors, actuators, and microprocessors. Potential applications include everything from spacecraft to cell phones.

Nanotechnology is one of the most exciting and challenging areas for composites. Polymers reinforced with low cost silicate (clay) nanoparticles are already being used in commercial production applications. Carbon nanotubes and graphite nanoplatelets have impressive mechanical, thermal, and electrical properties that make them attractive candidate reinforcements. In addition to these trends, it is likely that important new materials and applications will emerge.

Composites: Polymer–Polymer

R Talreja, Texas A&M University, College Station, TX, USA

Introduction

Alongside metals and ceramics, polymers form a main class of materials that offer a range of interesting properties for many engineering applications. Polymers in a monolithic or single-phase form may not possess the desired properties for a given application. They can be modified to have two phases or combined with other polymers to construct composites. Usually, the term polymer–polymer composite (PPC) refers to the case of rigid, rod-like polymer molecules dispersed at a molecular level in a flexible coil-like polymer. The rigid part is thus viewed as reinforcement and the flexible part as matrix. This article also includes the class of composites where polymer fibers are combined with a polymer matrix. Such composites are designated as fiber-reinforced polymer–polymer composites (FRPPC). To begin with, the polymer microstructure is briefly reviewed.

The Polymer Microstructure

A polymer is composed of molecules consisting of long sequences of atoms linked by covalent bonds. Most polymers have a linear skeletal structure, which may be represented by a chain with two ends. This gives the name "linear polymers." However, many polymers have a branched structure in which the main chain has side chains, or branches, or a three-dimensional network structure, in which the individual chains are connected to other chains at junction points. The network polymers are said to be cross-linked, and such nonlinear polymers can be formed by polymerization. The skeletal structure determines the properties of a polymer.

The polymers are commonly classified as thermosets, thermoplastics, and elastomers. Thermosets are normally rigid network polymers in which the chain motion is restricted by a high degree of cross-linking. Heating normally activates the cross-linking agent, which is the reason for calling them thermosets. Once formed, the thermosets tend to degrade rather than melt on application of heat. Thermoplastics are linear or branched polymers, which can be melted by application of heat. On cooling they solidify, allowing molding and remolding to different shapes. The cool-down from the molten state does not always cause crystallization in thermoplastics. In cases where crystallization occurs, it is often partial, giving the name "semicrystalline thermoplastics." The amorphous structure transition from a glassy (hard) state to a rubbery (soft) state occurs at the glass transition temperature (T_g). Elastomers are cross-linked polymers in a rubbery state. They are characterized by large, rapidly recoverable deformation. Elastomers, like thermosets, are intractable once formed and degrade rather than melt on heating.

Other variations of polymers exist. "Liquid crystalline polymers" have molecular alignment in one direction, but not a three-dimensional crystalline order. In recent years, such polymers have been developed with distinct regions of straight and rigid molecular chains. "Blends" are physical mixtures of two or more polymers, while "grafts" are formed by chemically attaching long side chains of a second polymer to the molecular chains of the base polymer. Copolymers have chemical combinations of molecules in the main chain. The set of molecules that repeat in the chain can be arranged in blocks, giving the designation "block copolymers," or be randomly distributed in a "random copolymer."

PPC Systems – Processing, Structure, and Properties

The rod-like molecules in PPC systems have high melting point, which makes it difficult to use melt processing for producing a single-phase material with a homogeneous dispersion of rigid molecules. Ternary solutions (a solvent, a rod-like solute, and a random-coil chain) have been shown theoretically to be good means of achieving this. This process requires a high degree of molecular orientation of the rod-like molecules in the random-coil matrix. Since the concentration of rod-like molecules needed is at or near the critical value to form anisotropic domains, the resulting viscosity of the solution is high, which makes orientation of the molecules by external shear suitable. Alternatives to physical blending are possible, for example, synthesis of block copolymers composed of flexible-coil segments and rigid-rod block segments.

The intended microstructure of aligned rigid rod-like molecules within the amorphous flexible coil-like matrix has been achieved in some PPC systems. For instance, a blend of a rod-like poly(*p*-phenylene benzobisthiazole) (PBT) and coil-like poly(2-5(6)-benzimidizole) (ABPBI) vacuum-cast from solution with up to 50 wt.% of PBT typically shows 3 μm long ellipsoids composed mainly of 10 nm PBT crystallites moderately well-aligned with the long axis. Similar morphology results in a triblock copolymer of ABPBI/PBT/ABPBI, but with smaller ellipsoids.

The rod-like molecules of polymers can potentially provide higher stiffness and strength than fibers that tend to have imperfect alignment and flaws. Furthermore, in an FRPPC imperfect adhesion between fibers and matrix can be a source of reduced properties. **Table 1** illustrates the tensile properties of PBT and ABPBI fibers and composites of these polymers. As shown in the data, better modulus and strength values are achieved in copolymers than in blends due to the smaller size of the PBT ellipsoids, leading to higher reinforcement efficiency. The fracture studies show that the PBT fiber fibrillates extensively upon fracture, while the PBT/ABPBI blend fibrillates moderately and the copolymer shows no evidence of fibrillation.

FRPPCs

Using polymer fibers as reinforcement in polymer matrix develops a wide range of polymer composites. Several high-strength polymer fibers have been developed for this purpose in recent years. The most widely used FRPPCs are aramid fibers in epoxy, polyethylene fibers in epoxy, and high-density polyethylene fibers in polyethylene.

Processing of polymers to produce high-modulus and high-strength fibers has two generic routes: (1) spinning of stiff, nematogenic polymers to form oriented structures in solid state, and (2) morphological manipulation of flexible polymers into highly oriented extended-chain fibers through complex processing. Aramid fibers are examples of the first processing route. They are spun from liquid-crystal dopes through a dry-jet wet-spinning process. Polyethylene fibers are produced by a gel-spinning process in which a low-concentration solution of ultrahigh molecular weight polyethylene is extruded to form a gel precursor fiber, which is then hot-drawn to draw ratios of 20 or more to produce a very high-oriented fiber with an extended-chain fibrillar structure. Other linear polymers such as polypropylene, polyoxymethylene, and aliphatic polyamides, nylon 6, and nylon 66, have also been used to produce high-modulus, high-strength fibers. These polymers have melt temperatures higher than polyethylene. The molten polymer is spun into filaments, which are then drawn to fibers of 1.5–6 times their undrawn length. Poly(ethylene terephthalate) (PET) fibers are also produced by this process. To improve properties, modification to PET is done by synthesizing copolyesters, which contain typically 90 mol.% PET and small amounts of ester-forming ingredients such as glycols and dicarboxylic acids.

The high degree of molecular orientation in the axial direction of polymer fibers produces high tensile modulus and strength in that direction. Typical values for some fibers are listed in **Table 2**. As shown in the table, the transverse strength values are low. The tensile transverse modulus is also low, typically less than 10% of the fiber-axis tensile modulus. The axial compressive strength is also much lower than

Table 1 Properties of PBT and ABPBI fibers and composites

Material	*Tensile modulus* (GPa)	*Tensile strength* (MPa)	*Strain to fracture* (%)
PBT fiber	320	3100	1.1
ABPBI fiber	36	1100	5.2
30%PBT/70% ABPBI blend film	1.1	35	5.6
30%PBT/70% ABPBI blend fiber	120	1300	1.4
30%PBT/70% ABPBI copolymer film	2.4	220	43
30%PBT/70% ABPBI copolymer fiber	100	1700	2.4

Table 2 Typical modulus and strength values of high-modulus, high-strength organic fibers

Fiber	*Tensile modulus* (GPa)	*Tensile strength* (GPa)	*Transverse strength* (GPa)
Gel PE	140	2.7	0.1
Kevlar 49	120	3.4	0.6
Kevlar 29	60	3.4	0.6
Thermotropic copolyester	60	3.0	0.1
Ordered polymer	265	3.0	1.5
Cellulose	25	1.5	N/A

the axial tensile strength. This limits the use of FRPPC in applications where compression and/or bending are involved. The molecular orientation in polymer fibers is also the cause of poor abrasion resistance.

Aramid fibers have a characteristic fibrillar structure. The Kevlar fibers exhibit a skin-core configuration with skin displaying a higher degree of fibrillar orientation than the core. This structure yields high tensile properties due to the axial fibrillar orientation but is not capable of sustaining large compressive stress due to buckling of the fibrils.

Polymer Fiber–Polymer Matrix Interfaces

One way to achieve good bonding at a polymer–polymer interface is by interdiffusion of molecular chains to develop entanglements of the two polymers. Due to the high molecular orientation along the axis of the polymer fiber, however, this is usually difficult to achieve. Heating the fiber to increase the polymer chain mobility often results in relaxation of the oriented molecules leading to degradation of fiber-axis properties. An alternative way is to use covalent, hydrogen and van der Waals interactions, or mechanical interlocking at the fiber–matrix interface. Effective bonding requires good wetting of the fiber surface by the matrix polymer during the composite processing. The surface energy of the matrix polymer should be lower than that of the fiber polymer to achieve good wetting. As examples, the surface energies of epoxy, polyethylene, polypropylene, and polyamide are 43, 33, 35, and 39 $mJ\,m^{-2}$, respectively. Another way of improving the interfacial bonding is by surface treatment of fibers. Typical surface treatments are plasma oxidation, fluorination, and acid or alkali wash. The plasma oxidation treatment of polyethylene fibers has shown an improvement of the interlaminar shear strength of epoxy reinforced with these fibers from 10 MPa in untreated state to 27 MPa. The accompanying reduction of tensile strength is found to be small. Still another way to improve fiber–matrix bonding in FRPPCs is by creating an interfacial region (interphase) of good properties. It is, for instance, possible in semicrystalline thermoplastic matrix composites to nucleate crystallization from the fiber surface. The transcrystalline layer formed tends to have laminae oriented normal to the fiber axis, resulting in good transverse strength.

Processing of FRPPCs

A common way to produce FRPPCs is by impregnation of fibers with the polymer matrix. The objectives of impregnation are to wet all fibers by the matrix and distribute the fibers uniformly in the matrix. If fiber bundles are used, the matrix should penetrate into the bundles and wet all fibers. Incomplete or imperfect impregnation causes dry fibers, resin-rich areas, and uneven distribution of fibers, leading to lower composite properties. Three common methods of impregnation exist, viz., by using melt, powder, or solution. In melt impregnation, the fibers (or fiber bundles) are fixed in a mold and the molten resin is transferred to the mold, often under pressure. Alternatively, the matrix polymer is used as a film, which is interspersed with layers or bundles of fibers. In this case, the mold is heated to melt the matrix polymer. The melt impregnation is not very effective in penetrating fiber bundles and wetting fibers if the melt viscosity is high. In powder impregnation, the matrix polymer is used as a fine powder. The particle size of the powder should be in the range of fiber diameter, that is 10–25 μm. This method works better at lower fiber volume fraction since at high fiber volume fraction it is difficult to uniformly distribute the powder between fibers. The third method is solution impregnation where the matrix polymer is dissolved in a liquid. For example, for polyethylene (PE) matrix a xylene solution with 5 wt.% PE is used. The impregnated fiber bundles are consolidated into a unidirectional prepreg, which is then laminated to produce a composite laminate. The deficiencies of this method are segregation and crystallization of matrix on fiber surfaces. These deficiencies can be partly overcome by using suspension impregnation where particles of matrix polymer are suspended in a solution. The solution is stirred during impregnation to prevent particle segregation.

Table 3 Typical properties of unidirectional glass fiber-reinforced epoxy (GFRP), carbon fiber-reinforced epoxy (CFRP), and two aramid fiber-reinforced epoxies (AFRP). The designation 29 and 49 are for Kevlar 29 and Kevlar 49 fibers, respectively. Fiber volume fraction is 60% in all cases.

Material	*Density* ($\times 10^3$ Kg m^{-3})	*Axial tensile modulus* (GPa)	*Trans. tensile modulus* (GPa)	*Shear modulus* (GPa)	*Axial tensile strength* (MPa)	*Trans. tensile strength* (MPa)	*Axial compr. strength* (MPa)	*Inter-laminar shear strength* (MPa)
GFRP	2.0	40	10	4.5	780	28	480	40

AFRP-29	1.4	50	5.0	3.0	1350	30	238	44
AFRP-49	1.4	76	5.6	2.8	1380	30	276	60

Properties of FRPPCs

The mechanical properties of polymers reinforced with carbon or glass fibers are generally superior to FRPPC systems. A comparison of typical values obtained in a 60% fiber volume fraction unidirectional lamina for a high-strength carbon fiber-reinforced epoxy, an E-glass fiber-reinforced epoxy, and two aramid FRPPCs (Kevlar 29 and Kevlar 49) is shown in **Table 3**. As illustrated by these values, the inferior compressive strength of aramid fiber-reinforced composites limits their use in some structural applications. On the other hand, these composites possess high ductility and toughness, which makes them attractive for structures subjected to impact. Increasingly, hybrid composites, combining aramid and carbon (and/or glass) fibers, are being used to achieve good stiffness, strength, and toughness properties.

For PE fiber-reinforced composites the main drawback is the temperature-dependent degradation of properties. Typically, the PE fibers display unstable properties beyond 130°C, and have significant creep at lower temperatures. When combined with a polymer matrix, for example epoxy, the composite shows strain rate dependent behavior. Consequently, in cyclic stressing a hysteresis heat accumulation occurs, which reduces the stiffness and strength properties.

In PE fiber-reinforced composites the stiffness and strength properties depend on the temperature at which the composite is processed by impregnation. For instance, if processing temperature is 120–130°C, the tensile modulus has a value in a relatively high range of 30–35 GPa, which comes down to 20 GPa at 140°C processing temperature. The tensile strength shows less sensitivity to the processing temperature. The compressive behavior is affected by the processing temperature similarly as in tension.

Computer Simulation Techniques in Condensed Matter Physics

K Binder, Johannes Gutenberg Universität Mainz, Mainz, Germany

Introduction

Computer simulation techniques in condensed matter physics aim to compute the structure and the physical properties (including also dynamic response functions and transport) from atomistic input. The theoretical basis of these approaches are quantum mechanics and statistical thermodynamics. There exist many variants of these methods, and it depends on the nature of the problem to find out which variant is most appropriate. Such simulations can complement both analytical theory and experiment, and due to the availability of cheap computing power

simulations have become an extremely widespread tool of research.

The conceptually simplest approach is the classical molecular dynamics (MD) method: one simply solves Newton's equations of motion numerically for the many-particle system (assuming that the N atoms or molecules in a volume V interact with effective potentials that are either phenomenologically assumed or fitted to electronic structure calculations). The basis of this method thus is classical mechanics, and one creates a deterministic trajectory in the phase space of the system. The idea is to take time averages of the observables of interest along this trajectory. The ergodicity hypothesis of statistical mechanics asserts that these time averages are equivalent to ensemble averages of the appropriate microcanonical (NVE) ensemble. Of course, Newton's equations of motion conserve the total energy E, and hence the conjugate intensive thermodynamic variables (temperature T, pressure p) can only be indirectly inferred and they exhibit statistical fluctuations. Since N is finite and sometimes even fairly small, such fluctuations cannot be neglected and need to be considered with care.

Sometimes one desires to directly realize other ensembles of statistical mechanics with a simulation, for example, the NVT or NpT ensemble. This is possible by introducing a coupling to suitable "thermostats" or "barostats."

An alternative way to carry out an MD simulation with $T = \text{const}$ introduces a weak friction force, together with random forces whose strengths are controlled by the fluctuation dissipation theorem. This method is closely related to the "Brownian Dynamics" (BD) method where one simulates Langevin equations (the inertial terms in the equations of motion being omitted). Clearly, this is a coarse-grained description of a physical system as only a subset of the degrees of freedom is explicitly considered, the remaining ones form the "heat bath." While this is not always a good description of the physical dynamics, such methods can be advantageous for the computation of static properties from averages along the stochastic trajectory in phase space.

A similar description applies to the importance sampling Monte Carlo (MC) method, where one creates a random walk-like trajectory in configuration space, controlled by transition probabilities that ensure the approach to thermal equilibrium through the detailed balance condition. Many of the practical limitations of simulations, such as "statistical errors," as well as systematic errors due to the finite size of the simulated system or the finite "length" of the simulated trajectory (or observation time, respectively) are common to all these simulation methods.

Of course, it is quantum mechanics and not classical mechanics that describes the basic physics of condensed matter. But attempting a numerical solution of the Schrödinger equation for a system of many nuclei and electrons is premature and still not feasible even with the fastest computers. Thus, approximations are needed: one very popular approach is the "*ab initio* MD" or "Car–Parrinello method" (CP), where some electronic degrees of freedom are included in MD via the density-functional theory (DFT). The huge advantage of this technique is that one no longer relies on effective interatomic potentials, which often are only phenomenologically chosen *ad hoc* assumptions, lacking any firm foundation in quantum chemistry. However, the disadvantage of this technique is that it is several orders of magnitude slower than classical MD, and hence only very short timescales and very small systems are accessible. Furthermore, the method cannot handle van der Waals-like forces well (e.g., in noble gases, one is still better off with the simple Lennard–Jones potential, amended by three-body forces).

In the standard CP method, the ionic motion is still treated classically. Alternatively, one can still use effective potentials between ions and/or neutral atoms as in classical MD or MC, but rely on quantum statistical mechanics for the ionic degrees of freedom. This is achieved by the path integral Monte Carlo (PIMC) or path integral molecular dynamics (PIMD). Such techniques are indeed crucial for a study of solids at low temperatures, to ensure that their thermal properties are compatible with the third law of thermodynamics. For most fluids, however, classical MD is sufficient (of course, quantum liquids such as helium are an exception).

Other variants of quantum Monte Carlo (QMC) have been developed in order to deal with electronic degrees of freedom on rigid lattices, desiring to describe magnetic systems (e.g., via the Heisenberg model where spin operators at neighboring lattice sites are coupled by exchange interactions), models for high T_c superconductors (e.g., using the Hubbard Hamiltonian, describing a hopping of electrons from site to site, and an on-site Coulomb repulsion), etc. These techniques ("diffusion Monte Carlo," "Green's function Monte Carlo," "variational Monte Carlo," "worldline Monte Carlo," etc.) are fairly specialized and complicated, and hence are not treated further here.

What information does one then wish to extract from the simulations? When systems in thermal equilibrium are considered, the first task is to calculate static properties. For example, in a fluid a basic property is the static structure factor $S(k), S(k) = \langle |\delta\rho(\boldsymbol{k})|^2 \rangle_T, \delta\rho(\boldsymbol{k})$ being a spatial Fourier transform of density fluctuations, $\boldsymbol{k}$ being the wave vector of a

scattering experiment. In addition, one may want to calculate time-dependent correlation functions that describe the decay of small thermal fluctuations in equilibrium systems with time. A quantity of this type is the intermediate scattering function $S(k,t) = \langle \delta\rho(-\boldsymbol{k},0)\delta\rho(\boldsymbol{k},t)\rangle$ or its Fourier transform with respect to time, $S(k,\omega)$. This "dynamic structure factor" is accessible to inelastic scattering of neutrons, X-rays, or light (with energy transfer $\hbar\omega$).

It is also possible to consider systems out of thermal equilibrium; for example, in solids under strong mechanical deformation, a crack may form and propagate. An important application of MD for fluids also is the study of systems exhibiting a steady state flow under shear deformation. The purpose of such nonequilibrium molecular dynamics (NEMD) work can be the estimation of transport coefficients (e.g., the shear viscosity) if the deformation is weak enough so that the system is still in the regime of linear response. However, the study of nonlinear phenomena also ("shear thinning," a decrease of the effective viscosity with increasing shear rate, or "shear melting" of colloidal crystals, etc.) may be of interest. In addition, one can study nonsteady state transient behavior, as it occurs, for example, after a sudden change from one thermodynamic state to another, and one wishes to study the approach of the system to its new thermal equilibrium. Classical examples of this problem are nucleation of fluid droplets in a supersaturated gas, or the kinetics of phase separation in a binary mixture ("spinodal decomposition") after a temperature quench. However, such processes are often too slow, and cannot be studied by NEMD, and one has to resort to a simulation of a coarse-grained model by nonequilibrium Monte Carlo (NEMC). This approach is suitable to deal also with irreversible growth processes far from equilibrium, such as diffusion-limited aggregation (DLA). This is an example of a mechanism of structure formation on mesoscopic scales of length and time that was discovered by simulations, and still lacks a good understanding in terms of the analytical theory.

In the following, the salient features of a few important simulation methods (classical MD, MC, PIMC) are briefly described. Also, limitations of simulations (e.g., due to the small size of the simulated system) are mentioned, and the extent to which these limitations can be overcome are discussed.

MD Algorithms

Consider a system of N particles (atoms) with Cartesian coordinates, $\boldsymbol{X} = \{\boldsymbol{r}_i\}, i = 1, \ldots, N$, in a d-dimensional space. The dynamics then is described by Newton's equations of motion, $m_i\ddot{\boldsymbol{r}}_i = \boldsymbol{f}_i = -\partial U_{\text{pot}}/\partial \boldsymbol{r}_i$, m_i being the mass of the ith particle, $\boldsymbol{f}_i$ the force acting on it. This force is assumed to be entirely due to interactions with other particles: $U_{\text{pot}}(\boldsymbol{X}) = U_{\text{pot}}(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_N) = \sum u(|\boldsymbol{r}_i - \boldsymbol{r}_j|)$, where the sum extends once over each pair i, j of particles, and it has been assumed for simplicity that U_{pot} is pairwise additive. Then $\boldsymbol{f}_i = -\sum_j \partial u(|\boldsymbol{r}_i - \boldsymbol{r}_j|)/\partial \boldsymbol{r}_i$. Note that $E = E_{\text{kin}} + U_{\text{pot}} = \sum_i m_i \dot{\boldsymbol{r}}_i^2/2 + U_{\text{pot}}$ is a constant of motion ($\dot{E} = \mathrm{d}E/\mathrm{d}t = 0$).

MD now means that Newton's equations of motion are integrated numerically, by a computationally efficient scheme, such as Verlet's algorithm

$$\boldsymbol{r}_i(t+\delta t) = 2\boldsymbol{r}_i(t) - \boldsymbol{r}_i(t-\delta t) + \frac{1}{m_i}(\delta t)^2 \boldsymbol{f}_i(t) + 0\{(\delta t)^4\} \quad [1]$$

where δt is the MD time step, and the velocity $\boldsymbol{v}_i(t)$ is updated similarly,

$$\boldsymbol{v}_i(t) = [\boldsymbol{r}_i(t+\delta t) - \boldsymbol{r}_i(t-\delta t)]/[2(\delta t)] + 0\{(\delta t)^3\} \quad [2]$$

This algorithm is manifestly time-reversible and in spite of inevitable errors due to the discreteness of the time step δt, it keeps an important symmetry property of Newton's equations. To understand how large δt can be chosen, consider argon as an example, where atoms interact with a Lennard–Jones potential, $u_{\text{LJ}} = 4\varepsilon[(\sigma/r)^{12} - (\sigma/r)^6]$, with $\sigma \approx 3.4$ Å, $\varepsilon/k_{\text{B}} \approx 120$ K ($k_{\text{B}} =$ Boltzmann's constant), and $m \approx 6.6 \times 10^{-23}$ g. Rescaling coordinates ($\boldsymbol{r}^* \equiv \boldsymbol{r}/\sigma$) yields ($\boldsymbol{r}_{ij}^* \equiv \boldsymbol{r}_i^* - \boldsymbol{r}_j^*$)

$$\boldsymbol{r}^*(t+\delta t) = 2\boldsymbol{r}^*(t) - \boldsymbol{r}^*(t-\delta t) - (\delta t/\tau_0)^2 \frac{\boldsymbol{r}_{ij}^*}{|\boldsymbol{r}_{ij}^*|} \times \sum_{j(\neq i)} [(r_{ij}^*)^{-13} - (r_{ij}^*)^{-7}/2] \quad [3]$$

where the natural time unit τ_0 of MD was defined as $\tau_0 = (m\sigma^2/48\varepsilon)^{1/2}$ which is roughly $\tau_0 \approx 3.1 \times 10^{-13}$ s for argon. In order to keep numerical errors small, one needs to choose $\delta t = 0.03\,\tau_0$ (or smaller), that is, $\delta t \approx 10^{-14}$ s. So even with a million time steps, one only reaches a real time of ~ 10 ns.

As mentioned above, from a statistical mechanics point of view this algorithm realizes the microcanonical NVE ensemble. Temperature T is then inferred from the kinetic energy,

$$T = \langle \hat{T} \rangle_{\text{NVE}}, \quad \hat{T} = 2E_{\text{kin}}/(3k_{\text{B}}N) = \sum_{i=1}^{N} m_i \boldsymbol{v}_i^2/(3k_{\text{B}}N) \quad [4]$$

Note that N is finite (typically $10^2 \leqslant N \leqslant 10^6$) and hence temperature fluctuations are non-negligible.

These fluctuations contain information on the specific heat C_V, since $[\langle \hat{T}^2 \rangle - \langle \hat{T} \rangle^2]/\langle \hat{T} \rangle^2 = 2(1-3k_B/2C_V)/(3N)$. Since the "length" of an MD run (i.e., its number of time steps) is finite, these fluctuations of T cause a statistical error in the estimation of temperature.

The pressure p can be estimated using the virial theorem,

$$p = \langle \hat{P} \rangle_{\mathrm{NVE}}, \quad \hat{P} = \left(2E_{\mathrm{kin}} + \sum_i \boldsymbol{r}_i \cdot \boldsymbol{f}_i \right) / 3V \quad [5]$$

and again statistical fluctuations need to be considered.

It is often desirable to realize the canonical (NVT) rather than the microcanonical (NVE) ensemble. In an MD framework, this can be done by extending the Lagrangian of the system by a variable, representing the thermostat which has a fictitious "mass" Q. This yields the Nose–Hoover algorithm, where Newton's equations of motion are extended by a "friction"-like term,

$$\ddot{\boldsymbol{r}}_i = \boldsymbol{f}_i/m_i - \zeta(t)\dot{\boldsymbol{r}}_i, \quad \dot{\zeta} = \left[\sum_i m_i \boldsymbol{v}_i^2 - 3Nk_B T \right] / Q \quad [6]$$

Thus the "friction coefficient" $\zeta(t)$ fluctuates around zero, responding to the imbalance between the instantaneous kinetic energy and the intended canonical average. The total energy no longer is conserved, and energy fluctuations are linked to the specific heat as ($\hat{H}$ is the Hamiltonian)

$$NC_V/k_B = [\langle \hat{H}^2 \rangle_{\mathrm{NVT}} - \langle \hat{H} \rangle_{\mathrm{NVT}}^2]/(k_B T)^2 \quad [7]$$

It is important to note, however, that dynamical correlation functions between observables such as $\langle A(0)A(t) \rangle$, where A is the observable of interest, are not precisely identical to the microcanonical ones. This is even more true for MD runs that realize the isothermal–isobaric (NpT) ensemble, where the pressure is given and the volume V rather fluctuates, by coupling to the so-called "Andersen barostat." Therefore, one often uses MD in NVT or NpT ensembles for equilibration (and the computations of static averages) only, generating a set of well-equilibrated system configurations, which are then used as initial states for runs where thermostats and/or barostats are switched off, realizing the runs in the NVE ensemble, where $\langle A(0)A(t) \rangle$ is computed as a time average, $\int_0^{t_{\mathrm{obs}}-t} \mathrm{d}t_0 [A(t_0)A(t_0+t)]/(t_{\mathrm{obs}}-t), t_{\mathrm{obs}}$ being the total "observation time" over which the run is extended.

In order to judge whether t_{obs} is large enough, it is important to know what the slow observables in the system are. A typical reason for slow relaxation is the presence of large "objects" of correlated sets of particles in the systems, which show slow motions. An example is "critical slowing down" near second-order phase transitions, where large "clusters" of the variable representing the local order parameter occur. For example, near the liquid–gas critical point, large density fluctuations occur which are correlated over a correlation length ξ which diverges at criticality in the thermodynamic limit ($N \to \infty$), and then also the corresponding relaxation time τ diverges. Another example are polymer chains in solution or melt – a flexible polymer consisting of N monomers relaxes in the melt on a timescale $\tau \approx N^2$ in the Rouse limit (unentangled chains) or even $\tau \propto N^3$ in the reptation limit of entangled chains (i.e., a snakelike motion of the chains along their own contour). Thus, MD simulations of critical phenomena as well as of polymeric systems or other soft matter systems with objects containing many subunits (membranes, microemulsions, etc.) are intrinsically difficult.

However, it should also be noted that another reason for slow relaxation are conservation laws. In the NVE and NVT ensembles, the average density $\langle \rho \rangle = N/V$ is strictly conserved. Assuming for local fluctuations in density $\delta\rho(\boldsymbol{r},t) - \langle \rho \rangle$ that Fick's law holds, a gradient $\nabla(\delta\rho(\boldsymbol{r},t))$ causes a density current $\boldsymbol{j}(\boldsymbol{r},t)$, D being a diffusion coefficient, $\boldsymbol{j}(\boldsymbol{r},t) = -D\nabla(\delta\rho(\boldsymbol{r},t))$. The conservation law implies the continuity equation $\partial\rho(\boldsymbol{r},t)/\partial t + \nabla \cdot \boldsymbol{j}(\boldsymbol{r},t) = 0$, and hence a diffusion equation for $\delta\rho(\boldsymbol{r},t)$ results, $\partial(\delta\rho(\boldsymbol{r},t))/\partial t = D\nabla^2(\delta\boldsymbol{\rho}(\boldsymbol{r},t))$. The Fourier components $\delta\rho_{\boldsymbol{k}}(t)$ of $\delta\rho(\boldsymbol{r},t)$ then satisfy the equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\delta\rho_{\boldsymbol{k}}(t) = -Dk^2\delta\rho_{\boldsymbol{k}},$$
$$\delta\rho_{\boldsymbol{k}}(t) = \delta\rho_{\boldsymbol{k}}(0)\ \exp(-Dk^2 t) \quad [8]$$

Therefore, the dynamic correlation function of density fluctuations at long wavelengths decays very slowly,

$$S_\rho(\boldsymbol{k},t) \equiv \langle \delta\rho(-\boldsymbol{k},0)\delta\rho(\boldsymbol{k},0) \rangle$$
$$= S(k)\ \exp(-t/\tau_{\boldsymbol{k}}), \quad \tau_k = (Dk^2)^{-1} \quad [9]$$

Equation [9] demonstrates the "hydrodynamic slowing down" $\tau_k \to \infty$ for $k \to 0$. Of course, due to finite size effects, this divergence of the relaxation time is cut off; in a (hyper)cubic system of linear dimension L with periodic boundary conditions, the smallest wave number is $k_{\min} = (2\pi)/L$, and hence the largest relaxation time is $\tau_{\max} = L^2/(4\pi^2 D)$. Clearly, this phenomenon makes the equilibration of very large systems difficult.

A brief mention is made of the way transport coefficients are estimated from simulations. The simplest case are self-diffusion coefficients, where one can apply the Einstein relation, following the mean square

displacements of "tagged" particles, $\langle [\boldsymbol{r}(t)-\boldsymbol{r}(0)]^2 \rangle = 2\mathrm{d}Dt$, $t \to \infty$. Transport coefficients relating to collective properties can be extracted from Green–Kubo relations, for example, the shear viscosity is related to time correlations of the off-diagonal components of the pressure tensor σ_{xy},

$$\eta = \int_0^\infty \mathrm{d}t \langle \sigma_{xy}(0)\sigma_{xy}(t) \rangle / (Vk_\mathrm{B}T) \qquad [10]$$

where

$$\sigma_{xy} = \sum_{i=1}^{N} \left\{ m_i v_i^x v_i^y + \frac{1}{2} \sum_{j(\neq i)} x_{ij} f_i^y(r_{ij}) \right\} \qquad [11]$$

Similar relations can be written down for thermal conductivity, electrical conductivity, interdiffusion coefficient in mixtures, etc. Alternatively, transport coefficients can be estimated from NEMD, creating via suitable boundary conditions, a steady state of the appropriate quantity (mass density of a particle species, heat, momentum density) through the system.

Importance Sampling Monte Carlo Methods

Most MC calculations aim at the estimation of thermodynamic averages by importance sampling methods. Considering a variable $A(\boldsymbol{X})$ where $(\boldsymbol{X})$ denotes a point in phase space, such averages are defined in classical statistical mechanics by

$$\langle A \rangle = \int \mathrm{d}\boldsymbol{X} P_\mathrm{eq}(\boldsymbol{X}) A(\boldsymbol{X}),$$

$$P_\mathrm{eq}(\boldsymbol{X}) = (1/Z) \exp[-\hat{H}(\boldsymbol{X})/k_\mathrm{B}T] \qquad [12]$$

where $\hat{H}(\boldsymbol{X})$ is the Hamiltonian of the system, and Z is the partition function

$$Z = \int \mathrm{d}\boldsymbol{X} \exp[-\hat{H}(\boldsymbol{X})/k_\mathrm{B}T] \qquad [13]$$

Note that when one deals with the simulation of a fluid, momenta of the particles need not be included in $\boldsymbol{X}$ since they cancel out from all averages. In addition, $\boldsymbol{X}$ may denote any subset of variables only, for the problem of interest. For example, dealing with the phase transition of an anisotropic magnet, one may approximate the crystal lattice as rigid, and then each lattice site i carries as single degree of freedom an Ising spin, $S_i = \pm 1$. The Ising model Hamiltonian then is

$$\hat{H}_\mathrm{Ising} = -J \sum_{\langle i \neq j \rangle} S_i S_j - h \sum_i S_i \qquad [14]$$

assuming a nearest neighbor pairwise exchange energy J and a coupling to a magnetic field h (choosing units such that the magnetic moment per spin is unity). Here $\boldsymbol{X}$ stands for $S_1, S_2, \ldots, S_N$, that is, the phase space is discrete, and $\int \mathrm{d}\boldsymbol{X}$ stands symbolically for summation over all 2^N microstates of the system.

Now the basic idea of MC sampling is to consider the task of computing $\langle A \rangle$ as a problem of numerical integration over the phase space, where one would approximate $\langle A \rangle$ by an average $\bar{A}$ over M points only,

$$\bar{A} = \frac{1}{M} \sum_{v=1}^{M} P_\mathrm{eq}(\boldsymbol{X}_v) A(\boldsymbol{X}_v) \qquad [15]$$

The difficulty, of course, is that the integration space is very high dimensional, and it is a problem to choose the sample of M points $\boldsymbol{X}_v$ appropriately. It is easy to see that a regular grid of points $\boldsymbol{X}_v$ does not work, but a uniform random sampling of phase space ("simple sampling") does not work either in most cases. A notable exception, of course, is the sampling of nonthermal random distributions, for example, the random occupation of lattice sites in a mixed crystal A_xB_{1-x} by A and B atoms can be simulated straightforwardly. Choosing random numbers η uniformly distributed between zero and unity, an A-atom is assigned to the considered lattice site if $\eta < x$, while otherwise the site is taken to be occupied by a B-atom. This straightforward use of MC sampling works only if the occupation probabilities of neighboring lattice sites are independent of each other, however. Other physically relevant problems where simple sampling works are the generation of random walks and (short) self-avoiding walks, the bond percolation problem (nearest neighbor links connecting lattice sites are chosen at random conducting or isolating, to understand the electrical conductivity of disordered solids), etc. However, simple sampling is not useful for the estimation of thermal averages when N is large. The reason is that it is only a very small region of phase space where the important contributions come from, and via simple sampling only very few points $\boldsymbol{X}_v$ would be drawn from this important region. This is seen when one considers the reduced distribution function $P_N(m)$ of the density m of some extensive variable, for example, the magnetization of the Ising magnet, $m = (1/N)\sum S_i$, where the sum runs over all lattice sites, or the internal energy, etc., $P_N(m) = \int \mathrm{d}\boldsymbol{X} \delta(m - (1/N)\sum S_i) P_\mathrm{eq}(\boldsymbol{X})$. Such distributions exhibit sharp peaks at the (*a priori* unknown) average value $\langle m \rangle$, of width proportional to $1/\sqrt{N}$. It is clear, however, that from simple sampling for large N, almost no states would be generated in the region where $P_N(m)$ has its peak; most of the computational effort would be wasted for exploring a completely uninteresting part of the phase space.

Thus a method is needed that leads one automatically to the important region of the phase space. Such a method is provided by the Metropolis importance sampling algorithm, which yields states $\boldsymbol{X}_\nu$, with a probability proportional to the Boltzmann factor. This is achieved by generating a Markov chain of states recursively one from the other, $\boldsymbol{X}_\nu \rightarrow \boldsymbol{X}_{\nu+1} \rightarrow \boldsymbol{X}_{\nu+2} \rightarrow \ldots$, using a properly chosen transition probability. For a fluid, the move from $\boldsymbol{X}$ to $\boldsymbol{X}'$ may mean a random displacement of a single randomly chosen particle; for an Ising model, it may mean a single spin is chosen at random and considered for a spin flip, or for exchange with one of its neighbors; but also flips of large clusters of spins in one move together may be carried out. Also moves that have no counterpart in reality are conceivable (e.g., in a dense polymer melt, one may select a pair of long chains that are close by each other, cut them in the middle, and reconnect the parts differently than previously). Even though such moves need not represent any physically plausible dynamics, they may provide an efficient sampling of the phase space. The great flexibility in the choice of such moves, adapted to the problem one wishes to study, is one of the particular strengths of the MC methods.

The states $\boldsymbol{X}_\nu$ are distributed according to the Boltzmann factor $P_{\text{eq}}(\boldsymbol{X})$ if the transition probability $W(\boldsymbol{X} - \boldsymbol{X}')$ satisfies the condition of detailed balance

$$P_{\text{eq}}(\boldsymbol{X})\, W(\boldsymbol{X} \rightarrow \boldsymbol{X}') = P_{\text{eq}}(\boldsymbol{X}')\, W(\boldsymbol{X}' \rightarrow \boldsymbol{X}) \qquad [16]$$

For instance, a choice that satisfies eqn [16] is simply

$$W(\boldsymbol{X} \rightarrow \boldsymbol{X}') = \begin{cases} \tau_0^{-1}, & \text{if } \delta\hat{H} \equiv \hat{H}(\boldsymbol{X}') - \hat{H}(\boldsymbol{X}) < 0 \\ \tau_0^{-1} \exp(-\delta\hat{H}/k_{\text{B}}T), & \text{if } \delta\hat{H} \geqslant 0 \end{cases}$$

Here, a constant τ_0 has been arbitrarily introduced to set a timescale, so that W gets the meaning of a transition probability per unit time (but one may choose $\tau_0 = 1$, of course, and normally one considers one Monte Carlo step (MCS) per degree of freedom as the natural unit of the MC "time"). This notion is useful, since MC sampling can be interpreted as "time averaging" along stochastic trajectories in phase space, described by a master equation for the probability $P(\boldsymbol{X}, t)$ that a state $\boldsymbol{X}$ occurs at time t,

$$\frac{\mathrm{d}}{\mathrm{d}t} P(\boldsymbol{X}, t) = -\sum_{\boldsymbol{X}'} W(\boldsymbol{X} \rightarrow \boldsymbol{X}') P(\boldsymbol{X}, t) + \sum_{\boldsymbol{X}'} W(\boldsymbol{X}' \rightarrow \boldsymbol{X}) P(\boldsymbol{X}', t) \qquad [17]$$

This rate equation describes the balance between the loss of probability by all processes $\boldsymbol{X} \rightarrow \boldsymbol{X}'$ that lead away from the considered state and the gain of probability due to the inverse process. Obviously, $\mathrm{d}P/\mathrm{d}t = 0$ if $P = P_{\text{eq}}(\boldsymbol{X})$, due to the detailed balance principle, eqn [16].

Of course, the dynamical properties of a system described by such a stochastic trajectory through phase space generated via MC will differ in general from dynamic properties deduced from the deterministic MD trajectories. In fact, the MC dynamics is of physical significance only when one deals with systems for which the considered degrees of freedom are a (slow!) subset weakly coupled to the remaining (fast!) degrees of freedom, that behave like a heat bath. This is the case for the Ising magnet and for diffusion in solid alloys $A_x B_{1-x}$, for instance. In both cases the phonons of the crystal act like a heat bath, causing random spin flips or random jumps of A or B atoms to vacant sites, respectively. Often the MC dynamics is considered as fairly realistic for random growth or aggregation phenomena on mesoscopic scales, such as diffusion-limited aggregation (DLA).

The dynamic interpretation of MC sampling in terms of a stochastic trajectory in phase space is important for the understanding of "statistical error," since the subsequently generated states $\{\mathbf{X}_\nu\}$ are highly correlated with each other. In fact, one can show that the expected mean square statistical error becomes

$$\langle (\delta A)^2 \rangle = \frac{1}{n} [\langle A^2 \rangle - \langle A \rangle^2](1 + 2\tau_{AA}/\delta t) \qquad [18]$$

where

$$\tau_{AA} = \int_0^\infty \Phi_{AA}(t)\mathrm{d}t, \quad \Phi_{AA}(t) \equiv [\langle A(0)A(t) \rangle - \langle A \rangle^2]/[\langle A^2 \rangle - \langle A \rangle^2] \qquad [19]$$

if n observations $\{A_\mu\}$ of the observable A separated by time increment δt are taken. If these n observations were statistically independent, the enhancement by the "dynamic factor" $(1 + 2\tau_{AA}/\delta t)$ would be absent. As noted in the discussion of MD methods, relaxation times τ_{AA} get large near critical points, or when one considers long wavelength Fourier components of a conserved quantity ("critical slowing down," "hydrodynamic slowing down," also hamper MC!). Also the questions of whether or not an algorithm is ergodic, and how fast equilibrium is reached or whether hysteresis may occur, etc., are important for both MD and MC.

A further limitation of simulations that may need consideration are finite size effects. Considering Fourier components such as $\delta\rho_{\boldsymbol{k}}$ (eqns [8] and [9]), one must note that in a finite system with periodic boundary conditions $\boldsymbol{k}$-space is quantized. For example, if one has a cubic simulation cell $L \times L \times L$, the allowed

wave vectors are $\boldsymbol{k}_n = (2\pi/L)(n_x, n_y, n_z)$ where n_α are integers. With respect to static phenomena, the gap in the spectrum of long wavelength modes affects physical properties for which these modes are important (e.g., long wavelength phonons cause the T^3 law for specific heats, if the crystal is treated by quantum statistical mechanics; long wavelength magnons in a Heisenberg ferromagnet cause a divergence of the longitudinal and transverse susceptibilities; capillary waves cause a divergence of interfacial widths, etc.). Thus for many physical properties, it is advisable to repeat the simulation for a range of values of L, and carry out a suitable extrapolation of the results to the thermodynamic limit, $L \to \infty$.

The problem of finite size effects is particularly cumbersome when one deals with phase transitions. However, the study of phase transitions is a problem for which simulations are often necessary, and, in fact, useful! One approach to overcome the limitation of finite size for such problems relies on the concept of finite size scaling. Consider, as a simple example, the transition of the Ising model {eqn [14]} from the paramagnetic phase at $T > T_c$ to a ferromagnetic state at $T < T_c$. Near the critical temperature T_c, spontaneous magnetization m_{sp} and susceptibility χ are singular in the thermodynamic limit, $m_{sp} \propto (1 - T/T_c)^{\beta}$, $\chi \propto |1 - T/T_c|^{-\gamma}$, where β, γ are "critical exponents." Varying H for $T < T_c$, however, m at $H = 0$ has a jump singularity from $-m_{sp}$ to $+m_{sp}$, χ then has a delta-function singularity: this is a special case of a first-order transition.

In a finite system, however, these singularities are always rounded. For example, χ for $H = 0$ as a function of T does not diverge, there is a peak of finite height only, which also is shifted away from T_c. Thus, it is a nontrivial problem to estimate both T_c and other critical properties (such as exponents) with sufficient accuracy.

For critical phenomena, finite size scaling rests on a comparison of lengths: the linear dimension L scales with the correlation length $\xi \propto |1 - T/T_c|^{-\nu}$ of the system. As a consequence, near T_c moments of the order parameter distribution depend on L and ξ basically via a scaling function of the ratio L/ξ, apart from a power-law prefactor $\langle |m|^k \rangle = L^{-k\beta/\nu} \tilde{M}_k (L/\xi)$, $L \to \infty, k$ integer, $\tilde{M}_k$ being a "scaling function"! Particularly useful are, thus, suitable ratios of moments where the power law prefactors cancel out, such as the reduced fourth-order cumulant

$$U_L(T) = 1 - \langle m^4 \rangle / [3 \langle m^2 \rangle^2] = \tilde{U}(L/\xi), \quad L \to \infty \qquad [20]$$

Since $\xi \to \infty$ as $T \to T_c$, all curves $U_L(T)$ must intersect at $T = T_c$ in a universal value $\tilde{U}(0)$; note that $U_L(T) \to 2/3$ for $T < T_c$ as $L \to \infty$, while $U_L(T) \to 0$ for $T > T_c$. If such a unique intersection point is found, it thus serves to find the location of T_c. If the intersections of different pairs $U_L(T)$, $U_{L'}(T)$ scatter, on the other hand, one can conclude that corrections to scaling are still pronounced, and the study of larger systems is required. At T_c, one also finds that $\langle |m| \rangle \propto L^{-\beta/\nu}, \chi \propto L^{\gamma/\nu}$, and thus one can estimate critical exponents.

Also, first-order transitions are rounded; while in the Ising model for $T < T_c$, two phases with $\pm m_{sp}$ occur precisely at $H = 0$, the distribution function of the magnetization simply is $P_\infty(m) = [\delta(m - m_{sp}) + \delta(m + m_{sp})]/2$, and for finite L, one observes two broadened peaks not only at $H = 0$ but over a range ΔH of fields, with $\Delta H \propto L^{-d}$, inversely proportional to the volume of the system. But the location of the first-order transition is found accurately from the "equal weight rule" for the two peaks.

The sampling of $P_L(m)$ is very useful since one can show that for $T < T_c$, one has $P_L(0)/P_L(m_{sp}) \propto \exp(-2L^{d-1}\sigma/k_B T)$, σ being the interfacial tension between the coexisting phases. Use of this formula, in fact, is one of the most powerful recipes to estimate interfacial free energies from simulations. Of course, $P_L(0)/P_L(m_{sp})$ for large L is extremely small, and thus this ratio cannot be sampled directly, but needs more advanced schemes that are not described here due to lack of space, such as "umbrella sampling" or "multicanonical MC."

Of course, the above comments discuss the study of phase transitions by simulations only in a nutshell, and the reader is directed to the "Further reading" section for further details.

Path-Integral Monte Carlo (PIMC)

Thermal averages for a quantum system are calculated, and thus eqns [12] and [13] are rewritten appropriately

$$\langle \hat{A} \rangle = Z^{-1} \operatorname{Tr} \exp(-\hat{H}/k_B T)\hat{A}, \qquad Z = \operatorname{Tr} \exp(-\hat{H}/k_B T) \qquad [21]$$

using a notation that emphasizes the operator character of the Hamiltonian $\hat{H}$ and observable $\hat{A}$. For simplicity, consider first the case of one particle in a potential $V(x)$ in one dimension, where $\hat{H} = -(\hbar^2/2m)\mathrm{d}^2/\mathrm{d}x^2 + V(x)$, m being the mass of the particle. In position representation $Z = \int \mathrm{d}x \langle x| \exp(-\hat{H}/k_B T)|x\rangle, |x\rangle$ being an eigenvector of the position operator. The problem now is that $\hat{H} = \hat{E}_{kin} + \hat{V}(x)$, where $\hat{E}_{kin}$ and $\hat{V}(x)$ do not commute. Applying the Suzuki–Trotter formula, P being a positive

integer

$$\exp[-(\hat{E}_{\text{kin}} + \hat{V})/k_{\text{B}}T] = \lim_{P\to\infty} [\exp(-\hat{E}_{\text{kin}}/k_{\text{B}}TP)\, \exp(-\hat{V}/k_{\text{B}}TP)]^P \quad [22]$$

one can reduce Z to ($x_{P+1} = x_1$)

$$Z = \lim_{P\to\infty} \left(\frac{k_{\text{B}}TmP}{2\pi\hbar^2}\right)^{P/2} \int \mathrm{d}x_1 \ldots \int \mathrm{d}x_P \times \exp\left(\left[-\frac{\kappa}{2}\sum_{S=1}^{P}(x_s - x_{s+1})^2 - P^{-1}\sum_{S=1}^{P} V(x_s)\right]/k_{\text{B}}TP\right) \quad [23]$$

where $\kappa \equiv (k_{\text{B}}T/\hbar)^2 mP$. Apart from the prefactor, eqn [23] is the configurational partition function of a ring polymer within the framework of classical statistical mechanics: P beads are coupled by harmonic springs with spring constant κ, and are exposed to a potential $V(x)/P$.

This approach is straightforwardly generalized to a system of N interacting quantum particles, if the quantum mechanical exchange is neglected: one ends up with a system of N classical cyclic "polymer chains." As a result of this isomorphism, methods for simulating classical systems (MC, MD) can be carried over to such quantum-mechanical problems, too. At high temperatures, κ gets very large, the cyclic chain contracts essentially to a point, while at low T the chains are spread out, representing zero-point motions. The lower the T is, the larger the P has to be: if σ is a characteristic distance over which the potential $V(x)$ changes, one must have $\hbar^2/m\sigma^2 \ll k_{\text{B}}TP$ so that two neighbors along the "polymer chain" are at a distance much smaller than σ. The typical size of the ring polymer, of course, is of the order of the thermal de Broglie wavelength λ_{T}: at very low temperatures (or for very light particles such as He atoms) λ_{T} becomes comparable to the interparticle spacing, and the precise formulation of the problem requires the correct incorporation of the statistics of the particles (Bose–Einstein versus Fermi–Dirac) into the formalism. For fermions, this leads to the famous difficulty known as "minus sign problem" – the distribution to be sampled loses its interpretation as a probability distribution, because it is no longer non-negative everywhere. Thus the study of systems such as liquid ^{3}He (or fermions on a lattice, a problem to which a similar formulation based on the Suzuki–Trotter decomposition is applicable) is still an active area of research. However, one may stress that the simplified formulation of PIMC (or PIMD, respectively) that ignores the statistics of the particles is useful (and indispensable!) to study the thermal properties of crystals (such as solid Ne or Ar, SiO_2, polyethylene etc.) at low temperatures (and obtain temperature dependences of lattice parameters, elastic constants etc., that are compatible with the third law of thermodynamics).

Concluding Remarks

In this article, the basic foundations of three important simulation methods (classical MD and MC, PIMC) have been briefly described, and some technical limitations as well as recipes of how they can be overcome have also been mentioned. However, there are many "tricks of the trade" that could not be described, due to lack of space: for example, one can switch on or off arbitrary perturbations or parts of the interparticle forces, and combine this with suitable thermodynamic integration methods to gain information on thermodynamic excess potentials, etc. Very important variations are also possible by a suitable choice of various boundary conditions (e.g., a combination of "tilted periodic" with "antiperiodic" boundary conditions allows the study of tilted interfaces in Ising systems). An important aspect also is that an analysis of conceptually important quantities (e.g., Voronoi polyhedra distributions in amorphous solids, ring statistics in molten silica, orientational order parameters in two-dimensional melting, etc.) is readily possible with simulations, while one can infer these quantities from experiment at best indirectly. Many such extensions of the techniques described here, as well as further simulation methods, and last but not the least, numerous application examples can be found in the "Further reading" section.

Conductivity, Electrical

J Bass, Michigan State University, East Lansing, MI, USA

Introduction

One important way to characterize a material is in terms of its electrical conductivity (or the inverse, its electrical resistivity). A metal conducts electricity well, and its resistivity usually increases with increasing temperature. Most elements (82 of the 104 naturally occurring ones) are metals. A semiconductor conducts electricity less well, and its resistivity usually decreases with increasing temperature. An insulator hardly conducts electricity at all; its resistivity is very large. This article deals with the electrical resistivity of pure metals and alloys. The focus is mainly on nonmagnetic metals – magnetic metals are covered elsewhere. References to both the theory of the electrical resistivity of metals, and to data on the resistivities of pure metals and alloys, are given in the Further Reading section.

Formally, the electrical conductivity tensor $\boldsymbol{\sigma}$ (and its inverse – the resistivity tensor $\boldsymbol{\rho}$) are defined by Ohms law:

$$\boldsymbol{J} = \boldsymbol{\sigma} \cdot \boldsymbol{E} \qquad [1]$$

and

$$\boldsymbol{E} = \boldsymbol{\rho} \cdot \boldsymbol{J} \qquad [2]$$

where $\boldsymbol{J}$ is the current density and $\boldsymbol{E}$ is the electric field (both vectors). In the general case, $\boldsymbol{\rho}$ is the inverse of the tensor $\boldsymbol{\sigma}$. However, if no magnetic field is present, and if the crystal structure of the metal is cubic – simple cubic (s.c.), face-centered cubic (f.c.c.), or body-centered cubic (b.c.c.) – then $\boldsymbol{\sigma}$ and $\boldsymbol{\rho}$ reduce to scalars, and $\rho = 1/\sigma$. Since many of the most common metals have cubic structures, the focus is on the case where ρ and σ are scalars, in which case it suffices to consider ρ, because σ is simply its inverse. Where appropriate, noncubic metals are discussed.

Near room temperature ($\sim$295 K), convenient units for ρ are micro-ohm cm ($\mu\Omega$ cm), since the resistivities of all pure elemental metals at 295 K range from $\sim$1.6 $\mu\Omega$ cm for Ag to somewhat over 100 $\mu\Omega$ cm for Mn, Gd, and Tb.

Measurements

The resistivity ρ at temperature T, $\rho(T)$, of a given metal or alloy is derived from a "four-probe" measurement of the electrical resistance $R = V/I$ of a long thin wire of known cross-sectional area $A = \pi r^2$, or a long, narrow film of area $A = Wt$, as shown in **Figure 1**. Here r is the radius of the wire, W and t are the width and thickness of the film, and the voltage leads are made long and thin to minimize perturbing the current flow. These geometries minimize "end effects," thereby ensuring that the current density $J = I/A$ is uniform across A, and contact effects by eliminating current flow into the voltage contacts. In such a case, measuring the voltage V across a well-defined length L of the sample gives $\rho = RA/L = VA/IL$.

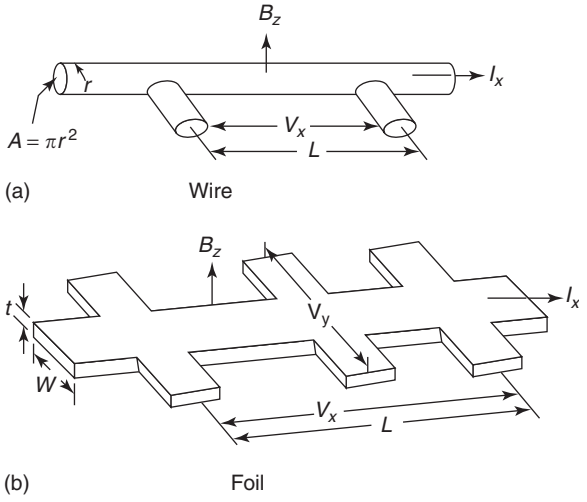

Figure 1 (a) Wire and (b) film geometries for measuring resistivities so that complications due to nonuniform current flow and contact resistances are minimal.

Strictly, as noted above, a unique value of $\rho(T)$ can be determined for either a single crystal or a polycrystalline sample of a cubic metal, but only for a single crystal of a noncubic metal that is oriented along a symmetry axis. Even in these cases, it will be seen below that $\rho(T)$ can depend upon the size of the sample if r or t are very small, and upon the content of impurities or other defects such as grain boundaries or dislocations, especially at low temperatures.

Theoretical Background

The first derivation of Ohm's law and σ was made by Drude in 1900, who used the classical kinetic theory to treat an assumed gas of free electrons in a metal. His result can be obtained by assuming that an electron of charge e and mass m is accelerated by an electric field E and is subject to a frictional retarding force proportional to its velocity v and inversely proportional to a relaxation time τ (a measure of the average time between scattering events). Then, at steady state, the electron is not accelerated, and

$$m\,\mathrm{d}v/\mathrm{d}t = 0 = eE - mv/\tau \;\rightarrow\; v = eE\tau/m \qquad [3]$$

Taking

$$J = nev \qquad [4]$$

(where e is the electron's charge and n is the number of electrons per unit volume), Ohm's law is obtained:

$$J = nev = (ne^2\tau/m)E \qquad [5]$$

with

$$\sigma = ne^2\tau/m \qquad [6]$$

The Bohr–Sommerfeld analysis of a quantum free-electron gas gives a similar expression, but with τ evaluated at the Fermi energy. If a mean free path λ between scattering events is defined as $\lambda = v_F\tau$, eqn [6] can be rewritten as

$$\sigma = ne^2\lambda/mv_F \qquad [7]$$

Inverting eqn [7] then gives

$$\rho\lambda = mv_F/ne^2 \qquad [8]$$

For a given metal or alloy at temperature T, eqn [7] shows that $\sigma \propto \lambda$, and eqn [8] shows that the product $\rho\lambda$ is a constant for a given metal, depending upon the particular metal only through n and v_F. Equation [8] can be used to estimate λ for a given value of ρ.

To generalize eqns [7] and [8] to real (as opposed to free-electron) metals, with real Fermi surfaces, one must turn to a more general analysis, such as the Boltzmann transport equation. Here, one defines an electron distribution function $f(\boldsymbol{k},\boldsymbol{r},t)$ such that $(4\pi^3)^{-1}\,f(\boldsymbol{k},\boldsymbol{r},t)\,\mathrm{d}\boldsymbol{k}\,\mathrm{d}\boldsymbol{r}$ gives the number of electrons of wave vector $\boldsymbol{k}$ (or crystal momentum $\hbar\boldsymbol{k}$, where $\hbar$ is Planck's constant divided by 2π) at point $\boldsymbol{r}$ within an element $\mathrm{d}\boldsymbol{r}$ in real space and $\mathrm{d}\boldsymbol{k}$ in wave vector space at time t. $f(\boldsymbol{k},\boldsymbol{r},t) = 1$ if all states with $\boldsymbol{k}$ and $\boldsymbol{r}$ are filled and 0 if all such states are empty. If the electron gas is at thermal equilibrium at a temperature T,

$$f_0 = 1/(\mathrm{e}^{(\varepsilon-\varepsilon_F)/k_BT} + 1) \qquad [9]$$

is the usual Fermi–Dirac distribution function. The Boltzmann transport equation for $f(\boldsymbol{k},\boldsymbol{r},t)$ is then

$$\partial f/\partial t + (\partial f/\partial \boldsymbol{r})(\partial \boldsymbol{r}/\partial t) + (\partial f/\partial \boldsymbol{k})(\partial \boldsymbol{k}/\partial t) = (\partial f/\partial t)_{\mathrm{scatt}} \qquad [10a]$$

where $(\partial f/\partial t)_{\mathrm{scatt}}$ is the rate of change of f due to scattering from defects, quantized lattice vibrations (phonons), or the sample surface. Since $\partial \boldsymbol{r}/\partial t = v$, and $\hbar(\partial \boldsymbol{k}/\partial t) = \boldsymbol{F}$, any external force $\boldsymbol{F}$, eqn [10a] may be rewritten as

$$\partial f/\partial t + v(\boldsymbol{k})(\partial f/\partial \boldsymbol{r}) + (1/\hbar)\boldsymbol{F}(\partial f/\partial \boldsymbol{k}) = (\partial f/\partial t)_{\mathrm{scatt}} \qquad [10b]$$

If both an electric field $\boldsymbol{E}$ and a magnetic field $\boldsymbol{B}$ are present, $\boldsymbol{F} = e\boldsymbol{E} + v\times\boldsymbol{B}$. In the absence of a magnetic field, eqn [10b] can be rewritten as

$$\partial f/\partial t + v(\boldsymbol{k})(\partial f/\partial \boldsymbol{r}) + (e/\hbar)\boldsymbol{E}(\partial f/\partial \boldsymbol{k}) = (\partial f/\partial t)_{\mathrm{scatt}} \qquad [10c]$$

If the focus is only upon the electrical conductivity σ of the bulk material, the temperature can be taken as constant across the sample, any changes in f with $\boldsymbol{r}$ can be neglected, and only the steady-state solution can be considered. Equation [10c] then reduces to

$$(e/\hbar)\boldsymbol{E}(\partial f/\partial \boldsymbol{k}) = (\partial f/\partial t)_{\mathrm{scatt}} \qquad [10d]$$

Because changes in f with $\boldsymbol{r}$ are neglected, this equation will not allow one to treat scattering at the sample surface (size effects). Such effects are discussed briefly below.

Finally, for the physics of present interest, the deviations of $f(\boldsymbol{k})$ from $f_0(\boldsymbol{k})$ will be small. These deviations can be considered by writing $f(\boldsymbol{k}) = f_0(\boldsymbol{k}) + g(\boldsymbol{k})$. In order to obtain Ohm's law, eqn [10d] must then be linearized (i.e., drop terms of higher order in $\boldsymbol{E}$), giving

$$(e/\hbar)\boldsymbol{E}(\partial f_0/\partial \boldsymbol{k}) = (\partial f/\partial t)_{\mathrm{scatt}} \qquad [11]$$

Equation [11] is the linearized Boltzmann transport equation in the absence of temperature gradients, magnetic fields, and size effects. In introductory and intermediate texts, it is usually simplified one more time by making the "relaxation time approximation,"

that is by taking

$$(\partial f/\partial t)_{\text{scatt}} = -g_k/\tau_k \qquad [12]$$

where τ_k is called the relaxation time. Since f_0 (see eqn [9]) is only a function of the energy ε_k, and $\boldsymbol{v} = (1/\hbar)\partial\varepsilon/\partial\boldsymbol{k}$, eqn [11] can be rewritten in the final form

$$e\boldsymbol{E}v_k(\partial f_0/\partial\varepsilon_k) = -g_k/\tau_k \qquad [13]$$

Generalizing eqn [4] gives $J = \int \mathrm{d}\boldsymbol{k}^3 e g_k v_k$ and some manipulation of eqn [13] leads to the relation

$$\sigma = (1/12\pi)(e^2/\hbar) \int \lambda_k \mathrm{d}S_k \qquad [14]$$

where λ_k is the mean free path of electrons of wave vector $\boldsymbol{k}$, and $\mathrm{d}\boldsymbol{S}_k$ is a differential area on the Fermi surface around wave vector $\boldsymbol{k}$. Equation [14] is the generalization of eqn [7].

For the present purposes, only one more result (the Bloch–Grüneisen equation for the temperature-dependent electrical resistivity of a free-electron gas (i.e., a spherical Fermi surface), in which the electrons are scattered only by phonons and with no participation of reciprocal lattice vectors (i.e., no Umklapp scattering)) is needed. The result, taken as their approximation for the resistivity of an ideally pure metal, ρ_{P}, is

$$\rho_{\text{P}} = (K/\vartheta)(T/\vartheta)(T/\vartheta)^4 \int_0^{\vartheta/T} 4z^4 \, \mathrm{d}z/(\mathrm{e}^z - 1) \qquad [15]$$

Since the interest here is only in the Bloch–Gruneisen prediction for the temperature dependence of ρ_{P}, several constants and parameters have been collected together into K, and only scaling parameter, ϑ, is left with the units of temperature.

At high temperatures, where $T \gg \vartheta$, the term $\mathrm{e}^z - 1$ in the denominator of the integral reduces to just z, leaving four powers of z inside the integral. The lower limit of the integral then gives zero, and the upper limit is proportional to $(\vartheta/T)^4$, which cancels the $(T/\vartheta)^4$ outside the integral, leaving just (T/ϑ). In this limit, ρ_{P} is proportional to T.

At low temperatures, where $T \ll \vartheta$, the upper limit can be approximated as infinity, turning the integral into just a number. The temperature dependence in this limit is then just that outside the integral, or T^5.

The Bloch–Gruneisen calculation thus predicts that ρ_{P} should be proportional to T at high T, and to T^5 at low T. A linear variation with T is often seen at high T (but not necessarily extrapolating to $\rho_{\text{P}} = 0$ at $T = 0$ as would be predicted by Bloch–Gruneisen). A strict T^5 variation is rarely, if ever, seen at low T. Deviations from the simple prediction occur for a variety of reasons, including: real Fermi surface effects such as Umklapp scattering; electron–electron scattering (which can give a T^2 variation); deviations from Matthiessen's rule; and the onset of superconductivity.

Experimental Temperature and Impurity-Concentration Dependence

From Bloch's theorem, the resistivity of a perfectly periodic metal should be zero. Resistivity results from scattering of conduction electrons by deviations from perfect periodicity, either due to the presence of defects at atomic sites (e.g., impurities, vacancies, dislocations, grain boundaries) or due to vibrations of the atoms of the lattice away from their equilibrium sites (quantized lattice vibrations are called phonons).

In a high-purity metal, scattering by phonons dominates at all but the lowest temperatures. As noted above, for a free-electron metal, the Bloch–Gruneisen model of $\rho(T)$ predicts a linear dependence upon T at high temperatures, and a more rapid decrease at lower temperatures, eventually reaching T^5 at cryogenic temperatures. **Figures 2–4** illustrate some of the behaviors of $\rho(T)$ at higher temperatures, using data for the simple f.c.c. metal Cu, which looks qualitatively like the expectation from Bloch–Gruneisen,

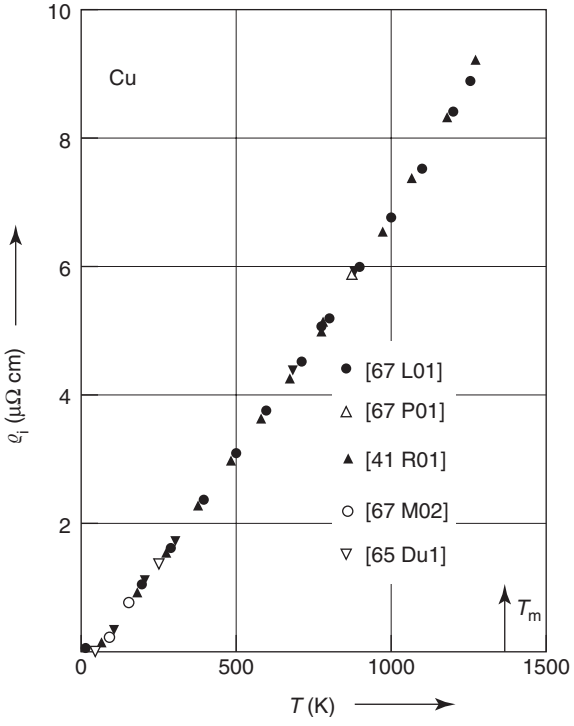

Figure 2 Resistivity as a function of temperature for Cu, a metal where the form of the resistivity is similar to that predicted by the Bloch–Gruneisen model.

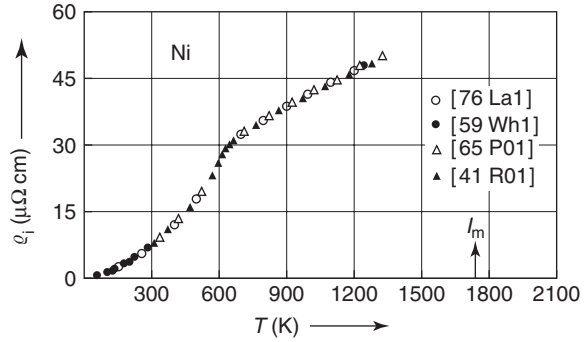

Figure 3 Resistivity as a function of temperature for Ni, a metal that becomes ferromagnetic below its Curie temperature of ~650 K.

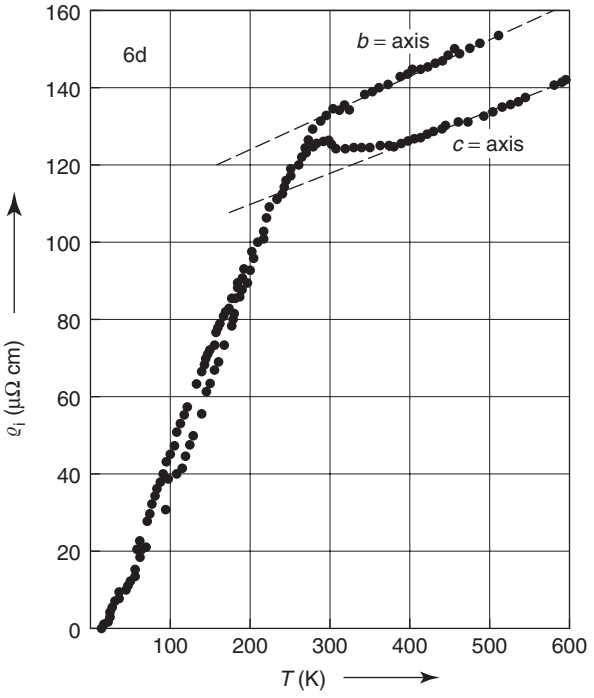

Figure 4 Resistivity as a function of temperature for a single-crystal sample of Gd, which has a noncubic crystal structure.

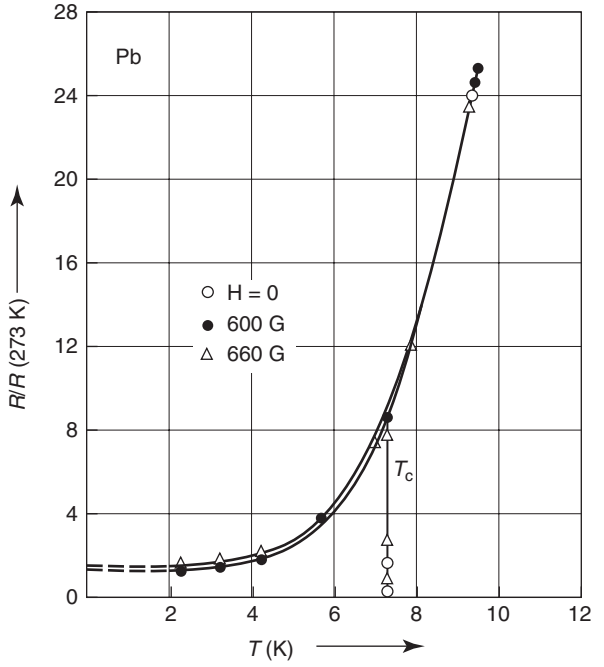

Figure 5 Low-temperature resistivity of Pb, which becomes superconducting (the resistivity drops to zero) in zero magnetic field at ~7.2 K. In a magnetic field of 600 Oe, Pb remains normal to the lowest temperature measured in this figure, and the resistivity at the lowest temperatures becomes constant, at a value determined by residual impurities.

the f.c.c. metal Ni, which undergoes a ferromagnetic phase transition at 630 K, and the hexagonal close-packed (h.c.p.) metal Gd, which undergoes magnetic phase transitions at 240 and 293 K. In the simplest case, Cu, at temperatures above ~100 K, $\rho(T)$ is approximately linear in T. At cryogenic temperatures, $\rho(T)$ decreases more rapidly than linearly with T. If the metal was perfectly pure, $\rho(T)$ would approach 0 as $T \rightarrow 0$ K, either smoothly if the metal remains "normal" (i.e., nonsuperconducting), or abruptly at a characteristic temperature, T_c, if the metal becomes superconducting. **Figure 5** shows an example of a superconductor, Pb, both in the zero magnetic field (open circles) where it becomes superconducting (resistance drops to zero) at $T_c = 7.2$ K and in magnetic fields (triangles and filled circles) large enough to keep it normal down to at least 2 K. In this article, the concentration is on nonsuperconducting behavior. Below ~8 K, the normal resistivity of Pb in a magnetic field decreases more rapidly than linearly with temperature, and then saturates to a constant value at the lowest temperatures. **Figure 6** shows, in Pd, a more complex low-temperature resistivity than just the Bloch–Gruneisen form; here $\rho(T)$ contains two terms, a T^2 term arising from electron–electron scattering, plus an approximately T^5 Bloch–Gruneisen-like term. As T decreases, **Figures 5** and **6** show that the temperature-dependent part of $\rho(T)$ eventually becomes smaller than the resistivity due to residual defects, and the measured resistivity (designated as residual resistivity, ρ_0) becomes closely independent of temperature (constant) at a value determined by the nature and concentration of these defects.

If a concentration c of a given defect is added to a "pure" metal, the resulting total resistivity $\rho_T(c, T)$ can often be approximated by simply summing the temperature-dependent resistivity, $\rho_P(T)$, of the ideally pure host metal and a temperature-independent term, $\rho_0(c)$, due to the presence of the defect. This

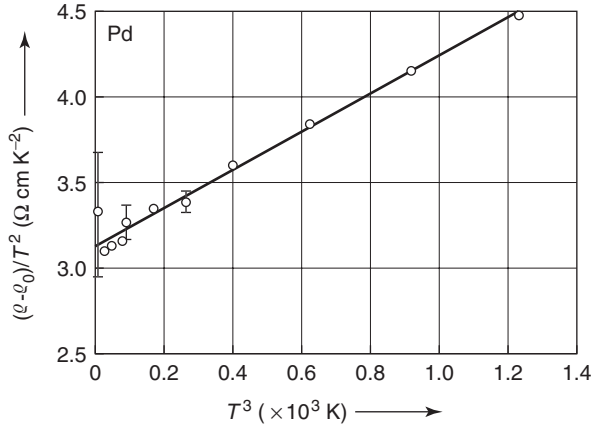

Figure 6 $(\rho - \rho_0)/T^2$ vs. T^3 for the transition metal Pd at low temperatures, where ρ_0 is the (constant) residual resistivity. In addition to an approximately T^5 Bloch–Gruneisen-like term, the data contain also a T^2 term due to electron–electron scattering.

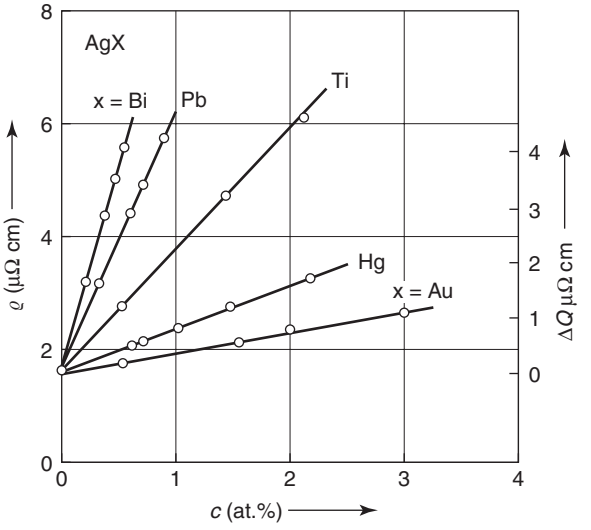

Figure 7 Resistivity vs. concentration (c in at.%) for Bi, Pb, Tl, Hg, and Au impurities in Ag, showing the expected linear variation with c, for small c.

result is called Matthiessen's rule:

$$\rho_T(c,T) \approx \rho_0(c) + \rho_P(T) \qquad [16]$$

The content of eqn [16] is twofold: (1) the most important feature of the defects is simply their presence, rather than that they vibrate differently from the host atoms; and (2) scattering of electrons from the defects is independent of scattering from the phonons. In practice, eqn [3] is used to define $\rho_P(T)$, by subtracting the low temperature constant limit of the data, ρ_0, from the measured $\rho(T)$ for the highest-purity samples available.

For small c, $\rho_0(c)$ is proportional to c, $\rho_0(c) = Kc$. The scale for K is $\mu\Omega\,\text{cm at.}\%^{-1}$, with values ranging from $0.1\,\mu\Omega\,\text{cm (at.}\%)^{-1}$ to $10\,\mu\Omega\,\text{cm (at.}\%)^{-1}$ for different impurities in different host metals. **Figure 7** shows examples of linear variations of $\rho_0(c)$ with c for dilute Ag-based alloys. Note that K increases with increasing difference between the number of "conduction electrons" for the impurity (Au = 1, Hg = 2, Tl = 3, Pb = 4, and Bi = 5) and for the host metal, Ag = 1. If the values of K for impurity A in host B and for impurity B in host A are closely the same, then the relation between $\rho_0(c)$ and c can be approximated over the whole range of alloy concentrations as

$$\rho_0(c) = Kc(1-c) \qquad [17]$$

In practice, the K values for different pairs of metals are usually different enough that eqn [17] is only a very rough approximation to reality. **Figure 8** shows an example of experimental data for PdAu alloys.

Careful measurements of $\rho_T(c,T)$ show that Matthiessen's rule is never exact. The resulting deviations from Matthiessen's rule (DMR) are defined by the

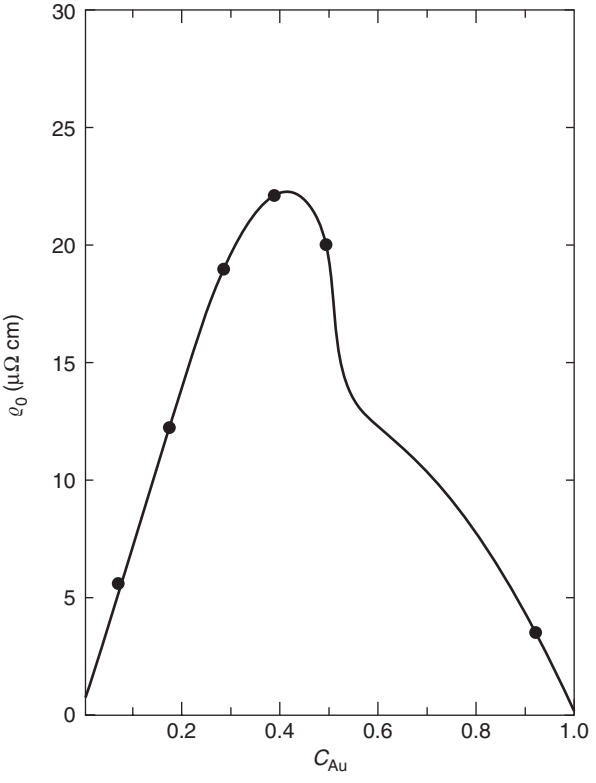

Figure 8 Residual resisitivity vs. Au concentration C_{Au} for PdAu alloys, showing that the residual resistivity need not be a symmetric function of C_{Au}.

relation

$$\Delta(c,T) = \rho_T(c,T) - \rho_0(c) - \rho_P(T) \qquad [18]$$

Such deviations have been studied for a variety of impurities and host metals. $\Delta(c,T)$ usually consists of

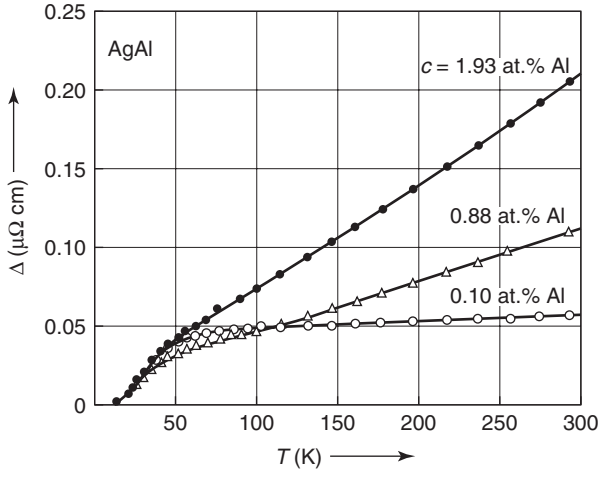

Figure 9 Deviation from Matthiessen's rule, Δ, vs. temperature for three alloys of Al in Ag.

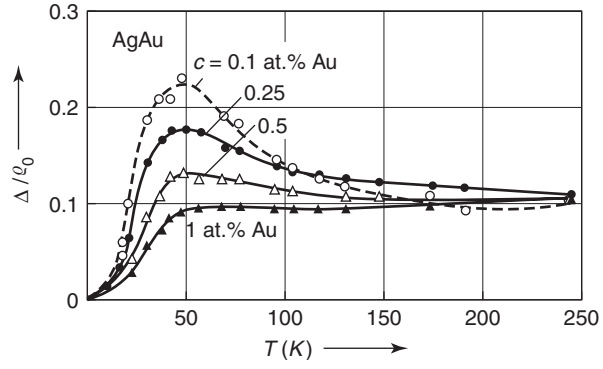

Figure 10 Normalized deviation from Matthiessen's rule, Δ/ρ_0, for a series of alloys of Au in Ag.

a low-temperature peak followed by a linear component at high T that can have positive, negative, or zero slope. **Figures 9** and **10** illustrate the forms seen.

Pressure

Measurements of ρ are almost invariably made at constant pressure P, usually at atmospheric pressure or in vacuum. Calculations of ρ, in contrast, are normally made by assuming constant volume V. Thus, to compare measurements and calculations, knowledge of how ρ changes with P is required. Studies of $\rho(P)$ are useful for providing such corrections (which are usually small) and also because measuring R is often the easiest way to study phenomena induced by an application of pressure, such as pressure-induced phase transitions. The relative ease of measuring R also makes it one of the properties of choice for studying phase transitions induced by temperature.

Size Effects (Mean Free Path)

If a sample wire or film is made so thin that there is a significant probability of electrons being scattered by the sample surface, and if such scattering is at least partly diffuse (i.e., with the final momentum of the scattered electron randomized in direction), then the resistance of the sample will increase due to such scattering. In the simplest case of a thin cylindrical wire of a free-electron metal of diameter d and completely diffuse scattering (i.e., the component of the electron's momentum along the wire or film is randomized by each collision), the total resistance $\rho_T(d)$ can be approximated by the relation

$$\rho_T(d) = \rho_B + (\rho\lambda)/d \qquad [19]$$

Here, ρ_B is the resistivity of the bulk material, and $\rho\lambda$ is a constant representative of the particular metal involved, as shown in eqn [8]. If one replaces ρ by the experimental resistivity of the metal at a particular temperature, then λ would be the experimental "mean free path" for free electrons in that metal at that temperature – that is, λ is the typical distance moved between scattering events that significantly change the direction of the electron's momentum. A qualitative insight into eqn [19] can be obtained by analogy with Matthiessen's rule, wherein the second term of eqn [19] represents the increase in resistivity when the sample diameter is equal to its mean free path. For partially specular scattering (mirror-like, in which the momentum component along the wire or film remains unchanged), or for the different geometry of a film, the equations are more complex, and the interested reader is referred to the Further Reading section. **Figure 11** shows examples of the applicability of eqn [19] for samples with different amounts of surface specularity.

Some Related Phenomena Outside the Purview of This Article

Magnetoresistance

The standard quasiclassical treatment of electrical conduction in metals outlined above can also be used to describe the phenomenon of magnetoresistance in nonmagnetic metals and alloys, as well as the changes in electrical resistivity that occur upon application of an external magnetic field.

Kondo Effect

In contrast, this standard quasiclassical analysis always yields, as a low-temperature limit, a constant resistivity, corresponding to the scattering of the conduction electrons by residual impurities. It could,

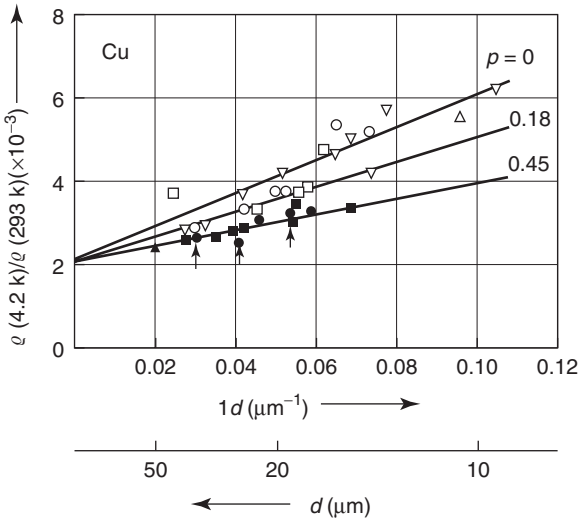

Figure 11 $\rho(4.2\,\mathrm{K})/\rho(293\,\mathrm{K})$ vs. inverse wire diameter, $1/d$, for a series of Cu wires with surfaces giving different amounts of diffuse scattering ($p = 0$ indicates estimated completely diffuse scattering).

thus, not explain observed deviations from this prediction for some magnetic impurities in nonmagnetic hosts, where the resistivity increases with decreasing temperature. This phenomenon was dubbed the "Kondo effect" when it was explained many years later by Kondo as arising from an anomalous scattering by a dilute concentration of localized magnetic moments in a metallic host. This phenomenon is described elsewhere in this encyclopedia.

Mesoscopic Effects

The standard quasiclassical analysis of metallic transport is also unable to explain mesoscopic effects in metallic samples with at least one dimension less than the phase coherence (or dephasing) length, which can be microns or more at cryogenic temperatures. These effects include weak localization in highly disordered metals, and oscillations with the magnetic field in multiply connected samples of size comparable to the dephasing length. To properly treat both the temperature dependence of transport in highly disordered metals, and the oscillatory response to magnetic fields of metallic rings with dimensions smaller than the dephasing length, one must take account of the interference between waves of electrons that follow different trajectories between two points in the sample.

Conductivity, Thermal

K Behnia, Ecole Supérieure de Physique et de Chimie Industrielles, Paris, France

Definition

Heat travels inside solids due to a property called thermal conductivity. The magnitude of thermal conductivity is specific to each element, alloy, or compound and is defined by the equation relating the heat flow to the thermal gradient produced by this flow:

$$J_q = -\kappa \nabla T \qquad [1]$$

Here, J_q and ∇T are vectors representing respectively heat current density and temperature gradient. Thermal conductivity κ is, in general, a second-rank tensor. However, when heat flows along a high-symmetry axis, the temperature gradient created is parallel to the axis and the thermal conductivity along that particular axis may be treated as a scalar. In SI units, J_q is expressed in $\mathrm{W\,m^{-2}}$ and ∇T in $\mathrm{K\,m^{-1}}$. The SI unit of thermal conductivity is therefore $\mathrm{W(K\,m)^{-1}}$.

Equation [1] is reminiscent of Ohm's law defining the electrical conductivity as the quantity relating the electric field to current density $\boldsymbol{J} = -\sigma \boldsymbol{\nabla} V$. Indeed, there are a number of analogies between the two transport properties. There is a big difference however: to conduct electric charge, a solid should host itinerant electrons. Otherwise, it would qualify as an (electric) insulator. In the world of heat conduction, such a sharp distinction between conductors and insulators does not exist. The fundamental reason behind this resides in the existence of phonons, which can carry heat even in the absence of any electronic heat conductivity.

Thermal Conductivity and Thermal Diffusivity

Equation [1] is relevant in the case of thermal equilibrium. In general, the exchange of heat implies a variation of temperature with time. Conservation of energy implies

$$c\frac{\partial T}{\partial t} = -\nabla \boldsymbol{J}_q \qquad [2]$$

where c is the heat capacity per unit volume of the compound. Since the specific heat of various compounds is usually expressed as heat capacity per unit mass (or molar mass), it should be multiplied by the density (or the molar density) of the compound to yield the c used here. A finite $\boldsymbol{J}_q$ means that the balance of heat entering to and exiting out of a volume element is not zero and the energy surplus (or deficit) changes the local temperature.

The combination of eqns [1] and [2] yields the so-called equation of heat, also called the Fourier equation:

$$\frac{\partial T}{\partial t} = D\nabla^2 T \qquad [3]$$

where $D = \kappa/c$ is called the thermal diffusivity. It has the dimensions of an area divided by time ($\mathrm{m^2\,s^{-1}}$ in SI units). Thermal diffusivity is thus thermal conductivity divided by specific heat.

Kinetic Theory of Heat Carriers

Electrons and phonons are the principal carriers of heat in a solid. Phonons are the elementary excitations of a vibrating crystal. In terms of solid-state physics, it is a particle with a definite energy and wave vector. Electrons here mean itinerant electrons capable of moving from one atom to the other. In order to grasp the basic differences between these two types of carriers, it is instructive to focus on a formula derived from the kinetic theory of gases. In this picture, the thermal conductivity is expressed as

$$\kappa = 1/3cvl \qquad [4]$$

where c is the specific heat per volume, v is the average velocity of the particles composing the gas, and l is the mean free path.

Phonons are bosonic quasiparticles with a specific heat displaying a T^3 temperature dependence at low temperature and then saturating to a constant value at temperatures of the order of the Debye temperature, Θ_D. The relevant velocity is the speed of sound (of the order of several $\mathrm{km\,s^{-1}}$ in a solid) and does not change much with temperature. Finally, the mean free path of phonons is limited by whatever impedes their free propagation in a crystal. At sufficiently low temperatures, nothing can scatter extended phonons of long wavelength. In this so-called "ballistic" regime, the mean free path of the phonon becomes comparable to the sample's dimensions.

Electrons are fermions. Their specific heat is a linear function of temperature in ordinary temperatures, which remain much smaller than the Fermi temperature of most metals. The relevant velocity for them is the Fermi velocity (of the order of several hundreds of $\mathrm{km\,s^{-1}}$ in common metals). Finally, even in the cleanest samples and at low temperatures, their mean free path seldom exceeds a micrometer.

Thermal Transport in Insulating Crystals

The case of insulators is simpler as there are no electrons to conduct or to scatter, and their thermal conductivity reflects the capacity of the lattice alone to conduct heat.

The Debye temperature sets the most important energy scale in this context, Θ_D. The thermal conductivity of an insulator peaks at a temperature, which is a fraction (often one-tenth) of Θ_D. This maximum marks the border between the two regimes: while at higher temperatures it is a phonon–phonon scattering which determines the phonon mean free path, l_{ph}, at lower temperatures, collision with defects becomes the predominant limit on l_{ph}. These two regimes are considered here separately:

1. *Low temperature* (*below* $T_{peak} \sim 0.1\Theta_D$). At this temperature range, the T^3 specific heat dominates the temperature dependence of thermal conductivity since l_{ph} displays a weak temperature dependence. With increasing temperature, l_{ph} decreases from the maximum attained in the $T = 0$ limit. Its temperature dependence is governed by the presence of defects in the crystal which scatter phonons in various ways. The cross section of a

phonon with a specific scattering center (such as a point defect, a line defect, a planar defect, or a dislocation) is a function of the phonon wavelength λ_{ph}. As the temperature rises, the dominant wavelength in the phonon population increases ($\lambda_{ph} \propto k_B T$). Therefore, the relative importance of different scattering mechanisms is shifted with the change in temperature.

2. *High temperature* (*above* $T_{peak} \sim 0.1\Theta_D$). The maximum is related to the inflection in the temperature dependence of C_{ph} and l_{ph}. It marks the beginning of the predominance of the phonon–phonon scattering, which leads to a sharper decrease in l_{ph}. This is a consequence of the rise in the phonon population with increasing temperature. On the other hand, the specific heat increases less rapidly and eventually saturates to a constant value. Therefore, the temperature dependence of κ is governed by $l_{ph}(T)$. The expected temperature dependence of the latter is T^{-1}. The minimum thermal conductivity at high temperature is imposed by the lattice spacing. Indeed, l_{ph} cannot become significantly lower than the latter.

The Case of Glasses

In amorphous solids, the mean free path of the phonon, even at low temperatures, does not exceed a few lattice constants. Therefore, the magnitude of thermal conductivity is drastically reduced. A generic feature of glasses is the absence of a maximum in the temperature dependence of thermal conductivity. Since l_{ph} presents a weak temperature dependence, the overall behavior is governed by the variation of the specific heat. The difference of conductivities between a glass and a crystal is largely reduced at high temperatures, because of the short l_{ph} for traveling phonons in both cases. In the intermediate temperature range, the peak is often replaced with a plateau (**Figure 1**).

Thermal Conductivity of Metals and the Wiedemann–Franz Law

In metals, heat is carried both by phonons and electrons. Lattice conductivity in metals suffers from the presence of electrons as additional scattering centers. In the peak region of thermal conductivity (around $0.1\Theta_D$), clean insulators can surpass clean metals as the best thermal conductors. In other words, the additional electronic thermal conductivity cannot compensate the loss in lattice thermal conductivity. The latter is proportional to the strength of electron–phonon coupling and introduces a T-square term to the temperature dependence of the phonon thermal conductivity.

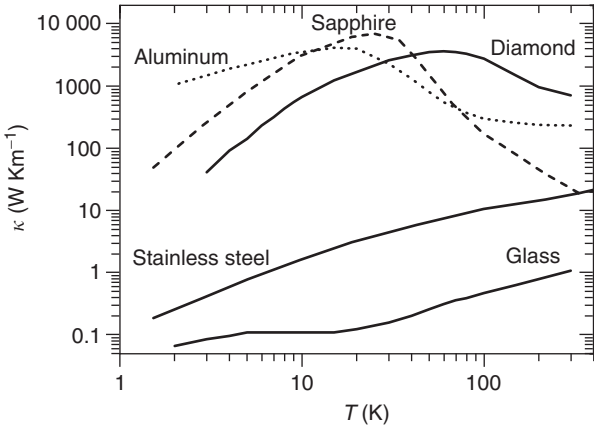

Figure 1 Thermal conductivity of insulating and metallic solids.

In most cases, the predominant contribution to heat transport in a metal is of electronic origin. The application of eqn [2] to electrons yields:

$$\kappa_{el} = 1/3 C_{el} v_F l_{el} = 1/3 C_{el} v_F^2 \tau \qquad [5]$$

where τ is the scattering time. This equation has a parenthood with the classical expression for electric conductivity:

$$\sigma = \frac{ne^2\tau}{m} \qquad [6]$$

with e and m representing the charge and the mass of electron, and n the carrier density. In both expressions, the conductivity is proportional to the scattering time. Thus, the ratio of the two conductivities is expected to be independent of scattering. Divided by temperature, this ratio yields the Lorentz number: $L = \kappa_{el}/\sigma T$. The Wiedemann–Franz law which establishes an intimate relationship between thermal conductivity and electric conductivity of a given metal, states that the Lorentz number is equal to a universal constant:

$$\frac{\kappa_{el}}{\sigma T} = \frac{\pi^2}{3}\left(\frac{k_B}{e}\right)^2 = L_0 \qquad [7]$$

where k_B is the Boltzmann constant and L_0 is the Sommerfeld number. Wiedemann and Franz formulated their empirical law in 1853 after measuring the conductivities of various metals at room temperature. The quantum theory of metals gave a solid foundation to this law which is expected to hold in the $T = 0$ limit irrespective of almost any particularity of any known metal. The fundamental reason behind its universality is easy to grasp. Whatever impedes the transport of charge by electrons would also affect the transport of entropy by them. The

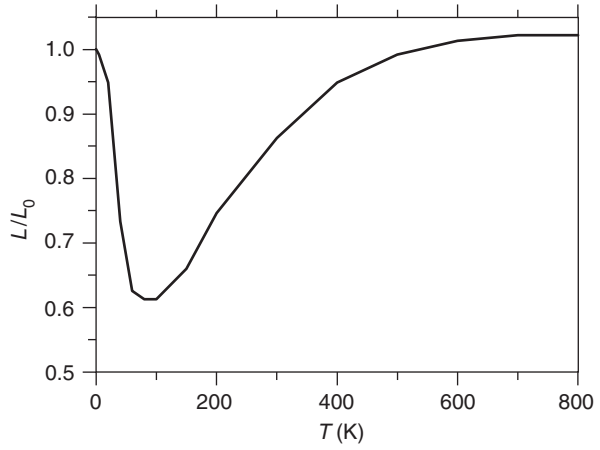

Figure 2 The temperature dependence of the Lorentz number in a common metal (aluminum).

ratio of the two conductivities, therefore, does not depend on the specific electronic properties of the metal.

The argument remains rigorously valid in the absence of inelastic collisions, that is, scattering events which do not imply a transfer of energy during the scattering. Such events occur at finite temperatures when electrons are scattered by phonons and disturb the transport of heat more efficiently. Indeed, such a collision may lead to a partial loss of the electron's energy (i.e., heat) without affecting its momentum producing a thermal resistance with no counterpart in the charge channel. At high temperatures, however, the loss of energy during inelastic collisions becomes negligible compared to the thermal energy, and the validity of the Wiedemann–Franz law is more or less restored (see **Figure 2**).

Superconductivity and Heat Transport

Many metals become superconductors below a critical temperature, T_c. The transition has drastic consequences on heat transport both by electrons and by phonons. At the onset of superconductivity, a gap opens up in the energy spectrum of the electronic spectrum and individual electrons end up in a superconducting condensate. This condensate lacks any degree of freedom in order to qualify as a carrier of entropy. Therefore, in the superconducting state, only the "normal fluid," that is, electronic excitations which happen to exist due to their thermal energy at finite temperature, can carry heat. The number of such excitations decreases exponentially with temperature and at sufficiently low temperature, they cease to play any significant role in thermal transport.

Phonon heat transport is also affected by the superconducting transition. At the onset of superconductivity in many metals, electrons are a principal source of scattering for phonons. When this is the case, the condensation of electrons leads to a sharp enhancement in the phonon mean free path and the phonon thermal conductivity. At very low temperatures, an ordinary superconductor conducts heat in a manner analogous to an insulator.

The other consequences of the superconducting transition on the thermal conductivity of electrons and phonons generate a wide variety of behaviors in real superconductors. If the electrons are the dominant heat carriers at the onset of superconductivity, then the superconducting transition is accompanied by a rapid decrease in the thermal conductivity of the system. On the other hand, if for any reason (a low carrier density, a low mean-free path, a high critical temperature, etc.) the lattice contribution happens to be significant in the normal state, the thermal conductivity can increase below T_c reflecting the enhancement of l_{ph}. The superconductor should be clean enough for this to happen, otherwise the impurity scattering of phonons is such that the disappearance of electrons would not present any significant change in phonon scattering. Thus, according to the numerous relevant parameters of each case, the superconducting transition can lead to a reduction, to an enhancement, or to no change in the thermal conductivity of the system.

The picture of heat transport in superconductors in this article has been somewhat modified by the results of the last two decades of research on unconventional superconductors. In high-T_c cuprates, the entry of the system into the superconducting state is accompanied with an upturn in thermal conductivity. It is now generally believed that part of this enhancement is due to an increase in the electronic component of thermal conductivity. While there is still no microscopic understanding of what happens, this extraordinary situation is interpreted as a signature of strong electron–electron scattering present in the normal state of the cuprates. In other words, the suppression of electrons leads to a lower number of heat carriers with a longer mean-free path in such a way that the overall result is a significant enhancement of thermal conductivity. A second feature of interest is the complex structure of the superconducting gap in unconventional superconductors. Since their gap is anisotropic with a magnitude which becomes zero along definite orientations, low-energy electronic excitations can survive down to $T = 0$. The electronic thermal conductivity is not expected to be an exponentially decreasing function of temperature. This has been confirmed by experiments probing heat transport by these "nodal" quasiparticles.

Magnetic Excitations as Heat Carriers

In a magnetically ordered solid, a new type of heat carriers appear. The elementary excitations of a magnetic lattice are called spin waves or magnons and can transport heat in a manner analogous to phonons. Most of the considerations regarding phonons are relevant for magnon heat transport with Curie or Néel temperature replacing the Debye temperature as the relevant energy scale. A quantitative isolation of the magnon contribution to heat transport is, however, a difficult experimental task as the deconvolution of various terms in their presence is far from obvious.

Entropy carriers associated with spin degrees of freedom are also expected in metals close to a magnetic stability. Such excitations, often called spin fluctuations or paramagnons, are reported to produce a substantial enhancement of thermal conductivity in a number of exotic metals.

Thermal Magnetoresistivity and the Righi–Leduc Effect

A magnetic field has no direct effect on heat transport by phonons. Electronic thermal conductivity, on the other hand, is affected by a magnetic field in a manner analogous to the electric conductivity. Usually, it is diminished as the magnetic field disfavors transport by charged particles.

In type II superconductors, a magnetic field penetrates the solid in the shape of mesoscopic filaments called vortices. These superconducting vortices constitute a new type of scattering centers for heat carriers. The contribution of their own movement to heat transport is often negligible.

In the presence of a magnetic field, the electronic thermal conductivity tensor presents a nondiagonal term, κ_{xy}. The trajectory of charged carriers is skewed under the influence of the Lorentz force (or magnetically aligned scattering centers). This creates a transverse heat current, which is balanced by a transverse thermal gradient. This is the Righi–Leduc effect, sometimes dubbed the thermal Hall effect in analogy to the famous electric one.

Measuring Thermal Conductivity

Experimental methods to determine thermal conductivity fall into two broad groups. Steady state or "static" methods study a sample time-independent temperature profile and measure κ using eqn [1]. In contrast, non-steady-state or "dynamic" methods work with a time-dependent temperature. They often yield a quantity akin to thermal diffusivity.

Measuring the thermal conductivity of a solid implies a reliable determination of the temperature gradient produced by a heat current, and the quality of an experimental setup depends on its ability to yield accurate values of these two quantities. This proves to be more difficult than the analogous case of electrical conductivity since charge can only travel through conductors but heat can be transmitted by conductors, insulators, and even vacuum.

Confocal Optical Microscopy

M J Solomon and M Kogan, University of Michigan, Ann Arbor, MI, USA

Introduction

Confocal optical microscopy is a direct visualization method that is increasingly applied in condensed matter physics to study the structure and dynamics of complex fluids. The focus of this article is the theory and practice of confocal microscopy as it relates to the areas of colloid physics, experimental statistical mechanics, and microrheology. Available instrumentation and methods are classified and their limitations discussed. Auxiliary methods, such as fluorescent particle synthesis and quantitative image processing, are also summarized. Finally, current applications of confocal optical microscopy in condensed matter physics are discussed.

Principle of Confocal Optical Microscopy

Standard optical microscopy techniques, including microscopy by bright field and epifluorescence illumination, fail for the optically dense specimens that are typical of applications in materials science and condensed matter physics. The origin of the optical density is often a combination of scattering due to strong refractive index contrast, emission due to high fluorophore density, or attenuation due to the long optical path of an object plane located deep in the specimen. This problem was first encountered and addressed in the life sciences. There, methods were sought to image deep into cellular tissue without the need for laborious sectioning. The technology developed, called confocal optical microscopy, combines optical components typical of microscopy and scattering devices. In particular, the detection path typical of optical microscopy is modified by the addition of a confocal pinhole at the image plane. This pinhole arrangement is typical of light scattering detection optics in that the aperture rejects light not originating from the vicinity of the object plane. The rejection renders an image of the object plane detectable that would otherwise be overwhelmed by unfocused out-of-plane emission. When the confocal detection scheme is combined with the capability to actuate the object plane through the specimen, a powerful technique for the imaging of three-dimensional (3D) volumes is realized. While fluorescence imaging is the most common application of confocal microscopy, visualization of structure by scattered or reflected light is also feasible. **Figure 1** shows the difference in image forming capability for a gelled colloidal suspension (volume fraction of 10%) imaged by confocal and epifluorescence microscopy.

The direct visualization of image volumes by confocal microscopy has been fruitfully applied in many areas of condensed matter physics. In experimental statistical mechanics, application of quantitative image processing to 3D intensity maps generated by confocal microscopy has been used to quantify the thermodynamic and structural properties of glasses and gels comprised of colloidal particles. The field-induced and template-induced crystallization of novel colloidal phases has been observed and quantified. The 3D structure of mesoporous phases has been discovered. The diffusivity of fluorescent probes in polymer networks has been quantified. Particle tracking routines applied to time series of confocal image volumes have observed cooperative motion in colloidal suspensions. These observations can be used to understand the fundamental origins of the glass transition.

These aforementioned applications require understanding of the spatial and temporal resolution of confocal microscopy, application of image processing tools to quantify acquired image volumes, and synthesis of model materials suitable for confocal imaging. These issues are discussed in subsequent sections. First, the device configurations commonly used in confocal microscopy are classified.

Confocal Laser Scanning Microscopy

The conceptual idea of rejecting out-of-focus emission from the detector by adding an aperture to the detection system has been implemented in two principal ways. **Figure 2a** shows the confocal laser scanning microscope (CLSM). The confocal aperture is

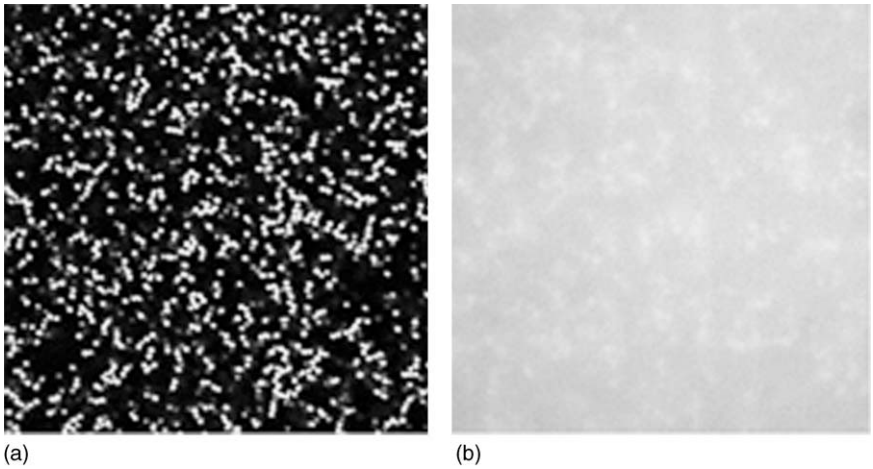

Figure 1 A depletion gel of fluorescent poly(methyl methacrylate) colloids $\sim 1.9\,\mu m$ in diameter dispersed in a refractive index and density-matched solvent imaged with a 1.4 NA objective by (a) confocal fluorescence and (b) epifluorescence microscopy. The comparison demonstrates the image-forming capability of confocal microscopy for the optically dense specimens that are characteristic of condensed matter physics and materials science.

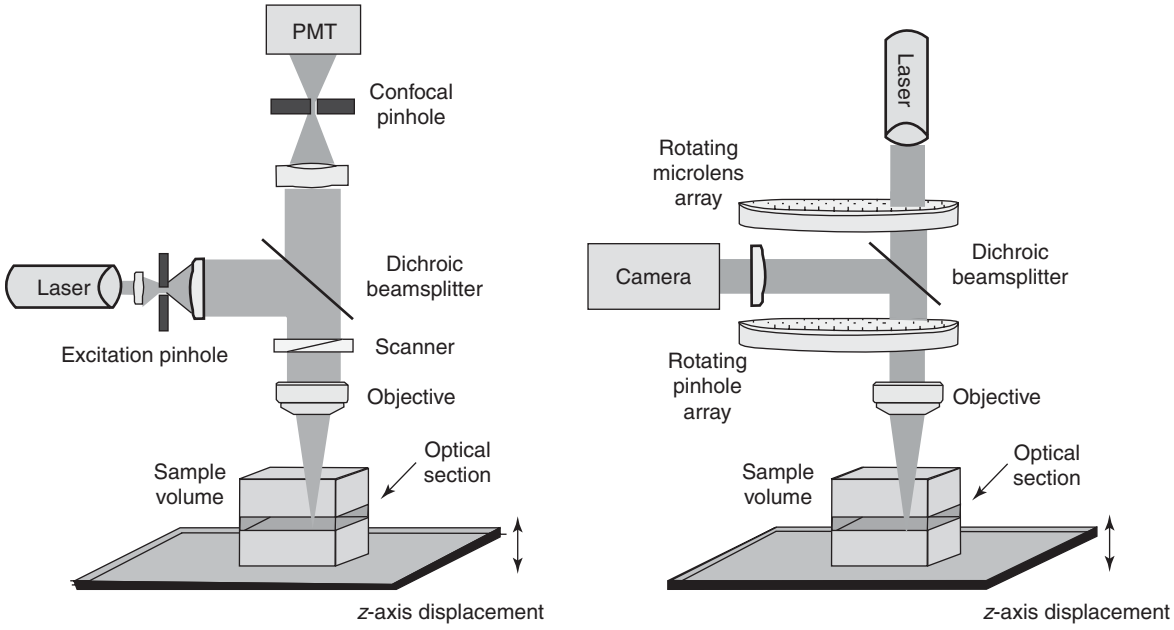

Figure 2 Schematics of the: (a) confocal laser scanning microscope and (b) Nipkow disk confocal microscope.

adjusted to accomodate the emission wavelength and to optimize the trade-off between axial resolution and emission collection efficiency inherent to confocal microscopy. In this configuration, the image is collected pointwise with a single detector, usually a photodiode or photomultiplier tube. In order to ensure sufficient emission from the excitation point in the objective plane, laser illumination is typical. Scanning mirrors manipulate the path of an expanded, spatially filtered source so that the illuminated point is rastered across the object plane. The speed of the galvanometrically actuated scanning mirrors determines the acquisition rate of a 2D image. At current capabilities a line scan can be executed at rates up to $\sim 1\,\text{kHz}$. Thus, a 512×512 pixel scan can be accomplished in less than 1 s. 3D image volumes are acquired by piezoelectric actuation of the specimen relative to the objective. This actuation can be conducted with nanoscale resolution and micrometer-scale repeatability. A $512 \times 512 \times 200$ 3D scan, a typical resolution, requires a few minutes with a best available CLSM.

Just as in the epifluorescence technique, in CLSM the excitation and emission illumination traverse the microscope objective in reverse directions. Typically, a dichroic beam splitter ensures that only emission from the specimen passes to the detector optics. Alternatively, an acoustooptic beam splitter provides flexibility in selecting transmission bands. CLSM is commonly used in fluorescence mode, and in some applications, it is of interest to monitor the emission of multiple fluorophores. Such detection is accomplished by excitation with multiple laser sources. The detection system must then separate the emission spectrum into bands corresponding to the wavelength ranges relevant to the multiple fluorophores. This decomposition can be accomplished with a cascade of dichroic filters. Alternatively, after the confocal pinhole, the emission can be spectrally resolved with a prism and adjustably filtered with mechanical slits before detection with a photomultiplier tube. Detection of up to four spectral regions is common. While fluorescence visualization is a frequent application of CLSM, some situations require analysis of reflected or scattered light. This method, called reflection CLSM, is of particular interest for measurements of topography in materials science and solid-state electronics.

The confocal imaging system is used in conjunction with the components of a standard optical microscope. In particular, the microscope objectives and specimen preparation for CLSM and optical microscopy are identical.

Variations on the design of **Figure 2a** include substitution of the confocal pinhole for a confocal slit. This configuration allows faster scanning with reduced resolution.

Nipkow Disk Confocal Microscopy

The pointwise scanning of CLSM imposes a significant limitation on the image acquisition speed of this method. The Nipkow disk confocal microscope, shown in **Figure 2b**, is an alternate method that can achieve video rate imaging. Current configurations

use two synchronized disks rotating at a rate that scans the image at 360 frames s^{-1}. One disk is patterned with an array of many thousands of pinholes. The pinhole diameter is optimized for high numerical aperture (NA) objective microscopy (optimization for NA = 1.4 is typical). The excitation illumination is chopped by the pinhole array. A second rotating disk, located prior to the pinhole disk, consists of a microlens array. Each microlens focuses excitation light onto a corresponding pinhole, thereby significantly increasing the excitation intensity supplied to the specimen. That is, the pinhole spacing must be significant relative to its diameter to reduce collection of defocused emission from one pinhole by a neighboring one. Thus, the pinhole disk has inherently low transmission efficiency without incorporation of the microlens array.

Emission from the specimen propagates through the rotating pinhole array in the reverse sense. In this case, each pinhole serves as the confocal aperture. The emission paths are diverted to the detection system by a dichroic beamsplitter. A photodiode array images the emission paths. Because the primary excitation is subdivided into a number of sources by the pinhole disk, multiple points of the objective plane are simultaneously interrogated. The read-out rate of the digital camera detector is currently the limiting step in the time required to acquire a 2D image. 3D image volumes are acquired by relative actuation of specimen and objective, just as for CLSM.

At full frame resolution, image acquisition rates for Nipkow disk confocal microscopy are about an order of magnitude faster than CLSM. However, because the primary incident laser source is subdivided into a number of beams, the excitation supplied to a particular point in the object plane is typically less than CLSM. In addition, the confocal aperture is not adjustable as is usually the case in CLSM.

Limits of Optical Resolution

Confocal microscopy presents unique opportunities for 3D imaging of microstructure; however, the method is an optical one and thus resolution limits are dictated by the wavelength of light. Here, two limits of optical resolution are considered. The first, resolution in the object plane (lateral optical resolution), is governed by the Rayleigh criterion. The second, resolution perpendicular to the object plane (axial optical resolution or optical section thickness), is dictated by the point spread function. The effect of confocal aperture diameter on resolution is also assessed.

The Rayleigh criterion labels two adjacent points in the object plane distinguishable if their airy diffraction disks (due to the finite aperture of objective) are resolved in the image plane. For unpolarized light, this lateral optical resolution is $0.61\lambda/\mathrm{NA}$ where λ is the wavelength of light and NA is the numerical aperture of the objective. For NA = 1.4, lateral resolution is $\sim 0.2\,\mu m$ and this is the best resolution currently possible for optical microscopy. The Rayleigh criterion is a useful estimate of lateral resolution in confocal microscopy.

In confocal microscopy, the criterion for axial object resolution commonly adopted is that two points oriented perpendicular to the object plane can be resolved if the first minima in their point spread functions (evaluated along the optical axis) are distinct. This criterion has the same physical basis as the one for the Rayleigh resolution and leads to a characteristic axial optical resolution of $2\lambda/(\mathrm{NA})^2$. For NA = 1.4, axial resolution is $\sim 0.5\,\mu m$, slightly greater than twice the lateral object resolution.

These resolution criteria are lower bounds. Actual devices achieve lower resolution due to polarization effects and nonidealities. For example, the confocal aperture diameter has a profound effect on optical section thickness. In scanning devices, this diameter is adjusted to optimize the trade-off between image intensity and axial resolution. Units scaled on characteristics of the diffraction point spread function are a convenient basis to specify the aperture diameter and its performance. The dimensionless lateral scale in the image plane is then $(2\pi/\lambda)(\mathrm{NA}/M)r_a$, where M is the magnification in the image plane and r_a is a particular image plane dimension such as the aperture radius.

Calculations and experiments for confocal visualization of well-defined geometries show that optical section thickness within a few percent of minimum is attained with a confocal aperture dimension that corresponds to one airy diffraction disk (cf. dimensional scaling above). Aperture reduction below this value yields only small improvement in resolution at the expense of reduced image intensity. As the confocal aperture is opened, progressively greater amounts of out-of-focus emission are admitted to the detector; however, resolution deteriorates. One way in which this effect has been quantified is by imaging a plane reflective coating. In this experiment, the half-width at half maximum of the axial intensity, a measure of the optical thickness, doubles as the aperture is increased from one airy disk to two. This experiment demonstrates that axial resolution is a severe function of the confocal aperture. **Figure 3** displays images that show the qualitative effect of confocal aperture on image intensity and resolution as the aperture is opened for a colloidal crystal of interest to soft condensed matter physics and materials science.

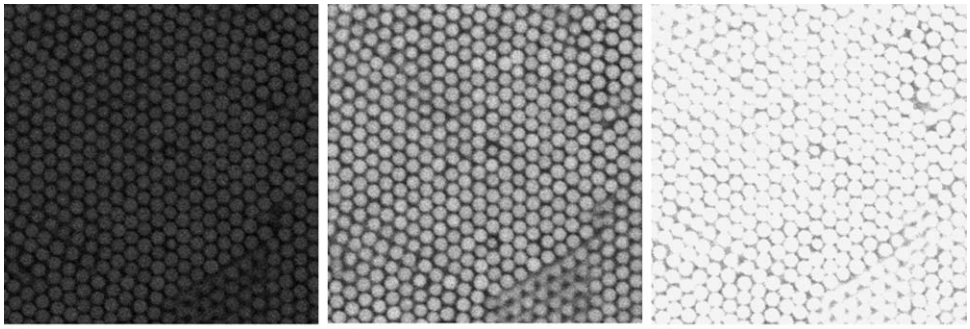

Figure 3 The effect of pinhole aperture on the image-forming capability of confocal laser scanning microscopy. In optical units nondimensionalized on the size of the airy diffraction disk, the images are for confocal apertures of 0.5, 1.0, and 2.0 (from left to right). The specimen is a colloidal crystal of colloidal poly(methyl methacrylate), diameter $\sim 1.9\,\mu m$, in a refractive index and density-matched solvent for which electrostatic interactions between the colloids have been screened by the addition of an organic salt.

The resolution of scanning confocal microscopes with slit apertures, developed for fast imaging, has also been studied by imaging a plane reflective mirror. In this case, the minimum axial thickness in the specimen achieved by a slit is $\sim 25\%$ greater than for a pinhole. In addition, in optical units, the half-width of the slit must be about a factor of 3 smaller than the pinhole radius to realize such a minimum axial resolution. This slit width reduces the intensity of the image received at the detector.

Model Materials for Confocal Imaging

Most applications of confocal microscopy in condensed matter physics have used fluorescent imaging. The need to incorporate fluorophores into structures to be imaged imposes a constraint on materials that can be studied. Thus, studies of experimental statistical mechanics and self-assembly using colloidal models require methods for syntheses of monodisperse colloidal particles. Determination of bulk behavior requires imaging deep within the sample, where effects of the sample boundary are minimized. To accomplish such imaging, the particle and suspending medium must be at least approximately refractive index matched; otherwise scattering reduces the intensity and image-forming quality of light returned to the detector.

A common approach to this challenge is to synthesize monodisperse colloids to which an oligomeric stabilizing layer is grafted to the particle surface. This steric layer ensures colloid stability in mixtures of organic solvents that match the refractive index of the colloid. A number of strategies exist to incorporate fluorescent dyes into silica or poly(methyl methacrylate) colloids during particle syntheses. For polymer colloids, the postsynthesis method of colloid swelling and dye absorption is also possible; however, these processes change the potential interactions between the colloids in ways that are poorly understood.

In addition to refractive index matching, solvent mixtures are often selected to match the density of particle and solvent so as to minimize colloid sedimentation (or flotation). Such particle motion, even when small, can destroy fragile gel or crystalline structures that arise due to the physical interactions between particles. Sedimentation also interferes with the study of Brownian and cooperative particle motion by particle tracking.

Long duration kinetic and dynamic studies require fluorescent dyes that are resistant to photobleaching. In the life sciences, the limitation of cytotoxity on dye concentration means that photobleaching is an important factor in dye selection. While the situation is less severe in condensed matter physics (because cytotoxic effects are absent), recent work has favored more photostable dyes over traditional ones such as fluorescein and rhodamine.

Quantitative Image Processing for Confocal Microscopy

The 3D map of fluorescent intensity provided by confocal microscopy is a powerful qualitative indicator of complex fluid behavior. An even more fruitful approach is to use image processing to extract quantitative measures of structure and dynamics from the fluorescence maps. In 2D microscopy, a number of approaches for the interrogation of particle locations using edge detection and thresholding have been developed. Alternatively, particles can be identified from local intensity maxima and their locations then refined to subpixel resolution according to the distribution of brightness in the vicinity of the

maxima. This latter approach, although computationally intensive, is readily extendable to the 3D particle location problem and has thus found wide application in confocal microscopy of colloidal systems. While estimates of the errors in particle location for these routines vary widely, the most significant determinant of the precision and accuracy of particle location is the delocalizing effect of Brownian motion on the timescale of image volume acquisition. For time series acquired at a rate such that the typical particle displacement is much less than the mean separation between particles, algorithms have been developed that reliably link particle locations in each frame into trajectories. This trajectory analysis yields dynamical information about Brownian and cooperative motion of the particles.

Once particle centroids and trajectories have been located, the information contained in the confocal image volumes has been transformed into output in the same format that would result from a computer simulation of a corresponding model system. (In a typical image volume of $40 \times 40 \times 20\,\mu m^3$ resolved by a high-resolution objective, the number of micrometer-sized particles is of order 10^4. This number is not too different from the state-of-the-art computer simulation.) Thus, all the tools of statistical mechanics developed for the analysis of molecular, Brownian, and Stokesian dynamics simulations can be applied to the experimental results. This formal correspondence between experiment and simulation offers an unusually rich avenue for direct comparison between the two. **Figure 4** displays the results of quantitative image processing of a depletion colloidal gel comprised of monodisperse fluorescent poly(methyl methacrylate) colloids of diameter $\sim 1.9\,\mu m$. The projections of the confocal image volume in two orthogonal planes qualitatively demonstrate the degree to which image processing methods locate the imaged particles.

Applications in Condensed Matter Physics

The qualitative fluorescence imaging and 3D sectioning capability of confocal microscopy have found wide application in the qualitative characterization of microstructure in colloidal suspensions, polymer gels, immiscible blends, and composites. Recently, the additional step of generating quantitative measures of complex fluid structure and dynamics from confocal microscopy has been taken. In this brief summary, the focus is on these new developments. These advances have been driven by three recent steps forward: (1) methods to synthesize monodisperse fluorescent colloidal particles have been discovered; (2) confocal microscopy, borrowed from the life sciences, has been applied to image materials comprised of colloidal particles; (3) techniques of quantitative image processing have been developed to extract the locations and trajectories of the colloidal particles.

Confocal microscopy has been used to interrogate the phase behavior of concentrated colloidal suspensions interacting through screened electrostatic forces. The self-assembly of colloidal particles into ordered crystals is a step in one method to produce photonic materials. The effect of an applied electric field on colloidal crystal structure has also been discovered. The nucleation and growth of crystal nuclei in colloidal suspensions has been directly visualized. The particle correlation function and coordination

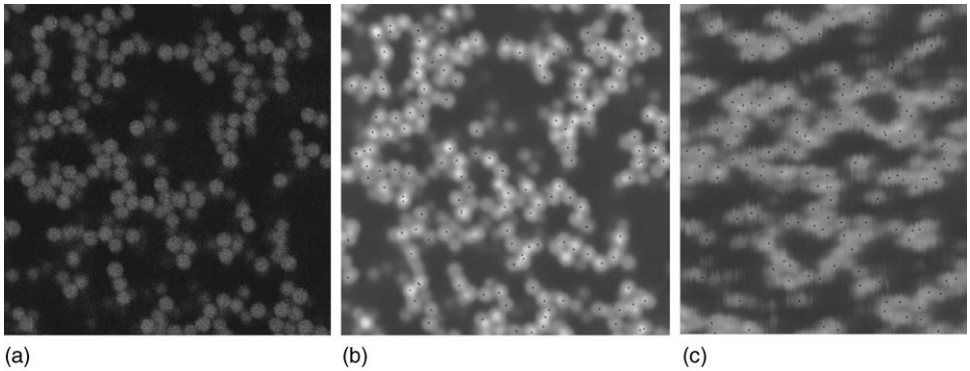

Figure 4 Illustration of methods for quantitative image processing. Image (a) is a representative 2D slice from a 3D image volume of a depletion gel of poly(methyl methacrylate) colloids (volume fraction of 10%, diameter 1.9 μm) imaged by CLSM. Image (b) shows a projection of ~20 2D lateral slices with an overlay of particle locations found within that volume by quantitative image processing. Image (c) shows a similar projection, but now in a plane that includes the axial direction of the microscope. Note that the optical resolution in the axial direction is reduced relative to the lateral direction because of the different characteristics of the 3D point spread function along the optical axis and in the objective plane.

number of hard-sphere glasses have also been quantified by direct visualization with confocal microscopy. Short-range attractive forces, included by conformational changes of grafted steric layers or by the depletion interactions induced by nonadsorbing polymer, lead to the assembly of amorphous gel structures. The clusters and voids that comprise these structures have been directly visualized with CLSM. Cooperative particle dynamics in the vicinity of the colloidal hard-sphere glass transition have been visualized by time-resolved confocal microscopy. The thermal fluctuations of gel backbone segments have likewise been quantified as have the flow-induced structures of colloidal gels as they are subjected to shear and compressional flow. These direct visualization studies of structure and dynamics in colloidal systems by confocal optical microscopy represent a new and fruitful approach to understand the behaviors of complex fluids that are of broad interest in soft condensed matter physics and materials science.

Copolymers

C Hagiopol, Georgia-Pacific Resins, Inc., Decatur, GA, USA

Introduction

Polymers and copolymers are macromolecular compounds. Polymers (homopolymers) are macromolecules with a uniform structure. Copolymers show heterogeneous compositions. Copolymer synthesis is a key to understanding the structure and properties of copolymers. Many organic compounds could be labeled as "monomers." However, despite the diversity of potential monomers, the number of industrially developed homopolymers is rather small. There are some applications, which demand a combination of physical and mechanical properties not available in any single polymer. It might seem possible to develop new materials showing a combination of properties by blending different homopolymers. Unfortunately, the mixing together of two dissimilar homopolymers usually does not result in a single compatible material, but rather in a biphasic mixture. Properties of physical blends are strongly dependent upon the degree of compatibility of the components. A very small number of high-molecular-weight amorphous polymer pairs are thermodynamically compatible, that is, truly soluble in each other. Incompatibility is observed in diluted solutions as well. This is a direct consequence of the well-known relationship for free energy (ΔG), given in the equation: $\Delta G = \Delta H - T\Delta S$. Due to their high molecular weight, polymers have very small entropies of mixing (ΔS). Therefore, even a slightly positive enthalpy (ΔH), generated by endothermic mixing, is sufficient to produce a positive free energy, thus resulting in incompatibility.

The incompatibility of the polymer blend provides a driving force for each to aggregate in separate phases. These two-phase morphological systems are coarse dispersions in which the particles are usually (a) large, (b) inhomogeneous, and (c) characterized by poor interphase adhesion. The poor interphase adhesion results in very poor mechanical properties. The properties of such mixtures are frequently unattractive because of defects arising from weakness, opacity, etc. It is possible to overcome these shortcomings by polymerizing a mixture of the two different monomers and obtain a mixture of the functional groups along the polymer chain.

The chain polymerization process in which two (or more) monomers are simultaneously polymerized is termed a copolymerization; its product is a copolymer.

During the copolymerization process, the macromolecular chain dimension depends on three statistic processes: initiation, propagation, and termination,

which are basically the same as those involved in polymerization processes. Different molecular chains will have different numbers of monomer units. A copolymer is a mixture of macromolecules having different lengths. Thus, a copolymer is always associated with an "average" molecular weight and with a molecular weight distribution. In the copolymer case, a new source of diversity is added to the molecular weight distribution: the chemical composition distribution. In terms of chemical composition distribution, two different aspects are recognized: on the one hand, there is a chemical distribution within a macromolecule (random or statistical, alternating, block copolymers), and on the other hand a difference in chemical composition between two molecules (e.g., molecules obtained at different conversions). This complexity can be further enhanced by changing the number of comonomers involved in copolymerization: two comonomers (binary copolymers), three comonomers (ternary copolymers), and so on. Very complex copolymer compositions are difficult to study but involve an immense potential for a large number of applications.

Almost all monomers with a carbon–carbon double bond undergo free-radical copolymerization. Ionic polymerization can be developed only on a limited number of monomers: monomers with electron-releasing substituents undergo cationic polymerization. Anionic polymerization occurs when electron-withdrawing groups are present.

Binary Copolymerization

Copolymerization reactions have been under investigation ever since the systematic study of polymer science began in the 1930s. Copolymers could not necessarily be expected to have the same composition as the mole ratio of the monomers in the feed mixture, but this was more likely to drift as the reaction progressed (conversion effect on copolymer composition). In binary copolymerizations, four chain-growth reactions [1]–[4] take place instead of a single chain growth in homopolymerization reactions. The rate of addition of a monomer to a radical (k_{ii} and k_{ij}) is assumed to be independent of the size and nature of the radical chain and is influenced only by the nature of the radical end group:

$$-M_1\bullet + M_1 \overset{k_{11}}{\rightarrow} -M_1\bullet \qquad [1]$$

$$-M_1\bullet + M_2 \overset{k_{12}}{\rightarrow} -M_2\bullet \qquad [2]$$

$$-M_2\bullet + M_2 \overset{k_{22}}{\rightarrow} -M_2\bullet \qquad [3]$$

$$-M_2\bullet + M_1 \overset{k_{21}}{\rightarrow} -M_1\bullet \qquad [4]$$

The assumption of a steady-state condition – $k_{ij}[M_i\bullet][M_j] = k_{ji}[M_j\bullet][M_i]$ – for the elementary reaction leads to an equation for instantaneous (m_i) copolymer composition

$$\frac{dM_1}{dM_2} = \frac{m_1}{m_2} = \frac{M_1}{M_2}\frac{r_1M_1 + M_2}{M_1 + r_2M_2} \qquad [5]$$

The parameters r_1 and r_2 are the monomer reactivity ratios and provide a measure of the preference a free radical has for reacting with its own monomer rather than with the comonomer in the mixture: $r_1 = k_{11}/k_{12}$ and $r_2 = k_{22}/k_{21}$. The reactivity ratios express the monomer relative reactivity with a copolymerization process. They are always positive. Any negative value is a miscalculation. Equation [5] shows that the copolymer composition depends on the comonomers (feed) composition and on the reactivity ratios. If $r_i < 1.0$, then the cross-propagation reactions – [2] and [4] – are faster than the homopropagation reactions – [1] and, respectively, [3]. Large values of r_i will then be indicative of a tendency to form long homopolymer sequences, whereas small values of r_i imply rapid cross-propagation reactions and represent a tendency towards alternation.

Styrene is the most used comonomer in copolymerization studies. An empirical scheme (Q–e scheme, where Q is the resonance stabilization parameter and e is the electronegativity parameter) was developed in order to characterize the monomer capabilities to be involved in a copolymerization process. In that empirical scheme, styrene was chosen as the standard ("reference monomer"). **Table 1** shows the copolymer composition (obtained at a very low conversion, $<1.0\%$) calculated by using eqn [5], for styrene copolymerization with different comonomers. For a given styrene concentration in the feed, the resultant copolymer will have different compositions: 24.6% styrene in the copolymer with *p*-methylstyrene, 35% styrene in the copolymer with vinyl methyl ketone, 50% in the copolymer with maleic anhydride, and 95% in the copolymer with vinyl acetate. When $r_1 \sim r_2 \sim 1$ (styrene/*p*-methyl styrene copolymerization), the copolymer composition is almost identical to the feed composition for the entire range of the feed composition ("ideal" copolymerization). That is a rare case. When $r_1 \ll 1.0$ and $r_2 \ll 1.0$ (styrene/maleic anhydride copolymerization), the comonomer ratio is ~ 1.0 (alternating copolymer) regardless of the feed composition. Due to a much more reactive styrene monomer ($r_1 \gg r_2$), the copolymer with vinyl acetate is very rich in styrene even at low styrene concentrations in feed.

Within a copolymer macromolecule, the probability that a monomer M_1 will add onto a radical

chain terminating in its own species, thereby forming an $-M_1-M_1\bullet$ sequence is

$$p_{11} = \frac{r_1}{r_1 + (M_2/M_1)}$$

In a similar way,

$$p_{22} = \frac{r_2 M_2}{r_2 M_2 + M_1}, \quad p_{12} = \frac{M_2}{r_1 M_1 + M_2}$$
$$p_{21} = \frac{M_1}{r_2 M_2 + M_1}$$

(also $P_{12} = 1 - P_{11}$ and $P_{21} = 1 - P_{22}$). The copolymer composition shows a statistical distribution of monomer units. Therefore, the sequence length reciprocals of conditional probabilities could be expressed as a number-average: $\bar{N}_1 = r_1(M_{10}/M_{20}) + 1$ and $\bar{N}_2 = r_2(M_{20}/M_{10}) + 1$. For alternating copolymers, $r_1 \ll 1.0$ and $r_2 \ll 1.0$ and $\bar{N}_1 = 1$ and $\bar{N}_2 = 1$.

This type of copolymer characterization is valid at very low conversion values only. Due to the differences in comonomer reactivity ($r_1 \neq r_2$), the unreacted comonomer composition (instantaneous "feed" composition, M_i and M_j) and the instantaneous copolymer composition ($m_i = (M_{i0} - M_i)/(1 - M_i - M_j)$) may drift with conversion (C) during batch copolymerization (eqn [6]).

$$C = 1 - \left(\frac{M_1}{M_{10}}\right)^{r_2/(1-r_2)} \left(\frac{M_2}{M_{20}}\right)^{r_1/(1-r_1)} \times \left(\frac{M_{10} - \frac{1-r_2}{2-r_1-r_2}}{M_1 - \frac{1-r_2}{2-r_1-r_2}}\right)^{(1-r_1r_2)/(1-r_1)(1-r_2)} \quad [6]$$

For styrene-vinyl-acetate copolymerization, **Figure 1** shows the unreacted styrene concentration (calculated with eqn [6]), which decreases (from the initial value of 0.25 mole fraction) as the conversion increases. Consequently, a greater amount of the other comonomer (vinyl acetate) is incorporated in the instantaneous copolymer. At ~30% conversion, there is no styrene left and a vinyl acetate homopolymerization starts.

The final material is a blend of a styrene–vinyl acetate copolymer having a styrene content ranging from 0.95 to 0 mole fraction. About 70% of that material is polyvinylacetate. That can result in less valuable heterogeneous products. By controlled feeding of the monomers into the polymerization reactor, it is possible to regulate the sequence distribution in random copolymers and obtain homogeneous copolymers up to high conversions.

Ternary Copolymers

The relative ratio between two comonomers is different in ternary copolymerization from that in the corresponding binary copolymerization. For styrene-*p*-methyl styrene copolymerization (almost an "ideal" copolymerization case – see **Table 1**), the presence of a third comonomer (acrylonitrile, see **Figure 2**) will change the ratio between styrene and *p*-methyl styrene in the copolymer. This change is more important at higher acrylonitrile concentrations and higher conversions.

Block Copolymers

Block copolymers are macromolecules of two or more chemically different chains joined together by covalent bonds. A variety of molecular architectures are

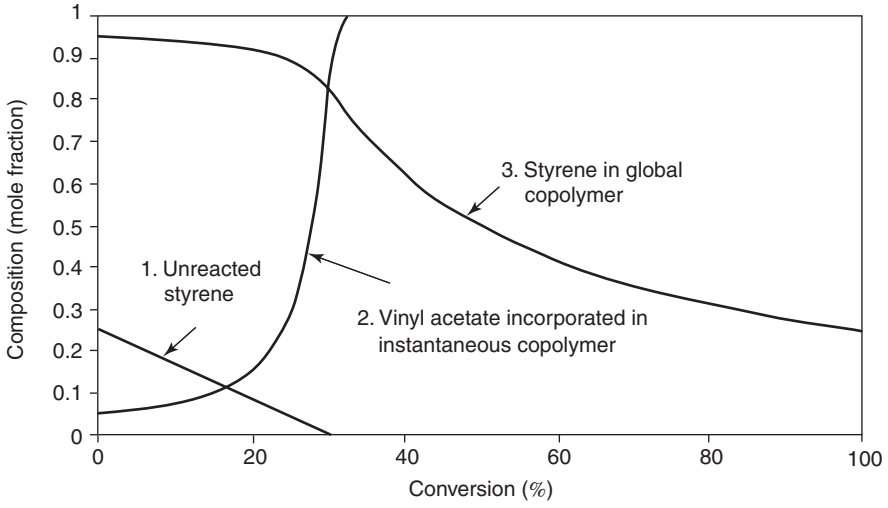

Figure 1 Styrene copolymerization with vinyl acetate: copolymer composition (instantaneous and overall composition) and the unreacted comonomer composition as a function of conversion.

Table 1 Styrene copolymerization

Styrene in feed (mole fraction)	*Styrene (M_1) in copolymer (mole fraction) for different copolymerizations*					
	M_2: p-methyl styrene		*M_2: maleic anhydride*		*M_2: vinyl acetate*	
	$r_1 = 0.89$	$r_2 = 0.99$	$r_2 = 0.05$	$r_1 = 0.005$	$r_2 = 56.0$	$r_2 = 0.01$

0.25	0.246		0.500		0.950	
0.50	0.487		0.511		0.983	
0.75	0.735		0.536		0.994	

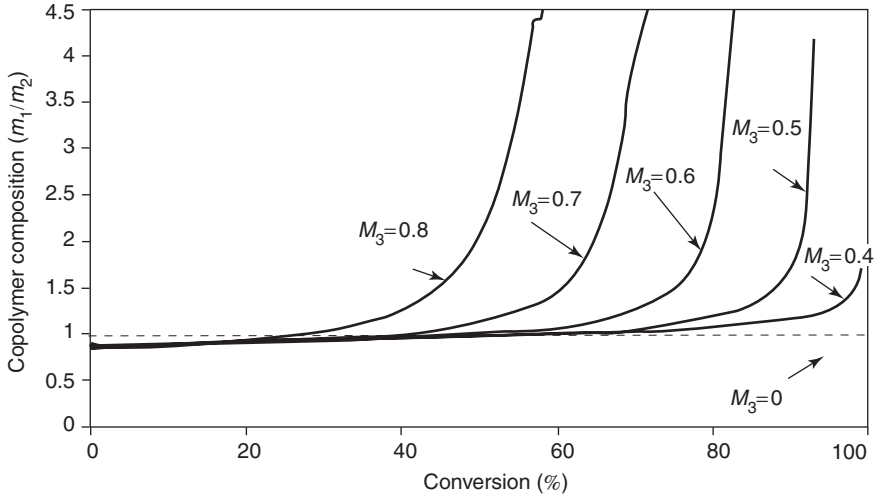

Figure 2 Ternary copolymerization of styrene (M_1) with *p*-methyl styrene (M_2) and acrylonitrile (M_3): the change in copolymer composition (styrene/*p*-methyl styrene ratio) with conversion, for different initial concentrations of acrylonitrile.

possible, for example, AB diblock, ABA triblock, and starblock copolymers. A block may have just one or a maximum of two covalent bonds with other blocks. The bonds are located at the ends of the blocks. There is an extreme case of statistical copolymers obtained through free-radical copolymerization ($r_1 \gg 1.0$ and $r_2 \ll 1.0$) when long sequences of $-M_1-$ units (blocks) are obtained. After the M_1 block, only one unit of M_2 can be inserted. For styrene (M_1) copolymerization with vinyl acetate ($r_1 = 56$ and $r_2 = 0.01$), and a molar ratio of monomers in feed of 1:1, the styrene block length will be of 57 units ($\bar{N}_{St} = 57$ and $\bar{N}_{VAc} = 1$): –[–A–]$_{57}$–[–B–]–[–A–]$_{57}$–[–B–]–. This type of copolymer is not yet a block copolymer.

Block copolymers may be synthesized by a special technique, which represents somehow a limitation in the final block copolymer structures. Special monomer structures and special catalysts are required in order to get a desired block copolymer structure. In ionic polymerization, monomers show a different reactivity as compared to the free-radical mechanism. In anionic copolymerization with butadiene, styrene has a reactivity ($0.02 < r_{St} < 0.04$) of ~ 10 times lower than in free-radical copolymerization ($0.4 < r_{St} < 0.6$). With the same type of process, butadiene is 10 times more reactive in anionic copolymerization ($11 < r_{Bu} < 14$) than in free-radical copolymerization with styrene ($1.3 < r_{Bu} < 1.5$). When styrene and butadiene (1:1 molar ratio) are charged together with the lithium alkyl catalyst solution into a batch reactor, the butadiene molecules polymerize first and with almost total exclusion of any styrene present: a long block of butadiene units is developed ($\bar{N}_{Bu} = 15$) before a styrene unit is incorporated. Only when all the butadiene monomers are consumed does styrene enter the polymer chain.

Living anionic copolymerization provides the maximum degree of control for the synthesis of copolymers with predictable well-defined structures. In order to retain the growing free-radical activity and for a narrow-molecular-weight distribution of polymers, living polymerization requires the absence of chain transfer and termination reaction. Block copolymers can be prepared by sequential monomer addition. Living cationic polymerizations are much more difficult to achieve. It is possible

to obtain block copolymers by a free-radical mechanism by reversible addition–fragmentation transfer (RAFT).

Much of the interest in block copolymers has arisen because of their remarkable microphase morphology. Block copolymers show properties quite different from either a random copolymer or a macroscopic blend of the corresponding two homopolymers. The component blocks are usually thermodynamically incompatible. That is why one of the characteristic features of block copolymers is the tendency for microphase separation to occur in the solid. This separation imparts many of the interesting and desirable properties displayed by block copolymers. The morphology of such multiphase systems influences their behavior and can be controlled by altering the ratio of block lengths, the molecular weight distribution, and the nature of the comonomers. The phase separation occurs in a block copolymer when the block molecular weights are higher than those required to produce phase separation in a blend of the corresponding homopolymers. The increasing tendency for segregation is stronger as the temperature decreases. In the majority of cases, the two types of polymer chains are not thermodynamically compatible but they are constrained to coexist at a molecular level by the bonds between them. In an AB poly(styrene-*b*-butadiene), up to a polystyrene content of $\sim 65\%$ the polystyrene is in the dispersed phase. At higher polystyrene contents, phase inversion takes place. In the presence of a solvent, as individual blocks are mutually incompatible, there is a ternary system in which the component blocks may interact with the solvent to different degrees. When a solvent is "good" for one block but "poor" for the other, anomalies in intrinsic viscosity–molecular-weight relations were observed. These anomalies are due to the tendency of the blocks with poor solvation to aggregate and form a micellar structure. The phase separation in the solution looks like the solid-state microstructure.

Graft Copolymers

Graft copolymers are macromolecules of two or more different chemical chains in which a chain (named backbone) has multiple branches formed from macromolecular chains with a chemical composition different from that of the backbone. The covalent bonds are randomly distributed along the backbone chain and are located at the end of the grafted branch. Unlike block copolymers, the graft copolymer can be synthesized more easily. Any macromolecular compound and almost any comonomer can be involved in a grafting process. Acrylonitrile–styrene–butadiene (ABS) grafted copolymers are synthesized by styrene–acrylonitrile copolymerization in the presence of the polybutadiene homopolymer. The grafted branches are formed through a chain transfer to polybutadiene, or by copolymerization of the vinyl double bond from polybutadiene. Macromonomers copolymerization is an elegant way to synthesize a graft copolymer. Polyethyleneoxide acrylate can be copolymerized with another acrylic ester, and a polyacrylate grafted with polyethylene-oxide will result.

The chemical structure of cellulose (poor solubility in common solvents, lack of thermoplasticity, etc.) can be modified by preparing a graft copolymer of cellulose, a process in which attempts have been made to combine synthetic polymers with natural polymers to produce materials with the best properties of both. Cellulose molecules are modified through the creation of branches of synthetic polymer that confer certain desirable properties to cellulose without destroying its intrinsic properties.

Copolymers in Blends

Many copolymers obtained at high conversion are blends. Their behavior in a complex mixture is of great interest. The compatible blends are characterized by a single-phase morphology. In the case of a homogeneous blend of two homopolymers, the glass transition temperature (T_g) will follow the simple additive rule (Fox equation): $1/T_g = (W_1/T_{g1}) + (W_2/T_{g2})$. An inhomogeneous blend will display at least two major glass transitions. A free-radical copolymer with a narrow chemical composition distribution has only one glass transition temperature. It has been shown that the T_g of a copolymer does not always obey the Fox equation. It is better described by the equation below, which takes into account the two consecutive monomer units (DYAD) distribution (AA, BB, AB, BA linkages on the chain backbone):

$$\frac{M_{cop}}{T_g} = \frac{[AA]M_a}{T_{gaa}} + \frac{[BB]M_b}{T_{gbb}} + \frac{[AB]M_a + [BA]M_b}{T_{gab}}$$

Most of the copolymers are actually blends of various copolymers with different chemical compositions. Styrene–methyl methacrylate copolymers with only a difference of 5% in styrene content become incompatible. They are blends and the "blends" issue is open to many choices. At similar compositions, both block copolymers and graft copolymers should be subjected to similar thermodynamic driving forces for phase separation, phase-size constraint, and compatibility with homopolymer mixture.

Block and graft copolymers are amphiphilic molecules because they may have affinity for two different types of environments. In a dispersed system, the graft and/or block copolymers self-organize at the interface and modify interfacial properties to a great extent, thus enhancing phase compatibility. In order to do so, their blocks or branches should be different enough and with a real affinity for those phases. Block and graft copolymers act as oil in oil emulsifiers. They may be absorbed at various surfaces: liquid/gas, liquid/liquid, solid/liquid, etc. The surface-active properties of block and graft copolymers have made them useful as dispersants, emulsifiers, foam stabilizers, and wetting agents. A large class of compatibilizers has been developed. Very attractive blends have been envisaged: inorganic fillers dispersed in rubber of plastic materials, wood flower dispersed in polyolefines, and glass fibers as reinforcement for tires. ABS copolymers consist of a dispersion of polybutadiene rubber particles in a matrix of styrene–acrylonitrile copolymer. Some of the styrene–acrylonitrile–copolymer (SAN) copolymer molecules are grafted to the rubber during polymerization. The grafted SAN acts as a dispersing agent.

Core Photoemission

P Padova and P Perfetti, CNR-ISM, Rome, Italy

Introduction

The photoemission technique is based on the extraction of an electron from a system (atoms, molecules, and solids) by a photon of energy $h\nu$. In core photoemission spectroscopy (CPS), the photon energy is sufficient to excite the electron from the core level into the vacuum. The first applications of CPS, also known as electron spectroscopy for chemical analysis (ESCA), used $Mg_{k\alpha}$(1254 eV) and $Al_{k\alpha}$(1486.6 eV) photons emitted by conventional X-ray sources. ESCA made it possible to study core levels and opened up an extraordinary as well as prolific field of research in physical chemistry. This kind of spectroscopy benefited from the advent of synchrotron radiation (SR), which is a brilliant, continuous radiation ranging from the infrared to X-rays. The electrons circulating at relativistic energy in a storage ring emit SR. The photon energy tunability of SR and the high-energy resolving power of the monochromators ($E/\Delta E \approx 10\,000$, from vacuum ultraviolet to X-rays) of third-generation SR machines have increased the accuracy of spectroscopic data. Thus, it is now possible to explore with more details the physical phenomena related to clean reconstructed surfaces and to the formation of adsorbate/substrate systems and band discontinuity at interfaces. Since the escape depth of electrons from a solid can be varied by an appropriate choice of the photon energy, it is also easier to separate bulk from surface effects and thereby improve the agreement between experiments and theory.

Here, the basic principles of core-level photoelectron spectroscopy are presented first and the origin of core-level lineshape broadening is then reviewed with the help of some experimental examples. Later, the concept of core-level binding energy is analyzed, taking into account all the possible mechanisms responsible for core-level chemical shifts, and some *ad hoc* experimental results are

illustrated. Finally, photoelectron diffraction for the determination of the surface/interface geometry and Schottky barrier height are examined, with the use of a few examples of CPS applications.

Basic Principles

In photoemission, a system containing N electrons in the initial state is left, after excitation, in a final state with $N-1$ electrons and one hole. The energy of the outgoing electron is influenced by the interaction between the photoelectron itself and the ionized system that is left behind. If the interaction is negligible (the so-called sudden approximation) and the photoelectron kinetic energy (E_k) is high, one can derive E_k (see **Figure 1a**), using Einstein's argument (proposed in 1905) to explain the photoelectric effect

$$E_k = h\nu - |E_B| - \Phi$$

where $h\nu$ is the energy of the incoming photon, Φ the work function of the emitting material, and E_B the one-electron binding energy (BE) of the core-level.

In the one-electron approximation, it is assumed that the $(N-1)$ electron orbitals will be the same in the final state as they were in the initial state. This is the so-called "frozen-orbital approximation." **Figure 1a** is an energy diagram of the photoexcitation of electrons in a solid; the vacuum energy E_{Vac} represents the zero of energy. In a solid, the core-level binding energy usually refers to the Fermi level, E_F. By measuring the kinetic energies of the photoelectrons emitted in the vacuum, it is possible to probe the occupied electron states of the system. Since every element has its own characteristic core-level spectrum, irrespective of the material it belongs to, CPS analysis is an extraordinary tool for identifying different atomic species in a chemical compound. An example of CPS analysis is the photoelectron spectrum of the indium arsenide clean surface shown in **Figure 1b**. In addition to the valence band emission at high kinetic energy, and secondary contribution peaked at low kinetic energy, two doublets are clearly visible. They have the binding energies characteristic of indium (In) 4*d* shells and arsenic (As) 3*d* shells, with angular momentum 5/2 and 3/2, respectively. Each level is separated by the spin–orbit interaction, which gives rise to the formation of a doublet. The spectrum in **Figure 1b** distinctly shows the In and As atomic species.

When there is strong interaction between the electrons and the potential of the photohole, the valence electrons get rearranged, with subsequent excitation of the rest of the system. This process costs energy and, as a result, the excited photoelectrons will

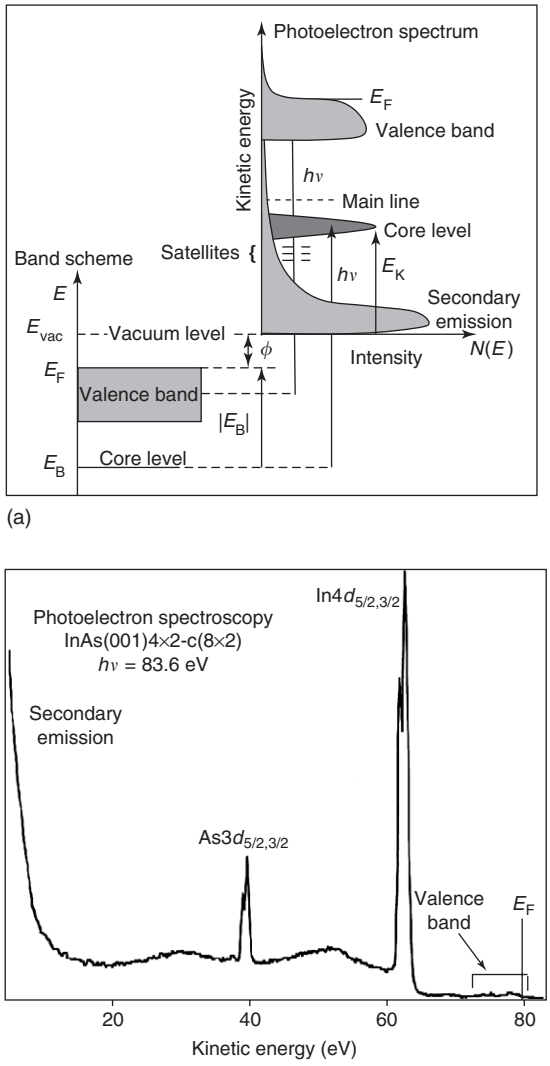

Figure 1 (a) Energy diagram of photoexcitation of electrons in a solid. Secondary emission, core-level, and valence band form the photoemission spectrum for no electron–electron interaction. Dotted lines: core-level main and satellite lines for electron–electron interaction (b) Photoelectron spectrum of the InAs clean surface. Valence band emission at high kinetic energy (in the vicinity of the Fermi level), secondary contribution, and two doublets of In4$d_{5/2,3/2}$ and As3$d_{5/2,3/2}$ at low kinetic energy.

appear at a lower binding energy (main line) than in the case of no interaction; the main line will be accompanied by extra lines, called "satellite lines," at higher binding energy (**Figure 1a**).

In a metal, the relaxation process can be due to electron–hole pair excitations at the Fermi level giving rise to an asymmetric core lineshape, or to collective electron oscillations related to the positive lattice ions (plasmons). Note that this phenomenon is intrinsic to the photoemission process and should be distinguished from extrinsic interaction of the photoexcited electrons with the other electrons of the system, along their path to the vacuum. Extrinsic

interactions can be simply described as scattering events that give rise to a smooth background of secondary electrons superimposed on the intrinsic primary photoelectron contribution and on a huge structure at very low kinetic energy (see **Figure 1b**).

Here, the expression of the photocurrent detected in a CPS experiment, with some approximations, is given

$$I \propto \sum_{f,i,k} |\langle \phi_{f,Ek}|\boldsymbol{r}|\phi_{i,k}\rangle|^2 \sum_s |c_s|^2 \cdot \delta(E_{f,k} + E_s(N-1) - E_0(N) - h\nu)$$

It is assumed that the final state, with $N-1$ electrons, has s excited states with energy $E_s(N-1)$; E_0 is the ground-state energy of the N electrons and $E_{f,k}$ is the kinetic energy of the photoelectron promoted from the initial state $\phi_{i,k}$ to the final state $\phi_{f,Ek}$. $|c_s|^2$ is the probability that the removal of one electron from the ground-state orbital ϕ_k is accompanied by the excitation of s states in the $N-1$ electron system. The energy conservation derived from the delta function in the relation tells one that, in addition to the main peak, a certain number of satellite structures due to the excitation of the system are left after the creation of a hole.

In a CPS experiment, the photoelectron intensity measured by the detector is the result of three separate processes: (1) the optical excitation of an electron, viewed as a purely bulk transition between the initial and final Bloch states of the crystal, (2) the propagation of the excited electron toward the surface, and (3) the escape of the photoelectron from the solid into the vacuum. This representation is known as the "three-step model" (**Figure 2**) and is most commonly used for interpreting CPS spectra because it is simple and the photoemission results are directly comprehensible.

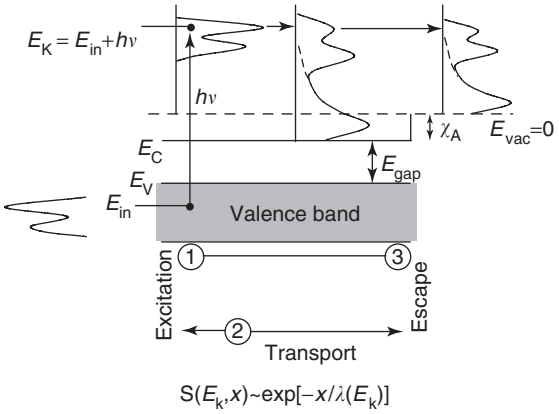

Figure 2 Three-step model. Step one: primary electron excitation. Step two: electron transport to the surface. Scattering processes reduce the primary-emission intensity and produce the secondary electron contribution, which is superimposed on the primary. Step three: transmission into the vacuum; here, the electron distribution is modified by the potential step at the surface. All energies are referred to E_{vac} which is set to zero.

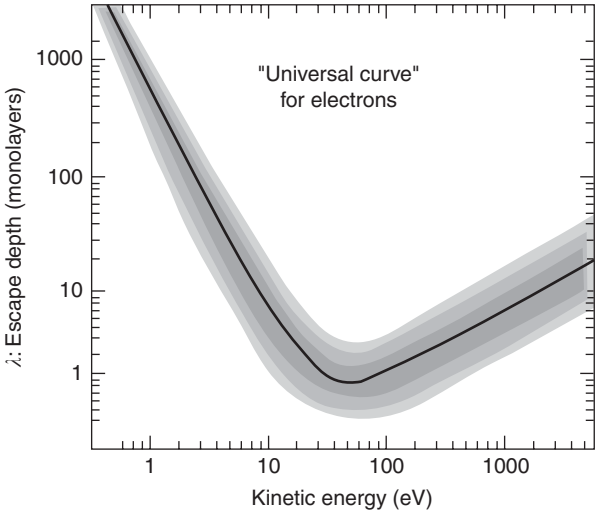

Figure 3 "Universal curve" for the kinetic energy dependence of the electron escape depth in a solid (λ).

Escape Depth and Surface Sensitivity

It has been seen that the photoelectrons lose energy while they travel to the surface and that many of them are unable to escape into the vacuum. The probability $S(E_k,x)$ that an electron with kinetic energy E_k, photoexcited at a distance x from the surface, will escape is given, in a first approximation, by

$$S(E_k, x) \propto \exp[-x/\lambda(E_k)]$$

where $\lambda(E_k)$ is the escape depth. **Figure 3** shows the so-called universal curve for the excited electrons escape-depth dependence on the kinetic energy. This curve, which is an average of measurements made on several different materials, establishes the dependence of λ on the kinetic energy of the emitted electrons. One can see from the figure that λ varies from tens of angstroms at low kinetic energy to a minimum of ~ 3 Å for $E_k = 50$ eV and then again up to ≈ 40–50 Å for $E = 1000$ eV. An interesting aspect of this behavior is that the photon energy can be chosen such that the surface or the bulk contribution shows up clearly in the CPS spectrum. It is to be noted that these contributions have different core-level binding energies because the surface and bulk atoms are not equivalent owing to the different chemical environments. However, this concept is explained in detail in the section on Si. For most of the elements, surface sensitivity is obtained for electron kinetic energies ranging between 20 and 50 eV. For Si, this minimum

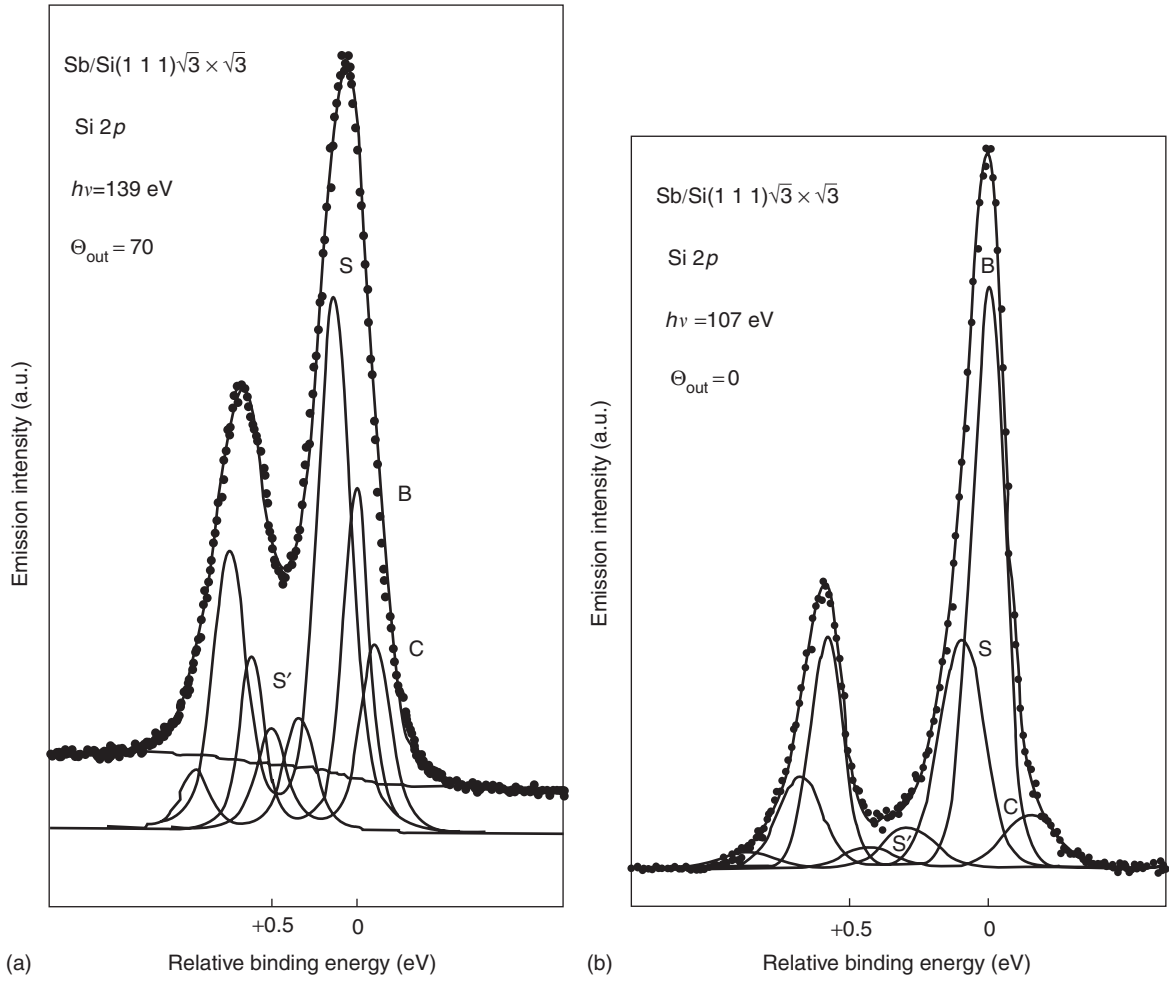

Figure 4 (a) Surface-sensitive ($\Theta = 70^\circ$, photon energy $h\nu = 139$ eV) and (b) bulk-sensitive ($\Theta = 0^\circ$, photon energy $h\nu = 107$ eV) Si 2*p* core levels on Sb/Si(1 1 1)$\sqrt{3} \times \sqrt{3}$. Also shown is bulk- and surface-component convolution of the spectra. (Reproduced from Cricenti, *et al.* (2000) Sb-terminated Si(1 1 0), Si(1 0 0), and Si(1 1 1) surfaces studied with high resolution core-level spectroscopy. *Applied Surface Science* 162–163: 380–383, with permission from Elsevier.)

corresponds to two layers (the Si lattice parameter is $a = 5.43$ Å). This small escape depth makes it possible to detect below one monolayer (ML) of chemically altered atoms at the surface or at an interface. (One ML is defined as the number of deposited atoms that equals the number of surface atoms of the substrate.) If it is impossible to exploit a tunable photon energy source, the surface effect can be enhanced by changing either the light incidence angle or the electron emission angle, or by taking advantage of the selection rules that support surface excitation processes. **Figure 4** shows the surface- and bulk-sensitive Si 2*p* core levels taken on the Sb/Si(1 1 1)$\sqrt{3} \times \sqrt{3}$ interface using SR. The spectra were collected at different surface sensitivities with emission angles $\Theta = 70^\circ$ ($\Theta = 0^\circ$) and photon energies of $h\nu$ 139 eV (107 eV). Convolution of the spectra will give rise to different components (for the convolution procedure, see the following section). To the left of the figure, the surface S contribution, due to interaction between Sb and Si atoms, dominates the spectrum because the escape depth parameter is minimum. On the other hand, the spectrum taken at lower photon energy and $\Theta = 0^\circ$ shows a dominant bulk contribution because of the increased escape depth λ.

Core-Level Lineshapes

In a core-level spectrum, three main contributions affect the lineshape:

1. *Core-hole lifetime*. The hole does not live infinitely. It can recombine with one of the outer electrons and the recombination energy can be released, with the emission of a photon (fluorescence), or transferred to an electron residing in another shell. The electron is then excited into the vacuum, and this is known as the Auger process

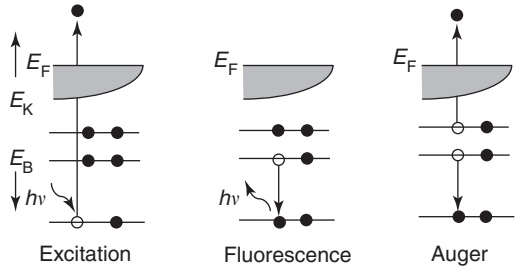

Figure 5 Schematic diagram of two possible electron–hole recombination processes after photoexcitation. In the fluorescence process, recombination arises with the emission of a photon. In the Auger process the recombination energy is transferred to another electron, with the formation of two holes.

(see **Figure 5**). The Heisenberg uncertainty principle states that the shorter the recombination time, the larger the uncertainty in one's knowledge of the energy of the emitted core electron, and hence one gets a wider lineshape. The intensity of the fluorescence and Auger processes depends on the atomic number Z of the atomic species considered, and the fluorescence channel is dominant for a high Z value. Both processes are responsible for the so-called intrinsic core-level lifetime.

2. *Phonon broadening*. This is a final-state effect and is due to the excitation of very low energy phonons (quantum lattice vibrations).
3. *Instrumental resolution*. This mainly depends on the monochromator and electron-energy analyzer and is usually calculated by a convolution of the two contributions.

The three sources of core-level broadening are generally well described by a Lorentzian and two Gaussian lineshapes. The Lorentzian function is characterized by a very sharp, narrow peak with most of its intensity located in the tails and is given by

$$F_L(E) \propto \Gamma_L^2/[(E - E_0)^2 + \Gamma_L^2]$$

where E_0 is the peak energy position and Γ_L is the full width half maximum (FWHM). The broadened lineshape, termed Gaussian, tends to have much smaller wings and greater intensity under the center peak than the Lorentzian lineshape and is given by

$$F_G \propto \exp(E - E_0)^2/\Gamma_G^2$$

where E_0 is the peak energy position and Γ_G is the FWHM. A best fit to the experimental data is usually performed with a theoretical Voigt function, which is a convolution between a Lorentzian and a Gaussian function. In a CPS spectrum, this analysis applies both to the surface and to the bulk contributions. The phonon broadening is easily derived from the Gaussian width once the experimental resolution is known.

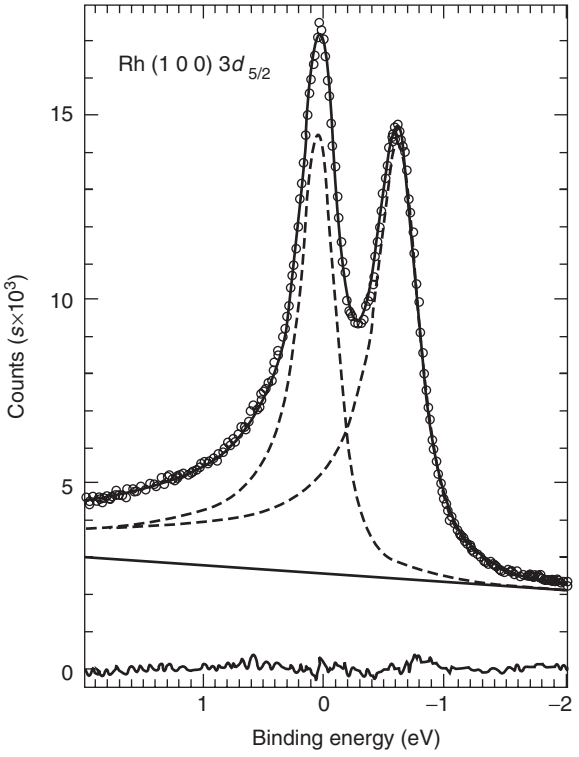

Figure 6 Core-level spectrum of Rh3$d_{5/2}$, showing the bulk peak and the surface chemical-shifted component (dashed lines). The data were taken on the clean (1 0 0) surface of Rh at a photon energy of 390 eV. The Doniach–Sunjic convolution (full line) closely reproduces the experimental result (open dots), particularly the asymmetric part due to the electron–hole pair excitation caused by core-hole screening. (Reproduced from Zacchigna, *et al.* (1996) Photoemission from atomic and molecular adsorbates on Rh(1 0 0). *Surface Science* 347: 53–62, with permission from Elsevier.)

Other possible sources of broadening are imperfections in the crystal, such as defects, surface reconstructions, and inhomogeneous strains, which are generally considered to affect the Gaussian width. Since these contributions are difficult to quantify, it is practically impossible to determine the intrinsic core-level lifetime. One of the goals of experimentalists is to reduce sample imperfections so as to obtain from the fitting procedure, the best upper limit for the core-level intrinsic lifetime. In metals, the intrinsic lifetime of the core hole is affected by the formation of electron–hole pairs, whose excitation energy is reflected in the low kinetic-energy part of the detected core-level spectrum. This phenomenon gives rise to an asymmetric lineshape. In this case a Doniach–Sunjic function is used for the fitting procedure, as reported in **Figure 6** for the asymmetric lineshape of the $3d_{5/2}$ peak of rhodium (Rh).

The Case of Si

Figure 7 shows an example of analysis of high-resolution CPS of Si 2p collected on the Ge/Sb/Si(0 0 1)

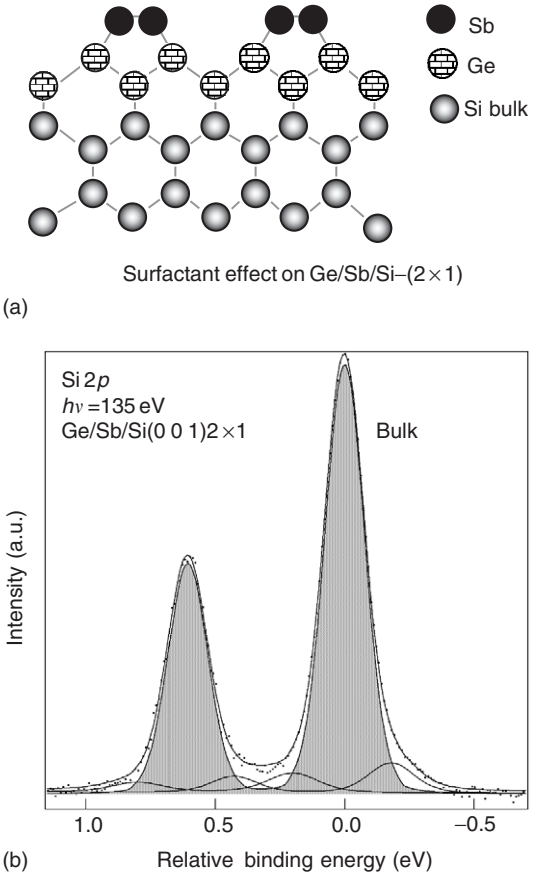

Figure 7 Side view of ball-and-stick model of (a) Sb surfactant effect on Ge/Sb/Si(0 0 1)2 × 1, and (b) Si 2*p* spectrum taken on hydrogenated Ge/Sb/Si(0 0 1) system. The spectrum shows the convolution of the Si 2*p* core level in surface (blank doublets) and bulk contributions (shaded doublet). The "bulk" component dominates the spectrum and demonstrates a nearly unreconstructed (1 × 1) configuration for the last layers of the Si in the Ge/Sb/Si structure. (Reproduced with permission from De Padova P, Larciprete R, Quaresima C, Ottaviani C, Ressel B, and Perfetti P (1998) Identification of the Si 2p surface core level shifts on the Sb/Si(0 0 1) – (2 × 1) interface. *Physical Review Letters* 81: 2320–2323; © American Physical Society.)

system. This interface was artificially created to organize the last silicon layer in a geometrical configuration very much like the bulk structure. The system was prepared by depositing 2.5 MLs of Ge on the interface formed of 1 ML of Sb on Si(0 0 1). This is an epitaxial growth, where the process of surface-energy minimization leads to an Sb–Ge site exchange process that segregates the antimony at the top of the surface and traps the Ge atoms between the Sb adlayer and the Si substrate. Antimony acts as a surfactant, and the insertion of the epitaxial layers of Ge leaves the interfacial Si atoms arranged in an almost perfect bulk-like (1 × 1) configuration. The final result of this process is shown schematically in **Figure 7a**. The system is characterized by high homogeneity and atomic order. The bulk-like atomic arrangement of the top silicon layers can be verified by convoluting the Si 2*p* core level with the use of the spin–orbit split Voigt functions. One can clearly see from **Figure 7** that the lineshape is completely dominated by the "bulk" component, and a comparison with **Figure 10** emphasizes the effect of the different atomic arrangement of the last silicon layers; here, indeed, the Si 2*p* lineshape contains many core-level components due to surface reconstruction.

The peak fit of the Si 2*p* core level on the Ge/Sb/Si system gives a Lorentzian FWHM $\Gamma_L = 20$ meV. This is one of the lower Lorentzian width values found for silicon. Higher gamma values have been found in other high-resolution results for a clean Si (1 1 1) surface with a complicated 7 × 7 reconstruction. The gamma value is an indication of the core-hole lifetime, and the above reported value of 20 meV can be considered as an upper limit of the intrinsic lifetime for silicon.

Binding Energy, Surface Core-Level Shift, and Chemical Shift

The binding energy E_B of a core level can be defined as the difference between the total energy of the unperturbed state with N electrons in its ground state $E_0(N)$ and the energy of the state formed by the hole and the $N-1$ remaining electrons after photoexcitation, $E_f(N-1)$

$$E_B = E_f(N-1) - E_0(N)$$

The absolute value of the measured core-level binding energy is influenced by several factors that can affect either $E_0(N)$ or $E_f(N-1)$. To explain the physical origin of the variation in the binding energy, one can define ΔE_B as the difference between the measured binding energy and the binding energy of an electron in its fundamental state in an isolated atom. From the preceding equation, one obtains

$$\Delta E_B = \Delta E_0 + \Delta E_f$$

Initial-State Effects

Initial-state effects in the binding energy of core electrons (ΔE_0) originate mainly from a change in the electrostatic interaction between the core electrons and the outer electrons. The change is determined by the variation in the charge distribution on the emitting atom and by the different physical situations. Consequently, the following can contribute to the variation in ΔE_0:

1. The charge transfer, which is due to the chemical bonds formed by the same atomic species in different chemical compounds.

2. The kind of atomic-species configuration, which depends on whether an atom is isolated or arranged in a molecule or a solid. For example, in a solid the atoms can exist either in a surface or in a bulk configuration; accordingly, on the emitting atom, the valence-electron distribution changes and, as a consequence, also the measured electron binding energy.
3. The "Madelung contribution," which is due to charge transfer between the emitter and the neighbor atoms, could be important in ionic compounds.

For surface atoms, a charge transfer causes binding energy shifts, called surface core-level shifts (SCLS). Contributions (1) and (2) are only schematic, since each change in configuration is always accompanied by bond modification; this is what happens to an atom that exists in different chemical compounds.

Core photoemission spectroscopy studies do not usually deal with evaluation of the absolute binding energy of a particular core-level but with the binding energy changes between two different chemical forms of the same atom. This energy difference is known as a "chemical shift."

Chemical shifts are quite important in identifying the chemical compounds present in a system and can also be extremely helpful in determining the structural properties by, for example, the surface diffraction technique. In a chemical bond between two different atoms, there is a charge transfer from the more electropositive atom to the more electronegative one. Recall that electronegativity is a measure of the attraction of an atom for electrons. Due to a Coulomb interaction between core and valence electrons, the charge transfer results in a more or less effective screening of the core hole, which affects the photoelectron kinetic energy. Consequently, if the CPS spectra of different compounds are compared, one sees that photoelectrons emitted from atoms in a higher oxidation state display higher kinetic energy (lower binding energy) and vice versa.

The Case of the Trans-Dinitrobis (Ethylene-Diamine) Cobalt(III) Nitrate Compound

The N1*s* core-level photoemission spectrum in the $[Co(NH_2CH_2CH_2NH_2)_2(NO_2)_2]NO_3$ compound, where the chemical shift concept is applied to identify nonequivalent nitrogen atoms in different compounds, is shown in **Figure 8**. The chemical shift is roughly proportional to the charge transfer and can be used to follow the chemical reactions of each *N* atom in different molecules. The binding energy of the core-level N1s increases with increasing "oxidation" number of the nitrogen atoms. This is the case of NH_2, NO_2, and NO_3 in $[Co(NH_2CH_2CH_2NH_2)_2(NO_2)_2]NO_3$.

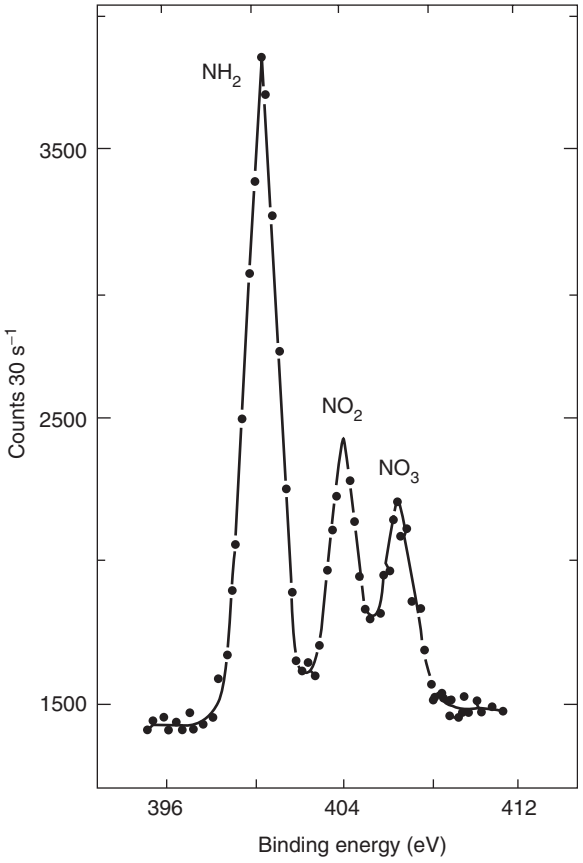

Figure 8 Chemical shift of the N1*s* core level in the $[Co(NH_2CH_2CH_2NH_2)_2]NO_3$ compound. (Reproduced with permission from Hendrickson, *et al.* (1969) *Inorganic Chemistry* 8: 2646; © American Chemical Society.)

The Case of a Clean Si(0 0 1)2 × 1 Surface

The $Si(0\,0\,1)2 \times 1$ surface can be considered as a pedagogical example to show the SCLSs. An ideal surface, considered as a truncation of the bulk lattice, for instance a covalent semiconductor of the IV group, is formed of a large number of broken bonds pointing out of the surface. These broken bonds, or dangling bonds, are energetically unstable, so the surface atoms reorganize to minimize the total energy at the surface, thus reducing the number of dangling bonds. The electronic properties of a clean reconstructed surface are different from those of an ideal surface due to the new type of bonds created. Several reconstructions can be induced on a surface sample as a function of parameters such as temperature, surface and bulk strains, crystallographic orientation, atomic species, and adsorbates. A schematic representation of the $Si(0\,0\,1)$ (1×1) and (2×1) reconstructions is shown in **Figure 9**. The

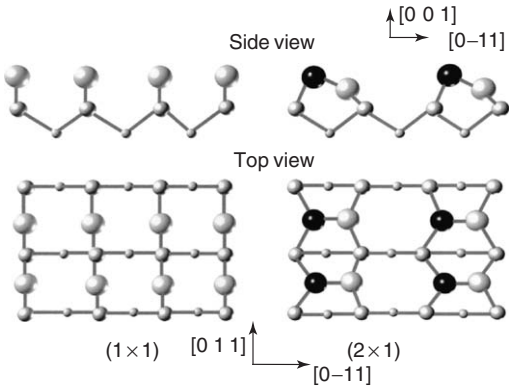

Figure 9 Ball-and-stick model of an ideally terminated (1 × 1) Si(0 0 1) and asymmetric dimer reconstructed structure Si(0 0 1)2 × 1.

(2 × 1) reconstruction is formed of buckled dimers. At liquid nitrogen temperature, the surface reconstruction changes again, forming a larger $c(4 \times 2)$ unit cell consisting of buckled dimers with up-and-down opposite orientation in the [1 1 0] and [1 – 10] directions. Various surface components associated with the reconstruction of clean Si(0 0 1) have been reported for the Si 2*p* core level, and attributed to nonequivalent dimer atoms and to the subsurface layer in contact with the dimers. **Figure 10** shows surface-sensitive, high-resolution photoemission spectroscopy of the Si 2*p* core level of clean Si(0 0 1)$c(4 \times 2)$. Many peaks are well resolved in the CPS spectrum. By convoluting the Si 2*p* spectrum with spin–orbit split Voigt functions, four components related to the $c(4 \times 2)$ reconstruction can be identified, in addition to the bulk component B. The four surface contributions *U*, *D*, *S*, and *C* are interpreted as "up" and "down" dimer atoms, second layer atoms, and subsurface layers or defects. The energy shifts with respect to the B component are $U = -498$ meV, $C = -200$ meV, $D = +60$ meV, and $S = +200$ meV. The up-and-down dimer atom contributions, at higher and lower binding energy relative to the bulk silicon B, are easily identified since, in the reconstruction process, there is a charge transfer from down to up atoms. A similar argument can be applied to the chemically shifted peak *S*. More uncertain is the interpretation of the *C* component.

Final-State Effects

Final-state effects influence the variation ΔE_B through ΔE_f. In a CPS process, the outer electrons probe a higher effective charge of the nucleus because of the creation of the hole. Thus, they relax and decrease both the total final energy and the photoelectron binding energy. ΔE_f is zero when the relaxation energy of the remaining electrons in the photoemission process

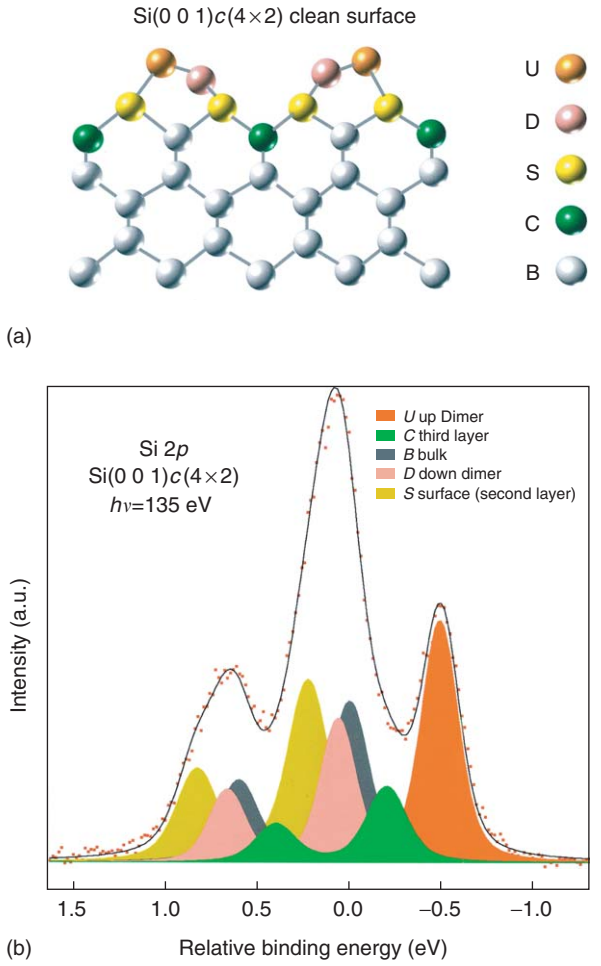

Figure 10 Surface-sensitive Si 2*p* core-level photoemission spectrum for the clean Si(0 0 1)-$c(4 \times 2)$ surface: (a) ball-and-stick model for the asymmetric dimer $c(4 \times 2)$ reconstructed structure; (b) convolution of the Si 2*p* spectrum in four surface contributions *U*, *D*, *S*, and *C*, in addition to the bulk component B. Each patterned atom corresponds to a nonequivalent Si atom. is negligible; this is called the Koopmans' approximation, and the photoelectron binding energy is that of the orbital from which it is removed. Finally, one may have two contributions to the relaxation process, one intra-atomic and the other extra-atomic.

Intra-atomic relaxation is practically independent of the neighbor atoms of the emitter (unless the emitter changes its valence electrons because of a charge transfer) and is typical of isolated atoms. It is already seen that the relaxation process often leaves the system in an excited state, which gives rise to extra "satellite lines," also called "shake-up lines," in the photoemission spectra.

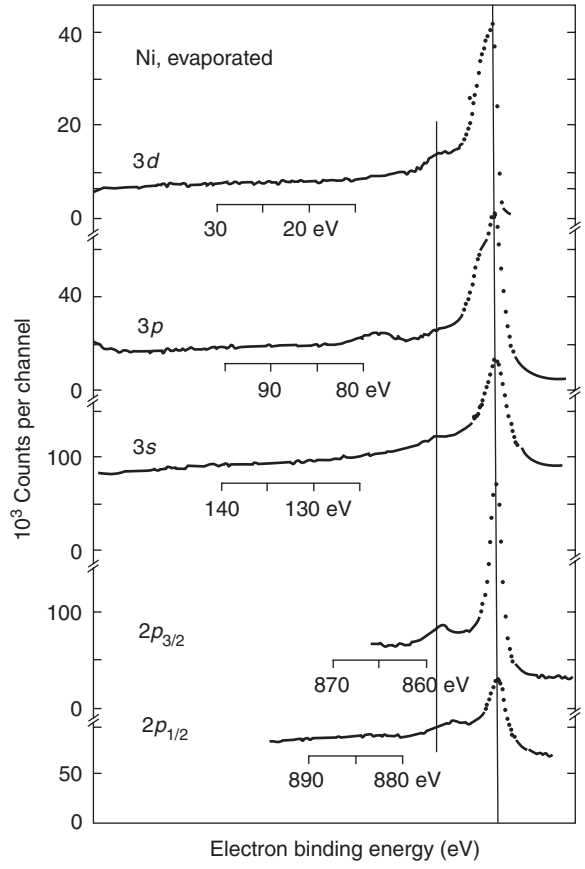

Figure 11 X-ray photoelectron spectroscopy spectra of the 3*d*, 3*p*, 3*s*, $2p_{3/2}$, and $2p_{1/2}$ core levels of Ni metal. The main lines are aligned. Figure 12 Schematic diagram of the Ni density of states, indicating the origin of the main and the satellite line for core ionization. C denotes a core-level; c^{-1} a core hole. The initial state is $c(3d^9 4s)$, and the two final states are $c^{-1}(3d^9 4s^2)$ (satellite) and $c^{-1}(3d^{10} 4s)$ (main line).

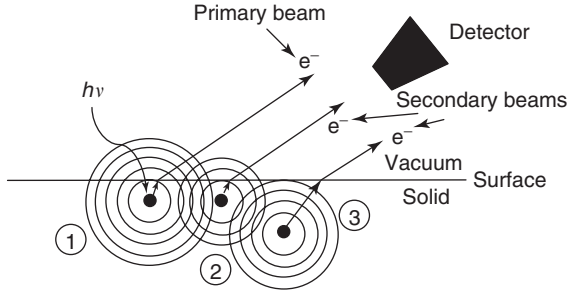

Figure 13 Photoelectron diffraction: A photon impinging on an atom (1) excites an electron represented by a primary spherical wave (primary beam), which is the part of the wave that goes directly into the vacuum. The part scattered by the other ions (2) and (3) inside the solid gives rise to secondary beams, which can interfere with each other on the detector.

Extra-atomic relaxation takes into account the effect of the relaxation energy of the valence electrons on the binding energy of the core orbital of the excited atom. This effect could be strongly influenced by the type of bonds that the emitting atom forms with the neighbor atoms. Note that the binding energy shifts depend on the more or less effective screening of the core hole, which is induced by the relaxing electrons. The shifts will be higher for *s* or *p* electrons than the more localized *d* electrons.

The Case of Ni

Figure 11 shows the CPS spectra of the 3*d*, 3*p*, 3*s*, $2p_{3/2}$, and $2p_{1/2}$ levels of Ni metal. In each case the spectrum consists of a main line accompanied by a satellite line, at about 6 eV higher binding energy. The main lines are aligned to demonstrate the constant distance of the satellite position. The origin of the 6 eV satellite can be explained in terms of final-state effects. In **Figure 12**, the basic physical model is summarized to illustrate the problem. The representation of the band structure of the Ni metal in the initial and final states shown in the figure indicates the origin of the main line and the satellite for the core ionization (c^{-1}). In the initial state $c(3d^9 4s)$, the $3d^9$ state is degenerate with the 4*s* band (left in the figure). In the final state, the electronic Coulomb attraction, due to the core hole created, pulls the unoccupied states below E_F, and the electron screening of the hole produces two effects. Consequent to the first effect, the $3d^9$ level gets filled and the electronic configuration $c^{-1}(3d^{10} 4s)$ (right in the figure) is produced. This is responsible for the main line visible in **Figure 11**. In the second effect, the *d* electrons at the Fermi level are scattered from the Ni ion on which the core hole resides, and a two-hole state

is created (center in the figure). This state is lower in energy than the one-hole state by about 6 eV (satellite line in **Figure 11**).

Photoelectron Diffraction

It has been already mentioned that CPS data can be used to give structural information about surfaces or interfaces by analyzing the diffraction pattern of the electrons emitted by a particular core level. **Figure 13** shows a schematic representation of photoelectron diffraction. The photoelectron, excited by a photon of energy, $h\nu$ can be directly revealed by a detector as a primary beam, or scattered by the neighbor atoms. The elastically scattered waves form secondary beams, which can reach the detector and interfere with each other and with the primary beam, giving rise to an interference pattern. By measuring the photoelectron intensity as a function of the electron wavelength and/or crystal orientation, one can derive structural information. The diffraction pattern must be compared with calculations performed with the use of a hypothetical crystallographic model for the structure considered.

An example of a photoelectron diffraction experiment on an interface is reported in **Figure 14**. The system is formed of one ML of copper embedded between the Ni substrate and a nickel overlayer of increasing thickness. The photoelectron intensity of the Cu $2p_{3/2}$ core level, excited by photons of 1254 eV, is detected as a function of the polar angle ϑ and the Ni overlayer coverage. Note that at high photoelectron energy the forward scattering is dominant, and one expects high photoelectron intensities in the direction connecting the emitting atom and the scatterer. As one can presume from **Figure 14**, the maximum intensity of the Cu $2p_{3/2}$ core level will be reached at $\vartheta = 45°$, for two MLs of Ni; in this case, the two Ni atoms are aligned in the forward direction. For a Ni coverage of four MLs, the maximum is attenuated because of defocusing effects.

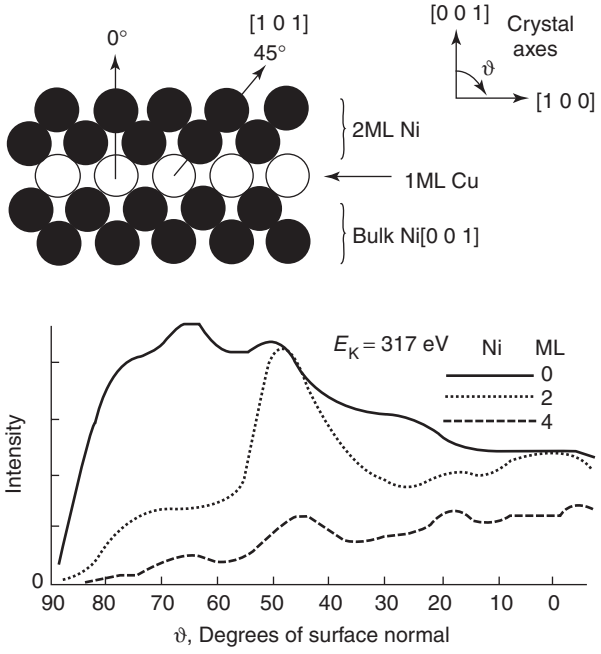

Figure 14 Photoelectron diffraction patterns obtained by scanning the intensity of Cu $2p_{3/2}$ in the (0 1 0) plane as a function of the polar angle ϑ. How to Measure the Schottky Barrier by Core-level Photoemission: The Case of Cs/GaSb(1 1 0)

Core-level analysis can provide a lot of information about the first stages of the formation of a metal–semiconductor interface and about the physics of the process. Here a useful application of the CPS technique through the measurement of the Schottky barrier height at a metal–semiconductor junction is illustrated. **Figure 15a** shows the band diagram of a metal and an *n*-type semiconductor before they come into contact. The bands are aligned to the vacuum level and, in the semiconductor, a flat band situation

is assumed, neglecting any possible band-bending due to the presence of surface states. The valence band and the core levels have well-defined binding energies relative to the vacuum level. ϕ_m and ϕ_s are the work functions, with $\phi_m > \phi_s$. When the two systems come into contact, as in **Figure 15b**, a thermodynamic equilibrium is reached by aligning the Fermi levels, with a subsequent charge transfer from the semiconductor to the metal. Band-bending forms at the interface, together with a charge depletion layer that extends some hundred Å inside the semiconductor, depending on the doping concentration. The Schottky barrier is proportional to the built-in potential V_B at the junction; it is given by $qV_B = (\phi_m - \phi_s)$ and is formed entirely after the deposition of a very small amount (a few MLs) of metal. A CPS spectrum, taken from the side of the metal, explores only the first layers of the semiconductor at the interface, picking up the binding energy of the core-level when it has reached the maximum band-bending. The measurement of the binding energy difference of the core levels $E_{B2} - E_{B1}$ before and after the interface growth provides the Schottky barrier height, once the position of the Fermi level on the clean semiconductor surface is known. The position can be found from the Fermi-level measurement on the gold sample in contact with the system under analysis. The Schottky barrier height can also be evaluated by measuring the shift of the top of the valence band as a function of metal coverage. This procedure is affected by an uncertainty in the measurement of the valence-band edge, due to the possible presence of adsorbate states. In **Figure 15a**, a flat-band semiconductor has been hypothesized, which is only an exception. A clean semiconductor surface usually has its own band-bending because of the presence of surface states in the bandgap, which pin the Fermi level. E_F can be obtained from knowledge of the doping concentration, and the photoemission valence band edge is measured with respect to E_F.

The photovoltage effect, which is an accumulation of positive charge in the depletion layer, can lead to additional band-bending. It is induced by incident light creating electron–hole mobile pairs that move in opposite directions in the electric field at the junction. As a result, a charge accumulation takes place at the interface, thereby reducing the band-bending. The photovoltage effect is strongly dependent on temperature, photon flux, and doping concentration and must be taken into account when performing a Schottky-barrier measurement by photoemission spectroscopy.

An example of an application of the Schottky-barrier height measurement is given in **Figure 16** for a Cs/GaSb(1 1 0) metal–semiconductor interface. **Figure 16a** shows the evolution of the Sb 4*d* core-level spectra for different Cs metal deposition thicknesses. The movement of the core-level doublet as a function of the cesium coverage gives an indication of band-bending formation. For a correct evaluation of the band-bending, the bulk contribution is obtained from a best fit to the experimental data (see **Figure 16a**). The position of the surface Fermi level, derived from the energy shift of the bulk peak as a function of Cs coverage, is plotted in **Figure 16c**. Here, one can note that the built-in potential at the junction is completed for a very small quantity of metal ($\sim$1 ML) and that the Schottky-barrier height is $\sim$0.5 eV. This value is not affected by the photovoltage effect, since GaSb is a small-gap semiconductor and heavily *n*-doped.

Crystal Field Splitting

I B Bersuker, University of Texas at Austin, Austin, TX, USA

Introduction

The basis of the crystal field theory (CFT) was created by Bethe in 1929 in his classical work "Term splitting in crystals." This publication contains, in essence, all the main elements of the modern theory. In the 1930s, some important results illustrating the efficiency of the CFT were obtained, including explanation of magnetic behavior of ions in weak and strong crystal fields, in particular, the reduction of the orbital magnetic moment, temperature dependence of the magnetic susceptibility, and the Jahn–Teller effect. More intensive development of CFT began in the 1950s when it was shown that this theory successfully explains the origin of absorption spectra in the visible and related regions, as well as a series of other optical, electric, magnetic, thermodynamic, and electron spin resonance properties of impurity centers in crystals and molecular coordination systems.

The main assumption of CFT is that while the impurity center (IC) or the central atom in clusters or molecular coordination compounds (hereafter denoted as IC) is considered with its detailed electronic structure, the atoms (ions) of the environment are implied to be "structureless" sources of electrostatic fields (sometimes allowing for their polarization in the field of the IC and other atoms). This assumption allows one to consider phenomena that take place mainly within the electronic shell of the IC, but do not involve the electronic structure of the environment explicitly. In spite of this significant limitation, the CFT, within the limits of its applicability, is a rather efficient means to investigate the many aspects of the electronic structure and properties of impurity centers in crystals and other local properties of polyatomic systems.

In accordance with the basic statements of the CFT, the electronic structure of the IC system is determined by the Schrödinger equation with the Hamiltonian H:

$$H = H_0 + V + W \qquad [1]$$

where H_0 includes all the interactions in the IC: the kinetic energy of its n electrons, the interaction between them and with the nucleus; V is the interaction between the IC electrons with the atoms of the environment taken as point charges q_i or dipoles μ_i; and W is the electrostatic interaction of the positive charge Ze of the IC nucleus with the crystal field charges or dipoles. Taking the origin of the polar coordinate system at the nucleus, the N ligand coordinates are denoted as $\boldsymbol{R}(R_i, \vartheta_i, \phi_i), i = 1, 2, \ldots, N$. Then

$$V = -\sum_{i=1}^{N} \sum_{j=1}^{n} \frac{eq_i}{|\vec{r}_j - \vec{R}_i|} \qquad [2]$$

and

$$W = \sum_{i=1}^{N} \frac{Zeq_i}{R_i} \qquad [3]$$

If $q_i < 0$, the value of V in [2] is positive, and hence the electron–ligand interaction destabilizes the IC; for $q_i > 0$, V is negative. The term W in [3] is usually not explicitly considered in the CFT, since it is independent of the electron coordinates and does not influence the electronic properties considered in CFT. Usually, the valence electrons of the IC are most important in CFT, so the number of terms in the first sum of eqn [2] equals the number of the valence electrons, while Ze is the effective charge of the remaining core.

Crystal Field Splitting (CFS) of the Energy Levels of One *d* Electron

Qualitative Aspects and Visual Interpretation

In accordance with the assumptions of the CFT, the crystal field influences the IC properties by changing its electronic structure. The main crystal field effect on the states of the IC is the splitting of its energy levels. The origin of this splitting is known in quantum mechanics as the Stark effect.

Consider the simplest (from the point of view of the CFT) case when the central ion of the IC in an octahedral environment contains only one d electron over the closed shell, for instance, in the $TiCl_6^{3-}$ cluster. The ground state of the Ti^{3+} ion is ^2D with an orbital momentum $L = 2$ (orbital degeneracy $2L + 1 = 5$) and a spin $S = 1/2$ (doublet state). The five orbital states are just the five possible angular states of the only d electron with identical radial parts. The real functions representating the three orbitals d_{xy}, d_{xz}, d_{yz} (known as t_{2g} orbitals) are oriented in space in such a

way that their distribution maxima (lobes) lie in the region between the coordinate axes. The remaining two orbitals d_{z^2} and $d_{x^2-y^2}$ (known as e_g orbitals) have their lobes oriented exactly along the axes.

Compare the electron distributions in the two types of d states, e_g and t_{2g}, say $d_{x^2-y^2}(e_g)$ and $d_{xy}(t_{2g})$, illustrated in **Figure 1**. Taking into account that the Cl^- ions have negative charges, it can be easily concluded that in octahedral complexes the $d_{x^2-y^2}$ electron is subject to a stronger electrostatic repulsion from the chlorines, than the d_{xy} one. Hence, the electron energies of these two states (which are equal in the free ion), under the electrostatic influence of the ligands, become different: the $d_{x^2-y^2}$ energy level is higher than the d_{xy} one. All the three t_{2g} states (d_{xy}, d_{xz}, d_{yz}) are fully equivalent with respect to the six ligands, and therefore they have the same (lower) energy forming a threefold degenerate term. It can be shown that the two e_g states also have equal energies, forming a twofold degenerate term.

Thus, the five d states that have the same energy in the free ion are divided into two groups of states with different energies under the octahedral field of the ligands. In other words, the fivefold degenerate D term of the free ion is split in the field of the ligands of an octahedral complex into two terms: threefold degenerate $^2T_{2g}$ and twofold degenerate ^2E_g:

$$^2\mathrm{D} \rightarrow {}^2T_{2g} + {}^2E_g \qquad [4]$$

It follows from this consideration that the CFS occurs as a result of the smaller repulsion (from the environment) of the t_{2g} states, than e_g states, but all the five states are equally destabilized in the field of the chlorine ions by an amount of E_0. This is illustrated in **Figure 2**.

For a tetrahedral complex, the qualitative picture of the term splitting is inverse to that of the octahedral case. Indeed, in the tetrahedral environment of four ligands, the t_{2g} orbitals are oriented with their lobes much closer to the ligands than the e_g orbitals; hence, the former are subject to stronger repulsion than the latter. Therefore, the energy levels of the t_{2g} orbitals are higher than those of e_g. Symmetry considerations and the calculations, given below, show that even in the tetrahedral system, the three t_{2g} states, as well as the two e_g states, remain degenerate forming the T_2 and E terms, respectively. Hence in a tetrahedral complex the splitting of the D term is (**Figure 3b**)

$$D \rightarrow T_2 + E \qquad [5]$$

which is very similar to that in an octahedral field, eqn [4]. But unlike the octahedral case, the T_2 has greater energy when compared to E, and the splitting magnitude, as well as the destabilization energy, is smaller.

Both the octahedral and tetrahedral symmetries appertain to the cubic groups of symmetry. In **Figure 3**, the splitting of the atomic D term in the field of eight ligands at the corners of a cube is also shown. If the symmetry of the ligand field is lowered, the terms T_2 and E may be subject to further splitting. **Figure 4** illustrates the expected CFS pattern for different symmetry environments of a d electron IC.

If the number of d electrons above the closed shell equals 9, the visual interpretation of the splitting becomes possible again; the d^9 configuration can be

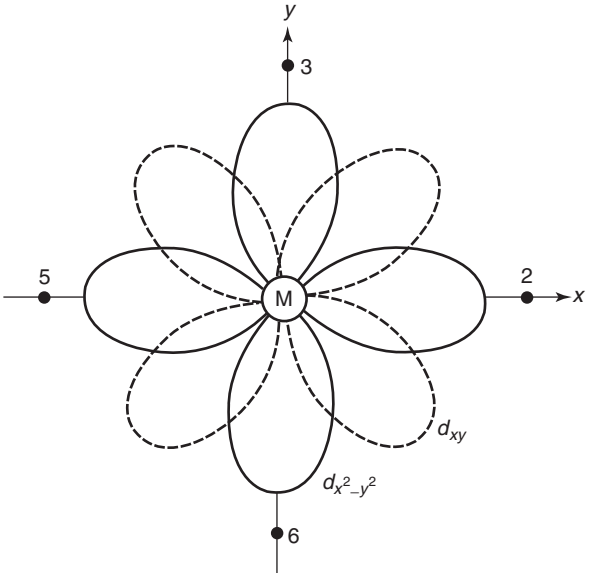

Figure 1 Comparison of electron distributions in the two d states, $d_{x^2-y^2}$ (solid line) and d_{xy} (dashed line) with respect to the four ligands in the xy-plane.

formally presented as one positive electronic charge above the closed-shell d^{10} configuration, that is, a d hole in the d^{10} shell. The ground state of the d hole is also ^2D, as for the d^1 configuration, and its splitting in crystal fields of different symmetries has the same components as d^1, but with their mutual arrangement inverse to that of d^1 (repulsion changed to attraction). This rule of inverse term splitting for complimentary electron configurations is valid for any pair of electronic configuration, d^n and d^{10-n} ($n = 1, 2, 3, 4$), in which the number of, respectively, d electrons and d holes over the closed shell d^{10} is the same.

Qualitatively, the expected CFS can be obtained directly from a group-theoretical analysis without solving eqn [6] below. **Table 1** illustrates the expected CFS of different atomic states in crystal fields of different symmetry.

Calculation of CFS Magnitudes

Assume first that the term V in eqn [1] is much smaller than the interatomic interactions H_0, and hence V can be considered as a perturbation to the solutions of H_0. This assumption is valid if the resulting term splitting obtained in this way is smaller than the energy gap between the terms of the free atom (or ion), solutions of H_0. Consider the case of one d electron above the closed shell, that is, the electron configuration of the IC $[A]d^1$, where $[A]$ is a closed shell. The solution for the free ion with the Hamiltonian H_0 yields the fivefold orbitally degenerate ^2D term. To reveal the modifications of this term under the perturbation V from [2], one has to solve the perturbation theory problem, which for fivefold degeneracy reduces to the secular equation of the fifth order with respect to the energy level corrections ε (m is the magnetic quantum number of the atomic d functions ψ_{lm} with $l = 2$):

$$\| V_{mm'} - \varepsilon\delta_{mm'} \| = 0, \quad m,\ m' = 2, 1, 0, -1, -2 \qquad [6]$$

where, in accordance with [2],

$$V_{mm'} = \sum_i eq_i \int \psi_m^* \psi_{m'} / |\boldsymbol{r} - \boldsymbol{R}_i| \, \mathrm{d}\tau \qquad [7]$$

The general expression for $V_{mm'}$ can be evaluated directly:

$$\begin{aligned} V_{mm'} = \sum_i eq_i \, [& A_{mm'} F_4(R_i) Y_4^{m-m'}(\vartheta_i, \phi_i) \\ & + B_{mm'} F_2(R_i) Y_2^{m-m'}(\vartheta_i, \phi_i) \\ & + D_{mm'} F_0(R_i) Y_0^{m-m'}(\vartheta_i, \phi_i) \end{aligned} \qquad [8]$$

where $A_{mm'}$, $B_{mm'}$, and $D_{mm'}$ are numerical constants, determined by corresponding Clebsh–Gordan

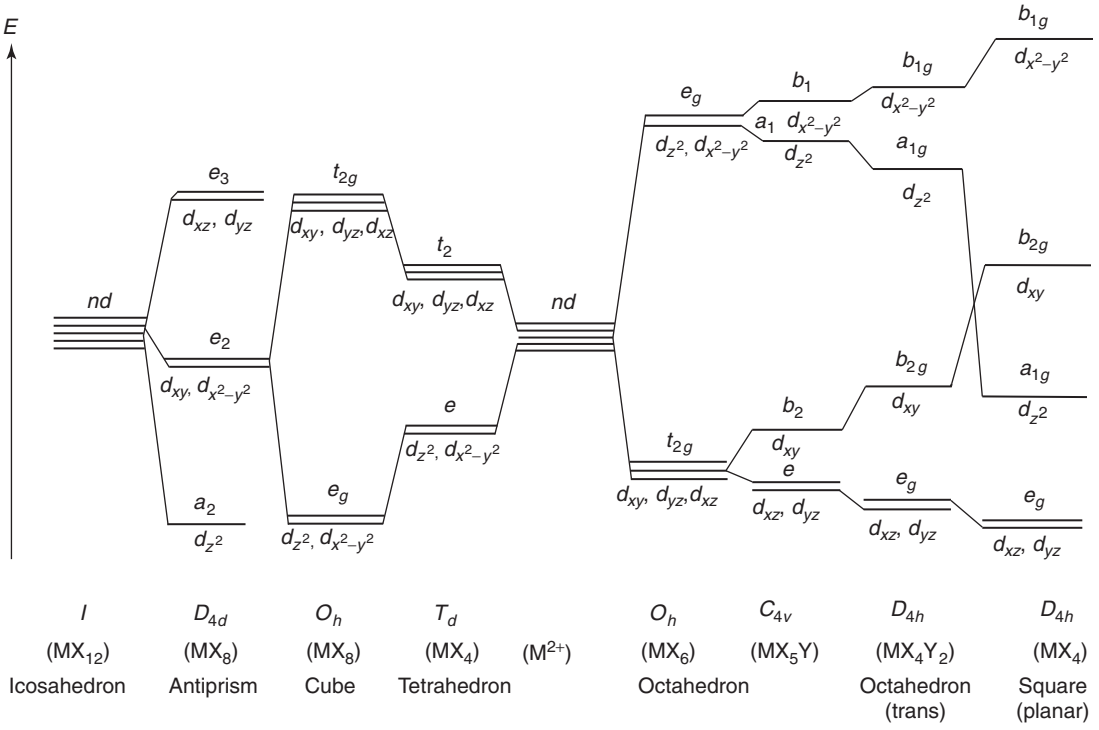

Figure 4 Splitting of *d* orbital energy levels in crystal fields of different symmetries. In MX_5Y and MX_4Y_2 clusters, the splitting of the T_{2g} and E_g terms can be inverted depending on the ratio of field strengths *X*/*Y*. 	T_{1u}	T_2	$A_2 + E$	$A_{2u} + E_u$	$A_1 + E$	$A_1 + B_1 + B_2$
	T_{2u}	T_1	$A_1 + E$	$B_{2u} + E_u$	$B_1 + E$	$A_1 + B_1 + B_2$

[a] Belonging to several types of symmetry means corresponding splitting.

coefficients, while the functions $F_k(R)$ are

$$F_k(R) = R^{-(k+1)} \int_0^R r^k R_{nl}^2(r) r^2 \, dr + R^k \int_R^\infty r^{-(k+1)} R_{nl}^2(r) r^2 \, dr \qquad [9]$$

with $R_{n2}(r)$ as the radial function of the *d* electrons with $l = 2$.

As an example, one can calculate the splitting of a *d* electron term in an octahedral crystal field of six identical ions at the corners of a regular octahedron. The ligand charges and coordinates are

$$\begin{aligned} &q_i = q, \qquad R_i = R, \quad i = 1, 2, \ldots, 6 \\ &\vartheta_1 = 0, \qquad \vartheta_2 = \vartheta_3 = \vartheta_5 = \vartheta_6 = \pi/2, \qquad \vartheta_4 = \pi \\ &\phi_2 = 0, \qquad \phi_3 = \pi/2, \qquad \phi_5 = \pi, \qquad \phi_6 = 3\pi/2 \end{aligned} \qquad [10]$$

Substituting these values into eqn [8] and solving eqn [6], the following result is obtained:

$$\begin{aligned}\varepsilon_1 = \varepsilon_2 = \varepsilon(E_g) = E_0 + (3/5)\Delta \\ \varepsilon_3 = \varepsilon_4 = \varepsilon_5 = \varepsilon(T_{2g}) = E_0 - (2/5)\Delta\end{aligned} \quad [11]$$

with

$$\Delta = \varepsilon(E_g) - \varepsilon(T_{2g}) = (5/3)eqF_4(R) \quad [12]$$

and

$$E_0 = 6eqF_0(R) \quad [13]$$

Thus, in accordance with the above described qualitative results, the d electron energy levels (^2D term) are split by the octahedral ligand field into a twofold (E_g) and threefold (T_{2g}) degenerate terms. Since $F_k > 0$, the twofold degenerate E_g term has higher energy than the T_{2g} term. The splitting magnitude Δ is the main CFS parameter. Note that the CFS preserves the center of gravity: the sum of the energy level displacements (from the E_0 value) multiplied by their degeneracies equals zero.

As compared to the octahedral crystal field, the corresponding splitting in the tetrahedral ones is inverted and smaller (**Figure 3**). Calculations yield

$$\begin{aligned}\varepsilon(T_2) = E_0^T + (2/5)\Delta_T \\ \varepsilon(E) = E_0^T - (3/5)\Delta_T\end{aligned} \quad [14]$$

where the splitting parameter Δ_T and destabilization energy E_0^T are

$$\Delta_T = (20/27)eqF_4(R) \quad [15]$$

$$E_0^T = 4eqF_0(R) \quad [16]$$

It is observed that with the same R and q, $\Delta_T = -(4/9)\Delta$, that is, the splitting magnitude in tetrahedral symmetry "ceteris paribus" is 4/9 times the octahedral splitting. In the cubic coordinate system (eight ligands at the corners of a cube), the splitting and destabilization energy are qualitatively similar to the tetrahedral case, but two times larger in magnitude:

$$\mathbf{\Delta}_C = (40/27)eqF_4(R) = 2\mathbf{\Delta}_T \quad [17]$$

$$E_0^C = 8eqF_0(R) = 2E_0^T \quad [18]$$

If the ligand is a point dipole, the term splitting is qualitatively the same, as in the case of point charges. Assuming that the dimensions of the dipole with the dipole moment μ_i are much smaller than the distance to the IC, one can obtain the following expression for the splitting magnitude in the octahedral case:

$$\Delta = -(5/3)\mu_i F_4'(R) \quad [19]$$

where the prime at F means its derivative; note that $F_4' < 0$.

For lower symmetry fields, the calculations can be carried out in a similar way.

CFS for Configurations with Several *d* Electrons

The Case of Weak Crystal Field

If the electronic configuration of the IC contains more than one d electron above the closed shell, the picture of possible energy terms and their splitting in the ligand fields is significantly complicated by the interaction between the d electrons. If the ligand field is not very strong, the atomic terms can still be classified by the quantum number of the total atomic momentum L, and the influence of the ligands can be taken as a perturbation of the atomic terms.

For the electronic configuration of the IC $[A](nd)^2$, the possible atomic terms are ^3F, ^3P, ^1G, $1D$, and ^1S, the ^3F term belonging to the ground state. The perturbation operator, following eqn [2], has two terms and the calculation of its matrix elements is similar to the d^1 case. For instance, for the ground-state term ^3F of the d^2 configuration in the octahedral field of O_h symmetry, the sevenfold orbital degeneracy ($L = 3,\ 2L + 1 = 7$) splits into three terms; $^3F \rightarrow {}^3A_g + {}^3T_{2g} + {}^3T_{1g}$, with energies:

$$\begin{aligned}\varepsilon(^3A_{2g}) = 2E_0 + (6/5)\Delta \\ \varepsilon(^3T_{2g}) = 2E_0 + (1/5)\Delta \\ \varepsilon(^3T_{1g}) = 2E_0 - (3/5)\Delta\end{aligned} \quad [20]$$

Since Δ and E_0 are positive, $^3T_{1g}$ is the ground term, and $^3T_{2g}$ and $^3A_{2g}$ follow consecutively (**Figure 5**). Their wave functions can be obtained as solutions of the secular equation [6] in the form of linear combinations of the atomic functions.

The splitting of other terms of the $[A](nd)^2$ configuration in obtained similarly (**Figure 5**):

^1D term:

$$\begin{aligned}\varepsilon(^1E_g) = 2E_0 + (12/35)\Delta \\ \varepsilon(^1T_{2g}) = 2E_0 - (8/35)\Delta\end{aligned} \quad [21]$$

^3P term:

$$\varepsilon(^3T_{2g}) = 2E_0 \quad [22]$$

^1G term:

$$\begin{aligned}\varepsilon(^1A_{1g}) = 2E_0 + (2/5)\Delta \\ \varepsilon(^1E_g) = 2E_0 + (2/35)\Delta \\ \varepsilon(^1T_{2g}) = 2E_0 - (13/35)\Delta \\ \varepsilon(^1T_{1g}) = 2E_0 + (1/5)\Delta\end{aligned} \quad [23]$$

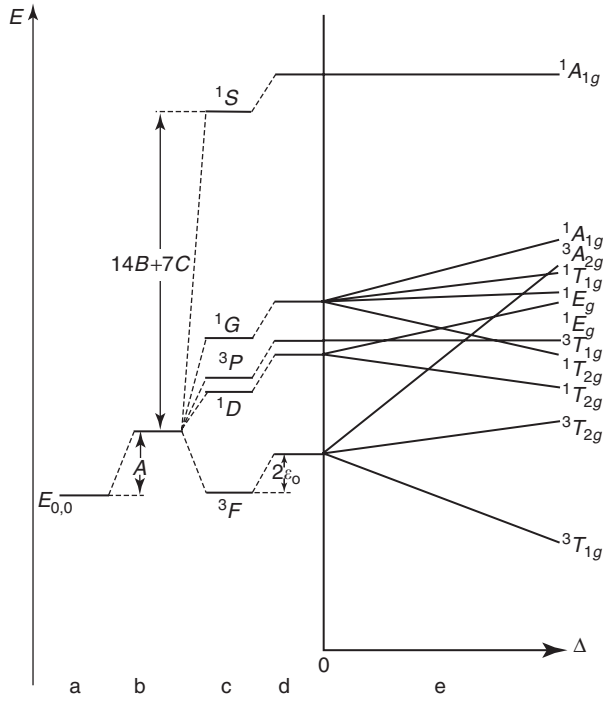

Figure 5 Splitting of the terms of the electronic d^2 configuration in octahedral crystal field (weak field limit): (a) *d* electron energy level, (b) electron interaction – spherical averaged part, (c) electron interaction – formation of atomic terms, (d) crystal field destabilization, (e) ligand field splitting as a function of △. This material is used by permission of John Wiley & Sons, Inc.)

^1S term:

$$\varepsilon(^1A_{1g}) = 12eqF_0 = 2E_0 \qquad [24]$$

The criterion of validity of the weak field approximations is that the term splitting is much smaller than the energy gap between the terms. As seen from **Figure 5**, for large Δ values, the components of the split terms even cross each other making the approximation of the weak field invalid.

As with one *d* electron, the tetrahedral splitting is similar to the octahedral one, but with the inverse order of the energy levels: $\varepsilon(^3A_2) < \varepsilon(^3T_2) < \varepsilon(^3T_1)$. Again, $E_0^T = (2/3)E_0$ and $\Delta_T = -(4/9)\Delta$, provided the ligand charges q and their distances R to the IC are the same, as in the octahedron. For systems with lower symmetries the calculations are more difficult, but they can be reduced by using the method of equivalent operators or irreducible tensor operators.

The qualitative picture of term splitting for electronic configurations $[A](nd)^n$ with $n > 2$ in fields of lower symmetry can be found directly by using the complimentary rule: the configurations d^n and d^{10-n} have mutually inverted schemes of term splitting. In the case of weak fields, this rule is also valid for the pairs of configurations d^n and d^{5-n}.

Strong Fields. Low-Spin and High-Spin Centers

In the other limit case, opposite to the weak field one, the effect of the ligand field on the states of the IC is strong; it surpasses the electrostatic interaction between the electrons. In this case, the orbital coupling between the electrons is broken and, in fact, the states with a definitive total momentum quantum numbers, *L* (*S*, *P*, *D*, states etc.) cease to exist. In other words, each *d* electron chooses its orientation in space under the influence of the ligand field rather than the other *d* electrons. A formally similar situation occurs when the orbital coupling between the electrons is broken by the spin–orbital interaction (cf. the *jj*-coupling scheme). This is the so-called "strong ligand field limit."

It follows that when the ligand field is strong, atomic term splitting cannot occur since the terms themselves are destroyed. To determine the states in this case, one should first find out the orientations of each of the *d* states in the ligand field, neglecting the electron interaction, and then evaluate the possible terms of the system taking into account the interaction of the electrons in these crystal-field-oriented electronic states. For one *d* electron in the octahedral field of the ligands, there are two nonequivalent orbital states: the more stable t_{2g} state (d_{xy}, d_{xz}, d_{yz}) in which the electrostatic repulsion from the six ligands is smaller, and the less stable (higher in energy by △) state e_g ($d_{x^2-y^2}$, d_{z^2}) in which the repulsion from the ligands is larger. Hence in the strong ligand field, neglecting the electron interaction, the *d* electrons first occupy the t_{2g} orbitals (maximum six electrons) and then the e_g orbitals (four electrons); the electron configuration is $(t_{2g})^n$ for $n < 6$, and $(t_{2g})^6(e_g)^{n-6}$ for $n > 6$. The energy terms can be obtained from these configurations by including the electron interaction.

Consider the case of the atomic electron configuration $[A](nd)^2$. The two *d* electrons in the ground state of an octahedral complex occupy two t_{2g} orbitals (the state with two electrons in one orbital is higher in energy) forming the $(t_{2g})^2$ configuration. In the excited states, one of the two *d* electrons can occupy the e_g orbital and form the $(t_{2g})^1(e_g)^1$ configuration, which has higher (by △) energy than $(t_{2g})^2$; the two electrons can occupy the e_g orbitals, resulting in the excited $(e_g)^2$ configuration, which has high energy compared to $(t_{2g})^1(e_g)^1$ (by △) and also compared to $(t_{2g})^2$ (by 2△).

Thus, the d^2 configuration in the strong octahedral field forms three configurations $(t_{2g})^2$, $(t_{2g})^1(e_g)^1$, and $(e_g)^2$ – situated consecutively with an energy

spacing $\triangle$ (**Figure 6c**). In each of these configurations, the electron interaction yields several terms, similar to the term formation in the free atom. The resulting terms for the $(t_{2g})^2$ configuration expressed by atomic Racah parameters A, B and C (obtainable from spectroscopic data) are as follows:

$$\begin{aligned}\varepsilon(^3T_{1g}) &= A - 5B \\ \varepsilon(^1T_{2g}) &= A + B + 2C \\ \varepsilon(^1E_g) &= A + B + 2C \\ \varepsilon(^1A_{1g}) &= A + 10B + 5C\end{aligned} \qquad [25]$$

The splitting of all the above configurations that emerge from d^2 is shown in **Figure 6e**. In particular, the ground state of the $(t_{2g})^2$ configuration $^3T_{1g}$ is the same as in the weak field limit. However, the sequence and spacing of the excited states is essentially different. The differences occur for $n = 4, 5, 6, 7$ in octahedral symmetry, and for $n = 3, 4, 5, 6$ in tetrahedral systems. It is important that in these cases, the spin multiplicity of the ground state is always lower in the strong field limit than in the weak field. Therefore, the centers with strong ligand fields are called low-spin centers, as distinct from complexes with weak ligand fields known as high-spin centers.

The criterion of validity for the strong field limit requires that the CFS is smaller than the energy gap $\triangle$ between the three configurations: $(t_{2g})^2, (t_{2g})^1\ (e_g)^1$, and $(e_g)^2$. For the splitting of the $(t_{2g})^2$ configuration the largest distance between its components in [25] is $15B + 5C$; hence, the condition of validity of the strong field approach is $15B + 15C \ll \triangle$. Otherwise the terms of the same symmetry from different configurations become strongly mixed (e.g., $^1T_{2g}$ from $(t_{2g})^2$ with $^1T_{2g}$ from $(t_{2g})^1(e_g)^1$); this is known as "configuration interaction."

For more than two d electrons, the criterion of validity of the strong field approximation can be established similarly. Of special interest are the cases of d^4, d^5, d^6, and d^7 in octahedral complexes and d^3, d^4, d^5, and d^6 in tetrahedral systems, for which the two-limit cases differ by the spin of the ground state. The pairing energy Π is defined as the difference between the energies of interelectron interactions in the low-spin and high-spin complexes, respectively, divided by the number of pairings destroyed by the low-spin → high-spin transition. It is obvious that the low-spin state is preferable if

$$\Pi < \triangle \qquad [26]$$

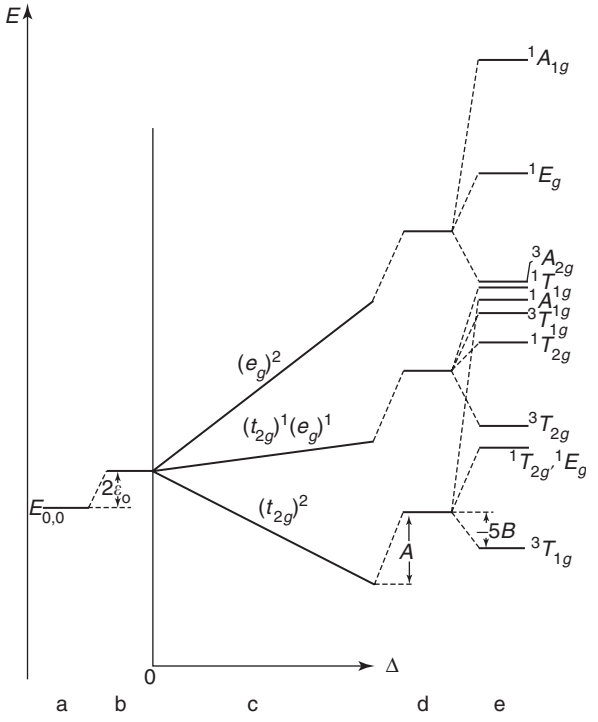

Figure 6 Splitting of the terms of the d^2 configuration in strong fields of octahedral symmetry: (a) d electron energy level, (b) crystal field destabilization, (c) crystal field splitting as a function of $\triangle$, (d) electron interaction destabilization, (e) electron interaction splitting. This material is used by permission of John Wiley & Sons, Inc.)

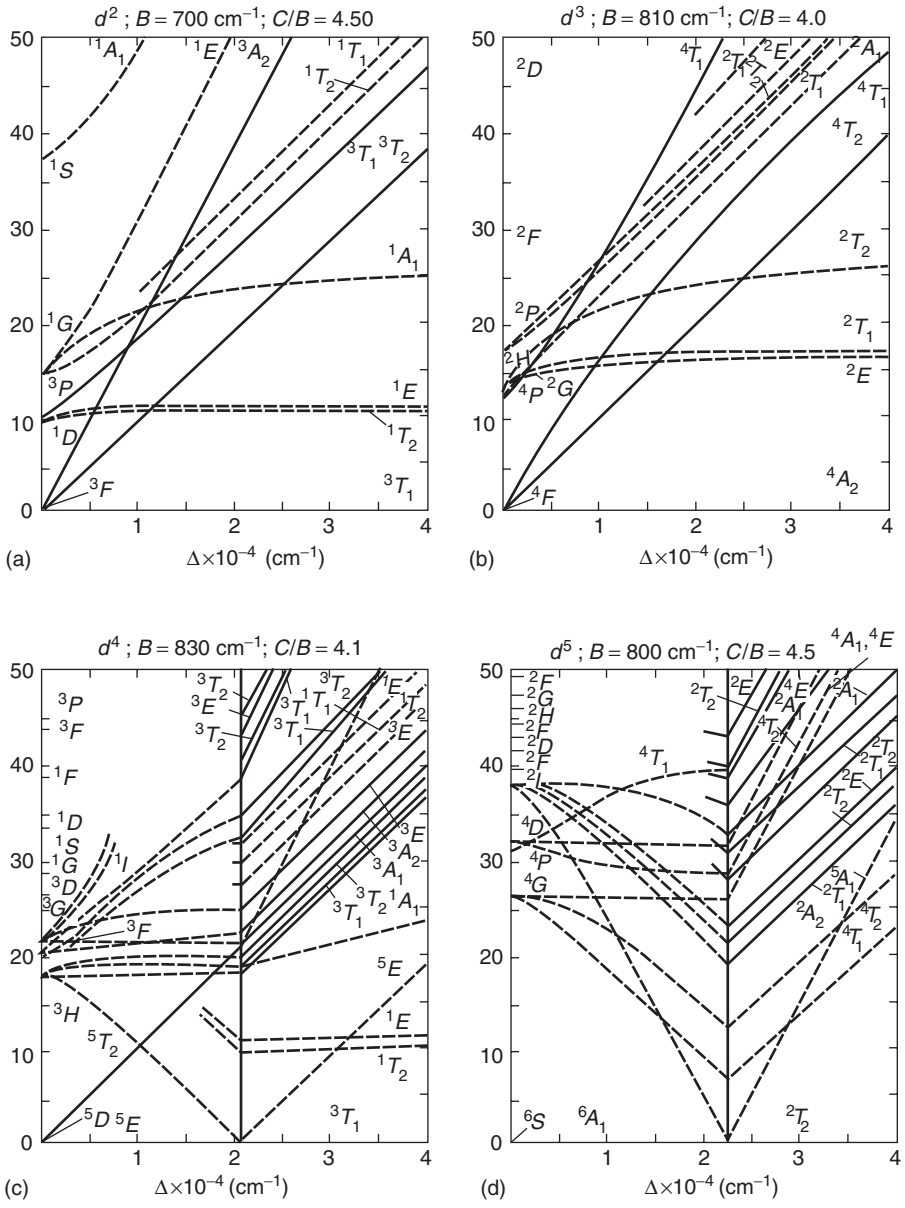

Figure 8 (a–g) The Tanabe–Sugano diagrams: energy terms of IC with d^n configurations, $n = 2, 3, \ldots, 8$, as a function of octahedral crystal fields $\triangle$ in 10^3 cm^{-1}. For convenience, the energy terms with multiplicities different from the ground state ones are given by dashed lines. The indices *g* and *u* are omitted. Some levels of minor significance are not shown. (Reprinted with permission from Bersuker IB (1996) *Electronic Structure and Properties of Transition Metal Compounds. Introduction to the Theory*. New York: Wiley; © Wiley. This material is used by permission of John Wiley & Sons, Inc.)

On the contrary, if

$$\Pi > \triangle \qquad [27]$$

the high-spin state is the ground state. The pairing energy is the lowest for the d^6 configuration, and hence the low-spin state is preferable in octahedral fields with this configuration as compared with others ceteris paribus. Since the $\triangle$ value in tetrahedral fields is significantly smaller than that for octahedral systems, the low-spin configuration for the former is much less probable than for the latter.

Tanabe–Sugano Diagrams

If the ligand field has intermediate strength for which neither the criterion of weak field nor of strong field is realized, the problem should be solved with the ligand field and electron interactions considered simultaneously to account for the configuration interaction, which produces repulsion of terms with the same symmetry ("nonintersection rule"). **Figure 7** illustrates this effect for the $^4T_{1g}(F)-{}^4T_{1g}(P)$ repulsion in octahedral ($^4T_1(F)-{}^4T_1(P)$ in tetrahedral)

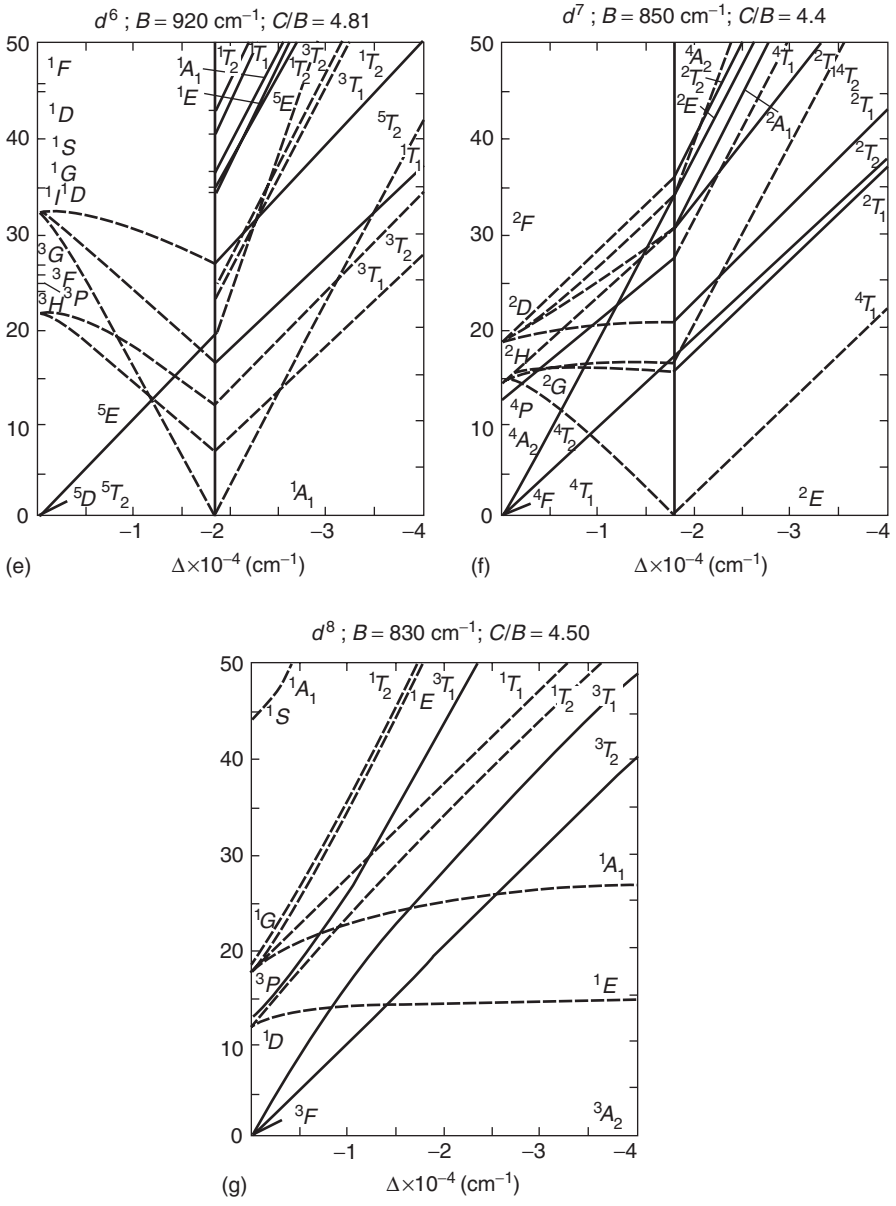

Figure 8 (Continued)

$d^3(d^7)$ IC. Energy level diagrams as functions of the CFT parameter Δ for all the d^n configurations ($n = 2$, 3, 4, 5, 6, 7, 8) were calculated numerically by Tanabe and Sugano (**Figures 8a–8c**). In these diagrams, the energy read off is taken at the ground state. Therefore, at a certain value of Δ (more precisely, Δ/B), there is a term crossing, the ground state changes and all the energy levels on the diagram are subject to a break. Usually at this break the ground-state multiplicity also changes, and there is a transition from the weak ligand field to the strong field. The Tanabe–Sugano diagrams give the most complete information about the electronic structure of the system in the CFT model.

f-Electron Term Splitting

One of the important features of *f* electrons is that they are usually screened from the ligand field by the outer *s*, *p*, *d* electrons and hence they are less affected by the ligands than the *d* electrons. On the other hand, the *f* electrons are subject to stronger spin–orbital coupling. For *f* electrons in weak fields, the atomic terms should be characterized (in addition to L and S) by the quantum number $J = L + S - 1,\ L + S - 2, \ldots, |L - S|$ that takes into account the spin–orbital interaction. Since the total spin S can be half-integer, J may also be half-integer. For instance, the states of one *f* electron are characterized by $L = 3, S = 1/2, J = 7/2$ and $5/2$,

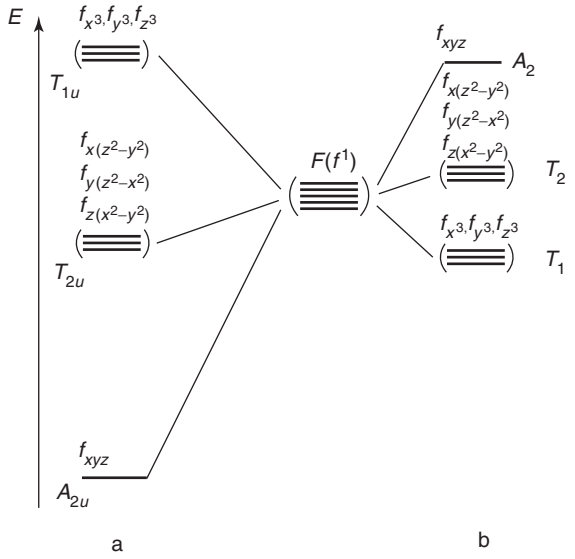

Figure 9 Splitting of the atomic energy levels of one *f* electron in (a) octahedral and (b) tetrahedral crystal fields (the spin–orbital interaction is neglected). (Reprinted with permission from *Electronic Structure and Properties of Transition Metal Compounds. Introduction to the Theory*. New York: Wiley; © Wiley. This material is used by permission of John Wiley & Sons, Inc.)

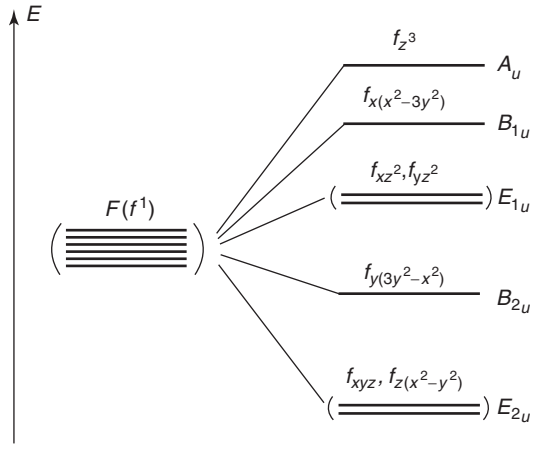

Figure 10 Splitting of one *f* electron energy levels in the field of a hexagonal biprism. (Reprinted with permission from Bersuker IB (1996) *Electronic Structure and Properties of Transition Metal Compounds. Introduction to the Theory*. New York: Wiley; © Wiley. This material is used by permission of John Wiley & Sons, Inc.)

and with the spin–orbital interaction included there are two terms: $^2F_{7/2,}$ $^2F_{5/2}$. The weak field approximation here means that the splitting of each of these terms by the ligand field can be considered separately.

A visual interpretation of the CFS can be obtained in a simplified model by neglecting the spin–orbital coupling. In particular, considering the angular distributions of atomic *f* electron functions (from the cubic set) and the corresponding electrostatic repulsion of the electron in these states from six point charges (or dipoles) of an octahedral cluster, one can conclude that in the three states f_{x^3}, f_{y^3}, and f_{z^3}, the repulsion is the greatest (and equal for all of them). In the other three states $f_{x(y^2-z^2)}$, $f_{y(z^2-x^2)}$, $f_{z(x^2-y^2)}$, the repulsion is equally strong but smaller than in the previous three states, and in the f_{xyz} state it is the smallest. Thus, the sevenfold orbitally degenerate *F* term of the free atom (ion) with one *f* electron is split by the octahedral crystal field into three terms from which one is nondegenerate and two are threefold degenerate, $F \rightarrow A_{2u} + T_{2u} + T_{1u}$ (**Figure 9**). In tetrahedral fields, similarly to *d* electron states, the CFS picture is inverted. By way of example, one can also show the scheme of splitting of the energy levels of an *f* electron in the field of a hexagonal biprism with the sixfold axis along the *z*-axis (**Figure 10**), which is realized, for instance, in uranyl centers (here the low-symmetry set of one-electron atomic angular *f* functions is used).

With the spin–orbital interaction included, the *f* electron CFS can be determined qualitatively by symmetry considerations. If *J* is an integer, the splitting coincides completely with that expected for the corresponding *L* value given in **Table 1**. For semi-integer *J* values, the double groups of symmetry should be employed, the terms being classified by their irreducible representations E_1', E_2' (twofold degenerate), G' (fourfold) or, respectively, $\Gamma_6, \Gamma_7, \Gamma_8$ in Bethe's notations (**Table 2**).

Table 2 Splitting of atomic terms with semi-integer *J* values in crystal fields of different symmetry

J	*Cubic symmetry* O'	*Tetragonal symmetry* D_4'	*Hexagonal symmetry* D_6'
1/2	E_1'	E_1'	E_2'
3/2	G'	$E_1' + E_2'$	$E_2' + E_3'$
5/2	$E_2' + G'$	$E_1' + 2E_2'$	$E_1' + E_2' + E_3'$
7/2	$E_1' + E_2' + G'$	$2E_1' + 2E_2'$	$E_1' + 2E_2' + E_3'$

Crystal Growth, Bulk: Methods

G Müller, University of Erlangen-Nuernberg, Erlangen, Germany
J Friedrich, Fraunhofer Institute IISB, Erlangen, Germany

Introduction

Many modern technological systems would not exist without the availability of synthetic single crystals. Therefore, the technology to prepare and to produce bulk single crystals – which is called "crystal growth" – is one of the current key technologies.

This article gives a brief overview about the techniques which are used to grow bulk single crystals of inorganic materials. The fundamental physical and physicochemical mechanisms which govern the crystal growth processes are treated elsewhere. The growth of epitaxial films as well as of organic materials are also not considered.

The structure of the article is sketched in **Figure 1**.

Melt Growth

The most frequently used and most important method of producing bulk single crystals is by solidifying

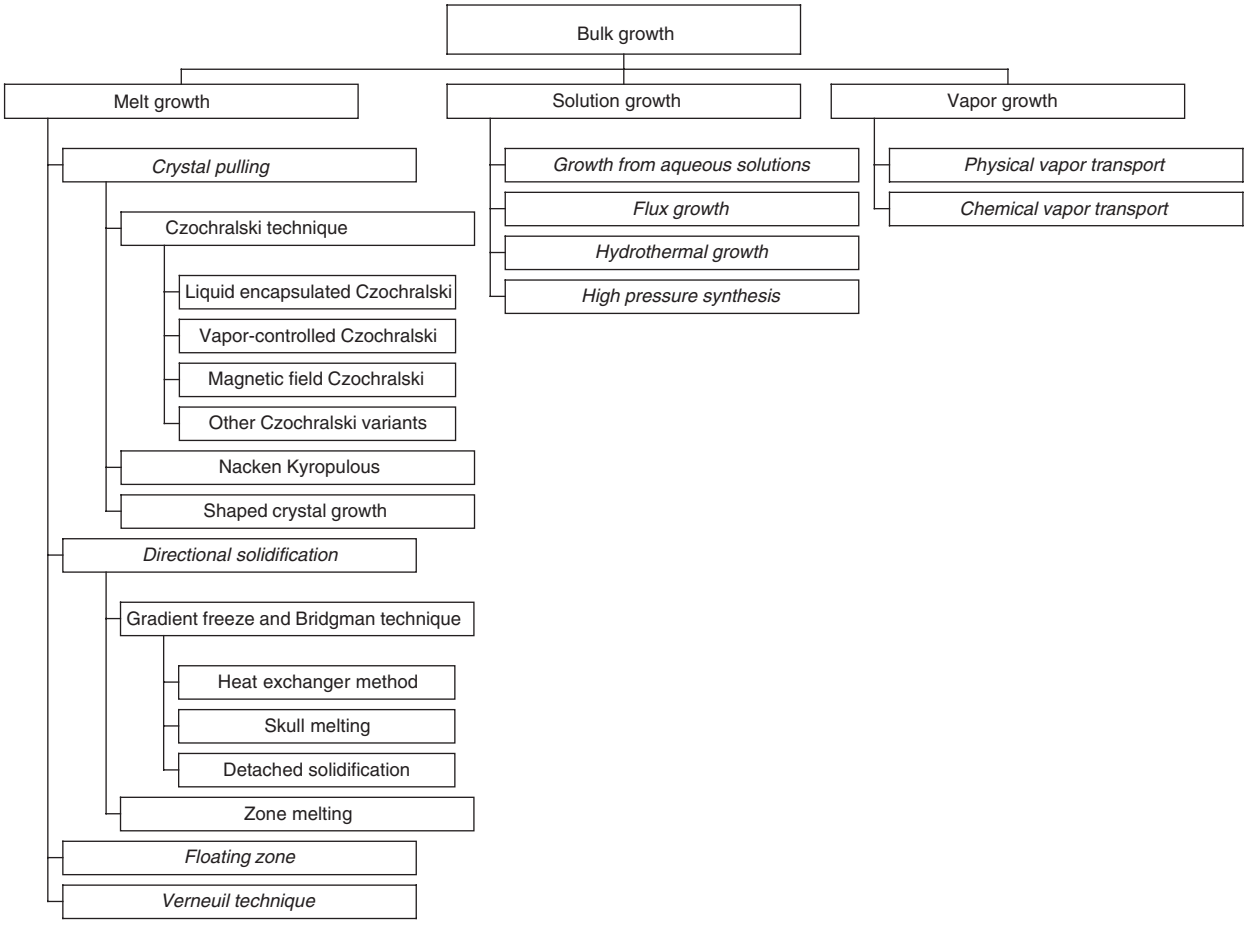

Figure 1 Overview of methods for bulk crystal growth.

the material from its melt (melt growth). Only if the crystal to be grown has no congruent melting point, or if the melting point or vapor pressure are too high, the crystals have to be grown either from solutions or from the vapor phase.

Crystal Pulling

Czochralski technique The Czochralski (Cz) method is the most important method for the production of bulk single crystals of a wide range of electronic and optical materials (**Figure 2**). At the beginning of the process, the feed material is put into a cylindrically shaped crucible and melted by resistance or radio-frequency heaters. After the feed material is completely molten, a seed crystal with a diameter of typically a few millimeters is dipped from the top into the free melt surface and a melt meniscus is formed. Then, after re-melting of a small portion of the dipped seed, the seed is slowly withdrawn from the melt (often under rotation) and the melt crystallizes at the interface of the seed by forming a new crystal portion. During the further growth process, the shape of the crystal, especially the diameter, is controlled by carefully adjusting the heating power, the pulling rate, and the rotation rate of the crystal. Therefore, an automatic diameter control is generally applied. This diameter control is based, either on the control of the meniscus shape (e.g., for silicon) or on the weighing of the crystal (e.g., for GaAs, InP) or of the melt (for oxides).

In order to control the convective heat and species transport in the melt including the shape of the solid–liquid interface, which plays one of the most dominant roles in terms of the crystal quality, a proper combination of crystal and crucible rotation is used during the whole process.

The most important technical application of the Cz method is the growth of dislocation – free silicon crystals with diameters of 300 mm and a weight up to 300 kg (**Figure 3**). Germanium crystals are also mainly produced by the Cz method as well as several technically important oxide and fluoride crystals like

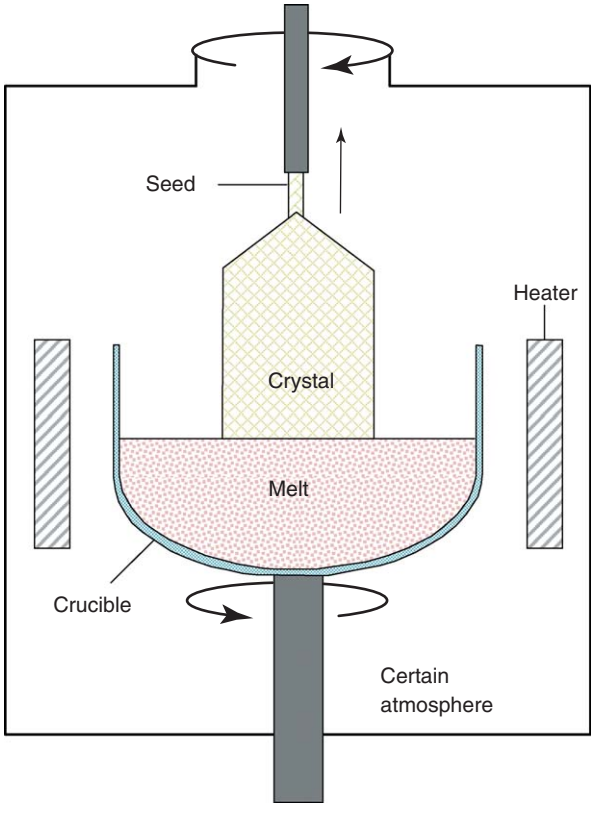

Figure 2 Schematic of the principle of the Cz method.

garnets, niobates, tantalates, silicates, vanadates, aluminates, and germanates.

If the material to be grown has a high partial pressure of one or more components, a modified Cz-setup is used (**Figure 4**), which is called the liquid-encapsulated Czochralski (LEC) method. In the LEC-setup a liquid, generally boric oxide, is placed at the top of the melt surface to encapsulate the melt. This liquid layer prevents the loss of a volatile component by evaporation from the melt if the pressure in the growth chamber exceeds the partial pressures of the components.

Today, the LEC-technique is the most widely used growth method for the compound semiconductors GaAs, GaP, InP as well as for PbSe, PbTe. For example, GaAs crystals are industrially produced with diameters of 150 mm and LEC growth of GaAs crystals with 200 mm in diameter is already demonstrated.

However, the low thermal conductivity of the liquid encapsulant causes large temperature gradients and large temperature nonlinearities in the growing crystal. This is unfavorable with respect to the crystal quality as a relatively large number of structural defects (many dislocations) are generated in the crystal compared to other growth techniques.

The high-temperature gradients of the Cz/LEC-method can be reduced by installing an additional inner growth chamber, with hot walls. In this inner growth chamber, a vapor pressure is generated by an extra source to prevent a decomposition of the crystal (the so-called vapor-controlled Czochralski technique (VCz)).

Although the VCz-method is a rather complex technique, it is successfully used to grow GaAs, InP, and BGO crystals with reduced defect densities not only in R&D, but also in industrial production.

The heat and species transport in the melt has a very strong influence on the crystal properties as they are responsible for the uniformity of dopants on the micro- and macro-scale as well as for the shape of the solid–liquid interface and, therefore, for the thermal stress generated in the crystal. During growth, the use of stationary or time-dependent electromagnetic fields enables the control of the flow in electrically conducting melts (e.g., semiconductors). A Lorentz force is generated in the melt, which depends on the magnetic field configuration and leads either to a damping of the flow or to a stimulation of a certain flow pattern.

Today, magnetic fields (**Figure 5**) are used in the industrial production of silicon crystals with 300 mm diameter as well as for growing InP crystals by the LEC and VCz methods.

In order to improve the axial uniformity of the dopant distribution in the grown crystal, the crystal can be grown in such a way that the melt volume is kept constant by supplying the solidified portion from a source. Such a source can be realized either by

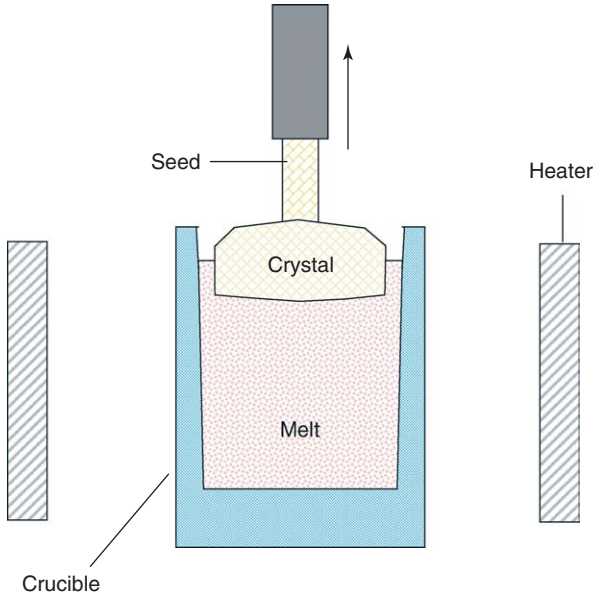

Figure 6 Schematic of the principle of the Nacken–Kyropulous method.

continuously supplying the melt with a feed (continuous Czochralski (CCz) method) or by placing an inner crucible with holes in a larger outer crucible (double crucible Czochralski technique). Although the feasibility of these methods was demonstrated, its use for production is limited owing to technical and material problems preventing a high yield.

Nacken Kyropulous The Kyropulous (or Nacken Kyropulous) method is rather similar to the Cz method. The main difference is that the crystal is not growing at the top of the melt as in the Cz method but is partly immersed in the melt (**Figure 6**). In order to extract efficiently the heat from the growing crystal, usually a seed with a large diameter is used. Growth is achieved by either lowering continuously the heating power or by pulling out the growing crystal carefully from the melt.

This method is widely used to produce alkali halide crystals for optical components (NaCl, KBr) and alkali iodides for scintillators (NaI, CsI). Crystals with dimensions over 500 mm have been achieved.

Shaped crystal growth For a variety of technological applications, crystals of specified size and shape such as plates, rods, tubes, fibers are required. Often it is more cost efficient to grow shaped crystals instead of preparing the needed shape from cylindrical boules as they are grown by, for example, the Cz method.

The diameter of a crystal in the Cz pulling techniques is controlled by the shape and position of the melt meniscus at the triple point crystal-melt-gas (or encapsulant). This control can be improved by using

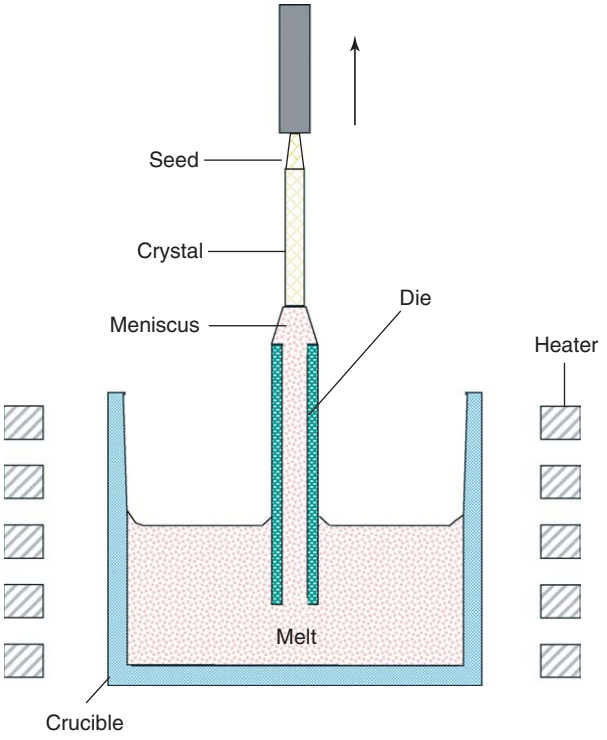

Figure 7 Schematic of the principle of the EFG method.

a die which is in contact to the melt. The melt raises in a narrow channel in the die due to capillary effects. When the seed crystal is dipped onto the melt portion at the top of the die, the meniscus is formed. Liquid solidifies at the seed while the seed is pulled away (**Figure 7**). This causes new liquid to raise up in the die. The heat of crystallization is removed from the solid–liquid interface very efficiently by conduction and by radiation.

The method for growing shaped crystals as described above is commonly known as the Stepanov method (nonwetting die-melt system) or edge-defined film-fed growth (EFG) (wetting die-melt system). In the case of fiber crystals, the method is also called micro pulling down method (μPD) because a crystal fiber with a diameter of only some hundred microns can be grown from a die by pulling the crystal downwards (**Figure 8**). Variants of the EFG method are the noncapillary shaping (NCS) method where the diameter of the die channel is greater than the value of the capillary constant (**Figure 8**). The NCS method offers advantages in order to avoid the generation of bulk micro defects in the growing crystal caused by gaseous or solid inclusions.

Applying a continuous displacement to the growing crystal or the die allows one to grow crystals with more complex shapes (**Figure 8**), for example, domes or hollow cones. This method is named growth from an element of shape (GES).

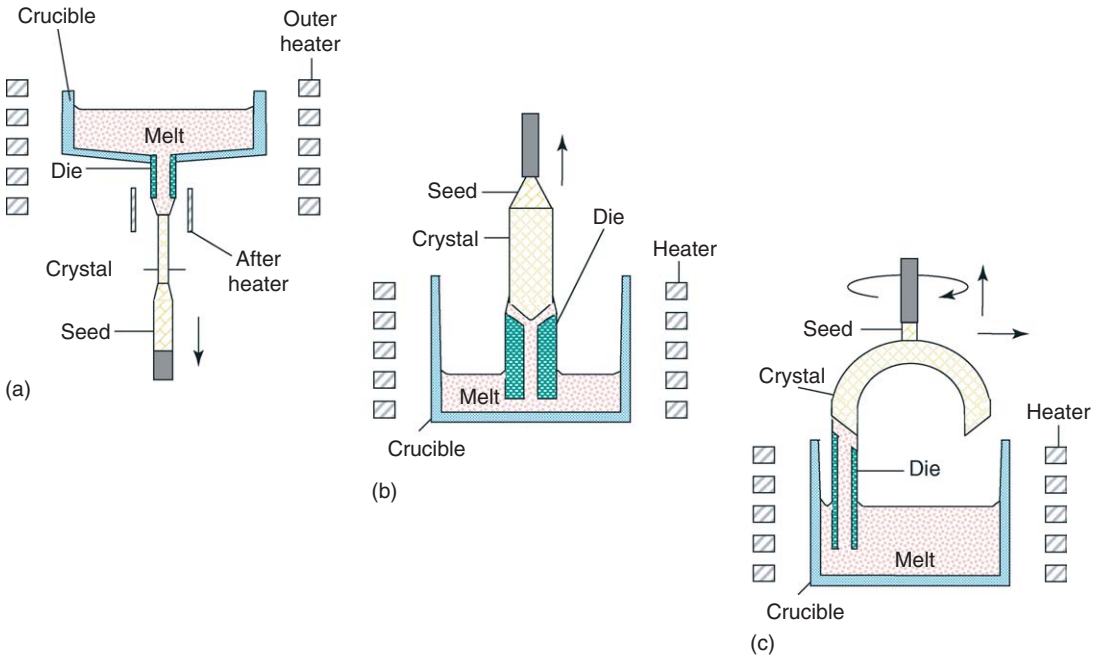

Figure 8 Schematic of the principle of the μPD (a), NCS (b), and GES (c) methods.

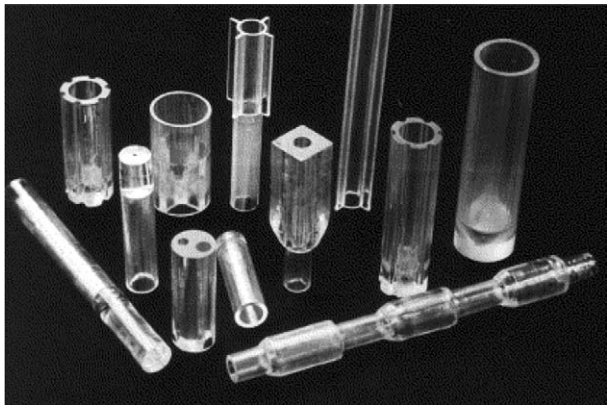

Figure 9 Shaped sapphire crystals grown by the EFG, NCS, and GES techniques. (Reproduced from Kurlov VN (2001) Properties, growth, and applications. In: *Encyclopedia of Materials: Science and Technology* pp. 8259–8265, with permission from Elsevier.)

Nowadays, shaped crystal growth is mainly used for production of silicon and sapphire. Sapphire crystals in the form of ribbons up to 150 mm in width, tubes up to 85 mm in diameter, fibers, near-net-shaped domes (up to 80 mm in diameter), rods of various cross sections, rods with capillary channels, etc., were grown by the shaped growth techniques described above (**Figure 9**).

For photovoltaic applications, the use of near-net shape silicon substrates reduces material losses and process costs by minimizing the efforts for slicing, grinding, and polishing, which is required in bulk-grown silicon. Therefore, the share of thin silicon ribbons or thin wall (octagonal) tubes grown by the EFG method (**Figure 10**) is continuously increasing in the substrate market for solar cells.

Directional Solidification

As against crystal pulling, the growth of single crystals in directional solidification is achieved by melting a charge in a crucible and by controlled freezing of the melt from one end (seed) to the other (tail). Directional solidification is the basic principle of controlled solidification of a melt. It has been used for many materials for a long time and has its greatest importance in the field of metallurgical casting.

Directional solidification has several advantages compared to the Cz methods. It operates usually under stable hydrodynamic conditions, it is well suited for computer modeling and for automatic process control, the crystal grows under low thermal stress conditions, cylindrical crystals are grown without any diameter control, and the equipment is less expensive.

However, a crucial limitation of directional solidification is that a strong interaction between the growing crystal and the crucible material might occur, resulting in crystal imperfections which limits the yield and hence the industrial applicability. Furthermore, the failures generated in the crystal during growth, for example, by twinning or polycrystal formation cannot be observed *in situ* during growth. A correction by re-melting as it is done in the Cz methods is, therefore, not possible.

Gradient freeze and Bridgman–Stockbarger techniques The crystal growth configuration consists typically of a tube furnace which provides a temperature profile with a negative gradient parallel to the growth direction (**Figure 11**). The method can be carried out by moving the growth interface in a horizontal or vertical direction. The single-crystal seed is positioned at one end of the boat or the lower end of the vertical crucible. Then, the crystal is directionally solidified by a controlled shifting of the temperature profile relative to the solid–liquid interface. Three possibilities exist: moving the crucible relative to the fixed furnace (Bridgman–Stockbarger method); moving the furnace relative to the fixed crucible; and without any mechanical movement, only shifting the temperature profile by a controlled change of the heating powers of the furnace (Tamann–Stoeber or gradient freeze method).

Figure 10 Silicon octagons grown by the EFG method. (Reproduced from Kalejs JP (2002) Silicon ribbons and foils – state of the art. *Solar Energy Materials and Solar Cells* 72(1–4): 139–153, with permission from Elsevier.)

Based on one of these principles, one calls the technique the horizontal Bridgman (HB) or the vertical Bridgman (VB) or the vertical gradient freeze (VGF) method. From an industrial point of view, the vertical configurations (VGF, VB) are preferred because they result in a higher yield of round wafers compared to the HB method.

The increasing interest in the use of the directional solidification results from the fact that it uses the simplest principle of melt growth and that the structural perfection of the single crystals with respect to thermal stress and dislocation formation is better than those of crystals produced by Cz methods.

Nowadays, the VGF or VB method is mainly used for the production of compound semiconductors such as high-quality GaAs and InP single crystals to be used as substrates for laser diodes or CdTe crystals for infrared and X-ray detectors. A variety of oxide and fluoride crystals are grown by VGF/VB methods for high-value applications. For example, CaF_2 crystals (**Figure 12**) are utilized as lenses for the deep ultraviolet wavelength in the semiconductor lithography technology. In the field of metallurgy,

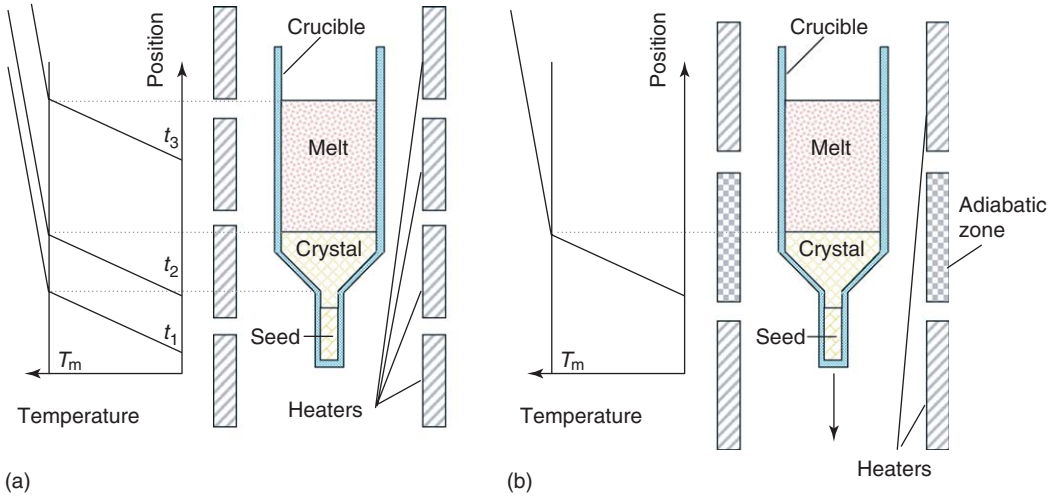

Figure 11 Schematic of the principle of directional solidification methods; (a) VGF and (b) VB method.

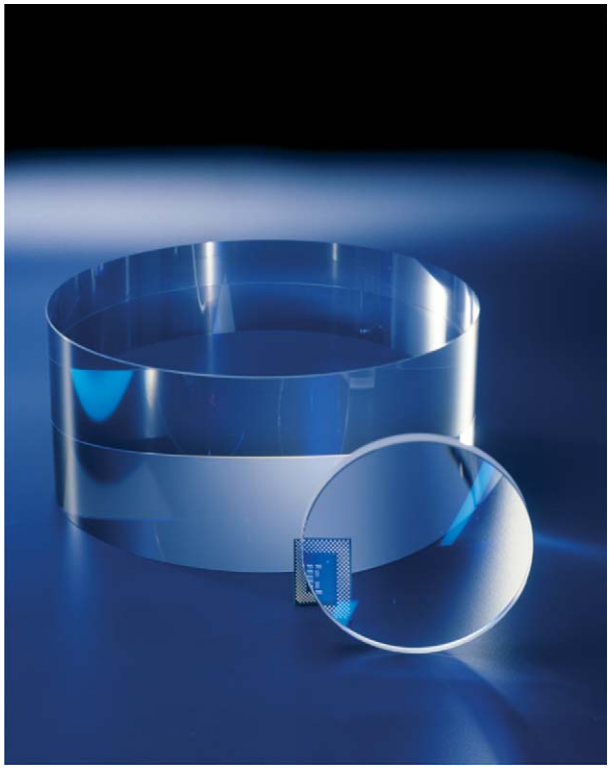

Figure 12 CaF_2 crystals as lense material for the microlithography are grown by modified Bridgman–Stockbarger methods. (Source: SCHOTT Lithotec.)

directional solidification is used to manufacture single crystalline turbine blades made from nickel-based superalloys (**Figure 13**).

The heat exchanger method (HEM) is a modified directional solidification technique. The original characteristic of HEM is that a gas-cooled heat exchanger is placed below the seed-crystal (**Figure 14**). After melting and homogenization, growth is initiated and carried out by increasing the cooling gas flow and decreasing the furnace temperature.

HEM was developed mainly for the growth of large sapphire crystals with diameters up to 500 mm. Several tons of solar-grade polycrystalline silicon as well as CdTe and BGO crystals are also grown by HEM. For these materials, the HEM technology is often fluently merged into the VGF/VB technology.

For refractory materials with high chemical reactivity and melting points above 2000°C, often no suitable crucible material exists. This problem is overcome by the "skull melting" technique, where the material to be grown serves as the crucible. RF heating is used to melt the charge contained in a water-cooled crucible (e.g., copper). As a result of the water cooling, a skull of sintered material is formed which acts as a noncontaminating crucible for the melt. Crystals are typically grown by directional solidification of the molten charge without a seed crystal.

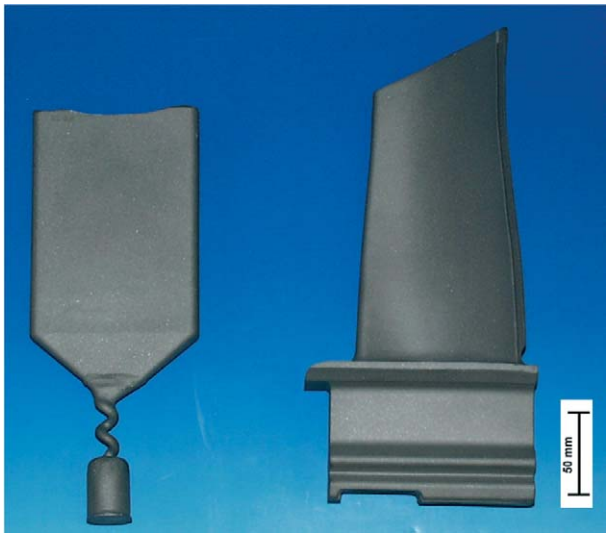

Figure 13 Single crystalline turbine blades made by directional solidification of nickel-based superalloys. (Reproduced with permission from Institute of Science and Technology of Metals, University Erlangen-Nuernberg.)

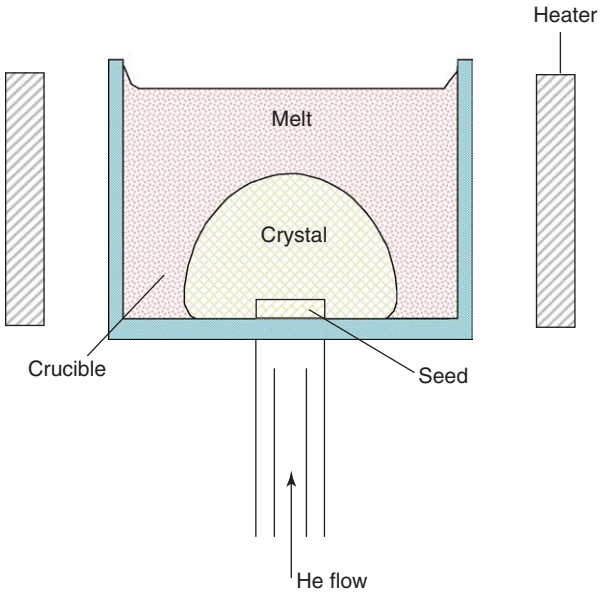

Figure 14 Schematic of the principle of the HEM method.

The method is used, for example, to grow 50–100 tons of cubic ZrO_2 per month for gemstones. Sometimes this technique is also named "cold crucible technology," especially when the melt is levitated by an RF field in such a way that no contact exists between the molten charge and the water-cooled crucible.

One interesting variant of the directional solidification method is the so-called detached solidification (**Figure 15**). In detached solidification, which is also called the de-wetting growth process, a small gap between the growing crystal and the crucible wall

exists. The formation and stability of such a gap depends on the wetting behavior between the melt and the crucible material, the contact angle, the growth angle, and external forces (especially a certain gas pressure difference between the gap and the top of the melt).

The experimental results achieved so far for CdTe, Ge, GeSi, and GaSb on earth and also under microgravity demonstrate that the structural perfection of the crystals is generally improved when the dewetting effect occurs. However, there still remains a lot of research to be done until this technology can be transferred into industrial production.

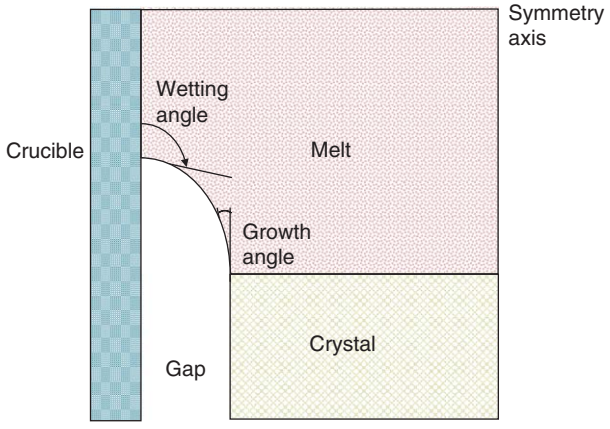

Figure 15 Schematic of the principle of detached solidification.

Zone melting in crucibles In zone melting only a part of the solid is melted in a crucible or a boat by using a resistance or induction zone heater (**Figure 16**). Growth is achieved by moving the heat source relatively to the axis of the container. Nowadays, the importance of zone melting for bulk crystal growth is mainly limited to its use for purification of the feed material. Impurities with a segregation coefficient $k_0 < 1$ can be accumulated very efficiently by multiple passes of melt zones toward the end of the ingot.

Floating Zone (Crucible-Free Zone Melting)

The floating zone (FZ) technique is a crucible-free crystal growth method. In FZ growth, the molten zone is kept between two vertical solid rods by its own surface tension (**Figure 17**). A single crystal is grown by dipping a seed crystal into one end of the zone and translating the molten zone toward the feed stock. The main advantage of the FZ technique is the absence of the container, which precludes a contamination by the crucible material and the generation of crystal defects caused by the interaction between the growing crystal and the container. Therefore, the technique is especially used for highly reactive materials, intermetallic compounds, and refractory materials. The heating of the molten zone can be achieved by several methods including RF induction, optical, electron beam, laser and resistance heating.

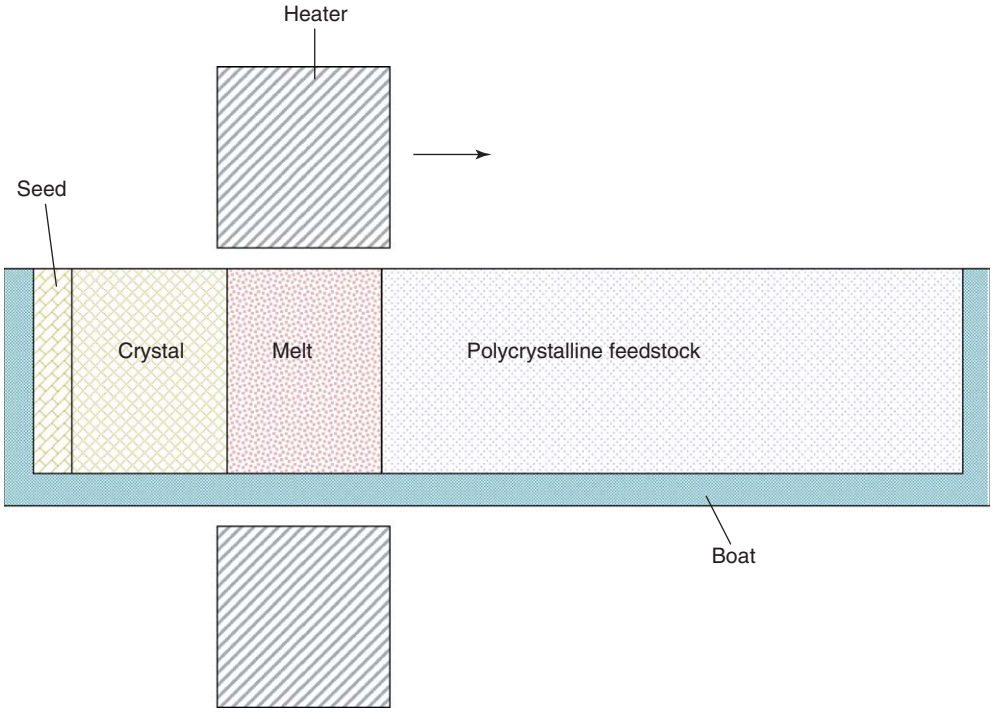

Figure 16 Schematic of the principle of zone melting.

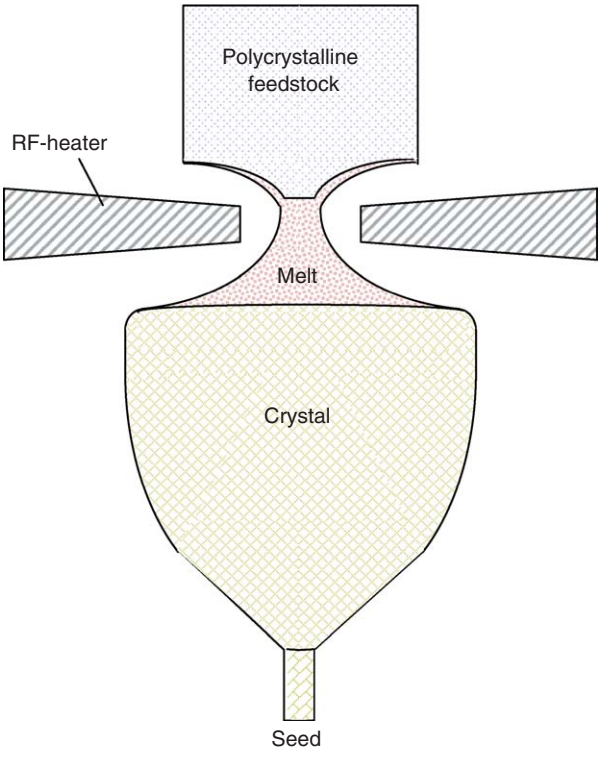

Figure 17 Schematic of the principle of the FZ method for growing Si crystals.

Figure 18 GaAs crystals grown by the FZ technique; left: sample grown in space under microgravity during the German Spacelab mission D2, right: sample grown on earth with maximum size. (Source: Crystal Growth Laboratory, Fraunhofer IISB, Erlangen.)

The industrial application of the FZ technique is rather limited because the maximum sample diameter is relatively small due to the difficulties in maintaining a stable molten zone. Usually the maximum height of the molten zone is a few millimeters, which is determined by the ratio between the surface tension and the density of the melt.

These difficulties were overcome in the industrial FZ growth of silicon by using the needle-eye technique. In the needle-eye technique, the shape of the molten zone is stabilized by the electromagnetic pressure field generated with a specially shaped RF-induction coil. The silicon crystals produced by this FZ technique have diameters of up to 200 mm and extremely low oxygen contamination ($< 10^{16}\,\mathrm{cm}^{-3}$). Such pure silicon substrates are needed for power electronic devices.

Crystals of other materials with higher density and lower surface tension, for example, GaAs can only be grown with larger diameters under microgravity conditions (**Figure 18**).

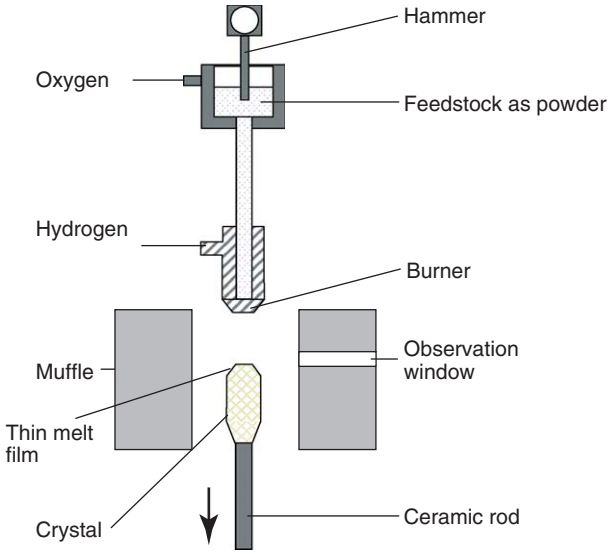

Figure 19 Schematic of the principle of the Verneuil method.

Verneuil Technique

The Verneuil technique (**Figure 19**), also called the flame fusion technique, is one of the oldest methods for growing refractory oxide crystals. The feed is a fine powder which is fused by an oxygen–hydrogen flame burner while falling down toward the growing crystal. A thin melt film is formed on top of the growing crystal, which is slowly pulled down. It is important to balance the rate of powder feed and the rate of pulling to maintain a constant growth rate

and crystal diameter. Otherwise, the thermal field in the vicinity of the solid–liquid interface is changed which results in poor crystal quality.

The advantage of this process is the low equipment costs. The main disadvantage is the extremely large temperature gradient causing a high density of stress-induced crystal defects. Therefore, often an after heater is used in order to prevent the crystal from cracking.

Nowadays, the Verneuil technique is exploited for the economic mass production of sapphire and ruby used in jewelry and precision bearings ($\sim$700 tons per year). Most high-melting oxide compounds can be grown using this technique.

Solution Growth

Opposite to melt growth where the crystal solidifies from its own melt, in solution growth the elements or compounds of the material to be crystallized are dissolved in a suitable solvent.

Principle

For crystal growth, the solution has to be supersaturated. This can be achieved by different means:

1. In the temperature changing technique, the solution is supersaturated by slow cooling as the solubility is usually decreasing with decreasing temperature (supersaturation is achieved by slow heating, if the solubility decreases with increased temperature)
2. In the evaporation technique, the supersaturation is obtained by controlled evaporating of the solvent at a constant temperature.
3. In the temperature gradient technique, two regions of different temperatures $T1$ and $T2$ are established. At the higher temperature $T1$, the material is dissolved, while at lower temperature $T2$ crystal growth takes place.

The growth rate is mostly limited by the transport rate of the solute to the growth interface. Therefore, an active mixing by an "accelerated crucible rotation technique" is used.

An important issue in solution growth is the selection of a suitable solvent. At the growth temperature, the solvent should generally have a sufficient solubility of the material to be grown as well as a low vapor pressure and low viscosity.

Low-Temperature Solution Growth

Low-temperature solution growth is one of the simplest methods to grow single crystals especially if aqueous solutions are used (**Figure 20**). Industrially important crystals grown by low-temperature solution growth are potassium dihydrogen phosphate (KDP, **Figure 21**) ammonium dihydrogen phosphate (ADP), both for electrooptic applications, and, for example, triglycine sulfate (TGS) for IR imaging applications.

Figure 21 KDP single crystal grown from aqueous solution. (Source: CEA.)

High-Temperature Solution Growth

Practically any material can be grown by high-temperature solution growth (often also called flux growth). Mainly low-melting temperature solvents

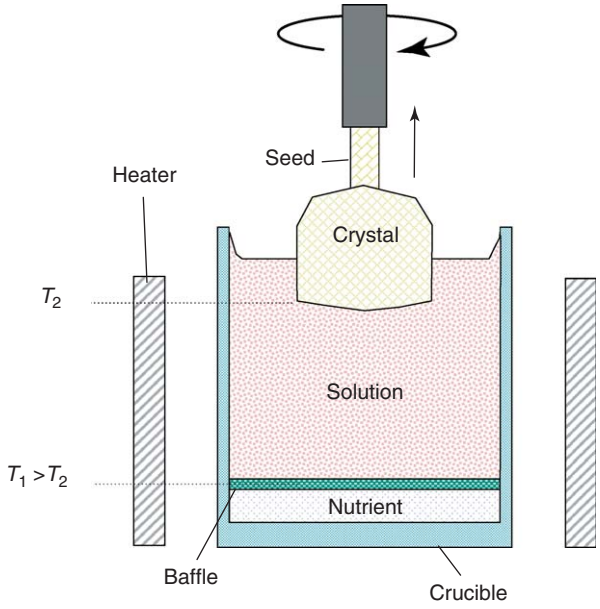

Figure 22 Typical equipment for the temperature gradient technique with top seeding (TSSG).

(fluxes), molten salts, and oxides are used. This method can be applied to congruent and non-congruent melting materials. Solution growth is also the preferable growth technique, if the material undergoes a destructive solid–solid phase transition below its melting point. It is also applied as liquid phase epitaxy to produce epitaxial layers on substrates. However, the growth rates are small compared to melt growth techniques and sometimes the solvent contaminates the crystal.

For a variety of technically important materials such as $Sr_{1-x}Ba_xNb_2O_6$ (SBN), $Pb_{1-x}Ba_xNb_2O_6$ (PBN), $LiNbO_3$, $BaTiO_3$, BBO, the so-called top-seeded solution growth method (TSSG) is used (**Figure 22**). TSSG corresponds to the CZ method; the only difference is that a solution is used instead of the melt.

In the field of semiconductor crystals, the use of solution growth is limited. In research laboratories the solution growth of ZnSe, ZnS, ZnTe, as well as of SiC and GaN is investigated.

Hydrothermal Growth

Hydrothermal growth refers usually to heterogeneous reactions in aqueous solvents or mineralizers above 100°C and under high pressure (several kbars). In hydrothermal growth, the high-pressure conditions are needed to enhance the solubility of the solute in the solvent. A precisely controlled temperature gradient is used to achieve the crystallization at the seed location (principle (3.) in the section "Principle").

Hydrothermal growth is extensively exploited to grow synthetic quartz (SiO_2) crystals. It is carried out in special vessels also called autoclave or bomb under pressures of typically 170 MPa and around 400°C. This technique has also been used to grow berlinite ($AlPO_4$), calcite ($CaCO_3$), and zincite (ZnO) crystals.

High-Pressure Synthesis

High-pressure synthesis refers to the growth of diamond crystals. In this method, anvils generate a pressure of around 60 kbar in the heated growth cell. The growth cell contains graphite mixed with a metal or alloy that serves as a solvent/catalyst. At around 1500°C diamond is the stable modification whereas graphite becomes meta-stable and is partially dissolved in the solvent. The solubility difference acts as a driving force for the conversion of carbon from graphite to diamond crystals in the solvent.

Vapor Growth

Vapor growth is like solution growth usually applied when melt growth is impractical. Due to the lower temperatures as compared to melt growth, many thermally activated processes like impurity incorporation, compositional uniformity, structural imperfection, are usually decelerated. Therefore, the crystal quality is enhanced. However, in vapor growth the growth rates are usually also considerably decreased due to the low density of crystal material in the gas phase, the low transport rate of the vapor to the growth region, and the decreased interface kinetics as the temperature is decreased.

Sublimation Technique

In physical vapor transport (PVT) often called as sublimation growth, a source material held at a temperature $T1$ sublimates, and its vapor is transported by diffusion and convection to the seed crystal held at a lower temperature $T2$ where it can crystallize. The supersaturation at the crystallization front depends on the difference of the partial pressures of the sublimated material in the source and growth region as well as on the total vapor pressure in the system. The supersaturation has to be precisely controlled in order to avoid parasitic nucleation.

Nowadays, the sublimation technique is industrially used to produce silicon carbide crystals with diameters of up to 100 mm (**Figure 23**). Typically, the growth takes place in an inductively heated graphite crucible at elevated temperatures ($T = 2100$–2400°C). A transport of Si, Si_2C, and SiC_2 gas species is established from the SiC source to the growing SiC

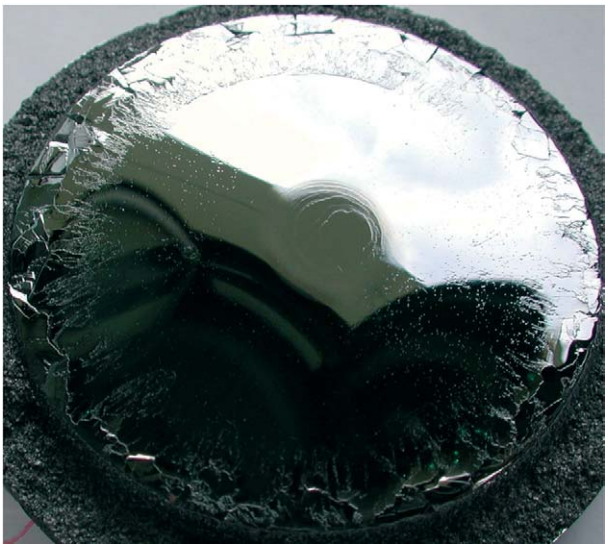

Figure 23 SiC crystal with 50 mm diameter grown by the PVT method. (Reproduced with permission from Institute for Material Science, Department of Electrical Engineering Materials, University Erlangen-Nuernberg.)

single crystal in an Argon ambient atmosphere ($p = 10$–100 mbar).

Also aluminum nitride is grown by PVT methods at temperatures above 2000°C. The PVT method is also used for II–VI compounds.

Chemical Vapor Transport and Chemical Vapor Deposition

In the chemical vapor transport (CVT) method, a reactive gas is used which reacts with the source material or gaseous chemical compounds containing the crystal components. This source material is transported as gaseous species to the growth zone of the reactor. Here, the reactions take place, forming the crystal components which are deposited at the growth interface.

CVT has less importance in bulk crystal growth, but is the dominant method for producing thin films. In bulk crystal growth, CVT is applied only on a laboratory level to grow a variety of materials especially chalcogenides. Nowadays, hydride vapor phase epitaxy (HVPE) as a variant of the CVT principle is used to grow thick free-standing gallium nitride substrates (**Figure 24**).

Conclusions

Bulk growth of inorganic crystals has become an important industrial key technology. Although methods to grow any inorganic crystal material are known in principle, continuous R&D efforts are necessary for a further development of the processes

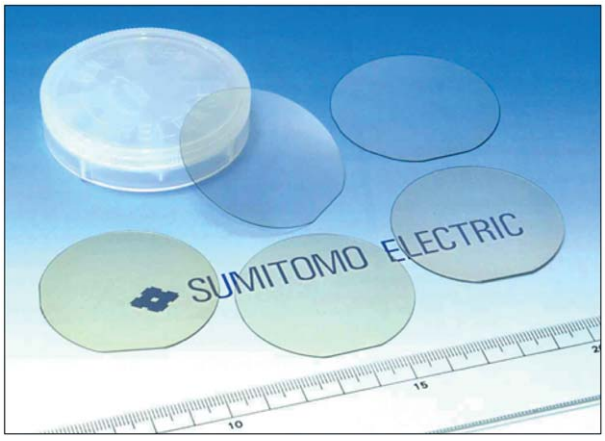

Figure 24 GaN substrates with 2'' diameter grown by the HVPE method. (Reproduced with permission from Sumitomo Electric Industries, Ltd.)

to fulfill the demands on crystal properties coming from the various fields of application. Among the most important R&D tasks are:

- up-scaling of the growth systems in order to grow crystals of larger dimension for higher productivity and yield,
- avoiding of crystal defects which are deleterious for the performance of devices made from the crystals,
- better control of crucial processing parameters in order to tailor the physicochemical properties of the crystals according to the needs of their applications, and
- an increased uniformity of the relevant crystal properties in the micro- and macroscale.

Crystal Growth, Bulk: Theory and Models

J J Derby, University of Minnesota, Minneapolis, MN, USA

Introduction

The growth of bulk crystalline materials remains one of the most challenging and astonishing technical endeavors of materials processing. For example, electronic-grade silicon grown by the Czochralski method is one of the purest and most perfect materials ever produced by mankind. Current production technology routinely achieves impurity levels of less than parts per billion in single-crystal ingots of up to 300 mm in diameter and over 200 kg in mass, and these crystals are completely free of dislocations. Indeed, it is even possible today to control the distribution of micro-defects, such as voids, in bulk silicon crystals. Advances in the production technology of bulk crystal growth to current levels would have been impossible without the application of theory and modeling to understand and improve these processes.

While silicon remains the foremost in economic importance, many other materials are produced in the form of bulk single crystals. Most of these are semiconductors or oxides and used as substrates for the fabrication of electronic, optical, or optoelectronic devices. The most common means for the production of these bulk crystals are melt-growth and solution-growth techniques. For more detailed information, one should consult the excellent overview on bulk crystal growth by Müller and Friedrich in this encyclopedia. Vapor, plasma, or molecular beam techniques, because of their slower growth rates, are rarely employed for the production of bulk crystals, though these methods are extremely important for the growth of thin films needed for device fabrication. Topics of film growth and epitaxy are covered elsewhere in this encyclopedia.

This article presents an overview of the theory and modeling of bulk crystal growth. It must be emphasized from the start that crystal growth is a fascinating, yet complex process that depends on a host of coupled physical phenomena ranging from thermodynamics to kinetics. While many behaviors can be described by relatively simple theories, there is still much that remains to be understood. Modeling, which can be broadly described as applied theory, is usefully employed for clarifying many aspects of crystal growth. However, the extent to which modeling can realistically represent bulk crystal growth is also limited, mainly due to the challenges in representing the many phenomena occurring at disparate length and timescales, and the limits of current computers and numerical algorithms. Nevertheless, advances in theory and modeling will continue to aid important advances in crystal growth technology.

Crystal Growth Theory

Crystal growth theory consists of mechanistic models of how and why a crystal grows from a fluid phase (either liquid or vapor). There are many ways that crystals of different materials grow under different conditions, and no single simple theory describes all of these behaviors. The ensuing discussion highlights some of the more useful theories for the description of the growth of bulk single crystals, starting first with thermodynamic concepts, followed by issues involving kinetics. Also, since bulk crystals are almost always grown from an existing seed crystal, crystal nucleation phenomena will not be addressed here.

Thermodynamics

The formation of a crystalline solid from a fluid is a first-order phase transformation, accompanied by discontinuous changes in enthalpy, entropy, and specific volume. However, under equilibrium conditions, the Gibbs energy is continuous from the solid to the fluid phases. Crystal growth occurs under nonequilibrium conditions, when the thermodynamically stable crystal phase coexists with a thermodynamically metastable phase, typically a supersaturated or supercooled fluid. The driving force for transition to the stable, crystalline phase is the difference in Gibbs energy between the two phases. All crystal growth

processes are designed to set up and maintain a precise driving force, ΔG, for crystallization, where G denotes the Gibbs energy associated with each phase. This driving force takes the form of an undercooling in temperature, ΔT, in melt growth and a supersaturation σ, or compositional difference, in solution growth. At the larger length scales involved with bulk crystal growth, the crystallization driving force is strongly impacted by the kinetics associated with energy and materials transport by diffusion and convection via fluid flow. The effects of continuum transport will be discussed in more detail in ensuing sections.

A solid crystal is separated from the surrounding fluid phase by a phase boundary or interface. The ordered crystalline structure of the solid, in contrast to the nearly disordered structure of the fluid, leads to interfacial energetic effects which are highly anisotropic and a function of interface orientation. Typically, these energetic differences are small compared to the crystallization driving force between the bulk phases; however, surface effects are important in many situations. Indeed, it is these energetics that prescribe the equilibrium shape that a crystal exhibits (via a shape minimization of the Gibbs energy of the crystal).

Under many situations, the surface shape which minimizes the Gibbs energy corresponds to an atomically smooth plane associated with the underlying crystalline structure and referred to as a singular face or facet. Under conditions not far from equilibrium, growth is characterized by how the addition of atoms to the surface affects the Gibbs energy of the surface. Often, growth occurs layer by layer, leading to faceted crystal shapes. The kinetics of mechanisms involved in layer growth are discussed in the ensuing section.

Some single crystals, especially metals grown form the melt, do not exhibit faceted interfaces under equilibrium conditions. This behavior is explained by a phenomenon known as an interface-roughening transition. The basic idea involves the change in Gibbs energy of an initially flat crystal surface with the addition of atoms during growth. There is an enthalpic driving force to add atoms to the surface, as they form new bonds to the surface and to each other. However, if there is a large change in entropy between the crystal and fluid phases, the Gibbs energy is lowest when there are just a few extra atoms on the surface or a few atoms missing in the plane below. Under these conditions, the surface is smooth, and the crystal exhibits a faceted shape; see **Figure 1a**. On the other hand, if the change in entropy between phases is small enough, as is common for most metals, then the Gibbs energy of the surface is minimized when half of the available surface sites are filled, resulting in a rough interface and a crystal shape which may be arbitrary; see **Figure 1b**. For melt growth, the Gibbs energy depends only on the temperature, and the nature of the interface is set only by the properties of the material. For solution growth, the Gibbs energy depends on temperature and composition, so it is possible to change the interface from smooth to rough, for example, by increasing the temperature of the system while maintaining a crystallization driving force in supersaturation.

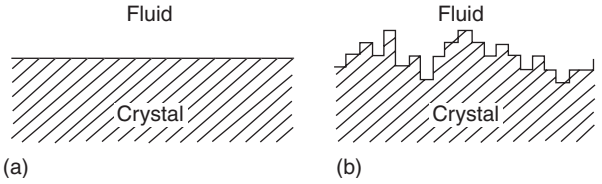

Figure 1 Schematic diagram of the limiting behaviors of a fluid–crystal interface: (a) smooth surface and (b) rough surface.

A final topic involving the thermodynamics of crystal growth is that of lattice defects arising during growth. Again, the basic idea goes back to thermodynamics and the minimization of the Gibbs energy for a crystalline material. If one considers a perfect crystal, the process of ordering of the atoms into a perfect lattice is characterized by a minimization of the enthalpy of the system. However, the total entropy of the system will be increased by disorder, that is, by defects in the perfect lattice. Since the Gibbs energy, G, contains both enthalpic and entropic components, that is, $G = H - TS$, where H is enthalpy, T is absolute temperature, and S is entropy, a minimization of G may be accomplished by some amount of disorder, becoming more important with increasing T. In a pure material, this disordering is manifested by the defective incorporation of atoms during growth, leading to point defects (either vacancies or interstitials) in the resulting crystal. Since the equilibrium of point defects is strongly dependent upon temperature, the details of the cool-down process of the crystal is very important in determining their ultimate fate during the growth of high-melting-point crystals, such as silicon. This relationship is much more complicated for multicomponent crystals, such as compound semiconductors. The interested reader is referred to the "Further Reading" section for more extensive discussions.

Kinetics

In addition to thermodynamic considerations, kinetic factors are always important in the growth of bulk crystals. It is useful to consider two limiting situations

according to the structure of the crystal surface, as depicted in **Figure 1**. If the crystal surface is atomically smooth, the crystal grows layer by layer and is limited by interfacial kinetics. On the other hand, if the surface is atomically rough, the incorporation of atoms into the crystal is very fast and the growth behavior is largely determined by the continuum transport of mass and energy. While real crystallization behavior is much more complicated, these two scenarios can be usefully employed to model the growth of many bulk crystals.

A simple theoretical model that gives insight to growth mechanisms is the Kossel–Stranski model, depicted in **Figure 2**, which assumes that a crystal is a simple cubic lattice comprised of atoms, or growth units. Each lattice site is either empty or occupied, and empty sites are forbidden below occupied sites. Growth then occurs by the addition of atoms to preexisting surfaces of the crystal. The change in the Gibbs energy of the surface by the addition of a growth unit is determined by its position relative to the other atoms, with the lowest surface energy corresponding to an atomically flat, singular surface, or facet. This is also often referred to as a Terrace–Ledge–Kink model for crystal growth.

The rate of growth of the crystal is determined by how fast new layers can be added. For a singular surface, the rate-determining step is the two-dimensional nucleation of a new layer, which is typically slow compared to transport. For a surface orientation far away from a facet direction, there are many steps along the surface so that the incorporation of atoms into the available steps is fast, and the growth of the crystal normal to the surface is limited by the rate of transport from the fluid phase to the surface. A general outcome of this mechanism is that the growth of any crystal is anisotropic and that the slowest growth will occur in directions normal to singular faces. If this is true and there are no transport limitations, then a growing crystal will eventually be bounded by the slowest growing faces, leading to a crystal with a faceted shape, which is often referred to as its growth habit.

However, there is a problem with the above theory,. If two-dimensional nucleation must occur to start a new layer on a singular surface, far higher driving forces than observed would be needed to obtain the growth rates obtained in experiments. Burton and Cabrera postulated that a near-singular, or vicinal, surface, such as depicted in **Figure 3a**, would contain enough steps to rectify this large discrepancy between theory and observation. At the same time, Frank noted that dislocations are present in nearly all crystals and that a screw dislocation intersecting a face would

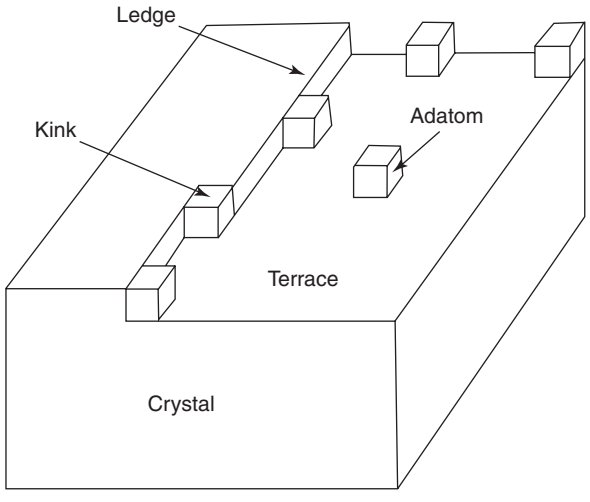

Figure 2 The Kossel–Stranski model depicts a crystal as a simple cubic lattice. Under growth conditions, adatoms adsorb to a terrace, then diffuse and incorporate into lower-energy ledge or kink sites.

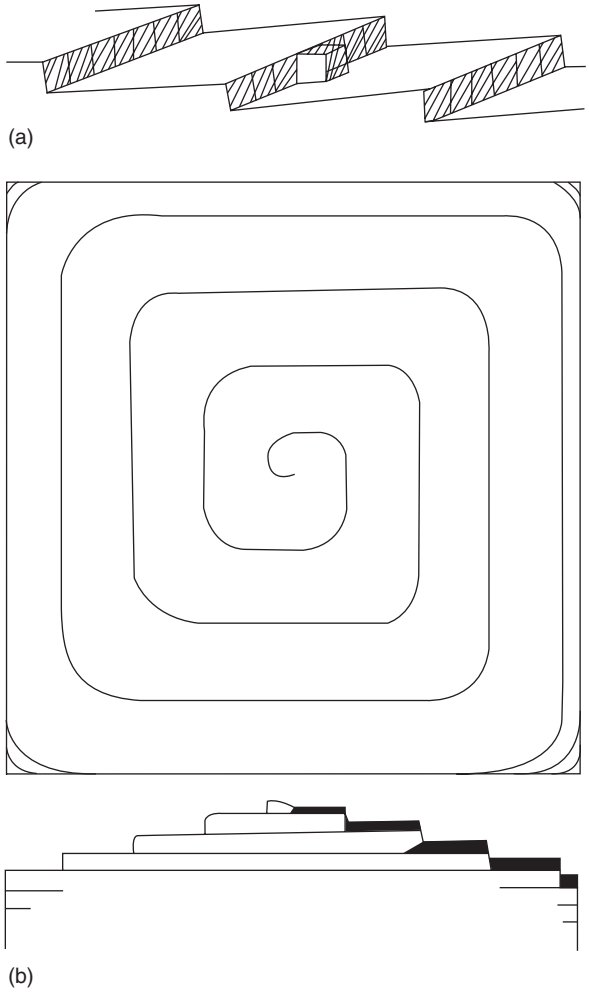

Figure 3 Schematic depictions of (a) steps along a vicinal surface and (b) steps around a screw dislocation.

act as a continuous source of steps, as indicated in **Figure 3b**. Burton–Cabrera–Frank, or BCF, theory describes the growth of singular crystal faces as a mechanism of step generation and movement.

The notion of rough versus smooth interfaces must also be modified to account for kinetic factors. Notably, if the driving force for crystallization is sufficiently high, a two-dimensional nucleation of new layers on a singular surface can occur fast and often enough to make the surface atomically rough. This phenomenon is known as kinetic roughening and is observed in vapor and molecular beam growth. It is much less likely to be observed during melt growth, because of the very high undercooling that would be required, or in bulk solution growth, since there are usually step sources available to allow the BCF mechanism of growth.

These theories give a qualitatively correct picture of the mechanisms behind crystal growth, although real behavior is much more complicated. The rather simple theories discussed above do not consider such effects as clustering of atoms on the surface, roughening to several layers within the crystal, the ordering of a liquid preceding the crystal interface, fluctuations, surface reconstruction, impurities or other chemical interactions involving noncrystallizing species, along with many others. There are still challenges for the theory of crystal growth.

Crystal Growth Modeling

Crystal growth modeling involves the construction of a mathematical description of a crystal growth system, the solution of the governing equations of the model, and the interpretation of the modeling results. The challenge for modeling bulk crystal growth is combining an appropriate description of crystallization behavior with a proper description of continuum transport in the bulk. The crystallization interface is part of a self-consistent solution to a mathematical moving-boundary problem, which also poses special challenges. Below, brief discussions of governing equations and solution techniques are presented for modeling continuum transport and the crystal interface in bulk crystal growth.

Continuum Transport

The transport of heat, mass, and momentum is important in bulk crystal growth processes. Governing equations are written to describe the conservation of these quantities within the solid crystal and the accompanying fluid phase. A brief accounting of these phenomena and their governing equations is given below.

Flow in the fluid phase is especially important for the transport of heat and mass via convection in bulk crystal growth systems. For liquids, such as the molten phase in melt growth or the solution phase in solution growth, flows are described by conservation equations written for momentum and continuity of an incompressible, Newtonian fluid with the application of the Boussinesq approximation to describe fluid density changes:

$$\rho\left(\frac{\partial \boldsymbol{v}}{\partial t} + \boldsymbol{v}\cdot\nabla\boldsymbol{v}\right) = -\nabla p + \mu\nabla^2\boldsymbol{v} + \rho_0\boldsymbol{g}[1 - \beta_T(T - T_0) - \beta_s(c - c_0)] + \boldsymbol{F}(\boldsymbol{v}, \boldsymbol{x}, t) \quad [1]$$

where ρ is the density of the fluid, $\boldsymbol{v}$ is the velocity field, t is time, ∇ is the gradient operator, p is the pressure field, μ is the fluid viscosity, $\boldsymbol{g}$ is the gravitational vector, β_T and β_s are the thermal and solutal expansivities, respectively, T is temperature, c is concentration, the subscript zero denotes the reference state about which the linear dependence of the density is approximated, and $\boldsymbol{F}(\boldsymbol{v}, \boldsymbol{x}, t)$ is an additional body force, for example, that which results from the application of a magnetic field to a conducting fluid. The requirement for continuity of the fluid phase takes on the following form

$$\nabla\cdot\boldsymbol{v} = 0 \quad [2]$$

which states that the divergence of the velocity field must be zero everywhere. Collectively, these two expressions constitute the celebrated Navier–Stokes equations.

Flows driven by buoyancy, referred to as natural convection, are important in all bulk crystal growth systems due to thermal or solutal gradients. In addition, temperature or compositional gradients along a liquid–gas interface can drive very strong flows arising from the variation of surface tension along the surface. Often referred to as Marangoni flows, these are important in many meniscus-defined melt-growth systems, such as the Czochralski and floating zone methods. Forced convection flows are driven by applied rotation of crystal or crucible or, in solution-growth systems, by pumping or stirring mechanisms. Also of great importance in many bulk growth systems are time-dependent or turbulent flows, which arise naturally if the driving forces are strong enough. These flows dramatically affect the nature of continuum transport to the crystal interface. The application of strong stationary or rotating magnetic fields has been applied to electrically-conductive melts in attempts to control such flows.

The transport of heat and mass can be determined from the solution of the appropriate governing

equations. The energy balance equation is given by the following expression:

$$\rho C_p \frac{\partial T}{\partial t} + \rho C_p \boldsymbol{v} \cdot \nabla T = \kappa \nabla^2 T \qquad [3]$$

where C_p is the heat capacity and κ is the thermal conductivity of the fluid. For media which possess some transparency to infrared radiation, the transport of energy via internal radiative transport may also be important in high-temperature crystal growth systems, and an extra term must be added to the above equation. The exchange of thermal radiation among surfaces is also very important in many high-temperature growth systems. These radiative processes are described by terms which are strongly nonlinear in temperature, thus posing significant modeling challenges. Heat transfer is also very strongly influenced by thermal boundary conditions, that is, the conditions imposed on the crystal and fluid by the system design. The modeling of heat transfer in high-temperature melt growth furnaces is itself a significant technical challenge due to complicated geometries and radiation heat transfer.

The conservation equation for a dilute species in a fluid is given by

$$\frac{\partial c}{\partial t} + \boldsymbol{v} \cdot \nabla c = \mathscr{D} \nabla^2 c \qquad [4]$$

where $\mathscr{D}$ is the diffusion coefficient of the species. Mass transfer in bulk crystal growth systems is largely determined by the interactions of diffusion and convection near the liquid–crystal interface. At a growing crystal surface, the equilibrium partitioning of a solute between solid and fluid phases coupled with diffusion and convection results in segregation, that is, the inhomogeneous distribution of a solute in a grown crystal. These phenomena are discussed in more detail in ensuing sections.

The Crystal Interface

The manner in which the crystal interface is represented is a central feature of bulk crystal growth models. A self-consistent growth model requires that the interface geometry be computed as part of the solution to the transport problem, that is, as a free or moving boundary. For the case of melt growth, a mathematical expression of the normal growth velocity of the interface, V_g is given by

$$V_g = \beta \Delta T \qquad [5]$$

where β denotes a kinetic coefficient and ΔT is the driving force for crystallization,

$$\Delta T = T_i - T_m\left(1 - \frac{\gamma}{L}\mathscr{H}\right) \qquad [6]$$

where T_i represents the interface temperature, T_m is the melting temperature of a planar interface, γ is a capillary coefficient, L is the latent heat of solidification, and $\mathscr{H}$ depicts the local mean curvature of the interface. For an atomically rough interface, the kinetic coefficient becomes large enough so that the undercooling ΔT goes to zero and $T_i = T_m(1 - \gamma\mathscr{H}/L)$. Here, the rate of interface movement is controlled by the flow of latent heat away from the interface. In many bulk melt-growth systems, the interface is flat enough so that capillarity is unimportant, and the interface is located along the melting point isotherm of the system, $T_i = T_m$.

From an algorithmic point of view, two methods are primarily employed for computing the location of the crystal interface. Front-tracking methods define a discrete moving surface to separate the interface between crystal and melt, and diffuse-interface methods treat the interface as a region of finite thickness across which physical properties vary rapidly but continuously from one bulk value to the other. Both methods have been used with great success to model different crystal growth problems. Front-tracking methods, such as the isotherm method, have an advantage in accuracy and numerical efficiency, but their implementation becomes problematic when the shape of the interface becomes complicated, for example, as in representing the shape of a dendrite. Diffuse-interface methods, such as the phase field method, come to the fore in such situations; they are able to compute interface shapes of great complexity, albeit at a higher computational cost for a given level of accuracy.

Modeling the growth velocity of a crystalline surface in bulk solution growth is much more problematic than in melt-growth systems, since interfacial kinetics are much more important. The simplest representation of interface velocity and growth is

$$V_g = \beta_k \sigma \qquad [7]$$

where β_k denotes a kinetic coefficient and σ is the supersaturation. The supersaturation is defined as $\sigma \equiv \Delta\mu_g/k_B T = \ln(C/C_e)$, where $\Delta\mu_g$ is the change in the chemical potential between the crystal and liquid, k_B is the Boltzmann constant, and C and C_e are the actual and equilibrium molar concentrations. The kinetic coefficient in this expression varies strongly as a function of the detailed nature of the surface, posing great challenges for realistic modeling. Indeed, predicting the shape of crystals growing from the solution phase is still a formidable undertaking; see the "Further reading" section for additional details.

Modern atomistic simulation techniques, such as molecular dynamics and kinetic Monte Carlo

methods, are being applied to model crystal interfaces. These techniques are showing great promise for obtaining a deeper understanding of crystal growth; however, they are typically restricted to describing systems characterized by very small length scales over very short time scales (see the "Further reading" section).

Crystal Growth Analysis

As previously emphasized, bulk crystal growth is characterized by strongly interacting and often very nonlinear phenomena. Theory and modeling have allowed many of these behaviors to be analyzed and understood; a few examples are discussed below.

Segregation

For a dilute species (often called a dopant) added to a pure material, the phase behavior of the nearly pure material can be described by a phase diagram of temperature plotted as a function of concentration (at constant pressure), as shown in **Figure 4a**. The important behaviors, from the point of view of crystal growth, are that the solid in equilibrium with the liquid at a fixed temperature differ in composition and that the equilibrium melting (or freezing) temperature is a function of composition. The first of these phenomena gives rise to segregation, referring to the partitioning of a dopant between the solid and melt which results in a crystal of inhomogeneous composition, even when grown from an initially uniform-composition melt. The second phenomenon, when coupled with segregation during growth, is responsible for the morphological instability known as constitutional supercooling and will be discussed in the next section.

Classic explanations of dopant segregation involve directional solidification, where a crystal is growing into a melt in one direction and both phases initially have the same solute composition, c_0. For the case of no melt mixing and a partition coefficient, k, less than unity, the dopant is rejected from the growing crystal and diffuses away from it. This flux causes the melt-dopant concentration at the interface to increase in time, until it is exactly c_0/k, as depicted schematically in **Figure 4b**. Under these conditions, axial segregation is said to be diffusion-limited and, barring initial and final transients, gives rise to a constant composition c_0 along the length of the crystal.

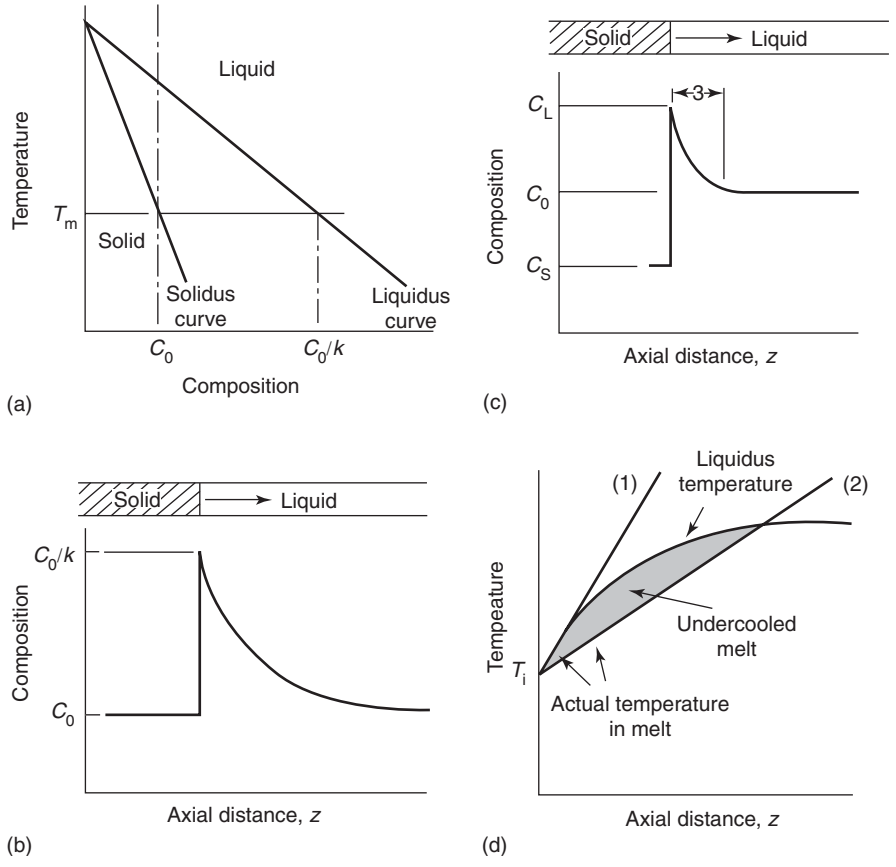

Figure 4 The solidification of a dilute binary alloy: (a) simplified phase diagram, (b) diffusion-limited axial segregation, (c) axial segregation as depicted by the BPS model, and (d) conditions leading to constitutional supercooling.

Convection in the melt disrupts this appealing diffusion-controlled scenario by altering the form of the concentration profile in the melt. The BPS model of Burton, Prim, and Schlicter postulates a stagnant film in front of the interface of thickness δ. Transport is assumed to occur only by diffusion within the film and by perfect convective mixing beyond the film, leading to the dopant concentration profile depicted in **Figure 4c**. Under this scenario, the axial distribution of a dopant in the crystal is given by

$$\frac{c_s}{c_0} = k_{eff}(1-f)^{(k_{eff}-1)} \quad [8]$$

where c_s is the concentration of dopant in the crystal, c_0 is the initial concentration of solute in the bulk, f is the fraction of melt solidified, and k_{eff} is an "effective" distribution coefficient given by

$$k_{eff} = \frac{k}{k + (1-k)\exp(-V_g\delta/\mathscr{D})} \quad [9]$$

where k is the equilibrium distribution coefficient, V_g is the growth velocity of the crystal, and $\mathscr{D}$ is the diffusion coefficient of the dopant in the melt. If $\delta \to \infty$, the effective segregation coefficient approaches unity, and the constant axial concentration profile for diffusion-controlled growth is obtained. As $\delta \to 0$, complete mixing of the melt is implied, $k_{eff} \to k$, and the Scheil equation for axial segregation is recovered. The BPS model is often very effective for fitting experimental segregation data by suitable choice of the parameter δ.

The simplicity and elegance of the BPS expression is perhaps a bit misleading, since it has virtually no predictive capabilities. The underlying idea for this model is too simple; there is no precise physical meaning of the parameter δ, since flows in real systems are never completely stagnant nor intense enough to produce perfect mixing. In addition, segregation across the face of the crystal can be more important than segregation along its length, and this effect is ignored in the one-dimensional solidification model discussed above. Numerical models are required for a more complete analysis of segregation in crystal growth (see the "Further reading" section).

Morphological Instability

The one-dimensional directional solidification model presented above can be used to understand the morphological stability of a crystal interface during growth. The situation in the melt in front of a growing interface is depicted in **Figure 4d**. An axial temperature gradient is applied to the system to maintain growth, with the interface at T_i and the temperature rising as it extends into the melt. Typically, thermal diffusion processes are much faster than mass diffusion, so the temperature profile is linear over the length scale characteristic of the dopant diffusion layer in front of the solidification interface. Also shown in this graph is a curve that denotes the equilibrium freezing temperature of the melt, or the liquidus temperature, in front of the interface. This changes with position due to the compositional profile in the melt set up by segregation and mass diffusion (see **Figure 4c**) and the dependence of the equilibrium freezing temperature on composition (see **Figure 4a**). Under the conditions depicted by temperature profile (1), the growth of the crystallization front into the melt is stable, since the actual temperature is always above the freezing temperature. However, if the thermal gradient is small enough, a situation depicted by profile (2) can arise. Here, much of the melt in front of the interface is below its freezing point, and a perturbation to the interface will grow rapidly into the supercooled region, resulting in an unstable growth interface. This situation is known as constitutional supercooling, and the criterion for it to arise is,

$$\frac{dT_L}{dz} < \frac{mc_0(1-k)V_g}{k\mathscr{D}} \quad [10]$$

where dT_L/dz denotes the axial temperature gradient of the melt at the interface and m is the slope of the liquidus curve on the binary phase diagram. The resultant behavior, which is often referred to as the Mullins–Sekerka instability, is a wavy interface, which, under larger driving forces, becomes successively more unstable in the form of cells and, eventually, dendrites.

Morphological instability can also arise during the bulk growth of crystals from a liquid solution; experiments have demonstrated that steps growing along a vicinal surface can be strongly affected by solution flowing above the surface. Under certain conditions, the density of growth steps redistributes along the surface, giving rise to regions where the steps are very closely spaced, which are known as step bunches. This step-bunching morphological instability is understood to be driven by the interaction of solution flow and mass transfer with the underlying distribution of steps. Flow in the same direction of the step can drive variations in the solute supersaturaton field to be out of phase with the distribution of steps, thereby destabilizing a train of initially evenly spaced steps. Flows opposite to the direction of step motion will generally stabilize perturbations to step spacing. It is postulated that step bunching may be a prelude to the formation of solvent inclusions during growth, but the detailed mechanisms involved are not yet well understood. Chernov provides an excellent overview of these phenomena.

Crystal Defects

Modeling has been gainfully employed to understand the origins of several types of defects in bulk crystals grown from the melt and to optimize growth conditions to reduce their numbers. During the growth of semiconductor crystals, a large number of dislocations can be produced via dislocation formation and multiplication processes driven by thermal stresses generated during growth and cooling. While the necking process developed by Dash for Czochralski growth has allowed large elemental semiconductor crystals (e.g., silicon and germanium) to be grown dislocation-free, large compound semiconductor crystals, such as gallium arsenide and cadmium telluride, are plagued by high levels of dislocations. Modeling heat transfer in growth systems has been successfully employed to minimize thermal stresses and dramatically reduce defect densities of bulk compound semiconductor crystals. Völkl provides an extensive review of this area.

Intrinsic point defects also arise naturally during the growth of all bulk crystals, and their fate under growth conditions determines the properties of the resultant material. As discussed previously, point defects arise from their entropic contribution to lowering the Gibbs energy of the crystal, which varies exponentially with temperature. Point defects also diffuse through the lattice via processes which are strongly thermally activated. There has been much recent progress in understanding how point defects arise, move, and interact in silicon to produce microdefects, such as voids arising from the condensation of excess vacancies and networks of dislocation loops formed by excess interstitials. Accurate modeling is required to predict these effects and optimize growth conditions. Such efforts have been referred to as defect engineering (see the "Further reading" section).

Process Engineering

Advances in computers and numerical algorithms are enabling increasingly powerful models for crystal growth systems to be used for scientific inquiry and engineering optimization. Modeling is a particularly powerful tool for obtaining a better understanding of melt crystal growth, since experimental observations of growth process are made difficult by high temperatures, long process times, and the extreme difficulty of measuring the state of the growing crystal *in situ*. From a technical perspective, the optimization of industrial-scale crystal growth processes via modeling is growing more important with each passing day.

An example of what modern process modeling can do is depicted in **Figure 5**, where the effects of a ampoule tilt and rotation are assessed for a Bridgman growth system. A schematic of the process is shown in **Figure 5a**, and a cut-away view of the three-dimensional finite element mesh employed by the model is shown in **Figure 5b**. This model solves for continuum transport coupled with the position of the melt–crystal interface using a front-tracking technique. Heat transfer boundary conditions are supplied by a furnace thermal analysis code. **Figure 5c** shows isoconcentration contours for a dopant in the melt, and pathlines for the melt flow field are depicted in **Figure 5d**. This information is needed to understand how operating conditions affect crystal growth and how the process can be improved.

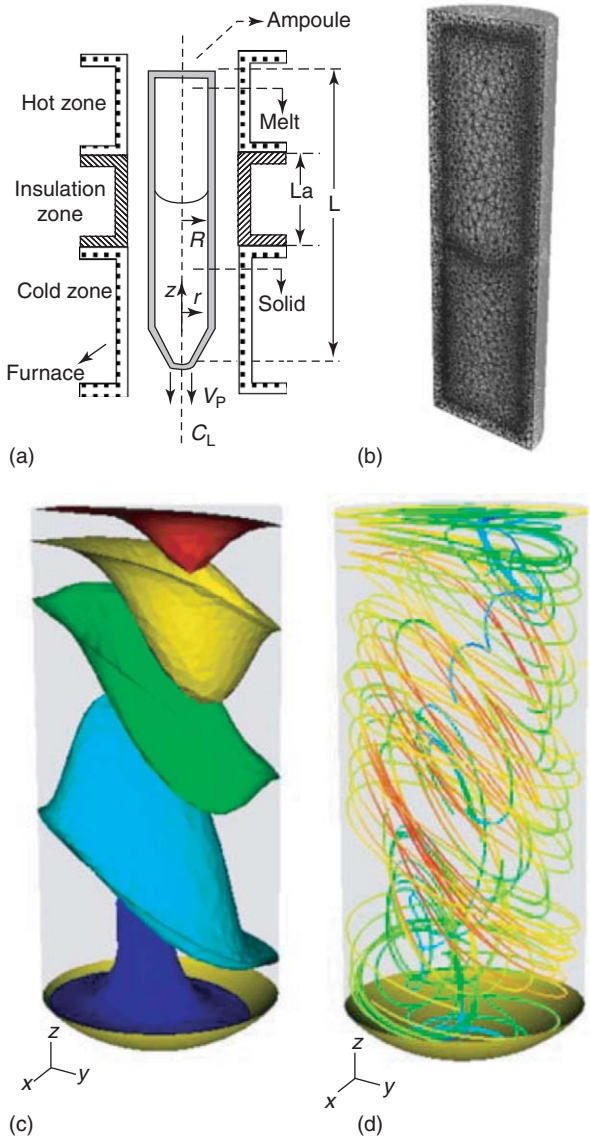

Figure 5 Process model for vertical Bridgman crystal growth system: (a) schematic diagram of process, (b) finite element mesh used in model, (c) isoconcentration surfaces caused by segregation, and (d) melt pathlines showing fluid flow in a tilted, rotated system.

Crystal Optics

D A Lyashenko and Yu P Svirko, University of Joensuu, Joensuu, Finland

Introduction

Crystal optics describes the optical phenomena in anisotropic media when light waves may behave differently depending on direction propagation and polarization. This branch of optics is named after natural crystals that are used in optical devices for many years. The crystal optics techniques and approaches can also be employed to describe light propagation in noncrystalline bulk media (e.g., in an isotropic liquid) when static external fields induce optical anisotropy or in artificial structures, which can be created by recent advances in material science.

Conventionally, crystal optics is restricted to the investigation of the optical propagation in transparent dielectric crystals leaving behind the dramatic enrichment of the propagation phenomena in the vicinity of the absorption resonances in crystalline media where the frequency and spatial dispersion may play decisive roles. Also, crystal optics studies the linear optical phenomena, which are governed by the second-rank tensor of the dielectric susceptibility. However, it is necessary to notice here that the nonlinear optical phenomena, which arise due to dependence of the light propagation effects on the light wave amplitude and are governed by the higher-rank tensors of nonlinear susceptibility, are much more sensitive to the crystal symmetry. Nevertheless, the core part of crystal optics "crystallized" in the pre-laser era and these intensity-dependent effects are studied in the framework of nonlinear rather than crystal optics. In this article, major effects in light propagation in anisotropic nonmagnetic media are discussed.

Maxwell Equations

Spatial and temporal evolutions of the electric field $\boldsymbol{E}$ and magnetic induction $\boldsymbol{B}$ of a light wave in nonmagnetic medium are described by the Maxwell equations:

$$\begin{aligned} \operatorname{curl} \boldsymbol{E} &= \frac{1}{c}\frac{\partial \boldsymbol{B}}{\partial t} \\ \operatorname{div} \boldsymbol{B} &= 0 \\ \operatorname{curl} \boldsymbol{B} &= \frac{1}{c}\frac{\partial \boldsymbol{D}}{\partial t} \\ \operatorname{div} \boldsymbol{D} &= 0 \end{aligned} \qquad [1]$$

The mutual orientation of the vectors $\boldsymbol{E}$, $\boldsymbol{B}$ and the electric displacement $\boldsymbol{D}$ in an electromagnetic wave propagating in a nonabsorbing anisotropic medium is determined by the Maxwell equations [1]. In the plane monochromatic wave with frequency ω and wave vector $\boldsymbol{k}$,

$$\begin{aligned} \boldsymbol{E}(t,\boldsymbol{r}) &= \boldsymbol{E}\,\mathrm{e}^{-\mathrm{i}\omega t+\mathrm{i}\boldsymbol{k}\boldsymbol{r}} + \boldsymbol{E}^{*}\mathrm{e}^{\mathrm{i}\omega t-\mathrm{i}\boldsymbol{k}\boldsymbol{r}} \\ \boldsymbol{B}(t,\boldsymbol{r}) &= \boldsymbol{B}\,\mathrm{e}^{-\mathrm{i}\omega t+\mathrm{i}\boldsymbol{k}\boldsymbol{r}} + \boldsymbol{B}^{*}\mathrm{e}^{\mathrm{i}\omega t-\mathrm{i}\boldsymbol{k}\boldsymbol{r}} \\ \boldsymbol{D}(t,\boldsymbol{r}) &= \boldsymbol{D}\,\mathrm{e}^{-\mathrm{i}\omega t+\mathrm{i}\boldsymbol{k}\boldsymbol{r}} + \boldsymbol{D}^{*}\mathrm{e}^{\mathrm{i}\omega t-\mathrm{i}\boldsymbol{k}\boldsymbol{r}} \end{aligned} \qquad [2]$$

the vectors $\boldsymbol{D}$, $\boldsymbol{B}$, and $\boldsymbol{k}$ are perpendicular to one another:

$$\begin{aligned} \boldsymbol{k}\times\boldsymbol{B} &= -\frac{\omega}{c}\boldsymbol{D} \\ \boldsymbol{k}\times\boldsymbol{E} &= \frac{\omega}{c}\boldsymbol{B} \end{aligned} \qquad [3]$$

That is, in any anisotropic medium, $\boldsymbol{D}\perp\boldsymbol{B}$ and $\boldsymbol{E}\perp\boldsymbol{B}$. However, vectors $\boldsymbol{E}$ and $\boldsymbol{D}$ are not necessarily collinear. The plane containing vectors $\boldsymbol{D}$ and $\boldsymbol{B}$ (and perpendicular to the wave vector $\boldsymbol{k}$) is called the wave front plane, while those containing pair $\boldsymbol{k}$, $\boldsymbol{H}$ and $\boldsymbol{k}$, $\boldsymbol{D}$ are called the polarization plane and vibration plane, respectively. The plane containing orthogonal vectors $\boldsymbol{E}$ and $\boldsymbol{B}$ is perpendicular to the energy flux vector $\boldsymbol{S} = (c/4\pi)[\boldsymbol{E}\times\boldsymbol{B}]$, which is not necessarily parallel to the wave vector $\boldsymbol{k}$ and determines the direction of the ray propagation in the medium (see **Figure 1**). Since the number of variables in Maxwell's equations is greater than the number of equations, an

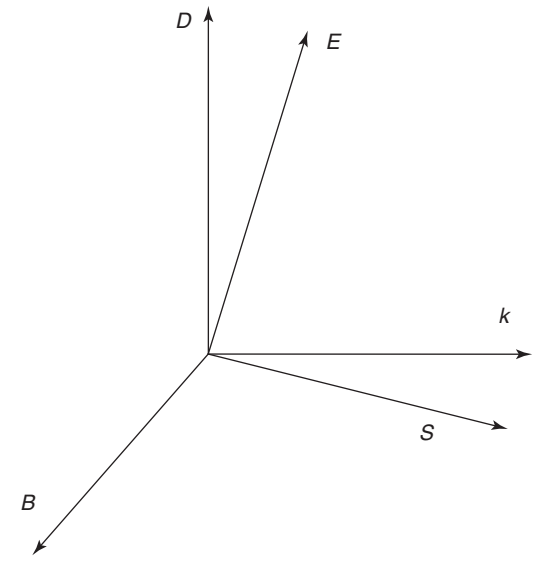

Figure 1 Mutual orientation of vectors $\boldsymbol{E}$, $\boldsymbol{B}$, $\boldsymbol{D}$, $\boldsymbol{k}$, and $\boldsymbol{S}$ in the anisotropic medium.

additional relationship (constitutive equation) is needed between electric displacement $\boldsymbol{D}$ and the wave fields. However, the electric and magnetic fields of the light wave in a nonmagnetic medium are related by the first Maxwell equation, that is, the constitutive equation can be reduced down to $\boldsymbol{D} = \boldsymbol{D}(\boldsymbol{E})$. This functional relationship between electric displacement and electric field strength should account for the material properties of the medium.

Constitutive Equation in Anisotropic Medium

Constitutive equations of the medium must obey the causality principle that ensures a retrospective relationship between $\boldsymbol{D}$ and $\boldsymbol{E}$: displacement at the moment is determined by the preceding electric field, but not by the future one. Similarly, the displacement is not necessarily local, that is, it could depend on the electric field not only at the point of observation, but also in some vicinity around it. With account for the causality and nonlocality, the constitutive equation for linear optics can be presented in the following form:

$$D_i(t,\boldsymbol{r}) = \sum_{j=x,y,z} \int_{-\infty}^{t} \mathrm{d}t_1 \int_V \mathrm{d}\boldsymbol{r}_1 \times \psi_{ij}(t-t_1, \boldsymbol{r}-\boldsymbol{r}_1) E_j(t_1, \boldsymbol{r}_1) \qquad [4]$$

Here, the subscripts label the Cartesian axes x, y, z of the laboratory frame, $\psi_{ij}(t-t_1, \boldsymbol{r}-\boldsymbol{r}_1)$ is the response function that describes the contribution into displacement at point $\boldsymbol{r}$ and time t resulting from the finite electric field at point $\boldsymbol{r}_1$ at time t_1. Since $\boldsymbol{E}$ and $\boldsymbol{D}$ are vector quantities, the response function is tensorial by nature and relates projections of the displacement and electric filed in the laboratory Cartesian frame. The properties of the response function are determined by the mechanism of the optical response in the medium and the medium symmetry. If the optical response is instantaneous, $\psi_{ij}(t-t_1, \boldsymbol{r}-\boldsymbol{r}_1) \propto \delta(t-t_1)$, that is, displacement at the moment t is given by the electric field at the same moment of time. If the response in a particular location only depends on excitation at this location, $\psi_{ij}(t-t_1, \boldsymbol{r}-\boldsymbol{r}_1) \propto \delta(\boldsymbol{r}-\boldsymbol{r}_1)$. In molecular media, the response function would normally have a maximum at $\boldsymbol{r} = \boldsymbol{r}_1$ and diminish for $|\boldsymbol{r}-\boldsymbol{r}_1| > a$, where a is the typical size of a molecule. In crystals, the effects of the spatial dispersion are often associated with excitation of quasiparticles such as excitons, which may have effective radii of up to hundreds of angstroms.

The constitutive equation can be reduced to a more familiar form if one considers propagation of a monochromatic wave with frequency ω and wave vector $\boldsymbol{k}$ (eqn [2]):

$$D_i = \sum_{j=x,y,z} \varepsilon_{ij}(\omega, \boldsymbol{k}) E_j \qquad [5]$$

where

$$\varepsilon_{ij}(\omega, \boldsymbol{k}) = \int_0^{\infty} \mathrm{d}\tau \int_V \mathrm{d}\boldsymbol{\rho} \psi_{ij}(\tau, \boldsymbol{\rho}) \mathrm{e}^{\mathrm{i}\omega\tau - \mathrm{i}\boldsymbol{k}\boldsymbol{\rho}} \qquad [6]$$

is the dielectric tensor that governs the propagation of the electromagnetic waves in the medium.

In the following, the spatial dispersion effects (i.e., the dependence of the dielectric tensor on the wave vector), which in most cases result in minor correction in the wave propagation in anisotropic media, are ignored. However, if the spatial dispersion is the only source of the optical anisotropy (e.g., circular birefringence in chiral liquids), it should be taken into account to describe the light propagation effects.

Dielectric tensor is symmetric with respect to permutation of its indices, $\varepsilon_{ij} = \varepsilon_{ji}$. This fundamental symmetry relation arises from the Onsager principle of symmetry of kinetic coefficients and holds in nonmagnetic media at thermal equilibrium. Another important property of the dielectric tensor is its Hermicity for nonabsorbing media, that is, $\varepsilon_{ij} = (\varepsilon_{ji})^*$ in the frequency region where the absorption losses are negligible. Correspondingly, the energy dissipation rate in the medium at frequency ω is given by the non-Hermitian part of the dielectric tensor:

$$Q = \frac{\mathrm{i}\omega}{8\pi} \sum_{i,k} (\varepsilon_{ij}^* - \varepsilon_{ji}) E_i E_j^* \qquad [7]$$

In the transparent medium the dielectric tensor is real, $\varepsilon_{ij} = (\varepsilon_{ji})^* = (\varepsilon_{ij})^*$, and, therefore, there exists a Cartesian frame in which it can be presented in the diagonal form:

$$\varepsilon_{ij} = \begin{pmatrix} \varepsilon_1 & 0 & 0 \\ 0 & \varepsilon_2 & 0 \\ 0 & 0 & \varepsilon_3 \end{pmatrix} \qquad [8]$$

$\varepsilon_1, \varepsilon_2$, and ε_3 are called the principal dielectric constants (or principal permittibilities) of the crystal that are always positive. The coordinate axes of this system are called principal dielectric axes of the crystal. In this coordinate frame, the constitutive equation [5] reduces down to $D_1 = \varepsilon_1 E_1$, $D_2 = \varepsilon_2 E_2$, $D_3 = \varepsilon_3 E_3$, that is, displacement and electric field will not parallel one another unless $\boldsymbol{E}$ coincides with one of the principal axes or the principal dielectric constants are equal.

If the optical response is not instantaneous, the dielectric tensor depends on the frequency, and,

therefore, both the orientation of the principal axes and the magnitude of the principal dielectric constants may vary with frequency. On the other hand, crystal symmetry imposes restrictions on the structure of the dielectric tensor and, therefore, on the number of nonequal principal dielectric constants. The competition between symmetry restrictions and frequency (also referred to as color) dispersion allows one to introduce three distinct groups in the optical classification of the crystals.

In cubic crystals, three crystallographically equivalent, mutually orthogonal directions may be chosen. In crystals of a cubic system, the principal dielectric constants are equal, $\varepsilon_1 = \varepsilon_2 = \varepsilon_3 = \varepsilon$. Therefore, the constitutive equation in cubic crystals is the same as that in an isotropic medium, $\boldsymbol{D} = \varepsilon \boldsymbol{E}$, that is, cubic crystals are optically isotropic. In these crystals, the frequency dispersion may change only the magnitude of the permittivity.

In crystals of trigonal, tetragonal, and hexagonal systems, the plane containing two equivalent perpendicular directions is perpendicular to the three-, four-, or sixfold rotation axis, respectively. Conventionally, this direction is chosen along the third principal axis. In these crystals, which are called uniaxial, relationship $\varepsilon_1 = \varepsilon_2 \neq \varepsilon_3$ holds at all frequencies.

In crystals of orthorhombic, monoclinic, and triclinic systems, no two equivalent directions can be chosen. These crystals in which $\varepsilon_1 \neq \varepsilon_2 \neq \varepsilon_3$, are called biaxial. In crystals belonging to the orthorhombic system, the directions of the principal axes are fixed and coincide with twofold rotation axes and/or symmetry planes. This ensures their independence from the wave frequency. This situation changes for crystals of the monoclinic system, in which only the twofold rotation axis exists, and correspondingly, orientation of just one principal axis does not show color dispersion. In crystals of the triclinic system, both the directions of the principal axes and magnitudes of the principal dielectric indices may change with frequency.

Fresnel Equation, Wave Vector Surface, and Ray Surface

Maxwell equations [3] allow one to arrive at the following equation for displacement:

$$\frac{\omega^2}{c^2}\boldsymbol{D} = [\boldsymbol{k} \times [\boldsymbol{E} \times \boldsymbol{k}]] = \boldsymbol{k}^2\boldsymbol{E} - (\boldsymbol{k}\boldsymbol{E})\boldsymbol{k} \qquad [9]$$

This gives three linear homogeneous equations for the Cartesian components of electric field in the principal crystal frame:

$$\begin{aligned}
&\left(k_2^2 + k_3^2 - \frac{\omega^2}{c^2}\varepsilon_1\right)E_1 - k_1k_2E_2 - k_1k_3E_3 = 0\\
&-k_1k_2E_1 + \left(k_1^2 + k_3^2 - \frac{\omega^2}{c^2}\varepsilon_2\right)E_2 - k_2k_3E_3 = 0\\
&-k_1k_3E_1 - k_2k_3E_2\\
&\quad + \left(k_1^2 + k_2^2 - \frac{\omega^2}{c^2}\varepsilon_3\right)E_3 = 0
\end{aligned} \qquad [10]$$

The compatibility condition for these equations is that the relevant determinant should vanish. This condition gives the so-called Fresnel's equation that defines the frequency dependence of the wave vector (or dispersion relation). By introducing vector $\boldsymbol{n} = (c/\omega)\boldsymbol{k}$ along the direction of propagation and effective refraction index $n = |\boldsymbol{n}|$, the Fresnel equation is conventionally presented in the following form:

$$\begin{aligned}
&n^2(\varepsilon_1 n_1^2 + \varepsilon_2 n_2^2 + \varepsilon_3 n_3^2)\\
&\quad - [n_1^2\varepsilon_1(\varepsilon_2 + \varepsilon_3) + n_2^2\varepsilon_2(\varepsilon_1 + \varepsilon_3)\\
&\quad + n_3^2\varepsilon_3(\varepsilon_1 + \varepsilon_2)] + \varepsilon_1\varepsilon_2\varepsilon_3 = 0
\end{aligned} \qquad [11]$$

When the direction of propagation is given, eqn [11] gives two different magnitudes of the effective refractive index. Fresnel's equation in coordinates $\{n_1, n_2, n_3\}$ defines the so-called wave vector surface.

Normal to the wave vector surface gives the direction of the energy propagation (Poynting vector) in the medium. Usually, it is described by the so-called ray vector $\boldsymbol{s}$, which is introduced by condition $(\boldsymbol{n}\boldsymbol{s}) = 1$. Since the Poynting vector is perpendicular to $\boldsymbol{E}$ and $\boldsymbol{B}$, one can readily arrive at

$$\begin{aligned}
\boldsymbol{s} \times \boldsymbol{B} &= -\boldsymbol{E}\\
\boldsymbol{s} \times \boldsymbol{D} &= \boldsymbol{B}
\end{aligned} \qquad [12]$$

By replacing $\boldsymbol{E}$ with $\boldsymbol{D}$ and $\boldsymbol{k}$ with $-(\omega/c)\boldsymbol{s}$ and vice versa in [3], one may arrive at [12]. This corresponds to the rule of duality in crystal optics. According to this rule, an equation valid for vectors $\boldsymbol{E}$, $\boldsymbol{n}$, and tensor ε_{ij} is also valid if these variables are replaced with $\boldsymbol{D}$, $\boldsymbol{s}$, and tensor $(\varepsilon_{ij})^{-1}$, respectively. For example, from Fresnel's equation [11], one can obtain the equation which defines the ray vector surface:

$$\begin{aligned}
&s^2(\varepsilon_3\varepsilon_2 s_1^2 + \varepsilon_1\varepsilon_3 s_2^2 + \varepsilon_1\varepsilon_2 s_3^2)\\
&\quad - [s_1^2(\varepsilon_2 + \varepsilon_3) + s_2^2(\varepsilon_1 + \varepsilon_3)\\
&\quad + s_3^2(\varepsilon_1 + \varepsilon_2)] + 1 = 0
\end{aligned} \qquad [13]$$

One can observe that when the direction of $\boldsymbol{s}$ is given, two rays with two different wave vectors can propagate in the crystal.

The above analysis can be visualized by means of simple geometrical constructions. One may draw the

ellipsoid that corresponds to the tensor $(\varepsilon_{ij})^{-1}$ with semiaxes equal to the square roots of the principal dielectric constants. This equation is called the ellipsoid of wave normals (also known as the index ellipsoid), and in the Cartesian frame with principal dielectric axes, it is described by the following equation:

$$\frac{x^2}{\varepsilon_1}+\frac{y^2}{\varepsilon_2}+\frac{z^2}{\varepsilon_3}=1 \qquad [14]$$

If the ellipsoid is cut by a plane which is orthogonal to vector $\boldsymbol{n}$, the intersection of the plane with the ellipsoid will be an ellipse (see **Figure 2**). The length of its axes determines the two values of the effective refractive index, while the axes determine the directions of the relevant vector $\boldsymbol{D}$. It is necessary to notice that unit vectors in these two directions and unit vector along $\boldsymbol{n}$ form Cartesian basis.

In order to find the orientation of the electric field in the medium, the ellipsoid that corresponds to the tensor ε_{ij} with semiaxes equal to the square roots of the inverse principal dielectric constants (the Fresnel or ray ellipsoid) is considered:

$$\varepsilon_1 x^2+\varepsilon_2 y^2+\varepsilon_3 z^2=1 \qquad [15]$$

If the ellipsoid is cut by a plane with normal $\boldsymbol{s}$, the intersection of the plane with the ellipsoid will be an ellipse, whose axes determine the two values of the effective refractive index and orientation of the relevant vector $\boldsymbol{E}$.

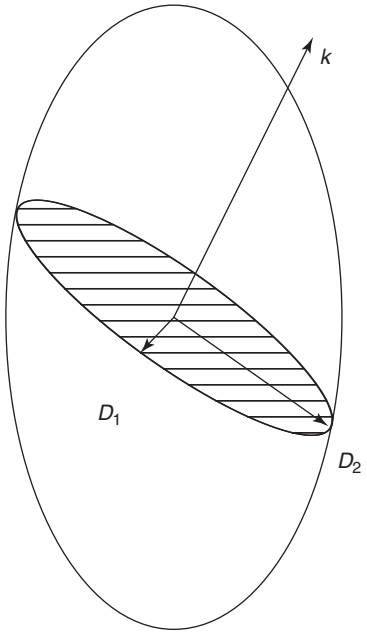

Figure 2 Ellipsoid of wave normals. The normal to the wave vector section of the ellipsoid is ellipse (shaded). The length of its semiaxes determines the values of the refractive index, while the orthogonal axes determine the directions of oscillations, i.e., transverse components $\boldsymbol{D}_1$ and $\boldsymbol{D}_2$ of the electric the displacement vector.

Optical Properties of Uniaxial Crystals

In uniaxial crystals, two principal dielectric constants are equal to one another ($\varepsilon_1=\varepsilon_2=\varepsilon_\perp$, $\varepsilon_3=\varepsilon_{||}$). This reduces the Fresnel equation [11] down to the product of two factors:

$$(n^2-\varepsilon_\perp)\times$$
$$[\varepsilon_{||}n_3^2+\varepsilon_\perp(n_1^2+n_2^2)-\varepsilon_{||}\varepsilon_\perp]=0 \qquad [16]$$

This implies that the wave vector surface for uniaxial crystals consists of two separate surfaces, a sphere and spheriod, which touch one another at opposite poles on the n_3-axis. Depending on the sign of $\varepsilon_\perp-\varepsilon_{||}$, the crystal is said to be a negative or a positive uniaxial crystal (the sphere lies outside or inside the spheroid, respectively; see **Figure 3**).

Correspondingly, there may exist two types of waves (ordinary and extraordinary waves) that propagate along a given direction in a uniaxial crystal. The relevant refractive indices are the following:

$$n_0=\sqrt{\varepsilon_\perp}$$
$$n_e=\sqrt{\frac{\varepsilon_{||}\varepsilon_\perp}{\varepsilon_\perp\sin^2\theta+\varepsilon_{||}\cos^2\theta}} \qquad [17]$$

where θ is the angle between the optical axis (the principal axis "3") and the wave normal. Two

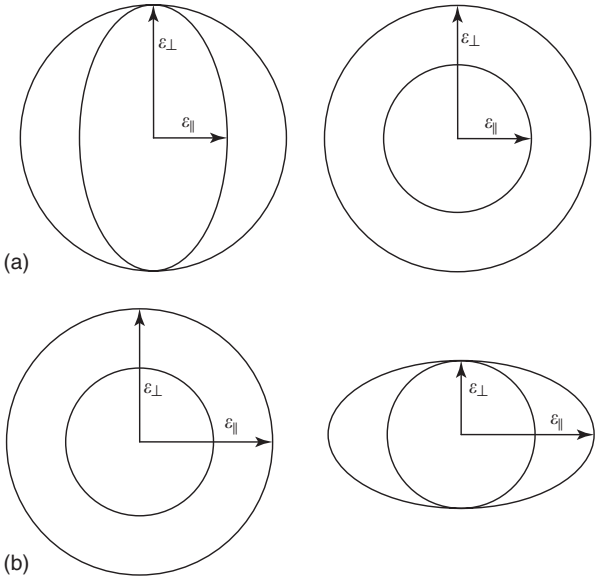

Figure 3 Orthogonal sections of normal surfaces for uniaxial crystals: (a) negative crystal – the sphere with radius equal to $\varepsilon_\perp$ lies outside the spheroid with main semiaxes $\varepsilon_\perp$ and $\varepsilon_{||}$. (b) positive crystal – the sphere with radius equal to $\varepsilon_\perp$ lies inside the spheroid with main semiaxes $\varepsilon_\perp$ and $\varepsilon_{||}$.

refractive indices are equal only at $\theta = 0$ when the wave normal coincides with the optical axis.

The ray surface can be found by replacing $\boldsymbol{n}$ with $\boldsymbol{s}$ and $\varepsilon_{\perp,||}$ with $(\varepsilon_{\perp,||})^{-1}$ in [16]. For the ordinary wave, the directions of the wave vector and ray vector are the same, that is, with respect to ordinary waves the crystal behaves like an isotropic medium. For the extraordinary wave, the directions of the ray vector and wave vector do not coincide; however, they lie in the plane containing the wave vector and the optical axis. This plane is called the principal plane. The angle θ' between the ray vector of the extraordinary wave and the crystal axes is given by the following equation: $\tan\theta' = (\varepsilon_{\perp}/\varepsilon_{||})\tan\theta$.

Since the four vectors $\boldsymbol{E}$, $\boldsymbol{D}$, $\boldsymbol{s}$, and $\boldsymbol{n}$ always lie in the same plane, the extraordinary wave is polarized so that vector $\boldsymbol{E}$ lies in the principal plane. Therefore, in the ordinary wave, vector $\boldsymbol{E}$ lies in the plane, which is perpendicular to the principal one.

Optical Properties of Biaxial Crystals

In biaxial crystals, the three principal values of the tensor are all different, that is, the wave normally becomes ellipsoid rather than spheroid as in uniaxial crystals. The direction of the principal axes may, in biaxial crystals, depend on frequency. The Fresnel surface can be obtained by solving eqn [11]. In the case of $\varepsilon_1 < \varepsilon_2 < \varepsilon_3$, the shape of one octant of the wave vector surface is shown in **Figure 4**.

The singular point of self-intersection (there are four such points, one in each quadrant) gives the direction of the optical axes or binormals of the crystal. The dashed line in **Figure 4** passes through two opposite singular points and is at the following angle to the "3"-axis:

$$\tan\beta = \sqrt{\frac{\varepsilon_3(\varepsilon_2 - \varepsilon_1)}{\varepsilon_1(\varepsilon_3 - \varepsilon_2)}} \qquad [18]$$

The directions of the optical axes are evidently the only ones for which the wave vector has only one magnitude.

The properties of the ray surface are entirely similar to those of the wave surface. The directions of the optical ray axes or biradials can be derived from [18] by replacing $\varepsilon_{1,2,3}$ with $(\varepsilon_{1,2,3})^{-1}$:

$$\tan\gamma = \sqrt{\frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_3 - \varepsilon_2}} \qquad [19]$$

The directions of the wave vector and the ray vector are the same only for light propagating along one of the principal axes.

Near a singular point, the inner and outer parts of the wave vector surface are cones with a common vertex and, therefore, the direction of the normal to the surface becomes indeterminate. This implies that the wave vector along the binormal corresponds to an infinity of ray vectors, whose directions occupy a certain conical surface, called the cone of internal conical refraction. Similar results hold for the wave vectors corresponding to a given ray vector. The ray vectors along the biradial correspond to an infinite number of wave vectors, whose directions occupy the cone of external conical refraction.

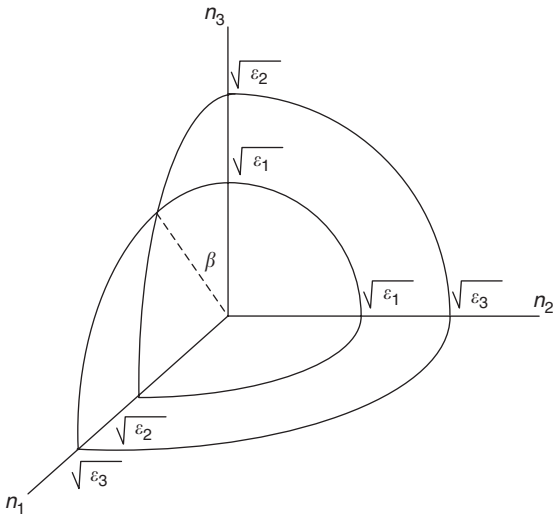

Figure 4 One octant of the Fresnel surface of a biaxial crystal with $\varepsilon_1 < \varepsilon_2 < \varepsilon_3$. Dashed line shows the optical axis (binormal) of the crystal. One can observe that a section of the Fresnel surface by the plane normal to one of the coordinate axes consists of an ellipse and a circle. In the plane $\{n_1, n_2\}$, ellipse with semiaxes ε_1 and ε_2 lies inside the circle with radius ε_3, while in the plane $\{n_2, n_3\}$, the circle with radius ε_1 lies inside the ellipse with semiaxes ε_2 and ε_3. In the plane $\{n_1, n_3\}$, the ellipse with semiaxes ε_1 and ε_3 crosses the circle with radius ε_2.

In observations of the internal conical refraction, one can use a crystal plate cut perpendicular to the binormal. When monochromatic light wave incidents normally on one of the crystal faces, the wave vector of the transmitted wave is parallel to the binormal and so the rays are on the cone of internal refraction. Therefore, a collimated light beam that enters the crystal spreads out into a hollow cone emerging from the crystal as a hollow light cylinder.

In order to observe the external conical refraction, the crystal plate must be cut perpendicular to the biradial, and small apertures should be placed in exactly opposite positions on both crystal facets. When the first aperture is illuminated by a focused beam, only rays that propagate along the biradial can reach the second aperture. Therefore, the relevant wave vectors occupy the cone of the external conical refraction. It is necessary to notice, however, that the cone of light emerging from the crystal does not exactly coincide

with the cone of external refraction because of the refraction on crystal-vacuum inteface.

Polarization Devices Based on the Crystal Optics

Since in the crystal two linear polarized waves with different wave vectors are allowed along a given direction, one can observe double refraction or birefringence at the vacuum–crystal interface. That is, an arbitrary polarized light beam entering an anisotropic crystal is divided into two beams with orthogonal linear polarizations. The direction of propagation of the beams is determined by the orientation of the incident wave vector with respect to the principal crystal axes and does not necessarily lie in the incident plane. These properties of the vacuum–crystal interface have enabled one to develop various devices to control and to investigate the polarization properties of light. The polarization devices belonging to two most common types are discussed below. These are polarizers that produce linear polarized light by splitting an elliptically polarized beam into two linearly polarized ones, and retarders that control the ellipticity of the light beam by changing the phase difference between its orthogonally polarized components.

The Nicol prism was invented in the nineteenth century and consists of a natural rhombic crystal of calcite, which is cut into two parts along a diagonal plane, and joined together again with Canada balsam (see **Figure 5**). For a given angle of incidence, at the vacuum–crystal interface a light beam splits into ordinary and extraordinary rays with effective refractive indices $n_0 = 1.6584$ and $n_e = 1.4864$, respectively. Since the refractive index of the Canada balsam $n_{balsam} = 1.5260$ satisfies the condition $n_e < n_{balsam} < n_0$, the ordinary ray undergoes total reflection at the Canada balsam joint while the extraordinary ray passes through. Therefore, the Nicol prism allows one to achieve linear polarization with practically no lateral displacement of the incident light beam. It is necessary to notice that a number of polarizing prisms (e.g., Glan–Foucault polarizer that employs total internal reflection similar to the Nicol prism and Wollaston prism that produce two orthogonally polarized output beams) have been devised.

The difference in the phase velocity of the ordinary and extraordinary waves in the birefringent crystal enables one to achieve a desired phase difference between them by changing the crystal thickness and/or the relevant refractive indices. Since the directions of vibrations in these waves are mutually orthogonal, the total phase difference accumulated between them determines the polarization of the transmitted light. Such devices are called compensators because they

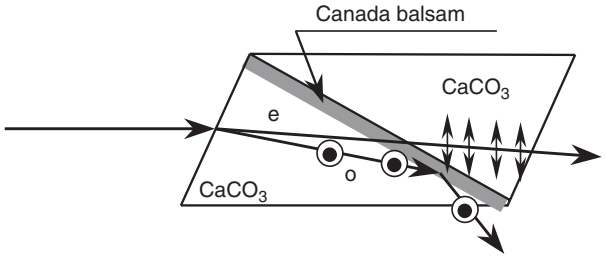

Figure 5 The Nicol prism produces the light beam polarized in the plane of the picture (e-beam). The orthogonally polarized o-beam undergoes total internal reflection on the calcite–Canada balsam interface.

enable one to compensate the phase difference between orthogonal components of the elliptically polarized light wave. It is noticed here that these devices may also be referred to as retarders, because they introduce a finite retardation of one component with respect to another.

A compensator is usually made from a parallel plate of birefringent crystal that cuts so that the optic axis is parallel to the front and back plates of the plate. At the vacuum–crystal interface ($z = 0$), the input wave at normal incidence divides into ordinary and extraordinary ones that propagate with phase velocities $v_0 = c/n_0$ and $v_e = c/n_e$, respectively, and linearly orthogonally polarized. If the components of the light field in eqn [2] at $z = 0$ are equal to E_x and E_y, respectively, those of the light waves emerging from the plate are given by $E_x \exp\{2i\pi n_0 d/\lambda\}$ and $E_y \exp\{2i\pi n_e d/\lambda\}$, where λ is the wavelength in vacuum. Therefore, the phase difference, which the plate introduces between the ordinary and extraordinary waves, is given by the following equation:

$$\Delta\phi = \frac{2\pi d}{\lambda}(n_0 - n_e) \qquad [20]$$

The quarter-wave plate has a thickness of $d = \lambda/4|n_0 - n_e|$ and introduces a phase difference $\Delta\phi = \pm\pi/2$ to the transmitted wave. This wave plate transforms linearly polarized wave into circularly polarized one and vice versa. In order to obtain circularly polarized wave from linearly polarized, the optical axis of the plate is oriented at 45° to the incident polarization azimuth so that $E_x(z = 0) = E_y(z = 0)$. In such a case, the amplitudes of the transmitted ordinary and extraordinary polarized waves remain equal in magnitude. However, they acquire the $\pm\pi/2$ phase shift, that is, $E_x(z = 0) = \pm\, iE_y(z = 0)$. This implies that the wave becomes left- or right-circular polarized depending on the relationship between n_0 and n_e.

The wave plate with thickness of $d = \lambda/2|n_0 - n_e|$ is called the half-wave-plate, which allows one to rotate the polarization azimuth by 90°. If the optical

axis of the plate is oriented at 45° to the incident polarization azimuth (that is, $E_x(z=0) = E_y(z=0)$), in the transmitted wave, the extraordinary polarized components acquire the π phase shift, that is, $E_x(z=d) = E_x(z=0)$ while $E_y(z=d) = -E_y(z=0)$. One can readily find that this corresponds to the rotation of the polarization azimuth by 90° or to the transformation of the left circular polarized beam to the right circular polarized one.

The frequency dispersion results in color sensitivity of the wave plates. In order to achieve compensation of the phase shift for any wavelength, devices based on the combination of edges are used. The most common examples are the Babinet and Soleil compensators.

Crystal Structure

J S Rutherford, National University of Science and Technology, Bulawayo, Zimbabwe

Introduction

The bulk of our experimental knowledge of chemical structure, the arrangement of atoms in space, comes from the study of crystalline solids. This article intends to explain the nature of this chemical information, and how it may be extracted from the experimental results, given the form of the theoretical model used to describe the crystal structure.

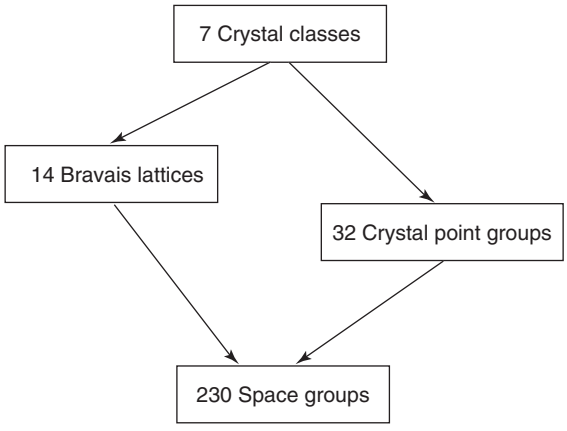
This article first discusses some relevant elements of crystal symmetry and explains how the crystal structure is coded in a typical theoretical model. The information available from experimental techniques are used to establish crystal structures, especially X-ray diffraction and also diffraction of neutrons and electrons. A very large number of crystal structures have now been determined by these methods, and the resulting information is held in various crystallographic databases; these will therefore be described, focusing on the information they contain on individual determinations, which will typically include lattice parameters and space group, as well as the details of the unit cell contents as described by the refinement model used.

It is important to be able to evaluate the reliability of geometric descriptors derived from such a model, so refinement models and the published measures of the quality of the experimental structures determined are discussed. This is followed by a review of derived parameters, that is, those geometric descriptors of chemical interest.

Crystal Symmetry

Ignoring defects, the crystal is a regular arrangement of identical building blocks, the unit cells, in three dimensions. The set of points equivalent to each other by the translation from one unit cell to another form a quasi-infinite three-dimensional geometric lattice, and, in order to describe a crystal structure, it is sufficient to define both this lattice and the structure or contents of an individual unit cell.

Crystal structures are characterized by their space group symmetry, that is, each structure falls into one of the 230 space group types detailed in International Tables for Crystallography. Each of these space groups falls into one of each of the broader categories of crystal system, Bravais lattice and crystal point group as shown below, that is, it will belong to a Bravais lattice and a crystal point group within its crystal class.



In general, a space group symmetry operation consists of a matrix $\boldsymbol{R}$ and a vector $\boldsymbol{t}$, which generate

$$\boldsymbol{x}' = \boldsymbol{R}\boldsymbol{x} + \boldsymbol{t}$$

where $\boldsymbol{R}$ is an operation of the corresponding crystal point group. When $\boldsymbol{R}$ is the identity operation (100/010/001) the overall operation is a lattice translation, and $\boldsymbol{t}$ will be integral unless the lattice is centered in some way. Other point symmetry operations $\boldsymbol{R}$ may be combined with fractional translations $\boldsymbol{t}$ to form alternate space group operations (screw axes and glide planes). When the possible combinations of Bravais lattices and crystal point groups are considered, and include the cases where screw axes and glide planes replace the pure rotation axes or mirror planes of the point group, the 230 space groups result. **Table 1** gives the crystal classes, along with, for each class, the lattice parameters required to define the unit cell, the possible centerings and the point groups, classified according to the presence of polarity and chirality. The equivalent points in the various centered lattices are shown in **Table 2**.

Unit Cell Contents

The unit cell of the crystal will normally contain a number of formula units of the constituent substance. Although the chemical formula may be easy to define in the case of elements and synthetic compounds, it may be problematic in the case of biological materials because of their complexity, and also for many minerals. Assuming that the formula mass, M, can be reasonably estimated, the number, z, of formula units per unit cell can be calculated from its dimensions, provided the density of the crystal, ρ, is known, since

$$z = \rho N_{\mathrm{A}}\, U/M$$

where N_{A} is Avogadro's number and U the cell volume.

For macromolecular crystals such as proteins, this process is complicated by the large and uncertain amount of solvent generally present in the crystal and so contributing to M, and by the difficulties in obtaining accurate density measurements.

Once the number of each type of atom is known, the next stage is to describe how the mean atomic positions are distributed within the unit cell. In a simple case, this merely means describing the contents of that normally smaller volume which may be used to generate the complete unit cell through the space group operations. This volume, in mathematical terms the fundamental domain of the space group, is referred to as the asymmetric unit. The asymmetric unit is not normally uniquely defined; however, when rotation or inversion axes are present, they must lie at the borders of the asymmetric unit. (Centers of symmetry $\bar{1}$ and mirror planes $m = \bar{2}$, are special cases of inversion axes.)

The volume of the asymmetric unit may be calculated using data from **Tables 1** and **2**. The number of equivalent points generated by each crystal point group is given in parentheses against it in **Table 1**. The

number of points equivalent by translation is given in **Table 2** for each lattice type. Multiplying these two numbers together will give the factor by which the asymmetric unit is smaller than the unit cell. For example, the trigonal space group $R3c$ has a rhombohedral lattice (triply primitive = 3) and belongs to point group $3m$ (order 6). The unit cell is therefore 18 times larger than the asymmetric unit. This number is termed the multiplicity of the general position of the space group; the explanation of this follows.

We can define another number z', the number of formula units in the asymmetric unit. For many structures $z' = 1$, and each of the atoms of the formula unit occupies a so-called general position within the asymmetric unit. In such a case, each atom's position is described by three arbitrary fractional coordinates (x_i, y_i, z_i). However, various exceptions exist. The most common is that $z' < 1$; this normally means that the positions of at least some of the atoms must coincide with one or more point symmetry elements (in addition to the identity), so that when the corresponding transformations are applied, their coordinates are unchanged. These atoms will lie on the boundaries of the asymmetric unit, and their coordinates will be restricted in some way. Such atoms are said to lie on special positions of the space group.

The various possible special or "Wyckoff" positions are listed, together with their multiplicities and local site symmetries, in International Tables for Crystallography. Where one or two coordinates are constricted, that special position type may be occupied by more than one type of atom (obviously with different free coordinates), whereas only one atom may occupy a special position comprising a set of points.

An example which illustrates many of these points, and where all the possible Wyckoff positions of the space group are used, is that of the isostructural crystals $M_3As_2O_8$ (M = Mg, Co). These have $z = 6$ in space group $I\,\bar{4}2d$. The Wyckoff positions for this space group are shown in **Table 3**; the general position with symbol e has multiplicity 16. This makes $z' = 3/8$ on the basis of the formula, and it immediately follows that elements M and As at least must lie on special positions or be disordered. The number of As atoms in the unit cell (12) cannot be satisfied by the multiplicity of one special position alone, and that of M (18) cannot even be satisfied by any combination of the special positions, which only have multiplicities of 8 or 4, unless some disorder is also present. The way in which these restrictions are resolved in the structure is also shown in **Table 3**, where all five Wyckoff position types are used. The As atoms are tetrahedrally coordinated (site symmetries 2 and $\bar{4}$ are subgroups of the tetrahedral group $\bar{4}3m$), and most of the M atoms are octahedrally coordinated (2 is a subgroup of $m\,\bar{3}m$), with one-ninth of the M atoms disordered among eight coordinate sites of symmetry $\bar{4}$.

On the other hand, for molecular crystals, it is possible for the molecule (formula unit) to itself have some internal symmetry, and that $z' < 1$ indicates that some point symmetry elements of the molecule coincide with the site symmetry of a special position. Depending on the situation, this might not require any individual atoms to lie in special positions. Also, for molecular crystals, cases where $z' > 1$ are not uncommon, and rare cases exist where $z' = 1$ does not correspond to one molecule in a general position, but more than one in distinct special positions.

Crystallographic Databases

The information on an individual structure will be held as a record on a crystallographic database. The main databases are CRYSTMET for metals and minerals, the Inorganic Crystal Structure Database (ICSD) for inorganic structures, the Cambridge Structural Database (CSD) for organic and organometallic structures, and the Protein Data Bank (PDB) for macromolecular structures. These are augmented by the Powder Diffraction File, the Surface Structure Database, and the Nucleic Acid Database for special purposes.

Table 3 Distribution of the atoms over the Wyckoff positions of I $\bar{4}2d$ in the tetragonal $M_3As_2O_8$ phases

Site multiplicity	*Wyckoff symbol*	*Oriented site symmetry*	*Representative coordinates*	*Atoms*	*Occupancy*	*Contribution to cell contents*		
						M	*As*	*O*
16	e	1	(*x*,*y*,*z*)	O(1)	1			16
				O(2)	1			16
				O(3)	1			16
8	d	•2•	(*x*, 1/4, 1/8)	M(1)	1	8		
				As(1)	1		8	
8	c	2••	(0, 0, *z*)	M(2)	1	8		
4	b	$\bar{4}$	(0, 0, 1/2)	M(3)	0.5	2		
4	a	$\bar{4}$	(0, 0, 0)	As(2)	1		4	
					Totals	18	12	48

The information held in a database record (individual crystal structure) will include composition, lattice parameters, and space group, as well as basic details of the experiment and refinement. Typically, the databases as a whole are relational, or are otherwise structured to facilitate a wide range of possible searches. They are regularly updated with new crystal structures, but only after each submission has undergone an extensive validation procedure to ensure consistency and completeness, and to identify duplicate or related entries. Specialized software for search, retrieval, and visualization is made available to subscribers, along with regular updates to the databases themselves.

Applications of the databases fall into two main categories. First, there are searches for a single record or a limited group of records, as an aid in identification, structure description, property prediction, or possibly even structure determination through structure type. However, increasingly the databases are resources for "data mining", the discovery of new information through statistical analysis of the entire database.

The Refinement Model

How to construct the standard refinement model of an inorganic or "small molecule" crystal structure is discussed here. The least-squares refinement, the predominant method, is assumed here. The mean positions of the nuclei are defined by their fractional coordinates – some of which may be constrained for atoms in special positions – and, for X-ray and electron diffraction, their surrounding electron density is assumed to be spherical, and is described by its Fourier transform, the scattering factor. The distribution of the instantaneous nuclear position about its mean is described by the Debye–Waller or temperature factor, either isotropic or anisotropic. The latter form requires six components for an atom in a general position or on a center of symmetry, but will be constrained for other types of special positions.

There will be an overall scale factor (sometimes more, depending on the details of the data collection), in addition to the parameters mentioned above. Atomic site occupancies may be varied to take account of disorder or substitution. Modern refinements may also vary the relative contributions from the various twin orientations which may be present, or the Flack parameter that describes the absolute structure (chirality) of a chiral crystal structure.

However, in evaluating the results of a crystal structure determination, it is important to distinguish those quantities which are determined in an unbiased way by the refinement, and those for which presumed chemical information was applied. In many cases, any attempt to refine all possible parameters is doomed to failure; but this does invalidate the results of a more cautious refinement. In practice, the parameters to be refined must be chosen in such a way as to maintain a well-behaved refinement process. The inclusion of parameters with little impact on the agreement between calculation and observation will produce near-singular least-squares matrices and hence excessive parameter shifts. For this reason chemical information is frequently included in the form of geometric constraints or, increasingly often these days, restraints. A typical constraint is to refine a molecule or group as a rigid body. In the case of restraints, the assumed dimensions of the molecule or group are treated as additional observations with appropriate estimated errors.

In X-ray diffraction, the weakly-scattering hydrogen atoms are normally constrained or restrained in some way, and their precise positions are usually unreliable.

Because of the limited quality of diffraction data from macromolecular crystals, it is not possible to refine such structures using the same sort of least-squares model as for small molecules, and so constraints or restraints are invariably necessary.

An alternative approach to crystal structure determination that is growing in popularity and reliability is that of Rietveld analysis of powder diffraction data.

Measures of Quality

The quality of a structure refinement is generally reported as the conventional R-factor

$$R = \frac{\sum_i |\Delta F_i|}{\sum_i |F_i^o|}$$

This quantity is related to the actual measure normally minimized, the weighted R-factor based on $|F|^2$

$$_2R_w = \frac{\sum_i w_i |\Delta F_i|^2}{\sum_i w_i |\Delta F_i^o|^2}$$

typically being about half. Another measure which may be reported is the goodness-of-fit S,

$$S = \frac{\sum_i w_i |\Delta F_i|^2}{n - m}$$

which should be about unity if the standard errors of the observations are correctly estimated, and the model used is adequate to fit the observations (i.e., the errors in the model are negligible).

The conventional R-factor is a good rough guide to the quality of a structure determination, but has shortcomings in terms of comparing refinements on different crystal structures, because it does not take account of the distribution of structure factors in each particular data set. Data sets of high variance (hypercentric

distributions, superlattices, and other pseudosymmetric structures), tend to refine to higher values of the *R*-factor, both because the higher proportion of very strong and very weak diffraction peaks that cannot be measured with the same precision as the others, and because such data sets are more sensitive to limitations in the model.

Typically, the databases allow some screening of the quality of the individual structure determinations in the search process. The CSD, for example, allows a cut-off maximum to be applied to the conventional *R*-factor, as well as the elimination of structures where disorder is present. It also allows the comparison of structures based on the quality of the derived geometric descriptors (see next section), in its case the average standard error in C–C bond lengths.

Derived Geometric Parameters

Much of the importance of crystal structure determination lies in the information available on bond lengths (i.e., internuclear distances), bond angles, and other geometric descriptors. These may be calculated by standard methods; either the fractional coordinates may be transformed to orthogonal distance coordinates,

$$X = ax$$

$$Y = ax\cos\gamma + by\sin\gamma$$

$$Z = ax\cos\beta + by\sin\beta\cos\alpha^* + cz\sin\beta\sin\alpha^*$$

where α^* is an angle of the reciprocal lattice, or the calculations may be made using the metric tensor for the crystal,

$$G = \begin{pmatrix} a\cdot a & a\cdot b & a\cdot c \\ b\cdot a & b\cdot b & b\cdot c \\ c\cdot a & c\cdot b & c\cdot c \end{pmatrix}$$

The first approach would be more appropriate for simple hand calculations, whereas the second is that used in molecular geometry programs.

It is also worthwhile to examine the validity of the anisotropic temperature factors determined by least-squares. These parameters may be visualized as ellipsoids using the ORTEP program (see **Figure 1**). Very large or distorted thermal ellipsoids on individual atoms may indicate large amplitude internal motion or even short-range static disorder. The TLS (T – translation, L – libration, S – screw correlation) matrix formalism may be used to test whether individual atomic displacements within a molecule or group are consistent with rigid-body motion.

In addition to bond lengths and angles, metal and inorganic structures are frequently described in terms of coordination polyhedra. For organic and organometallic structures, additional descriptors are required to describe the molecular or group conformation; these include torsion angles and the deviation from planarity of a group of atoms.

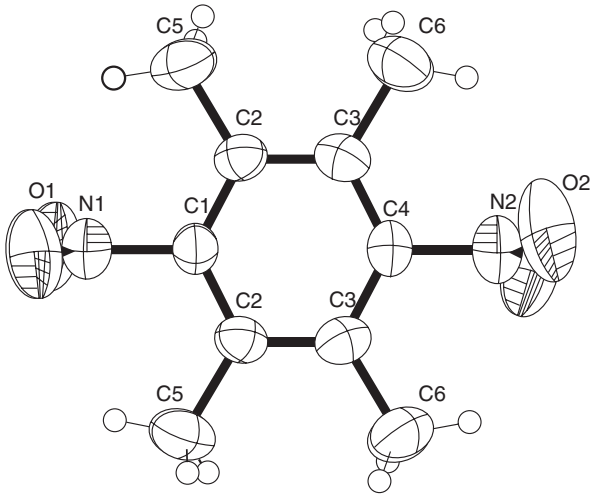

Figure 1 ORTEP drawing of an organic molecule in its crystal structure, showing hydrogen atoms as small spheres and non-hydrogen atoms as 50% probability ellipsoids. The elongation of the oxygen (labeled "O") ellipsoids indicates large amplitude librations about the C–N bonds.

The description of protein crystal structures is somewhat different. Precise bond lengths and angles are not experimentally accessible, but the various levels of organization are, these being:

1. primary structure, the sequence of amino acids present in each chain,
2. secondary structure, the local hydrogen-bonding patterns and chain torsion angles, which result in turn in the typical regular structures (helices and sheets),
3. tertiary structure, the three-dimensional relationships between the secondary structure elements, and
4. quaternary structure, the combination of protein chains to form the overall protein molecule.

Crystal Structure Determination

R Spagna, Istituto di Cristallografia CNR, Rome, Italy

Introduction

X-rays were discovered in 1895 by W C Roentgen. To ascertain the wave motion of X-rays, M von Laue, stimulated by Ewald's thesis, suggested an experiment where X-rays are made to strike a crystal of copper sulfate. Since a crystal is an arrangement of atoms that repeats itself in three dimensions, it should constitute a three-dimensional diffraction grating. The diffraction pattern obtained clarified definitively that X-rays are an electromagnetic radiation having proper wavelength (in the angstrom range, $\sim 10^{-10}$ m, like the interatomic distances). Then, W H Bragg and W L Bragg determined the first crystal structure, NaCl, which gave rise to crystallographic studies. The interactions between light and the object to be imaged are similar in both visible and X-ray cases. The similarities end when the scattered light is to be combined to form the image; opticians working with visible light have lenses to reconstruct the image. Unfortunately, there is no known way to focus X-rays with a lens. It is only possible to collect the intensities of the diffracted beams and the process of combining them must be done mathematically via Fourier synthesis. Since electrons are the objects that diffract the X-rays, a map of electronic density can be obtained and because the electrons are concentrated around the nuclei of atoms, the maxima indicate the atomic positions. In the Fourier synthesis, the coefficients are amplitudes of the scattered wave which are complex numbers: magnitudes and phases. From the experimental data, only the magnitudes and not the phases can be obtained. Therefore, it is not possible to calculate the electronic density map directly from experimental data: phases must be derived by other means. This is the so-called phase problem in crystallography.

In the following, the specimens that receive attention are single crystals, even if recent studies allow one to determine the crystal structure up to ~ 70 atoms from polycrystalline materials, that is, ensembles of a large number of small crystals.

Crystal Diffraction

A crystal is a periodic arrangement of a motif and it is convenient to think of a set of imaginary points which have a fixed relation in space to the atoms of the crystal. A set of points so formed constitutes a point lattice, which is defined as an array of points, each of which has identical surroundings. The unit cell is the smallest repeating unit that can generate the crystal with only translation operations. The space of the crystal is called "real space" (**Figure 1**).

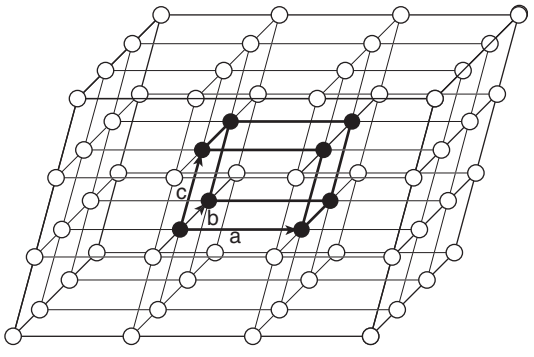

Figure 1 Perspective view of a crystal lattice.

Laue applied general wave-optical principles with a three-dimensional lattice concept to deduce three equations which must be simultaneously satisfied to explain the fact that X-rays are scattered selectively in certain well-defined directions.

The requirement for constructive interference is that the path length difference $(p_1 - p_2)$ between the incoming and the outgoing beams should be an integer number of wavelengths (**Figure 2**):

$$a(\cos\alpha_2 - \cos\alpha_1) = h\lambda$$
$$b(\cos\beta_2 - \cos\beta_1) = k\lambda$$
$$c(\cos\gamma_2 - \cos\gamma_1) = l\lambda$$

where a is the spacing along the crystallographic x axis, α_2 and α_1 are the angles of the outgoing and incoming beams with the x axis respectively, h is an integer; the other two equations have the same meaning.

Bragg saw that the conditions for constructive interference of X-rays were equivalent to that of a family of lattice planes, d_h, described by hkl Miller indices, ($\boldsymbol{h}$), reflecting the X-rays and considering spacing between the planes instead of spacing between atoms (the path length difference $AB + BC$ should be an integer number n of wavelengths):

$$n\lambda = 2d_h \sin\theta$$

where θ is the angle of reflection and n defines the order of reflection from that plane, (Bragg's law) (**Figure 3**).

Ewald gave a beautiful geometric interpretation of the diffraction condition by introducing the concept of "reciprocal lattice." Families of planes, **h**, can be represented by their normals specified as vectors having the lengths, d_h^*, inversely proportional to the d_h. In doing so, a three-dimensional array of points is produced having an inverse relation between the spacing of the points and the planes giving rise to them (**Figure 4**).

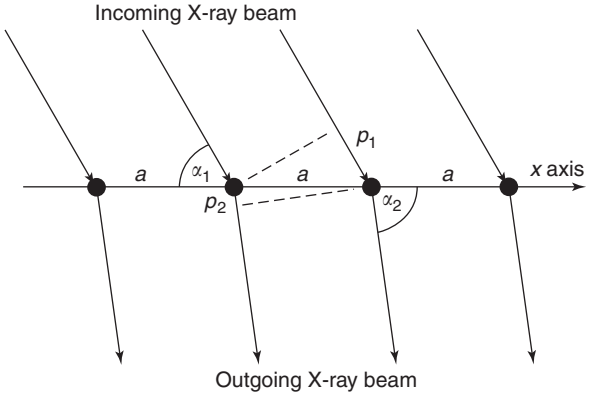

Figure 2 Diffraction from a row of lattice points, called ***x*** axis, with spacing *a*.

Then, he drew a sphere with radius $1/\lambda$ and imagined the crystal to be at C, while the origin of the corresponding reciprocal lattice was at O (**Figure 5**).

A set of (hkl) planes perpendicular to the paper and inclined to the incident X-ray beam XC at the appropriate Bragg angle θ is represented. CP is the direction of the diffracted beam. The perpendicular to OP at P intersects the incident beam at X, and the

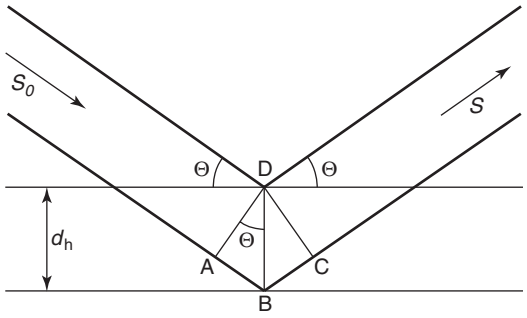

Figure 3 Reflection of X-rays from two lattice planes belonging to the family **h**. $d_{\mathbf{h}}$ is the interplanar spacing.

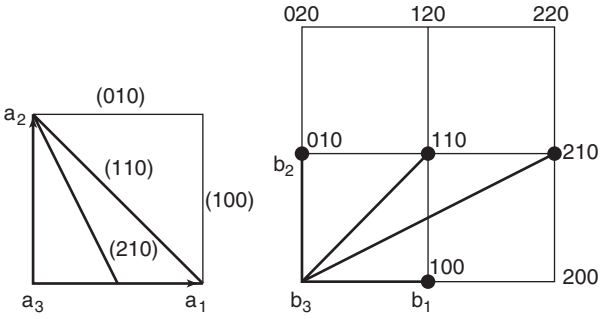

Figure 4 The crystal lattice and the corresponding reciprocal lattice. The axes $\mathbf{a}_3$ and $\mathbf{b}_3$ are normal to the drawing.

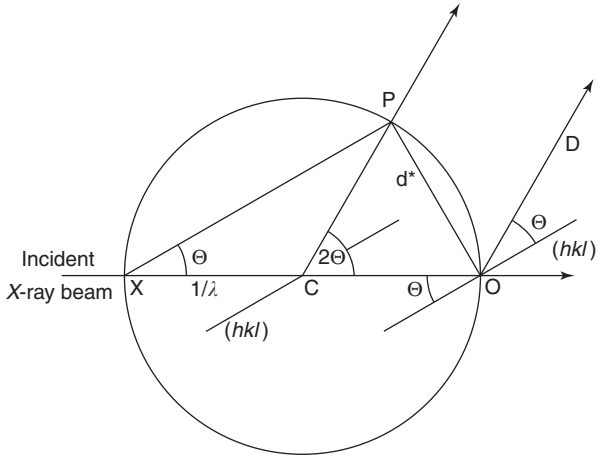

Figure 5 The Bragg equation interpreted in terms of the reciprocal lattice by Ewald.

angle PXO is equal to θ, then

$$\mathrm{PO} = \frac{2}{\lambda}\sin\theta$$

PO is normal to the set of $\boldsymbol{h}$ planes, and following the definition of the reciprocal space:

$$\mathrm{PO} = d^* = \frac{1}{d}$$

then

$$\frac{1}{d} = \frac{2}{\lambda}\sin\theta$$

according to Bragg's law.

To record a diffraction pattern, the crystal at C is rotated and the reciprocal lattice with its origin at O moves jointly. The sphere is stationary and each time a reciprocal lattice point passes through its surface, the Bragg condition for the corresponding set of planes is satisfied. A reflected beam is then produced and its direction is given by the line CP joining the crystal to where the reciprocal lattice point intersects the Ewald sphere.

Experimental Methods

In the laboratory sources, X-rays are produced when a beam of electrons, accelerated by high voltage, strikes a metal target, fixed or evenly rotating. The result is a filtered flux of photons, called a monochromatic beam, having a spectral bandpass, $\delta(\lambda)/\lambda$, very small and picked on the value of the characteristic line of the metal used as a target.

X-rays, as well as other types of electromagnetic radiation, are also generated by synchrotrons. In these installations, either electrons or positrons are accelerated at relativistic velocities and forced by special insertion devices to oscillate around the mean orbit. Some important properties of the radiation produced are the very high flux of photons, a broad continuous spectral range of energy, the narrow angular collimation, and a high degree of polarization. Using particular arrangements, a beam of broad wavelength bandpass, the polychromatic beam, or a beam having a narrow wavelength distribution at the wanted energy, that is, a monochromatic beam, can be selected. An experimental technique which uses a polychromatic beam is the Laue method. It was the first to be used and fell into disuse until a renewed interest by the advent of synchrotrons.

In a diffraction experiment, a crystal having a dimension generally in the range 0.5–0.1 mm is attached to a glass fiber which is fixed onto a pin on a goniometer head (**Figure 6**). The head is mounted onto a goniometer which allows one to set the crystal in different orientations in the X-ray beam. The crystal position is ideally in the center of the Ewald sphere.

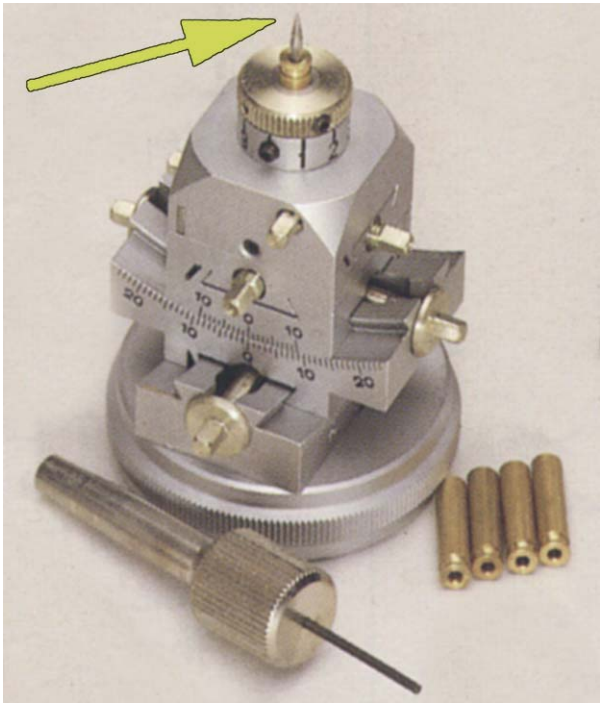

Figure 6 A goniometer head. The arrow shows the location of the crystal. (Reproduced with permission from Huber Diffraktionstechnic, Rimsting, Germany.)

The major differences between the experimental methods reside in the mechanics operating on the crystal and in the detector type. The film-based camera techniques are rotation/oscillation, Weissenberg and precession methods; the single counter or CCD device is used by the single-crystal diffractometer (**Figure 7**).

Nowadays, the oscillation method using electronic area detectors is commonly used in biocrystallography (**Figure 8**), while the diffractometer is widely used for small–medium size molecules.

Irrespective of the method used, two types of experimental data may be derived from measurements of the diffraction pattern: (a) the angles or directions of scattering, which can be used to measure the size and shape of the unit cell, and the corresponding Miller indices of the reflecting planes and (b) the intensities of the diffracted beams, $I_{\boldsymbol{h}}$.

Data Reduction

The amplitude of the scattered wave by a crystal is called the structure factor, $F_{\boldsymbol{h}}$, which is a function of the scattering atoms:

$$F_{\boldsymbol{h}} = \sum_{j=1}^{N} f_j \exp(2\pi \mathrm{i}\boldsymbol{h}\cdot\boldsymbol{x}_j)$$

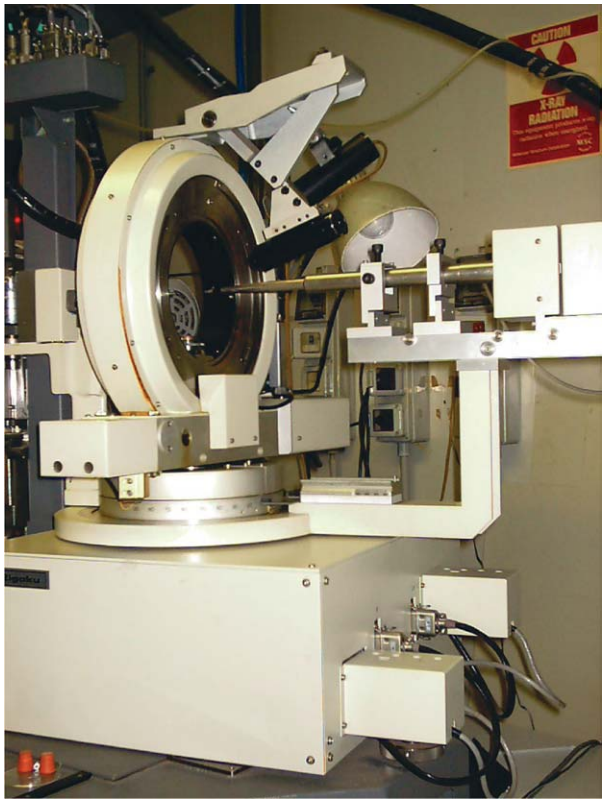

Figure 7 A single crystal 4-circle diffractometer using a rotating anodo X-ray source (Istituto di Cristallografia – Sezione di Monterotondo, Rome, Italy). (Reproduced with permission from Huber Diffraktionstechnic, Rimsting, Germany.)

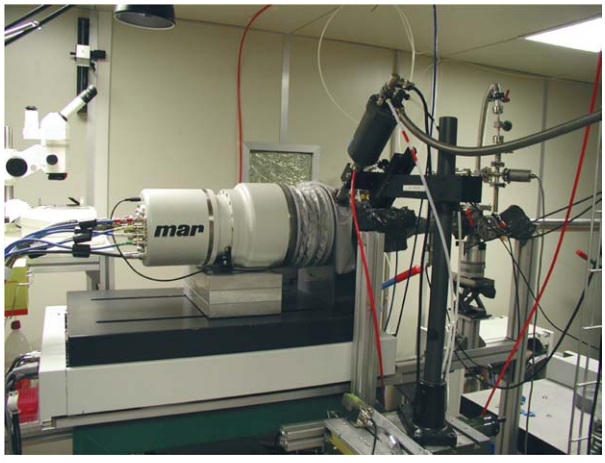

Figure 8 CCD setup on ELETTRA diffraction beam line. (Courtesy of Kristina Djinovic, Structural Biology Laboratory, Sincrotrone Trieste, Italy.)

where f_j is the scattering factor for the jth atom having $\boldsymbol{x}_j$ coordinates in the unit cell containing N atoms. The scattering factor gives the amplitude scattered by an atomic species in terms of the amplitude scattered by a free electron. This means that f depends on the atomic number of the species. The values of atomic scattering factors for neutral atoms are listed in the International Tables for Crystallography for values of $(\sin\theta)/\lambda$. The measured intensity is a function of $|F_h|^2$ and the kinematic theory gives a good approximation of the relationships between I_h and $|F_h|^2$:

$$I_h = KI_0LPTE|F_h|^2$$

where I_0 is the intensity of the incident beam, K takes into account universal and experimental dependent constants, P is the polarization factor, L is the Lorentz factor, T is the transmission factor, E is the extinction coefficient.

Lorentz Correction

Diffraction arises whenever reciprocal lattice nodes cross the Ewald sphere. Depending on the method used to record the reflection intensity and on the position of the reciprocal lattice node, the times required for different nodes to cross the Ewald sphere are different. The Lorentz correction takes into account this difference.

Polarization Correction

The intensity of the diffracted beam changes depending on the state of polarization of the incident beam and on the scattering angle.

Transmission Correction

This correction is related to the absorption of the incident and diffracted beams by the crystal, which depends on the material and the length of the path traveled by the radiation in it. There are analytical methods to calculate this correction which require a precise knowledge of the crystal shape, often very difficult to obtain. An experimental correction is the most widely used and it is designed to correct intensities measured with the diffractometer. It is based on the relative transmission factor plotted as a function of the scanning angle.

Extinction Coefficient

This coefficient depends on the mosaic structure of the crystal, that is, a real crystal can be schematized like a mosaic of very small crystalline blocks tilted very slightly toward each other at small angles, and has two components:

1. the primary one takes into account the loss of intensity due to multiple reflections from different lattice planes. Each scattering causes a phase lag of $\lambda/4$, thus a diffracted radiation is joined by a double scattered radiation with a phase lag of π, consequently destructive interference will result.

2. the secondary one takes into account the fact that the lattice planes first encountered by the primary beam will reflect a significant fraction of the primary intensity so that deeper planes receive less primary radiation. This causes a weakening of the diffracted beam observable for high-intensity reflections at low $\sin\theta/\lambda$ values in sufficiently perfect crystals.

By applying these coefficients to the measured intensities, $|F_h|^2$ is obtained and then:

$$|F_h| = (|F_h|^2)^{1/2}$$

Statistical Analysis

Wilson proposed a simple method to put the observed amplitudes $|F_h|_{obs}$ on an absolute scale, based on a statistical analysis. In fact, he showed that the average of the squared structure amplitudes should be

$$\langle |F_h|^2 \rangle = \sum_{j=1}^{N} f_j^2 = \sigma^2$$

assuming that thermal motion is isotropic and equal for all the atoms,

$$\langle |F_h|^2 \rangle_{obs} = K \langle |F_h|^2 \rangle \exp(-Bs^2)$$

where K is the scale factor and s is equal to $\sin\theta/\lambda$. A plot of the logarithm of the function versus s^2 at some average value of s^2 would derive the values of K and B.

Normalized Structure Factors

Once the intensities have been corrected for thermal motion and placed on an absolute scale, it is simple to obtain the normalized structure magnitudes $|E_h|$ from

$$|E_h|^2 = |F_h|^2/\varepsilon\sigma^2$$

where ε are numbers that vary with the space group and type of reflections. These quantities are independent of the scattering angle and correspond to idealized point atom structures:

$$E_h = \sum_{j=1}^{N} \exp(2\pi i \boldsymbol{h} \cdot \boldsymbol{x})$$

Owing to this peculiarity, the E_h plays a key role in direct method procedures (see below).

Probability Distribution

Hughes empirically, and Wilson by taking the analogy with the random-walk problem found that the X-ray intensities of a centrosymmetric crystal obey a Gaussian distribution. Expressed in terms of $|E|$, the centric distribution is

$$P_{\bar{1}}(|E|) = \sqrt{\frac{2}{\pi}} \exp\left(-\frac{|E|^2}{2}\right)$$

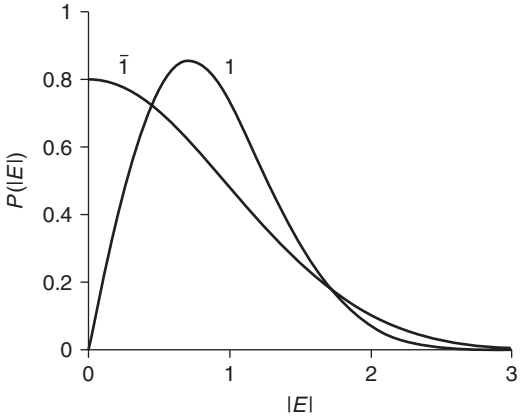

Figure 9 Probability distributions for centro ($\bar{1}$) and for non-centrosymmetric (1) structures.

In further studies, the acentric distribution was obtained (**Figure 9**):

$$P_1(|E|) = 2|E| \exp(-|E|^2)$$

These distributions are completely independent of the structure complexity. Theoretical values of the moments of higher order and of the percentages of $|E| < t$ (where $t = 1,2,3\ldots$) can be calculated from the distributions. These values can be compared with the corresponding experimental values to argue about the presence or absence of a center of symmetry.

The Patterson Function

Patterson introduced a function which is the convolution of electron density $\rho(\boldsymbol{x})$ with itself:

$$P(\boldsymbol{u}) = \int_V \boldsymbol{\rho}(\boldsymbol{x})\boldsymbol{\rho}(\boldsymbol{u}+\boldsymbol{x})\,\mathrm{d}\boldsymbol{x}$$

where V is the volume of the unit cell. The Patterson function can be directly calculated from the set of squared but not phased reflection amplitudes $|F_h|^2$

$$P(\boldsymbol{u}) = \frac{1}{V}\sum_{h} |F_h|^2 \cos 2\pi \boldsymbol{h} \cdot \boldsymbol{u}$$

The map computed gives a vectorial representation of the scattering objects. This depends upon the fact that while F_h is related to the distribution of the atoms in the crystal, $|F_h|^2$ depends on the distribution

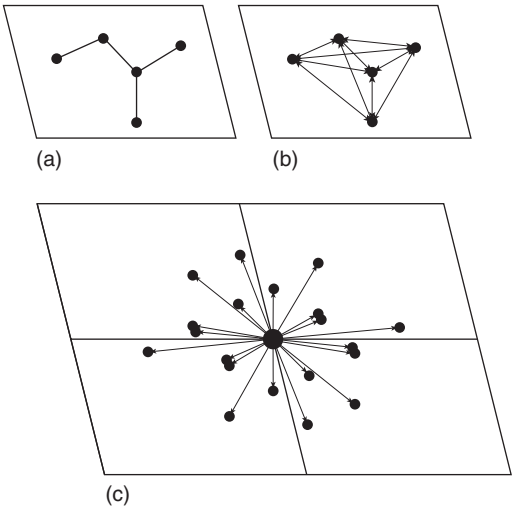

Figure 10 (a) Scheme of a five point atoms molecule, (b) drawing all interatomic vectors, (c) the Patterson function shows all vectors in (b) translated to a common origin.

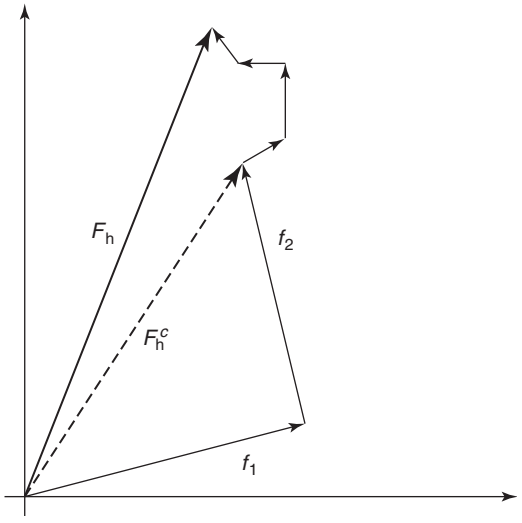

Figure 11 Argand diagram in which two heavy atoms (with atomic scattering factors f_1 and f_2) and four light atoms contribute to the structure factor F_h; the resultant of the contributions of the two heavy atoms (dashed vector) is quite close to F_h.

of interatomic distances. In fact,

$$|F_h|^2 = F_h \cdot F_h^* = \sum_{j=1}^{N} f_j^2 + \sum_{i \neq j=1}^{N} f_i f_j \cos[2\pi \boldsymbol{h} \cdot (\boldsymbol{x}_i - \boldsymbol{x}_j)]$$

depends on the distances $(\boldsymbol{x}_i - \boldsymbol{x}_j)$ between the i and j atoms.

In **Figure 10**, a planar structure of N atoms (a) and the corresponding interatomic vectors (b) are reported. Then this set of vectors has been translated to the origin (c), corresponding to the distribution of $N(N-1)$ peaks in the Patterson function. This higher density of peaks with respect to the electron density makes the Patterson map difficult to interpret even with a moderate number of atoms.

The Heavy Atom Method

Because the density in the Patterson map goes as squares of the numbers of electrons of the scattering atoms, Patterson maps of crystals that contain heavy atoms are dominated by the vectors between them.

Harker noticed that the symmetry of a crystal might provide particular vectors that would lead to a direct measure of the coordinates of individual atoms. For example, if the crystal's symmetry included an inversion center, there would be equivalent atoms at positions (x,y,z) and $(-x,-y,-z)$. The vector between these atoms would be found at $(2x,2y,2z)$ in the Patterson map, indicating the original atomic positions. This procedure greatly simplifies the interpretation of the Patterson map and allows one to obtain a good initial model; in fact, the structure factors F_h^c calculated with the heaviest atoms, f_1 and f_2, represent the predominant contribution to the structure factors F_h (**Figure 11**).

The phase φ_h^c is a good approximation of the true phase of F_h, and an electron density map using the observed structure factors and the calculated phases φ_h^c as coefficients can be computed. The remaining atoms will be found following the so-called method of Fourier synthesis recycling, that is described later.

Direct Methods

Direct methods are those methods that exploit relationships among the intensities to determine the crystal structure directly. They are today the most widely used tool for solving small- and medium-size crystal structures through powerful and sophisticated computer programs, such as *SIR97*, *SHELX*, *SAYTAN*.

In general, the phase, φ, and the amplitude, $|F|$, of a wave are independent quantities and only the amplitudes are obtainable from experiment. However, in X-ray diffraction it is possible to relate these quantities considering two properties of the electron density: (1) it is positive everywhere and (2) it is composed of discrete atoms.

The electron density, $\rho(\boldsymbol{x})$, expressed in terms of Fourier synthesis, is

$$\rho(\boldsymbol{x}) = V^{-1} \sum_{\boldsymbol{h}=-\infty}^{\infty} F_h \exp(-2\pi i \boldsymbol{h} \cdot \boldsymbol{x}) = V^{-1} \sum_{\boldsymbol{h}=-\infty}^{\infty} |F_h| \exp(i_n) \exp(-2\pi i \boldsymbol{h} \cdot \boldsymbol{x})$$

To compute, one needs to know the structure factors $F_{\boldsymbol{h}}$:

$$F_{\boldsymbol{h}} = |F_{\boldsymbol{h}}| \exp(\mathrm{i}\boldsymbol{\varphi}_n) = \sum_{j=1}^{N} f_j \exp(2\pi \mathrm{i}\boldsymbol{h} \cdot \boldsymbol{x}_j)$$

Experimentally, a large number, M, of amplitudes can be measured and then, a system of simultaneous equations formed by the definition of crystal structure factors can be written. The unknown quantities are the phases $\varphi_{\boldsymbol{h}}$ and the atomic positions $\boldsymbol{x}_j$, the known quantities are the $|F_{\boldsymbol{h}}|$ obtained from the measured intensities. Since the equation involves complex quantities, two equations, one for real and one for the imaginary part, can be considered. Therefore, there are $2M$ equations to determine $(M + 3N)$ unknown quantities and since the number of equations exceeds, by far, the number of unknowns, the problem to determine the phases is in principle over-determined.

Sayre derived a basic relationship between structure factors. Considering the structure composed of fully resolved and identical atoms, the two functions $\rho(\boldsymbol{x})$ and $\rho^2(\boldsymbol{x})$ must be very similar and show maxima at the same position (see the one-dimensional structure case reported in **Figure 12**).

The $\rho^2(\boldsymbol{x})$ can be also expressed in terms of Fourier synthesis

$$\rho^2(\boldsymbol{x}) = V^{-1} \sum_{\boldsymbol{h}=-\infty}^{\infty} G_{\boldsymbol{h}} \exp(-2\pi \mathrm{i}\boldsymbol{h} \cdot \boldsymbol{x})$$

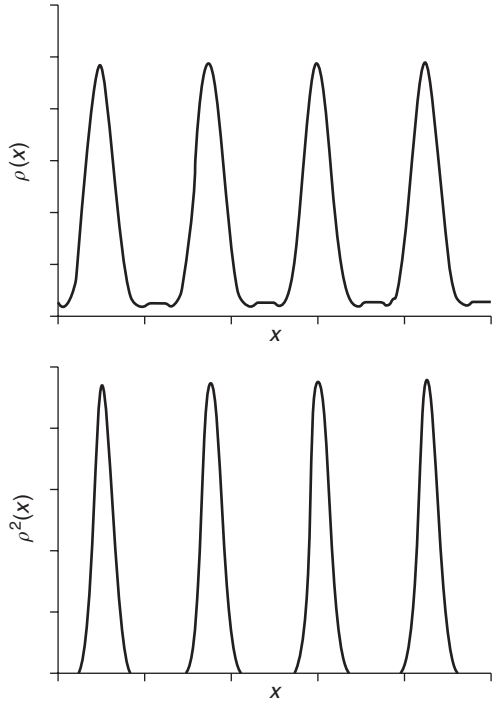

Figure 12 Calculation of $\rho(\boldsymbol{x})$ and $\rho^2(\boldsymbol{x})$ from 1D structure having four equal atoms at equal distance of 2.5 Å along the $\boldsymbol{x}$ axis. The graphics are not in the same scale and show the same position of the peaks.

The mathematical operation which relates the electron density and the structure factors is the Fourier transform, Γ:

$$\Gamma(\rho) = \frac{1}{V} F_{\boldsymbol{h}} = \frac{1}{V} f \sum_{j=1}^{N} \exp(2\pi \mathrm{i}\boldsymbol{h} \cdot \boldsymbol{x})$$

$$\Gamma(\rho^2) = \frac{1}{V} G_{\boldsymbol{h}} = \frac{1}{V} g \sum_{j=1}^{N} \exp(2\pi \mathrm{i}\boldsymbol{h} \cdot \boldsymbol{x})$$

where g is the scattering factor of the squared atom, and because of the convolution theorem, the $\Gamma(\rho^2)$ corresponds to the convolution product of $(1/V)F_{\boldsymbol{h}} * (1/V)F_{\boldsymbol{h}}$ obtaining

$$G_{\boldsymbol{h}} = \frac{1}{V} \sum_{\boldsymbol{k}} F_{\boldsymbol{k}} F_{\boldsymbol{h}-\boldsymbol{k}}$$

From the ratio of the previous equations

$$F_{\boldsymbol{h}} = \frac{f_{\boldsymbol{h}}}{g_{\boldsymbol{h}}} G_{\boldsymbol{h}} = \boldsymbol{\theta}_{\boldsymbol{h}} G_{\boldsymbol{h}}$$

then

$$F_{\boldsymbol{h}} = \frac{\boldsymbol{\theta}_{\boldsymbol{h}}}{V} \sum_{\boldsymbol{k}} F_{\boldsymbol{k}} F_{\boldsymbol{h}-\boldsymbol{k}}$$

which is the Sayre's equation, able to calculate the value of the structure factor $F_{\boldsymbol{h}}$ from the sum of the products $F_{\boldsymbol{k}} F_{\boldsymbol{h}-\boldsymbol{k}}$. Multiplying both sides by $F_{-\boldsymbol{h}}$,

$$|F_{\boldsymbol{h}}|^2 = \frac{\boldsymbol{\theta}_{\boldsymbol{h}}}{V} \sum_{\boldsymbol{k}} |F_{\boldsymbol{h}} F_{\boldsymbol{k}} F_{\boldsymbol{h}-\boldsymbol{k}}| \exp[\mathrm{i}(\boldsymbol{\varphi}_{-\boldsymbol{h}} + \boldsymbol{\varphi}_{\boldsymbol{k}} + \boldsymbol{\varphi}_{\boldsymbol{h}-\boldsymbol{k}})]$$

For large values of $|F_{\boldsymbol{h}}|$, the left-hand side will be large, real, and positive. It is therefore likely that the largest terms in the sum on the right-hand side will also be real and positive. It follows that, if $F_{\boldsymbol{k}}$ and $F_{\boldsymbol{h}-\boldsymbol{k}}$ also have large moduli, the phases are linked by the relationship:

$$\Phi_{\boldsymbol{h}\boldsymbol{k}} = \boldsymbol{\varphi}_{-\boldsymbol{h}} + \boldsymbol{\varphi}_{\boldsymbol{k}} + \boldsymbol{\varphi}_{\boldsymbol{h}-\boldsymbol{k}} \cong 0 (\mathrm{mod}\, 2\pi)$$

This probabilistic condition for three reflections with large structure factors has proved to be the most important original approach for the practical use of direct methods.

Structure Invariants

A structure invariant (s.i.) is a quantity which remains unchanged when the origin is arbitrarily shifted. The intensities are of course the most simple example of structure invariants while the phases are, in general, dependent on the choice of the origin. Under certain conditions, phase relationships between structure

factors are independent of this choice, since their values depend only on the structure and can be estimated. It is easy to show that the most general structure invariant relationship is represented by:

$$F_{h_1}F_{h_2}\cdots F_{h_m} = |F_{h_1}F_{h_2}\cdots F_{h_m}|\exp[\mathrm{i}(\varphi_{h_1}+\varphi_{h_2}+\cdots+\varphi_{h_m})]$$

where

$$h_1+h_2+\cdots+h_m=0$$

Since the moduli of the structure factors are invariants themselves, the angular part:

$$\Phi_m=\varphi_{h_1}+\varphi_{h_2}+\cdots+\varphi_{h_m}$$

is also an s.i.

Probability Methods

Probability methods were introduced by Hauptman and Karle, and led to the joint probability distributions of a set of normalized structure factors on the basis that the atomic coordinates were the primitive random variables uniformly and independently distributed, and the reciprocal vectors were assumed to be fixed. It may also be assumed that the reciprocal vectors are the primitive random variables while the crystal structure is fixed. The probabilistic approach yielded formulas to calculate phases or combination of phases which are s.i.'s by the $|E_h|$ alone. Considering the most important class of s.i's, the three-phase s.i. (triplets), the distribution associated derived by Cochran for a non-centrosymmetric structure is given by:

$$P(\Phi_{hk})=\frac{1}{L}\exp(G_{hk}\cos\Phi_{hk})$$

where L is a normalization factor and for equal atoms

$$G_{hk}=\frac{2}{\sqrt{N}}|E_hE_kE_{-h-k}|$$

where N is the number of atoms in the unit cell.

In **Figure 13**, the probability distributions for different values of the parameter G_{hk} are shown to have a maximum at Φ_{hk} equal to zero, and the variance decreases as G_{hk} increases.

In centrosymmetric crystals, the relation becomes:

$$S(-\boldsymbol{h})S(\boldsymbol{k})S(\boldsymbol{h}-\boldsymbol{k})\cong+$$

where $S(\boldsymbol{h})$ stands for the sign of the reflection $\boldsymbol{h}$ and the symbol $\cong$ stands for "probably equal." In this case, the basic conditional formula for sign determination is given by Cochran and Woolfson:

$$P_+=\frac{1}{2}+\frac{1}{2}\tanh\left(\frac{1}{\sqrt{N}}|E_{-h}E_kE_{h-k}|\right)$$

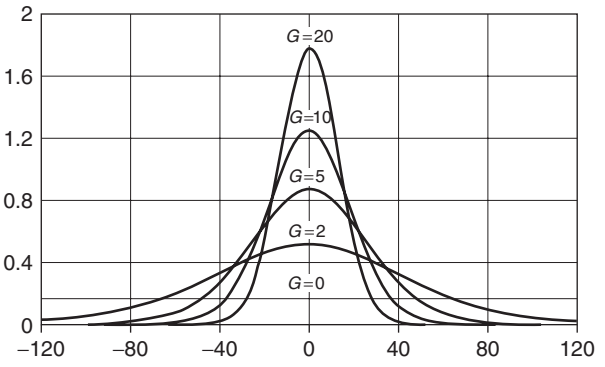

Figure 13 Trends of the probability distributions for different values of the parameter G_{hk}.

The larger the absolute value of the argument of tanh, the more reliable is the sign indication.

For fixed $\boldsymbol{h}$, let the vector $\boldsymbol{k}$ range over the set of known values E_kE_{-h-k}, then the total probability distribution of φ_h is given by the product of the single distributions, increasing the reliability of the estimate, in mathematical terms.

Calculation of the conditional joint probability distributions for φ_h, under the condition that several phases φ_k and φ_{h-k} are known, led to the tangent formula:

$$\tan\varphi_h=\frac{\sum_k|E_kE_{h-k}|\sin(\varphi_k+\varphi_{h-k})}{\sum_k|E_kE_{h-k}|\cos(\varphi_k+\varphi_{h-k})}$$

in which the summations are taken over the same sample of reciprocal vectors $\boldsymbol{k}$.

Formulations of the "nested neighborhood principle" and of the "representation theory" gave the basis to obtain joint probability distributions which improve the estimates for s.i.'s Furthermore, the latter formulated precise general rules for identifying the phasing magnitudes using the space-group symmetry. More complex formulas derived were also able to give indication of Φ_{hk} away from 0°.

Modified tangent techniques are used in almost all computer programs for the phase determination process.

Phase Determination

Once the structure factors are normalized, they are sorted in decreasing order of $|E|$. The s.i.'s are searched in the set of reflections with $|E|$ larger than a given threshold ($\sim$1.3). A typical procedure for phase determination uses a multisolution approach and for each trial, the following steps are performed:

1. assign random values to the phases of the selected reflections.
2. cyclically apply the tangent formula. Since this formula contains information on the positivity of

the electronic density, the phases may converge at the correct values, so defining the structure.
3. for each trial, compute a figure of merit, to estimate its goodness.

The electron density map corresponding to the trial with the highest figure of merit is calculated first.

For each electron density map, a procedure for its interpretation starts involving four steps:

1. peak search;
2. separation of peaks into clusters;
3. application of stereochemical criteria to produce molecular fragments to be processed in subsequent calculations; and
4. labeling of peaks in terms of atomic species. A cyclic procedure consisting of the structure factor and the diagonal least-squares calculations together with a Fourier synthesis provides a way of refining the structure model.

In Progress

Procedures based on direct methods more or less similar to those which have been described are able to solve the crystal structure for small- and medium-size molecules (up to 200 atoms in the asymmetric unit) in a routine way, but fail for bigger molecular structures. An analysis of the problem has been provided by Giacovazzo *et al*. Intuitively, it is seen that the reliability of the probability distributions for s.i.'s is an inverse function of N and as this number increases, the reliability of the relationships decreases whatever the value of the triple product of $|E|$s. The result is that the tangent formula is inadequate for macromolecules.

In spite of this consideration, recent programs – *Shake-and-Bake*, *SHELX-D*, *ACORN*, *SIR2002* – have enlarged the size of crystal structures solvable by direct methods. The key to this success is based on the cyclical use, in both real and reciprocal space, of the refinement of atomic parameters or phases, including the electron density modification procedure. Small proteins (up to 2000 atoms in the asymmetric unit and with data at atomic level resolution) have been solved *ab initio* by these new algorithms, rather expensive in terms of computer time.

Completing the Structure

The model obtained both by Patterson and by direct methods is often incomplete because not all the atoms have been localized. Assuming that the phase φ_h^c of $|F_h^c|$ is a good approximation of the true phase of F_h, an electron density map, using as coefficients the observed amplitudes with the corresponding calculated phases, is computed. This map will reveal

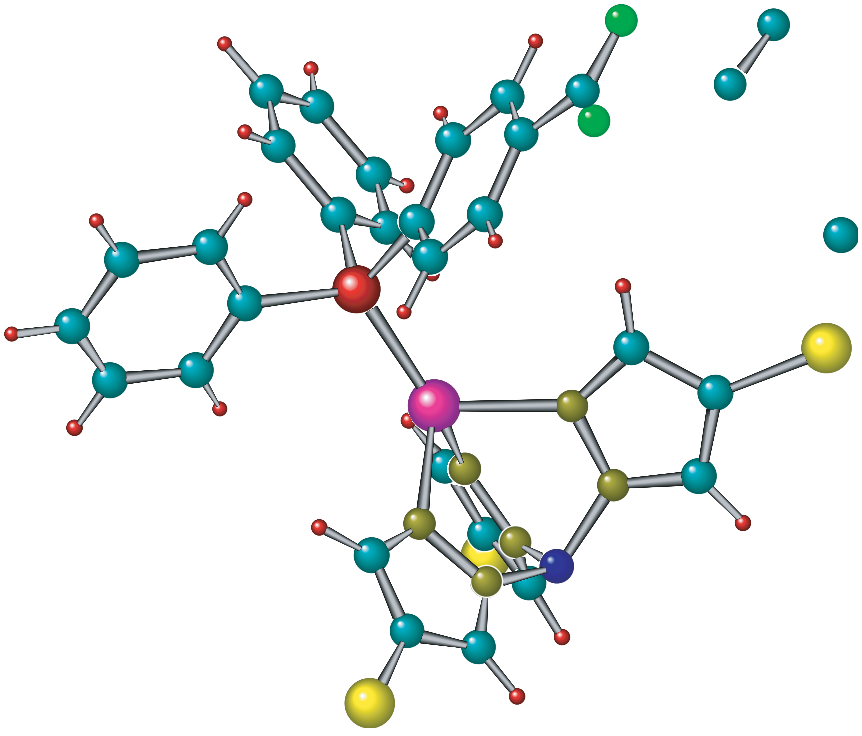

Figure 14 Example of a crystal structure.

new atoms of the structure and then new structure factors can be obtained. The new calculated phases will be used to compute new electron density maps. Each cycle will reveal new atoms until the structure is completed.

Difference Fourier Method

The electron density map

$$\rho_c(\boldsymbol{x}) = \frac{1}{V}\sum_{\boldsymbol{h}} F_{\boldsymbol{h}}^{c} \exp(-2\pi i \boldsymbol{h}\cdot\boldsymbol{x})$$

shows peaks at the positions of the given atoms, while

$$\rho_0(\boldsymbol{x}) = \frac{1}{V}\sum_{\boldsymbol{h}} F_{\boldsymbol{h}}^{0} \exp(-2\pi i \boldsymbol{h}\cdot\boldsymbol{x})$$

where $F_{\boldsymbol{h}}^{0} = |F_{\boldsymbol{h}}^{0}| \exp i\varphi_{\text{true}}$, represents the true structure. To compute the difference electron density map, assume $\varphi_{\text{true}} \approx \varphi_{\boldsymbol{h}}^{c}$:

$$\begin{aligned}\Delta\rho(\boldsymbol{x}) &= \rho_0(\boldsymbol{x}) - \rho_c(\boldsymbol{x}) \\ &= \frac{1}{V}\sum_{\boldsymbol{h}} (|F_{\boldsymbol{h}}^{0}| - |F_{\boldsymbol{h}}^{c}|) \exp(-2\pi i \boldsymbol{h}\cdot\boldsymbol{x} + i_{\boldsymbol{h}}^{c})\end{aligned}$$

If in the model an atom is missing, then $\rho_c(\boldsymbol{x})$ will be zero at the corresponding position, while $\rho_0(\boldsymbol{x})$ will show a maximum. The difference synthesis will also show a peak at the same position but it will be almost zero at the positions of the correct atoms in the model where $\rho_0(\boldsymbol{x}) \approx \rho_c(\boldsymbol{x})$.

Refining the Structure

Least Squares Method

Structure refinement involves "improving" the parameters of the model that give the best fit between the calculated diffraction intensities, F^c, and those observed in the experiment, F^0, to extract precise information about interatomic distances, bond and torsion angles, and other geometric features. One of the most widely applied is the method of least squares in which a weight $w_{\boldsymbol{h}}$ has to be associated to each $F_{\boldsymbol{h}}^{0}$. According to the theory, the quantity:

$$S = \sum_{\boldsymbol{h}} w_{\boldsymbol{h}} (|F_{\boldsymbol{h}}^{0}| - |F_{\boldsymbol{h}}^{c}|)^2$$

has to be minimized. Because the intensities do not depend linearly on the atomic parameters, the function $|F^c|$ has to be expanded in a Taylor series and the normal equations can be derived. The solution of the matrix provides shifts to be applied to the parameters. The procedure will be carried out until convergence is reached. To evaluate the average discrepancies between the calculated model values and the observed values, several statistical descriptors are computed. The most common parameter is the R factor:

$$R = \frac{\sum_{\boldsymbol{h}} (|F_{\boldsymbol{h}}^{0}| - |F_{\boldsymbol{h}}^{c}|)}{\sum_{\boldsymbol{h}} |F_{\boldsymbol{h}}^{0}|}$$

A critical examination of the statistical descriptors informs the crystallographer on the quality of the refined model and can reveal the presence of systematic errors or model inadequacy. Generally, for small- or medium-size structures, assuming good quality crystals, one should expect R values in the range 0.03 – 0.05 (**Figure 14**).

Crystal Structure Determination, History of

D Viterbo, Università del Piemonte Orientale "A. Avogadro," Alessandria, Italy

Introduction

The basic principles for obtaining accurate structural information from diffraction data have been outlined elsewhere in this encyclopedia. It has been shown that X-rays allow one to "see" the electron density distribution in a crystalline medium when the diffracted amplitudes are properly combined. These amplitudes, also called "Structure factors," are complex quantities and must be defined both in magnitude and phase, but unfortunately, because of the high energy of X-rays, in almost all diffraction experiments the phase information is lost, giving rise to the "phase problem in crystallography." The whole history of crystal structure determination is a fascinating account of the different mathematical and physical attempts at overcoming the phase problem. The success of these efforts is testified by the significant number of Nobel prizes awarded to the scientists who have contributed to this subject.

The main steps of the story will be described and it will be seen how, from the initial determination of the crystal structure of NaCl by W H and W L Bragg, structures of very complex biological assemblies such as viruses and ribosomes are solved nowadays. The focus is mainly on the methods concerning single crystals or polycrystalline materials, but mention will also be made of less ordered materials, such as fibers or membranes.

Basic Concepts

From the measured intensities of the beams diffracted by a crystal, what can only be derived are the magnitudes of the complex "structure factors," which are related to the atomic positions $\boldsymbol{x}_j = (x_j, y_j, z_j)$ of the N atoms in the crystal unit cell (i.e., to the structure) by the relation

$$F_{\boldsymbol{h}} = \sum_{j=1}^{N} f_j \exp(2\pi i \boldsymbol{h} \cdot \boldsymbol{x}_j) = |F_{\boldsymbol{h}}| \exp(i\varphi_{\boldsymbol{h}}) \qquad [1]$$

where f_j is the amplitude scattered by each atom, and the vector $\boldsymbol{h} = (hkl)$ indicates the diffraction direction in terms of the Miller indices of the crystal planes originating the corresponding Bragg reflection. The intensity $I_{\boldsymbol{h}}$ is related to $|F_{\boldsymbol{h}}|^2$ and the phase $\varphi_{\boldsymbol{h}}$ is lost in the squaring process. For centrosymmetric structures, the structure factors become real quantities and the phase reduces to a sign.

The electron density function within the crystal unit cell is related to the structure factors by the Fourier synthesis:

$$\begin{aligned}\rho(\boldsymbol{x}) &= \frac{1}{V}\sum_{\boldsymbol{h}} F_{\boldsymbol{h}} \exp(-2\pi i \boldsymbol{h} \cdot \boldsymbol{x}) \\ &= \frac{1}{V}\sum_{\boldsymbol{h}} |F_{\boldsymbol{h}}| \exp(i\varphi_{\boldsymbol{h}}) \exp(-2\pi i \boldsymbol{h} \cdot \boldsymbol{x}) \qquad [2]\end{aligned}$$

where V is the volume of the unit cell.

The Early Times and the Trial and Error Methods

After Laue's discovery (in 1912) of diffraction of X-rays by crystals (for which he was awarded the Nobel Prize in physics in 1914), in 1913 W L Bragg reformulated the theory of diffraction in terms of reflection by crystal planes, and, together with his father W H Bragg, he initiated the era of crystal structure determination.

W H and W L Bragg (**Figure 1**) were awarded the Nobel prize in physics in 1915, but because of the war, W L Bragg could only deliver the Nobel lecture in 1922. The reading of this lecture is fascinating as one is taken through the simultaneous interpretation of both X-ray spectra and crystal structures (with almost no information on atomic structure and dimensions), using the ***X-ray spectrometer***, the ancestor of modern diffractometers. "In this instrument X-rays coming from a tube are limited to a narrow beam by

Figure 1 Swedish postage stamp for the Nobel prize to W H and W L Bragg.

slits, and fall on a crystal at the center of the spectrometer table by which they are reflected; the reflected beam is received and measured in an ionization chamber."

The steps required to analyze a crystal structure by X-rays are clearly outlined:

- "Find the dimensions of the unit cell of the space lattice."
- "Calculate haw many atoms or molecules are contained within it, using as data the density of the crystal and the mass of each molecule."
- "Determination of the manner in which the atoms are grouped together to form each unit of the structure. It is here that the principal difficulty is experienced."

In order to overcome this difficulty, which is nothing but the phase problem, the essential ingredients of the so-called "trial and error" methods are outlined. "The structure of the group of atoms which composes the unit of the crystal grating influences the strength of the various reflections …. The rays are diffracted by the electrons grouped around the center of each atom. In some directions the atoms conspire to give a strong scattered beam; in others, their effects almost annul each other by interference. The exact arrangement of the atoms is to be deduced by comparing the strength of the reflections from different faces and in different orders."

The space group symmetry can be derived from the diffraction pattern (as is described elsewhere in this encyclopedia). For the simplest structures belonging to high symmetry space groups, such as NaCl and KCl, the atomic positions are uniquely defined by symmetry. For less simple structures, plausible atomic arrangements can be deduced on the basis of symmetry and of physical and chemical properties, and then, each hypothesis tested against the observed intensities: for each structural hypothesis, $|F_h|_{\text{calc}}$ can be calculated for all measured reflections using eqn [1] and compared with $|F_h|_{\text{obs}}$ derived from the corresponding observed intensities. An overall agreement factor

$$R = \frac{\sum_h ||F_h|_{\text{obs}} - |F_h|_{\text{calc}}|}{\sum_h |F_h|_{\text{obs}}} \qquad [3]$$

is then evaluated. A low value of R (say $R < 0.4$) will indicate a plausible structural model. This model will then be further validated by its ability of being completed and refined by the methods described elsewhere in this encyclopedia.

A detailed account of the "trial and error" methods is given in the book by H Lipson and W Cochran. These methods require great effort, ingenuity, and skill and were only used with simple structures. They are seldom used today to carry out standard structure analyses, but may still be used to obtain structural information when the diffraction pattern is less well-defined. Here, just two examples will be given. The first, in the realm of inorganic chemistry, is the determination of the structure of potassium alum $KAl(SO_4)_2 \cdot 12H_2O$ by Cork (1927) and C A Beevers and H Lipson (1934, 1935). As first determined by R W G Wyckoff (1923), the crystals belong to the centrosymmetric cubic space group $Pa\bar{3}(T_h^6)$, for which the equivalent positions are

	$x,y,z;\quad z,x,y;\quad y,z,x$	
	$\frac{1}{2}+x,\frac{1}{2}-y,\bar{z};\quad \frac{1}{2}+z,\frac{1}{2}-x,\bar{y};\quad \frac{1}{2}+y,\frac{1}{2}-z,\bar{x}$	
	$\bar{x},\frac{1}{2}+y,\frac{1}{2}-z;\quad \bar{z},\frac{1}{2}+x,\frac{1}{2}-y;\quad \bar{y},\frac{1}{2}+z,\frac{1}{2}-x$	
	$\frac{1}{2}-x,\bar{y},\frac{1}{2}+z;\quad \frac{1}{2}-z,\bar{x},\frac{1}{2}+y;\quad \frac{1}{2}-y,\bar{z},\frac{1}{2}+x$	
24 *d* 1	$\bar{x},\bar{y},\bar{z};\quad \bar{z},\bar{x},\bar{y};\quad \bar{y},\bar{z},\bar{x}$	
	$\frac{1}{2}-x,\frac{1}{2}+y,z;\quad \frac{1}{2}-z,\frac{1}{2}+x,y;\quad \frac{1}{2}-y,\frac{1}{2}+z,x$	
	$x,\frac{1}{2}-y,\frac{1}{2}+z;\quad z,\frac{1}{2}-x,\frac{1}{2}+y;\quad y,\frac{1}{2}-z,\frac{1}{2}+x$	
	$\frac{1}{2}+x,y,\frac{1}{2}-z;\quad \frac{1}{2}+z,x,\frac{1}{2}-y;\quad \frac{1}{2}+y,z,\frac{1}{2}-x$	
8 *c* .3.	$x,x,x;\ \frac{1}{2}+x,\frac{1}{2}-x,\bar{x};\ \bar{x},\frac{1}{2}+x,\frac{1}{2}-x;\ \frac{1}{2}-x,\bar{x},\frac{1}{2}+x$	
	$\bar{x},\bar{x},\bar{x};\ \frac{1}{2}-x,\frac{1}{2}+x,x;\ x,\frac{1}{2}-x,\frac{1}{2}+x;\ \frac{1}{2}+x,x,\frac{1}{2}-x$	
4 *b* .$\bar{3}$.	$\frac{1}{2},\frac{1}{2},\frac{1}{2};\quad \frac{1}{2},0,0;\quad 0,\frac{1}{2},0;\quad 0,0,\frac{1}{2}$	
4 *a* .$\bar{3}$.	$0,0,0;\quad 0,\frac{1}{2},\frac{1}{2};\quad \frac{1}{2},0,\frac{1}{2};\quad \frac{1}{2},\frac{1}{2},0$	

The unit cell contains 4 K, 4 Al, 8 S and 32 O atoms and 48 water molecules. The K and Al atoms should then be located in the fixed positions on the inversion centers *a* and *b*, with multiplicity 4. Locating the K atoms in *a* and the Al atoms in *b* or vice versa corresponds to the choice between two equivalent origins of the unit cell and is arbitrary. The eight S atoms must occupy the eightfold position *c*, but they are not definitely located since the *x* parameter (along the threefold axis) is not defined. The 32 O atoms cannot all be equivalent, since there is no position with a 32-fold multiplicity; they must occupy one general *d* position and one special *c* position. This choice is compatible with the known tetrahedral stereochemistry of the SO_4 group. Similarly, the most likely position of the 48 oxygen atoms (hydrogen atoms are not considered) of the water molecules (W)

is on two sets of general positions *d*. The most probable arrangement of atoms is thus:

- K and Al atoms on fixed special positions *a* and *b*;
- S atoms on special positions *c* with one parameter;
- O atoms on a set of special positions *c* with one parameter and a set of general positions *d* with three parameters; and
- W atoms on two sets of general positions *d* with six parameters.

This is a striking instance of the usefulness of space-group symmetry, which allows the simplification of the problem of determining the position of 96 atoms to that of determining just 11 parameters. Stereochemical considerations can further reduce the number of parameters, and other considerations, such as atomic radii and known bond distances and angles can further help in defining the most likely atomic arrangements to be tested against the observed diffraction intensities.

The second example, in the realm of organic chemistry, describes the structure determination of some aromatic compounds. As pointed out by W H Bragg (1929), "the major interest in the attempt to solve an organic structure lies in the determination of the position of the atoms in the molecule. This is a very difficult problem: but there are clear signs that the difficulties are yielding." The structure of hexamethylbenzene determined by K Lonsdale (1928, 1929) is the first case of a structure solved "with satisfactory completeness and certainty." On the basis of the available knowledge of the structure of graphite (H Ott, 1928) and of a careful analysis of the measured intensities, a good model of the structure was obtained, which gave a satisfactory agreement between observed and calculated structure factors. Some preliminary results on the structure of the aromatic rings had been obtained by W H Bragg (1921) from the study of the crystals of naphthalene and anthracene, but their correct structures were only determined later by K Banerjee (1930). The solution of the structure of hexamethylbenzene established that: (1) the molecules exist as separate entities in the crystalline state, (2) the benzene ring is hexagonal in shape and is planar, (3) the approximate ring C–C distance is 1.42 ± 0.03Å, and the C–CH_3 distance is 1.54 ± 0.12Å, (4) the ring possesses a center of symmetry and so the Kekulé static model with its three fixed double bonds must be excluded. Only the determination of the crystal structure could answer these fundamental questions, which are now basic concepts in organic chemistry.

Patterson and Fourier Methods

Without the phase information, it is impossible to calculate the electron density function $\rho(\boldsymbol{x})$ using eqn [2]. In order to overcome this difficulty, A L Patterson (1934, 1935) proposed to use a Fourier series similar to eqn [2] in which the coefficients were the squares of the structure factor moduli, $|F_h|^2$, directly derivable from the measured intensities. The Patterson function is the self-convolution of $\rho(\boldsymbol{x})$, and its maxima give information about the length and orientation of all the N^2 interatomic vectors linking the N atoms in the unit cell. In his 1935 paper, Patterson proved that some structures (KH_2PO_4, C_6Cl_6, and $CuSO_4 \cdot 5H_2O$; **Figure 2**) could be solved by his method.

The following step was the discovery by D Harker (1936) that the space group symmetry was reflected in the concentration of Patterson peaks on certain planes or lines. M J Buerger's (1946) "implication diagrams" and the "superposition methods" first proposed by D M Wrinch (1939) are general methods for recovering the atomic positions from a vector set and are described in the book by Buerger (1959). Although several fairly complex structures, composed of almost equal light atoms, have been solved from their Patterson functions, when the number of atoms increases, the number of interatomic vectors becomes very large and the Patterson map becomes almost featureless. However, if the structure contains some heavy atoms, prominent peaks corresponding to vectors between these atoms dominate the map. This is the basis of the very successful "heavy atom methods," which have since been used for the solution of thousands of crystal structures. One of the first cases is the solution of the structure of $NiSO_4 \cdot 7H_2O$ by C A Beevers and C M Schwartz (1935); the diffraction data from the "isomorphous" $MgSO_4 \cdot 7H_2O$ crystals were also used to help the solution. As will be seen, these methods turned out to be the key to the solution of protein structures. The great power of the heavy atom methods was shown by the solution of the large molecule of vitamin B12, for which D Crowfoot Hodgkin (**Figure 3**) won the 1964 Nobel prize for chemistry. Another important effect related to the presence of heavy atoms is that of "anomalous dispersion," which can be used not only to obtain phase information, but also to reveal the absolute configuration of a chiral compound (J M Bijvoet 1949).

Fourier methods are generally used for completing and refining the models obtained in the initial stages of structure solution, but in some special cases they can also be used in crystal structure determination. One of the first examples was the determination of the rather complex structure of platinum phthalocyanine by J M Robertson and I Woodward (1940), in which, because of symmetry, the heavy Pt atom must be located at the origin on the inversion center. The

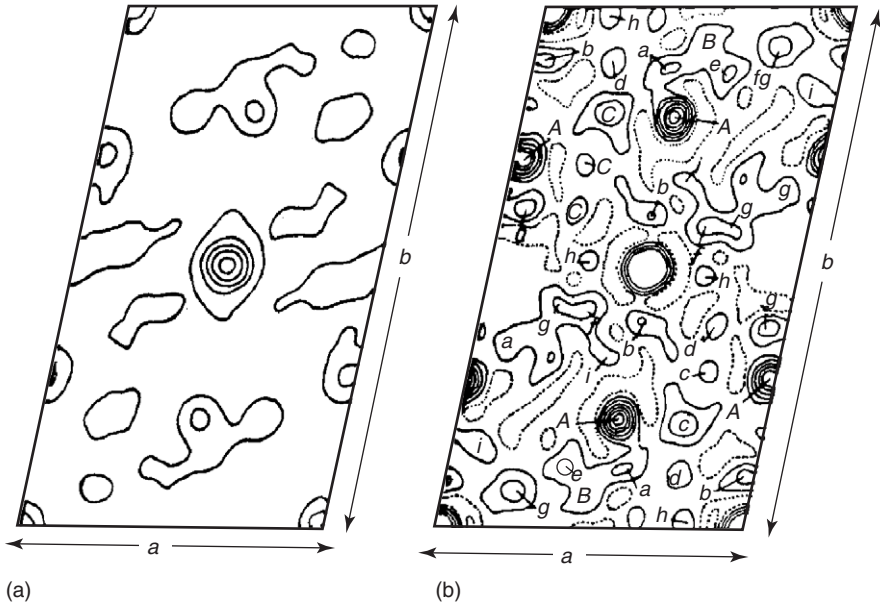

Figure 2 (001) projection of the Patterson function of $CuSO_4 \cdot 5H_2O$: (a) computed with $|F_h|^2$ coefficients; (b) computed with modified coefficients to increase resolution of peaks.

Figure 3 Dorothy Hodgkin and J D Bernal (in the center) with I Fankuchen and D Fankuchen.

(010) electron density projection (**Figure 4**) computed with all positive signs for the (*h*0*l*) reflections, as implied by the Pt position, revealed the light carbon and nitrogen atoms of the phthalocyanine molecule.

Direct Methods

Trial and error and Patterson methods require a great deal of human intervention and a search for more direct methods to derive the crystal structure from the diffraction data started quite early on, when H Ott (1927), K Banerjee (1933), and M Avrami (1938) proposed some algebraic methods for the solution of the structure factor equations as given in eqn [1]. Unfortunately these methods were of very limited practical use because they could only be applied to very simple cases.

The initial step toward the present direct methods (DM) is usually regarded as the work of D Harker and J S Kasper (1948), which appeared on the first issue of *Acta Crystallographica*, the journal of the newly born International Union of Crystallography. Their inequality relations between structure factors played an important part in the determination of the structure of decaborane, $B_{10}H_{14}$, by J S Kasper, C M Lucht, and D Harker (1950). J Karle and H A Hauptman (1950), by imposing the physical condition that the electron density is positive or zero everywhere, were able to generalize the inequalities into a determinantal form. The next step was the derivation by D Sayre (1952) of an equality relation between structure factors for structures composed of equal and fully resolved atoms. In 1953, Hauptman and Karle established the basic concepts and the probabilistic foundations of DM and derived formulas for the estimate of some linear combinations of phases called "structure invariants"; their results were collected in a monograph with the far-seeing and ambitious title *Solution of the Phase Problem. I. The Centrosymmetric Crystal* (**Figure 5**).

The theoretical development of DM continued for more than ten years, with important contributions also by other authors (among which W Cochran, W H Zachariasen, E F Bertaut, M M Woolfson), but the practical applications were very few. Indeed, until

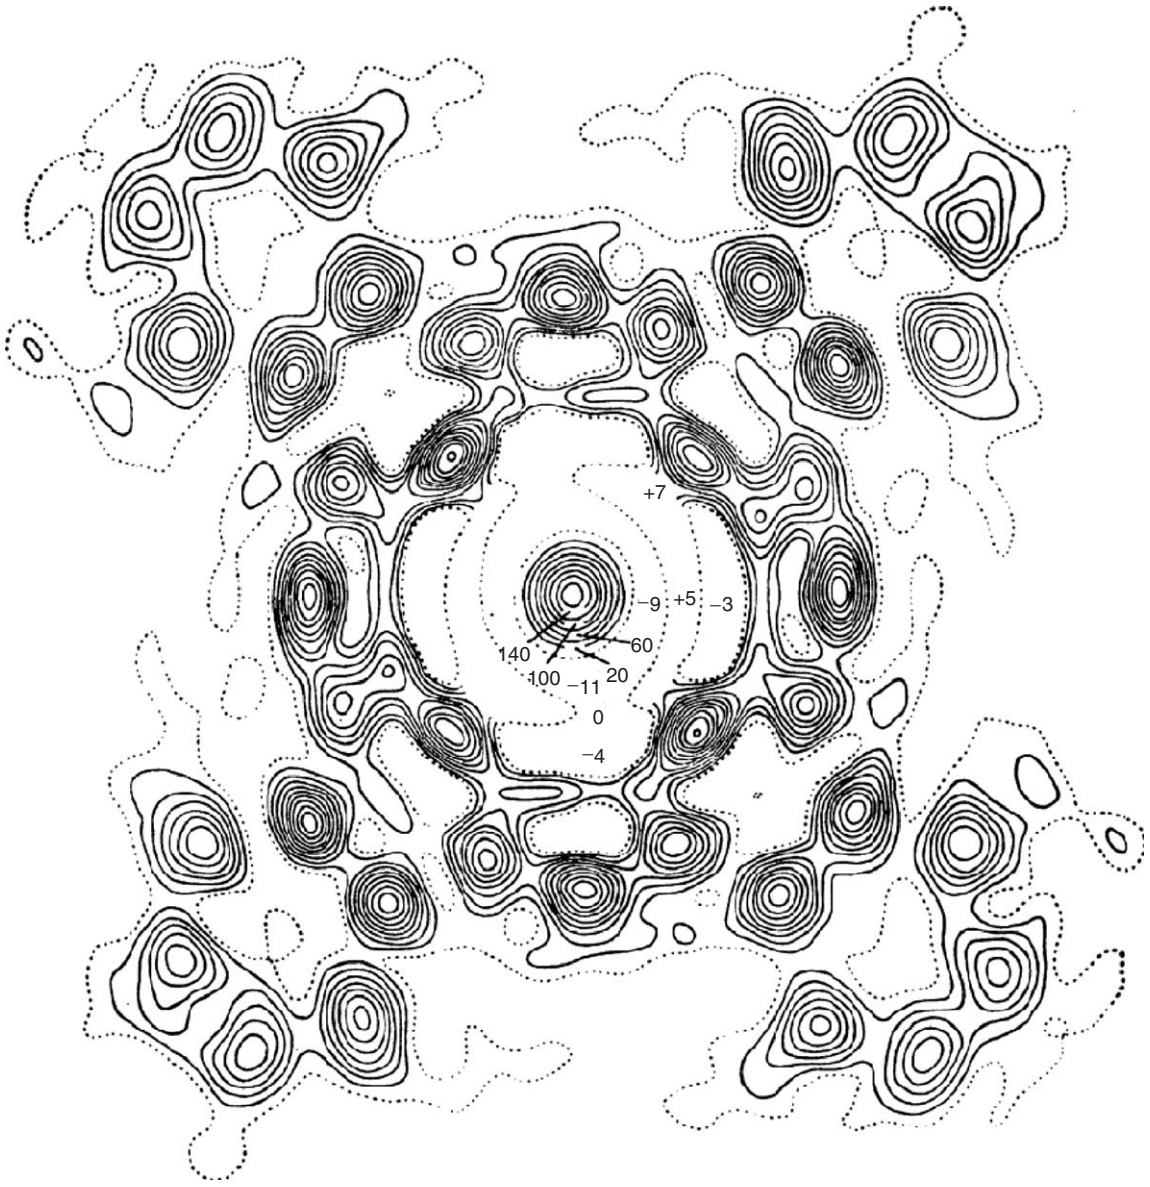

Figure 4 (010) projection of the electron density of Pt-phthalocyanine.

1967, less then 10% of the structures were solved by DM, and only the availability of faster computers and suitable programs triggered the fast growth of their use. By the mid-1970s, this exceeded 50%. The theoretical work became more strictly linked to the development of practical procedures. In 1966, J Karle and I Karle formulated the basic rules for the practical application of the "symbolic addition" methods, first proposed by W H Zachariasen (1952), and in 1968 G Germain and M M Woolfson proposed the "multisolution" methods, which were the basis for the very successful MULTAN program (G Germain, P Main and M M Woolfson, 1970). The continuous progress and success of DM in solving increasingly complex crystal structures was the motivation for conferring in 1985 the Nobel prize in chemistry on the mathematician H Hauptman and the physicist J Karle. The theoretical and practical developments of DM are still continuing and today they are also capable of solving small proteins from diffraction data at atomic resolution.

Polycrystalline Materials

So far only the use of X-ray diffraction by single crystals has been considered, but it is well known that many materials cannot be easily obtained in this form, but only as polycrystalline samples composed of very small crystallites (a powder). Very early on, W Friedrich (1913), P Debye and P Scherrer (1916), and

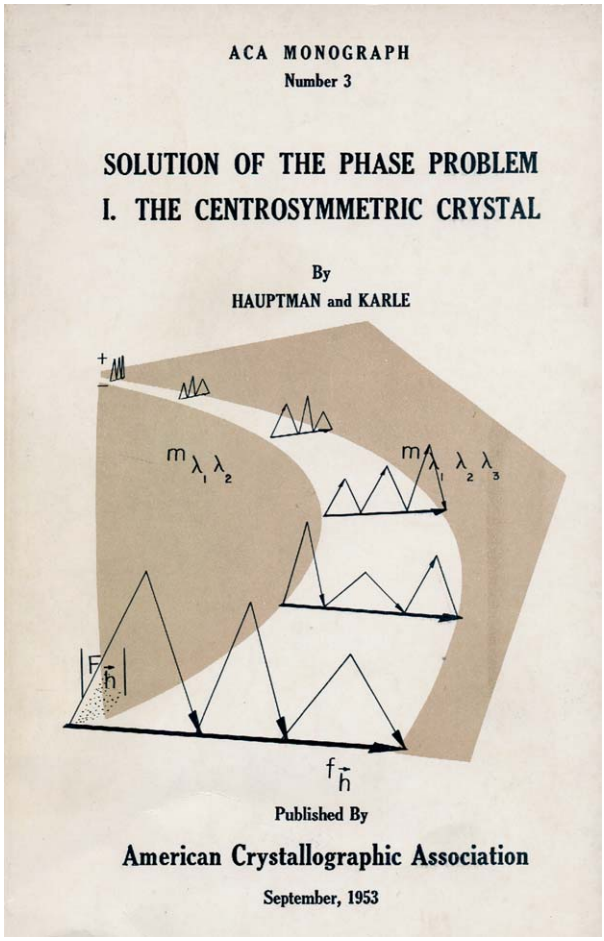

Figure 5 Cover of the 1953 monograph by H Hauptman and J Karle.

A W Hull (1917) obtained diffraction diagrams from powder samples and gave their theoretical interpretation. The diffraction pattern of every polycrystalline sample is like its fingerprint, and powder patterns soon became a widely used analytical method for the identification of crystalline species. Unfortunately in powder patterns, different reflections tend to overlap and this problem becomes more severe for more complex structures. The derivation of the indices and intensity of the individual reflections, of the cell parameters, and of the space group symmetry becomes much more difficult. In more recent years, several algorithms for the analysis of diffraction patterns were proposed and implemented in computer programs, but the most relevant step was the use of the full profile fitting method proposed by H M Rietveld (1969). These theoretical developments, together with the advent of more accurate instrumentation and the use of synchrotron radiation, have opened the way to the *ab initio* solution of fairly complex crystal structures (both by Patterson and by DMs) of compounds which cannot be obtained as suitable single crystals.

Impact of the Development of Experimental and Computational Techniques

The progress of crystal structure determination was also marked by the developments in X-ray sources and detectors. In the early days sealed tubes were used, and the most common detector was a photographic film on which intensities were usually estimated by a painstaking visual comparison with a suitable scale. Around the 1960s, diffractometers with counter detectors appeared and for special applications, they were equipped with the more intense X-ray source of a rotating anode generator. The most recent advances are the advents: (1) of the very intense, collimated, and tuneable synchrotron radiation, (2) of powerful focusing devices, and (3) of electronic area detectors.

In the early days the computational effort needed to carry out a crystal structure determination appeared quite formidable and almost impossible to be carried out by hand. The summation of a 3D Fourier series such as eqn [2], involving hundreds or thousands of terms, could not be conceived. Only 2- and 1D projections involving fewer terms could be computed by some ingenious devices such as Lipson and Beevers (1936) strips or some optical methods. The advent of punched-card machines in the 1940s and their rapid development into electronic computers also marked a breakthrough in crystal structure determination. In the early 1960s, huge machines using punched cards or paper tapes and magnetic tapes were employed; their computing power was less than that of a modern palm-top computer and the calculation of a 3D electron density map could take a few hours (a few seconds on modern PC). As already mentioned, the advent of faster computers allowed and triggered the formulation of more demanding algorithms, and of the corresponding software for the solution and refinement of crystal structures of increasing complexity. Additionally, information technology allowed the setting up of structural databases collecting almost half a million structures; their search is an invaluable source of physical, chemical, and biological information.

Solution of Biological Macromolecules

Parallel to the development of the structural crystallography of small and medium size molecules, it was soon recognized that X-ray diffraction methods could provide detailed structural information also for large biological macromolecules. Indeed, globular proteins can often be crystallized and these crystals, although usually with a poorer degree of order, have the same regularities in external form and the same

optical characteristics as the crystals of simple substances. In 1934 J D Bernal and D Crowfoot, and in 1935 D Crowfoot obtained the first X-ray single crystal photographs of pepsin and insulin. The patterns contained thousands of reflections, as expected for crystals of large molecules. The route was opened, but these studies also emphasized the difficulty of the task. In 1936 M Perutz joined Bernal's lab and was soon inspired by his "visionary faith in the power of X-ray diffraction to solve the structures of molecules as large and complex as enzymes or viruses at a time when the structure of ordinary sugar was still unsolved." This was the beginning of his lifelong dedication to the study of crystalline hemoglobin. After a long battle in trying some very ingenious but unsuccessful methods to derive phase information, in 1953, triggered by the recent success in binding mercury to hemoglobin, he was led to propose the use of the isomorphous replacement method for the solution of protein structures. The full success of this idea was only achieved six years later in 1960, when it led to the determination of the hemoglobin structure at 5.5 Å resolution. Meanwhile, J Kendrew had also applied isomorphous replacement to the smaller myoglobin molecule and succeeded in building an atomic model of the structure at 2 Å resolution. In 1962, M Perutz and J Kendrew were awarded the Nobel prize in chemistry (**Figure 6**). The following years were rich with theoretical, computational, and instrumental developments, which allowed the solution of more protein structures. In 1972, the Protein Data Bank was established and the number of deposited coordinates of macromolecular structures has increased almost exponentially since then. The improvement of the isomorphous replacement technique was paralleled by new phasing methods, such as anomalous dispersion and molecular replacement, new refinement algorithms, their automation, and the use of computer graphic tools for the interpretation of the electron density maps. There were progresses in instrumentation for data collection and synchrotron radiation became available. Increasingly larger structures of viruses and other biological assemblies could be solved: in 1982, A Klug was awarded the Nobel prize in chemistry for "his structural elucidation of biologically important nucleic acid-protein complexes," in 1988 J Deisenhofer, R Huber, and H Michel were awarded the same prize "for the determination of the three-dimensional structure of a photosynthetic reaction centre," and in 2003 R MacKinnonn, together with P Agre, was awarded the prize "for structural and mechanistic studies of ion channels."

Less Ordered Structures

So far the use of X-ray diffraction from crystals has been considered, that is, from regular 3D arrangements of atoms or molecules. The contrasting situation is that of totally amorphous materials with no long-range order, but rather a continuity of intermediate partially ordered states is present in nature. The "paracrystal" model for the general interpretation of the diffraction patterns of these systems was proposed by R Hosemann (1950).

Already in 1913 W Friedrich had found that paraffin gives a strong X-ray powder reflection, and between 1923 and 1929, several diffraction studies were conducted on long-chain fatty acids.

Several natural substances, such as cellulose, silk, hair, nerve, sinew, and muscle occur as fibers; X-ray fiber diagrams were first reported by R O Herzog and W Jancke (1921). Later the work of W T Astbury and others (1932, 1934) resulted in a classification of

Figure 6 The Nobel prize winners in 1962: from left M Wilkins, M Perutz, F H C Crick, J Steinbeck, J D Watson, and J Kendrew.

Figure 7 Rosalind Franklin and her diffraction pattern of the B form of DNA.

the fibrous proteins. In particular keratinous proteins, such as those which constitute the skin and horny structures of mammals, the feathers of birds, the scales of reptiles, and the flagella of some bacteria, were investigated.

The most famous work based on the interpretation of a fiber diffraction pattern was that on the structure of DNA by F H C Crick, J D Watson, M Wilkins, and R Franklin. The first paper was published by Watson and Crick (1953), who, together with M Wilkins, were awarded the Nobel prize in medicine in 1962 (**Figure 6**). The essential contribution of Rosalind Franklin (**Figure 7**) could not be recognized because of her death in 1958 at the age of 37, and the story of DNA turned out to be a tale of competition and intrigue, told from different points of view by J Watson (2001), A Sayre (2000), B Maddox (2002), and M Wilkins (2003) in fascinating books.

Among other paracrystalline systems, liquid crystals were first analyzed in 1922 by G Friedel, who opened the route to the structural elucidation of the different types of mesomorphic phases and of natural and artificial membranes.

Conclusions

Structure determination by X-ray diffraction is one of the most powerful tools for seeing the arrangement of atoms and molecules in a material and has greatly contributed to the advances of different branches of science.

In physics, it contributed to the understanding of the electronic structure of solids and was the background for the discovery of new materials such as the superconducting ceramic materials by J G Bednorz and K A Müller (Nobel prize in physics in 1987).

In chemistry, it allowed a more profound understanding of the nature of the different types of chemical bonds, as was clearly shown by L C Pauling, who was awarded the Nobel prize in chemistry "for his research into the nature of the chemical bond and its application to the elucidation of the structure of complex substances." He was the first to show that polypeptide chains in proteins could form α-helices and β-pleated sheets (1951), basic information that was essential in the analysis of the structures of all biological macromolecules. More recently, the very

fruitful concept of supramolecular chemistry was the motivation of the 1987 Nobel prize in chemistry to J M Lehn together with D J Cram and C J Pedersen.

In life sciences, knowledge of the ternary and quaternary structure of proteins and biological assemblies opened the route to the elucidation of the molecular bases of biological processes and is an essential part of molecular biology. The 3D structure of drug molecules and of some of their receptors is the basis for modern drug design strategies.

Mineral crystals were the first to be discovered and studied by man, but the advent of X-ray crystallography opened a completely new scenario in the field of earth sciences. For instance, the knowledge of the structures of the different types of silicates and of rock-forming minerals allows a better understanding of petrogenetic processes.

In materials sciences, structural information is the basis for the tailoring of new materials with specific properties. An example is the stereospecific polymerization and the synthesis of sterically regular polymers for which K Ziegler and G Natta were awarded the Nobel prize in chemistry in 1963.

Crystal Symmetry

Th Hahn, Institut für Kristallographie, RWTH Aachen, Germany
H Klapper, Mineralogisch-Petrologisches Institut, Universität Bonn, Bonn, Germany

Introduction

Among the various states of condensed matter, the crystalline state is governed by symmetry more than any other state (e.g., liquids, glasses). This is because all atoms of one type in a solid compound display the same structural behavior and adopt, as far as possible, the same atomic environment around them. This applies to all kinds of atoms in the compound and results from the tendency of any system to minimize its free energy. As a first consequence, this leads to three-dimensional periodicity (translational symmetry) of the atoms (ions, molecules) in a crystal structure. As a second consequence, further symmetries, such as rotations, reflections, and inversions (through a point), may occur.

As a rule, symmetry in science is described mathematically in terms of the "group theory." For crystals, the main symmetry groups are point groups, translation groups, and space groups (these are discussed elsewhere in this encyclopedia). Group elements are the symmetry operations discussed in the section "Crystallographic symmetry operations and symmetry elements." Fundamentals of crystallography and of crystallographic symmetry groups can be found in text books of crystallography and in *ITA* (2002) (cf. section "Further reading").

Two levels of crystalline symmetry must be distinguished:

1. "Microscopic" symmetry of the crystal structure: this implies a three-dimensional periodicity which is described by translation groups and their lattices. Furthermore, all permissible combinations of translations with reflections, rotations and inversions, including screw rotations and glide reflections, can occur as elements of space groups.
2. "Macroscopic" symmetry of the single (bulk) crystal: it is derived from the microscopic symmetry (space group) of the crystal structure by the suppression of all translations, both lattice translations and translation components of screw rotations and glide reflections. This leads to the point group of the crystal, which represents its morphological symmetry as manifested by the general face form, which may develop under ideal conditions during crystal growth. Furthermore, the symmetry of physical properties of crystals, in particular of tensor properties, is also described by point groups. Note that in this description, the macroscopic crystal is considered as an anisotropic homogeneous continuum.

Lattices and Their Symmetries

The symmetry operations of a crystal are "isometries" or "rigid motions", that is, mappings which preserve distances and, hence, angles and volumes also. The simplest motion is a translation which is a parallel displacement of an object by a translation vector $\boldsymbol{t}$. The three-dimensional periodicity (translation symmetry) of the (infinitely extended) crystal structure is described by the infinite set $\{\boldsymbol{t}\}$ of all translation vectors $\boldsymbol{t}$ mapping the structure onto itself, that is, by the lattice. It is represented by the equation

$$\{\boldsymbol{t}\} = \{m \cdot \boldsymbol{a} + n \cdot \boldsymbol{b} + p \cdot \boldsymbol{c}\} \quad (-\infty < m, n, p < +\infty) \qquad [1]$$

with $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$ three linearly independent basis vectors spanning a three-dimensional parallelepiped called unit cell. Each translation t maps the crystal structure onto itself and is, hence, a symmetry operation of the crystal.

Equation [1] implies that for a given basis vector set $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$, one unique lattice $\{\boldsymbol{t}\}$ is defined. On the other hand, one and the same lattice can be generated by infinitely many different triplets $\boldsymbol{a}'$, $\boldsymbol{b}'$, $\boldsymbol{c}'$ of linearly independent lattice vectors, each triplet spanning a "primitive" (smallest) unit cell (this triplet is called "primitive basis" here). All these triplets are equally correct lattice bases. As will be shown below, one (or at most two) particularly symmetry-adapted basis vector sets are conventionally accepted by all scientists.

There exist four different types of lattice symmetries in two dimensions and seven in three dimensions. These so-called "lattice point symmetries" are defined as the symmetries of the infinite surrounding of each lattice point by the other lattice points. These lattice symmetries are also called "holohedries" (holohedral point groups), a term which stems from the old morphological classification, meaning "full face form." These holohedries determine the seven three-dimensional crystal systems and crystallographic coordinate systems: triclinic (anorthic), monoclinic, orthorhombic, tetragonal, trigonal/rhombohedral, hexagonal, cubic (see **Table 1**, see footnote there about trigonal/rhombohedral). Geometrically, these holohedral lattice symmetries are brought out directly in the so-called "Wigner–Seitz cells" or "Dirichlet domains" (see *ITA* (2002)).

Crystallographic Coordinate Systems

"Primitive" Crystallographic Coordinate Systems

Whereas in physics and chemistry normally Cartesian coordinate systems are used, in crystallography quite different systems are applied. Here it is customary that every crystal receives its own specific crystallographic coordinate system, based on the symmetry of the crystal and characterized as follows:

1. Basis vectors are three linearly independent, shortest ("primitive") translation vectors of the crystal lattice (see eqn [1]). This implies six lattice parameters: three axial lengths a, b, c, and three interaxial angles α, β, γ. ("Primitive" means that the unit cell spanned by the three basis vectors contains only one lattice point, in contrast to "centered cells," see the next section.)
2. The origin of the coordinate system is free in principle, but for convenience in computation, it is usually chosen in a center of symmetry (inversion center), if present, otherwise in a point of high site symmetry of the space group (e.g., in an intersection of two or more symmetry axes).

The advantage of such a crystal-specific coordinate system is that all lattice points receive integer coordinates, and this applies to all choices of a primitive coordinate system for a given crystal. Note that the lattice parameters of a crystal vary with temperature and pressure.

Table 1 Crystal systems, lattice point symmetries, conventional crystallographic coordinate systems and Bravais lattice types in two and three dimensions. The lattice point symmetries (column 2) are given in Hermann–Mauguin (left) and in Schoenflies symbols (right); see Section "Symbols for point groups and space groups"

Crystal system	*Lattice point symmetry (holohedry)*		*Conventional coordinate system (restrictions on cell parameters $a, b, c, \alpha, \beta, \gamma$)*	*Bravais lattices*[a]
Two dimensions				
Oblique (monoclinic)	2		None	*mp*
Rectangular (orthorhombic)	2*mm*		$\gamma = 90^\circ$	*op*, *oc*
Square (tetragonal)	4*mm*		$a = b, \gamma = 90^\circ$	*tp*
Hexagonal	6*mm*		$a = b,\ \gamma = 120^\circ$	*hp*
Three dimensions				
Triclinic (anorthic)	$\overline{1}$	C_i	None	a*P*
Monoclinic	2/*m*	C_{2h}	$\alpha = \gamma = 90^\circ$ (unique axis *b*)	*mP*, *mC* *mA*, *mI*
			$\alpha = \beta = 90^\circ$ (unique axis *c*)	*mP*, *mA* *mB*, *mI*
Orthorhombic	2/*m* 2/*m* 2/*m*	D_{2h}	$\alpha = \beta = \gamma = 90^\circ$	*oP*, *oI*, *oF* *oA*, *oB*, *oC*
Tetragonal	4/*m* 2/*m* 2/*m*	D_{4h}	$a = b,\ \alpha = \beta = \gamma = 90^\circ$	*tP*, *tI*
Trigonal[b]				
Rhombohedral lattice	$\overline{3}$ 2/*m*	D_{3d}	$a = b = c,\ \alpha = \beta = \gamma \neq 90^\circ$	*hR*
Hexagonal lattice	6/*m* 2/*m* 2/*m*	D_{6h}	$a = b,\ \alpha = \beta = 90^\circ, \gamma = 120^\circ$	*hP*
Hexagonal	6/*m* 2/*m* 2/*m*	D_{6h}	$a = b,\ \alpha = \beta = 90^\circ, \gamma = 120^\circ$	*hP*
Cubic	4/*m* $\overline{3}$ 2/*m*	O_h	$a = b = c,\ \alpha = \beta = \gamma = 90^\circ$	*cP*, *cI*, *cF*

[a] Bravais lattices (column 4): The lower-case first letter of the symbol identifies the crystal system. Note that the trigonal and the hexagonal system both receive the letter *h*. Second letter of the symbol: *p*, *c* in two dimensions: primitive and centered cell. Three dimensions: *P* = primitive cell; *A*, *B*, *C* = one-face centered cell on (b, c), (*a*,*c*) or (*a*,*b*) face; *I* = body centered cell; *F* = all-face *centered cell*; *R* = rhombohedral centering of the hexagonal cell.

[b] In the trigonal crystal system two Bravais lattices, *hR* and *hP*, with different holohedries, $\overline{3}$ 2/*m* and *6/m 2/m 2/m*, occur. Both are normally described by "hexagonal axes."

Conventional Crystallographic Coordinate Systems

In order to define a unique crystallographic coordinate system for each crystal, special conventions have to be devised. It turns out, however, that the use of a special primitive coordinate system, as described in the preceding section, would indeed always characterize the crystal lattice uniquely, but in many cases would not bring out the symmetry of the crystal. This, however, is a universally accepted objective for the definition of the conventional crystallographic coordinate system in the form of a symmetrical parallelepiped as unit cell.

For this reason, the 14 Bravais types of lattices are considered, with the provision that all Bravais lattices with the same holohedry should have the same conventional coordinate system. A consequence of this procedure is that only for primitive Bravais lattices, all lattice points receive integer coordinates, whereas for centered lattices of the same lattice, symmetry points with fractional coordinates 1/2, 1/3, and 2/3 (and no others) appear. In this way, seven conventional coordinate systems result, which apply to the crystals of all 14 Bravais lattice types. As a typical example, the cubic crystal system is considered: for the primitive cubic lattice *cP*, the conventional coordinate system employs the three shortest lattice vectors with right interaxial angles $\alpha = \beta = \gamma = 90^\circ$. In this case, the conventional coordinate system is at the same time a primitive crystallographic basis. For the body-centered and all-face-centered cubic Bravais lattices *cI* and *cF*, however, only a fraction of the lattice points (1/2 for *cI* and 1/4 for *cF*) have integer coordinates represented by 0,0,0, whereas the remaining centering lattice points have fractional coordinates: 1/2, 1/2, 1/2 for *cI*, and 1/2, 1/2, 0 & 0, 1/2, 1/2 & 1/2, 0, 1/2 for *cF*. If only primitive cells were used, the coordinate system for *cP* would remain the same (cube = 90° rhombohedron), whereas for *cI* and *cF* rhombohedral cells with $\alpha = 109.47^\circ$ and $\alpha = 60^\circ$, respectively would result which would not display the cubic symmetry.

The conventional crystallographic coordinate systems are collected in **Table 1**, which lists the four plane and the seven spatial lattice symmetries with their point-group symbols and the restrictions on the general lattice parameters $a, b, c, \alpha, \beta, \gamma$ imposed by the lattice symmetry. The symbols of the Bravais lattices which belong to a given coordinate system are listed too. These symmetry criteria uniquely determine five of the seven three-dimensional coordinate systems because these five exhibit three or more symmetry directions ("blickrichtungen"): orthorhombic, tetragonal, rhombohedral, hexagonal, cubic. For the two exceptions, triclinic and monoclinic, no or only one symmetry direction exists. In these cases, metrical criteria, such as reduced bases (i.e., choice of the three (triclinic) or two (monoclinic) shortest lattice translations as basis vectors), have to be applied. It should be noted that for historical reasons, in the monoclinic system two different "settings" are in use, which are distinguished by the labeling of the unique symmetry axis: "unique axis *b*" and "unique axis *c*" settings. The *b*-axis setting is the more frequently used one (see Part 2 of *ITA* (2002)).

There is one case in which not one but two different conventional coordinate systems are in use, for trigonal crystals with a rhombohedral *hR* lattice. These crystals are alternatively described by "rhombohedral axes" or, more frequently, by "hexagonal axes," whereby the first case corresponds to a primitive rhombohedral unit cell, the second to the triple R-centered hexagonal unit cell. In contrast, crystals with a hexagonal *hP* lattice are always described by "hexagonal axes."

Detailed descriptions of the conventional crystallographic coordinate systems and reduced bases can be found in sections 1.2, 2.1, 8.3.1, 9.1 and 9.2 of *ITA* (2002).

Crystallographic Symmetry Operations and Symmetry Elements

Symmetry Operations

The following types of symmetry operations exist in crystals and are elements of crystallographic symmetry groups:

1. Translations (already treated in the section "Lattices and their symmetries").
2. Rotations around an axis, reflections across a plane and inversions in a point, as well as their combinations, that is, rotoinversions and rotoreflections. These operations constitute the so-called point-group operations, which leave at least one point of space invariant.
3. Combinations between point-group operations and translations, leading to screw rotations and glide reflections. Both types occur only in space groups, not in point groups. Screw rotations are rotations by an angle $\varphi = 360^\circ/n$, followed by a translation (screw component) parallel to the rotation axis. Glide reflections are reflections across a plane, followed by a translation (glide component) parallel to the plane. The screw and glide components are rational fractions of a lattice translation.

An important fact of crystallographic symmetry is the restriction of the rotation angles φ by the translation lattice to $\varphi = 180^\circ, 120^\circ, 90^\circ, 60^\circ$, defining twofold, threefold, fourfold, and sixfold rotations and screw rotations. This is the consequence of the three-dimensional periodicity of crystals. Apart from a simple mathematical proof (see section "Matrix representation of symmetry operations"), this result is immediately obvious from the fact that a plane can be covered without gaps and overlaps only by parallelograms and their special forms (rectangles, rhombuses, squares), and by triangles and hexagons, but not by pentagons (corresponding to a rotation angle of 72°), heptagons, octagons, etc. Hence, rotation axes other than two-, three-, four-, and sixfold axes are not possible in crystals.

Symmetry Elements

In addition to symmetry operations (which represent "action" on an object), symmetry can also be described in (static) geometrical terms, known as symmetry elements. They form the geometric locus (geometric element), oriented in space, at which a symmetry operation or a cyclic group of operations is performed (plane for a reflection, line for a rotation, point for an inversion), together with a description of these operations. In other words, the symmetry element is the "invariant subspace" of a given operation, that is, the set of fixed points which are invariant under the operation.

Symmetry elements are reflection (mirror) planes, glide planes, rotation axes, screw axes and centers of symmetry. For rotoinversions and rotoreflections, the symmetry element consists of two items: axis and inversion point on the axis, or axis and mirror plane normal to the axis. For screw rotations and glide reflections, the screw and glide components have to be removed first in order to obtain the "fixed points" for screw axes and glide reflections.

Note that the group elements of a symmetry group are the symmetry operations, not the symmetry elements. This discrepancy of nomenclature has historical reasons and is the source of frequent misunderstandings.

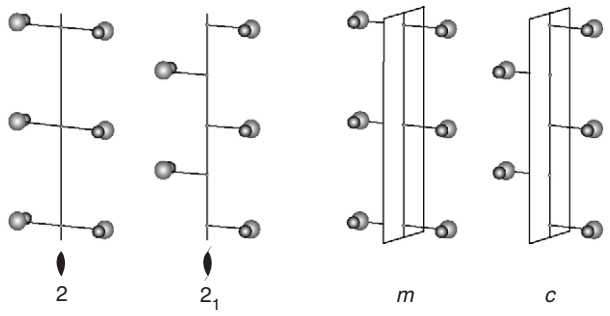

Figure 1 Symmetry elements in crystals: twofold rotation and screw axes 2 and 2_1 (left pair), and reflection and glide planes *m* and *c* (right pair). The "objects" are polar two-atomic molecules, in order to bring out the orientational differences between rotations and reflections. Note that each diagram extends over two translation periods along *c*. The graphical symbols underneath the diagrams are explained in **Table 2**.

The crystallographic symmetry elements (reflection and glide plane, rotation and screw axes, and rotoinversion axes) are illustrated in **Figures 1–3**. Printed and graphical symbols of all symmetry elements are collected in **Table 2**. Further details are given in Parts 1 and 8.1 of *ITA* (2002) and the references quoted therein. Complete "frameworks of symmetry elements" for the 17 plane groups, the 230 space groups, and the 32 crystallographic point groups are presented in Parts 6, 7 and 10.1 (and explained in section 2.2.6) of *ITA* (2002).

Matrix Representation of Symmetry Operations

General Relations

In the mathematical treatment of symmetry operations, normally the coordinate system, that is, the set of basis vectors $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$ and the origin, is considered to be at rest, whereas the object is mapped onto itself (special affine mapping). (Equivalently, it is equally correct to transform the coordinate system, whereby the object is considered to be at rest.) A general symmetry operation transforms a point X with coordinates x, y, z into a symmetrically equivalent point $\tilde{X}$, with coordinates $\tilde{x}$, $\tilde{y}$, $\tilde{z}$ according to

$$\begin{aligned}\tilde{x} &= W_{11}x + W_{12}y + W_{13}z + w_1\\ \tilde{y} &= W_{21}x + W_{22}y + W_{23}z + w_2\\ \tilde{z} &= W_{31}x + W_{32}y + W_{33}z + w_3\end{aligned} \qquad [2]$$

or, in matrix notation:

$$\begin{pmatrix}\tilde{x}\\ \tilde{y}\\ \tilde{z}\end{pmatrix} = \begin{pmatrix}W_{11} & W_{12} & W_{13}\\ W_{21} & W_{22} & W_{23}\\ W_{31} & W_{32} & W_{33}\end{pmatrix}\cdot\begin{pmatrix}x\\ y\\ z\end{pmatrix} + \begin{pmatrix}w_1\\ w_2\\ w_3\end{pmatrix}$$

$$\tilde{\boldsymbol{r}} = \boldsymbol{W}\cdot\boldsymbol{r} + \boldsymbol{w} = (\boldsymbol{W},\boldsymbol{w})\cdot\boldsymbol{r} \qquad [3]$$

The (3×3) matrix $\boldsymbol{W}$ is the rotation part, and the (3×1) column matrix $\boldsymbol{w}$, the translation part of the symmetry operation. The matrices $\boldsymbol{W}$ represent all point-group operations, rotations, reflections, inversions, and rotoinversions. The two parts $\boldsymbol{W}$ and $\boldsymbol{w}$ can be assembled into an (augmented) (4×4) matrix $\mathbb{W}$ according to

$$\begin{pmatrix}\tilde{x}\\ \tilde{y}\\ \tilde{z}\\ 1\end{pmatrix} = \left(\begin{array}{ccc:c} W_{11} & W_{12} & W_{13} & w_1\\ W_{21} & W_{22} & W_{23} & w_2\\ W_{31} & W_{32} & W_{33} & w_3\\ \hdashline 0 & 0 & 0 & 1\end{array}\right)\cdot\begin{pmatrix}x\\ y\\ z\\ 1\end{pmatrix}$$

$$= \left(\begin{array}{ccc:c} & \boldsymbol{W} & & \boldsymbol{w}\\ \hdashline 0 & 0 & 0 & 1\end{array}\right)\cdot\begin{pmatrix}x\\ y\\ z\\ 1\end{pmatrix} = \mathbb{W}\cdot\mathbb{r} \qquad [4]$$

Since every symmetry transformation is a "rigid-body motion," the determinant of the matrices $\boldsymbol{W}$ and $\mathbb{W}$ is

$$\det \boldsymbol{W} = \det \mathbb{W} = \pm 1 \qquad [5]$$

The sequence of two symmetry operations (successive application) is given by the product of their (4×4) matrices $\mathbb{W}_1$ and $\mathbb{W}_2$:

$$\mathbb{W}_3 = \mathbb{W}_2\cdot\mathbb{W}_1 \qquad [6]$$

whereby, $\mathbb{W}_3$ is again a symmetry operation.

The inverse operation $\mathbb{W}^{-1}$ is defined by $\mathbb{W}\cdot\mathbb{W}^{-1} = \mathbb{I}$, whereby $\mathbb{I}$ is the (4×4) unit matrix representing the identity operation:

$$\mathbb{W}^{-1} = \left(\begin{array}{ccc:c} & \boldsymbol{W}^{-1} & & -\boldsymbol{W}^{-1}\cdot\boldsymbol{w}\\ \hdashline 0 & 0 & 0 & 1\end{array}\right) \qquad [7]$$

Finally, the augmented matrix for a translation $\boldsymbol{t}$ is

$$\mathbb{T} = \left(\begin{array}{ccc:c} & \boldsymbol{I} & & \boldsymbol{t}\\ \hdashline 0 & 0 & 0 & 1\end{array}\right), \qquad \boldsymbol{t} = \begin{pmatrix}t_1\\ t_2\\ t_3\end{pmatrix} \qquad [8]$$

and $\boldsymbol{I}$ the (3×3) unit matrix.

Note on the matrices $\boldsymbol{W}$ and $\theta\cdot k$ of eqns [3] and [4]: The rotation parts $\boldsymbol{W}$ of these matrices leave an atom located in the origin of the coordinate system invariant, that is, the symmetry element of $\boldsymbol{W}$ intersects the

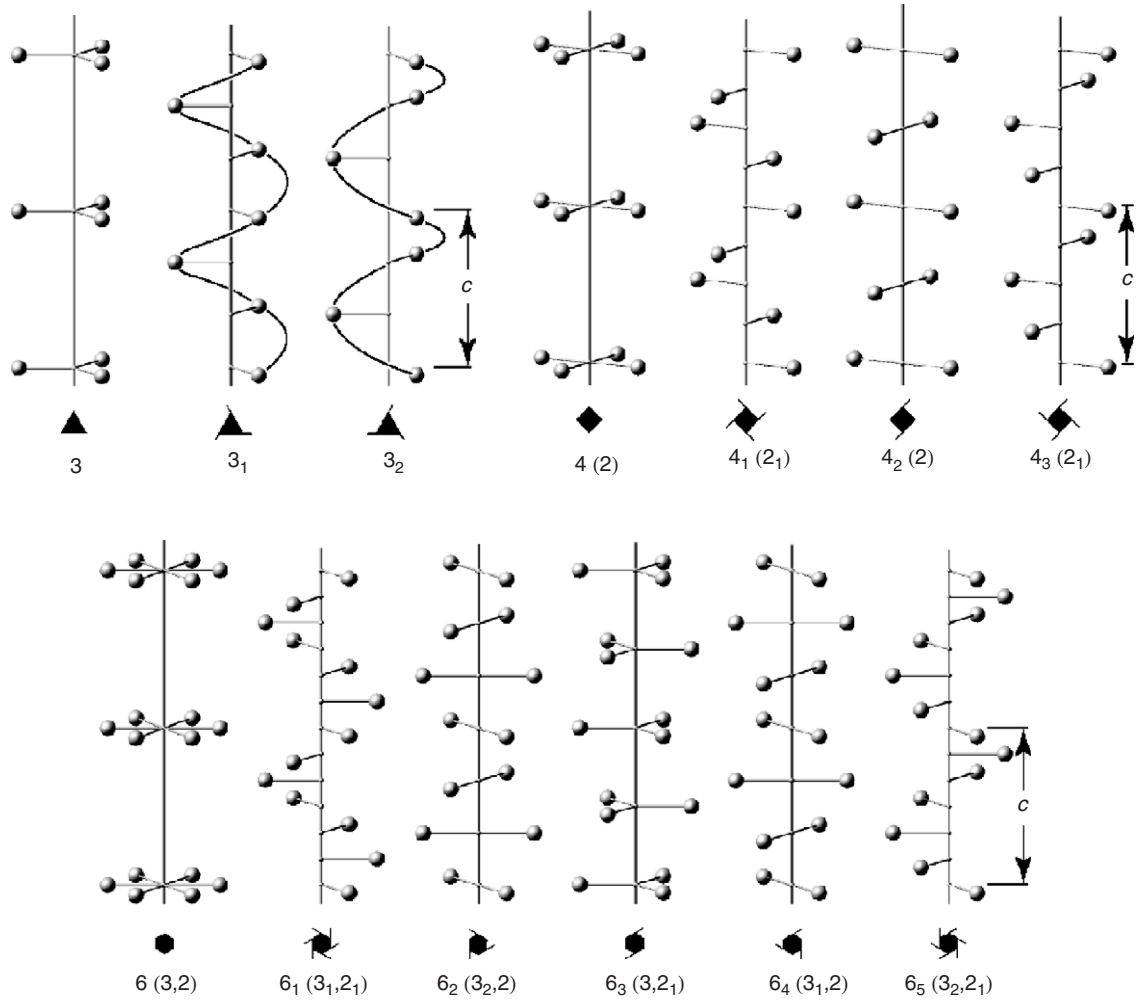

Figure 2 Symmetry elements in crystals: threefold rotation and screw axes (top row), fourfold rotation and screw axes (top row), and sixfold rotation and screw axes (bottom row). Each diagram extends over two translation periods along *c*. For the screw axes 3_1 and 3_2, the course of the screws (helices) is indicated in order to show the enantiomorphism (mirror images) of the two screw axes. The subelements (subgroups) of each symmetry element (cyclic group) are given in parentheses. The graphical symbols are explained in **Table 2**.

origin. The translation parts $\boldsymbol{w}$ consist of two components, first the (intrinsic) "screw or glide component" of a screw rotation or glide reflection (if present), second the "location parameter," which depends on the location of the symmetry element with respect to the origin. Thus, for a pure rotation or reflection through the origin, $\boldsymbol{w} = (w_1, w_2, w_3) = (0, 0, 0)$.

Geometric Interpretation of (Crystallographic) Symmetry Matrices

A (3×3) matrix $\boldsymbol{W}$ of a rigid motion has two essential invariants, that is, two quantities which do not change under a transformation of the coordinate system and, hence, can serve to identify the "nature" of the motion. These quantities are the determinant, $\det \boldsymbol{W}$, and the trace, $\mathrm{tr}\, \boldsymbol{W} = W_{11} + W_{22} + W_{33}$. Their properties are as follows:

1. A rotation by an angle φ and its representation in a Cartesian coordinate system x_1, x_2, x_3 are assumed, whereby the rotation axis intersects the origin and is parallel to x_3. The rotation matrix is

$$\boldsymbol{W} = \begin{pmatrix} \cos\varphi & \sin\varphi & 0 \\ -\sin\varphi & \cos\varphi & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

The trace is $\mathrm{tr}\, \boldsymbol{W} = 1 + 2\cos\varphi$, valid for any coordinate system. Since this rotation maps a lattice point with integer coordinates onto another lattice point, all elements of the matrix, if referred to a crystallographic coordinate system, must be integers,

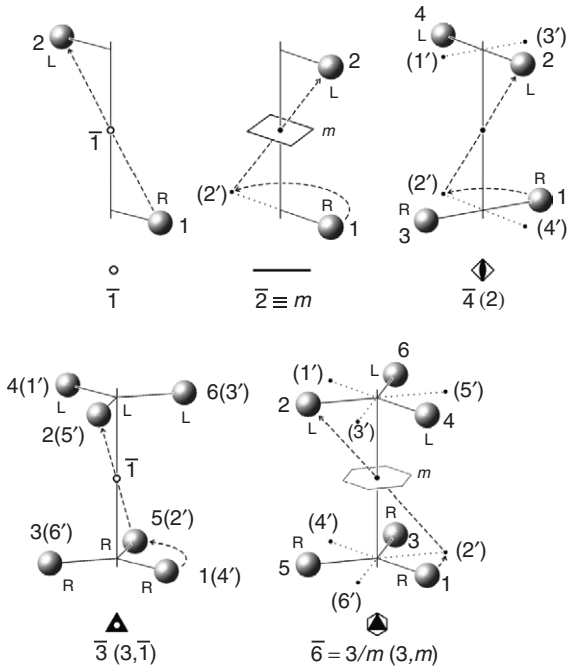

Figure 3 Symmetry elements in crystals: the five crystallographic rotoinversion axes $\bar{1}$, $\bar{2}$, $\bar{4}$, $\bar{3}$, $\bar{6}$ (orders 2, 2, 4, 6, 6, resp.), and their action on a spherical object. Starting from object 1, objects 2, 3, … are successively generated. The intermediate positions of the object (between the rotation and the inversion part of the operation) are labeled by numbers in parentheses. For all groups the first operation $1 \rightarrow (2') \rightarrow 2$ is indicated by dashed arrows. The labels R and L denote the handedness (right or left), if the object is chiral (starting object 1: R). All odd powers of rotoinversions are hand-changing (R↔L), even powers hand-preserving (R→R, L→L). Note that for axes $\bar{n}$ with n odd (i.e., for $\bar{1}$ and $\bar{3}$), the inversion point is a center of symmetry $\bar{1}$ (i.e., a subelement). For axes $\bar{n}$ with $n = 4k + 2$ (i.e., $\bar{2}$ and $\bar{6}$), a mirror plane m normal to the axis and intersecting the inversion point is a subelement, whereas for $n = 4k$ (i.e., $\bar{4}$) neither $\bar{1}$ nor m occur as subelements. The subelements of the rotoinversion axes are noted in parentheses.

hence tr $W = 1 + 2\cos\varphi = m$, and $\cos\varphi = 1/2\,(m-1) = 1/2p$ (m, p integers). Since $\cos\varphi$ is restricted to the range -1 to $+1$, only the following values of $\cos\varphi$ are compatible with lattice symmetry: $\cos\varphi = +1, +1/2, 0, -1/2, -1$, corresponding to rotation angles of $0^\circ \equiv 360^\circ$, 60°, 90°, 120°, and 180°. This is the famous "crystallographic restriction," which filters out the five permissible φ-angles (and their multiples) from the infinity of "n-fold rotations" with $\varphi = 360^\circ/n$.

2. Since symmetry operations are rigid motions which preserve distances, angles, and volumes, the determinant of their matrices must be $+1$ or -1:

   det $W = +1$: rotation; handedness (left or right) of object retained;

   det $W = -1$: reflection, inversion, rotoinversion : handedness of object reversed;

3. By combining the possible values of det W and tr W, the "nature" of a symmetry operation by means of its (3×3) symmetry matrix W is identified, as shown in **Table 3**.
4. By more detailed analysis of the (3×3) "point-group" matrices W and the augmented (4×4) "space-group" matrices $\mathbb{W}$, further characteristics of symmetry operations can be derived, that is, the orientation of the axis or of the plane in the given coordinate system, as well as the location of the symmetry element (plane, axis, point) in the unit cell relative to the chosen origin (see *ITA* (2002), Part 11).
5. In order to illustrate the previous somewhat abstract considerations, some examples of (4×4) matrices for (glide) reflections and (screw) rotations, together with their geometric elements, are given in **Table 4**. A list of all (3×3) matrices occurring in crystallographic point and space groups is available in Part 11 of *ITA* (2002).
6. It should be noted that in quasicrystals (i.e., forms of solid matter not based on exact three-dimensional periodicity but rather on "quasiperiodicity"), symmetries may occur which go beyond the "crystallographic restriction" discussed above under point 1. For instance, quasicrystals with icosahedral symmetry (containing fivefold rotations), as well as with tenfold and twelvefold rotations have been found.

Symbols for Point Groups and Space Groups

So far, "individual" symmetry operations and symmetry elements have been treated with their printed and graphical symbols, see **Table 2**. In order to combine these into symbols for crystallographic point and space groups, rules for the combination have to be specified. There are two types of group symbols in use: the oldest are the Schoenflies symbols contained in Schoenflies' classic work of 1891. The second are the Hermann-Mauguin symbols, derived around 1928 in several papers by Hermann and Mauguin. The latter are now predominantly used in crystallography and crystal-structure analysis, and are customarily called "international symbols." Schoenflies symbols are often preferred in spectroscopy and in studies of molecules.

Schoenflies Symbols

These symbols are based on group theory and use capital letters to indicate the major types of symmetry groups.

C: Cyclic groups C_1, C_2, C_3, C_4, C_6 of order $n = 1, 2, 3, 4$ and 6;

Table 2 Printed and graphical symbols for symmetry elements in two and three dimensions. For glide planes only a few selected examples are given

Printed symbol	*Symmetry element and its orientation, glide and screw vectors* $\boldsymbol{t}$	*Graphical symbol normal to plane of projection*
m	Reflection (mirror) plane (three dimensions) Reflection (mirror) line (two-dimensions)	
a, *b*, or *c*	"Axial" glide plane	
a	$\perp[0\,1\,0]$ or $\perp[0\,0\,1]$ $\quad \boldsymbol{t} = 1/2\boldsymbol{a}$	
b	$\perp[1\,0\,0]$ or $\perp[0\,0\,1]$ $\quad \boldsymbol{t} = 1/2\boldsymbol{b}$	
c	$\perp[1\,0\,0]$ or $\perp[0\,1\,0]$ $\quad \boldsymbol{t} = 1/2\boldsymbol{c}$	
g	Glide line (two dimensions) $\perp[0\,1]$; $\perp[1\,0]$; $\quad \boldsymbol{t} = 1/2\boldsymbol{a}$; $1/2\boldsymbol{b}$ (resp.)	
n	"Diagonal" glide plane $\perp[0\,0\,1]$; $\perp[1\,0\,0]$; $\perp[0\,1\,0]$; $\boldsymbol{t} = 1/2(\boldsymbol{a}+\boldsymbol{b})$; $1/2(\boldsymbol{b}+\boldsymbol{c})$; $1/2(\boldsymbol{a}+\boldsymbol{c})$ (resp.)	
d	"Diamond" glide plane (pair of planes)	
	Orthorhombic: $\perp[0\,0\,1]$; $\perp[1\,0\,0]$; $\perp[0\,1\,0]$; $\boldsymbol{t} = 1/4(\boldsymbol{a}\pm\boldsymbol{b})$; $1/4(\boldsymbol{b}\pm\boldsymbol{c})$; $1/4(\boldsymbol{c}\pm\boldsymbol{a})$ (resp.) Cubic (examples): $\perp[1\,1\,0]$; $\perp[0\,1\,1]$; $\perp[1\,0\,1]$; $\boldsymbol{t} = 1/4(-\boldsymbol{a}+\boldsymbol{b}\pm\boldsymbol{c})$; $1/4(\pm\boldsymbol{a}-\boldsymbol{b}+\boldsymbol{c})$; $1/4(\boldsymbol{a}\pm\boldsymbol{b}-\boldsymbol{c})$ (resp.)	
1	None (identity)	
2, 3, 4, 6	*n*-fold rotation axis, *n* (three dimensions) *n*-fold rotation point, *n* (two dimensions)	
$\overline{1}$	Center of symmetry, inversion center	
$\overline{2} = m, \overline{3}, \overline{4}, \overline{6}$	Rotoinversion axis, $\bar{n}$, with inversion point on the axis[a]	
2_1		
3_1, 3_2	*n*-fold screw axis, n_p	
4_1, 4_2, 4_3	The screw component is the fraction p/n $\boldsymbol{t}$ of the shortest lattice translation $\boldsymbol{t}$ parallel to the axis	
6_1, 6_2, 6_3, 6_4, 6_5		

[a] The inversion point is a center of symmetry (inversion center) if $\boldsymbol{n}$ is odd.

Notes: 1. The graphical symbols (column 3) refer to planes and axes oriented normal to the plane of projection.

2. Diamond glide planes *d* occur only in orthorhombic *F* space groups, in tetragonal *I* space groups, and in cubic *I* and *F* space groups. They always occur in pairs with alternating vectors, for instance, 1/4 ($\boldsymbol{a}+\boldsymbol{b}$) and 1/4 ($\boldsymbol{a}-\boldsymbol{b}$). The second power of a glide reflection *d* (i.e., the result of two successive applications) is a lattice centering vector. The name "diamond glide" is due to its pronounced occurrence in the diamond structure.

3. Rotoreflections are not listed here, because they correspond to rotoinversions according to the following scheme: two-, three-, four-, and sixfold rotoreflections are identical with the rotoinversions $\overline{1}$ (inversion), $\overline{6}$, $\overline{4}$ and $\overline{3}$, respectively. Note that the even two- and sixfold rotoreflections (corresponding to the odd rotoinversions $\overline{1}$ and $\overline{3}$) contain a symmetry (inversion) center.

4. The following pairs of screw axes are "enantiomorphic," i.e. each pair consists of a right- and a left-handed screw axis: (3_1, 3_2), (4_1, 4_3), (6_1, 6_5) and (6_2, 6_4). The screw axes 2_1, 4_2, 6_3 are "neutral." Note that all rotation and screw axes may accommodate enantiomorphic structures, whenever the building units (atomic groups, molecules) of the structure are "chiral," i.e., either all right- or all left-handed.

5. A right-handed screw rotation is customarily defined as a counter-clockwise rotation with the screw vector pointing toward the observer.

Table 3 Crystallographic symmetry operations as derived from their traces tr $\boldsymbol{W}$ and determinants det $\boldsymbol{W} = +1$ and -1

	det $\boldsymbol{W} = +1$					det $\boldsymbol{W} = -1$				
tr $\boldsymbol{W}$	$+1$	$+1/2$	0	$-1/2$	-1	$+1$	$+1/2$	0	$-1/2$	-1
H.-Mauguin symbol of operation	1	6	4	3	2	$\overline{1}$	$\overline{6} \equiv 3/m$	$\overline{4}$	$\overline{3}$	$\overline{2} \equiv m$
Schoenflies symbol of operation	C_1	C_6	C_4	C_3	C_2	C_i	C_{3h}	S_4	C_{3i}	C_s
Order n of operation[a]	1	6	4	3	2	2	6	4	6	2

[a] The "order" n of the operation $\boldsymbol{W}$ is the order of the cyclic group generated by $\boldsymbol{W}$, i.e., the power n of $\boldsymbol{W}$ for which the identity 1 is reached: $\boldsymbol{W}^n = 1$.

Table 4 Examples of augmented (4×4) matrices of symmetry operations (referred to the appropriate conventional coordinate system)[a]

Inversion with center in x_0, y_0, z_0

$$\left(\begin{array}{cccc} -1 & 0 & 0 & 2x_0 \\ 0 & -1 & 0 & 2y_0 \\ 0 & 0 & -1 & 2z_0 \\ \hline 0 & 0 & 0 & 1 \end{array}\right)$$

Twofold rotation along z in x_0, y_0, z

$$\left(\begin{array}{cccc} -1 & 0 & 0 & 2x_0 \\ 0 & -1 & 0 & 2y_0 \\ 0 & 0 & 1 & 0 \\ \hline 0 & 0 & 0 & 1 \end{array}\right)$$

Twofold screw rotation along z in x_0, y_0, z

$$\left(\begin{array}{cccc} -1 & 0 & 0 & 2x_0 \\ 0 & -1 & 0 & 2y_0 \\ 0 & 0 & 1 & 1/2 \\ \hline 0 & 0 & 0 & 1 \end{array}\right)$$

Glide reflection n with plane $\perp x$ in x_0, y, z

$$\left(\begin{array}{cccc} -1 & 0 & 0 & 2x_0 \\ 0 & 1 & 0 & 1/2 \\ 0 & 0 & 1 & 1/2 \\ \hline 0 & 0 & 0 & 1 \end{array}\right)$$

Fourfold (screw) rotation 4_p with $p = 0, 1, 2, 3$ along z in 0, 0, z (§)

$$\left(\begin{array}{cccc} 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & p/4 \\ \hline 0 & 0 & 0 & 1 \end{array}\right)$$

Fourfold rotoinversion $\bar{4}$ along z in 0, 0, z

$$\left(\begin{array}{cccc} 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ \hline 0 & 0 & 0 & 1 \end{array}\right)$$

Threefold (screw) rotation 3_p with $p = 0, 1, 2$ along z in 0, 0, z (§)

$$\left(\begin{array}{cccc} 0 & -1 & 0 & 0 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & 1 & p/3 \\ \hline 0 & 0 & 0 & 1 \end{array}\right)$$

Sixfold (screw) rotation 6_p with $p = 0, 1, 2, 3, 4, 5$ along z in 0, 0, z (§)

$$\left(\begin{array}{cccc} 1 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & p/6 \\ \hline 0 & 0 & 0 & 1 \end{array}\right)$$

Threefold rotation 3 around body diagonal x, x, x (cubic system) (#)

$$\left(\begin{array}{cccc} 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ \hline 0 & 0 & 0 & 1 \end{array}\right)$$

[a] The matrices in this table represent the "first powers" of the operations. Higher powers are obtained by repeated multiplication of the matrix. For point-group operations of order 2 ("binary" operations: inversions, twofold rotations, reflections), the second power is the identity, i.e., binary operations are their own inverses.
(§) Note that $p = 0$ stands for a normal (nonscrew) rotation.
(#) Cyclic permutation of the coordinates. This matrix also represents the one threefold rotation around x, x, x in the rhombohedral coordinate system. There are four equivalent cubic body diagonals x, x, x; $-x, x, x$; $x, -x, x$ and $x, x, -x$ with different cyclic permutations of $+1$ and -1.

C_s = reflection group (s = *Spiegel*symmetry) of order 2;
C_i = inversion group of order 2;

D: Dihedral groups D_2, D_3, D_4, D_6, that is, a cyclic group C with additional twofold rotation axes normal to the main symmetry axis. The order m of these groups is twice that of the corresponding C_n group: $m = 2n$.

T: Tetrahedral group (order $n = 12$);

O: Octahedral group (order $n = 24$).

Subscripts h, v, and d indicate the presence of mirror planes perpendicular (h = horizontal) and parallel (v = vertical, d = diagonal) to the main symmetry axis, which is considered to be vertical, for example, $C_{2h}, D_{4h}, T_h, O_h, C_{2v}, C_{6v}, D_{3d}$. The Schoenflies symbols are independent of any coordinate system.

These symbols apply to three-dimensional crystallographic point groups. Space groups are indicated by superscripts added to the corresponding point-group symbols, for example, $C_{2h}^5, D_2^4, D_{2h}^{16}, T_h^7, O_h^9$. This implies that the Schoenflies symbols carry no information about the nature of the space group. No Schoenflies symbols exist for two-dimensional groups.

Hermann–Mauguin (International) Symbols

These symbols have, as their basis, the seven different point symmetries of the Bravais lattices. Every lattice, if viewed along a general direction, exhibits only inversion symmetry $\overline{1}$. There are, however, between zero (triclinic) and 13 (cubic) specific directions, along which symmetries above $\overline{1}$ are seen. These so-called "lattice symmetry directions" (blickrichtungen) and the symmetries seen along them are characteristic for the seven types of lattice symmetries (holohedries), see **Table 1**. They can be grouped

Table 5 Representative lattice symmetry directions for two and three dimensions. The number in parentheses refers to the number of equivalent symmetry directions of the given set, e.g., cubic [1 0 0] (3) refers to the three equivalent directions [1 0 0], [0 1 0], [0 0 1]

Lattice	*Symmetry direction (position in Hermann–Mauguin symbol)*		
	Primary	*Secondary*	*Tertiary*
Two dimensions			
Oblique (monoclinic)	Rotation	------	------
Rectangular (orthorhombic)	point	[1 0] (1)	[0 1] (1)
Square (tetragonal)	In	[1 0] (2)	$[1\bar{1}]$ (2)
Hexagonal	plane (1)	[1 0] (3)	$[1\bar{1}]$ (3)
Three dimensions			
Triclinic (anorthic)	None		
Monoclinic	[0 1 0] (1) (unique axis *b*) [0 0 1] (1) (unique axis *c*)	------	------
Orthorhombic	[1 0 0] (1)	[0 1 0] (1)	[0 0 1] (1)
Tetragonal	[0 0 1] (1)	[1 0 0] (2)	$[1\,\bar{1}\,0]$ (2)
Hexagonal	[0 0 1] (1)	[1 0 0] (3)	$[1\,\bar{1}\,0]$ (3)
Rhombohedral (hexagonal axes)	[0 0 1] (1)	[1 0 0] (3)	------
Rhombohedral (rhombohedral axes)	[1 1 1] (1)	$[1\,\bar{1}\,0]$ (3)	------
Cubic	[1 0 0] (3)	[1 1 1] (4)	$[1\,\bar{1}\,0]$ (6)

into none (triclinic), one (monoclinic), two (rhombohedral), and three (all other lattices) classes of equivalent symmetry directions (e.g., the fourfold cubic rotation axes [1 0 0], [0 1 0], [0 0 1] form one class). These classes are arranged in a well-defined sequence (called "positions"), which is again characteristic for each crystal system. They form, thus, the basis of the Hermann–Mauguin (international) point-group and space-group symbols.

The representative lattice symmetry directions for these classes are presented in **Table 5**, both for two- and three-dimensional lattices. The three columns define the "position" of an entry in a Hermann–Mauguin group symbol (primary, secondary, and tertiary position). The entries in an actual symbol are those symmetry axes and symmetry planes, which are "observed" for the corresponding blickrichtung. A slash indicates the occurrence of a mirror (glide) plane perpendicular to an axis (e.g., $4/m$, $2_1/c$). In this way, the international point-group symbols are obtained. This process is illustrated, first for "point groups," by the following examples:

1, $\bar{1}$ triclinic; no symmetry direction, since $\bar{1}$ is a point (Schoenflies symbols C_1, C_i);

2, m, $2/m$ monoclinic; only one symmetry direction along which is "seen" a twofold axis, the normal to a mirror plane or the combination of both (Schoenflies symbols C_2, C_s, C_{2h});

$mm2$ orthorhombic; three perpendicular symmetry directions, two of which carry normals to mirror planes, the third a twofold axis (Schoenflies symbol C_{2v});

$4/m$ tetragonal, short for $4/m11$, since only the primary blickrichtung carries symmetry (Schoenflies symbol C_{4h});

$6/m2/m2/m$ (short: $6/mmm$) hexagonal holohedry; three classes of symmetry directions, the primary single direction is populated by a sixfold rotation axis and a perpendicular mirror plane: $6/m$. The three equivalent secondary and three equivalent tertiary directions are populated by twofold axes with perpendicular mirror planes, leading to a total of seven "occupied" blickrichtungen (Schoenflies symbol D_{6h});

$4/m\bar{3}2/m$ (short: $m\bar{3}m$) cubic holohedry; point group of highest crystallographic symmetry; along the three cube edges of the cubic unit cell, symmetry axes/planes $4/m$ occur, the four body-diagonal directions of the cube are populated by $\bar{3}$ inversion axes, and the six face diagonals carry $2/m$ symmetries. In total, there are 13 symmetry directions with 48 symmetry operations ($=$group order) (Schoenflies symbol O_h).

The space-group symbols are modifications of the point-group symbols in two ways: first, the letter with the centering type of the appropriate Bravais lattice, *P*, *A*, *B*, *C*, *I*, *F*, *R* is added in front of the symbol. Second, as appropriate, the symbols for rotation axes are substituted by those of screw axes,

and the symbols of reflection planes by those of glide planes. Lattice symmetry directions, which do not carry any symmetry, are represented by the symbol "1", as in $P31m$ and $P3m1$, or are left empty as in $P6_3/m$, short for $P6_3/m11$.

This procedure leads to the following full (and short) symbols, given as examples:

Monoclinic: $P2_1/c$, $C2/c$ (two of the frequently encountered space groups);

Orthorhombic: $P2_12_12_1$, $P2_1/n\ 2_1/m\ 2_1/a$ ($Pnma$), $C2/m\ 2/c\ 2_1/m$ ($Cmcm$), $I2_1/b\ 2_1/c\ 2_1/a$ ($Ibca$);

Trigonal: $P31m$, $P3m1$, $R3m$;

Hexagonal: $P6_3/m$, $P6_522$, $P\overline{6}2m$, $P6_3/m\,2/c\ 2/m$ ($P6_3/mcm$);

Cubic: $I2_13$, $I2_1/a\overline{3}$ ($Ia\overline{3}$), $P4_332$, $F\overline{4}3c$, $F4/m\overline{3}\ 2/m$ ($Fm\ \overline{3}m$), $I4_1/a\overline{3}\ 2/d$ ($Ia\overline{3}d$).

It is not possible to treat here the details of the derivation and the nomenclature of space groups. This topic requires a certain amount of practical acquaintance. The *International Tables,* Vol. A [*ITA* (2002)], contain complete listings and explanations of the 17 plane (two-dimensional) groups, the 230 space groups and the 32 crystallographic point groups. The so-called "subperiodic groups" (number of periodic dimensions lower than the total number of dimensions of the group), i.e., frieze, layer and rod groups, are presented in Vol. E (2002) of the *International Tables*. For textbooks, please see "Further reading" below.

Nomenclature

$\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$	Basis vectors of a lattice
a, b, c, α, β, γ	Lattice parameters
t; $\boldsymbol{t}$	Translation; translation vector
P, A, B, C, I, F, R	Centering types of lattices
X; $\tilde{X}$	Point; transformed point
x, y, z; $\tilde{x}$, $\tilde{y}$, $\tilde{z}$	Coordinates of points X and $\tilde{X}$
$\boldsymbol{r}$; $\tilde{\boldsymbol{r}}$	Location vector; transformed location vector
W	(3×3) matrix, rotation part of a symmetry operation
$\boldsymbol{w}$	(3×1) column, translation part of a symmetry operation
W_{ij}; w_k	Elements of W and $\boldsymbol{w}$
$\mathbb{W}$, $\mathbb{T}$, $\mathbb{r}$	(4×4) augmented matrix; (4×4) augmented matrix of pure translation; (4×1) augmented vector
(hkl)	Miller indices of a crystal face (lattice plane)
$[uvw]$	Direction indices of a crystal edge (lattice direction)

Schoenflies Symbols

$C_n = C_1$, C_2, C_3, C_4, C_6	Cyclic group of order $n = 1, 2, 3, 4, 6$
C_s; C_i	Reflection group; inversion group (order 2)
S_4	Rotoinversion (rotoreflection) group of order 4
$D_n = D_2, D_3$, D_4, D_6	Dihedral group of order $m = 2n = 4, 6, 8, 12$

T	Tetrahedral group (order 12)
O	Octahedral group (order 24)

Hermann–Mauguin (International) Symbols

$n = 1, 2, 3, 4, 6$	n-fold rotation axes (order n)
$\overline{n} = \overline{1}, \overline{2} \equiv m,$ $\overline{4}, \overline{3}, \overline{6} \equiv 3/m$	n-fold rotoinversion axes (orders 2, 2, 4, 6, 6, resp.)
$n_p = 2_1, 3_1, 3_2, 4_1, 4_2, 4_3, 6_1, 6_2, 6_3, 6_4, 6_5$	n-fold screw axes (order ∞)
m ($\equiv \overline{2}$)	reflection (mirror) plane (order 2)
a, b, c, n, d	glide reflection planes (order ∞)
g	glide line (two dimensions, order ∞)

Crystal Tensors: Applications

D R Lovett, University of Essex, Colchester, UK

Introduction

The application of crystal tensors to crystals with different structures and hence different symmetries is discussed in this article. For most applications, crystals need careful selection to process the appropriate symmetry for the particular application. Many of the terms and equations used have been introduced in this encyclopedia elsewhere to which the reader is also referred.

Electrical and Thermal Properties

Much of the early applications of tensors to crystal properties concerned the electrical and thermal resistivities and conductivities of materials and more complicated effects, such as the Hall effect. The consequence of applying voltages or thermal gradients across anisotropic crystals in arbitrary directions is demonstrated in this encyclopedia elsewhere. The strength of the theory is in suggesting the principal directions in which measurements should be made. Resistivity and conductivity are symmetrical second-rank tensors relating two vector quantities, and for the majority of crystal systems the maximum number of independent coefficients is two, although this rises to three in the orthorhombic system, four in the monoclinic system, and six in the triclinic system. Early measured examples of room-temperature coefficients were for metals, such as cadmium (hexagonal $6/mmm$) with ρ_1 and ρ_2 having the value 6.80 and ρ_3 having the value 8.30 in units of $10^{-8}\Omega$ m. Another example is tin (tetragonal structure, $4/mmm$) with ρ_1, ρ_2 equal to 9.9 and ρ_3 equal to 14.3. These values show that any measurements off the principal directions would require interpretation by a tensor theory. Similarly, notable examples for thermal conductivites are graphite (hexagonal, $6/mmm$) with k_1 of 6.5 and k_3 of 11.3 W m^{-1} °C^{-1}, and quartz (trigonal, 32) with k_1, k_2 of 9.24 and k_3 of 6.65.

In the Hall effect, a magnetic field is applied perpendicular to the electric current flow and a voltage is established perpendicular to both. It can be expanded from the relationship between electric field and current, $\boldsymbol{E}_{\mathrm{I}} = \rho_{ij}\boldsymbol{J}_i$, where $\boldsymbol{J}$ is the current density, $\boldsymbol{E}$ is the electric field, and ρ_{ij} is the resistivity:

$$\rho_{ij} = \rho_{ij}^{(0)} + \rho_{ijk}B_k + \rho_{ijkl}B_kB_l$$

where $\rho_{ij}^{(0)}$ represents resistivity as just discussed, ρ_{ijk} the Hall tensor, and ρ_{ijkl} the longitudinal magnetoresistance. ρ_{ijk} is a third-rank axial tensor (i.e., its sign can be $\pm$), but it can be rearranged as a second-rank antisymmetric tensor. Details are omitted here, but in the most complex case of a triclinic crystal, there are up to nine independent values. Most crystals have a maximum of three independent coefficients.

Elasticity

This is the classic case of a fourth-rank tensor. The reduction of the number of coefficients is discussed in this encyclopedia elsewhere and, in addition, there is an extensive literature regarding relationships between stiffness (equivalent to Young's modulus) and compliance coefficients. Examples of well-established values of the compliance matrix (s_{ij}) are given in **Table 1** to demonstrate variability.

Optoelectronic Effects and Devices

Currently, the application of crystal tensors is playing an essential role in the understanding of optoelectronic effects and the setting up of electrooptic devices. The application of an electric field alters the dielectric constant of many materials and even if a crystal is anaxial (i.e., it behaves isotropically) without the field, it may become uniaxial and thus double refracting with the field. In addition, crystals that are already uniaxial or biaxial usually show a change in

Table 1 Examples of values of compliance at room temperature

Crystal	*Class*	s_{11}	s_{12}	s_{44}	s_{33}	s_{13}	s_{14}	s_{66}
Sodium chloride	*m*3*m*	22.1	−4.5	78.3				
Aluminium	*m*3*m*	15.9	−5.8	35.2				
Copper	*m*3*m*	14.9	−6.3	13.3				
Nickel	*m*3*m*	7.99	−3.12	8.44				
Tungsten	*m*3*m*	2.57	−0.73	6.60				
Tin	4/*mmm*	18.5	−9.9	57.0	11.8	−2.5		135
ADP	$\bar{4}\,2m$	18	7	113	43	−11		162

their refractive index components in the presence of an appropriate electric field.

The electric displacement $\boldsymbol{D}$ can be written as

$$\boldsymbol{D} = \varepsilon\varepsilon_0\boldsymbol{E} = \varepsilon_0(1+\chi)\boldsymbol{E} = \varepsilon_0\boldsymbol{E} + \varepsilon_0\chi\boldsymbol{E}$$

where χ, the electric susceptibility, represents the way the material responds to the electric field, ε is the relative electric permittivity, and ε_0 the permittivity of free space. Alternatively, $\boldsymbol{P}$, the polarization term, can be written as

$$\boldsymbol{D} = \varepsilon_0\boldsymbol{E} + \boldsymbol{P}$$

In general, the polarization term can be expanded as a power series in $\boldsymbol{E}$:

$$\boldsymbol{P} = a\boldsymbol{E} + b\boldsymbol{E}\times\boldsymbol{E} + c\boldsymbol{E}^3 + \text{higher terms}$$

The first term on the right-hand side of the equation is the linear term, the next term is the nonlinear quadratic term, and so on. The coefficients a, b, etc., are such that the series converges. It is only in some materials that the coefficients are such that the nonlinear terms are useful. It is common practice to use the reciprocal dielectric constant, the optical impermeability η, and write out the optical impermeability in the form of the change that occurs with application of the field. Thus,

$$\Delta\eta_{ij} = \eta_{ij}(\boldsymbol{E}) - \eta_{ij}(\boldsymbol{E}=0) = r_{ijk}E_k + s_{ijkl}E_kE_j$$

The r_{ijk} components are the linear electrooptic coefficients and are often called the Pockels coefficients. They give rise to the linear Pockels effect. The s_{ijkl} components produce the quadratic effect that is often referred to as the Kerr electrooptic effect. The latter effect can be expected to be small compared with the linear effect, but the linear effect cannot be present in centrosymmetric crystals. Judicious selection of crystals makes both these effects and further effects practicable. In general, both the linear and quadratic coefficients vary with the wavelength of light. This means that the coefficients need to be known for different wavelengths but this can have its advantages; for instance, it can lead to useful phase matching.

The Pockels Effect

The optical indicatrix can be written in the presence of an electric field $\boldsymbol{E}$ as $\eta_{ij}(\boldsymbol{E})x_ix_j = 1$ (where $i,j = 1,2,3$ produce the general form for the indicatrix) and in the absence of a field as $\eta_{ij}x_ix_j = 1$. The η tensor is symmetric so that i and j can be permuted. The coefficients can also be reduced into a contracted form but the contracted forms cannot be transformed according to the rules for tensors. Equalities for the contracted subscripts for the linear electrooptic coefficients become as a consequence $r_{11k} = r_{1k,}$ $r_{22k} = r_{2k}$, $r_{33k} = r_{3k}$, $r_{23k} = r_{32k} = r_{4k}$, $r_{13k} = r_{31k} = r_{5k}$, and $r_{12k} = r_{21k} = r_{6k}$ for $k = 1,2,3$. If these subscripts are now used for linear change of the optical impermeability only, the optical indicatrix becomes

$$\left(\frac{1}{n_1^2} + r_{1k}E_k\right)x_1^2 + \left(\frac{1}{n_2^2} + r_{2k}E_k\right) \times x_2^2 + \left(\frac{1}{n_3^2} + r_{3k}E_k\right)x_3^2 + 2r_{4k}E_kx_2x_3 + 2r_{5k}E_kx_3x_1 + 2r_{6k}E_kx_1x_2 = 1$$

where $k = 1,2,3$. The above equation is a general form of the ellipsoid with the principal axes not assumed to coincide with the principal Cartesian axes x_1, x_2, and x_3. If it is possible for them to coincide, then the equation simplifies and leaves out the crossed x terms. Crystals that are widely used for Pockels devices include lithium niobate, ammonium dihydrogen phosphate (and potassium dihdrogen phosphate, for which the same arguments apply), and gallium arsenide. These three cases are examined to see how the application of crystal tensors leads to slight differences in their use.

Lithium Niobate

The lithium niobate crystal has a trigonal cell of crystal symmetry $3m$. Although the cell can be represented in rhombohedral form, it is easier to use a hexagonal cell (containing six molecules). There is then a threefold rotational axis, which is parallel to the [0 0 0 1] direction (using hexagonal indices) and mirror planes of type $(2\,\bar{1}\,\bar{1}\,0)$. The usual configuration is to apply the electric field along the c- (i.e., x_3-) axis. The x_1-axis is defined such that one of the mirror planes is perpendicular to it in order to obtain the electrooptic components. (The components would come out in a slightly different form if x_2 rather than x_1 was defined to have the mirror plane perpendicular to it.) Carrying out the symmetry operations for $3m$, the contracted form r_{mn} can be further reduced to the form

$$\begin{pmatrix} 0 & -r_{22} & r_{13} \\ 0 & r_{22} & r_{13} \\ 0 & 0 & r_{33} \\ 0 & r_{51} & 0 \\ r_{51} & 0 & 0 \\ -r_{22} & 0 & 0 \end{pmatrix}$$

With the electric field along the x_3-axis, $k = 3$, and cross-product terms in x_1, x_2, and x_3 disappearing, the general equation becomes

$$\left(\frac{1}{n_o^2} + r_{1k}E_k\right)x_1^2 + \left(\frac{1}{n_o^2} + r_{2k}E_k\right) \times x_2^2 + \left(\frac{1}{n_e^2} + r_{3k}E_k\right)x_3^2 = 1$$

In addition to the changes mentioned, n_1 and n_2 have been made equal to the ordinary refractive index n_o and n_3 to the extraordinary refractive index n_e. It can now be seen that when an electric field $\boldsymbol{E}$ is applied, the semi-axes of the ellipsoid become (see **Figure 1**)

$$n_{x_1} = n_{x_2} = n_o - n_o^3 r_{13} E/2$$

and

$$n_{x_3} = n_e - n_e^3 r_{33} E/2$$

Consequently, for a light beam passing along the x_1-axis, the birefringence becomes

$$n_{x_3} - n_{x_2} = (n_e - n_o) - (n_e^3 r_{33} - n_o^3 r_{13})E/2$$

Thus, the birefringence can be written as

$$\Delta n = \Delta n_{E=0} - \alpha E$$

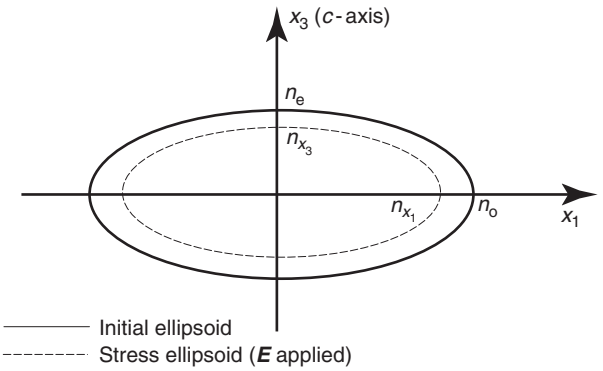

Figure 1 Refractive index ellipsoids for lithium niobate with and without applied electric field.

where

$$\alpha = \tfrac{1}{2}(n_e^3 r_{33} - n_o^3 r_{13})$$

For lithium niobate, in this configuration the magnitude of α is $1.1 \times 10^{-10}\ \mathrm{m\,V^{-1}}$. By altering the magnitude of the electric field, any desired state of polarization can be obtained. Alternatively, by correctly choosing an initial thickness of the crystal, using crossed linear polarizers in front and behind the crystal, and modulating the electric field, the amplitude of the transmitted light can be modulated.

Ammonium Dihydrogen Phosphate

With ammonium dihydrogen phosphate (ADP), a similar setup can be used but ADP is uniaxial. ADP belongs to the crystal class $\bar{4}2m$ and the higher symmetry leads to fewer coefficients:

$$\begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ r_{41} & 0 & 0 \\ 0 & r_{41} & 0 \\ 0 & 0 & r_{63} \end{pmatrix}$$

The presence of the r_{63} terms leads to a modified indicatrix ellipsoid. The two alternative cases are discussed. First, an electric field parallel to the x_3 (c-axis) is considered again. The equation for the ellipsoid can be written as

$$\frac{x_1^2 + x_2^2}{n_o^2} + \frac{x_3^2}{n_e^2} + 2r_{63}Ex_1x_2 = 1$$

The presence of the electric field means that the ellipsoid is modified such that it is no longer symmetrical about the x_3-axis and the material acts as biaxial. What was a circular cross section now becomes elliptical with new axes Ox_1' and

Ox_2' rotated by 45° from the original axes. The semi-axes become

$$n_{x_1'} = n_o - \tfrac{1}{2}n_o^3 r_{63}E \quad \text{and}$$
$$n_{x_2'} = n_o + \tfrac{1}{2}n_o^3 r_{63}E$$

As a consequence, a slice of crystal cut perpendicular to the Ox_3-axis will act like a birefringent plate with a fast axis Ox_1' and a slow axis Ox_2', and a birefringence of

$$\Delta n = n_{x_1'} - n_{x_2'} = n_o^3 r_{63}E$$

This configuration is useful for switching. With faces cut perpendicular to Ox_3 (perpendicular to the c-axis) and with no field applied, the crystal appears isotropic to a beam of light passing through in the x-direction. Once an electric field is applied, birefringence is established. If a voltage V is applied to a crystal of thickness L, the electric field is V/L and a phase difference for the two perpendicular components is

$$\delta = \frac{2\pi}{\lambda}L\Delta n = \frac{2\pi}{\lambda}n_o^3 r_{63}V$$

With crossed polarizers before and after the crystal, a sinusoidal form of output is obtained. For no applied voltage, the transmission is zero; for applied voltage, it is finite. Alternatively, the applied voltage can be modulated and a phase modulation produced.

Gallium Arsenide

Gallium arsenide (also indium arsenide, cadmium telluride, and similar materials) has crystal class $\bar{4}3m$. As this is a high-symmetry class, there is only one independent term

$$\begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ r_{41} & 0 & 0 \\ 0 & r_{41} & 0 \\ 0 & 0 & r_{41} \end{pmatrix}$$

and so $r = r_{41}$. With n the refractive index before application of the electric field, the equation applicable in the presence of an electric field becomes

$$\frac{1}{n^2}(x_1^2 + x_2^2 + x_3^2) + 2r \times (x_2x_3E_1 + x_1x_3E_2 + x_1x_2E_3) = 1$$

It is normal to use a configuration in which the electric field is in the $\langle 1\,0\,0\rangle$, $\langle 1\,1\,0\rangle$, or $\langle 1\,1\,1\rangle$ direction. Again, this has application to optical modulation.

The Quadratic Electrooptic Effect (The Kerr Effect)

The effect can occur in crystals of any symmetry. If the Kerr tensor components are represented by s_{ijkl} (notation can vary), then pairs of i, j and k, l permute, but in the reduced notation it is not necessary that $s_{mn} = s_{nm}$. There is a maximum of 36 components, but once again crystal symmetry criteria will reduce the number.

Barium titanate, $BaTiO_3$, is taken as an example. Below 120°C, it has a tetragonal structure of class $4mm$. A suitable direction in which to apply the electric field is [1 1 0]. In this case, the electric field $\boldsymbol{E}$ can be resolved as $E/\sqrt{2}$ along x_1- and x_2-directions and it is zero in the x_3-directions. By applying symmetry arguments, it can be shown that the pattern of components is

$$\begin{pmatrix} s_{11} & s_{12} & s_{12} & 0 & 0 & 0 \\ s_{12} & s_{11} & s_{12} & 0 & 0 & 0 \\ s_{12} & s_{12} & s_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & s_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & s_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & s_{44} \end{pmatrix}$$

The indicatrix takes the form

$$\left(\frac{1}{n^2} + \frac{s_{11}E^2}{2} + \frac{s_{22}E^2}{2}\right)(x_1^2 + x_2^2) + \left(\frac{1}{n^2} + s_{12}E^2\right)x_3^2 + 2x_1x_2s_{44}E^2 = 1$$

All other terms are zero. However, to get the ellipsoid into a form related to the principal axes, it is necessary to carry out a 45° rotation so that the principal axis is in the same direction as the electric field, this direction becoming a direction of symmetry. If this is done, the revised indicatrix takes the form

$$\left(\frac{1}{n^2} + \frac{s_{11}E^2}{2} + \frac{s_{22}E^2}{2} + s_{44}E^2\right)x_1'^2 + \left(\frac{1}{n^2} + \frac{s_{11}E^2}{2} + \frac{s_{22}E^2}{2} - s_{44}E^2\right) \times x_2'^2 + \left(\frac{1}{n^2} + s_{12}E^2\right)x_3'^2 = 1$$

Comparing this equation with the standard equation for the indicatrix gives

$$(n_{x_1})^{-2} = n^{-2} + (s_{11} + s_{12})E^2/2 + s_{44}E^2$$
$$(n_{x_2})^{-2} = n^{-2} + (s_{11} + s_{12})E^2/2 - s_{44}E^2$$
$$(n_{x_3})^{-2} = n^{-2} + s_{12}E^2$$

Usually, the change in n will be small so that expansion of n to third order gives

$$\begin{aligned} n_{x_1} &= n - n^3(s_{11} + s_{12})E^2/4 \\ &\quad - n^3 s_{44}E^2/2 \\ n_{x_2} &= n - n^3(s_{11} + s_{12})E^2/4 \\ &\quad + n^3 s_{44}E^2/2 \\ n_{x_{31}} &= n - n^3 s_{12}E^2/2 \end{aligned}$$

and the quadratic dependence on the applied electric field.

It is already indicated that ADP and KDP are of crystal class $\bar{4}2m$ and so their Kerr effect matrix is

$$\begin{pmatrix} s_{11} & s_{12} & s_{13} & 0 & 0 & 0 \\ s_{12} & s_{11} & s_{13} & 0 & 0 & 0 \\ s_{31} & s_{131} & s_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & s_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & s_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & s_{66} \end{pmatrix}$$

It is common to apply the electric field along the Ox_3 optic axis. The crystal remains uniaxial with the indicatrix now of the form

$$\left(\frac{1}{n_o^2} + s_{13}E_k\right)x_1^2 + \left(\frac{1}{n_o^2} + s_{13}E_k\right)x_2^2 + \left(\frac{1}{n_e^2} + s_{33}E_k\right)x_3^2 = 1$$

If the birefringence before the application of the electric field is $\Delta n_{E=0}$ and after is Δn, then the change in birefringence is

$$\Delta n_{E=0} - \Delta n = \tfrac{1}{2}(n_e^3 s_{33} - n_o^3 s_{13})E^2$$

The first-order change in birefringence due to the Pockels effect was $(1/2)n_o^3 r_{63}E$, so that if it is assumed that $n_e \approx n_o$, the ratio of the second-order effect to the first-order one is $((s_{33} - s_{13})/r_{63})E$. For ADP and KDP, the ratio for $(s_{33} - s_{13})/r_{63}$ is $\sim 10^{-6}$ m V^{-1}. However, because the constants for optical effects are very dependent on the frequencies used (the materials show optical dispersion), it is not realistic here to give tables of magnitudes for specific materials for any of the optical coefficients.

Second Harmonic Generation and Phase Matching

Frequency doubling, also called second harmonic generation, has had important application for increasing the frequency range available from lasers. What is required is nonlinear coupling between two light beams, normally of the same frequency. However, it is necessary that the second harmonic waves generated are all in phase. Birefringent crystals are normally used and matching of indices of refraction is required, necessitating the application of crystal tensors.

In an application of nonlinear optics such as this, it is normal to use polarization $\boldsymbol{P}$ in the formulation. The change in optical impermeability is written as

$$\begin{aligned} \Delta\eta_{ij} &= \eta_{ij}(\boldsymbol{P}) - \eta_{ij}(\boldsymbol{P} = 0) \\ &= f_{ijk}P_k + g_{ijkl}P_kP_j \end{aligned}$$

where $\boldsymbol{P}$ has replaced $\boldsymbol{E}$ and the Pockels and Kerr coefficients are now defined as f_{ij} and g_{ijkl}. The polarization can be expanded in the form

$$\begin{aligned} P_i &= \varepsilon_0\chi_{ij}E_j + 2d_{ijk}E_iE_k \\ &\quad + 4\chi_{ijkl}E_jE_kE_l \end{aligned}$$

where χ_{ij}, d_{ijk}, and χ_{ijkl} are the linear, second-order nonlinear, and third-order nonlinear susceptibilities, respectively. Third-order effects can lead to Raman and Brillouin scattering but it is the second-order effect that can be used for frequency doubling. If the sinusoidal optical fields associated with the two light rays are of the form $E_j^{\omega_1}e^{i\omega_1 t}$ and $E_k^{\omega_2}e^{i\omega_2 t}$, then these can give rise to field variations at frequencies $m\omega_1 + n\omega_2$, where m and n are integers. Taking m and n each as 1 to give a variation $\omega_3 = \omega_1 + \omega_2$,

$$P_i^{\omega_3} = 2d_{ijk}E_j^{\omega_1}E_k^{\omega_2}$$

and if $\omega_1 = \omega_2$, then $P_i^{2\omega} = 2d_{ijk}E_j^{\omega}E_k^{\omega}$. There will be no physical difference between the jk and kl components so that notation suffixes can be once again replaced with matrix notation suffixes. Similar symmetry restrictions apply as they do for the electrooptic matrix components r_{mn} and magnitudes are related but different. Hence, there is a close connection between the electrooptic effects and second harmonic generation.

Now it is necessary to match the indices such that $k^{2\omega} = 2k^{\omega}$ or $\Delta k = k^{2\omega} - 2k^{\omega} = 0$. But $\Delta k = (2\omega/c)(n^{2\omega} - n^{\omega})$, where $n^{2\omega}$ and n^{ω} are the refractive indices at the two frequencies and c the velocity of light in vacuo. Equal values of $n^{2\omega}$ and n^{ω} can be achieved in a birefringent crystal by a matching between refractive indices for the ordinary and extraordinary rays by choosing a correct direction Θ for the light for Δk to be zero. This is shown in **Figure 2** for a negative uniaxial crystal, where differences between the surfaces have been greatly magnified. The condition for Θ is given by

$$\frac{\cos^2\Theta}{(n_o^{2\omega})^2} + \frac{\sin^2\Theta}{(n_e^{2\omega})^2} = \frac{1}{(n_o^{\omega})^2}$$

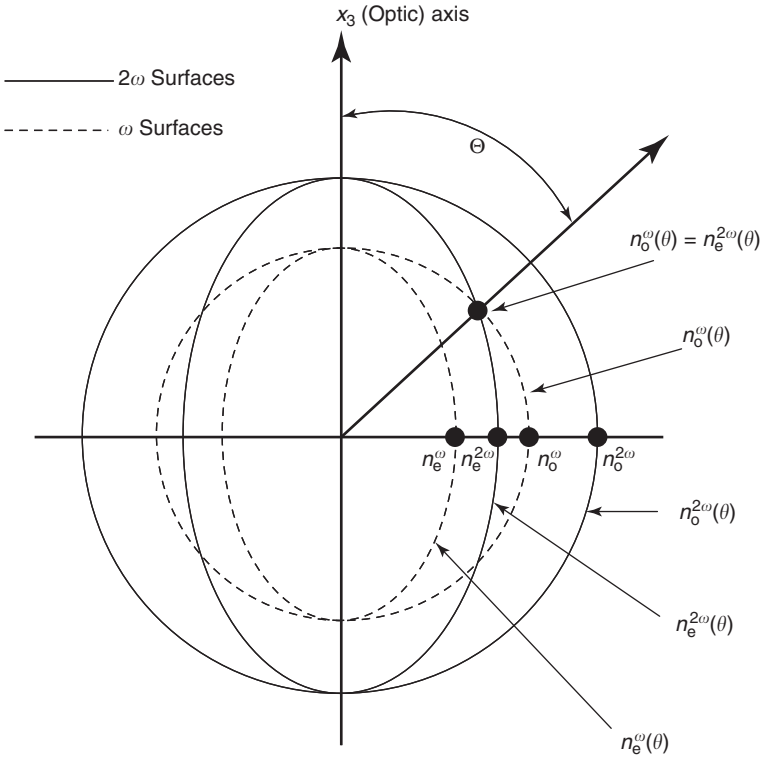

Figure 2 Phase matching between ordinary and extraordinary rays in a negative uniaxial crystal.

Crystalline materials that are often used for such matching are KDP and ADP, which have significant differences between their ordinary and extraordinary refractive indices.

Some Further Applications

There are many other applications of tensors to the interpretation of effects in crystals that have not been mentioned. For instance, in the pyroelectric effect a change in temperature leads to a change of electric dipole moment Δp_i that is related to the temperature change ΔT by the pyroelectric coefficients p_i, which are vector components. A small change in temperature ΔT leads to an electric dipole moment according to $\Delta P_i = p_i \Delta T$. A complication is that the size of the effect also depends on whether the sample is clamped or not clamped during heating. Only crystals with no center of symmetry can exhibit the effect. All materials, which are pyroelectric, must also be piezoelectric. For the latter case, the relationship becomes $P_i = d_{ijk} s_{jk}$, where d_{ijk} are the piezoelectric moduli, which would seem to have 27 components in general but whose number of components can be reduced to 18 for even the most general (triclinic) case. There is also the inverse case of a strain produced by an electric field. As in the case of pyroelectricity, there are differences for the piezoelectric effect and the converse effect according to the applied conditions, for example, whether the sample is under constant stress or constant strain.

When stress is applied to a crystal, there may not only be an electric moment produced but the refractive index may be altered as well. The stress is directional and so an isotropic crystal may become either uniaxial or biaxial. This gives rise to the photoelastic effect (and hence the photoelastic tensor). This effect underlies the Perspex modeling of objects and machinery to study stresses. The application illustrates how even a noncrystalline material that starts isotropic can become anisotropic under stress.

Rather than applying macroscopic stresses to a crystal, acoustic waves can be passed through, leading to another interesting set of applications, namely acoustooptics.

This article has shown the wide range of applications of crystal tensors and it has demonstrated how, especially with low-symmetry crystals, the effects can become complicated and difficult to interpret. Perhaps the main power of the theory of crystal tensors, and hence its application, is to predict the best directions in which to cut and use crystals so as to produce maximized effects and keep the complications to a minimum.

Nomenclature

B	magnetic field
c	velocity of light in vacuo
$\boldsymbol{D}$	dielectric displacement (electric flux density)
d_{ijk}	piezoelectric modulus, second-order nonlinear susceptibility
$\boldsymbol{E}$	electric field
k	wave vector
$\boldsymbol{L}$	thickness
n, n_i	refractive index
n_o	ordinary refractive index
n_e	extraordinary refractive index
P, P_i	polarization
p_i	pyroelectric coefficient
r_{ijk}, r_{ij}	Pockels coefficients, reduced matrix coefficients
s_{ij}	elastic compliance (matrix form)
s_{ijkl}, s_{ij}	Kerr electrooptic coefficients, reduced matrix coefficients
ε_0, ε	permittivity of free space, relative permittivity
η_{ij}	optical impermeability
λ	wavelength
ρ, ρ_{ij}	electrical resistivity
ρ_{ijk}, ρ_{ijkl}	Hall effect, longitudinal magnetoresistance
χ, χ_{ijkl}	electric susceptibility, third-order electric susceptibility
ω	angular frequency
Θ	phase matching angle

Crystal Tensors: Introduction

D R Lovett, University of Essex, Colchester, UK

Introduction

A crystal is inherently symmetrical, hence it presents the same aspect from a number of different directions. The properties of a single crystal generally depend on the direction in which the properties are measured. However, as a result of the crystal symmetry, there are different directions in which the physical properties of the crystal are the same. What is needed is a method of exploiting the inherent symmetry in order to simplify the formulation of the physical properties. The use of tensors is one such tool. This article explains what tensors of different ranks are, and shows how such tensors can be used to describe the directional variation of the physical properties within crystals.

Second-Rank Tensor Illustrated by Electrical Resistivity

The application of the technique and a demonstration of the symbols used can be shown mostly easily by looking at electrical resistivity. Assume an electric current density J passing through a crystalline sample when an electric field E is established within the sample. These quantities are related by

$$E = \rho J$$

where ρ is the electrical resistivity of the sample. If the sample is isotropic, that is, its properties are the same in all directions, then the electric current and the electric field will be in the same direction and ρ is a scalar. This is not necessarily so in a crystal. Resolving the electric field into components in different directions, generally using Cartesian coordinates, leads to components in high-resistivity and low-resistivity directions, and when combined these produce an overall current which is rotated compared with the applied electric field. An everyday analogy is that when a supermarket trolley is pushed it may not move off in exactly the direction of the force! Mathematically, one can now express the relationship between current density and electric field in the form:

$$E_1 = \rho_{11}J_1 + \rho_{12}J_2 + \rho_{13}J_3$$
$$E_2 = \rho_{21}J_1 + \rho_{22}J_2 + \rho_{23}J_3$$
$$E_3 = \rho_{31}J_1 + \rho_{32}J_2 + \rho_{33}J_3$$

Linearity between E and J components has been assumed here, equivalent to assuming Ohm's law. Alternatively, the three combined equations can be written in a matrix form or even more simply by:

$$E_p = \sum_{q=1}^{3} \rho_{pq} J_q = \rho_{pq} J_q$$

Here, the convention is that when the dummy suffix (the repeated q) appears on the right-hand side, then the summation is assumed with the dummy suffix taking values of 1, 2, and 3. Resistivity ρ now has nine components and the resistivity is in the form of a so-called second tensor, which is often represented more generally as T_{pq}. Not all these components are necessarily independent, and for instance, by considering its symmetry, it can be shown (and this is perhaps fairly obvious) that a crystal with a simple hexagonal structure has only two independent components, $\rho_{11} = \rho_{22}$ in the hexagonal (basal) plane, and ρ_{33} perpendicular to this plane.

For the above, the Cartesian axes have been selected carefully with axis x_3 perpendicular to the basal plane. However, the axes may be selected arbitrarily, or alternatively a crystal may have been cut for physical examination in a different way. A significant aspect of using tensors to represent physical quantities is that the tensors can be transformed for appropriate rotation of the Cartesian axes. Consider as the common origin a point O (**Figure 1**) and original axes Ox_1, Ox_2, and Ox_3. One has new axes Ox'_1, Ox'_2, and Ox'_3, where the superscript $'$ is used to distinguish a new axis from an old axis. Then l_{ip} is used to represent the cosine of the angle between the old axis Ox_p and the new axis Ox'_i. A table showing the so-called direction cosines is now constructed. For instance, l_{21} represents the direction cosine of Ox'_2 with respect to Ox_1 and so on:

	x_1	x_2	x_3
x'_1	l_{11}	l_{12}	l_{13}
x'_2	l_{21}	l_{22}	l_{23}
x'_3	l_{31}	l_{32}	l_{33}

Not all the ls are independent, as the mutual orientation of the two sets of axes can be specified by three parameters, so the dependence of the ls can be expressed as:

$$l_{ik} l_{pk} = \delta_{ip}$$

where $\delta_{ip} = 1$ if $i = p$, and $\delta_{ip} = 0$ if $i \neq p$. The squares of the direction cosines must add to one across the rows and down the columns.

Having set up these direction cosines, it can be shown that the resistivity component δ'_{ij} relative to one set of axes is related to the resistivity component δ_{pq} relative to the other set by:

$$\delta'_{ij} = l_{ip} l_{jq} \delta_{pq}$$

and more generally, any second-rank tensor will usually transform (but see later, the section concerning axial tensors) as:

$$T'_{ij} = l_{ip} l_{jq} T_{pq}$$

The tensor has nine components. Similarly, a vector has three components (that is, it is a first-rank tensor). A third-rank tensor has 27 components and transforms according to:

$$T'_{ijk} = l_{ip} l_{jq} l_{kr} T_{pqr}$$

and so on.

For the higher-rank tensors, a calculation of physical effects would become very complex if all the components were independent. However, Neumann's principle, which states that the symmetry elements of any physical property of a crystal must include the symmetry elements of the crystal, can be utilized. The physical properties may and often do include more symmetry than the point group. Physical properties that can be characterized by second-rank tensors must be centrosymmetric, whereas the crystal itself may not be. This may be seen by expressing

$$p_i = T_{ij} q_j$$

Reversing the directions of p and q changes the sign of each of their components but leaves T_{ij} unchanged.

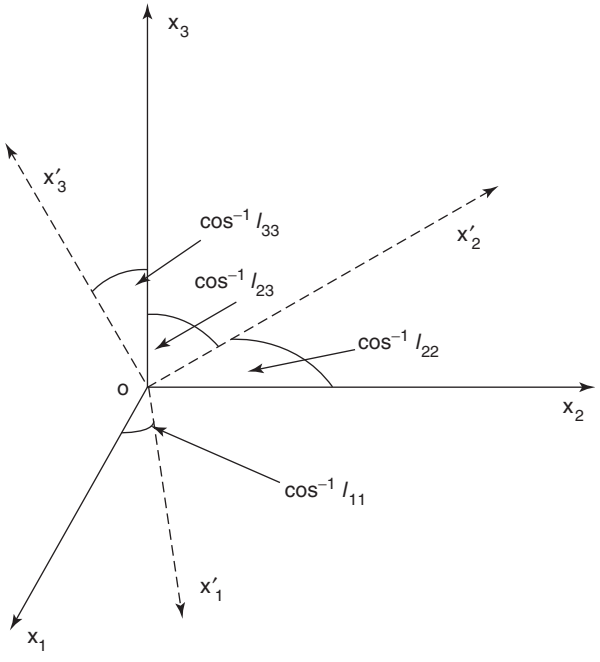

Figure 1 Rotation of axes.

Representation Quadric for Symmetrical Second-Rank Tensor

Second-rank tensors are said to be symmetrical if $T_{pq} = T_{qp}$. Most common second-rank tensors describing physical properties are symmetrical although the thermoelectric tensor is an exception. Alternatively, if $T_{pq} = -T_{qp}$, the tensor is said to be antisymmetrical. A quadric can be represented by the equation

$$S_1x_1^2 + S_2x_2^2 + S_3x_3^2 = 1$$

provided it is described relative to the principal axes. Similarly, if a symmetrical second-rank tensor of general form,

$$T_{pq} = \begin{bmatrix} T_{11} & T_{12} & T_{13} \\ T_{21} & T_{22} & T_{23} \\ T_{31} & T_{32} & T_{33} \end{bmatrix}$$

is described with respect to the principal axes, it becomes:

$$T_{pq} = \begin{bmatrix} T_{11} & 0 & 0 \\ 0 & T_{22} & 0 \\ 0 & 0 & T_{33} \end{bmatrix} = \begin{bmatrix} T_1 & 0 & 0 \\ 0 & T_2 & 0 \\ 0 & 0 & T_3 \end{bmatrix}$$

where T_1, T_2, and T_3 are the principal coefficients of the tensor T_{pq}. Further consideration of the condensed (single subscript) notation for the two subscripts will come a little later. If T_1, T_2, and T_3 are all positive, the tensor can be represented by an ellipsoid whose semiaxes have lengths of $1/\sqrt{T_1}, 1/\sqrt{T_2}$, and $1/\sqrt{T_3}$. If two of the principal components are positive and one is negative, the surface is a hyperboloid of one sheet; if one is positive and two are negative, it is a hyperboloid of two sheets, and if all the three are negative, the surface is an imaginary ellipsoid. However, for conductivity and resistivity the coefficients are positive, thus giving a real ellipsoid. Only three components are ever necessary to define a second-rank tensor referred to as the principal axes. However, if these axes need to be defined in relation to conventional crystallographic axes as is required for monoclinic and triclinic crystals, then up to a further three coefficients are necessary.

Second-Rank Tensor as Illustrated by Thermal Conductivity and Resistivity

In order to see easily and visually what happens if a crystal is not aligned with a principal axis in the same direction as the driving force within the crystal, it is advantageous to look at the heat flow. In an isotropic medium, heat conductance can be represented by the equation:

$$h = -k \text{ grad } T$$

where k is the thermal conductivity and is a constant having the same value in any direction in the medium. Also,

$$\text{grad } T = \partial T/\partial x_1 + \partial T/\partial x_2 + \partial T/\partial x_3$$

and this is the temperature gradient. The heat flow h per unit area is in the direction of the greatest fall of temperature, that is, in the direction of –grad T. In suffix notation, the equation for heat conduction may be written as

$$h_i = -k\partial T/\partial x_i$$

But just as in the case of electrical resistivity, thermal conductivity may vary with crystallographic direction, and hence the heat flow may not be in the same direction as the maximum temperature gradient. The thermal conductivity equation is then written as

$$h_i = -k_{ij}\partial T/\partial x_j$$

where k_{ij} is the second-rank thermal conductivity tensor. Alternatively, one can use the thermal resistivity tensor r_{ij} to obtain

$$\partial T/\partial x_i = -r_{ij}h_j$$

k_{ij} and r_{ij} are symmetrical tensors having three components when referred to their principal axes. If this is done, then $k_1 = 1/r_1$, etc. Otherwise, in general, reciprocals cannot be taken.

To show the more general use of tensors, consider the heat flow in two crystalline samples of different geometries as shown in **Figure 2a**. The first example shows a very thin sample with a large heat source

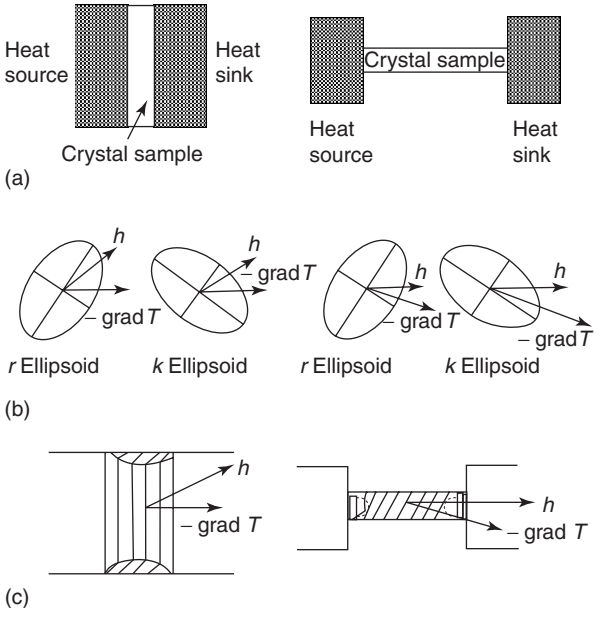

Figure 2 (a) A thin wide and a long narrow sample, (b) cross sections of the conductivity and resistivity ellipsoids, and (c) distortion of the isothermals.

and sink on opposite faces in a setup that is similar to the classical disk experiment for measuring the thermal conductivity of an isotropic sample of poor conductivity. The isothermal surfaces must be parallel to the end faces and it is easier, when one has an arbitrarily oriented crystal, to represent the setup by the conductivity equation. Alternatively, if a long narrow sample is used as in **Figure 2b**, then the heat flow is parallel to the sides and the resistivity equation is preferable. **Figures 2c** and **2d** show the k and r ellipsoid in each case (cross sections of the three-dimensional ellipsoids), whereas **Figures 2e** and **2f** show that some distortion of the isothermals occurs near the edges. It can be seen from these diagrams that measurements and their interpretation are easier if the crystal is aligned with major axes parallel to the heat source and sink.

Third-Rank Tensors

These arise when a tensor relates a vector to a second-rank tensor. If no simplification were possible, then there would be 3^3, that is, 27, components. In practice, the largest possible number is 18 in triclinic crystals without inversion symmetry, but the number reduces rapidly with crystals showing higher symmetry. Properties that involve third-rank tensors include the piezoelectric effect, the linear electrooptic (Pockels) effect, and the Hall effect. However, to demonstrate the reduction of the number of tensor components further, consider the fourth-rank tensors.

Fourth-Rank Tensor as Illustrated by Elasticity

Young's modulus is given by stress divided by strain and, as both stress and strain can be represented by second-rank tensors, the modulus can be represented by a fourth-rank tensor. Stress is the force acting in any direction divided by the area. It is easiest to consider forces acting on a cube of unit dimensions (**Figure 3**). Here, it can be seen that σ_{22} is the normal force acting on one of the faces, and σ_{12} and σ_{32} are the shear components. For there to be no turning of the overall cube, $\sigma_{ij} = \sigma_{ji}$.

Strain e is the extension divided by the original length, and can either be tensile of the form e_{11} or a shear of the form e_{12}, etc. The problem in defining the shear strain is that any pure rotation must be eliminated. Any tensor can be divided into the sum of a symmetrical and an antisymmetrical tensor. Without going into detail here, to remove the rotation, the symmetrical parts of the shear strain components e_{ij} are taken, and the new tensor is called ε. Also, $\varepsilon_{ij} = \varepsilon_{ji}$ for no overall rotation of the body. The diagonal components of the tensor are the tensile strains (positive) or compressive (negative) strains, and the off-diagonal components are the shear strains.

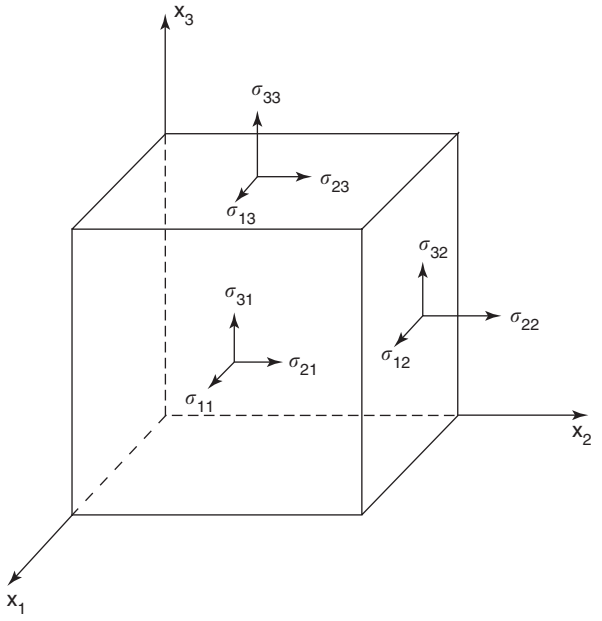

Figure 3 Normal and shear components of stress on a cubic element.

Strain is the response of the crystal to an influence. If this influence arises from a change within the crystal itself, then the resulting tensor will reflect the symmetry properties of the crystal. If however, as is more usual, the strain arises from external forces, then these will not be related to the crystal properties. The tensor will not conform to Neumann's principle and is an example of a field tensor. Tensors that are governed by Neumann's principle are called "matter" tensors.

Having looked at stress and strain, it is possible to set up the relationship for elasticity. As before, starting with an isotropic material such as a polycrystalline sample, Hooke's law may be expressed in the form:

$$\sigma = c\varepsilon$$

where c is Young's modulus or the elastic stiffness. Alternatively,

$$\varepsilon = s\sigma$$

where s is the elastic compliance. The above two equations become in tensor notation:

$$\sigma_{ij} = c_{ijkl}\varepsilon_{kl} \qquad \text{and} \qquad \varepsilon_{ij} = s_{ijkl}s_{kl}$$

where c_{ijkl} is the fourth-rank tensor for stiffness, and s_{ijkl} is the fourth-rank tensor for compliance. As one already has $\sigma_{ij} = \sigma_{ji}$ and $\varepsilon_{ij} = \varepsilon_{ji}$, the result obtained is:

$$c_{ijkl} = c_{jikl} = c_{ijlk} = c_{jilk} \qquad \text{and}$$
$$s_{ijkl} = s_{jikl} = s_{ijlk} = s_{jilk}$$

Thus the number of components has been reduced to 36. These can be represented in a 6×6 matrix, a type of representation which is used fairly generally. What must be remembered is that as soon as components are represented in a matrix form, the rules of transformation cannot be followed for change of axes.

Making use of the symmetry in the first and last suffixes and following standard convention:

Tensor notation suffixes	11	22	33	23	32	31	13	12	21
Matrix notation suffixes	1	2	3	4		5		6	

As a consequence, the relationships are expressed as

$$\sigma_m = c_{mn}\varepsilon_n \quad \text{and} \quad \varepsilon_m = s_{mn}s_n$$

where m and n take on the values 1 to 6. Thus, the principal components of stress take on the notation $\sigma_1, \sigma_2,$ and σ_3. This is a common form of notation for the principal components of a second-rank tensor. This is so even if the tensors are not involved in the setting up of a higher-rank tensor in which a matrix notation is fully used. However, there is a complication in that one does not end up with the correct matrix forms of the equations for the relationships between stress and strain without some modification of the transformations. There are more pairs of type 23 than of those type 11, for instance. The conventional way around for stress and strain is to transform as follows:

$$\begin{bmatrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33} \end{bmatrix} \rightarrow \begin{pmatrix} \sigma_1 & \sigma_6 & \sigma_5 \\ \sigma_6 & \sigma_2 & \sigma_4 \\ \sigma_5 & \sigma_4 & \sigma_3 \end{pmatrix}$$

$$\begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} & \varepsilon_{13} \\ \varepsilon_{21} & \varepsilon_{22} & \varepsilon_{23} \\ \varepsilon_{31} & \varepsilon_{32} & \varepsilon_{33} \end{bmatrix} \rightarrow \begin{pmatrix} \varepsilon_1 & \varepsilon_6/2 & \varepsilon_5/2 \\ \varepsilon_6/2 & \varepsilon_2 & \varepsilon_4/2 \\ \varepsilon_5/2 & \varepsilon_4/2 & \varepsilon_3 \end{pmatrix}$$

In addition, factors of 2 and 4 are to be introduced as follows:

$$\begin{aligned} s_{ijkl} &= s_{mn} \quad \text{for } m = 1,2,3 \text{ and } n = 1,2,3 \\ 2s_{ijkl} &= s_{mn} \quad \text{for either } m \text{ or } n = 1,2,3 \\ 4s_{ijkl} &= s_{mn} \quad \text{for both } m \text{ and } n = 1,2,3 \end{aligned}$$

But

$$c_{ijkl} = c_{mn} \text{ for all } m \text{ and } n$$

The matrix for stiffness becomes:

$$\begin{pmatrix} c_{11} & c_{12} & .. & .. & .. & c_{16} \\ c_{21} & c_{22} & .. & .. & .. & c_{26} \\ c_{31} & .. & .. & .. & .. & .. \\ c_{41} & .. & .. & .. & .. & .. \\ c_{51} & .. & .. & .. & .. & .. \\ c_{61} & .. & .. & .. & .. & c_{66} \end{pmatrix}$$

and similarly for compliance.

For other conversions of fourth-rank tensors to the matrix notation, it is necessary to check just how the transformation has been carried out.

Having reduced the number of components so far, it can be further shown (by energy considerations when stresses are applied) that c_{mn} will be the same as c_{nm}, and s_{mn} will be the same as s_{nm}. The number of independent components is then reduced to 21. This is still a large number but just as with second-rank tensors, one can look at the effect of different crystal symmetries. For higher-symmetry crystals, this can be achieved more easily by inspection to see how pairs of suffixes transform with a change of axes as symmetry operations specific to the crystal are carried out. **Table 1** shows the maximum number of independent components that are left for fourth-rank tensors and for other tensors for a selection (but only a selection) of crystal systems. The table gives an idea of the variation of the number of coefficients. Although, in principle, one can go to higher-rank tensors above the fourth, this is less usual.

Axial Tensors

There are some cases where axes and hence vectors transform not according to $r'_i = l_{ip}r_p$ (i.e., as $r'_1 = l_{11}r_1 + l_{12}r_2 + l_{13}r_3,$ etc.) but according to $r'_i = \pm\, l_{ip}r_p$ (i.e., as $r'_1 = \pm l_{11}r_1 \pm l_{12}r_2 \pm l_{13}r_3,$ etc.), where $+$ means a transformation that leaves the hand of the axes unchanged and $-$ changes the hand (whether left-handed or right-handed). Such vectors are called axial vectors whereas true vectors are called polar vectors. A polar vector can be shown to be an arrow pointing in a specific direction. An axial vector needs a right-handed or left-handed screw to represent it. Polar vectors (angular velocity would be such an example) are referred to as right-handed axes.

Axial tensors can similarly exist and they are sometimes called pseudotensors. The most common example is optical activity which is a rotation of the plane of polarization as light passes through a crystal and where the property transforms according to $T'_{ij} = \pm l_{ip}l_{jq}T_{pq}$. In this case, the plus and minus

signs give rise to positive and negative rotations of the plane of polarization.

To see what happens in particular crystals for particular tensor applications, it is necessary to look at the transformations for different crystal symmetries. Both rotation planes and mirror planes need to be considered. Consider first the transformation of an axial vector. It is necessary to combine the effects of both the transformation of the coordinate axes and the sense of rotation. Doing this, it can be shown that for a diad (twofold rotation) axis and for threefold, fourfold, and sixfold axes, axial vectors behave in a similar way to polar tensors. So $r'_i = l_{ip} r_p$ for axes of rotation. On the other hand, when the effect of mirror planes is looked at and also when the effect of a centre of symmetry is considered, there is a reversal of sign compared with the situation for a polar tensor. Hence, $r'_i = \pm l_{ip} r_p$ for planes and centers of symmetry.

Similarly for an axial tensor, the specific symmetry needs to be considered. For a second-rank tensor applied to a crystal having a centre of symmetry, 1 goes to -1, 2 to -2, 3 to -3. In addition, there is a change of rotation so that with two negative signs for the change of axes and the additional change for rotation, $T'_{ij} = T_{pq}$ is the result.

Tensors for Crystal Optics

Crystal optics incorporates a more complex situation than that for physical effects such as electrical and thermal conductivity. Passage of light involves propagation of transverse electromagnetic waves. Unless plane-polarized light is used, there will be wave vibrations (electric and magnetic vectors) in all directions orthogonal to the direction of propagation. If the direction of propagation is taken to be x, then for a single wave, if the electric vector is varying in the y direction, the magnetic vector varies in the z direction. It is the electric vector that is taken as the defining vector. For nonpolarized light, the electric vectors for all the waves can be resolved into orthogonal y and z directions. It is the interaction of these electric vector components, with possibly different strengths, with the atoms of the crystal that can give rise to the light being slowed down by different amounts for the two components. These two components, the component resolved in the y direction and the component resolved in the z direction, may each have its own velocity. The crystal in question exhibits a so-called birefringence or double refraction. So in understanding what will happen and making use of the properties of crystal tensors, one must in general also know about the nature of the light being used, that is, whether it is polarized (and in which direction it is polarized) or unpolarized. Even if a crystal does not exhibit birefringence in its natural state, it may do so under stress or under the application of independent electric or magnetic forces. This can lead to a number of interesting and useful effects (refer to "See also" section).

Here, the main implications for uniaxial and biaxial crystals are considered. In an isotropic medium, the dielectric properties at optical frequencies are represented by the equation

$$D = \varepsilon_0 K E = \varepsilon E$$

E is the electric field, ε_0 is the permittivity of free space, K is the dielectric constant for the isotropic medium, ε is the permittivity of the medium, and D is the dielectric displacement or electric flux density. The corresponding equation for an anisotropic

medium involves K and ε becoming symmetrical second-rank tensors:

$$D_i = \varepsilon_0 K_{ij} E_j = \varepsilon_{ij} E_j$$

This equation is similar to that for heat flow using the conductivity tensor. Also, just as the reciprocal tensor can be used in heat flow, that is the thermal resistivity tensor, the reciprocal dielectric tensor $(K^{-1})_{ij}$ can be similarly used. It is normally represented by the symbol η_{ij} and is called the optical impermeability. The ellipsoid is given the special name of the optical indicatrix. If the principal values of the refractive index are defined as $n_1, n_2,$ and n_3, and $x_1, x_2,$ and x_3 are used for the principal axes of this representational ellipsoid, the equation for the ellipsoid is

$$\frac{x_1^2}{n_1^2} + \frac{x_2^2}{n_2^2} + \frac{x_3^2}{n_3^2} = 1$$

The principal values of the refractive index are related to the principal components of the dielectric tensor and the optical impermeability tensor by

$$n_1 = \sqrt{K_1} = 1/\sqrt{\eta_1}$$
$$n_2 = \sqrt{K_2} = 1/\sqrt{\eta_2}$$
$$n_3 = \sqrt{K_3} = 1/\sqrt{\eta_3}$$

An alternative way of writing the equation for the ellipsoid is

$$\eta_1 x_1^2 + \eta_2 x_2^2 + \eta_3 x_3^2 = 1$$

For cubic crystals the principal refractive indices are equal, the indicatrix is consequently a sphere, and no double refraction occurs. For the cases of tetragonal, hexagonal, and trigonal crystals, the indicatrix becomes an ellipsoid of revolution about the principal symmetry axis. This principal axis is called the optic axis. There are two principal values of the refractive index and the crystals are called uniaxial. The refractive index, as measured in the direction of the principal axis, would correspond to n_1 in the above equation. In this case it is generally referred to as n_E, the extraordinary refractive index. The other principal value corresponding to $n_1 = n_2$ is referred to as n_O, that is the ordinary refractive index. The electric vectors of the light rays passing in the direction of the optic axes lie within this cross-sectional plane with $n_1 = n_2$, and all the rays travel in the direction of the optic axis with equal speed (there is no birefringence).

For orthorhombic, monoclinic, and triclinic crystal systems, the ellipsoid for the indicatrix is triaxial. There are now two circular cross sections (**Figure 4**), and the two directions perpendicular to these circular cross sections are referred to as the optic axes. Optically, the crystals are referred to as biaxial. There is no birefringence exhibited in these two directions as the electric vectors for the light lie within one of the circular planes of the indicatrix.

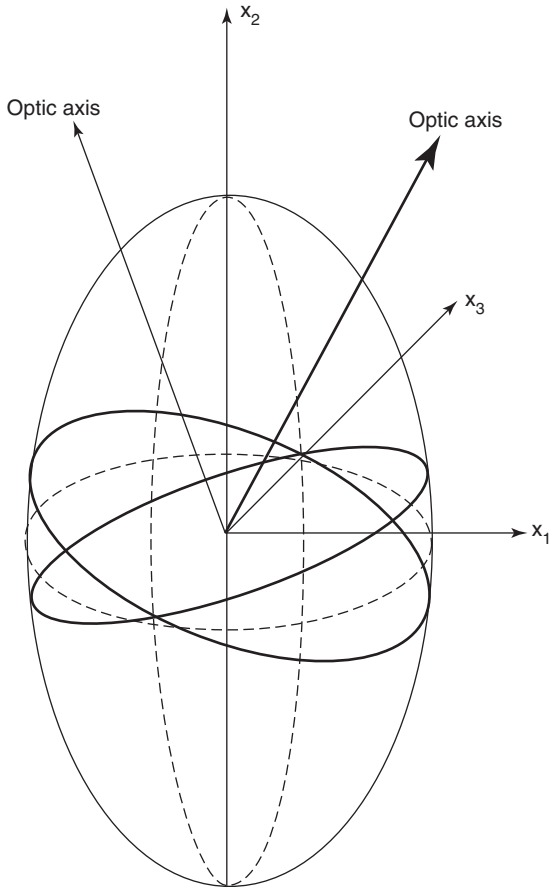

Figure 4 Ellipsoid for the indicatrix in a biaxial crystal.

Wave Surfaces

The wave surface, that is the optical front, for light passing through a crystal is different from the indicatrix but related to it. Consider a point surface of light and see where the light gets to over a particular time. If the light travels outward with the same speed in all directions, the surface is a sphere. But as has been seen not only will there be a variation of speed with direction for many crystals, but the speed will also vary for variation of orientation of the electric vectors perpendicular to the direction of passage of the light. As indicated above, in the direction of the optical axis in a uniaxial crystal, all the rays proceed with the same speed and this is determined by the refractive index n_O. Perpendicular to the optic axis, rays move with the full range of possible velocities determined by the extreme (principal) values of the refractive index, n_O and n_E. Consequently, the wave surfaces for a uniaxial crystal can take one of the two alternatives shown in **Figure 5**. Which alternative applies depends

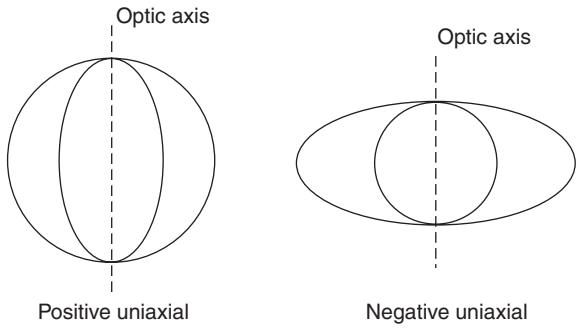

Figure 5 Wave surfaces for uniaxial crystals.

on whether $n_O > n_E$ (positive uniaxial) or $n_O < n_E$ (negative uniaxial). There is an extra complication in that surfaces are also often used to show the variation of the wave vector k with direction. As $k = 2\pi/\lambda$, the wave vector surface gets larger as the wavelength gets smaller, whereas the distance traveled and hence the size of the wave surface gets smaller.

The situation is more complicated in biaxial crystals and this is discussed for specific applications elsewhere in the encyclopedia (refer "See also" section). It is the application of crystal tensors to optical materials as used in electronic devices which has proved to be of particular importance in recent years.

Crystalline Organic Metals

T Ishiguro, Kyoto University, Kyoto, Japan

Introduction

Organic materials showing high electrical conductivity with a weak temperature dependence are called organic metals. The number of the charge carriers in metals is kept almost constant against temperature variation, in contrast to semiconductors, in which the number is determined by thermal activation processes. In the organic conductors, the charge carriers consist of the delocalized π-electrons at the highest occupied molecular orbital (HOMO) or the lowest unoccupied molecular orbital (LUMO), consisting of a $2p_z$ orbital of carbon (C) atom, a $3p_z$ orbital of sulfur (S) atom, or a $4p_z$ orbital of selenium (Se) atom. Structurally, organic metals are classified into two categories. Polymeric materials represented by polyacetylene and polypyrrole form the first group. A typical structural motif of these materials is an assembly of fibrils formed by bundled polymer chains, which normally cannot be prepared in single crystalline forms. In most cases, the polymers themselves are insulators and the metallic properties are induced by chemical doping. Crystalline organic materials, forming the second group, are characterized by the regular arrays of molecules (TTF, TMTTF, etc.) as shown in **Figure 1**.

The vast majority of crystalline organic metals consists of two kinds of molecules combined with the charge transfer interaction. By transferring the charge from one type of molecules (donors) to the other type (acceptors), partial filling of the bands is achieved, allowing movement of conduction of the π-electrons. In special cases, however, single molecular metals can be formed, such as in single crystals of $Ni(tmdt)_2$. In these materials, the minima of a LUMO are lower than the maxima of a HOMO so that the π-electrons are transferred between the orbitals within the molecule, and the conductance becomes metallic without the charge transfer. Also, the assembly of C atoms connected with sp^2-bonding and containing delocalized π-electrons, such as a fullerene C_{60} molecule, functions as a metal, when it is combined with an alkali metal (A) to form A_3C_{60}, through a charge transfer from A to C. Starting with the molecular and electronic structure, the features of the conducting and superconducting states are presented in this article.

Molecular Structure and Electronic Structure

Molecular Structure

The molecules shown in **Figure 1** are nearly planar and can be assembled to form face-to-face stacks so

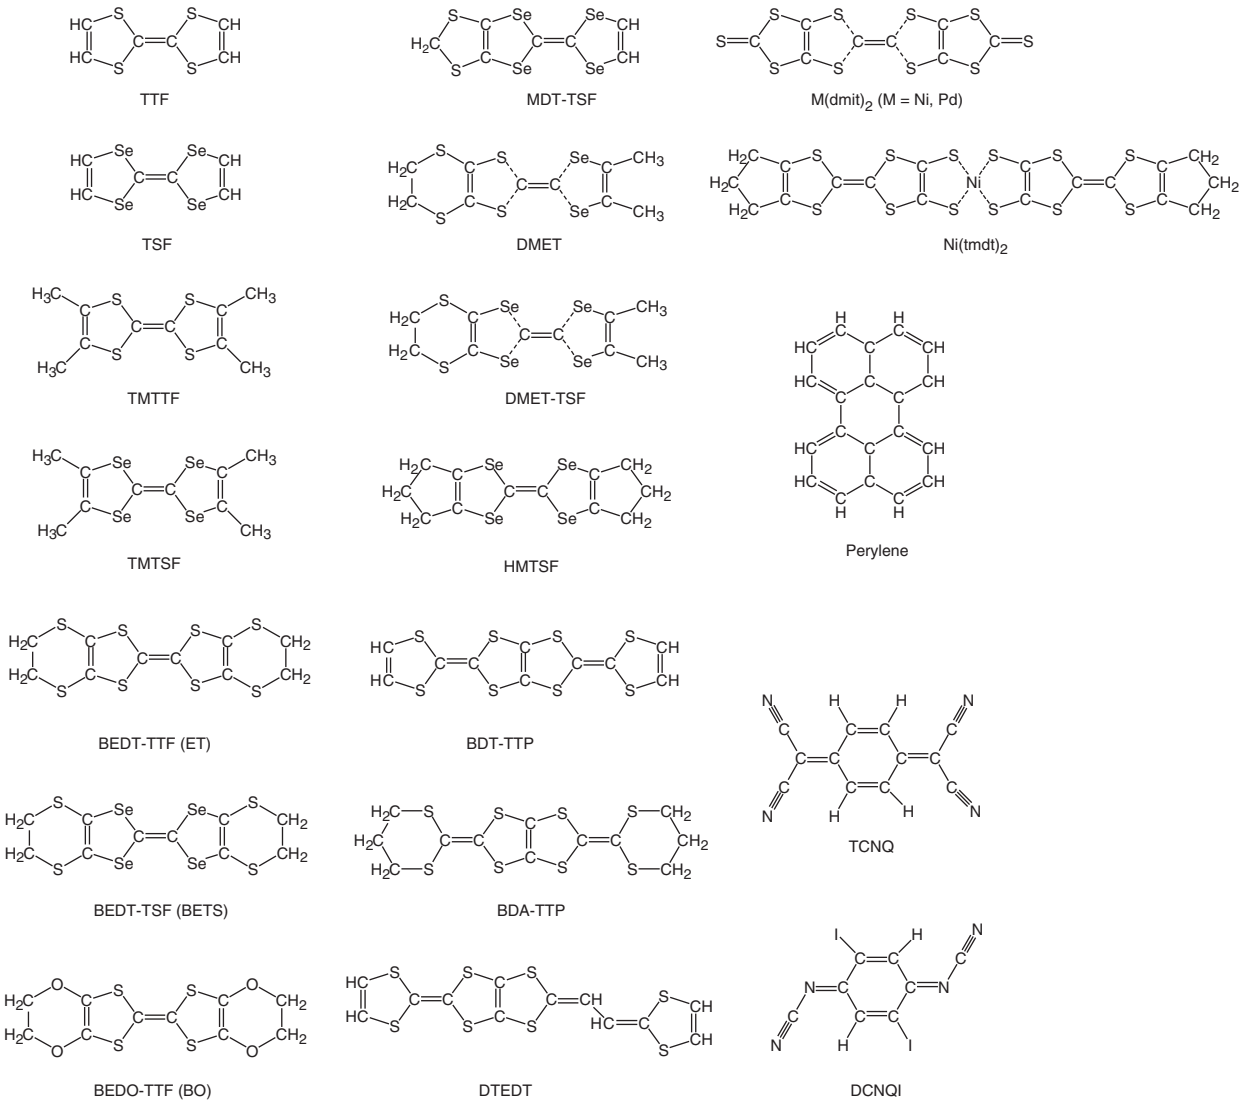

Figure 1 Chemical formulas of basic molecules constructing crystalline organic conductors.

that the π-electron orbitals overlap on adjacent molecules. When the donor and acceptor molecules are stacked separately to form segregated columns, each column works as a one-dimensional electrical conductance channel. When the overlap of π-electron orbitals in the side-by-side direction is not negligible, the conductivity can be quasi-two-dimensional (Q2D) or quasi-three-dimensional (Q3D). The pronounced anisotropy in the electron transfer brings about conductors of a restricted dimensional nature.

In the charge transfer salt TTF·TCNQ, which triggered an excitement about the organic metal in the 1970s, the electronic charge is transferred from TTF to TCNQ. Since the charge transfer is incomplete (0.59 e per molecule, where e is the charge of the electron), the columns of TTF and TCNQ work as hole and electron conductors, respectively. Since the electron transport between the columns is much weaker than within the columns, the electronic structure is characterized by two channels of Q1D nature (**Table 1**). In the case of $(TMTSF)_2X$ and $(TMTTF)_2X$

Table 1 Material types, their conducting channels and the conductance dimensionality (Q1D, Q2D, and Q3D)

Materials	*Conducting channels*	*Dimensionality*
$(TMTSF)_2X$	TMTSF columns	Q1D
TTF·TCNQ	TTF columns and TCNQ columns	Q1D
β-$(BEDT\text{-}TTF)_2X$	BEDT-TTF columns with intercolumn coupling	Q2D
κ-$(BEDT\text{-}TTF)_2X$	BEDT-TTF layers	Q2D
$Ni(tmdt)_2$	$Ni(tmdt)_2$ columns with intercolumn coupling	Q3D
A_3C_{60}	f.c.c.-packed C_{60}	3D

($X = PF_6$, AsF_6, ClO_4, etc.), the columns of TMTSF and TMTTF work as Q1D conductors, while the counter anions X^- having a closed electronic shell do not form a conduction path. For molecules such as BEDT-TTF and BEDT-TSF (also abbreviated as ET and BETS, respectively), forming charge transfer salts (BEDT-TTF)$_2X$ ($X = I_3$, $Cu(NCS)_2$, $Cu[N(CN)_2]Cl$), and (BEDT-TSF)$_2X$ ($X = GaCl_4$, $FeCl_4$), the side-by-side type contacts of the molecules bring about a π-electron transfer that is as substantial as the face-to-face type contacts. Consequently, the molecules form conducting layers separated by the layers of counter anions of X^-. Within the layer plane, BEDT-TTF and BEDT-TSF molecules can be arranged in several different patterns and the resulting crystalline structures are differentiated by Greek letters such as α, β, κ, λ, θ, etc. The arrangement in the κ-type, however, has no columnar motif but a checkerboard pattern with pairs of BEDT-TTF molecules. In these cases, the electronic structure has a Q2D character.

For A_3C_{60} compounds, the spherical C_{60} molecules form a face-centered-cubic (f.c.c.) lattice, while the alkali metal atoms occupy the interstitial openings of the cubic lattice regularly. The resultant structure remains 3D providing the isotropic conductor. The single component conductor $Ni(tmdt)_2$ also shows the quasi-three-dimensionality due to the intercolumn interaction.

Electronic Structure

The electronic structure of low-dimensional organic metals, such as (TMTSF)$_2X$, (BEDT-TTF)$_2X$, has been calculated by the tight-binding band model, taking into account the electron transfer between the molecular orbitals, derived by the extended Hückel method, but neglecting the transfer in the least conductance direction. This relatively simple method has been applied successfully to derive Fermi surfaces in these conductors, due to the fact that the HOMO bands, serving for the charge transport, are energetically separated from the other bands. In these salts, according to the chemical formula with the monovalent anion X^-, the charge per donor molecule is $+0.5\,e$, so that the bands formed by the orbitals of the donor molecules should be quarter-filled. In reality, however, the resultant electronic band is half-filled because of the dimerization of the donor molecules. The cross sections of the Fermi surfaces for typical organic metals are illustrated in **Figure 2**. To obtain more detailed and a 3D electronic structure including the least conduction direction, methods such as the local density-functional calculation and the first-principles calculation are applied. It is also important to take into account the electron correlation energy, which can be comparable to the transfer energy and change the metal to be an insulator for the half-filled case.

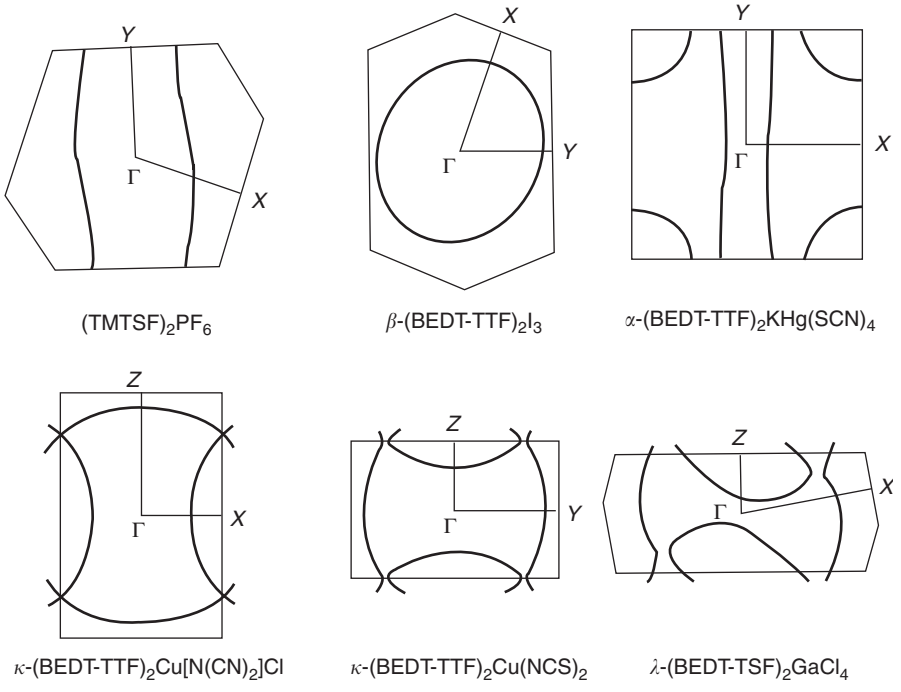

Figure 2 Fermi surface cross sections of typical crystalline organic metals.

Electron Dynamics in Crystalline Organic Metals under Magnetic Field

For the 2D organic metals, the magnetoquantum oscillations (the Shubnikov–de Haas and the de Haas–van Alphen effect) have been observed very clearly in the resistivity, the magnetization, the heat capacity and so on, due to the high density of states, characteristic to the band structure with restricted dimensionality, and the high-crystalline perfection of the compounds. From the experimental results, the cross-sectional areas of the Fermi surface and the effective mass of the charged carriers have been derived. The reported effective mass values are listed in **Table 2**. The larger mass values from the de Haas effect were obtained in the higher magnetic field region, associated with the magnetic breakdown phenomena between the adjacent Fermi surfaces. The cyclotron resonance due to the transitions of the electrons between the Landau levels gave lower mass values compared to those obtained from the de Haas effect. The difference has been ascribed to the effect of the electron correlation on the mass derived from the quantum oscillation. The effective masses derived from the plasma frequency found in the optical spectra are also listed in **Table 2**. The difference in the mass values is related to the electronic polarization within the conducting plane.

In the Q2D metal with a weak interlayer interaction such as (BEDT-TTF)$_2X$ salts, the Fermi surface, possessing a cylindrical shape in a purely 2D case, exhibits periodical swelling (warping) along the cylinder axis. The magnetic phenomena such as magnetoresistance, magnetization, and magneto-acoustic absorption exhibit an oscillatory change with the angle of the magnetic field from the cylinder axis without showing a shift in the oscillation phase by the field strength, in contrast to the de Haas effect. This is called the angle-dependent magnetoresistance oscillation (AMRO) and is well explained by the semiclassical theory, demonstrating that all of the electron orbits near the Fermi surface enclose the same cross-sectional area at certain magnetic field directions. From the analysis of the oscillation phase, the diameters of the Fermi surface cross section can be derived.

For Q1D metals such as (TMTSF)$_2X$ salts, the electron orbits on the Fermi surface are not closed in the momentum space (**Figure 2**), except in a very limited region. When the magnetic field is applied almost perpendicular to the most conducting axis, the electrons near the Fermi surface traverse the Fermi surface, being driven by the Lorentz force. In the real space, this makes a wavy motion due to a back-and-forth oscillation corresponding to the Bragg reflection at the Brillouin zone boundaries. The angular dependence of the magnetoresistance shows the extrema at certain crystalline directions, when the trajectories of the electrons, traversing the momentum space, satisfy certain commensurability conditions with respect to the geometry of the Brillouin zone. The observed angle dependence enables one to derive the transfer integrals and the geometrical parameters on the Fermi surface of the Q1D metal. The wavy amplitude decreases inversely proportional to the magnetic field, resulting in the confinement of the electron motion within the layer at a very high field.

Ground States in Normal Conductors

Since the low-dimensional metallic state is intrinsically unstable, organic metals show a variety of specific types of order at low temperatures as their ground states such as the Peierls insulator, the spin-density wave (SDW) state, the spin-Peierls state, the Mott insulating state, and the Wigner crystalline state.

Peierls Insulator

The 1D metal responds in a divergent way to the external perturbation with $2k_F$ periodicity (k_F: Fermi wave number). This instability of the electron system is removed by a $2k_F$ periodic modulation of the electron density as predicted by R E Peierls. **Figure 3** shows the interaction of the $2k_F$ phonons with the electrons near the Fermi level. In this case, through the electron–phonon interaction, the lattice is modulated

with the same wave number and the mixed wave called a charge-density wave (CDW) is formed. The resultant electronic state has a gap at the Fermi level for single electron excitations and hence becomes insulating. However, the collective CDW excitation can slide through the crystal if there are no obstacles to pin it. The corresponding Fröhlich mode was first introduced to explain the superconductivity mediated by an electron–phonon interaction. In reality, however, the free-sliding mode of the CDW is restricted by defects and by interactions between CDWs on different chains. As a result, the CDWs are pinned to form the static lattice deformation and thereby the insulating state is called the Peierls insulator.

Experimentally, the transition to the Peierls insulating phase is detected as a change in the resistivity from a metallic decrease to a nonmetallic increase on cooling and a reduction of the paramagnetic spins by free carriers (**Table 3**). The accompanying lattice modulation with a period of π/k_F is found as the superlattice, which can be detected by X-ray and neutron scatterings. The typical transition behavior was seen in TTF·TCNQ. It is noteworthy that the bond alternation in polyacetylene polymer has been ascribed to the Peierls interaction.

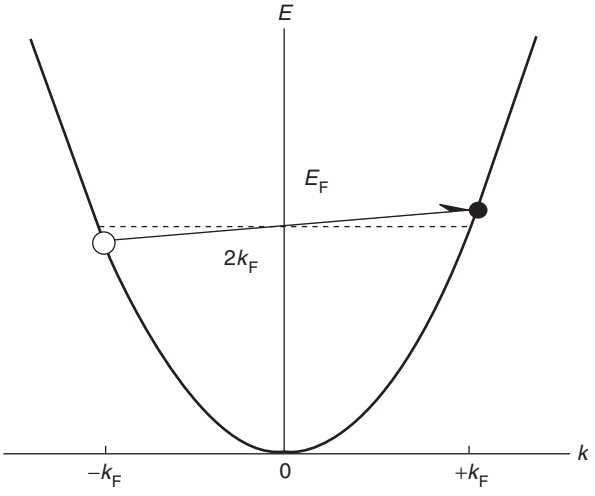

Figure 3 Interaction of $2k_F$ perturbation exciting the electron near the Fermi level E_F in a 1D metal.

For 1D metals, the Fermi surface is represented by the parallel planar sheets separated by $2k_F$: the Fermi surfaces can be superposed to the adjacent ones by a $2k_F$ shift in the momentum space. In general, when the Fermi surface can be superposed partially or entirely to the other Fermi surface by a parallel shift, it is said that the Fermi surfaces are nested. Whenever the Fermi surface has a nesting property, the electronic state becomes unstable against the density wave formation. When the electron transfer in the direction perpendicular to the 1D axis is not negligible, the planar sheets of the 1D Fermi surface can be warped to lose the nesting property, resulting in the suppression of the Peierls insulating state.

SDW State

For a metal with Fermi surfaces satisfying the nesting condition, provided that the on-site Coulomb repulsion is predominant, the SDW phase is formed by suppressing the Peierls instability. In this case, the charges distribute uniformly on the sites, while the electron spins order antiferromagnetically with a $2k_F$ periodicity. No lattice modulation accompanies the SDW, in contrast to the CDW.

The SDW transition is found in $(TMTSF)_2PF_6$ at 12 K at ambient pressure as a transition to the insulating state. The spin susceptibility decreases on the transition for a magnetic field applied parallel to the easy axis of spins, whereas it is almost unchanged for a field perpendicular to the easy axis (**Table 3**). When the field along the easy axis is increased, the metamagnetic transition with spin flip is observed. The antiferromagnetic (AF) ordering is detected by the AF resonance and also as a broadening in the NMR line shape. The AF phase in $(TMTSF)_2PF_6$ is suppressed by an application of pressure due to an increase in the transfer energy in the transverse direction of the columns. It enhances the Fermi surface warping (**Figure 2**), resulting in the depression of the nesting condition. On the suppression of the AF phase, the superconductivity phase appears in this salt. On the other hand, when the magnetic field is applied perpendicular to the most conducting plane, the transfer in the direction perpendicular to the

Table 3 Comparison of nonmetallic ground states

	Peiers state	*SDW state*	*Spin–Peierls state*	*Mott state*	*Wigner crystal*
Dimensionality	one	one	One	two/one	two/one

Lattice modulation	yes	no	Yes	no	no

NM: nonmagnetic, AF: antiferromagnetic, PM: paramagnetic.

most conducting plane is suppressed because of the confinement effect for the open orbit electrons toward the one-dimensionality, resulting in the enhancement of the SDW state and the field-induced SDW transition.

Spin-Peierls State

For the 1D metal with a half-filled band, when the adjacent spins form singlet pairs by an exchange interaction, the nonmagnetic ground state with a gap for single electron excitation, called the spin-Peierls state, is formed. In this case, the $2k_F$ lattice modulation appears to be associated with the dimerization of the spin structure. $(TMTTF)_2PF_6$ is known to show the spin-Peierls state. It has been demonstrated that, with an increase of the intercolumn interaction by pressure, $(TMTTF)_2PF_6$ undergoes a series of transitions from the spin-Peierls state, the SDW state, the superconducting state, and the normal metallic state.

Mott Insulating state

For several 2D half-filled electronic systems supposed to be metals, the electron localization takes place due to a strong on-site Coulomb interaction. When the energy of the on-site Coulomb interaction becomes greater than the transfer energy between the molecules, a transition to the so-called Mott insulating state takes place. The spins are ordered antiferromagnetically in the nonmetallic state. A typical example is found in κ-$(BEDT\text{-}TTF)_2Cu[N(CN)_2]Cl$. In this case, with an increase in the bandwidth by pressure, the metallic state is restored.

Wigner Crystal State

When the long-range Coulomb interaction works, the electrons are localized by mutual repulsion to form a Wigner lattice, even in the quarter-filled state of the 1D metal. As an example of the Wigner crystal, the formation of a $4k_F$ modulation in a 1D metal $(DI\text{-}DCNQI)_2Ag$ has been pointed out. In this case the electrons occupy half of the sites, resulting in a charge disproportionation to the sites. A similar ordering is found in the 2D electron system on the surface of superfluid He and at the semiconductor interface.

Organic Superconductors

In 1963, a model of an organic polymer superconductor possessing a high-transition temperature was proposed by W A Little. It had generated a strong interest in the development of organic superconductors. However, the superconducting organic polymer has not been synthesized to date. In 1979, superconductivity in organic materials was discovered in the Q1D charge transfer salt $(TMTSF)_2PF_6$ under pressure by the group of D Jérome and K Bechgaard. Subsequently, in 1984, the β-$(BEDT\text{-}TTF)_2I_3$ which possessed a layered structure, was found by the group of I F Schegolev and E B Yagubskii to be superconducting. This structure belongs to a second large family of organic superconductors including those with T_c exceeding 10 K. In the following, $(BEDT\text{-}TSF)_2X$ salts involving stages of interplay with magnetism, as well as the other types of exotic organic superconductors and the fullerene superconductors are presented. All known organic superconductors belong to the type-II superconductors.

TMTSF Superconductors

The charge transfer salt $(TMTSF)_2PF_6$ which showed an SDW state at ambient pressure displayed superconductivity at 1.2 K under pressure by suppressing the SDW. The pressure–temperature phase diagram has demonstrated that the SDW phase exists in proximity to the superconductivity phase, suggesting that the mechanism of the superconductivity is exotic and the pairing through a spin-fluctuation coupling is probable. The salt $(TMTSF)_2ClO_4$, showing superconductivity at ambient pressure, was experimentally useful to characterize the anisotropic nature. It showed a notable anisotropy in the critical magnetic field. The evaluated superconductivity coherence lengths are listed in **Table 4**. Although the anisotropy is obvious, even the shortest coherence length is longer than the intermolecular distance in each direction in this salt.

It is noteworthy that the size of the counter anion plays an essential role in determining the T_c of organic

Table 4 Superconductivity parameters of typical organic superconductors

Materials	T_c (K)	ξ_1 (nm)	ξ_2 (nm)	ξ_3 (nm)

T_c: transition temperature.
ξ_1, ξ_2, and ξ_3: coherence length ($\xi_1 \geqq \xi_2 \geqq \xi_3$).
[a] and [b] are derived under the assumption of $\xi_1 = \xi_2$ and $\xi_1 = \xi_2 = \xi_3$, respectively.

superconductors by working as a spacer between TMTSF molecules. The role is referred to as the chemical pressure effect, in contrast to the ordinary (physical) pressure effect. The superconductivity in organic materials shows a number of unconventional features. It is very sensitive to crystalline disorder. The alloying of TMTSF and the anion represented in the form of $(TMTSF)_{2-x}(TMTTF)_x(ClO_4)_{1-y}(ReO_4)_y$ can destroy the superconductivity with the composition of a few percent of x or y. A similar effect is caused by the radiation damage at the level of 100 ppm. The isotope effect studied by the replacement of H-atoms in TMTSF with deuterons gave a reduction in T_c too large for the pairing by the phonon mechanism. The proton NMR relaxation experiment showed the absence of the Hebel–Schlichter peak expected for isotropic pairing. All these unusual results motivated the detailed study of the mechanism of superconductivity, with special interest to a possibility of triplet pairing. In $(TMTSF)_2PF_6$, the upper critical field obtained in the applied magnetic field precisely oriented in certain crystalline directions, far exceeds the Pauli paramagnetic limit, suggesting that the superconducting pairs are not in the spin-singlet state. The NMR Knight-shift experiment on ^{77}Se asserted the lack of spin susceptibility variation on the superconducting transition, in accordance with the triplet pairing.

BEDT-TTF Superconductors

Salts of the general formula $(BEDT\text{-}TTF)_2X$ present a variety of superconductors due to the freedom in the stacking arrangement of BEDT-TTF molecules. The salt β-$(BEDT\text{-}TTF)_2I_3$ undergoes a superconductivity transition at 1.5 K at ambient pressure, while another phase, formed through the process which lets a hydrostatic pressure environment pass through, exhibits T_c of 8 K. Due to the values of their T_c, the two phases are called β_H- and β_L-type, respectively. The difference between the phases is ascribed to the presence of the incommensurate modulation in the position of the ethylene C_2H_4 fragments at the end of the BEDT-TTF molecule, accompanied by a weak potential disorder, for the β_L-type. The superconductivity is suppressed for an alloy, such as $(BEDT\text{-}TTF)_2(I_3)_{1-x}(IBr_2)_x$, with x exceeding 20%.

The κ-type salts represented by κ-$(BEDT\text{-}TTF)_2Cu(NCS)_2$, κ-$(BEDT\text{-}TTF)_2Cu[N(CN)_2]Br$, and κ-$(BEDT\text{-}TTF)_2Cu[N(CN)_2]Cl$ show typical 2D superconducting properties, where the superconducting coherence length in the direction perpendicular to the layer (**Table 4**) is short compared to the interlayer spacing (1.6, 1.5, and 1.5 nm, respectively). In these cases, the superconductivity transition is influenced by a thermal fluctuation, especially strongly under the magnetic field applied perpendicular to the superconducting plane, so that the upper critical field expected in the mean field theory cannot be determined. These 2D superconductors bear close similarity to the layered CuO_2 superconductors with respect to low carrier density, strong electron correlation, short coherence length, and proximity to the AF phase. In contrast to the CuO_2 superconductors, however, they undergo superconducting transition without doping and are characterized by weaker electron correlations. Experimental studies on the magnetic penetration depth, NMR, μSR, specific heat, thermal conductivity, electron tunneling spectroscopy, and magnetization suggest superconductivity in presence of the gap nodes. However, recently, some experiments have suggested superconductivity in the absence of the gap nodes.

BEDT-TSF Superconductors

BEDT-TSF molecules can form superconducting layers with anion layers containing the localized magnetic ion Fe^{3+} in a high 5/2-spins state as well as with nonmagnetic ions such as $GaCl_4^-$, $GaBr_4^-$, and $InCl_4^-$. The salt λ-$(BEDT\text{-}TSF)_2GaCl_4$ undergoes a superconducting transition at 6 K, while λ-$(BEDT\text{-}TSF)_2FeCl_4$ shows a transition to the AF insulating state at 8 K, after showing a similar temperature dependence of the resistivity down to the transition temperature. With the external field applied parallel to the conducting plane, λ-$(BEDT\text{-}TSF)_2FeCl_4$ is changed to be a ferromagnetic metal, and above 17 T it reveals superconductivity in the field interval up to 44 T. The reentrant superconductivity is explained in terms of the Jaccarino–Peter mechanism, in that the exchange field supplied from the magnetic ions to π-electrons is compensated by the external magnetic field to show superconductivity. In the high magnetic field applied precisely parallel to the superconducting plane, λ-$(BEDT\text{-}TSF)_2GaCl_4$ was found to show the spatially modulated order parameter phase predicted by Fulde–Ferrell and Larkin-Ovchinnikov. A similar situation was reported for κ-$(BEDT\text{-}TTF)_2Cu(NCS)_2$ and κ-$(BEDT\text{-}TTF)_2Cu[N(CN)_2]Cl$.

Alloys such as λ-$(BEDT\text{-}TSF)_2Ga_{1-x}Fe_xBr_yCl_{4-y}$ show superconductivity in a wide range of variations in x and y. This contrasts with the cases for TMTSF and BEDT-TTF superconductors which show sensitivity to disorder. The alloying varies the concentration of the magnetic ions with x and the anion volume with y. The latter, known as the chemical pressure effect, works consistently with the pressure effect.

For κ-$(BEDT\text{-}TSF)_2FeBr_4$, the AF state appearing at 2.6 K was found to remain in the superconducting state appearing at 1.1 K, resulting in the coexistence of the two phases.

Other Types of Organic Superconductors

The effort at synthesis brought about a notable variety of molecules forming superconducting salts. Unsymmetrical donors such as DMET, which is the hybrid molecule of TMTSF and BEDT-TTF, provide superconducting salts such as $(DMET)_2AuI_2$. Here, the unsymmetrical molecules in the columns are stacked alternately in direction so that the resultant assembly has a twofold symmetry. Apart from salts with a TTF-type skeleton, superconductors were found with a TTP-type skeleton such as BDA-TTP and DTEDT, among salts such as $(BDA\text{-}TTP)_2SbF_6$ and $(DTEDT)_3AuI_2$. Superconductivity was also found in materials based on the acceptor molecule $M(dmit)_2$ ($M = Ni$, Pd), and in salts such as $(TTF)[Ni(dmit)_2]_2$ and $N(CH_3)_4[Pd(dmit)_2]_2$.

A_3C_{60} Superconductors

By doping alkali metals such as K and Rb to C_{60} crystals, the superconductors K_3C_{60} and Rb_3C_{60} with T_c of 19.3 and 30 K, respectively, were synthesized. The maximum T_c reached for $RbCs_2C_{60}$ was 33 K. In these cases, the superconductivity is isotropic. The transition temperature increases with an increase in the intermolecular distance of the C_{60} molecules, which was demonstrated by the chemical pressure effect as well as the physical pressure effects by the replacement of alkali metals. A combination with ions of different valences such as alkali-earth atoms, has brought about superconductors such as Ca_5C_{60}.

Cyclotron Resonance: Metals

J Singleton, Los Alamos National Laboratory, Los Alamos, NM, USA

Introduction

Landau quantization may occur when electrons in a solid are subjected to a magnetic field. The excitation of electrons from one Landau level to another by photons results in a resonant contribution to the magnetic-field-dependent, high-frequency conductivity. It is this phenomenon that is known as "cyclotron resonance." This article is chiefly concerned with the electronic "scattering rate" τ_{CR}^{-1} that can be deduced from a cyclotron resonance experiment; this is associated with the finite energy width of the Landau

levels caused by their limited lifetime. By convention, the scattering rate is defined as the reciprocal of a notional scattering time τ_{CR}, which is sometimes also referred to as the "Landau-level lifetime." It should be noted that a simple-minded first analysis of a cyclotron resonance experiment often yields an "apparent" scattering rate, which may bear little relationship to the actual scattering processes present; it can contain contributions due to experimental factors that mask the true result. Apparent cyclotron scattering rates are distinguished throughout by using the subscript "M," which stands for "measured," hence the notation τ_{CRM}^{-1}.

Another concern is the relationship of τ_{CR}^{-1} to the "apparent" scattering rates deduced from other techniques such as de Haas–van Alphen (or Shubnikov–de Haas) oscillations (τ_{dHvA}^{-1}) and measurements of the electronic conductivity $\sigma(\tau_{\sigma}^{-1})$. It should be noted that τ_{CR}^{-1} is preferable to τ_{dHvA}^{-1} as a guide to the true energy width of the Landau levels due to scattering. It is also found that there can be considerable differences between τ_{CR} and τ_{σ}.

In order to keep the discussion as general as possible, electrons in a solid are generally referred to as "quasiparticles". This enables the descriptions that follow to encompass not only both carrier types (electrons, holes) but also systems in which effects such as electron–electron and electron–phonon interactions are significant and describable by the Landau Fermi-liquid theory.

This article deals with cyclotron resonance in metals; the most fundamental definition of a metal is "a solid with a Fermi surface." From the cyclotron resonance viewpoint, this broad class of materials must be separated into three groups:

1. metals with a high electron density, including elements such as Cu, Au;
2. intermediate electron-density systems, often of reduced dimensionality, such as crystalline organic metals and certain oxides (e.g., Sr_2RuO_4); and
3. low electron-density systems, such as degenerate semiconductors, and semiconductor heterojunctions.

The distinction between these three groups results from the ease with which light of the appropriate frequency to excite cyclotron resonance (usually in the GHz to THz range) can penetrate the sample. Hence, the rest of the article is arranged as follows. The second section presents a brief introduction to Landau quantization. The third section deals with experimental techniques for elemental metals and the extraction of true scattering rates from the apparent rate produced by fitting experimental data. Intermediate electron-density systems and degenerate semiconductors are dealt with in the fourth section; the experimental techniques and the extraction of scattering rates from data are treated in separate subsections. However, the causes of the difference between τ_{CR} and τ_{dHvA} are similar in both types of "metal," and so are treated in a common subsection. Systems containing two or more distinct types of quasiparticles are described in the fifth section; often the interactions lead to a single cyclotron resonance rather than two distinct resonances. Finally, the sixth section covers the distinctions between the effective masses measured in different experiments, and the seventh section mentions two effects closely related to cyclotron resonance.

Landau Quantization: A Brief Description

In order to gain a qualitative understanding of the principles of the various measurement techniques for cyclotron resonance, it is useful to consider the semiclassical equation of motion of a quasiparticle of charge q, energy E, and wave vector quantum number $\boldsymbol{k}$, subjected to the Lorentz force:

$$\hbar\frac{\mathrm{d}\boldsymbol{k}}{\mathrm{d}t} = q\boldsymbol{v}\times\boldsymbol{B} \qquad [1]$$

Here, $\boldsymbol{B}$ is the magnetic induction and $\boldsymbol{v}$ is the quasiparticle's velocity, defined as

$$\boldsymbol{v} = \frac{1}{\hbar}\nabla_{\boldsymbol{k}}E(\boldsymbol{k}) \qquad [2]$$

where $\nabla_{\boldsymbol{k}}$ is the gradient operator in k-space. Equations [1] and [2] imply that (1) the component of $\boldsymbol{k}$ parallel to $\boldsymbol{B}$ is constant; and (2) $\mathrm{d}\boldsymbol{k}/\mathrm{d}t$ is perpendicular to $\nabla_{\boldsymbol{k}}E(\boldsymbol{k})$. This means that the quasiparticle path is one of constant energy.

The Fermi surface is of course a surface of constant energy. Under the action of a magnetic field, quasiparticles on the Fermi surface remain on that surface while moving on paths which lie in planes perpendicular to the magnetic field (see **Figure 1**). The band

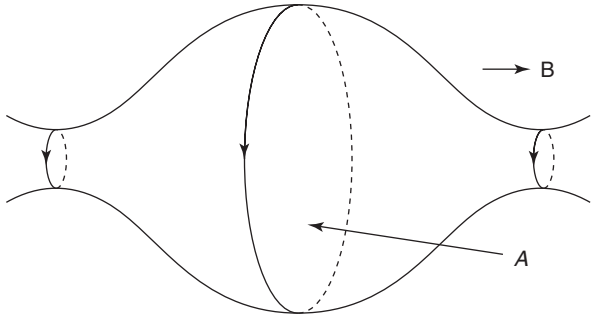

Figure 1 Orbits on a Fermi surface section are in planes perpendicular to $\boldsymbol{B}$. Here, A represents the k-space cross-sectional area of the orbit. The two orbits shown are "extremal" orbits.

structure of solids is such that in many cases, a constant energy path of this kind forms a closed orbit (or "cyclotron orbit") of cross-sectional area (in k-space) A (**Figure 1**). Standard texts (such as those by Ashcroft and Mermin or Singleton) show that the angular frequency ω_c associated with this periodic orbit is

$$\omega_c = \frac{qB}{m^*_{CR}} \quad [3]$$

where

$$m^*_{CR} = \frac{\hbar^2}{2\pi}\frac{\partial A(E, k_\parallel)}{\partial E} \quad [4]$$

The quantity defined in eqn [4] is known as the cyclotron mass or cyclotron effective mass.

From a quantum-mechanical viewpoint, the cyclotron orbital motion corresponds to the quantization of the quasiparticle's motion in the plane perpendicular to $\boldsymbol{B}$, resulting in an energy spectrum

$$E(\boldsymbol{B}, k_\parallel) = (l + \tfrac{1}{2})\hbar\omega_c + E(k_\parallel) \quad [5]$$

Here, l is an integer $(l = 0, 1, 2, \ldots)$ known as the Landau quantum number, and $E(k_\parallel)$ is the energy associated with the unaffected wave vector $k_\parallel$ in the direction parallel to $\boldsymbol{B}$. The quantization of the quasiparticle's energy in the plane perpendicular to $\boldsymbol{B}$ is known as "Landau quantization," and the energy levels defined by l are called "Landau levels."

Cyclotron resonance occurs when a photon promotes a quasiparticle from a full state in one Landau level to an empty state in another Landau level. Owing to the fact that photons of the appropriate energy carry very little momentum, such transitions conserve $k_\parallel$. Hence, cyclotron resonance occurs when the photon energy ($h\nu$ or $\hbar\omega$) corresponds to multiples of $\hbar\omega_c$.

Cyclotron Resonance in Elemental Metals

Experimental Considerations

The field components of electromagnetic radiation decay with distance z into a conducting material as $\exp(-z/\delta)$, where $\delta = \left(\frac{1}{2}\sigma\omega\mu_r\mu_0\right)^{-1/2}$ is the skin depth or anomalous skin depth; here σ is the conductivity of the material, $\mu_r\mu_0$ is its permeability, and ω is the angular frequency of the radiation. Metals have rather

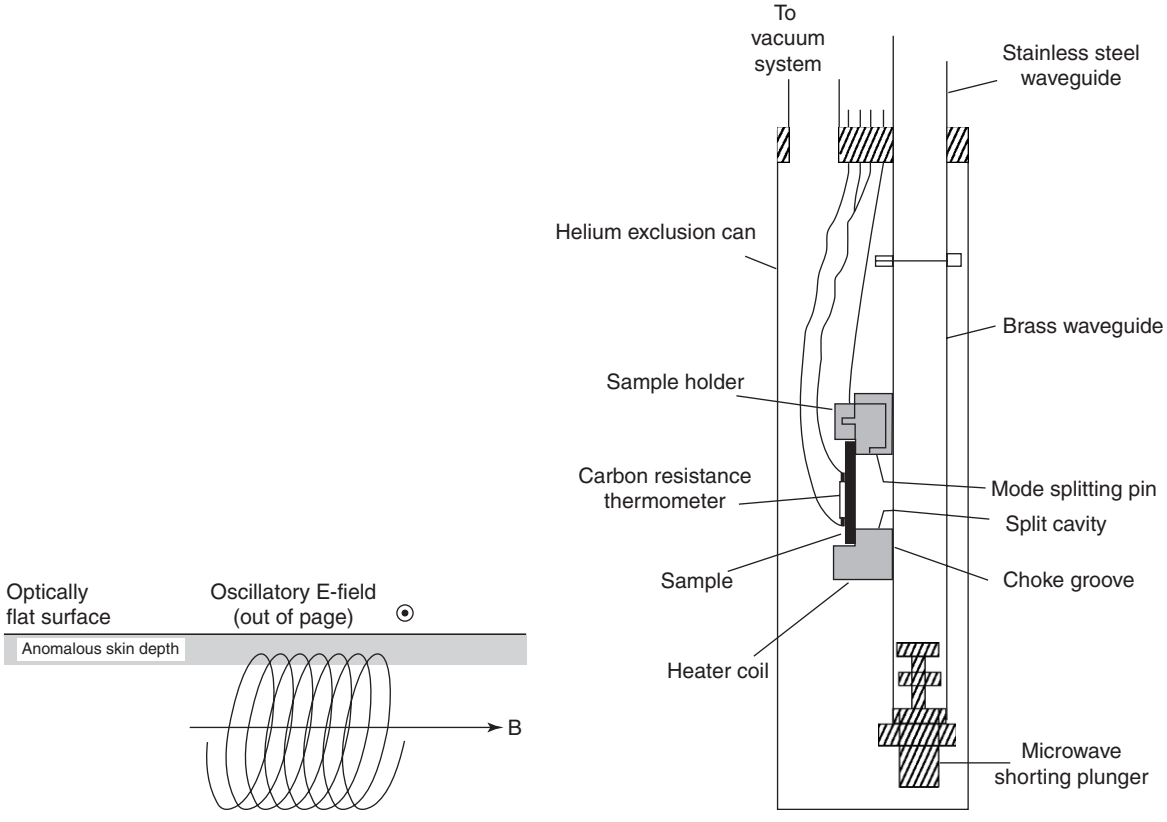

Figure 2 Left: geometry of a cyclotron resonance experiment in a metal. The shaded region indicates the skin depth for the radiation; the helical orbits of the electrons are shown schematically (from Singleton J, *Band theory and electronic properties of solids* (Oxford University Press, 2001), chapter 8). Right: a practical implementation of the Azbel'–Kaner technique. The sample acts as one wall of a microwave resonant cavity; the whole apparatus is immersed in a liquid helium dewar which sits inside an iron-yoked electromagnet. (Modified from Häussler P and Welles SJ (1966) *Physical Review B* 152: 675.)

high conductivities; moreover, typical effective masses in metals combined with the magnetic fields readily available in laboratories have meant that frequencies $\omega/2\pi \sim 1 - 100$ GHz have tended to be applied in cyclotron resonance experiments. This combination of factors results in a small skin depth; hence, radiation cannot penetrate far into the crystal. These considerations dictate the geometry of the cyclotron resonance measurement (see **Figure 2**); such a configuration is often referred to as the Azbel'–Kaner geometry.

The magnetic field is applied parallel to the surface of the crystal, which is placed in the region of an oscillating electric field in a resonant cavity; the E-field $\boldsymbol{E}$ of the radiation is arranged to be perpendicular to the quasistatic magnetic field $\boldsymbol{B}$ and parallel to the surface. Examination of eqns [1] and [2] shows that the projection of an electron's real-space orbit in a plane perpendicular to $\boldsymbol{B}$ is the same shape as its k-space orbit rotated by $\pi/2$ radians. The paths of electrons on closed Fermi surface orbits are therefore helices with axes parallel to $\boldsymbol{B}$ in real space.

If the angular frequency of the radiation $\omega = j\omega_c$, where j is an integer, then the electrons on a helical path corresponding to the cyclotron frequency ω_c will receive a "kick" from the radiation's electric field every time they come within a skin depth of the surface; this results in absorption of energy. Usually, ω is kept constant and the field is swept, so that absorptions, seen as resonances in the surface impedance, are uniformly spaced in $1/B$ (see **Figure 3**).

Extraction of Scattering Rates

Lindholm and Le Page and others have demonstrated that a magnetic field which is very accurately parallel to a very flat sample surface is required for a successful measurement; if this is not the case, the helical electron paths drift in and out of the skin depth, causing a smearing of the features in the surface impedance. If the surface is flat, and the magnetic field is accurately parallel to it, then the surface impedance Z becomes

$$Z \propto \frac{e^{i\pi/3}}{s} \qquad [6]$$

with

$$s^3 \approx \sum_j p_j R(\lambda_j) + R_{NR} \qquad [7]$$

to reasonable accuracy. Here, the index j labels the various Fermi surface orbits involved; in practice, it is found that only "extremal orbits" make a significant resonant contribution. Extermal orbits are defined by $dm^*_{CR}/dk_{\parallel} = 0$; frequently, these are just the maximum- and minimum-area closed orbits for a particular direction of the magnetic field (see **Figure 1**.) In such regions, a large number of electrons have almost identical masses (and thus almost identical ω_c), providing a large contribution to Z. The term R_{NR} encompasses nonresonant processes, whilst the resonant contributions are described by the function λ_j:

$$\lambda_j = 2\pi\frac{\omega}{\omega_{cj}}\left(\frac{1}{\omega\tau_{j\mathrm{CRM}}} + i\right) \qquad [8]$$

Note that a cyclotron frequency ω_{cj} and an apparent scattering time $\tau_{j\mathrm{CRM}}$ have been identified for the jth orbit. As long as the electronic dispersion relationship is nearly parabolic close to the Fermi surface, $R(\lambda_j)$ takes the simple form:

$$R(\lambda_j) = \frac{1}{1 - e^{-\lambda_j}} \qquad [9]$$

In practice, the sample orientation is chosen so that only one or two extremal orbits are possible, simplifying the features observed in Z; an example is shown in **Figure 3**.

The above expressions for Z have been used to fit experimental data under a variety of valid approximations; typical examples are given by Lindholm and Le Page, and Häussler and Wells and references therein. It is found that the apparent scattering time $\tau_{j\mathrm{CRM}}$ encompasses several contributions:

$$\frac{1}{\tau_{j\mathrm{CRM}}} = C_{msj}\omega + C_{srj}\omega^{1/3} + \frac{1}{\tau_{impj}} + \frac{1}{\tau_{phononj}} + \frac{1}{\tau_{e-ej}} \qquad [10]$$

The first two terms on the right-hand side of eqn [10] are due to the so-called "mass spread" ($C_{msj}\omega$) and the effects of surface roughness ($C_{srj}\omega^{1/3}$). The former term has the following origin; as has been mentioned above, the resonance spectrum is dominated by extremal orbits about the Fermi surface, defined by $dm^*_{CR}/dk_{\parallel} = 0$. In such regions, a large number of electrons have almost identical masses (and thus almost identical ω_c), providing a large contribution to Z. The fact that higher derivatives of m^*_{CR} do not vanish in real Fermi surfaces causes "mass-spread"; a distribution of cyclotron frequencies leads to a smearing of the resonant features which at first sight looks as though it is due to scattering. This effect is represented by the term $C_{msj}\omega$ in eqn [10].

Because both the mass-spread and surface roughness terms consist of a constant times ω raised to a small power, they may be distinguished from the other (frequency-independent) contributions by measuring the surface impedance at more than one frequency.

The last three (frequency-independent) terms in eqn [10] are caused by the actual scattering mechanisms; their sum is τ^{-1}_{CRj}. A weighted average of all of

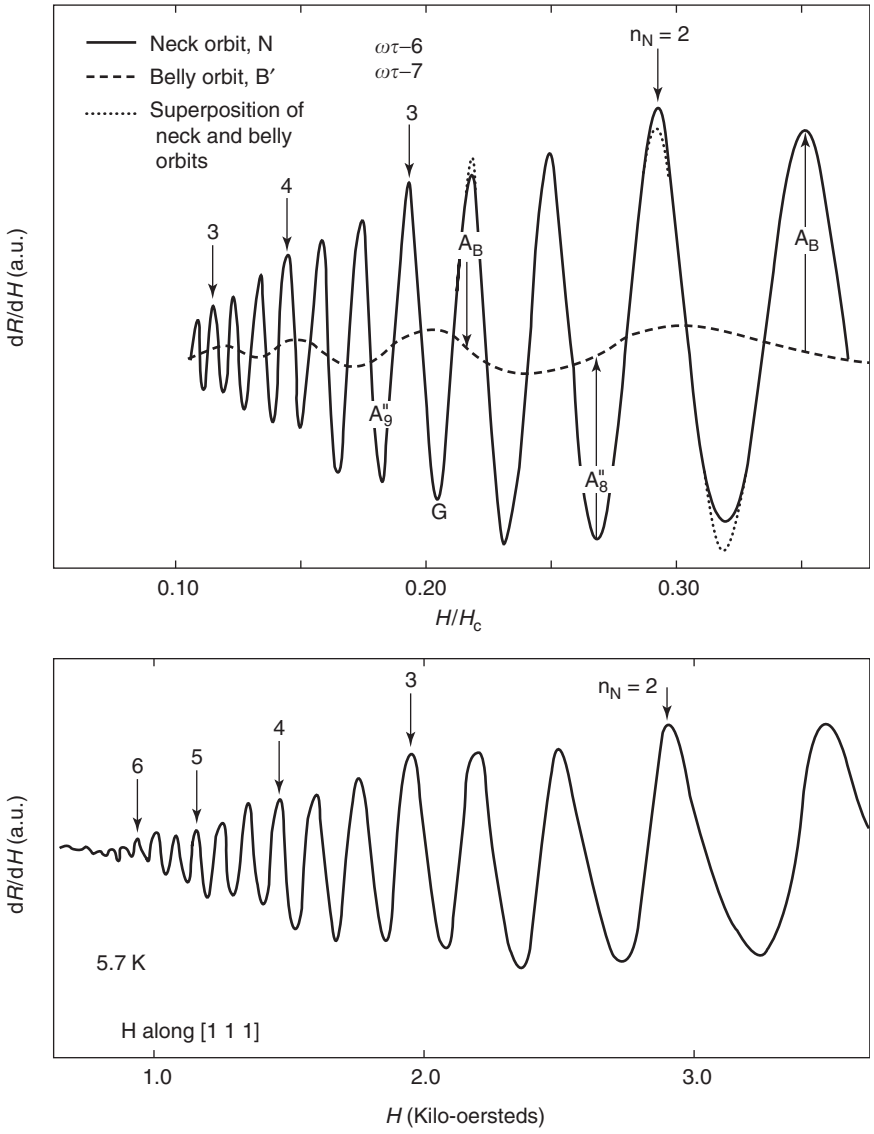

Figure 3 Combined cyclotron resonance signals from extremal belly orbits B' and neck orbits N in copper; the field is in the [1 1 1] direction. The upper curve is a theoretical simulation that shows the two contributions separately (dashed and dotted curves) and combined (solid curve). The lower part of the figure shows experimental data. The fortuitous factor of 3 between the cyclotron periods of the two orbits facilitates separation of the two contributions. (After Hässler P and Welles SJ (1966) *Physical Review B* 152: 675.)

the electron-impurity scattering processes leads to the term $\tau_{\text{imp}j}$, whilst $\tau_{\text{phonon}j}$ and $\tau_{\text{e}-\text{e}j}$ are due to electron–phonon scattering and electron–electron scattering events, respectively. The three terms may be distinguished by observing their temperature dependences:

$$\frac{1}{\tau_{\text{imp}j}} = \text{constant}, \qquad \frac{1}{\tau_{\text{phonon}j}} \propto T^3 \quad \text{and} \quad \frac{1}{\tau_{\text{e}-\text{e}_j}} \propto T^2 \qquad [11]$$

The origins of the temperature power laws for these mechanisms are dealt with in standard texts such as Ashcroft, Mermin, and Singleton.

Layered Metals and Degenerate Semiconductor Systems

Layered Metals: Experimental Considerations

Fermi surfaces and resonant cavity techniques There has been great recent interest in layered materials, as there are many correlated-electron systems which have very anisotropic electronic band structure. Examples include crystalline organic metals and superconductors, the "high-T_c" cuprates, and layered ruthenates and manganites. In the context of the current discussion, such systems have two distinctive features.

1. Typically, their quasiparticle densities are rather lower than those in elemental metals; hence, their

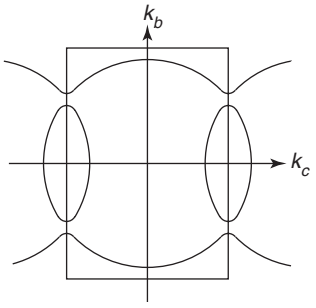

Figure 4 Brillouin zone and Fermi surface of κ-(BEDT-TTF)$_2$Cu(NCS)$_2$, showing the open, quasi-one-dimensional sections, and the closed, quasi-two-dimensional pocket. (Modified from Singleton J (2000) *Reports of Progress in Physics* 63: 1111.)

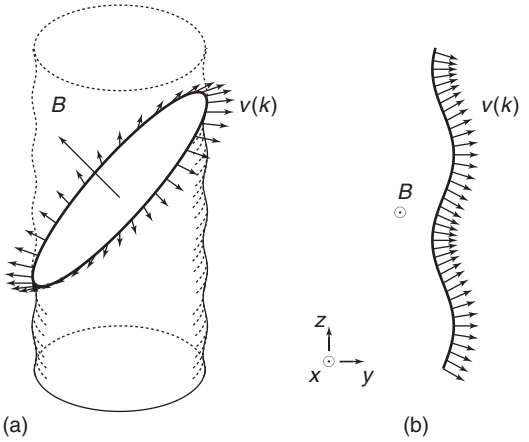

Figure 5 (a) Schematic side view of the warping (corrugation) of a closed section of a Fermi surface caused by finite interplane transfer integrals. The arrows indicate the velocities of a quasiparticle following a closed orbit about the Fermi surface in a plane perpendicular to the magnetic field ***B***. (b) An open section of the Fermi surface. In an in-plane magnetic field, quasiparticles are driven across the Fermi surface, so that their velocities (shown by arrows) rock from side to side. (After Singleton J (2000) *Reports of Progress in Physics* 63: 1111.)

skin depths tend to be larger, and the effects of screening are reduced.

2. These systems may often be described by a tight-binding Hamiltonian in which the ratio of the interlayer transfer integral $t_\perp$ to the average intralayer transfer integral $t_\parallel$ is $\ll 1$. This results in very anisotropic electronic properties.

Figure 4 shows the cross section of the Fermi surface of a typical example, the organic superconductor κ-(BEDT-TTF)$_2$Cu(NCS)$_2$, parallel to the highly conducting planes. The Fermi surface consists of both open and closed sections; it is customary to label such sections "quasi-one-dimensional" and "quasi-two-dimensional," respectively. The names arise because the Fermi surface is a surface of constant energy, and so eqn [2] shows that the velocities of quasiparticles at the Fermi surface will be directed perpendicular to it. Therefore, referring to **Figure 4**, quasiparticles on the closed Fermi surface pocket can possess velocities which point in any direction in the (k_b, k_c) plane; they have freedom of movement in two dimensions and are said to be quasi-two-dimensional. By contrast, quasiparticles on the open sections have velocities predominantly directed parallel to k_b and are quasi-one-dimensional.

Thus far, only a cross section is considered through the Fermi surface parallel to the highly conducting planes (**Figure 4**). In the interlayer direction (also known as the interplane direction), the dispersion is very small, due to the small interlayer transfer integrals. For the purpose of this discussion, the quasiparticle dispersion is written as

$$E(\boldsymbol{k}) = E(k_x, k_y) - 2t_\perp \cos(k_z d) \qquad [12]$$

where k_x (and k_y) and k_z are the components of the wave vector parallel (k_x, k_y) and perpendicular (k_z) to the conducting planes, and $t_\perp$ is again the interlayer transfer integral. The presence of dispersion in the interlayer direction results in a slight warping of the Fermi surface, shown schematically for a closed pocket in **Figure 5a**.

As before, when a magnetic field is introduced, eqns [1] and [2] indicate that the k-space path of the quasiparticle is defined by the intersections of surfaces of constant energy with planes perpendicular to ***B***. Therefore, for almost all directions of the magnetic field, quasiparticles on the closed sections of the Fermi surface will be able to complete the closed k-space orbits in the plane perpendicular to ***B*** (see **Figure 5a**); in contrast, the quasiparticles on quasi-one-dimensional sections of the Fermi surface will not complete the closed orbits (see **Figure 5b**).

The experimental detection of cyclotron resonance depends on the effect that the quasi-particle paths have on the high-frequency conductivity. Equation [2] shows that the quasiparticle velocity must always be perpendicular to the Fermi surface. Hence, as the quasiparticles traverse the orbits shown in **Figure 5a** and **5b**, the corrugations of the Fermi surface cause their velocity vectors to rock back and forth. It is the evolution of the quasiparticle velocities with time that affects the conductivity of the system, and thus enables cyclotron resonance to be detected. Cyclotron resonance is of course associated with the closed orbits of **Figure 5a**; the open orbits shown in **Figure 5b** lead to a related resonant contribution to the high-frequency magnetoconductivity, known as a Fermi surface

traversal resonance (FTR) (see the "Further reading" section for more information on FTRs).

As mentioned above, the low electron densities of these materials compared to those in typical elemental metals result in a larger skin depth; hence, with careful planning, an experiment can be arranged in which a substantial fraction of a typical crystalline sample (volume ~ 0.01–$0.1\,\mathrm{mm}^3$) can be penetrated by radiation with frequencies ~ 10–$100\,\mathrm{GHz}$. Therefore, the experimental response is typically much more determined by the frequency-dependent bulk conductivity, rather than the surface impedance.

The evolution of the quasiparticle's velocity can be related to its contribution to the frequency-dependent conductivity of the metal using the frequency-dependent Boltzmann transport equation (also known as the Chambers equation):

$$\sigma_{ij}(\omega) = \frac{e^2}{4\pi^3} \int \mathrm{d}^3k \left[-\frac{\partial f_0(\boldsymbol{k})}{\partial E(\boldsymbol{k})}\right] v_i(\boldsymbol{k}, 0) \int_{-\infty}^{0} v_j(\boldsymbol{k}, t) \times \cos(\omega t) \mathrm{e}^{t/\tau}\, \mathrm{d}t \qquad [13]$$

Here, τ is the relaxation time (not necessarily the same as τ_{CR}), $v_i(\boldsymbol{k}, t)$ is the ith component of the velocity of a quasiparticle with wave vector $\boldsymbol{k}$ at time t, and $f_0(\boldsymbol{k}) = (\mathrm{e}^{(E(\boldsymbol{k})-E_{\mathrm{F}})/k_{\mathrm{B}}T} + 1)^{-1}$ is the Fermi function. This is an integral (over all states at the Fermi surface) of the velocity–velocity correlation function for each Fermi surface orbit.

The mechanism for detecting cyclotron resonance can be understood by examining **Figure 5a**. For a general direction of the magnetic field (as shown in **Figure 5**), the corrugations of the Fermi cylinder will cause a quasiparticle's interplane (z) velocity to acquire an oscillatory component as it is driven round an orbit about the Fermi cylinder. These oscillatory interplane velocities contribute at a particular frequency (and, perhaps, its harmonics) to eqn [13]; hence they are detectable as resonances in the high-frequency interplane conductivity $\sigma_{zz}(\omega)$.

Note that if the corrugations are not exactly perpendicular to the cylinder axis, then even a magnetic field parallel to the cylinder axis (i.e., in the interplane z-direction) will induce an oscillatory interplane component of the quasiparticle velocity and hence a resonant response in σ_{zz}. This resonant response in σ_{zz} occurs at integer harmonics of the cyclotron frequency, $j\omega_{\mathrm{c}}$; these can be caused both by the orbit traversing j corrugations or by the presence of nonsinusoidal corrugations.

In addition, Nam *et al.* proposed a mechanism for cyclotron resonance harmonics in the intraplane high-frequency conductivity components σ_{xx} and σ_{yy}; this results from Fermi surface cross sections that are nonelliptical. Unless the Fermi surface lacks inversion symmetry, this mechanism generates only odd harmonics. Both types of cyclotron resonance mechanisms with their attendant harmonics were reported by Rzepniewski *et al.* in the layered perovskite Sr_2RuO_4.

Cyclotron resonance in such materials is observed using millimeter-wave cavity perturbation techniques such as those described by Schrama *et al.* and Mola *et al.* (see **Figure 6**). Such measurements probe the bulk conductivity properties of anisotropic conductors. Changes in the dissipation of the cavity (Q-factor) are measured as a function of an external quasistatic magnetic field $\boldsymbol{B}$ with the millimeter-wave frequency ν held constant. It is assumed that changes in the dissipation of the cavity are due to changes in the dissipation of the sample inside.

The sample is placed in the cavity such that the millimeter-wave magnetic field $\boldsymbol{H}_{\mathrm{osc}}$ is polarized parallel to the sample's highly conducting planes (perpendicular to the c-axis) (see **Figure 6**). The response of an anisotropic conductor in this electromagnetic environment is understood by examining the polarizations of the currents induced in the sample by $\boldsymbol{H}_{\mathrm{osc}}$. For $\boldsymbol{H}_{\mathrm{osc}}$ parallel to the (a, b) plane (the highly conducting plane), both in-plane and interlayer currents are induced (**Figure 6**). These currents flow within a distance $\sim\delta$ (here δ is the skin depth) from the sample's edges and faces (**Figure 6b**). The in-plane ($\delta_{\parallel}$) and interlayer ($\delta_{\perp}$) skin depths give information about σ_{zz} and a combination of σ_{xx} and σ_{yy}, respectively.

Extraction of the apparent scattering rates in layered metals As described by Schrama *et al.* and Mola *et al.*, changes in the Q-factor of the resonant cavity can be related via the skin depths to changes in the components of the sample's conductivity tensor. Generally, the most reliable method of extracting the apparent scattering time is to fit the high-frequency conductivity directly (see **Figure 7**); for example, McKenzie suggests an interlayer conductivity

$$\frac{\sigma_{zz}(\omega)}{\sigma_{zz}(\omega = 0)} = \sum_{-\infty}^{\infty} \frac{[J_j(k_{\mathrm{F}} c \tan\theta)]^2}{1 + (\omega - j\omega_{\mathrm{c}} \cos\theta)^2 \tau_{\mathrm{CRM}}^2} \qquad [14]$$

for layered materials with weak interlayer coupling that has been successfully applied to organic conductors. Here, j is an integer, J_j is the jth Bessel function, c is the interlayer lattice spacing, k_{F} is the Fermi wave vector, and θ is the angle between the magnetic field and the normal to the conducting planes. Note that the apparent scattering time τ_{CRM} is always a fit parameter in such methods.

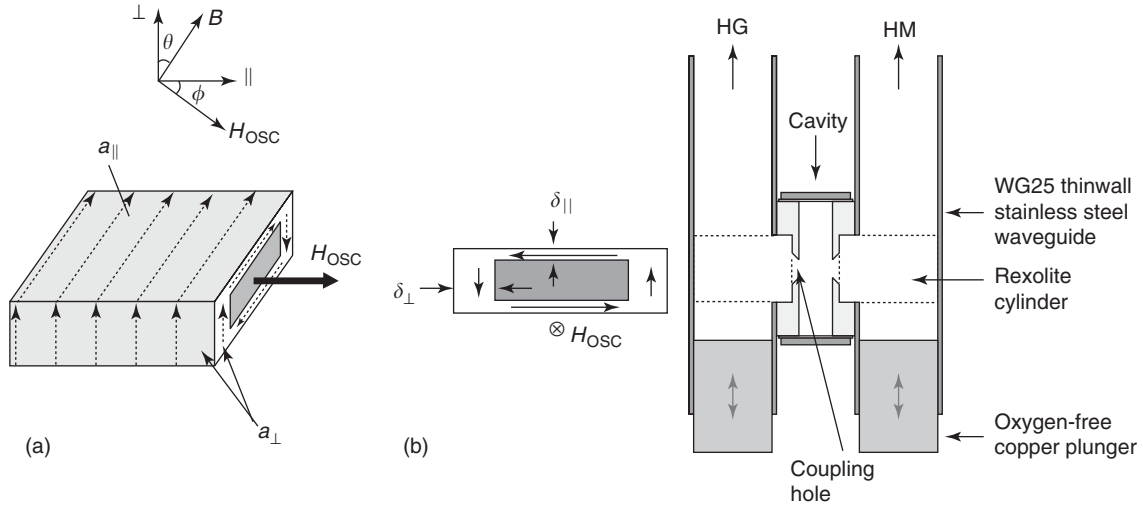

Figure 6 Experimental configuration for cyclotron resonance in a layered metal. Left: (a) the sample is placed in the cavity with the oscillating millimeter-wave field $\boldsymbol{H}_{osc}$ in the highly conducting planes ($\parallel$ direction). (b) Both in-plane and interplane oscillating currents J_{osc} are induced. In the skin-depth regime, in-plane currents flow within a surface layer of thickness $\delta_{\parallel}$ parallel to large sample faces, and interplane currents flow within a thicker layer $\delta_{\perp}$ parallel to sample edges. Right: schematic of the vertical cross section of a rectangular cavity that can be used for cyclotron resonance measurements of a layered metal. The cavity is placed between two waveguides that lead to the source (HG) and detector (HM). The cavity is held in this position by two Rexolite cylinders of 3 mm diameter which are fitted in the recessed area around the coupling holes and which extend through the holes (3 mm diameter) in the waveguides. The sample is placed on a thin mylar film in the cavity center, in the *H*-field antinode of the TE_{102} mode of the cavity. The advantage of such a cavity system is that it allows the cavity and the sample to be rotated in the vertical quasistatic magnetic field (provided by either a superconducting or a Bitter magnet); because the cavity rotates, the sample remains in the same high-frequency electrodynamic environment. Hence, the magnetic-field-orientation dependence of the cyclotron resonance can be studied (the mechanism for rotating the cavity has been omitted for clarity). (Modified from Schrama JM, *et al.* (2001) *Journal of Physics*: *Condensed Matter* 13: 2235.)

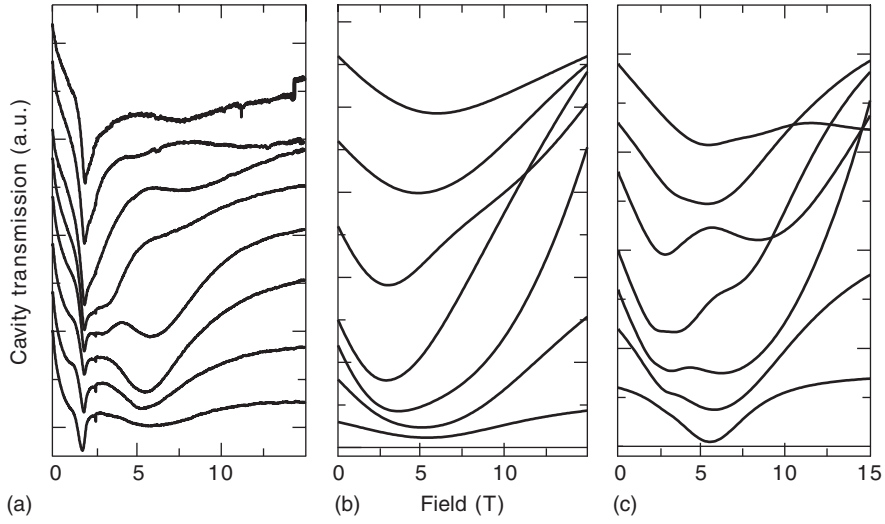

Figure 7 (a) Cyclotron resonance data for the quasi-two-dimensional organic conductor β''-(BEDT-TTF)$_2$$SF_5CH_2CF_2SO_3$. The data are in the form of cavity transmission versus magnetic field; the frequency of the measurement is 71 GHz, and the temperature is 1.5 K. Field sweeps for several orientations θ of the cavity and sample in the quasistatic field are shown (see **Figure 6**); $\theta = 0$ corresponds to the field being perpendicular to the highly conducting planes of the sample. The sharp slope downwards and small minimum at low fields are associated with the superconducting-to-normal transition of the sample and a background feature in the cavity response. The small sharp feature is the conduction-electron spin resonance of the sample. The cyclotron resonances are the broader features at higher fields. (b) A model of the data using eqn [14] with k_F calculated for this particular sample orientation and $\tau_{CRM} = 1.22 \times 10^{-12}$; the latter value was derived from a simple treatment (see eqn [16]) of Shubnikov–de Haas oscillations from the same sample. Note how the predicted resonances are too broad. (c) A repeat of (b) for $\tau = 7 \times 10^{-12}$ s; note how the predicted resonance widths are similar to the experimental ones. All figures are for θ between 0° and 70° in 10° steps. (Modified from Singleton J and Edwards RS (2003) In: Herlach F and Miura N (eds.) *High Magnetic Fields*, *Science and Technology*, vol. 2, 85 pp. Singapore: World Scientific.)

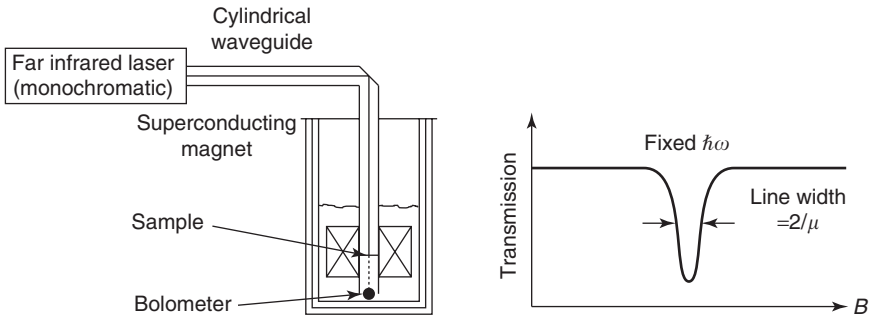

Figure 8 Schematic of a cyclotron resonance experiment in a semiconductor.

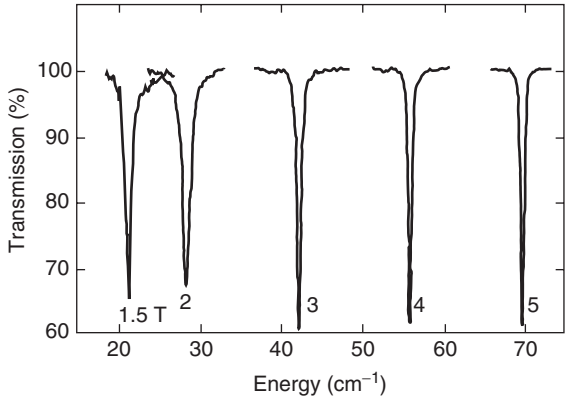

Figure 9 Cyclotron resonances in a GaAs-(Ga,Al)As heterojunction at $T = 4.2\,\mathrm{K}$; the magnetic field has been applied perpendicular to the two-dimensional electron layer, which has an areal carrier density of $\sim 9 \times 10^{10}\,\mathrm{cm}^{-2}$. The data have been recorded by fixing the magnetic field at 1.5, 2, 3, 4, and 5 T; at each field, a Fourier-transform spectrometer has been used to record the transmission of the sample as a function of energy. (Data from Wiggins G, University of Oxford.)

Cyclotron Resonance in Semiconductors

Experimental details The number densities of carriers in semiconductor samples are much lower than those in metals, so that the radiation can completely penetrate even large samples. A simple transmission arrangement is usually adopted (see **Figure 8**). The cyclotron resonance is usually recorded by measuring the sample transmission; experiments are carried out either by fixing the magnetic field and varying the energy of the radiation (see **Figure 9**), or by using a fixed-frequency source (such as a far-infrared laser, which can give a number of monochromatic laser lines in the wavelength range 40–1000 μm) and sweeping the magnetic field (see **Figure 8**).

The magnetic field is usually provided by a superconducting magnet ($B = 0$ to $\sim 20\,\mathrm{T}$). As the whole of the cyclotron orbit experiences the electric field of the radiation (cf. the situation in metals; see above), the quantum-mechanical selection rule for the Landau-level quantum number ($\Delta l = \pm 1$) holds. Thus, the resonance condition is

$$h\nu \equiv \hbar\omega = \hbar\omega_c = \frac{eB}{m^*_{CR}} \qquad [15]$$

where $\nu(\omega)$ is the frequency (angular frequency) of the radiation.

As stated earlier, the degenerate semiconductor systems (e.g., heterojunctions) are dealt with in the first section. In such samples, free carriers are present even at low temperatures; typical cyclotron resonance data are shown in **Figure 9**. However, it is worth mentioning that in lightly doped samples, the carriers must be excited into the bands by either raising the temperature to cause the impurities to ionize (but not so far as to broaden the Landau levels) or by additionally illuminating the sample with above bandgap radiation.

Extraction of apparent scattering times in semiconductor systems In some situations where both the scattering time (or mobility) and the density of the carriers are low (e.g., bulk degenerate semiconductors), the measured line width of the cyclotron resonance can give information about the true scattering rate τ^{-1}_{CR} directly. Via the uncertainty principle, the scattering induces a frequency uncertainty $\Delta\omega_c \sim \tau^{-1}_{CR}$. If the experiment is a fixed-frequency, swept-field one, this translates to an uncertainty (that is, resonance width) in magnetic field of $\Delta B = \Delta\omega_c m^*_{CR}/q \sim m^*_{CR}/q\tau_{CR}$. Provided that $m^*_{CR} \approx$ the effective mass for linear motion (and this is often true in direct-gap semiconductors such as GaAs), it is apparent that ΔB is of the order of the reciprocal of the carrier mobility. More precise derivations show that the full-width at half-maximum is in fact twice the reciprocal of the mobility.

However, in systems such as GaAs-(Ga, Al)As heterojunctions, where both the scattering time (or mobility) and the equivalent three-dimensional carrier density in the two-dimensional layer are relatively

large, there is a very marked contribution to the cyclotron resonance line width due to the impedance mismatch between the vacuum and the carriers. The effect is illustrated in **Figure 10**; often this "mismatch" contribution to the line width eclipses that due to scattering. The problem can be ameliorated by evaporating a surface metallic layer of carefully chosen thickness on the sample (see, for example, the paper by Watts *et al.* in the literature list), but the most reliable method to extract the apparent scattering rate is to perform a full modeling of the transmission or reflectivity of the sample, as carried out in **Figure 10**.

Contributions to the Apparent Scattering Rate in Layered Metals and Semiconductor Heterostructures

Comparisons with other methods A measure of the scattering rate in metallic systems is often derived from the rate at which magnetic quantum oscillations (such as de Haas–van Alphen oscillations) grow in amplitude with the increasing magnetic field; the dominant term in the Lifshtiz–Kosevich formula (see, e.g., the book by Shoenberg in the Further reading section) describing this phenomenon is $\exp[-14.7m\ \mathrm{CR}^*\ T_\mathrm{D}/B]$ (SI units). The constant describing the phase smearing of the oscillations due to Landau-level broadening is the so-called Dingle temperature, T_D.

If one were to assume that T_D is solely due to scattering (i.e., the energy width of the Landau levels detected by the de Haas–van Alphen effect is associated only with their finite lifetime due to scattering), then T_D would be related to the scattering rate τ_dHvA^{-1} by the expression

$$T_\mathrm{D} = \frac{\hbar}{2\pi k_\mathrm{B}\tau_\mathrm{dHvA}} \qquad [16]$$

In many experimental works, it is assumed that the τ_dHvA deduced from T_D in this way is a true measure of the scattering rate; it will be noted shortly that it is not!

Another measure of the scattering rate can be found by measuring the zero-magnetic-field electrical conductivity; in layered systems, one must be careful to ensure that this is the intralayer component of the conductivity. If there is a dominant single carrier type of known density n, then the Drude expression $\sigma = nq^2\tau_\sigma/m^*$ can be used to estimate τ_σ. It is universally found that $\tau_\sigma \geqslant \tau_\mathrm{dHvA}$; in some cases such as semiconductor heterojunctions, τ_σ can be one to two orders of magnitude greater than τ_dHvA.

Finally, if these scattering times are compared with the τ_CRM deduced from cyclotron resonance experiments, the following is found:

$$\tau_\sigma \geqslant \tau_\mathrm{CRM} \geqslant \tau_\mathrm{dHvA} \qquad [17]$$

For some layered metals (see, e.g., the work of Hill in "Further reading" section), the τ_CRM measured in

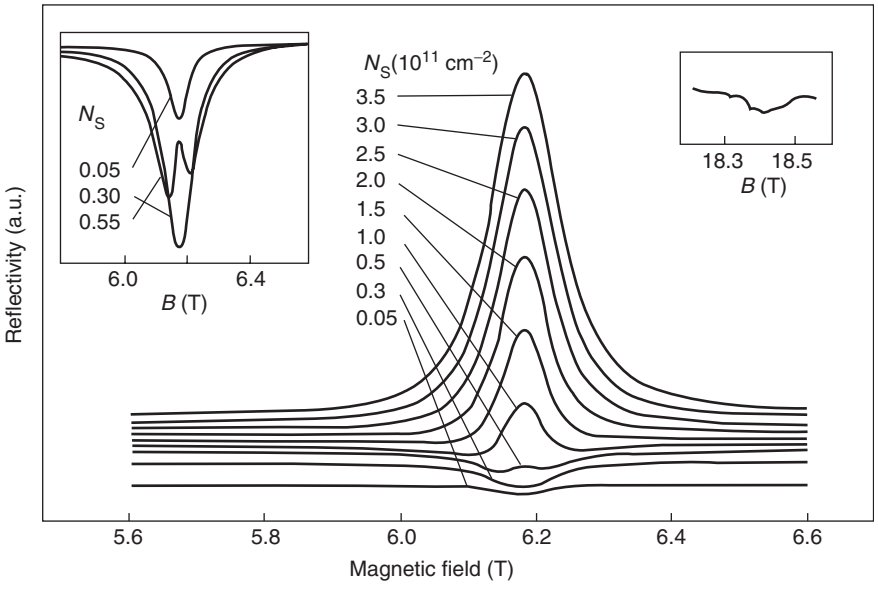

Figure 10 Model calculations for the reflectivity of a GaAs-(Ga,Al)As heterojunction at a photon energy $\hbar\omega = 10.43$ meV for several values of the areal electron density N_s; each calculation is displaced vertically for clarity. The cyclotron resonance shows up as a dip in the reflectivity signal at low N_s but becomes a peak at higher carrier densities. Note that although the scattering rate is kept constant ($\tau = 10.6$ ps), the full-width at half-maximum of the resonance grows with increasing N_s. Similar effects are seen in the transmission of the sample. The left-hand inset shows an expansion of the low-density part of the main figure; the right-hand inset contains experimental data for a photon energy of 31.05 meV and $N_s = 0.3 \times 10^{11}\ \mathrm{cm}^{-2}$. (Modified from Langerak CJGM, *et al.* (1988) *Physical Review B* 38: 13133.)

cyclotron resonance has been found to be four to ten times larger than τ_{dHvA}. An example of this is shown in **Figure 7**, where the insertion of the scattering rate inferred from Shubnikov–de Haas oscillations (**Figure 7b**) into a model for the cyclotron resonance produces line widths that are much too broad. A more realistic line width is obtained with a longer scattering time (**Figure 7c**).

The importance of spatial inhomogeneities The difference between any measurement of the Landau-level broadening and the scattering rate deduced from a conductivity measurement is easy to grasp; a quasiparticle will be removed from a Landau-level eigenstate by any scattering event, small- or large-angle. Conversely, small-angle scattering events hardly affect the conductivity, because they cannot randomize a quasiparticle's excess forward momentum (see **Figure 11** and standard texts such as Ashcroft and Mermin or Singleton). In the most thoroughly studied systems of reduced dimensionality, semiconductor heterostructures, and Si MOSFETs, it is found that $\tau_\sigma \approx \tau_{dHvA}$ in systems in which large-angle scattering (e.g., due to impurities in the conducting channel) dominates. On the other hand, in systems in which small-angle scattering (e.g., due to remote impurities) is pre-eminent, $\tau_\sigma \gg \tau_{dHvA}$. Having seen this, the remaining task is to explain how two measurements of the Landau-level width (cyclotron resonance and de Haas–van Alphen effect) can yield such different answers.

The difference between τ_{CRM} and τ_{dHvA} turns out to be due to spatial inhomogeneities or potential fluctuations. Screening is less effective in systems containing low densities of quasiparticles (such as layered metals or semiconductor heterojunctions), compared to that in elemental metals; hence, variations in the potential experienced by the quasiparticles can lead to a spatial variation of the Landau-level energies (see **Figure 11**). Even in the (hypothetical) complete absence of scattering, Harrison, for example, has shown that this spatial variation would give the Landau level a finite energy width (see **Figure 11**) and therefore lead to an apparent Dingle temperature

$$T_D = \frac{\bar{x}[1-\bar{x}]F'(\bar{x})^2 a}{\pi k_B m^*}\sqrt{\frac{\hbar e^3}{2F}} \qquad [18]$$

Here, F is the magnetic-quantum-oscillation frequency, and $F' = dF/dx$; x represents the (local) fractional variation of the quasiparticle density due to the potential fluctuations and $\bar{x}$ is its mean.

The Dingle temperature measured in experiments therefore normally represents a combination of the effects described by eqns [16] and [18]. Hence, the simple-minded use of eqn [16] to yield τ_{dHvA} from T_D tends to result in a parameter that is an overestimate of the true scattering rate (see **Figure 11**). By contrast, cyclotron resonance (shown by vertical arrows in **Figure 11**) is a "vertical" transition (due to the very low momentum of the photon); it measures just the true width of the Landau levels due to scattering (represented by shading).

Summary

This has been a complicated section, with many parameters and effects to grasp. It is therefore worth giving a summary of the factors affecting

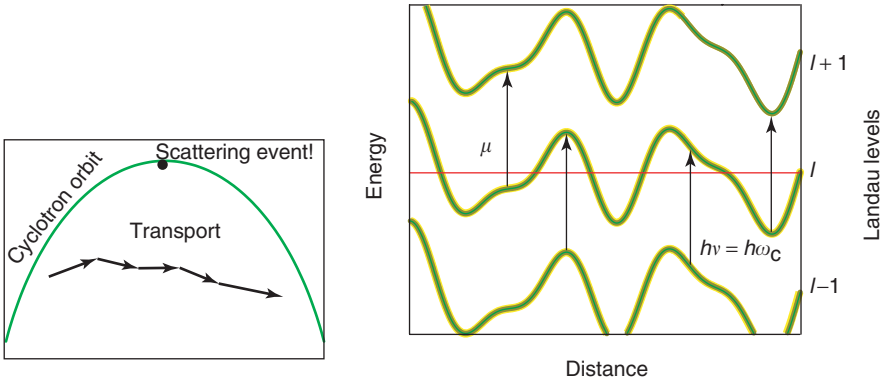

Figure 11 Left: an illustration of the difference in scattering rates in Landau quantization and electrical conductivity. Any scattering event (small- or large-angle) during the cyclotron orbit terminates that particular Landau state. By contrast, small-angle scattering is not effective at randomizing the quasiparticle's excess forward momentum in a transport (conductivity) measurement. Right: an illustration of the effect of spatial inhomogeneities on Landau-level widths and energies. The variations in the potential experienced by the electrons make the Landau levels (shaded curves) move up and down in energy as one moves through the sample. As the field is swept, the levels move up through the chemical potential μ and depopulate, resulting in the de Haas–van Alphen and Shubnikov–de Haas effects. The Dingle temperature essentially parametrizes the movement of the total energy width of a Landau level through μ; hence, it measures a width that includes the energy variation due to inhomogeneities. By contrast, cyclotron resonance (shown by vertical arrows) is a "vertical" transition; it measures just the true width of the Landau levels due to scattering (represented by shading).

measurements of the scattering rate in layered metals and degenerate semiconductor systems.

Provided a proper treatment of the sample's high-frequency magnetoconductivity is used, the scattering rate τ_{CRM}^{-1} deduced from a cyclotron resonance experiment is a good measure of the energy width of the Landau levels due to their finite lifetime. In other words, $\tau_{\mathrm{CRM}} \approx \tau_{\mathrm{CR}}$. (Once this has been realized, cyclotron resonance can be used to give quantitative details of the quasiparticle scattering mechanisms; see Further reading section for more details.)

By contrast, the apparent scattering rate deduced from a simple-minded treatment of de Haas–van Alphen and Shubnikov–de Haas oscillations can contain very significant contributions from spatial inhomogeneities.

Finally, the scattering rate τ_{σ}^{-1} measured in a zero-field conductivity experiment can be very significantly different from τ_{CR}^{-1}, because the two measurements are sensitive to different types of scattering processes.

Systems With Two Interacting Carrier Populations

Cyclotron resonance data can sometimes be difficult to interpret in systems containing two distinct quasiparticle populations that interact. An example is given by *p*-doped GaAs-(Ga,Al)As heterojunctions, containing two hole spin subbands with differing effective masses. One would expect two distinct cyclotron resonances; however, depending on the temperature, photon energy, and the field, a single resonance is frequently observed. This results from the interactions between the two types of quasiparticles; the overall energy of the system is reduced if these interactions constrain both populations to have the same cyclotron frequency.

Cole *et al*. have derived expressions for the high-frequency magnetoconductivity $\sigma(\omega)$ that can be very generally used to treat such situations; they allow the scattering rates and effective masses for each type of quasiparticle to be extracted, and also enable their interactions to be quantified.

Which Effective Mass Does a Cyclotron Resonance Experiment Measure?

Cyclotron resonance is potentially a very interesting measure of the interactions in narrow-bandwidth metallic systems. In a translationally invariant system, the mass m_{CR}^{*} measured in a cyclotron resonance experiment should not contain any contribution from the interactions between the carriers themselves; this is known as Kohn's theorem. In the language of the Fermi-liquid theory, in such a situation, cyclotron resonance measures the dynamical mass $m_{\lambda\mathrm{CR}}$, whereas a thermodynamic measurement such as the de Haas–van Alphen oscillations reveals the effective mass m^{*}, which also contains contributions from the Coulomb interactions between the quasiparticles.

A simple band-structure calculation essentially uses ions and molecules which are rigidly fixed in a perfectly periodic arrangement to obtain a periodic potential and hence the bands. However, the ions and/or molecules in a substance will in general be charged, or at the very least possess a dipole moment; as an electron passes through the solid, it will tend to distort the lattice around it owing to the Coulomb interactions between the ions and molecules and its own charge. This leads to the electron being accompanied by a strain field as it moves through the substance; alternatively, one can consider the electron being surrounded by virtual phonons. This affects the way in which the electron can move through the substance and usually acts to increase the apparent mass.

In the following, the orbitally averaged (cyclotron) mass is dealt with for consistency; other "effective masses" (e.g., for linear motion) are renormalized in an analogous way. If m_{bCR} is the cyclotron mass calculated in the band-structure calculations, then the electron–lattice interactions discussed above will result in a cyclotron dynamical mass, $m_{\lambda\mathrm{CR}}$, where

$$m_{\lambda\mathrm{CR}} \approx (1+\lambda) m_{\mathrm{bCR}} \qquad [19]$$

where λ is an electron–phonon coupling constant.

The interactions between the electrons themselves must also be taken into account. As electrons are highly charged, they repel each other; therefore, as an electron is moved across a sample under consideration by an external force, in effect there will be a backflow of electrons caused by this repulsion. Thus, it is "harder" to move electrons about than expected, that is, their apparent effective mass is heavier than $m_{\lambda\mathrm{CR}}$. The effective masses m^{*} measured in experiments such as the de Haas–van Alphen effect include this contribution from the interactions between the electrons, so that

$$m^{*} \approx \left(1 + \frac{F_{\mathrm{s}}^{1}}{3}\right) m_{\lambda} \qquad [20]$$

where F_{s}^{1} is a constant known as a Fermi-liquid parameter. (For a more detailed discussion of such effects, the reader is referred to the "Further reading" section.)

In practice, however, real systems do not possess translational invariance. Although the mass m_{CR}^{*} measured in a cyclotron resonance experiment does generally differ from that obtained from the de Haas–van Alphen effect (m^{*}), the simple expectations

of eqn [20] often do not hold; in one or two instances, m^*_{CR} was even found to be greater than m^*. Nevertheless, a comparison between a cyclotron resonance experiment and the de Haas–van Alphen effect is often a good guide to the strength of the interactions in a system.

Effects Related to Cyclotron Resonance

There are one or two effects related to cyclotron resonance that go beyond the scope of this article but which should nevertheless be mentioned for completeness. One is "surface cyclotron resonance," an effect due to excitation of quasiparticles between levels caused by crossed electric and magnetic fields at the surface of a sample. Interested readers are referred to the articles by Koch and Jensen and by Merkt in the literature list. The other one is the FTR due to the magnetic-field-induced motion of quasiparticles across open sections of a Fermi surface; a discussion and relevant literature are given in the article by Schrama *et al*.

Nomenclature

A	cross-sectional area of the Fermi surface
$\boldsymbol{B}$	magnetic induction
E	energy of a quasiparticle
$\boldsymbol{E}$	electric field
j	a general integer used as a label
$\boldsymbol{k}$	quasiparticle wave vector quantum number
$k_\parallel$	the component of $\boldsymbol{k}$ parallel to $\boldsymbol{B}$
l	Landau-level quantum number
m^*_{CR}	cyclotron effective mass
m^*	the quasiparticle mass measured in a de Haas–van Alphen experiment
q	quasiparticle charge: $q = \pm e$
t	time
$t_\perp$, $t_\parallel$	transfer integrals
$\boldsymbol{v}$	quasiparticle velocity
Z	surface impedance
ν	frequency of photons used to excite cyclotron resonance
σ, σ_{ij}	conductivity, general element of conductivity tensor
τ_{CR}	scattering time associated with Landau-level broadening
τ_{CRM}	apparent scattering time from a cyclotron resonance measurement
τ_{dHvA}	apparent scattering time deduced from a de Haas-van Alphen measurement
τ_σ	scattering rate inferred from a zero-field conductivity measurement
ω	angular frequency of photons used to excite cyclotron resonance
ω_c	cyclotron (angular) frequency

Cyclotron Resonance: Semiconductors

D R Leadley, University of Warwick, Coventry, UK

Introduction

Semiconductors, as a class of materials, have attracted a huge amount of attention not only due to their intrinsic fascination but also due to their use in electronic and optoelectronic applications. At the most basic level, it is important to measure values for the electron and/or hole effective mass m^*, which is related to the band structure and determines how fast these charge carriers can be accelerated. Such measurements have been performed using the phenomenon of cyclotron resonance (CR) since it was first proposed, by Shockley in 1953, on a whole variety of elemental and compound semiconductors including bulk 3D and layered 2D structures. However, cyclotron resonance is capable of providing much more information than just the value of m^* concerning the band structure of the host material as well as the interactions of electrons with each other and the surrounding lattice.

This article reviews the basic mechanism of CR, considers how the resonance may be observed experimentally, and then discusses some of the information that can be obtained from the resonance position and line width. In particular, it addresses the issue of how the measured m^*_{CR} should be related to the band edge value m^*_0 and how energy level crossings, polaron coupling, spin splitting, and collective interactions affect the measured CR position.

So What Is Cyclotron Resonance?

In a magnetic field B, the previously continuous spectrum of electronic energies becomes quantized into a discrete set of Landau levels (LLs) (as described elsewhere in this volume) with energies

$$E_l(B, k_\parallel) = \left(l + \tfrac{1}{2}\right)\hbar\omega_c \pm \tfrac{1}{2}g\mu_B B + E(k_\parallel) \qquad [1]$$

where l is an integer, $\omega_c = eB/m^*$ is the cyclotron frequency, by analogy to cyclotron motion in free space when $m^* = m_0$, the second term accounts for spin splitting, and $E(k_\parallel)$ is the energy of motion (or confinement) parallel to the magnetic field. The number of occupied LLs is known as the filling factor ν. (Care is required with this number as different workers may, or may not, include spin and valley degeneracy: a full LL could be described as having $\nu = 1$ in a bulk semiconductor, $\nu = 2$ in a GaAs heterojunction, or $\nu = 4$ in an Si MOSFET.) Since the free carrier density in most semiconductors is much smaller than the atomic density, the Fermi surface only extends to a small fraction of the Brillouin zone and, to a first approximation, can be regarded as ellipsoidal; so the cyclotron mass is equivalent to the effective mass for transport in a plane perpendicular to B.

Transitions can be made between these LLs by absorbing a photon of the appropriate energy $\hbar\omega = \hbar\omega_c$ – this is the cyclotron resonance. The examples in this article are taken from degenerate semiconductors, where the optical transitions are within either the conduction or the valance band. Traditionally, nondegenerate semiconductors have also been studied by CR using cross-bandgap radiation. These interband transitions can reveal a wealth of information about the electronic structure of semiconductors, but are less straightforward to analyze as both bands are involved and are not considered further here.

Most CR experiments are conducted in the Faraday geometry, where the direction of propagation of the radiation is along B. Hence, the oscillating electric field is polarized in the plane perpendicular to the magnetic field, and this is the direction of the electron motion that is sensed. Another consequence of the low free carrier density is that the skin depth will be large and the same electric field is seen throughout the sample, irrespective of the magnetic field, so the radiation couples to the center of mass motion of the electrons and is insensitive to carrier–carrier interactions – Kohn's theorem. The CR transition has the selection rule $\Delta l = \pm 1$, which accounts for the unit of angular momentum absorbed from the photon, and is spin preserving. The choice of sign means that, by circularly polarizing the radiation only, certain transitions will occur: conduction band electrons will only be excited to higher LLs by σ^+ polarization, so this is termed electron-active, and the hole CR will generally only be excited with σ^- polarization (although σ^+ will excite certain transitions in the valence band between heavy and light hole levels).

Scattering processes within the semiconductor means that the LLs are not infinitely narrow, so the CR is broadened and the line width can be used as a quantitative measure of the sample quality. If the average carrier scattering time is τ, then CR can be observed provided $\omega_c\tau > 1$, which, in a semiclassical view, means the carrier must substantially complete a cyclotron orbit before scattering. This condition can be rewritten as $\mu B > 1$ (as mobility $\mu = e\tau/m^*$), setting a minimum magnetic field of $1/\mu$ for the observation, that is, 10 T for a $1000\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$

sample. In practice, this means CR is normally recorded at low temperature (4.2 K), where the mobility is highest, and low-mobility semiconductors can only be accessed with the highest available magnetic fields.

Further broadening of the CR line can arise from dielectric mismatch, especially within layered structures and at frequencies close to poles in the dielectric response. In some cases, this can completely mask the effects of lifetime broadening and even change the line from the clean Lorentzian of **Figure 1** to a differential shape, from which it is much more difficult to extract the true resonance position. This effect can often be corrected for by modeling the dielectric response of the particular sample being investigated.

Magnetoplasmon Mode

The above description of CR as a resonant absorption is adequate in most cases, but is an oversimplification. The CR absorption spectrum can be calculated within the linear response theory as being proportional to the real part of the dynamical conductivity. FIR illumination presents a long wavelength perturbation to the electron plasma, which has a collective response. In a magnetic field, the plasma excitation modes occur close to the integer multiples of $\hbar\omega_c$. The lowest of these is referred to as the magnetoplasmon mode, and at small wave vector k, is equivalent to forming a magnetic exciton with an electron in the upper LL and a hole remaining in the lower LL. The excitation has an energy $E(k) = \hbar\omega_c + \delta E(k)$, where the second term is the magnetoexciton binding energy due to electron correlations. Pure CR corresponds to the $k = 0$ limit of the magnetoplasmon, in which limit $\delta E(k) \to 0$ due to Kohn's theorem. However, lattice defects, impurities, band nonparabolicity, and the structural asymmetry often found in 2D systems can break translational invariance and allow $k \neq 0$ modes to mix with the pure CR mode at $k = 0$. Coupling to other plasmon modes of the electron gas is then possible, especially when a metallic grating is applied to the surface of the semiconductor that imposes spatial periodicity on the FIR excitation and selects particular wave vectors. Although there have been suggestions of coupling to such magnetoplasmons in GaAs and GaN 2DEGs, the details of these measurements are currently not explained.

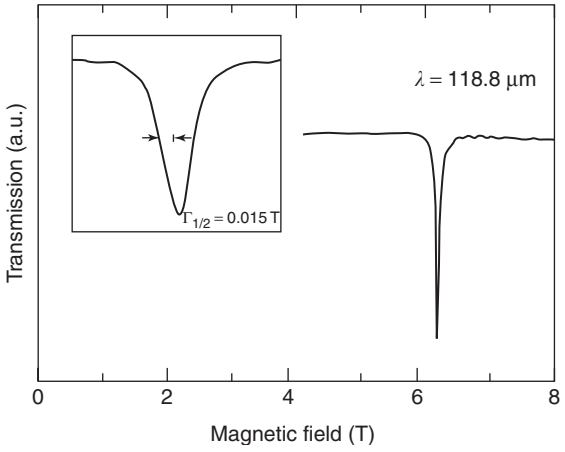

Figure 1 Typical FIR transmission through a high-mobility GaAs 2DEG showing a very narrow CR. (Reprinted with permission from Hopkins *et al.* (1987) *Physical Reviews B* 36: 4789; © American Physical Society.)

Experimental Techniques

Experimentally, the CR condition for a particular specimen can be satisfied and the resonance directly detected in one of two ways: either by applying a fixed frequency of radiation and varying the magnetic field, or by fixing the field and varying the frequency.

Swept Field, Fixed Frequency

Conceptually, the former is more straightforward. Magnetic fields up to ~ 30 T can now be generated in resistive magnets, that are designed to be swept, and wire-wound pulsed magnetic coils extend this field range to some 60 T. For a typical semiconductor, the effective mass is in the range of $0.01–1.0\,m_0$ which, at the now routinely accessible field of ~ 10 T, means sources of far infrared (FIR) radiation are required in the 10–1000 μm range (1–100 meV). Suitable monochromatic FIR can be obtained from a molecular gas laser, filled with methanol or deuterated methanol at low pressure, that is pumped by a CO_2 laser operating at 9–11 μm. Although thousands of lines can be obtained from such optically pumped FIR lasers, most experiments are limited to ~ 20 strong lines, with 118.8 μm being the most popular. The transmitted FIR is usually detected by a cooled C bolometer or Ge photodetector and noise reduced by phase locking with chopping of the CO_2 laser beam. To avoid interference fringes and distorted line shapes, samples are wedged by a few degrees. This experimental arrangement works well, but there are a number of practical difficulties: for example, the limited number of strong FIR lines, stabilization of the FIR intensity over the time of the magnet sweep, transmission of FIR to the sample through transparent windows and evacuated metal light pipes, which need to be highly polished on the inside to avoid attenuation, and the limited sensitivity of the detection arrangement. The last of these can sometimes be improved by taking the ratio of signals from

bolometers mounted just above and below the sample. It is also possible to detect the CR through changes in the resistance of the sample being investigated in a photoconductivity measurement. FIR experiments provide much higher resolution than the earlier microwave experiments in fields below 1 T, where the geometry of the microwave resonant cavity has to be considered and tuned carefully, although the quality of that data is a tribute to the skill of the researchers. Measurements at high fields can also be made in the "quantum limit," where only one LL is initially populated as opposed to the classical limit at low fields, where many LL transitions are involved and broaden the resonance. Between these limits, studies have been made of the effect of filling factor on the line width, which can oscillate with the density of available initial and final states.

Megagauss fields At higher pulsed magnetic fields now available in the megagauss region (>100 T), the more powerful CO_2 laser can be used directly, and other possible sources include water vapor, CO, and HeNe lasers. At the shorter wavelengths, fast HgCdTe photovoltaic detectors can be used to detect the rapid change in IR intensity. Magnetic fields up to 180 T can be produced using the single turn coil technique pioneered in the University of Tokyo. A capacitor bank is discharged through the coil to give currents of order 2 MA for $\sim 7\,\mu$s. The maximum field is set by the size of the capacitor bank and the coil diameter, which is ~ 10 mm. Although the coil explodes violently outwards, the cryostat and sample are left intact and the experiment can be repeated. Data from the detector and a pickup coil are transmitted via optical fiber to a shielded room where they are recorded on a fast multichannel digitiser. The pick-up voltage allows the field to be calibrated each time to an accuracy better than 2%. A set of typical CR recordings are shown for several II–VI semiconductors in **Figure 2**.

Even higher fields, beyond 600 T, can be obtained using an electromagnetic flux compression technique. A primary pulse current through an outer primary coil seeds a magnetic field and induces an opposing secondary current within an inner copper ring. The repulsive forces generated rapidly squeeze the ring causing it to implode and compress the trapped magnetic flux to a very high field density. Unfortunately, the entire cryostat and sample are destroyed in this one shot experiment! However, the extreme fields mean that CR can be studied in generally very low-mobility materials, such as the dilute magnetic semiconductor $In_{1-x}Mn_xAs$, where high doping with magnetic impurities reduces the mobility. Data are shown in **Figure 3** for a temperature-dependent study of CR in

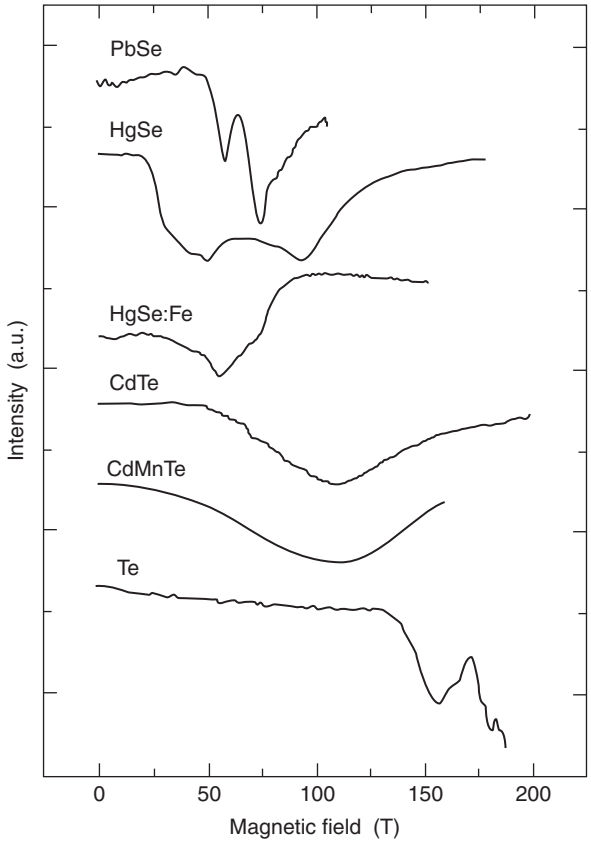

Figure 2 FIR transmission through a variety of II–VI semiconductors using a CO_2 laser with single turn coils. (Reproduced from Puhlmann *et al.* (1998) *Physica B* 246–247: 323–327, with permission from Elsevier.)

CdS. Notice that at room temperature the CR peak is over 100 T wide. (Further development of this technique continues in megagauss facilities, particularly in Tokyo University and the Humboldt University, Berlin, with fields of 300 T reported in 5 mm single turn coils and flux compression at 1000 T.)

By contrast, CR has also been observed at very low fields (20 mT), in very high quality GaAs/GaAlAs heterojunctions where the mobility exceeds $10^6\,cm^2\,V^{-1}\,s^{-1}$, using microwave radiation from 17 to 90 GHz Gunn diodes. At these low fields, the cyclotron radius is $\sim 0.2\,\mu$m which enables potential fluctuations in the sample to be observed on this macroscopic scale.

Fourier Transform Spectroscopy

The advent of reliable high-field superconducting magnets and Fourier transform infrared (FTIR) spectrometers in the late 1980s provided a real alternative to the swept field CR measurements at discrete energies, although that is still the only way for fast measurements in pulsed magnets. In this technique, the FIR source is a heated metal wire or globar producing a broad spectrum of radiation that passes

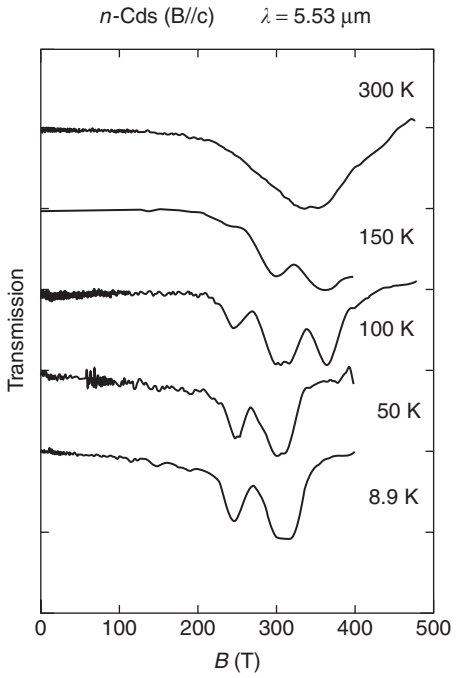

Figure 3 Temperature dependence of IR transmission through *n*-CdS at 5.53 μm using ultrahigh magnetic fields. The electron CR line at 300 K is replaced by other lines related to impurity and phonon-coupled CR as the temperature is reduced. through a Michelson interferometer before passing through the sample and being detected by a cooled Si bolometer. By rapidly scanning the moving mirror in the interferometer, and recording the FIR intensity as a function of its position, an interferogram can be produced that is inverted by a hard-wired fast Fourier transform to yield a transmission spectrum with a resolution of $\sim 0.1\,\mathrm{cm}^{-1}$ (0.01 meV). Each scan only takes a fraction of a second, but can be repeated many times to increase the signal-to-noise ratio. Intensity variation in the source spectrum and detector response can be removed by taking the ratio of spectra with and without the sample present. In practice, a set of transmission spectra are usually recorded as the magnetic field is stepped through the range of interest (**Figure 4**) and differences are detected from the ratio of adjacent spectra. As a result of FTIR spectroscopy, the CR can be followed continuously as a function of magnetic field or energy, which allows measurements of band nonparabolicity and subband structure to be made.

Free-Electron Lasers

The limitation of a fixed number of FIR laser lines can also be overcome by using a free-electron laser

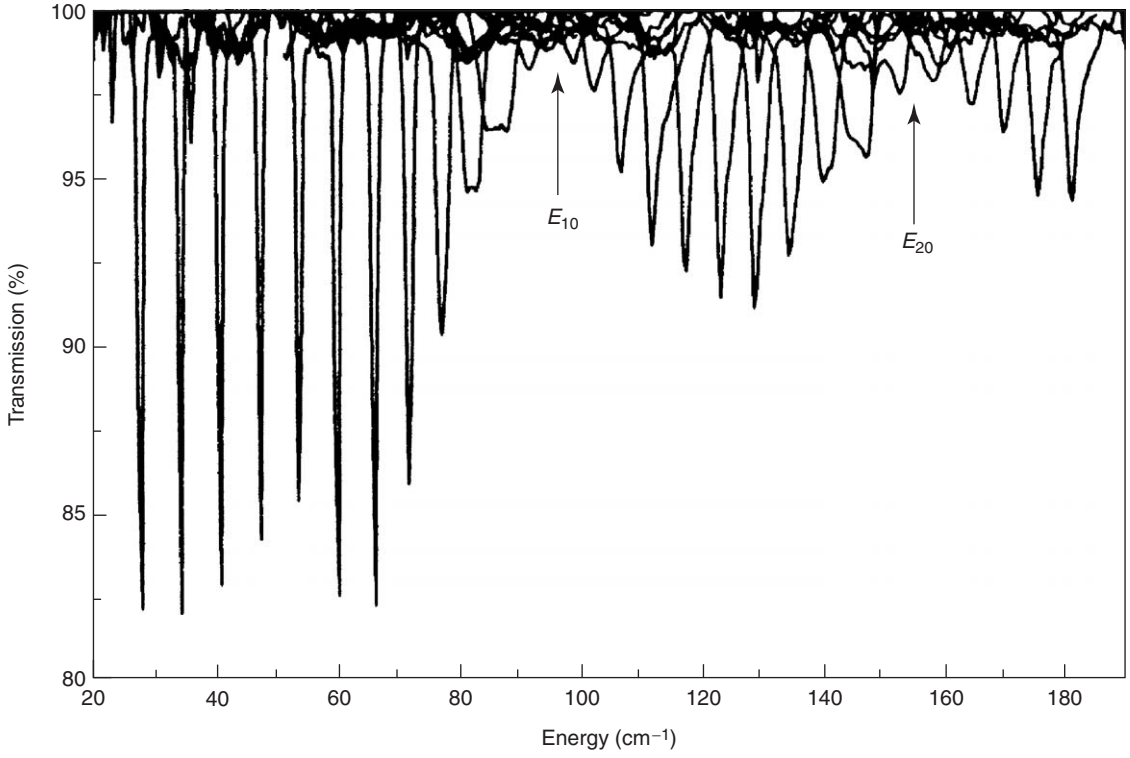

Figure 4 Series of FTIR spectra from 2 to 14 T at 0.5 T steps for a GaAs heterojunction at 3.5 K. The arrows indicate resonant intersubband coupling at 12.4 and 20 meV. (Reprinted with permission from Michels *et al.* (1995) *Physical Review B* 52: 2688; © American Physical Society.)

(FEL) that can provide radiation from UV to microwaves. The FEL system consists of an electron accelerator, an undulator in which the electrons emit synchrotron radiation, and an optical resonator. For a given undulator, the output is continuously tunable over a wide range, for example, 30–250 μm, and without changing the accelerator energy, the FIR can be rapidly scanned over a factor of 2 in wavelength. Since the electrons become bunched within the undulator, they emit radiation in a train of picosecond-duration micropulses within a macropulse that lasts for 0.01–5 ms with a ~10 Hz repetition rate, depending on the installation. At the FELIX facility in the Netherlands, a fast-pulsed magnet is synchronized to sweep during the arrival of the FIR macropulse enabling CR measurements at fields up to 60 T.

Time-resolved CR has been studied since the 1970s on the microsecond scale looking at, for instance, exciton lifetimes, but at the Stanford FEL installation, synchronization to the micropulses enables this to be performed on a picosecond timescale. This allows the carrier relaxation dynamics to be studied in a magnetic field, particularly when implemented in a pump-and-probe experiment with a mode-locked Ti:sapphire laser (**Figure 5**).

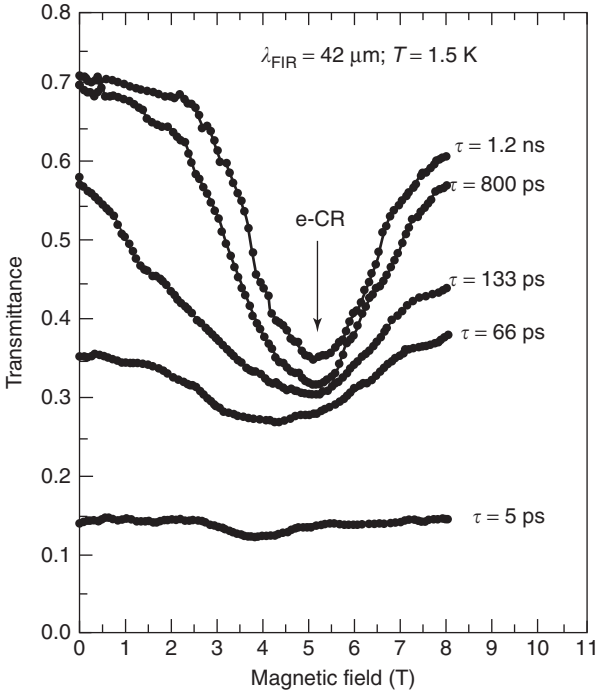

Figure 5 Picosecond time-resolved CR in InSb using micropulses from an FEL. Initially, the very high density of photocreated electrons produces a very wide CR due to carrier scattering, only after ~1 ns equilibrium is restored. (Reprinted with permission from Kono *et al.* (1999) *Applied Physics Letters* 75: 1119–1121.)

Optically Detected Cyclotron Resonance

Rather than monitoring the FIR absorption directly, optically detected cyclotron resonance (ODCR) detects the variation in photoluminescence (PL) excited by a visible laser. ODCR provides several benefits: undoped samples can be studied since the visible laser pump provides carriers, the conduction and valence band can be studied simultaneously, and the photomultiplier tubes (PMTs) or CCDs used to detect PL offer much greater sensitivity than the usual FIR detectors. Typically, the luminescence is dispersed into a PMT, with a monochromator having a sufficiently wide exit slit to record the integrated intensity from a single PL line without the need to adjust for the diamagnetic shift when sweeping the magnetic field, and detected at the chopping frequency (~2 kHz) of the visible laser. This output is fed into a second lock-in amplifier referenced to the more slowly chopped FIR to produce the ODCR signal. ODCR can then either be recorded as a function of the magnetic field or a function of the PL energy at fixed field.

ODCR is clearly only suited to direct bandgap semiconductors that have a strong PL signal. Studies in bulk GaAs show the free-electron CR transitions and also reveal transitions from the ground to excited states of donor-bound impurities (**Figure 6**). Chemical shifts due to different donor atoms also appear with improved resolution over photoconductivity measurements. The mechanism behind ODCR is thought to be that the FIR illumination liberates electrons from donor sites to the conduction band, increasing the impact ionization of bound excitons and so reducing the PL signal, which is predominantly due to excitonic recombination. The free electron-related luminescence makes a much smaller contribution to the PL and has been shown to increase in GaAs, as expected in this impact ionization mechanism, but decrease in other measurements where lattice heating is more important. Charged excitons, or trions labeled X^-, can also be considered as particles with energy quantized into a set of LLs, and CR between these can be used to extract the trion effective mass and lifetime. In quantum wells, the ODCR signal is strongly dependent on the filling factor and, when the cyclotron energy exceeds the inter-subband separation, can show a complete transfer of luminescence intensity from the ground to second subband at resonance.

A development of ODCR is far infra-red-modulated photoluminescence (FIRM-PL) whereby the whole PL spectrum is recorded at a fixed magnetic field, by dispersing the luminescence signal onto a CCD with typically a 1 m spectrometer. Two series of such spectra are taken as the magnetic field is

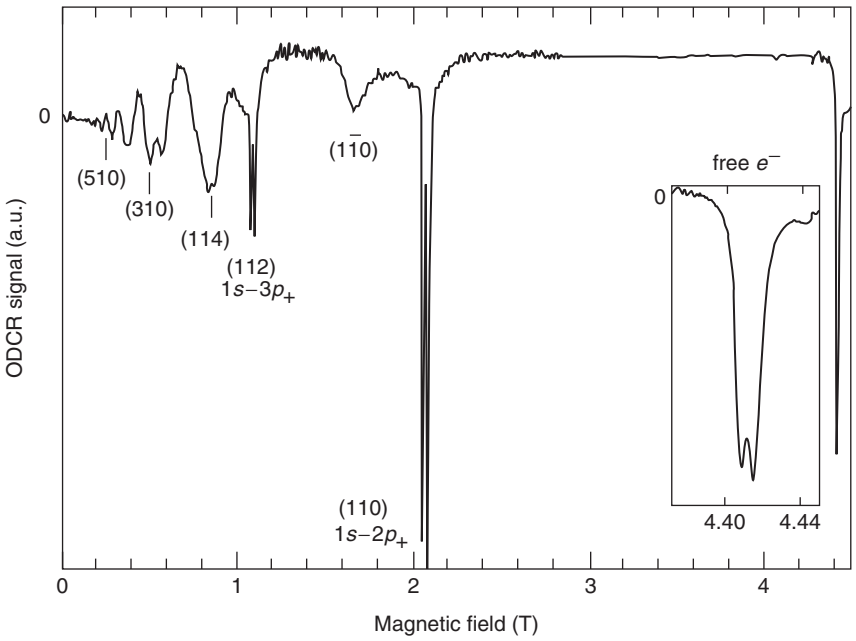

Figure 6 ODCR signal from bulk GaAs for an FIR wavelength of 163 μm, showing free-electron CR at 4.4 T, including a spin-split peak, and excitonic transitions at lower fields. stepped, with and without FIR radiation, and the CR contribution for each of the PL lines can be seen in their difference (**Figure 7**). By studying these differences, as functions of magnetic field, PL, and FIR power, a lot can be learned about the energy levels and carrier dynamics within the semiconductor. However, these data have to be interpreted carefully to account for the changes in carrier distribution and increase in nonradiative recombination due to FIR heating.

Effective Mass Measurements

Measurable features of CR include the peak position, amplitude, and line width. The integrated intensity of a CR line can be used to obtain the density of carriers responsible for the absorption, and the line width gives a measure of their mobility. Here, much emphasis will be on the position of the resonance, although discontinuities in position are usually accompanied by increases in line width. In many CR experiments, the position of the resonance is often recorded in terms of an effective mass, which removes a linear background compared to the energy of the transition. For an idealized, isotropic semiconductor with a single parabolic energy band (i.e., $E \propto k^2$), CR would yield the same value of effective mass m^*_{CR} irrespective of the photon energy absorbed or the direction of measurement. However, real materials are not that simple.

Crystalline Anisotropy

Crystalline anisotropy can be defined through a tensor as follows:

$$\left(\frac{1}{m^*_{\mathrm{CR}}}\right)_{ij} = \frac{1}{\hbar^2}\frac{\partial^2 E}{\partial k_i \partial k_j} \qquad [2]$$

which will depend on details of the electronic band structure and the underlying crystal structure. The value measured for m^*_{CR} in a CR experiment is an average over the extremal orbit taken by an electron around the Fermi surface perpendicular to the applied magnetic field. No crystalline structure can be spherically symmetric, so there is an inevitable amount of anisotropy. By rotating a sample about a magnetic field, applied along one of the three principal crystalline axes, this mass anisotropy can be mapped out for each electron and hole band (**Figure 8**). This early CR data on Si and Ge were instrumental in working out the band structure of these, and other materials, and continues to be used as high-quality crystals of new semiconductors, for example, SiC, ZnO, GaN, type IIb diamond, become available. As another example from the narrow-gap layered semiconductors, CR has shown that although their crystal structure is the same as that of Bi_2Se_3, it has a single conduction band minimum at the Γ point whilst Bi_2Te_3 has six ellipsoids, like Si. Further, by substituting some of the Bi by Sb, a material is formed with two distinct conduction bands.

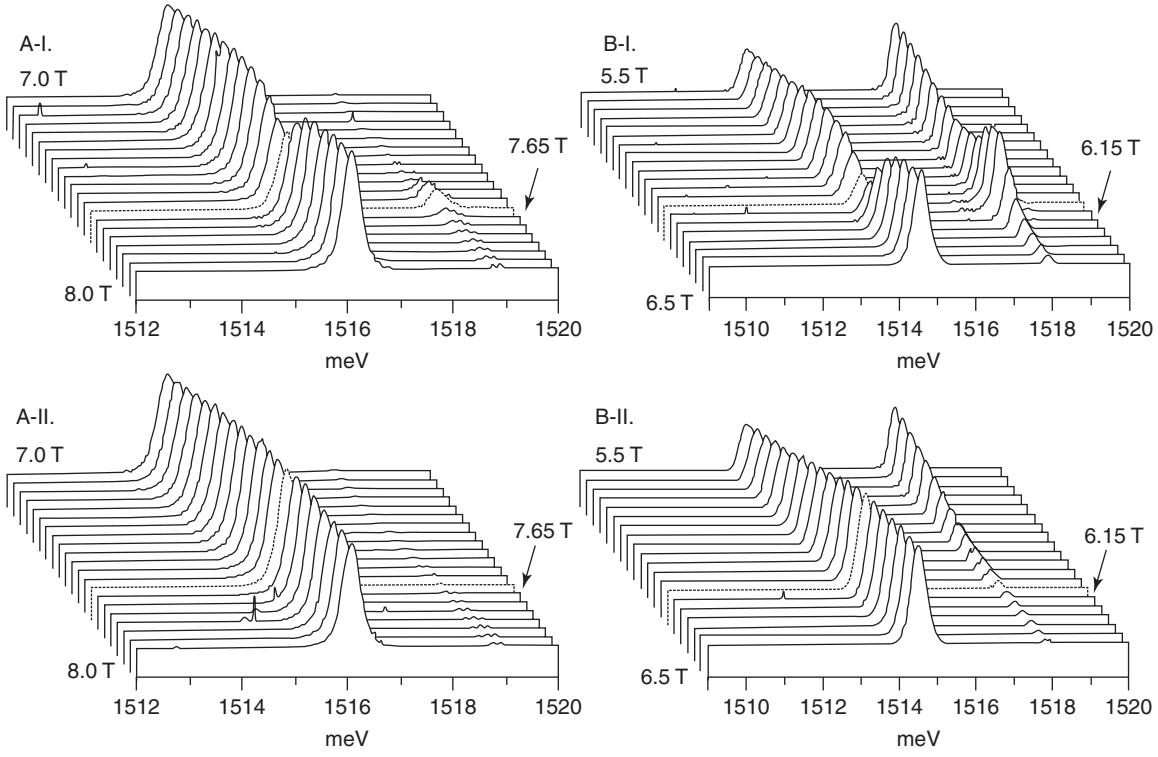

Figure 7 FIRM-PL: PL spectra of a GaAs2DEG with (I) and without (II) FIR radiation at (A) 96.5 μm and (B) 118.8 μm taken over a 1 T range about the CR position, indicated by arrows. Note the transfer of PL intensity from the E_0 to E_1 lines at resonance. (Reprinted with permission from Chang CC and Nicholas RJ (1999) A far infrared modulated photoluminescence FIRM-PL study of cyclotron resonance in a 2D electron gas in GaAs/AlGaAs hetero-junctions. *Semiconductor Science and Technology* 14: 768–774; © IOP Publishing.)

The anisotropy becomes very large in low-dimensional structures formed from semiconductor heterostructures, where there is considerable confinement energy in one (or more) direction(s), and the incorporation of strain into pseudomorphic layers, for example, $Si/Si_{1-x}Ge_x$ or $GaAs/In_xGa_{1-x}As$, adds further anisotropy especially to the valence band where heavy and light hole bands show considerable mixing. CR has been used as a valuable tool for verifying or adjusting band structure calculations, especially for *p*-type quantum wells with many crossing and anticrossing energy levels.

Nonparabolicity

Semiconductors also, inevitably by definition, have a small energy difference between the maximum of the valence band and the conduction band minimum. The perturbation theory shows that the effect of multiple bands is to change the curvature of each as a function of energy, known as nonparabolicity. This clearly affects m^*_{CR} which can be calculated, using a five-band $k \cdot p$ model, as

$$m^*_{CR} = m^*_0 \left\{ 1 - \frac{2K_2}{E_g}([l+1]\hbar\omega_c + \langle T_z \rangle) \right\} \quad [3]$$

where $\langle T_z \rangle$ is the kinetic energy parallel to the magnetic field, E_g is the bandgap, and K_2 is a factor characterizing the nonparabolicity. K_2 is normally negative, so the mass increases with energy. This increase can be observed (**Figure 9**) by changing the FIR frequency, as when the CR transition occurs at higher field, $\hbar\omega_c$ is greater and the final state is higher in the band. Similarly, at fixed frequency, transitions between different LLs may be resolved as distinct lines with, for example, $l = 1$ to 2 occurring 10% higher in field than $l = 0$ to 1. Low-temperature CR measurements show that m^*_{CR} also increases with carrier concentration, due to band filling increasing the energy of the initial state – the Moss–Burnstein shift. For these reasons, it is necessary to extrapolate a series of measurements back to zero frequency and zero carrier concentration if the band edge mass m^*_0 is required.

Measurements at higher temperatures show an apparent increase in mass due to thermal motion contributing to $\langle T_z \rangle$, but this can be corrected by using eqn [3] to show a temperature-independent m^*_0. If lines from different LLs are unresolved, the mass will also appear to increase with temperature as higher LLs contribute more through the Boltzmann factor. Another important contribution to $\langle T_z \rangle$ is

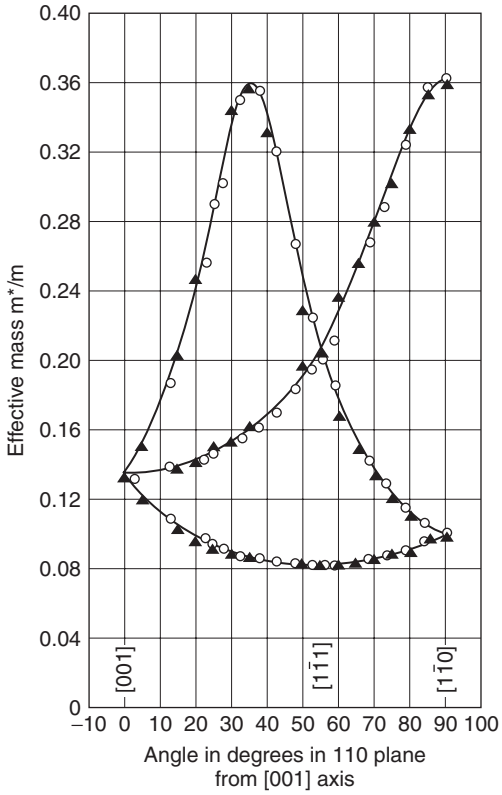

Figure 8 Effective mass of electrons in Ge measured by CR for different crystalline directions. Solid lines are calculations. (Reprinted with permission from Dresselhaus, Kip, and Kittel (1955) *Physical Review* 98: 368–384; © American Physical Society.)

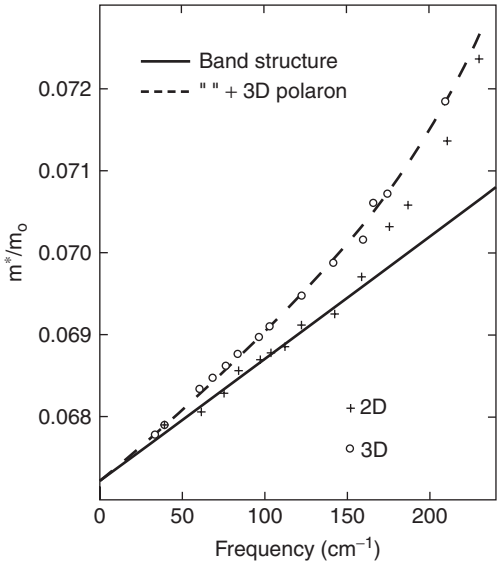

Figure 9 Energy dependence of m^*_{CR} in 3D and 2D GaAs, showing the band structure and polaron contributions to nonparabolicity. (The 3D results are shifted up by $0.0012\,m_0$ for comparison.)

the confinement energy in heterostructures, which generally results in 2D systems having larger m_0^* than the corresponding bulk semiconductor (**Figure 10**).

Polaron Coupling

In polar semiconductors, there is an additional contribution to the nonparabolicity from polaron coupling, of similar magnitude to that from the band structure. When an electron moves, it attracts (repels) the positive (negative) ions and the associated strain field dresses the electron into a composite particle known as a polaron, having a greater effective mass expressed as $m^*_{pol} = m^*(1 + \alpha/6)$, where α is the Fröhlich coupling constant that varies from 0.07 in GaAs to 1.2 in ZnO. This leads to a nonparabolicity contribution of

$$K_2^{pol} = -\frac{3\alpha E_g}{40\hbar\omega_{LO}} \qquad [4]$$

where ω_{LO} is the longitudinal optic phonon energy, which explains the apparent discrepancy between a calculated value of -1.4 for K_2 in GaAs with the -1.8 measured by CR. While this mass enhancement is clearly observed in bulk semiconductors, it can be screened out in a 2DEG at low temperatures, reappearing at higher temperatures where the screening is less efficient as shown in **Figure 10**.

Another way to view the effects of electron–phonon coupling is shown in **Figure 11**. Anticrossing between the second LL and first LL plus an LO phonon opens an energy gap and bends energy levels, even well away from the resonant polaron condition, where $\hbar\omega_c = \hbar\omega_{LO}$. The two branches of this upper level can be traced out using CR at energies above and below the reststrahlen band; however, close to this region, careful interpretation of the results is required to account for the FIR transmission and internal reflections especially in layered heterostructures. Some CR measurements within the opaque reststrahl of GaAs have been made by viewing CR in reflection, whereby the light passed through a thin 2D layer on the way to and back from the highly reflective bulk substrate, and by mounting very thin layers on a transparent substrate. For InSe, $\alpha = 0.3$ which leads to a very large resonant polaron splitting and allows CR lines from both branches to be seen outside the reststrahl over a wide field range.

Besides changing the CR energy, the additional electron–phonon scattering at resonance leads to an increase in the line width. Inter-Landau level transitions can also occur via phonon absorption/emission when the optic phonon energy is an integer multiple of the cyclotron energy – known as magnetophonon resonance (MPR). It is seen at temperatures $\sim$80–200 K, where there is a favorable balance between

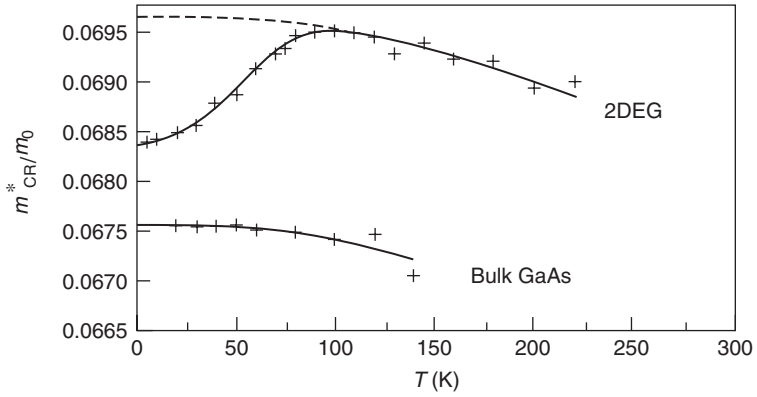

Figure 10 Comparison of the temperature dependence of m^*_{CR} in 3D and 2D GaAs. Temperature-dependent screening of the polaron contribution in 2D is seen by the difference between the dashed extrapolation from high temperature and the data. Note the increase due to confinement in 2D. (Adapted with permission from Hopkins *et al.* (1987) *Physical Review B* 36: 4789; © American Physical Society.)

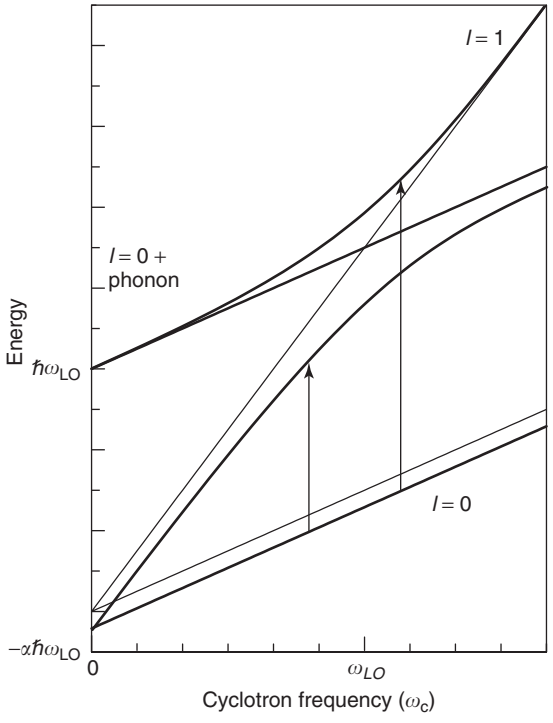

Figure 11 Schematic representation of the polaron coupling between the first two LLs. Dashed lines show the unperturbed levels, arrows are the CR transitions.

phonon population and LL broadening. While MPR is normally observed as peaks in the magnetoresistance, it can also be seen through oscillations in the CR line width.

Shifts and Coupling of the Resonance

It is already seen that the CR position can be altered by the electron–phonon interaction. This section discusses some of the other mechanisms responsible for moving and broadening the absorption lines.

Subband Structure

2D systems may have several electric subbands, due to confinement as distinct from the different symmetries of heavy and light holes. Transitions between LLs of different subbands are usually forbidden, but the presence of a magnetic field component in the 2D plane mixes these states forming resonant subband-Landau-level coupling (RSLC) between, for instance, the $l = 1$ LL of the E_0 subband and the $l = 0$ level of the E_1 subband. Thus, subband energies can be detected in tilted field CR as a discontinuity in m^*_{CR} as a function of energy (or field, as these are usually FTIR experiments), accompanied by an increase in the line width at the RSLC condition (**Figure 4**). This method has been successfully used to elicit the energy level spectra for a wide variety of structures, including heterojunctions, quantum wells, and superlattices. In high-quality samples, the CR splits to reveal transitions to the upper and lower branches, and shows a transfer of oscillator strength from one to the other on passing through the resonance. By contrast to direct inter-subband transitions, which require the light to be polarized perpendicular to the interface and exhibit a significant depolarization shift, in CR, the light is polarized parallel to the interface (even in tilted fields due to the high dielectric constant of most semiconductors) and depolarization shifts are very small.

Shifted CR

The resonance position can, however, be shifted if carriers are bound to a harmonic potential Δ when the CR position is described by $(\hbar\omega)^2 = (\hbar\omega_c)^2 + \Delta^2$. This is the case in *n*-ZnO and *n*-CdS, where the electrons are in very shallow traps (not bound impurity

states), resulting in trapped (not free) electron CR, and can also be seen in quantum wells, where fluctuations in well width lead to carriers being confined to localized islands. For shifted CR to be observed, the localization length needs to be greater than the cyclotron radius, but not so large that the perturbation is the same for the initial and final state.

Landau Level Hybridization

An interesting example of level crossing occurs in InAs/GaSb heterojunctions, where the conduction band minimum in InAs can be below the valence band maximum in GaSb. This leads to a semimetallic system with spatially separated electron and hole gases, unless the structure contains narrow quantum wells (usually of the InAs), where the additional confinement uncrosses the energy gap to produce a semiconducting arrangement. CR can be observed between both electron and hole LLs, and by following their position as a function of magnetic field, the relevant band edge energies can be found. In the semimetallic system, strong oscillations of the CR line width and amplitude have been observed that disappear when the electron and hole layers are separated by a thin barrier ($\sim$2 nm AlSb). These oscillations correspond to line width maxima whenever electron LLs and hole LLs cross, at which point energy gaps arise from hybridization of the electron and hole LLs. The hybridization only happens when the electron and hole wave functions can overlap by tunneling through the interface, which is why a thin barrier is sufficient to remove the effect. Similar hybridization effects have been seen in coupled GaAs quantum wells, forming symmetric and antisymmetric wave functions.

Spin Splitting

As evident from eqn [1], there are separate LL fans for each spin state and, in a nonparabolic band, the spin preserving CR transitions will be at different energies for spin-up and spin-down carriers, which enables the g-factor to be measured. FIR only excites bare electrons in a homogeneous layer (Kohn's theorem), so the g-factor measured in CR is the single-particle value and not the enhanced value detected in transport measurements. While this splitting is small in wide-gap materials, such as GaAs, where $g = -0.44$, and only observed in the quantum limit (see below), spin split CR is readily seen for narrow-gap semiconductors, such as InSb (**Figure 12**), where the proximity of conduction and valence bands leads to strong nonparabolicity as well as a large g-factor. For InAs with $g = -15$, the spin energy gap is so large that at low density and temperature, only the lower spin state is populated and only one CR line

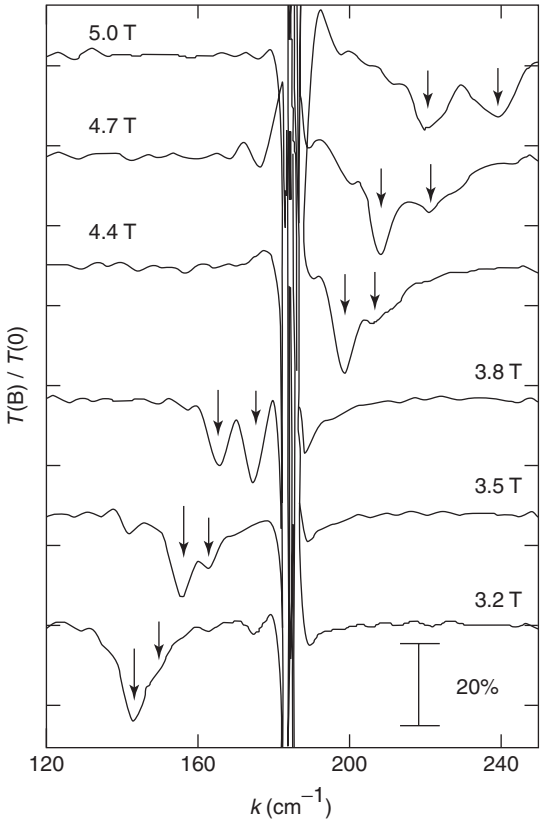

Figure 12 FRIR spectra showing clearly resolved spin splitting in InSb quantum wells on either side of the reststralen band due to absorption of InSb like optic phonons around 180 cm^{-1}. (Reproduced from Khodaparast *et al.* (2004) Spin effects in InSb quantum wells. *Physica E* 20: 386–391, with permission from Elsevier.)

observed, but once the second spin level becomes populated at higher temperature (or density), the second line appears. The onset of the second line can be used as a measure of carrier density.

Dilute magnetic semiconductors, such as $In_{1-x}Mn_xAs$, have been observed to have ferromagnetic phases below $\sim$50 K that are of interest for spintronic applications. The ferromagnetic exchange between Mn ions is believed to be hole mediated and strongly affect both the conduction and valence band parameters due to the narrow bandgap. Megagauss hole CR, in **Figure 13**, shows lines that shift to lower fields and intensify as the ferromagnetic phase is entered, consistent with the additional Mn exchange field increasing the spin splitting. In this regime, $k \cdot p$ calculations show that the spin splitting varies with temperature, magnetic field, and Mn concentration leading to g-factor that varies from -20 to $+100$. Again, CR experiments are vital to validate and refine these calculations.

Although spin–split electron CR is commonly observed in bulk GaAs, it has only been seen in 2DEGs at very low electron densities with $\upsilon < 1/10$.

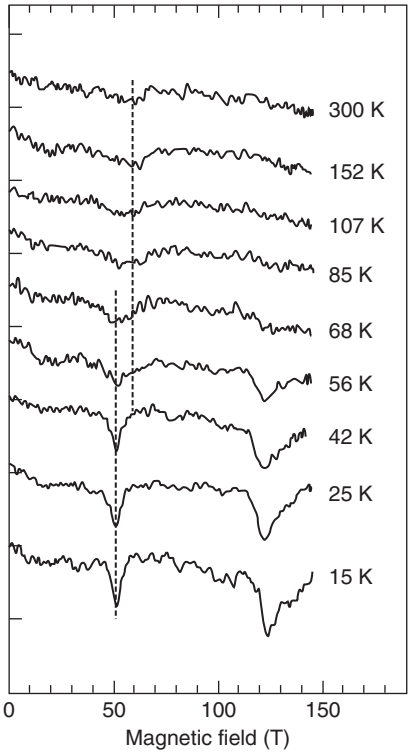

Figure 13 CR spectra at 10.6 μm from a InMnAs/GaSb heterojunction in magnetic fields up to 150 T. On cooling through the ferromagnetic transition at 55 K an additional line appears. (Reproduced from Khodaparast *et al.* (2004) High-field cyclotron resonance studies of InMnAs-based ferromagnetic semiconductor heterostructures. *Physica E* 21: 978–982, with permission from Elsevier.)

At this very low filling factor and 100 mK, only the lowest transition is seen at the position expected in bulk GaAs. The upper spin level becomes thermally populated and two lines appear by 1 K with their relative intensities following the level of populations governed by Boltzmann statistics and separated by the spin splitting expected in the single-particle picture. For $1/10 < \nu < 1/6$, this picture starts to break down with a smaller splitting than expected and for $\nu > 1/6$, through to $\nu = 2$, only one line is seen that shifts from the position of the lower spin transition by up to half the spin splitting as the temperature increases. These results have been explained by a model, whereby the cyclotron motions of the two spin states are coupled by the Coulomb interaction, which depends on the total electron density. The CR spectrum consists of hybridized spin-up/spin-down states with the position of the single peak determined by the relative spin population. Throughout the temperature and field region where fractional quantum Hall effect (FQHE) features are seen in transport experiments, there are no deviations of CR mass or line width showing that CR is not affected by the electron correlations responsible for FQHE.

A similar two-component situation arises in Si where there is a mass splitting between the two- and fourfold degenerate valleys. Again, only a single CR line is observed until the system is considerably perturbed by uniaxial stress. Attempts to explain this rely on electron–electron interactions perturbing the single-particle states.

Summary

The basis of CR in semiconductors has been discussed with an emphasis on the various experimental techniques that can be employed and the information that can be extracted. CR has been applied to a wide variety of different bulk materials and heterostructures, including elemental semiconductors, wide and narrow gap III–Vs, II–VIs, and magnetics. Although only a limited number of examples have been given here, the same principles apply to all materials. Each time better material becomes available, CR reveals more about the band structure, and as experimental facilities improve, the technique can be extended to more imperfect crystals. However, there are still unexplained couplings and anomalies reported that test our understanding of the way electrons interact with radiation in semiconductors.

This article has concentrated on FIR absorption as a measurement technique. Transitions from higher to lower LLs can also produce emission at the CR energy, and indeed, cyclotron resonance laser action was demonstrated in Ge in the 1980s. While this is an important aspect of CR in semiconductors, it is beyond the scope of the present article.

Deep-Level Spectroscopy and Auger Spectra

R Colle, Università di Bologna, Bologna, Italy
S Simonucci, Università di Camerino, Camerino, Italy

Introduction

"Spectroscopy" can be defined as the study of processes that, in a very general and schematic way, can be described as follows

$$P(|i;\varepsilon,\boldsymbol{p},\alpha>)+T(|I;E,\boldsymbol{\pi},\beta>)\rightarrow \tilde{T}(|F;\tilde{E},\tilde{\boldsymbol{\pi}},\beta>)+\tilde{P}(|f;\boldsymbol{\varepsilon},\tilde{\boldsymbol{p}},\tilde{\boldsymbol{\alpha}}>)+\cdots$$

where P is a projectile (e.g., a photon, an electron, a proton, or a heavier particle) in a given initial state $|i\rangle$ (characterized by its energy ε, momentum $\boldsymbol{p}$, and/or quantum numbers α), and T is a target (e.g., an atom, or a molecule, or a condensed system) in a given initial state $|I\rangle$ with energy E, momentum $\boldsymbol{\pi}$, and quantum numbers β. Products of this generalized collision that conserves energy and momenta can be the same colliding species in different states, or different species resulting from the fragmentation and/or annihilation of the projectile and/or the target.

In greater detail, deep-level spectroscopy is a specific branch of spectroscopy that studies excitations or ionizations of the inner-shell (deep level) electrons of atoms, molecules, and condensed systems, produced by impact with X-ray photons, high-energy electrons, or (less frequently) heavy particles. Different emission products can be collected and lead to different experimental methods: electron spectrometry, fluorescence spectrometry, ion spectrometry, and their combinations in coincidence measurements, which completely define the full emission pattern following the collision.

A specific class of experiments is that in which the particles selected by the detector are electrons of energies characteristic of the target and, in good approximation, independent of the way in which the system has been ionized or excited. These electrons are called Auger electrons in the name of the French physicist who, in 1924, using a Wilson chamber to study X-ray photoionization of atoms, observed the appearance of fast electrons with energy dependent on the photon energy, and slow electrons with energy independent of that, but characteristic of the emitting atom. Auger also observed that each pair of fast (photo-)electron and slow (Auger-)electron originated from the same point (atom), but the directions of emission of the two electrons were random and mutually independent; furthermore, photoelectrons not accompanied by an Auger electron were also present.

The typical experimental apparatus used for deep-level spectroscopies consists of a source of projectiles prepared with specific characteristics and ejected through a collimated beam into the reaction volume where collisions between particles and targets take place. Specific reaction products are then accepted by a detector in the direction of its finite entrance slit and counted in terms of their kinetic energy (or momentum, or other properties) thus providing intensity distributions, for example, $I_\lambda(E_{\text{kin}};\hat{k})$, that represents the energy spectrum of the particles λ ejected along the direction $\hat{k}$. Global spectra, independent of the direction of emission, are then obtained by integrating these intensity distributions, that is, by collecting particles from all the directions of emission. In coincidence measurements and in more sophisticated experiments, several detectors are used simultaneously to obtain spectra that plot conditional intensities, for example, the probability of finding two or more particles with selected energies along specific directions.

The essential parameters that characterize these experiments are

- properties and preparation of the incident projectiles, for example, in the case of photons: energy (selected by a monochromator), intensity, and polarization;
- targets of the experiment, that is, observables of interest and dynamics of these observables induced by the collision; for example, in the case of atomic systems: energy levels, transition rates, angular distributions of ejected fragments, cross sections of fragmentation processes, and so on; and

- position and properties of the detector(s), that is, acceptance solid angle, transmission, resolution, and efficiency.

The experiment can be performed at a different level of accuracy, meaning with a different resolution: in an "ideal experiment," the target and projectile are prepared in a well-defined initial state and the collision products are collected in coincidence and completely characterized in their final states. Optimal resolution has been significantly approached in recent experiments of electron spectrometry on light atoms and on simple molecules, excited or ionized by monochromatized energy-tunable synchrotron radiation.

The theoretical analysis of these experiments is based on the well established and formally developed branch of quantum mechanics known as "quantum collision or scattering theory." Its effective implementation for a quantitative study of real experiments, however, is quite difficult and becomes progressively less accurate and more phenomenological as the number of particles in the system increases.

This article considers photoprocesses in atomic systems produced by the absorption of a monochromatized (λ) energy-tunable ($\hbar\omega$) radiation in the X-ray region, that is, 0.1 Å $< \lambda <$ 100 Å; 128 keV $> \hbar\omega >$ 128 eV. These processes provide a unique opportunity to explore the dynamics of the many-body interactions in quantum systems, since the radiation–matter interaction, which changes the internal structure of the target, has the special advantage of being known exactly.

The quantum theory of photoionization is summarized briefly.

Theory of Photoionization

Using the first-order time-dependent perturbation theory and dipole approximation, one can prove that the correct quantum-mechanical transition rate (probability per unit time) of a photoionization process, in which an atomic system in its ground state $|\Psi_o\rangle$ is promoted to a final state $|\Psi^-_{\alpha k}\rangle$ by an incident radiation field of frequency ω and polarization direction $\hat{\varepsilon}$ inside a volume V, can be expressed by

$$\frac{dW_{o\to\alpha}}{d\boldsymbol{k}} = \frac{2\pi}{\hbar}|\langle\Psi_o|\hat{H}_{int}|\Psi^-_{\alpha k}\rangle|^2 \times \delta(\hbar\omega + E_o - E)$$

$$\hat{H}_{int} = \left(\frac{2\pi\hbar\omega}{V}\right)^{1/2} \times e^{-i\omega t}\hat{\varepsilon} \times \sum_j q_j \boldsymbol{r}_j$$

where $\{q_j\}$ are the charges of the particles in the target, $E = E_\alpha + \varepsilon_k$ is the energy of the scattering state, and E_o that of the ground state. In this expression, $\Psi^-_{\alpha k}$ is a scattering wave function with normalization $\langle\Psi^-_{\alpha k}|\Psi^-_{\beta p}\rangle = \delta_{\alpha\beta}\delta(\boldsymbol{k}-\boldsymbol{p})$ and incoming-wave boundary condition (–); the latter assures the appropriate asymptotic behavior of the wave function for a process in which a particle is ejected from the target along a specific direction $\hat{k}$. The wave function $\Psi^-_{\alpha k}$ represents the final state of the process with one electron ejected with momentum $\boldsymbol{k}$ and energy $\varepsilon_k = \hbar^2k^2/2m$, and the ionized target left in a state $|\alpha, E_\alpha\rangle$. Upon dividing the transition rate by the incident photon current density c/V, one gets the (triple) differential cross section of the $|o\rangle \to |\alpha, \boldsymbol{k}\rangle$ process

$$\frac{d\sigma_{o\to\alpha}}{d\boldsymbol{k}} = \left(\frac{4\pi^2\omega}{c}\right)|\langle\Psi_0|\hat{O}_{\hat{\varepsilon}}|\Psi^-_{\alpha k}\rangle|^2 \times \delta(\hbar\omega + E_o - E)$$

where $\hat{O}_{\hat{\varepsilon}} = \hat{\varepsilon}\cdot\sum_j q_j \boldsymbol{r}_j$ is the dipole operator. Note that, if the state $|\alpha, E_\alpha\rangle$ of the ionized target is an excited state with finite lifetime $\tau = \hbar/\Gamma_\alpha$, the δ-function in the above expression is substituted by a Lorentzian function L_{Γ_α} such that

$$\lim_{\Gamma_\alpha\to 0}\frac{\Gamma_\alpha/2\pi}{(\hbar\omega + E_o - E)^2 + (\Gamma_\alpha/2)^2} = \delta(\hbar\omega + E_o - E)$$

The above cross section gives the angular distribution of a photoelectron ejected from the target along a direction $\hat{k}$ defined in the target frame. The corresponding direction of emission in the laboratory frame can be easily obtained if one knows the target orientation. If, however, the irradiated system consists of an ensemble of randomly oriented targets, the theory shows, in agreement with the experiment, that the measured angular distribution of the photoelectrons ejected along a given direction $\hat{r}$, defined with respect to the quantization axis $\hat{z}$ (which, for linearly polarized light, is the same as the electric field direction,) is given by the simple expression

$$\frac{d\sigma_{o\to\alpha}}{d\hat{r}} = \frac{\sigma_{o\to\alpha}}{4\pi}[1 + \beta\, P_2(\cos\theta)],$$
$$\cos\theta = \hat{r}\cdot\hat{z}$$

Here $\sigma_{o\to\alpha}$ is the total cross section of the process, $P_2(\cos\theta) = (1.5\cos^2\theta - 0.5)$ is the second Legendre polynomial, and β is called the angular distribution or anisotropy parameter.

If the X-ray photon absorption gives rise to a metastable state $|\Phi_r\rangle$ embedded in the continua of M decay channels $\{|\psi^-_{\alpha k}\rangle\}$, the appropriate scattering wave function for the final state of the process is given by Fano's theory of the interaction between

discrete and continuous states

$$|\Psi^-_{\alpha\boldsymbol{k}}\rangle = |\psi^-_{\alpha\boldsymbol{k}}\rangle + |\Phi^-_r\rangle \frac{\langle\Phi_r|\hat{H}-E|\psi^-_{\alpha\boldsymbol{k}}\rangle}{E-E_r-\mathrm{i}\Gamma_r/2}$$

$$|\Phi^-_r\rangle = \Phi_r\rangle + \sum_\beta \int \frac{|\psi^-_{\beta\boldsymbol{p}}\rangle \mathrm{d}\boldsymbol{p} \langle\psi^-_{\beta\boldsymbol{p}}|\hat{H}-E|\Phi_r\rangle}{E-(E_\beta+\varepsilon_p)-\mathrm{i}0^+}$$

where $\{E_\beta\}$ are the energies of the ionized target and E_r that of the metastable state, whose natural width is Γ_r. The cross section of the process is, therefore, given by

$$\frac{\mathrm{d}\sigma_{\mathrm{o}\to\alpha}}{\mathrm{d}k} = \left(\frac{4\pi^2\omega}{c}\right) \left| \langle\Psi_\mathrm{o}|\hat{O}_{\hat{\varepsilon}}|\psi^-_{\alpha\boldsymbol{k}}\rangle + \langle\Psi_\mathrm{o}\left|\hat{O}_{\hat{\varepsilon}}\right|\Phi^-_r\rangle \frac{\langle\Phi_r|\hat{H}-E|\Psi^-_{\alpha\boldsymbol{k}}\rangle}{E-E_r-\mathrm{i}\Gamma_r/2} \right|^2 \times \delta(\hbar\omega+E_\mathrm{o}-E)$$

and consists of three contributions: that due to the direct photoionization (square modulus of the first amplitude), that due to the two-step process (square modulus of the second term) with a characteristic Lorentzian profile, and an interference term which can distort the Lorentzian profile asymmetrically.

For two-step photoionization processes (emission of a photoelectron with momentum $\boldsymbol{p}$ and energy ε_p, followed by Auger decay with an electron ejected with momentum $\boldsymbol{k}$ and energy ε_k), one can approximate the scattering wave function with the product

$$|\Theta^-_{\alpha\boldsymbol{k}\boldsymbol{p}}(E)\rangle \simeq |\Psi^-_{\alpha\boldsymbol{k}}(E_p)\rangle |\eta_{\boldsymbol{p}}(\varepsilon_p)\rangle$$

where $\Psi^-_{\alpha\boldsymbol{k}}$ is the wave function for the decay process, $\eta_{\boldsymbol{p}}(\varepsilon_p)$ is the spin orbital of the ejected photoelectron and $E = E_\alpha + \varepsilon_k + \varepsilon_p = E_p + \varepsilon_p$ is the energy of the stationary state. The (sixfold) differential cross section, that gives the conditional probability of collecting the photoelectron with momentum $\boldsymbol{p}$ and the Auger electron with momentum $\boldsymbol{k}$ simultaneously, is given by

$$\frac{\mathrm{d}^2\sigma_{\mathrm{o}\to\alpha}}{\mathrm{d}\boldsymbol{k}\,\mathrm{d}\boldsymbol{p}} = \left(\frac{4\pi^2\omega}{c}\right) |\langle\Psi_\mathrm{o}|\hat{O}_{\hat{\varepsilon}}|\Theta^-_{\alpha\boldsymbol{k}\boldsymbol{p}}\rangle|^2 \delta(\hbar\omega-\Delta) \propto \frac{|\langle\Psi_\mathrm{o}|\hat{O}_{\hat{\varepsilon}}|\Phi^-_r;\eta_{\boldsymbol{p}}\rangle\langle\Phi_r|\hat{H}-E_p|\Psi^-_{\alpha\boldsymbol{k}}\rangle|^2}{(E_p-E_r)^2+\Gamma_r^2/4} \times \delta(\hbar\omega-\Delta)$$

where $\Delta = E - E_\mathrm{o}$ and the contribution of the direct double photoionization has been neglected. In Auger spectroscopy, only electrons produced by the decay process are recorded; therefore, the cross section relevant to an experiment, in which they are collected from all the directions and selected in terms of their kinetic energy ε, is given by

$$\frac{\mathrm{d}\sigma_{\mathrm{o}\to\alpha}}{\mathrm{d}\varepsilon} = \int \delta(\varepsilon-\varepsilon_k)\mathrm{d}\boldsymbol{k} \int \frac{\mathrm{d}^2\sigma_{\mathrm{o}\to\alpha}}{\mathrm{d}\boldsymbol{k}\,\mathrm{d}\boldsymbol{p}}\,\mathrm{d}\boldsymbol{p} \propto \frac{\mathscr{D}_r(\omega,\varepsilon)\mathscr{M}_{r\alpha}(\varepsilon)}{(\varepsilon_\mathrm{A}-\varepsilon)^2+\Gamma_r^2/4}$$

where $\varepsilon_\mathrm{A} = E_r - E_\alpha$ is the nominal Auger energy of the ejected electrons and

$$\mathscr{D}_r(\omega,\varepsilon) = \int |\langle\Psi_0|\hat{O}_{\hat{\varepsilon}}|\Phi^-_r;\eta_{\boldsymbol{p}}\rangle|^2 \delta(\hbar\omega-\Delta)\,\mathrm{d}\boldsymbol{p}$$

$$\mathscr{M}_{r\alpha}(\varepsilon) = \int |\langle\Phi_r|\hat{H}-E_p|\Psi^-_{\alpha\boldsymbol{k}}\rangle|^2 \delta(\varepsilon-\varepsilon_k)\,\mathrm{d}\boldsymbol{k}$$

The structure of this cross section shows that, in the two-step approximation, the Auger lines have a Lorentzian shape of width equal to the natural width of the core-ionized state. Note that, in this approximation, the angular distribution of Auger electrons ejected from an ensemble of randomly oriented targets has exactly the same structure as that given above for photoelectron emission. If, however, the decay process is not clearly separate from the primary photoionization, the scattering wave function $\Theta^-_{\alpha\boldsymbol{k}\boldsymbol{p}}$ cannot be approximated by a simple product, and antisymmetrization and correlation contributions have to be included.

Photoprocesses in Atomic Systems

Since, in the independent particle model of an atomic system, each electron is described by a single-particle function (called spin–orbital and corresponding to a specific energy level) and the dipole operator is a single-particle operator, one expects that the main photoprocesses are one-electron processes, that is, one-electron excitations with discrete spectrum and one-electron ionizations with continuous spectrum. However, since the electronic motion is correlated by the Coulomb interaction potential:

$$\hat{V}_\mathrm{c} = \frac{1}{4\pi\varepsilon_0} \sum_{i<j} \frac{e_0^2}{|\boldsymbol{r}_i - \boldsymbol{r}_j|}$$

many-electron processes induced by the photointeraction are also possible. Among them, the most important ones are two-electron processes, that are classified as satellite or direct processes when two electrons are simultaneously excited or ionized or one is excited and the other ionized, and two-step processes when the primary excitation or ionization of an inner-shell electron is followed by radiative decay (fluorescence) or nonradiative (autoionization

or Auger) decay. It is clear that, in the case of two-step processes, the final state can also be reached through a direct path, which can compete and interfere with the two-step path modifying the spectral profiles appreciably. In this case, the distinction between direct and two-step processes breaks down and a unified description of the global process is necessary.

These processes are separately considered.

Direct Photoionizations

A direct photoionization is a one-step process in which a monochromatized X-ray photon of energy $\hbar\omega$ is absorbed by the target and leads to the emission of a photoelectron of energy $\varepsilon = \hbar\omega - E_I$, if $\hbar\omega$ is greater than the ionization energy (E_I) of the system and the recoil energy of the target (due to conservation of the total momentum) is negligible. This radiation–matter interaction mode is called photoelectric effect and the resulting structures in the energy spectrum of the ejected photoelectrons are called main photolines, if produced by a simple ionization, and satellites or discrete photolines, if produced by processes in which one electron is ionized and another one simultaneously excited. The continuous energy distribution due to direct double ionizations, in which two ejected electrons share the available energy, are called continuous satellites.

The photoelectron spectra show the dependence of the electron yield, that is, of the number of electrons recorded within a certain time interval at a given intensity of the incident light, on the measured kinetic energy ε or on the modulus of the binding energy $|E_B| = E_I = \hbar\omega - \varepsilon$ of the ejected electrons, or on the photon energy (see **Figure 1**). In these spectra, one observes discrete structures (peaks) at specific energy positions, with different height and width, two features that are related to the intensity (probability) of the specific process. The theory shows that the appropriate measure of the intensity is the area under the photoline, a number which strongly depends on the lineshape. This shape is the result of three contributions: (1) the energy distribution of the incident radiation, usually described by a Gaussian function G_B, centered at the nominal photon energy and with full width at half maximum (FWHM) equal to the "bandpass" (selected energy interval) of the monochromator; (2) the energy distribution of the core-hole state, that is described by a Lorentzian function L_Γ, whose FWHM Γ is called the natural or inherent width of the state; and (3) the spectrometer function, usually approximated by a Gaussian function G_{sp}, centered at a nominal kinetic energy ε_0 and with FWHM equal to the "pass-energy" of the spectrometer. The convolution of these three functions yields the experimental distribution function $F_{exp}(\varepsilon) = G_{sp} \otimes L_\Gamma \otimes G_B$ of photoelectrons detected at a given energy ε. The measured intensity along a given direction $I_{exp}(\varepsilon, \hat{k})$ is the area under the photoline recorded within a certain time interval, in which N_{ph} photons per second hit a sample of targets of density ρ. This intensity, corrected for the efficiency and luminosity of the spectrometer (S), is given by the

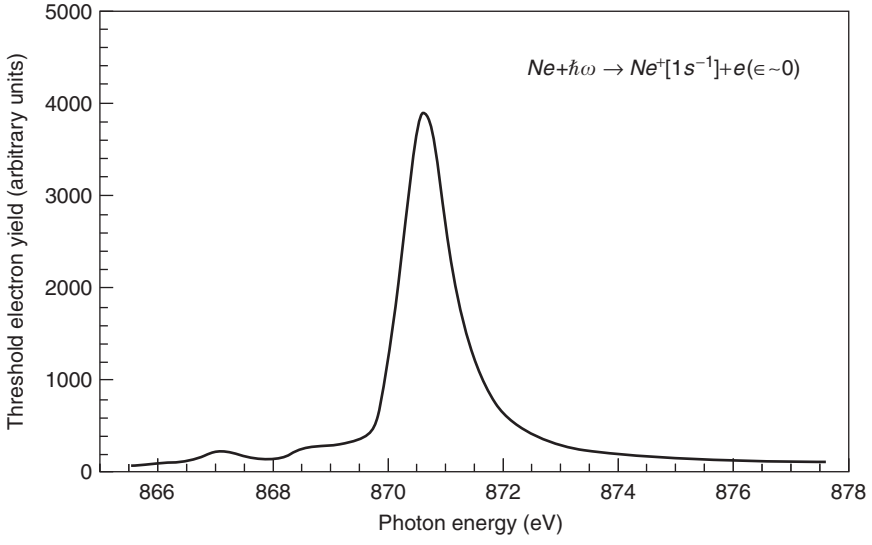

Figure 1 Threshold photoelectron spectrum in the region of Ne[$1s^{-1}$] ionization. The satellites on the low-energy side of the spectrum are due to the decay of metastable Ne[$1s\,2s^2 2p^6 np, n = 3, 4, \ldots$] states; the broadening on the high-energy side is due to post-collision interaction (PCI) between the slow photoelectron and the faster Auger electron emitted in the decay of the inner hole (see text). (Adapted from Avaldi L, Dawber G, *et al.* (1995) Measurement of Ne 1s and 1s nl satellite photoelectron spectra near threshold. *Physical Review A* 51: 5025.)

expression

$$I_{\exp}(\varepsilon, \boldsymbol{k}) = N_{\text{ph}}\ \rho S F_{\exp}(\varepsilon)\frac{\mathrm{d}\sigma}{\mathrm{d}\boldsymbol{k}}$$

where $\mathrm{d}\sigma/\mathrm{d}\boldsymbol{k}$ is the differential cross section of the process, which is independent of the specific features of the experiment and can be predicted *ab initio* by the theory. Note that X-ray photons interact with matter not only through photoelectric effect, but also through Compton and coherent scattering. In the Compton (incoherent) scattering, one photon collides with the target losing part of its energy and deflecting from the original direction. Results of this collision are electrons ejected with lower energies and a broad spectral distribution of scattered photons (Compton profile), related to the momentum distribution of the electrons in the target. Compton scattering is important especially at high X-ray energies and with elements of low atomic number. In the coherent (or elastic) scattering, instead, one photon is scattered without excitation or ionization of the target. This process occurs mostly at low energies and with elements of high atomic number.

Decay Processes

The absorption of a monochromatized X-ray photon can lead to the creation of a core-excited or a core-ionized state, which is metastable and spontaneously decays with a characteristic lifetime into a lower-energy state. In particular, when the frequency of the incident X-ray photon is tuned below or closely above a core-ionization threshold, core-excitations take place and the process is called resonant X-ray scattering or X-ray Raman scattering. The decay process can follow either a radiative path (i.e., emission of X-ray photons of energies $\{\hbar\omega\}$ and intensities $\{I_{\text{R}}(\hbar\omega)\}$ that constitute the fluorescence spectrum) or a nonradiative path (i.e., autoionization (after core-excitation) and Auger decay (after core-ionization) with emission of Auger electrons of characteristic energies $\{\varepsilon_j^{\text{A}}\}$ and intensities $\{I_{\text{A}}(\varepsilon_j^{\text{A}})\}$ that constitute the Auger spectrum). The global decay probability can be partitioned into a fluorescence yield: $\omega_{\text{R}} = I_{\text{R}}/(I_{\text{R}} + I_{\text{A}})$ and an Auger yield: $\omega_{\text{A}} = I_{\text{A}}/(I_{\text{R}} + I_{\text{A}})$, where $I_{\text{R}} = \sum_{\omega} I_{\text{R}}(\hbar\omega)$ and $I_{\text{A}} = \sum_j I_{\text{A}}(\varepsilon_j^{\text{A}})$ are the intensities of the radiative (R) and nonradiative (A) decay channels. One can predict from the theory and observe experimentally that, for atomic numbers $Z<30$, the Auger yield is bigger than the fluorescence yield, while for $Z>30$ the radiative decay becomes dominant.

The decay processes correspond to electronic transitions between levels that, in atoms, are classified according to their quantum numbers $(n, l,\ j = l \pm 1)$. These levels are grouped into shells and subshells that, in spectroscopic notation, are

- K-shell $(n = 1,\ l = 0,\quad j = 1/2|N_{\text{max}}^{\text{el}} = 2)$, the most tightly bound shell which contains a maximum number of electrons $N_{\text{max}}^{\text{el}} = 2n^2 = 2$;
- L-shell $(n = 2|N_{\text{max}}^{\text{el}} = 8)$, the next most tightly bound shell which consists of three subshells: $L_{\text{I}}(n = 2,\ l = 0,\ j = 1/2|N_{\text{max}}^{\text{el}} = 2j + 1 = 2)$, $L_{\text{II}}(n = 2,\ l = 1,\ j = 1/2|N_{\text{max}}^{\text{el}} = 2)$, $L_{\text{III}}(n = 2,\ l = 1,\ j = 3/2|N_{\text{max}}^{\text{el}} = 4)$;
- M-shell $(n = 3|N_{\text{max}}^{\text{el}} = 18)$ with five subshells: $M_{\text{I}}(n = 3,\quad l = 0, j = 1/2|N_{\text{max}}^{\text{el}} = 2)$, $M_{\text{II}}(n = 3,\ l = 1,\quad j = 1/2|N_{\text{max}}^{\text{el}} = 2)$, $M_{\text{III}}(n = 3, l = 1, j = 3/2|N_{\text{max}}^{\text{el}} = 4)$, $M_{\text{IV}}(n = 3,\ l = 2,\ j = 3/2|N_{\text{max}}^{\text{el}} = 4)$, $M_{\text{V}}(n = 3, l = 2, j = 5/2|N_{\text{max}}^{\text{el}} = 6)$;

and so on, until the last natural element, uranium $(Z = 92)$, with the last two electrons in the subshell O_{VIII}.

Fluorescence spectra The radiative decay of metastable states gives rise to emission of X-ray series, that are classified according to the shell that is filled and to the relative intensity of the emitted radiation. Thus, for example, the K-series corresponds to the filling of the K-shell and one distinguishes between the more intense K_α-rays produced by $L \rightarrow K$ transitions: $K_{\alpha_1}(L_{\text{III}} \rightarrow K)$ and $K_{\alpha_2}(L_{\text{II}} \rightarrow K)$, and the less intense K_β-rays produced by $M,N \rightarrow K$ transitions: $K_{\beta_1}(M_{\text{III}} \rightarrow K)$, $K_{\beta_2}(N_{\text{II,III}} \rightarrow K)$, $K_{\beta_3}(M_{\text{II}} \rightarrow K)$, $K_{\beta_4}(N_{\text{IV,V}} \rightarrow K)$, $K_{\beta_5}(M_{\text{IV,V}} \rightarrow K)$. The L-series corresponds to the filling of vacancies in the L-subshells and one distinguishes between the more intense $L_{\alpha 1}$- and $L_{\alpha 2}$-rays produced by $M_{\text{V,IV}} \rightarrow L_{\text{III}}$ transitions, and the less intense L_β-rays produced by $M,N,O \rightarrow L$ transitions: $L_{\beta_1}(M_{\text{IV}} \rightarrow L_{\text{II}})$, $L_{\beta_2}(N_{\text{V}} \rightarrow L_{\text{III}})$, $L_{\beta_3}(M_{\text{III}} \rightarrow L_{\text{I}})$, $L_{\beta_4}(M_{\text{II}} \rightarrow L_{\text{I}})$, $L_{\beta_5}(O_{\text{IV,III}} \rightarrow L_{\text{III}})$.

In addition to the main transitions, there are also satellite lines that are due to the radiative decay of two- and three-hole states produced in the primary photoionization, for example, $KL \rightarrow LL$ and $KLL \rightarrow LLL$ transitions. An example of fluorescence spectrum is shown in **Figure 2**, where the intensity of the X-rays produced by main and satellite transitions following 1*s* ionization of Ne is plotted as a function of the energy of the emitted radiation.

Auger spectra The nonradiative decay of core-ionized states gives rise to Auger spectra in which the electrons are detected with energies characteristic of the target and mostly independent of the photon energy. The transitions associated to the spectral lines are called normal (or diagram) Auger if the initial state of the decay is a core-hole state, produced by

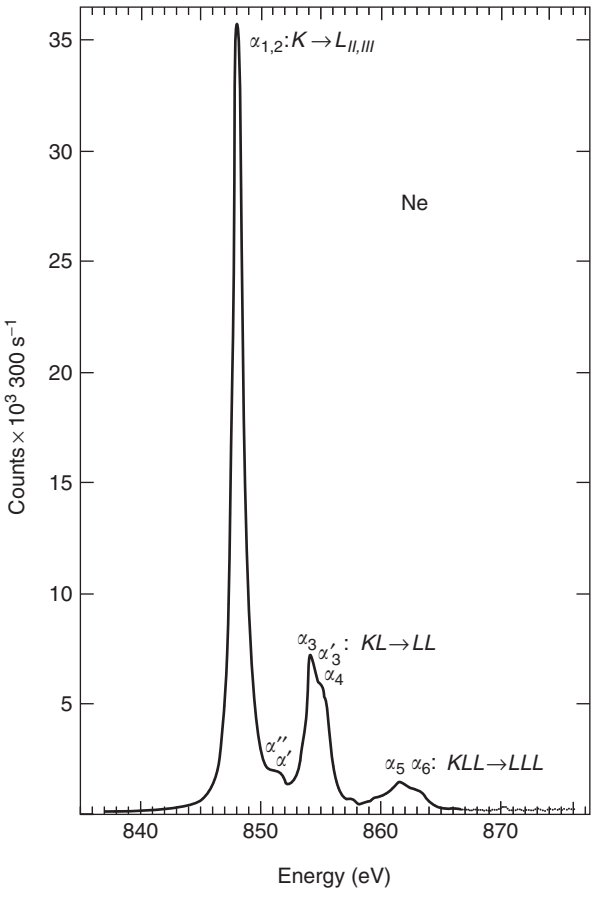

Figure 2 Fluorescence spectrum following 1*s* ionization of Ne: the main line is produced by the superposition of the $K \rightarrow L_{II,III}$ transitions; the less intense lines on the high-energy side of the spectrum are due to satellite transitions. (Adapted from *Physica Scripta* 7: 173 (1973).)

the absorption of a photon whose energy is higher than the core-ionization threshold. The emitted electrons have nominal energies $\{\varepsilon_j^{\mathrm{A}} = E_{\mathrm{i}}(1\mathrm{h}) - E_{f_j}(2\mathrm{h})\}$ resulting from the difference between the energy of the initial (i) one-hole (1 h) state and the energy of each (j) two-hole (2 h) final (f) state of the target. The Auger transitions are usually classified as main (or diagram) transitions, if the initial hole is in the *K*-shell, for example, $K \rightarrow L_1L_2$ in Ne, and Coster–Kronig and super Coster–Kronig transitions, if the final state has, respectively, one or two holes in the same shell in which the initial state has its hole. Examples of Coster–Kronig and super Coster–Kronig transitions are, respectively, the $L_{\mathrm{I}} \rightarrow L_{\mathrm{II,III}}\, M_{\mathrm{I}}$ transitions in Mg and the $N_{\mathrm{II,III}} \rightarrow N_{\mathrm{IV,V}}\, N_{\mathrm{IV,V}}$ transitions in Xe.

The shape of a typical Auger line, (i.e., that produced by a decay process completely separated from the primary photoionization (two-step process)) is obtained from the convolution of two Lorentzian functions $L_{\Gamma \mathrm{i}}$ and $L_{\Gamma \mathrm{f}}$ (that give the energy distributions of the initial (i) corehole and the final (f) two-hole state of the process) with the spectrometer function G_{sp} centered at a nominal kinetic energy. This convolution yields the experimental distribution function $F_{\mathrm{A}}^{\mathrm{fi}}(\varepsilon) = G_{\mathrm{sp}} \otimes L_{\Gamma_{\mathrm{f}}} \otimes L_{\Gamma_{\mathrm{i}}} = G_{\mathrm{sp}} \otimes L_{\Gamma_{\mathrm{fi}}}$ of the Auger electrons recorded at a given energy ε. In this expression $L_{\Gamma_{\mathrm{fi}}} = L_{\Gamma_{\mathrm{f}}} \otimes L_{\Gamma_{\mathrm{i}}}$ is a Lorentzian with FWHM $\Gamma_{\mathrm{fi}} = \Gamma_{\mathrm{f}} + \Gamma_{\mathrm{i}}$. The intensity of the Auger electrons produced by the transition is given by the expression

$$I_{\mathrm{A}}^{\mathrm{fi}}(\varepsilon) = N_{\mathrm{ph}}\ \rho S F_{\mathrm{A}}^{\mathrm{fi}}(\varepsilon) \sigma_{\mathrm{ph}} \omega_{\mathrm{A}}^{\mathrm{fi}}$$

where σ_{ph} is the photoionization cross section (first step of the process) and $\omega_{\mathrm{A}}^{\mathrm{fi}}$ the partial Auger yield (second step of the process). Note that, when the photon energy is close to the core-ionization threshold, the Auger emission can be influenced by the presence of a slow photoelectron. The resulting interaction between the two escaping electrons in the field of the doubly ionized target is called post-collision interaction (PCI). The main consequence of PCI is an energy distribution of the emitted electrons that is no longer described by a Lorentzian function, but becomes asymmetric, broadened, and displays maximum shift in energy.

Together with the lines associated with the normal Auger transitions, one also observes satellite lines, which are called photosatellites if produced by the decay of one-hole states in which another electron has been simultaneously ejected (shake-off), for example, $KL \rightarrow LLL$, or excited (shake-up) to an empty level (L^*). In the latter case, the electron can either be directly involved in the following decay process, for example, $KL^* \rightarrow LL$ (participator transition), or act as spectator, for example, $KL^* \rightarrow LLL^*$ (spectator transition). An example of Auger spectrum with photosatellites is given in **Figure 3**.

In addition to these satellites produced by two-electron processes in the primary photoionization, there are also satellites due to double Auger transitions that are three-electron processes in which the third electron is either excited to an empty level, for example, $K \rightarrow LLL^*$ (discrete double), or ejected into the continuum, for example, $K \rightarrow LLL$ (continuous double). A schematic representation of normal and satellite transitions from core-hole and shake-modified core-hole states is given in **Figure 4**.

A separate group of peaks is that in which the initial state of the decay process is a core-excited state of the neutral system, that is, a discrete metastable state produced by the absorption of a monochromatized photon of energy $\hbar\omega_{\mathrm{res}}$ below the core-ionization threshold, for example, $1s \rightarrow np$ in Ne. The autoionization of this state produces electrons with nominal energies $\{\varepsilon_j^{\mathrm{A}} = \hbar\omega_{\mathrm{res}} - E_{\mathrm{f_j}}(1\mathrm{h})\}$

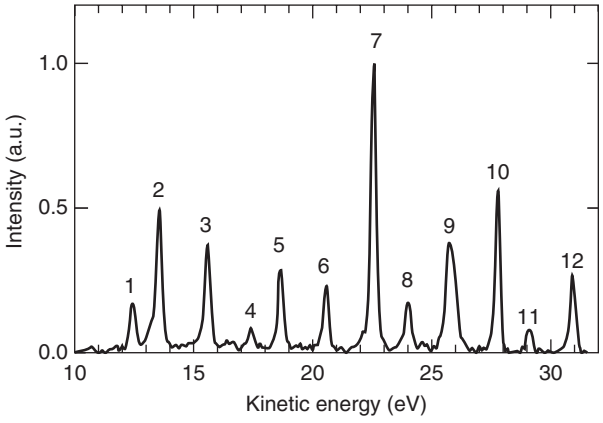

Figure 3 Neon $LL^* \rightarrow LL$ Auger spectrum. Lines 1,3,4,6 correspond to transitions $Ne^+[2s^12p^5(^3P)(3p,4p)] \rightarrow Ne^{2+}[2s^22p^4(^1D_2, ^3P)]$, lines 2,5,8,11 to transitions $Ne^+[2s^02p^6(^1S)(3p,4p)] \rightarrow Ne^{2+}[2s^12p^5(^1P,^3P)]$, lines 7,9,10,12, to transitions $Ne^+[2s^12p^5(^1P)(3p,4p)) \rightarrow Ne^{2+}[2s^22p^4(^1D_2, ^3P)]$. Figure 4 Selection of possible decay processes from core-hole and shake-modified core-hole states. The energy-level diagram (not to scale) is for electrons in 1*s*, 2*s*, 2*p* shells, in an excited orbital and in the continuum (shaded area).

either through a participator or a spectator transition. These excitations with their autoionization decay are called resonances and ought to be described as one-step processes (called Auger resonant or Auger resonant Raman), since the shape of the emission spectra are strongly dependent on the energy of the exciting radiation. The final state of these resonances can be reached via two indistinguishable pathways (a direct photoionization and a two-step process); it follows that the corresponding amplitudes can interfere and give rise to peculiar asymmetric lineshapes, called Fano profiles: see **Figure 5**.

Due to their similarity with a normal Auger process, the spectator transitions are also called resonance Auger or autoionization spectator transitions. Furthermore, due to correlation effects (orbital relaxation) during the decay process, it is also possible that the spectator electron can be promoted into a different orbital (shake-up) or even ejected into the continuum (shake-off). These processes are called shake-modified spectator transitions or resonance shake transitions.

Finally, there are also combinations of radiative and nonradiative transitions, called radiative Auger decay, in which the emission of a photon is accompanied by the simultaneous excitation or ejection of one electron.

Photon Impact Versus Electron Impact

Using high-energy electrons as projectiles instead of monochromatized photons, the energy transfer to the target covers a broad energy range: from zero up to the energy of the electron beam. It follows that the excitation/ionization of the target is not selective, but many different states of the neutral or ionized target can be populated; furthermore, the autoionization of these states produces additional structures in the electron spectrum. As a matter of fact, one collects a

large number of scattered and primary electrons with a wide range of kinetic energies. Hence, in noncoincidence experiments, the Auger lines are superimposed on a large and smooth background of electrons. Furthermore, at low-impact energies the production mechanism for satellites may be different for electron and photon impact. Finally, in the Auger decay of a metastable state produced by electron impact, there are, indeed, three electrons outgoing in the field of the ionized target; it follows that the presence of one electron with low kinetic energy is highly probable. This is the reason why, for electron impact, PCI does not vanish even for high energies of the projectile.

Molecular Spectra

The specificity of the molecular spectra resides on the presence of nuclear degrees of freedom in the target, that can be excited by the projectile and participate in the decay process. Final possible results of a collision between a molecule (M) and a photon are

$$
\begin{aligned}
& M + \hbar\omega \\
& \quad \rightarrow M^{n+} + n\, e^- \qquad \text{(ionization)} \\
& \quad \rightarrow M^* + \hbar\omega' \qquad \text{(resonance fluorescence)} \\
& \quad \rightarrow A + B \qquad \text{(neutral dissociation)} \\
& \quad \rightarrow A^+ + B + e^- \qquad \text{(dissociative ionization)} \\
& \quad \rightarrow A^+ + B^- \qquad \text{(ion pair formation)}
\end{aligned}
$$

In many cases, these channels are in mutual competition and characterized by the presence of intermediate metastable states, in which the target is electronically and/or vibrationally and/or rotationally excited. The result is a large number of spectral lines that, in principle, can be classified by the electronic, vibrational, and rotational quantum numbers of the final states of the ionized molecule. In many cases, however, the finite resolution of the electron spectrometer(s) does not allow one to separate these lines which, therefore, collapse into broad spectral profiles. Coincidence techniques (such as ion/photo- or Auger-electron, ion/ion, photo-electron/Auger-electron and their combinations) are the most powerful methods to investigate the dynamics of these processes that, in coincidence experiments, are treated as state-selected reactions.

The theoretical approach to study these processes is the same outlined above, but requires the use of wave functions that depend explicitly on both the electronic $\{\boldsymbol{r}\}$ and the nuclear $\{\boldsymbol{R}\}$ coordinates and, in Born–Oppenheimer approximation, are products of the type:

$$\Psi_{\alpha k}(\{\boldsymbol{r}\}\{\boldsymbol{R}\}) = \psi^{\mathrm{el}}_{\alpha_e \boldsymbol{k}}(\{\boldsymbol{r}\}, \{\boldsymbol{R}\}) \times \psi^{\mathrm{nu}}_{\alpha_n}(\{\boldsymbol{R}\})$$

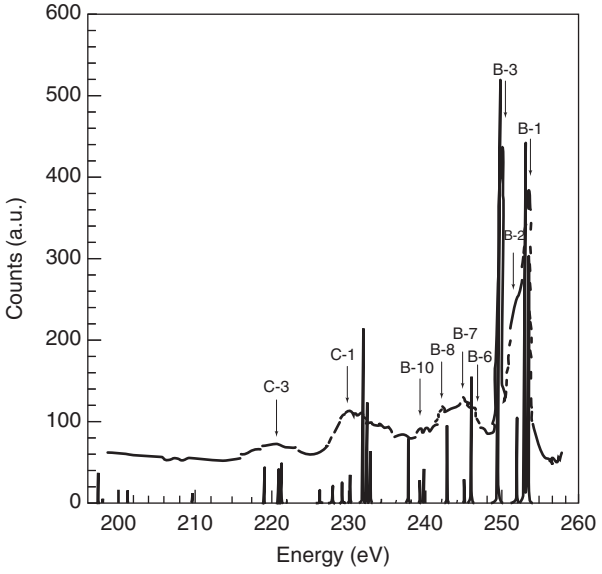

Figure 6 Calculated electronic transitions (see text) in the C1 *s*-Auger spectrum of the carbon monoxide, compared with the experimental spectrum (upper continuous line). (Adapted from Colle R and Simonucci S (1993) Multichannel resonance processes: theory and application to the Auger spectra of the CO molecule. *Physical Review A* 48: 392.)

The Auger spectroscopy has been applied to gas-phase molecules mainly to obtain information on their dicationic states. Auger spectra, however, also contain considerable chemical information on the local structure around the core-ionized atom, and it is often possible to recognize local similarities in Auger spectra of different molecules with the same functional group.

In **Figure 6**, the $C\,1s$ Auger spectrum of the carbon monoxide is shown in the region dominated by the normal $K \rightarrow YY$ transitions, where Y can be either a weakly ($Y = W$) or a strongly ($Y = S$) bound orbital; in particular, the C-lines correspond to $K \rightarrow WS$ transitions and the B-lines to $K \rightarrow WW$ transitions.

Deep-Level Spectroscopies of Atoms in Solids

Photoelectron, Auger-electron, and X-ray spectroscopies are increasingly used as tools for investigating solid-state systems in order to get information on electronic, structural, and dynamical properties of the system, and to know the type, arrangement, and properties of the atomic species on the surface and below the surface of the solid.

A powerful method for chemical analysis is electron spectroscopy for chemical analysis (ESCA), in which an X-ray beam of discrete energy is directed onto the specimen and the emitted electrons are collected and energy analyzed. The resulting spectra are, in general, simple and characterized by relatively

narrow and well-defined peaks that allow the identification of the emitting atoms.

Another method to have qualitative and quantitative information on the composition of the solid sample is the electron probe microanalysis, in which the X-rays emitted after ionization by electron impact are analyzed.

A more recent technique developed to obtain information on the structure of molecules (mainly low-Z molecules) bonded to or absorbed on a surface is near edge X-ray absorption fine structure (NEXAFS), also known as X-ray absorption near edge structure (XANES). This technique selects an atomic species through its K-edge and probes its bonds to intra-and extramolecular (i.e., surface atoms) neighbors by analyzing the prominent, structure-sensitive resonances in the first ~ 30 eV above the K-edge. An example is given in **Figure 7**.

The Auger spectroscopy of atoms in solids detects only the Auger electrons coming from the few outermost layers of the solid: the mean escape depth of these electrons may extend, indeed, from two to four atomic layers (4–8 Å), since Auger electrons produced below these layers lose enough energy to be scattered out of the peak into the inelastic background. The resulting Auger peaks contain information not only about the solid-state environment of the emitting atom, but also on the atom itself, and this is the reason of the importance of the Auger spectroscopy as an analytic tool. Auger spectroscopy also provides a useful technique for investigating two-particle density of states, hole–hole Coulomb interaction, and correlation effects. Unfortunately, the complexity of these spectra quite often obscures the results of this technique. The complexity is due to the overlap of adjacent lines, to the fact that, in general, the initial state of the decay process is not a simple one-hole state, to the difficulty in distinguishing between Auger and shake-modified transitions, and to the presence of plasma loss peaks (associated with both the elastic peaks and the more pronounced Auger peaks) and ionization loss peaks, due to incident electrons that lose part of their energy in the ionization of other atoms.

The Auger spectra of solids are thus characterized by a large background of electrons scattered inelastically by the atoms of the solid. These electrons have energies distributed over a wide range and constitute the so-called background of secondary electrons, whose intensity can be even two or three orders of magnitude bigger than the Auger signal. This is the reason why, instead of reporting the number of electrons recorded as a function of their kinetic energy, the Auger spectra of solid samples are often constructed by plotting the energy derivative of this number. An example is given in **Figure 8**.

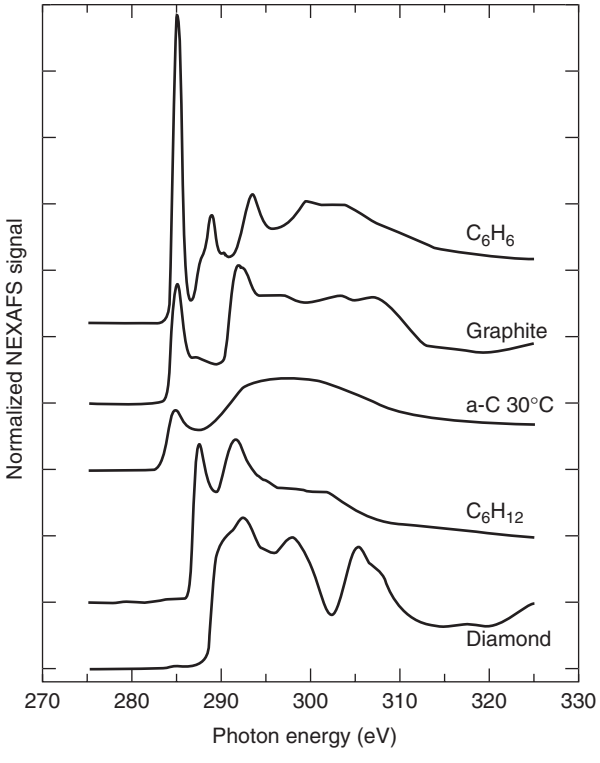

Figure 7 C1*s* NEXAFS spectra of various molecules and solids. (Adapted from Comelli G, Stöhr J, *et al.* (1988) Structural studies of argon-sputtered amorphous carbon films by means of extended X-ray-absorption fine structure. *Physical Review B* 38: 7511.)

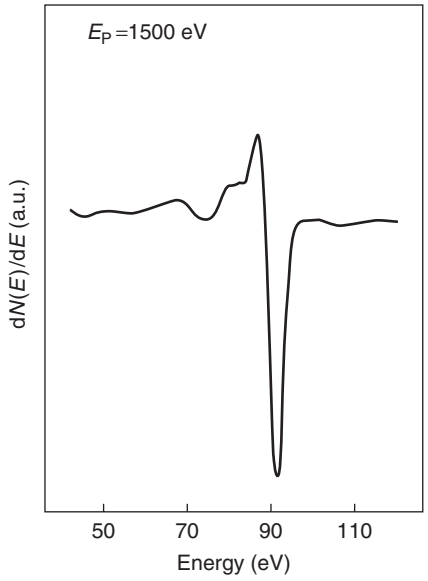

Figure 8 $L_{II,III}$ Auger-emission band of Si(1 1 1). (Adapted from Melles J, Davis L, and Levenson L (1974) Auger satellites of the $L_{2,3}$ Auger emission bands of Al, Si, and P. *Physical Review B* 9: 4618.)

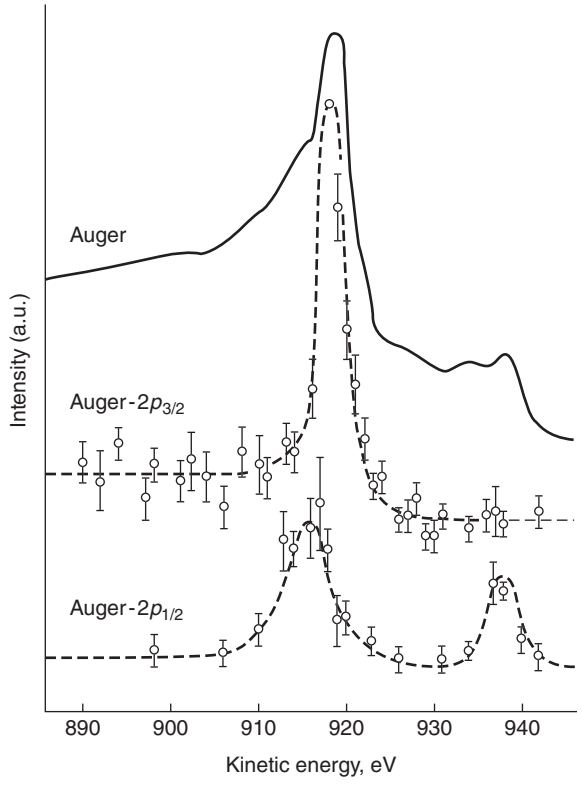

Figure 9 Auger and Auger–photoelectron coincident spectra of Cu. The second and third curves are the Auger spectrum in coincidence respectively with the $2p_{3/2}$ and $2p_{1/2}$ photoelectrons. Experimental points with error-bars are reported. (Adapted from *Physical Review Letters* 41: 1826 (1978).)

The complexity of the Auger spectra of atoms in solids is also the reason why much of the theoretical formulations is still phenomenological or semiempirical, and is quite often based on simplifying assumptions or model Hamiltonians, which try to simulate the real systems still allowing for analytical or numerical solutions.

Photoelectron/Auger-electron coincident spectroscopies have been recently explored to gain a better understanding of the correlations in solid-state systems. Detecting Auger- and photoelectrons simultaneously that are correlated in time and originate from the same core-ionization event, removes, indeed, most of the uncertainties and limitations of the standard Auger spectroscopy. Three different classes of experiments have been developed: (1) Auger spectra measured at fixed photoelectron energy; (2) photoelectron spectra measured at fixed Auger-electron energy; and (3) angular distribution patterns of Auger–photoelectron pairs. A highlighting example of the capability of these techniques to separate overlapping components of an Auger spectrum is given in **Figure 9**, where Auger and Auger–photoelectron coincidence spectra of copper are compared.

Finally, a recent technique, called either photoelectron or Auger-electron holography (depending on the process under consideration) is mentioned, which allows one to get three-dimensional images of the close vicinity of a given near-surface atom emitter. Using this technique, one records, on a photographic plate, the interference pattern (hologram) of a known reference wave (the photoelectron or Auger-electron wave emitted by the excited atom) with an unknown object wave (the superposition of the waves emitted by the surrounding atoms and due to multiple scattering processes); the obtained hologram is then illuminated with an appropriate decoding wave. The images of the atoms of the surface are obtained by means of computer reconstruction methods similar to those used in optical holography.

Defect Centers in Insulating Solids, Optical Properties of

G Baldacchini, ENEA, Frascati Research Center, Frascati, Italy

Introduction

As is well known from solid-state physics, crystalline materials (often also amorphous materials like glasses and ceramics) are of great interest in basic and applied research mainly because they contain defects. Indeed, properties of crystals or alloys such as mechanical strength, electrical and thermal conductivity, magnetic status, diffusion, and optical absorption and emission, are strongly dependent on crystalline irregularities and foreign impurities. For instance, impurities in metals increase their strength, decrease the electrical and thermal conductivity, and influence greatly the diffusion processes. Impurities in semiconductor and insulating crystals give them unusual electrical properties, which are used in electronic devices. Finally the optical properties are so deeply changed that new absorption and emission effects take place.

In so far as the optical properties are concerned, most insulating crystals (henceforth "crystals") are completely transparent, which is a consequence of their large bandgap. Indeed, the valence and conduction bands are separated by more than $\sim 3\,\text{eV}$ (400 nm), which is the upper limit for the detection of the human eye, and so the visible radiation cannot excite electrons from the valence band to the conduction band. In such crystals, the valence band is completely full of electrons, while the conduction band is empty, which explains their electrical and thermal insulating properties. **Figure 1** shows the absorption spectrum of a typical crystal, in this case an alkali halide (AH), which absorbs in the ultraviolet (UV) and in the infrared (IR) region of the spectrum, but not in the visible (VIS) part, that is, from ~ 1.7 to 3.1 eV (720 to 400 nm). The UV absorption is associated with the electronic excitations, whereas the IR band is due to lattice optical phonons, the so-called restrahl absorption.

When defects are introduced in the crystal, different effects can occur, depending on the nature of the defects. They can be extended, like dislocations, and so their electrons can be described by quasiperiodic or periodic wave functions as the electrons in the original crystal and, as a consequence, the optical properties change all over the spectrum. In practice, it is like dealing with a slightly new and different crystalline solid, and so this case is of no interest here. The situation is different when defects are localized, because the electrons bound to the defects cannot be described by the same wave functions as the electrons in the crystal, and so their eigenvalues too cannot be similar to those of the pure crystal. In this case new absorption bands appear in the wide region of the energy gap of **Figure 1**, where electron–crystal states do not exist. **Figure 2** shows a few typical absorption bands found in an AH crystal containing different kinds of point defects. The absorption bands are limited on the high-energy side by the ultraviolet absorption edge, E_g, of the crystal and on the low-energy side by the infrared (IR) lattice absorption. When these bands fall in the visible region of the spectrum, the crystal displays a

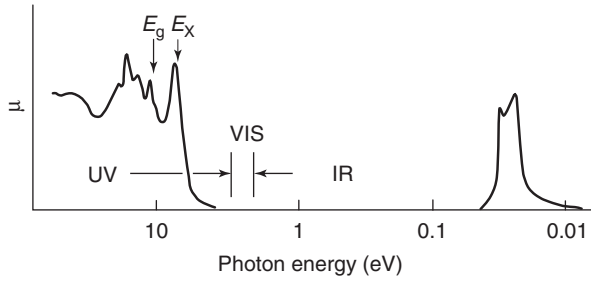

Figure 1 Absorption coefficient of a typical AH crystal as a function of energy in a log scale in order to show the wide range of the spectrum and the energy gap well inside the ultraviolet region. The absorption at high energy rises with electronic excitation (the labeled structures belong to excitons), while at low energy the peaks are associated with optical phonons. (Reproduced from Knox RS and Teegarden KJ (1968) Electronic excitations of perfect alkali halide crystals. In: Fowler WB (ed.) *Physics of Color Centers*. New York: Academic Press.)

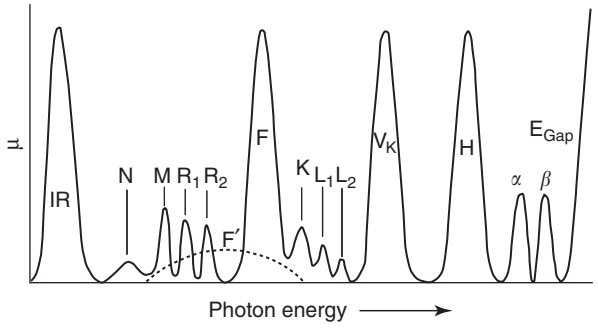

Figure 2 Schematic absorption coefficient of typical intrinsic point defects in AH crystals as a function of energy, which has been reversed with respect to **Figure 1**. The various absorption bands, which have been associated with well-defined color centers as labeled, rise in the wide crystal gap between the IR and ultraviolet E_g absorption of the crystal. (Reproduced from Townsend PD and Kelly JC (1973) *Colour Centres and Imperfections in Insulators and Semiconductors*. London: Sussex University Press.)

coloration that varies from blue to red, and for this reason point defects are usually referred to as color centers (CCs) in the literature.

There are several other kinds of crystals in nature, and it would be impossible even to simply consider them all in this article, which focuses only on the AHs, as shown in **Figures 1** and **2**. They are ionic crystals with a lattice cubic structure, and there are 20 of them, due to the combination of five alkaline metal atoms (Li, Na, K, Rb, Cs) with four halide atoms (F, Cl, Br, I), among them the well-known common salt, NaCl. However, it must be borne in mind that most of the optical properties of AHs are similar to those of other crystals, and so several approaches utilized in the AHs can also be extended to others. In other words, the simple AH crystals represent almost a model case for the crystals in general.

In so far as the point defects are concerned, they can be divided into intrinsic and extrinsic ones. Vacancies (empty lattice positions) and interstitials (lattice ions moved out of lattice positions) belong to the first class, while impurities belong to the second class. Impurities can be positive or negative atomic or molecular ions, which occupy the lattice positions or cause lattice distortions referred to as off-center situations; when they are monovalent, isoelectronic ions, they simply occupy the lattice positions, but when they are divalent or aliovalent ions, they produce vacancies nearby to keep the whole crystal electrically neutral. Finally, the intrinsic defects can bind themselves to the extrinsic ones, giving rise to defects associated with the impurities.

It is clear from the above discussion that the subject of defects in crystals is vast and, in particular, the extrinsic defects, due to their sheer large number represent an independent field of research in solid-state physics. In spite of their importance, these defects are not considered here and this article will be limited to addressing the intrinsic defects, which belong to the same constituents of the crystal (the CCs), and the intrinsic defects perturbed by foreign impurities (the perturbed CCs).

Color Centers

In 1863, a crystal of NaCl was colored at high temperature in Na vapors. However, this result and others obtained subsequently also in connection with the discovery of natural radioactivity and X-rays, which both produced coloration in several crystals in 1896, were considered mere scientific curiosities up to $\sim$1920 when a systematic research was started at Göttingen, Germany, by RW Pohl and co-workers.

Prior to 1940, CCs in AHs were characterized well enough as far as light absorption was concerned. At the same time, research in this field started to move outside Germany, where it was confined for almost a generation; important contributions were soon added elsewhere. For instance, there were high expectations for fluorescence in the near IR after optical pumping in the CC absorption bands in the visible region. After World War II, research was resumed and a lively debate started again about the existence of emission after optical excitation of the F center, which, as shown below, is the prototype of all CCs. Eventually, luminescence was found in 1954, and the optical cycle of the F center and other kinds of CCs was completely clarified subsequently.

As shown in **Figure 2**, there are several kinds of CCs that have been discovered and called differently. **Table 1** lists the known CCs with their old and actual denomination, without claiming to be a complete list. By looking at the basic structure of the CCs, there are only two species of them, that is trapped-hole and trapped-electron centers. Both of them appear, for instance, by irradiating AH crystals with X-rays, the former always having their bands, as V_k in **Figure 2**, at higher energies with respect to the latter, as F in the same figure. Although they were discovered at the same time long ago, the trapped-hole centers are not yet well known. Indeed, they produce so many absorption bands that it has proved to be difficult to associate each of them with well-defined centers and, as a result, only a few among them have been identified structurally. Moreover, trapped-hole centers never became as popular as trapped-electron centers. The latter have given rise to a much richer scientific production, as compared to the trapped-hole centers, which will not be discussed here.

CCs can be produced by resorting to chemical and physical methods. Among the first ones, the additive method is the most known and utilized to obtain homogeneously colored samples, while the electrolytic method is much simpler although the coloration is rather inhomogeneous. Usually, all crystals can be colored by irradiating them with ionizing radiation, UV light, X-rays, γ-rays, electron beams and elementary particles, ions, etc. **Figure 2** shows the absorption bands corresponding to several CCs produced with the previous methods in a typical AH crystal. If these bands are excited optically, it is possible to observe, especially from trapped-electron centers, emission bands that are strongly Stokes-shifted and often very intense. **Figure 3** gives the absorption and emission bands of the F center in KCl for various temperatures where, besides the Stokes shift, the broadening and peak positions show a sizeable temperature dependence. Similar properties belong also to the other CCs in KCl crystal, which are reported schematically in **Figure 4**, where on the left side there

Table 1 List of known color centers, with their previous and actual denomination

Actual notation	*Old notation*	*Description*
Trapped hole centers		
V_K	V_K	Self-trapped hole on a pair of halogen ions
H	H	Hole trapped along four halogen ions
V_4	V_4	A halogen di-interstitial
H_A, H_B	V_1	H center adjacent to alkali impurity ions
I^-	I	Interstitial halogen ion
I	[a]	Interstitial atom
[a]	F (halogen)$^-$	Mixed hole centers
[a]	V_2, V_3, …	Unidentified hole centers
Trapped electron centers		
F^+	α	A halogen ion vacancy
[a]	β	Not a CC but an excitation related to an F center
F	F	A halogen ion vacancy with one electron
F_2	M(C)	Two adjacent F centers
F_3	R_1(E), R_2(D)	Three adjacent F centers
F_4	N_1(G), N_2(G)	Four adjacent F centers
[a]	O	Unidentified electron center
F^-	F′	A halogen ion vacancy with two electrons
F_2^-	M′	Two adjacent halogen vacancies with three electrons
F_2^+	M^+	Two adjacent halogen vacancies with one electron
F_3^-	R′	Three adjacent halogen vacancies with four electrons
F_3^+	[a]	Three adjacent halogen vacancies with two electrons
F_4^-	N′	Four adjacent halogen vacancies with five electrons
F_A	A	An F center adjacent to one alkali impurity ion
F_B	B	An F center adjacent to two alkali impurity ions
F_C	[a]	An F center adjacent to three alkali impurity ions
F_H	[a]	An F center adjacent to a halide impurity ion
$(F_2)_p$	[a]	An F_2 center perturbed by defect centers
$(F_2^+)_{A/H}$	[a]	An F_2^+ center adjacent to an impurity positive/negative ion
$(F_2^+)_p$	[a]	An F_2^+ center perturbed by defect centers
F_4-like	[a]	An F_4 center perturbed by defect centers
$Tl^\circ(1)$	[a]	A halogen ion vacancy with one neutral Tl atom
F_Z	Z_1	An F_2^+ center with divalent positive ions
U	U	An F center adjacent to one hydrogen atom
U_1	U_1	An interstitial hydrogen negative ion
U_2	U_2	An interstitial hydrogen atom

[a] No correspondent notations exist.

is an essential design of the structure of a few centers as described in **Table 1**, while on the right side their absorption and emission bands are approximately sketched. It is immediately observed that CCs in KCl absorb light mostly in the VIS region and emit through the entire near-IR region, a property which is common to all CCs in the other AH crystals. Indeed, the elementary processes responsible for such behavior are practically the same in all of them, and the following sections will discuss the F center, as also the F_A and F_H centers, the three of them representing a good sample of all CCs.

F Centers

The F center, an electron trapped in an anion vacancy, is the simplest point defect, and for this reason it is also a prototype case study for all the other more complex CCs, as is the hydrogen atom with respect to atoms and molecules. In the normal state, the electron of the F center (see **Figure 4**) moves inside the cage of the six positive ions surrounding the anion vacancy, a situation equivalent to an electron in a box, a well-known problem in quantum mechanics. The separation of the first two quantum states, corresponding to the 1*s*, and 2*p* levels, is given by

$$E_{2p} - E_{1s} = 3\pi^2\hbar/8ma^2 = A/a^2 \qquad [1]$$

where $\hbar$ is the reduced Planck constant, m is the mass of the electron, and a is the nearest-neighbor lattice separation. This expression, known as the Mollwo–Ivey law, fits the experimental data of the absorption peak energies of the known F centers surprising well, as reported in **Figure 5**.

If eqn [1] is applied to the known emissions of the F centers, it fails completely. Indeed, the electron in the 2*p* state is not confined anymore in the previous

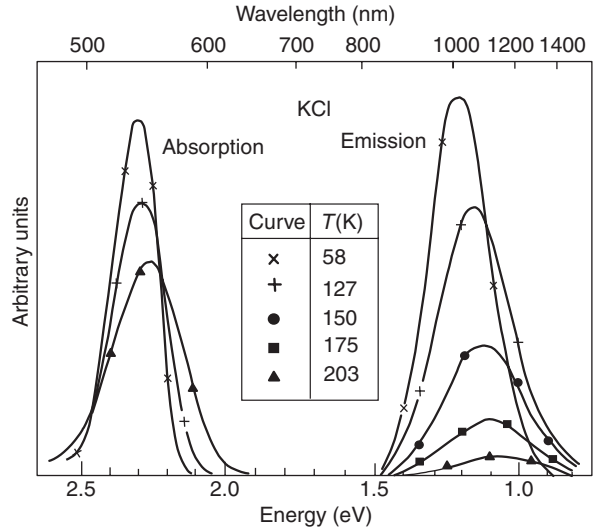

Figure 3 Absorption and emission bands of F centers in KCl as a function of temperature. (Reproduced from Luty F (1961) *Senderdruck aus Halbleiterprobleme Band VI*. Braunschweig: Verlag Friedr. Vieweg & Sohn.)

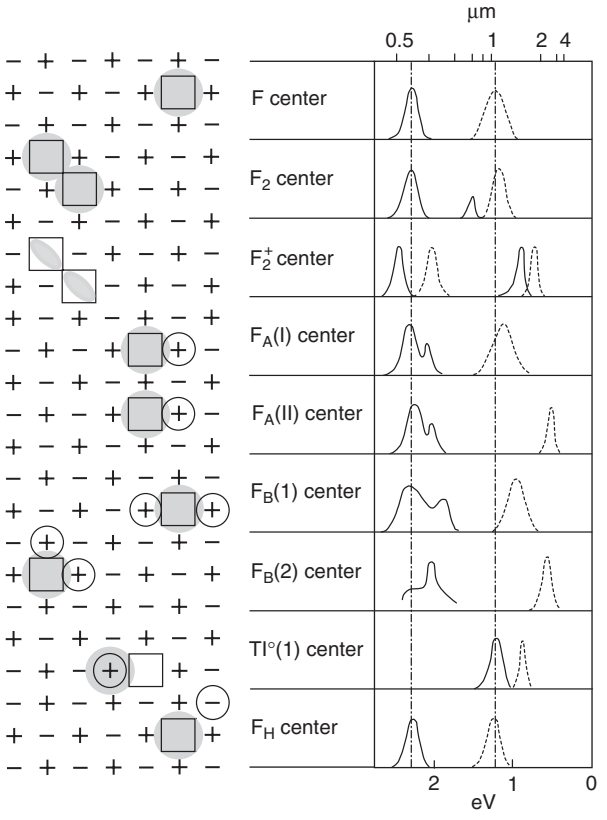

Figure 4 Structural models, absorption (solid line) and emission (dashed line) behaviors of the F center and of relatively simple aggregated centers in KCl at low temperatures. On the left, the square represents the halogen vacancy, the circle the foreign ion, and the shaded area the approximate electron density. (Reproduced from Baldacchini G (1997) Optical excitation and relaxation of solids with defects. In: Di Bartolo B (ed.) *Spectroscopy and Dynamics of Collective Excitations in Solids*. New York: Plenum.)

cage, but rather it moves outside it as well and feels an average potential that can be approximated by a Coulomb field with an effective mass m^* and a high frequency (ω_∞) dielectric constant. The separation of the first two quantum states can be derived by the Rydberg law, and is given by

$$E_{2p} - E_{1s} = 3e^4 m^* / 128\pi^2 \hbar^2 \omega_\infty^2 = E/\omega_\infty^2 \qquad [2]$$

The experimental data of the emission peak energies reported in **Figure 6** show that the functional dependence of eqn [2] is verified well enough. It is worth noting that the number of experimental points reported in **Figure 6** is smaller than that reported in **Figure 5**, an important occurrence, which will be discussed later.

It is known that the previous unusual properties are a consequence of the electron–lattice interaction, which, for instance, is missing in atoms where the absorption and emission spectra coincide. This peculiar situation of the CCs is better described by the configuration coordinate diagram shown in **Figure 7**. The two parabolas describe the energy of the F center in the ground, 1*s*, and excited, 2*p*, states as a function of the normal-mode coordinate, Q, which represents the displacement of the surrounding ions from the equilibrium positions. The amount of horizontal displacement between the two parabolas is a measure of the electron–lattice coupling, which is quite strong in the case of F centers in AHs. Indeed, they have very big Stokes shifts, as shown in **Figures 3**, **5**, and **6**, and usually the more the 2*p* parabola moves to the right, the less energetic is the emission, that is, the Stokes shifts are proportional to the electron–lattice couplings; this statement is valid for all point defects in crystals.

At low temperatures, the electron of the F center occupies the bottom of the 1*s* parabola, which is the ground state (GS). Optical excitation produces a vertical transition (Frank–Condon principle) to the 2*p* state in a highly excited vibrational level (i.e., absorption, A). The vibronic system, electron + phonon (phonon being an elementary excitation of the lattice vibration), relaxes very quickly, $\sim 10^{-12}$ s, to the bottom of the 2*p* parabola, which is called the relaxed excited state (RES). The electron can remain in this state for a relatively long time, $\sim 10^{-6}$ s, before returning to the unrelaxed GS with a vertical transition accompanied by light emission. In the end, a further lattice relaxation completes the optical cycle to the GS.

However, the emission, which is also called the ordinary luminescence (OL), is not the only radiative process that takes place after the excitation. Indeed, a

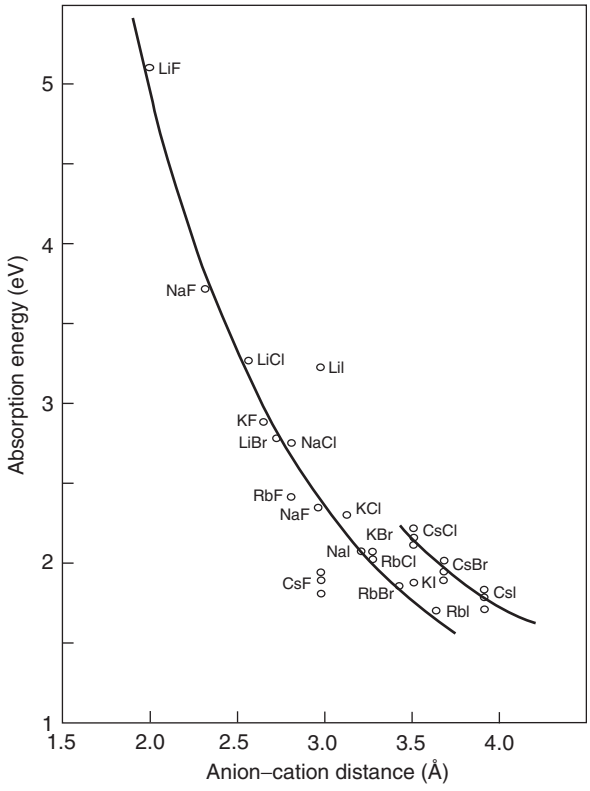

Figure 5 Peak position at low temperature of the F-center absorptions as a function of the nearest-neighbor distance. Continuous lines are best fits of eqn [1] to the experimental data. (Reproduced from Baldacchini G (1992) Relaxed excited states of color centers. In: Di Bartolo B (ed.) *Optical Properties of Excited States in Solids*. New York: Plenum.)

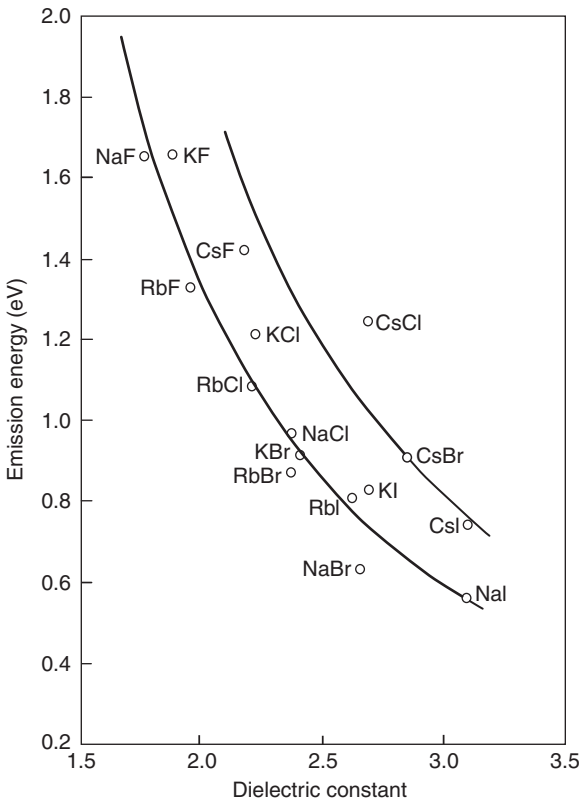

Figure 6 Peak position at low temperature of the F-center emissions vs. the dielectric constant at high frequency. Continuous lines are best fits of eqn [2] to the experimental data. (Reproduced from Baldacchini G (1992) Relaxed excited states of color centers. In: Di Bartolo B (ed.) *Optical Properties of Excited States in Solids*. New York: Plenum.)

little beyond the obvious Rayleigh line, a structured emission reveals the presence of Raman scattering (RS), which gives detailed information on the lattice modes coupled to the electronic transition. Still beyond, and up to the OL, there is a very weak emission tail that originates from decaying processes during the fast relaxation, and is commonly known as hot luminescence (HL).

So, with the previous model, which is based on the results from molecular chemistry and physics, the main optical properties of the F center and, for similitude, of the other point defects are well understood by now.

F_A Centers

As F centers are the simplest CCs, F_A centers are the simplest among the perturbed CCs, as shown in **Figure 4**. They were discovered during World War II in Gottingen and were originally called A centers (see **Table 1**).

Because of their axial symmetry due to the neighbor impurity ion, the absorption band splits into two separate bands, which is a characteristic common to all F_A centers, and related to reorientation processes which are optically induced and thermally activated. The case of their emission is different, which can be either similar to the F center (with a broad band with the usual Stokes shift), or a narrow band with a much bigger Stokes shift. Because of this peculiar difference, F_A centers have been traditionally divided in type I and type II, respectively, as shown in **Figure 4**. The reason for such a difference has been identified in the so-called saddle-point lattice configuration, formed by two vacancies separated by the impurity ion in an interstitial position. Thus, the ionic potential assumes the aspect of a double well, which can accommodate (much better than a single well) the two lobes of the $2p$ wave function. As a consequence, the RES become energetically deeper with a larger Stokes shift with respect to the F center.

Several attempts have been made to forecast the typology of F_A centers in AHs and, by taking into account the dimension of the ions, the effective charge parameter, and the residual covalent bonding, it is possible to give fairly good indications. So, the

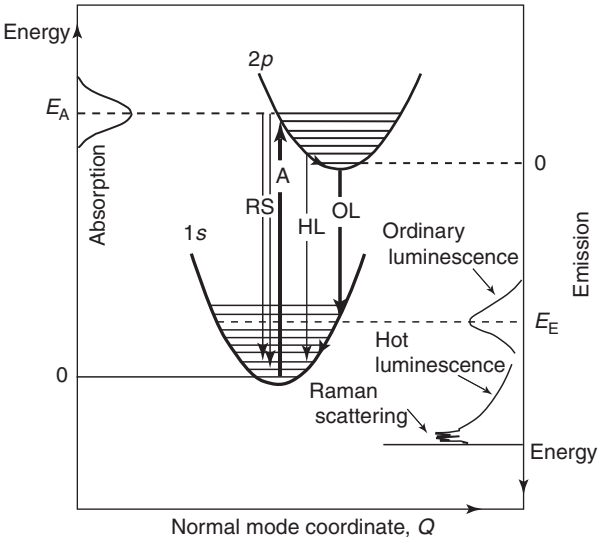

Figure 7 Configuration coordinate diagram illustrating the absorption and emission phenomena of the F center. The RS and HL are usually a few orders of magnitude less intense than OL (see text for details). (Reproduced from Baldacchini G (1992) Relaxed excited states of color centers. In: Di Bartolo B (ed.) *Optical Properties of Excited States in Solids*. New York: Plenum.)

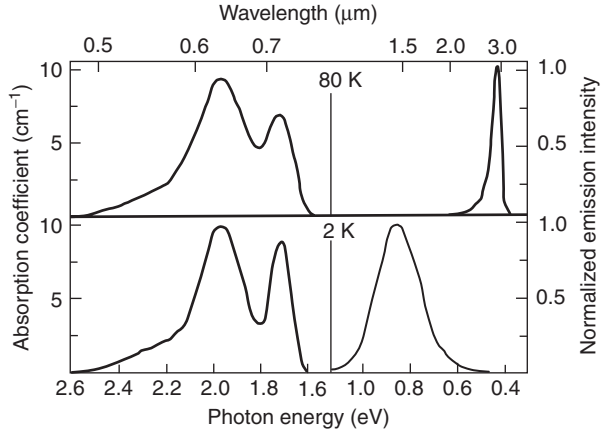

Figure 8 Absorption (left) and emission (right) at two temperatures of an $RbCl:Li^+$ crystal containing F_A centers. The luminescence is excited in both cases by an He–Ne laser. (Reproduced from Baldacchini G (1997) Optical excitation and relaxation of solids with defects. In: Di Bartolo B (ed.) *Spectroscopy and Dynamics of Collective Excitations in Solids*. New York: Plenum.)

experimental observation in 1988 that both type I and II centers can coexist in the same crystal host at different temperatures was an absolute surprise. **Figure 8** shows the absorption and emission spectra of the same crystal $RbCl : Li^+$ containing F_A centers at two temperatures. While the typical emission of type II centers is observed at 80 K, at 2 K the emission band is large and peaked at $\sim$0.85 eV, much like the F emission band in the same crystal peaked at 1.09 eV. It has also been shown that the two emissions are strongly temperature correlated, in the sense that while the intensity of type I band increases with temperature, the intensity of type II band decreases, and their temperature behavior can be described by a thermally activated process. This means that both types of F_A centers coexist in the same host crystal, separated by a potential barrier that can be overcome by a thermal excitation. This picture is very likely common to all F_A centers, because the thermally assisted type I to type II transition has also been observed in $KF : Na^+$, type II F_A center well known until recently for its characteristic emission at 0.6 eV at 100 K, which moves to 1.3 eV at 2 K.

F_H Centers

As simple as the F_A centers, the F_H centers differ from them by the charge of the impurity neighbor ion, which is negative in this case. These centers have been studied for long but, contrary to what happens to the F_A centers, their optical properties do not show sizeable changes with respect to the F centers, unless molecular ions such as OH^- and CN^- are used as impurities.

First, when F centers and molecular ions are aggregated, in general the absorption bands become broader but not much different from the original F band with both types of ions, while the emission is completely quenched with OH^- and almost unchanged by CN^- ions. Moreover, it has been shown that the electronic energy of RES is efficiently transferred to the stretching vibrational mode of the ions, where it is converted in lattice vibrations (phonons which ultimately are equivalent to heat) in the case of OH^-, and in vibrational IR emission at $\sim$0.25 eV in the case of CN^-. These novel properties are clearly very interesting and also very complex, because they reflect the elementary interactions of small atomic entities with all their peculiarities. As a consequence, they have produced many results, which are not considered in detail here. The present focus is on the recently discovered aspect concerning the optical and thermal bistability of the $F_H(OH^-)$ centers.

When OH^- ions are aggregated to F centers in a KBr crystal, the absorption spectrum changes as reported in **Figure 9**. The dotted absorption curve represents the band of the F centers in KBr in the same experimental conditions, for comparison. When the sample is cooled to 1.9 K, band I is observed first, but upon optical irradiation at 580 nm, as marked by the left arrow, band II is obtained. Conversely, band I appears again upon optical irradiation at 650 nm, as

marked by the right arrow. This bidirectional conversion can be repeated any number of times with no loss of absorption intensities. Moreover, if the temperature is increased up to 100 K, the original absorption band undergoes various conversions at well-defined temperatures, which indicates the existence of thermally assisted conversions. This complex situation has been ascribed to the different orientations assumed by the OH^- molecular dipole perpendicular or parallel to the F center–ion direction.

Besides the knowledge of the exact microscopic model, the F_H center displays an interesting and uncommon optical bistable process in KBr and recently also in KI, which means, again as for F_A centers, that it could be a general phenomenon in the AHs.

Applications

The basic research in CCs has also been accompanied by progress in their applications. Following the first experiments with natural radioactivity, there was an attempt, during World War II, to use the AHs to measure the artificial radioactivity from nuclear reactions, which failed because of the fading coloration in the majority of the crystals. At the same time, the process of coloration was also studied for the realization of cathode-ray screens for radar, but never really employed, in favor of more suitable solid-state materials. Later, after the discovery of the luminescence, stimulated emission was observed in F_A centers in 1965 and subsequently the first CC laser realized in 1974. Contemporarily, the possibility of storing images in three-dimensional holographies was demonstrated again with F_A centers. Moreover, the generation of hole burnings in inhomogeneously broadened absorption bands, the so-called zero-phonon lines, of F_3^+ centers opened the way to the practical fabrication of massive optical information storage.

In the subsequent years, CCs have been used mostly in the dosimetry techniques, where they had intrinsic

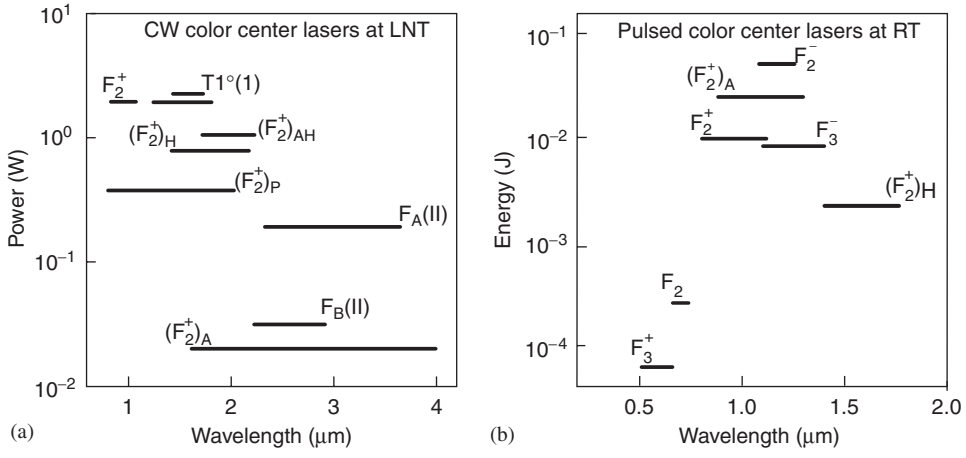

Figure 10 (a,b) Average power (energy) and tunability range in cw (pulsed) regime of the most common CC lasers in AHs working at liquid nitrogen temperature (room temperature) vs. wavelength. (Reproduced from Baldacchini G (1999) New luminescent phenomena in color centers. In: Struck CW, Mishra KC, and Di Bartolo B (eds.) *Electrochemical Society Proceedings*, vol. 98–24. Pennington, NJ: The Electrochemical Society.)

advantages over other materials, and in the laser field, where they reached a complete maturity by covering the spectral range between 0.8 and 4 μm, as shown in **Figure 10** which refers to continuous wave (cw) and pulsed-laser modes, respectively. These lasers, which are tunable and possess a very high spectral purity, have contributed greatly to the advancement of other scientific and technological sectors, such as high-resolution molecular spectroscopy, and communication via optical fibers where they have initiated the propagation of the soliton waves.

Nowadays, while the dosimetry use is still continuing, many CC lasers are no longer utilized, mainly because of new and simpler solid-state laser sources in the same spectral range. Indeed, as seen in **Figure 10**, most CC lasers operate at liquid nitrogen temperature, a practice which is rather cumbersome for users, especially when it is possible to avoid it. However, in special experiments, they still represent the only laser sources with the required characteristics, and this applies especially in the case of pulsed CC lasers at room temperature, which generally use the LiF crystal.

Conclusions

CCs represent one of the oldest fields in solid-state physics, having been studied for almost 150 years. They are well understood, but at the same time there are still many sectors which have to be clarified, although nowadays only a few of them are still tackled for use in applications.

First, as has already been mentioned earlier the known emissions of the F centers are much less than the number of AHs. Indeed, although all F centers display a normal light absorption, many of them do not produce any emission at all under optical excitation. This lack of emission refers to the phenomenon of quenching, which has plagued the CCs since the beginning, explaining also the delay in the discovery of emission. Many quenching factors are known to work effectively for CCs, but there are still several aspects waiting to be clarified, which are important also for other point defects in different materials, such as solid-state lasers.

Figures 5 and **6** also show that the experimental points cannot be fitted by a unique curve, a fact that underlines the hidden complexity of the F centers, which are in any case the simplest known defects in insulating crystals. Indeed, by taking into consideration all the properties such as the extension of the wave function, higher-lying levels, Stark effect, uniaxial stress effects, magnetic effects, RES lifetime, etc., it is possible to compare them quantitatively with a unique comprehensive theoretical model in the case of F centers in KCl. But when the same vibronic model is applied to the F centers in other AHs, there is no satisfactory agreement.

About two decades ago, an expert in this field said: "Evidently a vibronic model for the RES that provides a completely consistent quantitative explanation for all data has not been achieved." The situation does not look too different even now. This deadlock is certainly a consequence of the CCs being much more complex than they appeared to be at first sight, but it is also due to the scarce scientific interest in CCs. Indeed, many researchers switched their investigations to other more remunerative fields, as a consequence of the strong applications bias of most of the funding agencies.

However, there have been important contributions in the area of point defects lately, and among them those regarding LiF have been particularly notable. This AH crystal is distinguished by its peculiar properties. It is practically immune to moisture, possesses one of the lowest indexes of refraction and the largest bandgap, is colored only by means of ionizing radiation, and its CCs are stable at room temperature. Last but not the least, F centers do not produce any significant luminescence, while a large number of more complex CCs are optically active in the VIS and near IR region. They are also efficient light emitters, for example, almost all the laser emission in **Figure 10b** corresponds to LiF. In recent years, it has been applied successfully in the form of thin films, as passive and active waveguides, with interesting implications in fiber-optic communications. Moreover, it has proved to be a very good detector for soft X-rays; in several ways it's more efficient and sharper with respect to the detectors used at the moment for the same purposes. In conclusion, LiF salt is becoming a new interesting photonic material with promising developments in basic research and applications as well, mainly because of the long history of studies on CCs in AH crystals.

Deformation Processing

D Raabe, Max-Planck-Institut für Eisenforschung, Düsseldorf, Germany

Introduction

Modern manufacturing is to a large extent based on deformation processing. This applies in particular to elastic–plastic matter such as metallic alloys, composites, and polymers. Understanding of these materials and more advanced deformation processing techniques are paramount to modern manufacturing and product development. The current state in this field is characterized by the close integration of engineering concepts pertaining to manufacturing technology and materials physics on the one hand, and by the close integration of experiment, industrial processing, and computer simulation on the other.

Deformation processing encompasses such different techniques as forging, rolling, extrusion, drawing, or bending. Modern understanding of these techniques consists not only in attaining mere shape changes of plastic matter but also in optimizing their microstructures and properties.

This article gives a brief introduction to some important forming processes and simulation methods in this field.

Basic Types of Deformation Processes

Deformation processes use irreversible deformation to permanently change the shape of sufficiently ductile workpieces and to obtain desired microstructures and material properties at the same time. This means that deformation processes work in the elastic–plastic regime of the stress–strain curve of the material. The layout and understanding of such processes require knowledge about the mechanical and microstructural properties of the deformed materials, the external loads and contact boundary conditions such as friction, as well as the tool design. For a concise overview of the basic deformation processes, it is pertinent to focus on the four main bulk deformation processes, namely, rolling, forging, extrusion, and bulk drawing and on the four main sheet deformation processes, namely, bending, drawing, stretching, and shearing.

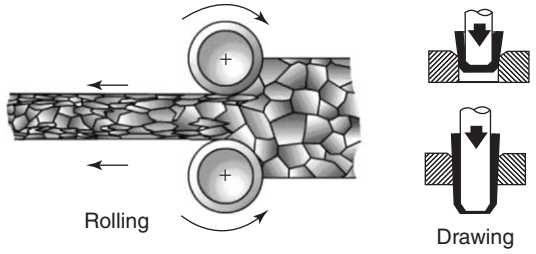

Figure 1 Schematics of two important deformation processes.

Rolling is characterized by two opposing rolls which reduce the thickness of a plate of material essentially under compression (see **Figure 1**). Forging is a process where two opposing dies form a part under large compressive stresses. This process is usually performed at elevated temperatures for reducing the required forces. Extrusion and drawing are compressive bulk forming processes where the material is forced (pushed or drawn) through a die opening, thereby reducing its cross section. Bending is a method of stressing a workpiece beyond its elastic limit, without substantial cross-sectional thinning, so that when stress is released the workpiece does not return to its original shape. Drawing, stretching, and shearing are related processes of working metal blanks in dies on a press into complex shapes.

Basics about the Simulation of Deformation Processes

Simulations of deformation processes are usually based on solving large sets of differential equations associated with a well-posed forming problem by use of nonlinear finite element methods in conjunction

with detailed physically based constitutive descriptions of the mechanical behavior of the processed materials. The underlying mechanical continuum formulations approximate force and momentum equilibrium as well as displacement compatibility on the basis of energy minimization considerations. The development of physically based laws for constitutive materials as input to such simulations has increasingly gained momentum in this field, because deformation processing does not only aim at shape changes of matter but also at optimizing microstructures and properties of the formed product.

Primary objectives of deformation simulations are the prediction of material shape, the minimization of failure, the optimization of material flow, and the calculation of final microstructures and properties after forming. Further applications are in the fields of optimizing tool designs, predicting tool forces, and simulating the final surface appearance of the part. The latter aspect involves both macroscopic (e.g., wrinkling) and microstructural (e.g., ridging, orange peel) mechanisms of surface plasticity. Related applications are encountered in the field of automotive crash simulations.

Rendering continuum-type forming simulations scientifically sound, predictive at the microstructure scale, in good accord with experiment, and at the same time economically rewarding requires that the materials involved are properly specified in terms of their respective constitutive behavior. For this purpose, finite element simulations can use four sets of material input data, covering hardening, forming limits, surface roughness development, and anisotropy (**Figure 2**).

Engineering of Tensorial Materials

The yield surface represents the generalization of the yield point from uniaxial tensile testing to general stress states. Expanding the yield point into a closed yield surface is required only if the material under inspection shows elastic–plastic anisotropy, that is, if it deforms differently in different directions. Such a behavior is the rule and not the exception in real materials. Strong elastic–plastic anisotropy is encountered, for instance, in metals, composites, and polymers.

The origin of elastic–plastic anisotropy in these materials is the crystalline arrangement of the atoms and the topological arrangement of the phases. Metallic matter, which is the typical material encountered in deformation processing, occurs in polycrystalline form, where each grain has a different crystallographic orientation, shape, and volume fraction. The distribution of the orientations is referred to as crystallographic texture. The anisotropy of the elastic tensor and the discreteness of crystallographic slip along certain lattice directions on preferred crystal planes also entails an anisotropic integral response of such specimens during loading. While the

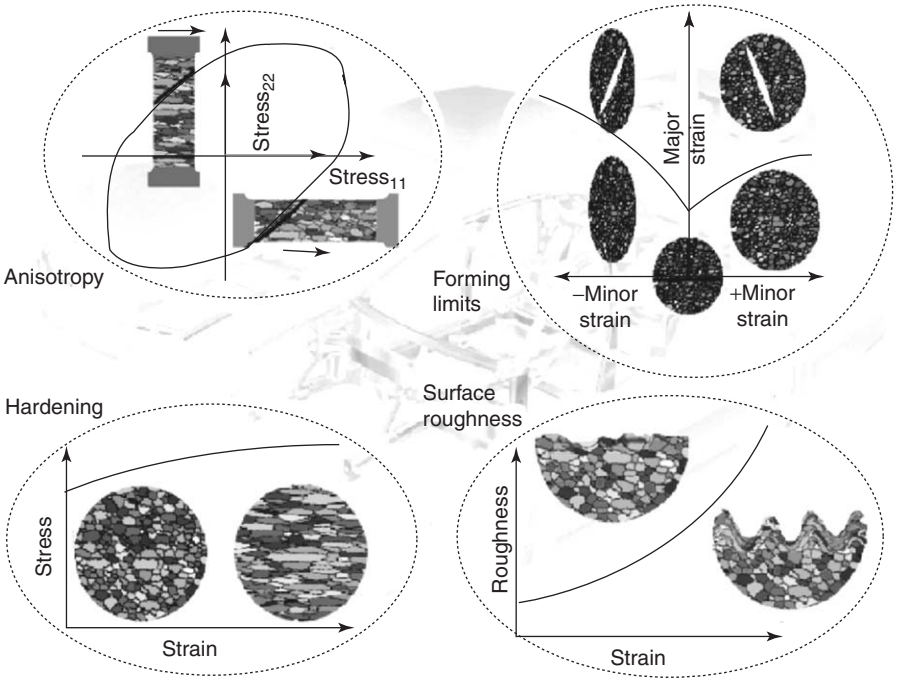

Figure 2 Modern finite element approaches that aim at simulating realistic forming operations typically require material input data about strain hardening, failure (forming limits), crystallographic and morphological anisotropy, and surface roughness.

deformation of single crystals is now well understood, plasticity of polycrystals is less clear. This is essentially due to the intricate elastic–plastic interactions occurring during co-deformation among the individual anisotropic crystals. This interaction leads to strong heterogeneity in terms of strain, stress, and crystal orientation. Another difficulty in the anisotropy of polycrystals lies in the fact that crystals rotate during forming, owing to the skew-symmetric portion of the displacement gradients created by crystal slip. This means that texture and anisotropy change during forming. In this context, it must be underlined that crystallographic orientation changes are principally nonreversible owing to the orientation sensitivity of strain path changes and the orientation dependence of strain hardening.

Elastic Anisotropy

Elastic anisotropy of crystals departs from the directionality of the electronic bond and the resulting crystalline structure. For small deviations of atoms from their equilibrium positions, the reversible elastic response to loads can be approximated by a linear relationship, which is referred to as Hooke's law. In this framework, the linear elastic constants can be derived as the components of the second derivative of the electronic potential. The elastic constants can be written in the form of a fourth-rank elastic stiffness tensor C_{ijkl} or in the form of a fourth-rank elastic compliance tensor S_{ijkl} according to

$$\sigma_{ij} = C_{ijkl}\varepsilon_{kl}, \quad \varepsilon_{ij} = S_{ijkl}\sigma_{kl}$$

Symmetry relations and thermodynamic considerations reduce the 81 elastic constants to a set of 3 (C_{1111}, C_{1122}, C_{2323}) in the case of cubic crystal symmetry (which corresponds to C_{11}, C_{12}, C_{44} in reduced matrix notation) and to a set of five independent numbers (C_{1111}, C_{1122}, C_{1133}, C_{3333}, C_{2323}) in the case of hexagonal crystal symmetry (which corresponds to C_{11}, C_{12}, C_{13}, C_{33}, C_{44} in reduced matrix notation).

Plastic Anisotropy

The plastic anisotropy of crystalline matter also departs from the directionality of the electronic bond and the resulting crystal lattice structure. Both aspects determine which slip planes and translation vectors (Burgers vectors) are important for the motion of lattice dislocations or the activation of plastically relevant athermal transformations. The main consequence of this anisotropy in the present context is that metals are deformed in a discrete rather than in a continuum fashion, rendering plasticity an intrinsically anisotropic property of metals. In the simple case of plastic isotropy, each arbitrary stress state imposed on a sample will entail plastic yielding at the same value. The sum of all these possible stress states at which plastic deformation is sustained is referred to as the yield surface. In cases where the material is anisotropic, the yield surface deviates from a spherical shape.

The shape of the yield surface can be understood in terms of the activation of single-slip systems. Assuming that the Burgers vectors b_j and the slip plane normals n_i of the s different slip systems available in a particular crystal lattice are known, their orientation factors m_{ij} are (**Figure 3**)

$$m_{ij}^{s} = n_i^s b_j^s$$

with the symmetric parts

$$m_{ij}^{\mathrm{sym},s} = \tfrac{1}{2}(n_i^s b_j^s + n_j^s b_i^s) \ \text{(crystal coordinates)}$$

when given in crystal coordinates. All vectors used in the equations are normalized. Transforming the latter equation into the sample coordinate system leads to

$$m_{kl}^{\mathrm{sym},s} = \tfrac{1}{2}(a_{ki}n_i^s\, a_{lj}b_j^s + a_{lj}n_j^s\, a_{ki}b_i^s)$$
(sample coordinates)

where a_{ki} and a_{lj} are the transformation matrices between the crystal coordinate system and the sample coordinate system. Using the s different orientation factors, $m_{kl}^{\mathrm{sym},s}$ of the s different available slip systems for the transformation of an external load into the slip geometry provides a kinematic formulation for the yield surface of a single crystal. Positions below the yield surface result in no plastic deformation on the assigned slip systems, and deformation begins

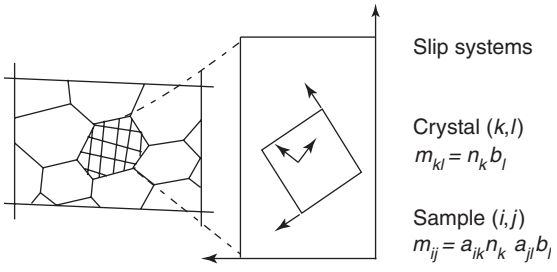

Figure 3 The plastic anisotropy of crystalline matter departs from the directionality of the electronic bond and the resulting crystal lattice structure. Both aspects determine the slip planes and translation vectors on which crystal lattice dislocations move during plastic deformation. The diagram shows the different coordinate system and the resulting relevant geometrical transformation operations.

at the lines corresponding to specific slip systems.

$$m_{kl}^{\mathrm{sym},s}\sigma_{kl} = \tau_{\mathrm{crit},+}^{s,\mathrm{active}}$$

$$m_{kl}^{\mathrm{sym},s}\sigma_{kl} = \tau_{\mathrm{crit},-}^{s,\mathrm{active}}$$

for the active slip systems, and

$$m_{kl}^{\mathrm{sym},s}\sigma_{kl} < \tau_{\mathrm{crit},+}^{s,\mathrm{nonactive}}$$

$$m_{kl}^{\mathrm{sym},s}\sigma_{kl} < \tau_{\mathrm{crit},-}^{s,\mathrm{nonactive}}$$

for the nonactive slip systems. One must note that the Einstein summation rule applies in all equations if not stated otherwise.

Most points on the single-crystal yield surface describe single-slip conditions. In the graphical representation of the yield surface, single-slip generally takes place when the stress tensor (in vector notation, using the tensor–vector transformation rule $\sigma_\lambda^{\mathrm{T}} = \{1/\sqrt{6}(2\sigma_{33} - \sigma_{11} - \sigma_{22}),\ 1/\sqrt{2}(\sigma_{22} - \sigma_{11}),\ \sqrt{2}\sigma_{23},\ \sqrt{2}\sigma_{13}, \sqrt{2}\sigma_{12},\}$) points at one of the planes rather than at one of the corners (see **Figures 4–6**).

Polyslip conditions, usually required for polycrystal deformation owing to the satisfaction of strain rate compatibility among the grains, are characterized by conus coordinates of the stress state. The conus positions for the stress can be calculated using a conventional polycrystal homogenization approach, for instance, the Taylor–Bishop–Hill theory of strain-rate homogeneity (indicated by σ^{TBH} in **Figure 6**). Such polycrystal models represent smoothing approaches that handle the compatibility of stress or strain required for a polycrystal to deform coherently. The corresponding multislip positions of the stress tensor, satisfying an externally imposed strain rate, are then denoted as Taylor positions. It must be noted, in this context, that the Taylor factor generally takes the form of a stress shape tensor for the crystal yield surface rather than that of a factor owing to its dependence on the strain rate tensor. Its magnitude for a given strain rate determines the kinematic size of the yield surface in the corresponding stress direction characterizing the correct polyslip conus and thus the kinematic portion of the corresponding stress state. The symbols $D^{s=1}$ and $D^{s=2}$ in the figure indicate the single-slip strain states from slip systems 1 and 2. Using these two slip systems allows one to realize any strain rate state in the respective conus by a linear combination of $D^{s=1}$ and $D^{s=2}$. For cubic crystals the yield surface reveals four classes of Taylor states for polyslip and one for single slip. These yield states are referred to as

penta-slip state (5 active slip systems):

$^5M_{pq}^{i}$ (f.c.c., b.c.c. (reduced): $i = 56$)

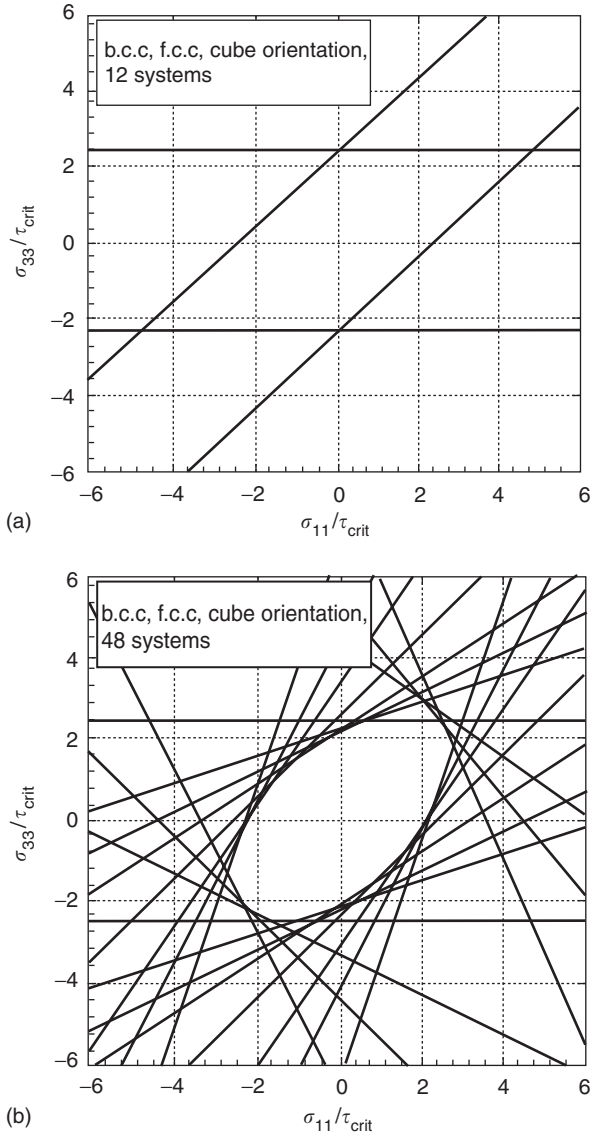

Figure 4 A simple Schmid-type formulation considering the different orientation factors of all available slip systems which essentially transforms an external load into shear stresses acting on the slip systems provides a kinematic formulation for the yield surface of a single crystal. The yield surface shown in (a) was derived using the 12 {1 1 0}⟨1 1 1⟩ slip systems. The yield surface shown in (b) was derived using the 12 {1 1 0}⟨1 1 1⟩, 12 {1 1 2}⟨1 1 1⟩, and 24 {1 2 3}⟨1 1 1⟩ slip systems (b.c.c.). The figure indicates that b.c.c. alloys, therefore, behave plastically principally different from f.c.c. alloys.

tetra-slip (4 active slip systems):

$^4M_{pq}^{j}$ (f.c.c., b.c.c. (reduced): $j = 108$)

tri-slip (3 active slip systems):

$^3M_{pq}^{k}$ (f.c.c., b.c.c. (reduced): $k = 135$)

bi-slip (2 active slip systems):

$^2M_{pq}^{l}$ (f.c.c., b.c.c. (reduced): $l = 66$)

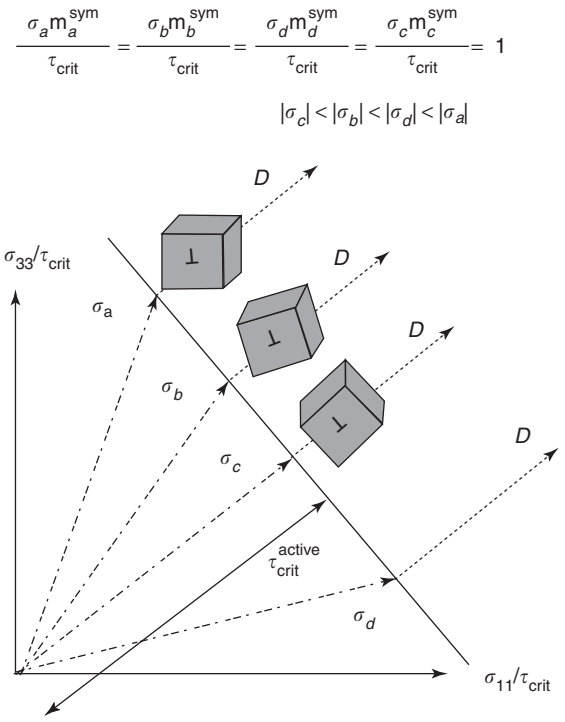

Figure 5 Most points on the single-crystal yield surface describe single-slip conditions. In the graphical representation of the yield surface, single slip generally takes place when the stress state (in vector notation) points at a hyperplane rather than a hyperconus. The strain rate tensor is indicated by ***D*** and *m* is the Schmid factor, that is, the dyadic product of the slip elements. The small cubes placed in the figure indicate the changing relative orientation between the external reference system and the crystal coordinate system.

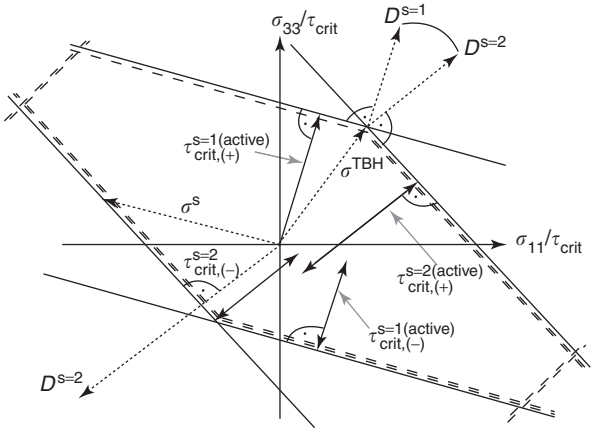

Figure 6 Polycrystal deformation requires polyslip conditions in order to satisfy strain rate compatibility among the grains. Polyslip states are crystallographically characterized by hyperconus coordinates of the stress state. The conus positions for the stress can be calculated using a conventional homogenization approach, for instance, the Taylor–Bishop–Hill theory (indicated by σ^{TBH}). The symbols $D^{s=1}$ and $D^{s=2}$ indicate the single-slip strain states from slip systems 1 and 2. Using these two slip systems allows one to realize any strain rate state in the respective conus by a linear combination of $D^{s=1}$ and $D^{s=2}$.

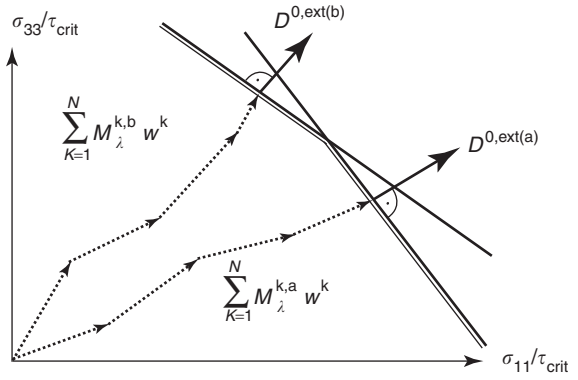

Figure 7 The Taylor stress state for a polycrystalline aggregate can, for a given external strain rate state, be integrated as a volume-weighted sum of all Taylor factors derived separately for each grain for the respective boundary condition. In the figure, *M* is the Taylor tensor, *D* the strain rate and *w* the volume fraction. The counter *k* sums over all crystals in the aggregate.

$$\text{single-slip (1 active slip system):}\quad {}^{2}M_{pq}^{n}\ (\text{f.c.c., b.c.c. (reduced):}\ n = 24)$$

where f.c.c. denotes face-centered cubic and b.c.c. denotes body-centered cubic crystal structure. The term "reduced" indicates that only the first 12 $\{1\,1\,1\}\langle 1\,1\,0\rangle$ b.c.c. slip systems have been considered here. The number at the end of each row gives the number of different conus cases (and single-slip cases) for the respective Taylor state. The total Taylor stress state for a polycrystalline aggregate can, for a given external strain rate state, then be integrated as a volume-weighted sum of all Taylor tensors derived separately for each grain for this boundary condition (**Figure 7**).

Empirical Approximations of the Yield Surface

The first empirical mathematical description of an anisotropic plastic yield surface was suggested in 1928 by von Mises in the form of a quadratic function. This approach, which was originally designed to empirically approximate the plastic anisotropy of single crystals, was in 1948 rendered by Hill into a generalized form using the Huber–Mises–Hencky approach. In Hill's form the yield surface amounts to

$$\begin{aligned} f(\sigma_{ij}) = (&F(\sigma_{22}-\sigma_{33})^2 \\ &+ G(\sigma_{33}-\sigma_{11})^2 + H(\sigma_{11}-\sigma_{22})^2 \\ &+ 2L\sigma_{23}^2 + 2M\sigma_{13}^2 + 2N\sigma_{12}^2)^{1/2} \end{aligned}$$

where *F*, *G*, *H*, *L*, *M*, and *N* are the anisotropy coefficients. The above equation can be

rewritten as

$$f(S_{ij}) = ((G+H)S_{11}^2 + (F+H)S_{22}^2 + (F+G)S_{33}^2 - 2HS_{11}S_{22} - 2GS_{11}S_{33} - 2FS_{22}S_{33} + 2LS_{23}^2 + 2MS_{13}^2 + 2NS_{12}^2)^{1/2}$$

where S_{ij} are the deviatoric stress components. The shape coefficients of Hill's quadratic yield function can be fitted from experimentally obtained mechanical data such as the Lankford values taken in different directions of a specimen. Scaling can be provided by the yield stress obtained from uniaxial tensile testing. While the Lankford coefficients and the yield stress can be determined from tensile testing, the direct measurement of mechanical response under complex loads is an intricate task. Although Hill-based anisotropy simulations (referring to the 1948 model by Hill) provide good approximations at least of the initial plastic anisotropy in some cases, it is less applicable when anisotropy is characterized by a sixfold slip symmetry due to its simple quadratic form.

Due to this principal shortcoming, a number of optimized empirical anisotropic yield surface concepts with higher-order polynomial forms have been proposed, such as those introduced later by Hill and by Barlat, that are better suited for f.c.c. alloys and many b.c.c. steels. In recent years, various authors have presented improved empirical yield surface approaches, where the yield function can be fitted using both mechanically obtained and even texture-based data.

The chief advantage of using an empirical anisotropic yield surface function as a constitutive law in metal-forming finite element simulations is time efficiency, and the simple mechanical methods with which it can be derived. The main disadvantage of empirical yield surface functions is that the anisotropy of polycrystalline matter generally changes during forming owing to the change of texture. This evolution of anisotropy is not mapped by a corresponding change of the shape of the yield surface. In other words, the same yield surface shape is used throughout a given finite element simulation without making a physically meaningful update of its steadily changing shape. Although empirical constitutive laws can be used to gradually change the yield surface shape during forming, their capability is typically constrained by a lack of physical information about the actual development of the crystallographic texture during forming.

Crystallographic Approximations of Elastic Anisotropy

An important problem in the field of deformation simulation is the approximation of the elastic response of a sample under load. The macroscopic elastic properties of a textured polycrystal can be calculated by formulating appropriate volume-weighted means of the individual elastic single-crystal tensor, rotated parallel to the respective local coordinate system of each individual crystal. This average value of the integral elastic tensor must therefore take into account all individual orientations of the grains which are described by the orientation distribution function.

An early homogenization approach for the elastic response under an external load was suggested by Voigt, who assumed that, in the case of a macroscopically prescribed strain rate state, each material portion is in the same strain rate state as the entire sample, irrespective of its spatial position in the specimen. The strain rate would then be homogeneous throughout the sample. However, in a polycrystalline sample, the elastic response typically varies from grain to grain, due to the spatially changing crystal orientation. Since in the Voigt model the prescribed strain rate is the same everywhere in the sample, the stress must vary. The Voigt limit for the elastic response of a polycrystalline sample can thus be calculated by weighting the tensor of the elastic stiffness as a function of orientation with the orientation distribution function. A different approach to treating the homogenization problem in an elastically loaded polycrystalline sample was suggested by Reuss. He suggested that in the case of a macroscopically prescribed stress state, each material portion is in the same stress state irrespective of its spatial position in the specimen. The stress would then be homogeneous throughout the specimen. The elastic response may then vary from grain to grain, in accord with the local orientation of the crystal. Since in the Reuss model the prescribed external stress is constant throughout the specimen, the strain must vary according to the local grain orientation. Consequently, the elastic Reuss limit can be calculated for a polycrystal by weighting the tensor of the elastic compliance as a function of orientation with the orientation distribution function. Since neither the Voigt nor the Reuss method provides reliable approximations to the elastic modulus of a polycrystal, Hill defined an average modulus that consists of the equally weighted results of both the above models.

Crystallographic Approximations of the Yield Surface

Materials subjected to forming operations develop or inherit morphological textures (e.g., elongated grains, chemical segregation, or second phases with elongated topology entailing directional effects) as

well as crystallographic textures (orientation distribution of the crystallites constituting polycrystalline matter). Both types of textures can directly serve as input data for the calculation of the yield surface shape using the Taylor–Bishop–Hill (crystallography) or self-consistent type (crystallography, morphology) approaches.

The experimental input data for deriving the yield surface from the crystallographic texture of polycrystals can be determined using X-ray, neutron, or electron diffraction experiments. Since texture-based yield surface approximations use the complete crystallographic anisotropy information of a specimen, they are often superior to empirical approaches which rely on a small set of mechanical parameters. However, modern empirical approaches for the approximation of the yield surface typically use the Taylor–Bishop–Hill type crystal simulations on the basis of experimental texture data to provide tangents for a better fit of the yield surface functions.

Besides its clear physical basis, another advantage of crystallographic yield surface approximations lies in its capability to incorporate both kinematical and kinetic plasticity effects. In this context, it must be considered that the crystallographic texture gives only the respective anisotropic shape function for a particular polycrystalline sample, but the texture dependence of the internal stress and the individual hardness of the different grains are typically ignored by the constitutive laws employed in homogenization approaches. However, it is principally feasible to generalize the crystallographic yield surface concept by enriching it with the individual strength of each grain. This leads to a formulation of the following kind:

$$f(S_{ij}) = \frac{1}{V}\int_V M_{ij}(\boldsymbol{g}, D_{ij})\tau_{\text{crit}}(D_{ij}, \boldsymbol{g})\ \mathrm{d}V \approx \sum_{k=1}^{N} M_{ij}^{k}\tau_{\text{crit}}^{k} w^{k}$$

where $f(S_{ij})$ is the yield surface, V the sample volume, M_{ij} the Taylor shape function obtained by homogenization theory as a function of strain rate D_{ij} and rotation matrix $\boldsymbol{g}$, τ_{crit} the flow stress of each individual grain, and w the volume fraction of each grain (**Figure 8**).

Although texture-based yield surface approximations have a crisp physical basis in that they incorporate crystal anisotropy in a genuine fashion, they have the shortcoming of ignoring texture changes during forming. This means that, as far as texture update during forming is concerned, there is basically little difference between the predictive capabilities of empirical and texture-based yield surface approximations, particularly if one considers that recent

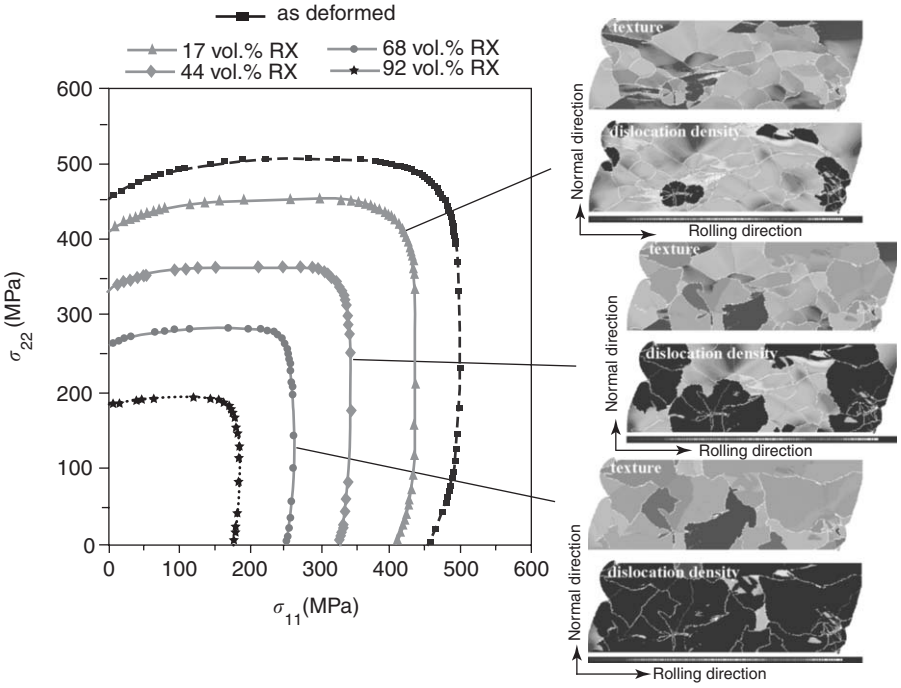

Figure 8 Coupled crystallographic–kinetic yield functions obtained by including both the texture and the texture-dependent flow stress of each individual grain weighted by its respective volume. The left-hand side of the diagram shows a portion of the planar yield surface as it anisotropically shrinks during partial recrystallization. The right-hand side shows three subsequent time steps of a simulation where the upper diagram gives the texture and the lower the dislocation density.

approaches use both mechanical and texture-related information to fit the yield function. These methods could be referred to as hybrid anisotropy yield criteria or semi-empirical yield criteria.

Constitutive Model for Crystal Plasticity Finite Element Simulations

Crystal plasticity phenomena can be directly linked with nonlinear variational formulations. The current approaches in this domain provide a direct means for updating the local crystallographic and hardening state of the material via integration of the evolution equations for the crystal lattice orientation and the critical resolved shear stress. The deformation behavior of the crystal volume elements are, at each integration point, governed by a crystal plasticity model which accounts for discrete plastic deformation by crystallographic slip and for the rotation of the crystal lattice during deformation. The crystal plasticity finite element models typically use space and time as independent variables and the crystal orientation and the accumulated slip as dependent variables (**Figure 9**).

In most large-strain constitutive crystal plasticity models, one assumes the stress response at each macroscopic continuum material point to be potentially given by one crystalline volume point. The constitutive equation for the stress in each grain is then expressed in terms of

$$\boldsymbol{T}^* = \boldsymbol{C}\boldsymbol{E}^*$$

where $\boldsymbol{T}^*$ is the Cauchy stress produced by the crystalline portion, $\boldsymbol{C}$ is the fourth-order elastic tensor, and $\boldsymbol{E}^*$ an elastic strain measure obtained by polar decomposition,

$$\boldsymbol{E}^* = \tfrac{1}{2}(\boldsymbol{F}^{*\mathrm{T}}\boldsymbol{F}^* - 1)$$

which leads to a stress measure, the elastic work conjugate to the strain measure $\boldsymbol{E}^*$,

$$\boldsymbol{T}^* = \boldsymbol{F}^{*-1}(\det(\boldsymbol{F}^*)\boldsymbol{T})(\boldsymbol{F}^*)^{-\mathrm{T}}$$

where $\boldsymbol{T}$ is the symmetrical Cauchy stress tensor in the grain, and $\boldsymbol{F}^*$ is a local elastic deformation gradient defined in terms of the local total deformation gradient $\boldsymbol{F}$ and the local plastic deformation gradient $\boldsymbol{F}^{\mathrm{p}}$. The relation between the elastic and the plastic portion of $\boldsymbol{F}$ amounts to

$$\boldsymbol{F}^* = \boldsymbol{F}(\boldsymbol{F}^{\mathrm{p}})^{-1}, \quad \det(\boldsymbol{F}^*) > 0, \ \det(\boldsymbol{F}^{\mathrm{p}}) = 1$$

The plastic deformation gradient is given by the flow rule

$$\dot{\boldsymbol{F}}^{\mathrm{p}} = \boldsymbol{L}^{\mathrm{p}}\boldsymbol{F}^{\mathrm{p}}$$

with $\boldsymbol{L}^{\mathrm{p}}$ being the plastic flow rate. In crystals, $\boldsymbol{L}^{\mathrm{p}}$ is composed of the superposition of the resolved crystallographic plastic shear rates, $\dot{\gamma}^{\alpha}$, such that

$$\boldsymbol{L}^{\mathrm{p}} = \sum_{\alpha} \dot{\gamma}^{\alpha}\boldsymbol{S}_0^{\alpha}, \quad \boldsymbol{S}_0^{\alpha} = \boldsymbol{m}_0^{\alpha} \otimes \boldsymbol{n}_0^{\alpha}$$

where $\dot{\gamma}^{\alpha}$ is the shearing rate on the slip system α, and $\boldsymbol{m}_0^{\alpha}$ and $\boldsymbol{n}_0^{\alpha}$ denote the slip direction and the slip plane normal of the slip system, respectively, in the initial unloaded configuration. The shearing rate on each slip system depends on the resolved shear τ^{α} and the slip resistance s^{α} of that slip system, and it is taken as

$$\dot{\gamma}^{\alpha} = \dot{\gamma}_0 \left| \frac{\tau^{\alpha}}{s^{\alpha}} \right|^{1/m} \operatorname{sign}(\tau^{\alpha})$$

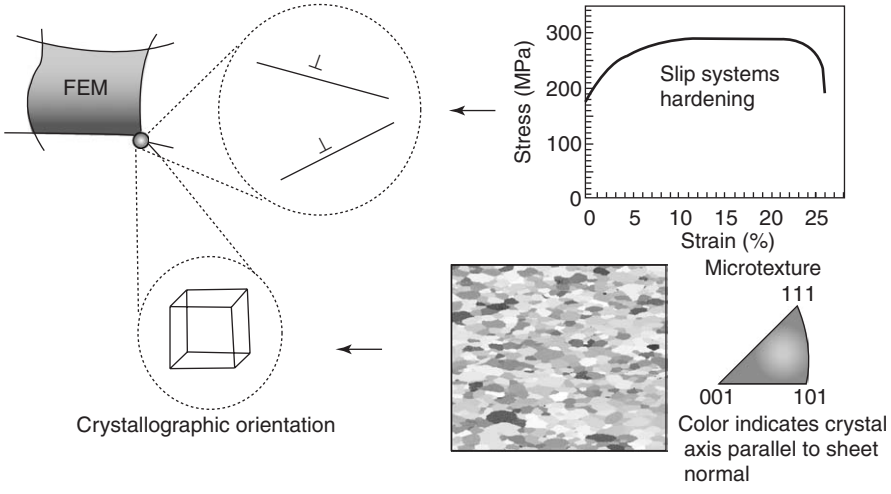

Figure 9 Schematical drawing showing the mapping of a set of orientations (microtexture) on the integration points of a crystal plasticity finite element mesh.

where $\dot{\gamma}_0$ denotes a reference value of the slip rate and m represents the strain rate sensitivity parameter. The evolution of the slip system resistance can be taken as

$$\dot{s} = \sum_{\beta} h^{\alpha\beta} |\dot{\gamma}^{\beta}|, \quad h^{\alpha\beta} = q^{\alpha\beta} h^{(\beta)},$$

$$h^{(\beta)} = h_0 \left(1 - \frac{s^{\beta}}{s_s}\right)^a$$

where $q^{\alpha\beta}$ are the components of a matrix that describe the latent hardening behavior of the crystal, and h_0, a, and s_s are slip system hardening parameters.

Density-Functional Theory

S Kurth, M A L Marques, and E K U Gross, Freie Universität Berlin, Berlin, Germany

Introduction

Density-functional theory (DFT) is a successful theory to calculate the electronic structure of atoms, molecules, and solids. Its goal is the quantitative understanding of material properties from the fundamental laws of quantum mechanics.

Traditional electronic structure methods attempt to find approximate solutions to the Schrödinger equation of N interacting electrons moving in an external, electrostatic potential (typically the Coulomb potential generated by the atomic nuclei). However, there are serious limitations of this approach: (1) the problem is highly nontrivial, even for very small numbers N and the resulting wave functions are complicated objects and (2) the computational effort grows very rapidly with increasing N, so the description of larger systems becomes prohibitive.

A different approach is taken in density-functional theory where, instead of the many-body wave function, the one-body density is used as the fundamental variable. Since the density $n(\boldsymbol{r})$ is a function of only three spatial coordinates (rather than the $3N$ coordinates of the wave function), density-functional theory is computationally feasible even for large systems.

The foundations of density-functional theory are the Hohenberg–Kohn and Kohn–Sham theorems which will be reviewed in the following section. In the section "Approximations for the exchange–correlation energy," various levels of approximation to the central quantity of DFT are discussed. The section "Results for some selected systems" will present some typical results from DFT calculations for various physical properties that are normally calculated with DFT methods. The original Hohenberg–Kohn and Kohn–Sham theorems can easily be extended from its original formulation to cover a wide variety of physical situations. A number of such extensions are presented in the section "Extensions of DFT," with particular emphasis on time-dependent DFT.

Hohenberg–Kohn and Kohn–Sham Theorems

In ground-state DFT one is interested in systems of N interacting electrons described by the Hamiltonian

$$\begin{aligned}\hat{H} &= \hat{T} + \hat{V} + \hat{V}_{\mathrm{ee}} \\ &= -\sum_{i=1}^{N} \frac{\nabla_i^2}{2} + \sum_{i=1}^{N} v(\boldsymbol{r}_i) + \frac{1}{2} \sum_{i=1}^{N} \sum_{\substack{j=1 \\ i=j}}^{N} \frac{1}{|\boldsymbol{r}_i - \boldsymbol{r}_j|}\end{aligned} \qquad [1]$$

with the kinetic, potential, and interaction energy operators $\hat{T}$, $\hat{V}$, and $\hat{V}_{\mathrm{ee}}$, respectively.

The central statement of formal density-functional theory is the celebrated Hohenberg–Kohn theorem which, for nondegenerate ground states, can be summarized in the following three statements:

1. The ground state electron density $n(\boldsymbol{r})$ of a system of interacting electrons uniquely determines the external potential $v(\boldsymbol{r})$ in which the electrons move and thus the Hamiltonian and all physical properties of the system.
2. The ground-state energy E_0 and the ground-state density $n_0(\boldsymbol{r})$ of a system characterized by the potential $v_0(\boldsymbol{r})$ can be obtained from a variational principle which involves only the density, that is, the ground-state energy can be written as a functional of the density, $E_{v_0}[n]$, which gives the ground-state energy E_0 if and only if the true ground-state density $n_0(\boldsymbol{r})$ is inserted. For all other densities $n(\boldsymbol{r})$, the inequality
$$E_0 = E_{v_0}[n_0] < E_{v_0}[n] \qquad [2]$$
holds.
3. There exists a functional $F[n]$ such that the energy functional can be written as
$$E_{v_0}[n] = F[n] + \int \mathrm{d}^3 r v_0(\boldsymbol{r}) n(\boldsymbol{r}) \qquad [3]$$

The functional $F[n]$ is universal in the sense that, for a given particle–particle interaction (the Coulomb interaction in our case), it is independent of the potential $v_0(\boldsymbol{r})$ of the particular system under consideration, that is, it has the same functional form for all systems.

The proof of the Hohenberg–Kohn theorem is based on the Rayleigh–Ritz variational principle and will not be repeated here. The interested reader is referred to excellent reviews given in the "Further reading" section.

From the Hohenberg–Kohn variational principle, that is, the second statement given above, the ground-state density $n(\boldsymbol{r})$ corresponding to the external potential $v(\boldsymbol{r})$ can be obtained as a solution of the Euler equation
$$\frac{\delta E_v[n]}{\delta n(\boldsymbol{r})} = \frac{\delta F[n]}{\delta n(\boldsymbol{r})} + v(\boldsymbol{r}) = 0 \qquad [4]$$

The formal definition of the Hohenberg–Kohn functional $F[n]$ is well known:
$$\begin{aligned} F[n] &= T[n] + V_{\mathrm{ee}}[n] \\ &= \langle \Psi[n] | \hat{T} | \Psi[n] \rangle + \langle \Psi[n] | \hat{V}_{\mathrm{ee}} | \Psi[n] \rangle \end{aligned} \qquad [5]$$
where $\Psi[n]$ is that N-electron wave function which yields the density n and minimizes the expectation value of $\hat{T} + \hat{V}_{\mathrm{ee}}$. However, the explicit density dependence of $F[n]$ remains unknown. Approximations have been suggested, the oldest one being the well-known Thomas–Fermi approximation (which precedes the Hohenberg–Kohn theorem historically). Unfortunately, the accuracy of known approximations to $F[n]$ is rather limited in practical calculations. Therefore, eqn [4] is rarely used in electronic structure calculations today.

Instead, the Hohenberg–Kohn theorem provides the basic theoretical foundation for the construction of an effective single-particle scheme which allows for the calculation of the ground-state density and energy of systems of interacting electrons. The resulting equations, the so-called Kohn–Sham equations, are at the heart of modern density-functional theory. They have the form of the single-particle Schrödinger equation
$$\left[-\frac{\nabla^2}{2} + v_{\mathrm{s}}(\boldsymbol{r}) \right] \varphi_i(\boldsymbol{r}) = \varepsilon_i \varphi_i(\boldsymbol{r}) \qquad [6]$$

The density can then be computed from the N single-particle orbitals occupied in the ground-state Slater determinant
$$n(\boldsymbol{r}) = \sum_i^{\mathrm{occ}} |\varphi_i(\boldsymbol{r})|^2 \qquad [7]$$

The central idea of the Kohn–Sham scheme is to construct the single-particle potential $v_{\mathrm{s}}(\boldsymbol{r})$ in such a way that the density of the auxiliary noninteracting system equals the density of the interacting system of interest. To this end one partitions the Hohenberg–Kohn functional in the following way:
$$F[n] = T_{\mathrm{s}}[n] + U[n] + E_{\mathrm{xc}}[n] \qquad [8]$$
where $T_{\mathrm{s}}[n]$ is the noninteracting kinetic energy,
$$U[n] = \frac{1}{2} \int \mathrm{d}^3 r \int \mathrm{d}^3 r' \frac{n(\boldsymbol{r}) n(\boldsymbol{r}')}{|\boldsymbol{r} - \boldsymbol{r}'|} \qquad [9]$$
is the classical electrostatic energy of the charge distribution $n(\boldsymbol{r})$, and $E_{\mathrm{xc}}[n]$ is the so-called exchange–correlation energy which is formally defined by
$$E_{\mathrm{xc}}[n] = T[n] + V_{\mathrm{ee}}[n] - U[n] - T_{\mathrm{s}}[n] \qquad [10]$$

From the above definitions one can derive the form of the effective potential entering eqn [6]
$$v_{\mathrm{s}}[n](\boldsymbol{r}) = v(\boldsymbol{r}) + \int \mathrm{d}^3 r' \frac{n(\boldsymbol{r}')}{|\boldsymbol{r} - \boldsymbol{r}'|} + v_{\mathrm{xc}}[n](\boldsymbol{r}) \qquad [11]$$

where the exchange–correlation potential v_{xc} is defined by

$$v_{xc}[n](\boldsymbol{r}) = \frac{\delta E_{xc}[n]}{\delta n(\boldsymbol{r})} \qquad [12]$$

Since $v_s[n](\boldsymbol{r})$ depends on the density, eqns [6], [7], and [11] have to be solved self-consistently. This is known as the Kohn–Sham scheme of density-functional theory.

Approximations for the Exchange–Correlation Energy

Clearly, the formal definition [10] of the exchange–correlation energy is not helpful for practical calculations and one needs to use an approximation for this quantity. Some of these approximations are discussed in the following.

While DFT itself does not give any hint on how to construct approximate exchange–correlation functionals, it holds both the promise and the challenge that the true E_{xc} is a universal functional of the density, that is, it has the same functional form for all systems. On the one hand this is a promise because an approximate functional, once constructed, may be applied to any system of interest. On the other hand, this is a challenge because a good approximation should perform equally well for very different physical situations.

Both the promise and the challenge are reflected by the fact that the simplest of all functionals, the so-called local density approximation (LDA), or its spin-dependent version, the local spin density approximation (LSD), has remained the approximation of choice for quite many years after the formulation of the Kohn–Sham theorem. In LDA, the exchange–correlation energy is given by

$$E_{xc}^{LDA}[n] = \int d^3r n(\boldsymbol{r}) e_{xc}^{unif}(n(\boldsymbol{r})) \qquad [13]$$

where $e_{xc}^{unif}(n)$ is the exchange–correlation energy per particle of an electron gas with spatially uniform density n. It can be obtained from quantum Monte Carlo calculations and simple parametrizations are available. By its very construction, the LDA is expected to be a good approximation for spatially slowly varying densities. Although this condition is hardly ever met for real electronic systems, LDA has proved to be remarkably accurate for a wide variety of systems.

In the quest for improved functionals, an important breakthrough was achieved with the emergence of the so-called generalized gradient approximations (GGAs). Within GGA, the exchange–correlation energy for spin-unpolarized systems is written as

$$E_{xc}^{GGA}[n] = \int d^3r f(n(\boldsymbol{r}), \nabla n(\boldsymbol{r})) \qquad [14]$$

While the input e_{xc}^{unif} in LDA is unique, the function f in GGA is not, and many different forms have been suggested. When constructing a GGA one usually tries to incorporate a number of known properties of the exact functional into the restricted functional form of the approximation. The impact of GGAs has been quite dramatic, especially in quantum chemistry where DFT is now competitive in accuracy with more traditional methods while being computationally less expensive.

In recent years, still following the lines of GGA development, a new class of "meta-GGA" functionals has been suggested. In addition to the density and its first gradient, meta-GGA functionals depend on the kinetic energy density of the Kohn–Sham orbitals,

$$\tau(\boldsymbol{r}) = \frac{1}{2}\sum_{i}^{occ} |\nabla \varphi_i(\boldsymbol{r})|^2 \qquad [15]$$

The meta-GGA functional then takes the form

$$E_{xc}^{MGGA}[n] = \int d^3r\, g(n(\boldsymbol{r}), \nabla n(\boldsymbol{r}), \tau(\boldsymbol{r})) \qquad [16]$$

The additional flexibility in the functional form gained by the introduction of the new variable can be used to incorporate more of the exact properties into the approximation. In this way, it has been possible to improve upon the accuracy of GGA for some physical properties without worsening the results for others.

Unlike LDA or GGA, which are explicit functionals of the density, meta-GGAs also depend explicitly on the Kohn–Sham orbitals. It is important to note, however, that one is still in the domain of DFT since, through the Kohn–Sham equation [6], the orbitals are functionals of the Kohn–Sham potential and therefore, by virtue of the Hohenberg–Kohn theorem, also functionals of the density.

Such orbital functionals, or implicit density functionals, constitute a wide field of active research. Probably the most familiar orbital functional is the exact exchange energy functional (EXX):

$$E_x^{EXX}[n] = -\frac{1}{2}\sum_{\sigma}\int d^3r \int d^3r' \times \sum_{i,j}^{occ} \frac{\varphi_{i\sigma}(\boldsymbol{r})\varphi_{i\sigma}^*(\boldsymbol{r}')\varphi_{j\sigma}(\boldsymbol{r}')\varphi_{j\sigma}^*(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{r}'|} \qquad [17]$$

At this point, some remarks about similarities and differences to Hartree–Fock theory are in order. If

one uses the exact exchange functional [17] and neglects correlation, the resulting total energy functional is exactly the Hartree–Fock functional. However, in exact-exchange DFT this functional is evaluated with Kohn–Sham rather than Hartree–Fock orbitals. Furthermore, the Hartree–Fock orbitals are obtained from a minimization without constraints (except for orthonormality) which leads to the nonlocal Hartree–Fock potential. The exact-exchange Kohn–Sham orbitals, on the other hand, are obtained by minimizing the same functional under the additional constraint that the single-particle orbitals come from a local potential. Therefore, the total Hartree–Fock energy is always lower than the total energy in exact-exchange DFT but the difference has turned out to be very small. However, single-particle properties such as orbitals and orbital eigenvalues can be quite different in both approaches. For example, Kohn–Sham exact-exchange energy spectra are usually much closer to experiment than Hartree–Fock spectra, indicating that exact-exchange DFT might be a better starting point to include correlation than Hartree–Fock spectra.

In order to go beyond exact-exchange DFT, one might be tempted to use the exact-exchange functional in combination with a traditional approximation such as LDA or GGA for correlation. Since both LDA and GGA benefit from a cancelation of errors between their exchange and correlation pieces, an approach using LDA or GGA for only one of these energy components is bound to fail. The obvious alternative is to use approximate, orbital-dependent correlation energy functionals. One systematic way to construct such functionals is known as Görling–Levy perturbation theory. Structurally, this is similar to what is known as Møller–Plesset perturbation theory in quantum chemistry. However, it is only practical for low orders. A more promising route uses the fluctuation–dissipation theorem which establishes a connection to linear response theory in time-dependent DFT.

A final class of approximations to the exchange–correlation energy are the so-called hybrid functionals which mix a fraction of exact exchange with GGA exchange,

$$E_{\mathrm{x}}^{\mathrm{HYB}}[n] = aE_{\mathrm{x}}^{\mathrm{EXX}}[n] + (1-a)E_{\mathrm{x}}^{\mathrm{GGA}}[n] \qquad [18]$$

where a is the (empirical) mixing parameter. This exchange functional is then combined with some GGA for correlation. Hybrid functionals are tremendously popular and successful in quantum chemistry but much less so in solid-state physics.

This last fact highlights a problem pertinent to the construction of improved functionals: available approximations are already very accurate and hard to improve upon. In addition, and this makes it a very difficult problem, one would like to have improved performance not only for just one particular property or one particular class of systems but for as many properties and systems as possible. After all, the true exchange–correlation energy is a universal functional of the density.

Results for Some Selected Systems

Over the years, a vast number of DFT calculations have been reported and only the scantiest of selections can be given here. Results are given for different functionals in order to illustrate the performance of the different levels of approximation. It should be kept in mind, however, that while there is only one LDA functional, there are several GGA, meta-GGA, or hybrid functionals which have been suggested and whose results for a given system will vary.

In solid-state physics, typical quantities calculated with ground-state DFT are structural properties. In **Table 1**, equilibrium lattice constants and bulk

moduli for a few solids are presented. LDA lattice constants are usually accurate to within a few percent. On average, GGA and meta-GGA give some improvement. For bulk moduli, the relative errors are much larger and improvement of GGA and meta-GGA as compared to LDA is statistical and not uniform. There are however some properties that are systematically improved by GGA. For example, GGA cohesive energies for transition metals are on average better by almost half an order of magnitude than the LDA values.

Possibly the best known success of GGA is the correct prediction of the ferromagnetic b.c.c ground state of iron for which LDA incorrectly gives a nonmagnetic f.c.c. ground state. The calculated magnetic moments shown in **Table 2** illustrate the improved performance of GGA also for this quantity.

One of the standard uses of DFT in solid-state physics is the calculation of band structures. Usually one interprets and compares the Kohn–Sham band structure directly with experimental energy bands. Strictly speaking, this interpretation has no sound theoretical justification since the Kohn–Sham eigenvalues are only auxiliary quantities. Experience has shown, however, that LDA or GGA band structures are often rather close to experimental ones, especially for simple metals. On the other hand, a well-known problem in semiconductors and insulators is that both LDA and GGA seriously underestimate the bandgap. This deficiency is corrected when using the exact-exchange functional (see **Table 3**).

Since DFT also has gained a tremendous popularity in the world of quantum chemistry, finally some results for the atomization energies of small molecules are presented in **Table 4**. Similar to the cohesive energy of solids, one sees a clear improvement as one goes from LDA to GGA. Further improvement is achieved on the meta-GGA level but, for this particular quantity, the accuracy of the hybrid functional is truly remarkable. Unfortunately, however, the accuracy of hybrid functionals for molecular properties does not translate into an equally good performance for solids.

Extensions of DFT

The original theory of Hohenberg, Kohn, and Sham can only be applied to quantum systems in their (nondegenerate) ground-state. Over the years a number of extensions have been put forth (with varying degree of success). In fact, density-functional theories have been formulated for relativistic systems, superconductors, ensembles, etc. Here, only a small selection of extensions of DFT is reviewed. Special attention is paid to time-dependent DFT, as this theory is becoming particularly popular in the calculation of excited-state properties.

Spin Density-Functional Theory

Most practical applications of DFT make use of an extension of the original theory which uses the partial densities of electrons with different spin σ as independent variables,

$$n_\sigma(\boldsymbol{r}) = \sum_i^{\text{occ}} |\varphi_{i\sigma}(\boldsymbol{r})|^2 \qquad [19]$$

Table 4 Atomization energies (in units of $1\,\text{kcal}\,\text{mol}^{-1} = 0.0434\,\text{eV}$) of 20 small molecules. Zero-point vibration has been removed from experimental energies[a]

[a] LSD, GGA, and meta-GGA results from Kurth S, Perdew JP, and Blaha P (1999) *International Journal of Quantum Chemistry* 75: 889; results for the hybrid functional from Becke AD (1998) *Journal of Chemical Physics* 98: 5648.

rather than using the total density of eqn [7]. Again, the single-particle orbitals are solutions of a noninteracting Schrödinger equation [6], but the effective potential eqn [11] now becomes spin-dependent by using the exchange–correlation potential

$$v_{\mathrm{xc}\sigma}[n_\uparrow, n_\downarrow](\boldsymbol{r}) = \frac{\delta E_{\mathrm{xc}}[n_\uparrow, n_\downarrow]}{\delta n_\sigma(\boldsymbol{r})} \qquad [20]$$

instead of the one given in eqn [12]. Spin-density-functional theory (SDFT) relates to the original formulation of DFT as spin-unrestricted Hartree–Fock relates to spin-restricted Hartree–Fock theory. It allows for a straightforward description of systems with a spin-polarized ground state such as ferromagnets.

Density-Functional Theory for Superconductors

In 1988, triggered by the remarkable discovery of the high-T_c materials, Oliveira, Gross, and Kohn proposed a density-functional theory for the superconducting state. Their theory uses two independent variables – the "normal" density, $n(\boldsymbol{r})$, and a nonlocal "anomalous" density $\chi(\boldsymbol{r}, \boldsymbol{r}')$. This latter quantity reduces, under the appropriate limits, to the order-parameter in Ginzburg–Landau theory. With these two densities it is straightforward to derive a Hohenberg–Kohn-like theorem and a Kohn–Sham scheme. The resulting equations are very similar to the traditional Bogoliubov–de Gennes equations for inhomogeneous superconductors, but include exchange and correlation effects through a "normal,"

$$v_{\mathrm{xc}}[n, \chi](\boldsymbol{r}) = \frac{\delta E_{\mathrm{xc}}[n, \chi]}{\delta n(\boldsymbol{r})} \qquad [21]$$

and an "anomalous" exchange–correlation potential,

$$\Delta_{\mathrm{xc}}[n, \chi](\boldsymbol{r}, \boldsymbol{r}') = -\frac{\delta E_{\mathrm{xc}}[n, \chi]}{\delta \chi^*(\boldsymbol{r}, \boldsymbol{r}')} \qquad [22]$$

Unfortunately, only few approximations to the exchange–correlation functionals have been proposed so far. From these, both an LDA-like functional aimed at describing electron–electron correlations and the development of a scheme that incorporates strong electron–phonon interactions and electron screening are mentioned. In this framework it is now possible to calculate transition temperatures and energy gaps of superconductors from first principles.

Time-Dependent Density-Functional Theory

Several problems in physics require the solution of the time-dependent Schrödinger equation

$$\mathrm{i}\frac{\partial}{\partial t}\Psi(\underline{\boldsymbol{r}}, t) = \hat{H}(t)\Psi(\underline{\boldsymbol{r}}, t) \qquad [23]$$

where Ψ is the many-body wave function of N electrons with coordinates $\underline{\boldsymbol{r}} = (\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N)$, and $\hat{H}(t)$ is the operator (1) generalized to the case of time-dependent external potentials. This equation describes the time evolution of a system subject to the initial condition $\Psi(\underline{\boldsymbol{r}}, t = t_0) = \Psi_0(\underline{\boldsymbol{r}})$. The initial density is n_0.

The central statement of time-dependent density-functional theory (TDDFT), the Runge–Gross theorem, states that, if Ψ_0 is the ground state of $\hat{H}(t = t_0)$, there exists a one-to-one correspondence between the time-dependent density $n(\boldsymbol{r}, t)$ and the external potential $v(\boldsymbol{r}, t)$. All observables of the system can then be written as functionals of the density only. The Runge–Gross theorem provides the theoretical foundation of TDDFT. The practical framework of the theory is given by the Kohn–Sham scheme. A system of noninteracting electrons is defined, obeying the one-particle Schrödinger equation

$$\mathrm{i}\frac{\partial}{\partial t}\varphi_i(\boldsymbol{r}, t) = \left[-\frac{\nabla^2}{2} + v_{\mathrm{s}}(\boldsymbol{r}, t)\right]\varphi_i(\boldsymbol{r}, t) \qquad [24]$$

Similar to static Kohn–Sham theory, the Kohn–Sham potential is usually written as

$$v_{\mathrm{s}}[n](\boldsymbol{r}, t) = v(\boldsymbol{r}, t) + \int \mathrm{d}^3 r' \frac{n(\boldsymbol{r}', t)}{|\boldsymbol{r} - \boldsymbol{r}'|} + v_{\mathrm{xc}}[n](\boldsymbol{r}, t) \qquad [25]$$

where $v(\boldsymbol{r}, t)$ includes both the static Coulomb potential of the nuclei and the explicitly time-dependent contribution of an external electromagnetic field. The exchange–correlation potential, v_{xc}, is chosen such that the density of the Kohn–Sham electrons

$$n(\boldsymbol{r}, t) = \sum_i^{\mathrm{occ}} |\varphi_i(\boldsymbol{r}, t)|^2 \qquad [26]$$

is equal to the density of the interacting system. Clearly, v_{xc} is a very complex quantity – it encompasses all nontrivial many-body effects – that has to be approximated. The most common approximation to $v_{\mathrm{xc}}(\boldsymbol{r}, t)$ is the adiabatic local density approximation (ALDA). In the ALDA it is assumed that the exchange–correlation potential at time t is equal to the ground-state LDA potential evaluated with the density $n(\boldsymbol{r}, t)$, that is,

$$v_{\mathrm{xc}}^{\mathrm{ALDA}}[n](\boldsymbol{r}, t) = v_{\mathrm{xc}}^{\mathrm{unif}}(n(\boldsymbol{r}, t)) \qquad [27]$$

Following the same reasoning it is simple to derive an adiabatic GGA or meta-GGA.

Two regimes can usually be distinguished in TDDFT (or more generally in time-dependent quantum mechanics), depending on the strength of the

external time-dependent potential. If this potential is "weak," the solution of the time-dependent Kohn–Sham equations can be circumvented by the use of linear (or low-order) response theory. In linear response, one looks at the linear change of the density produced by a small (infinitesimal) change in the external potential – information which is contained in the so-called linear density response function χ. Within TDDFT, χ can be calculated from the Dyson-like equation

$$\chi(\boldsymbol{r}t,\boldsymbol{r}'t') = \chi_s(\boldsymbol{r}t,\boldsymbol{r}'t') + \int d^3x \int d^3x' \int d\tau \int d\tau'$$
$$\chi_s(\boldsymbol{r}t,\boldsymbol{x}\tau)\left[\frac{\delta(\tau-\tau')}{|\boldsymbol{x}-\boldsymbol{x}'|} + f_{xc}(\boldsymbol{x}\tau,\boldsymbol{x}'\tau')\right]\chi(\boldsymbol{x}'\tau',\boldsymbol{r}'t') \qquad [28]$$

where χ_s is the (noninteracting) Kohn–Sham response function. The exchange–correlation kernel f_{xc} is defined as

$$f_{xc}(\boldsymbol{r}t,\boldsymbol{r}'t') = \left.\frac{\delta v_{xc}(\boldsymbol{r},t)}{\delta n(\boldsymbol{r}',t')}\right|_{n_0} \qquad [29]$$

where the functional derivative is evaluated at the initial ground-state density n_0. If one puts $f_{xc} = 0$ in [28], the well-known random phase approximation (RPA) to the excitation energies is obtained. Knowledge of χ allows for the calculation of linear absorption spectra. Here one has to distinguish between finite and extended systems. The optical absorption spectrum of a finite system is essentially given by the poles of χ. For an extended system, the spectrum is obtained from the imaginary part of the dielectric function, which can be written (in frequency space) as

$$\varepsilon^{-1}(\boldsymbol{r},\boldsymbol{r}',\omega) = \delta(\boldsymbol{r}-\boldsymbol{r}') + \int d^3x \frac{\chi(\boldsymbol{x},\boldsymbol{r}',\omega)}{|\boldsymbol{r}-\boldsymbol{x}|} \qquad [30]$$

Most calculations performed within this scheme approximate the exchange–correlation kernel by the ALDA. For finite systems, excitation energies are of excellent quality for a variety of atoms, organic and inorganic molecules, clusters, etc. Unfortunately, the situation is different for extended systems, especially for large-gap semiconductors. In **Figure 1** the ALDA optical absorption spectrum of silicon together with an RPA calculation, a Bethe–Salpeter calculation (a method based on many-body perturbation theory), and experimental results are shown. It is clear that ALDA fails to give a significant correction over RPA. In momentum space, the Coulomb interaction is simply $1/q^2$. It is then clear from [28] that if f_{xc} is to contribute for small q – which is the relevant regime for optical absorption – it will have to behave asymptotically as $1/q^2$. The ALDA kernel approaches a constant for $q \to 0$ and is therefore incapable to correct the RPA results. Recently several new kernels have been proposed that overcome this problem. One of them, the RORO kernel, has the simple form

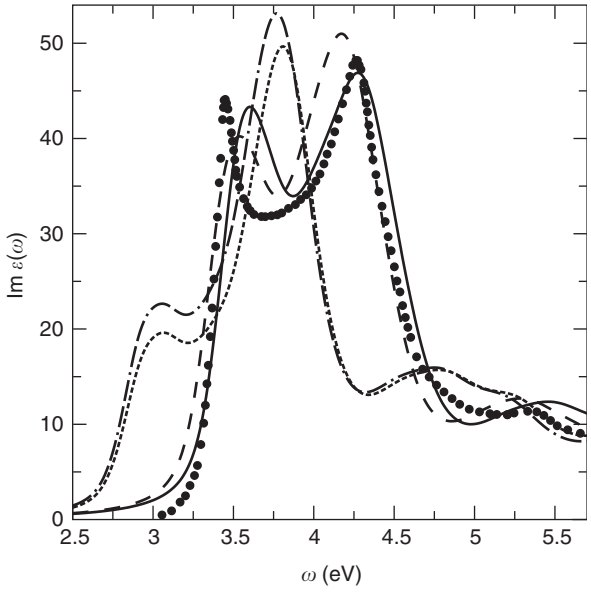

Figure 1 Optical absorption spectrum of silicon. The curves are: thick dots – experiment dotted curve – RPA; dot-dashed curve – TDDFT using the ALDA; solid curve – TDDFT using the RORO kernel; dashed curve – Bethe-Salpeter equation. $$f_{xc}^{RORO}(\boldsymbol{r},\boldsymbol{r}') = -\frac{\alpha}{4\pi}\frac{1}{|\boldsymbol{r}-\boldsymbol{r}'|} \qquad [31]$$

where α is a phenomenologically determined parameter. Taking $\alpha = 0.12$ yields the curve shown in **Figure 1**, which is already very close to the experimental results.

Conclusions

There is no doubt that DFT has become a mature theory for electronic structure calculations. The success of DFT is based on the availability of increasingly accurate approximations to the exchange–correlation energy. Research into the development of still more accurate approximations continues. In static DFT, orbital functionals seem to be promising candidates to achieve this goal. In time-dependent DFT as well as in other extensions of DFT, development of approximations is still at a much earlier stage.

Applications of DFT abound. In solid-state physics, DFT is the method of choice for the calculation of material properties from first principles. While

traditional, static DFT calculations have mainly focused on structural ground-state properties such as lattice parameters, TDDFT also allows for the calculation of excited state properties such as absorption spectra. In quantum chemistry, the decade-long dream of electronic structure calculations with "chemical accuracy" appears within reach with DFT. Due to the favorable scaling of the computational effort with increasing system size and also to the ever-increasing computational power of modern computers, DFT calculations are now feasible for systems containing several thousand atoms. This opens the way for applications of DFT to biologically relevant systems.

Deterministic Aperiodic Solids, Electronic Properties of

J Bellissard, Georgia Institute of Technology, Atlanta, GA, USA

Aperiodic Media

Since the early 1970s, several classes of aperiodic solids have been the focus of attention. Examples of such materials are the following:

1. Electrons in a uniform magnetic field are sensitive to the vector potential which cannot be constant in space at nonvanishing magnetic field, thus breaking the translation symmetry.
2. Randomly distributed impurities or defects break the translation invariance in crystal-like normal metals or doped semiconductors. However, electrons feel them only at low temperature. Similarly, only phonons of short wavelength are sensitive to disorder.
3. Amorphous materials, such as glass, silicon (in its amorphous phase), even liquids at short timescales, have been considered as such in the literature.
4. Artificial structures, such as superlattices or arrays of quantum dots, are technologically available and can be designed to break the translation symmetry.
5. Quasicrystals, such as $Al_{62.5}Cu_{25}Fe_{12.5}$ or $Al_{70.5}Pd_{22}Mn_{7.5}$ have a point-like diffraction spectrum with symmetries (such as the fivefold or tenfold symmetries) incompatible with spatial periodicity.

In view of their growing importance, there is a need for mathematical and numerical methods to study them, since the usual Bloch theory cannot be used,

due to the lack of translation symmetry. To avoid complexity, as a first approximation, the degrees of freedom (electrons, holes, phonons, lacunæ) are considered as independent and moving in an infinite volume limit ideal solid.

Transport Mechanisms

Various mechanisms of transport can be observed experimentally in aperiodic materials:

1. For metals, the conductivity increases as the temperature decreases. Moreover, the Fermi liquid theory (Landau) predicts
2. Thermally activated processes, (if a gap arises at the Fermi level), give

$$\sigma(T) \overset{T\downarrow 0}{\sim} T^{-2}$$

3. For weakly disordered systems (strongly doped semiconductors, normal metals), there is a residual conductivity at low temperature, due to quantum interferences

$$\sigma(T) \overset{T\downarrow 0}{\sim} \mathrm{e}^{-\Delta/T}$$

4. In strongly disordered systems (lightly doped semiconductors) with small density of states (DOS) at the Fermi level, Mott variable range hopping predicts in dimension d

$$\sigma(T) \overset{T\downarrow 0}{\sim} \sigma_0 > 0$$

5. High-quality quasicrystals are metallic alloys but their conductivity decreases with the temperature (see **Figure 1**) and exhibits a scaling behavior

$$\sigma(T) \overset{T\downarrow 0}{\sim} \mathrm{e}^{-(T_0/T)^{1/(d+1)}}$$

$$\sigma(T) \overset{T\downarrow 0}{\sim} \sigma_0 + aT^{\gamma}, \quad 1 < \gamma < 1.5$$

on a large range of temperatures (from 50 mK to 1000 K in some cases). In most cases $\sigma_0 > 0$ (residual conductivity), but there are examples for which $\sigma_0 \approx 0$ (**Figure 1**).

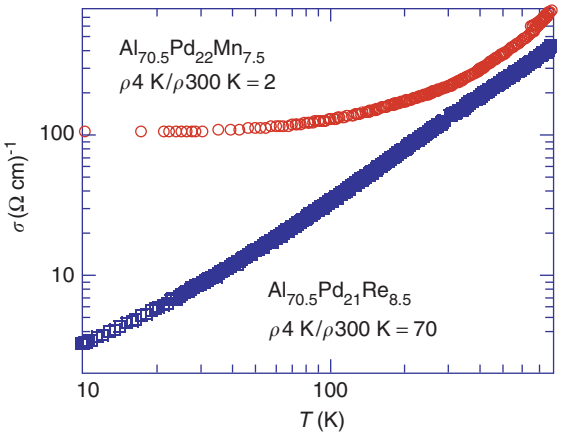

Figure 1 Conductivity of two examples of quasicrystals.

The Hull

The "Hull" of an aperiodic solid and its canonical transversal, or atomic surface, is the main construction (as the Brillouin zone for a crystal). It represents in a compactified way all possible samples of the material that can be ideally produced.

As a good approximation, atomic nuclei are supposed to be frozen at their ideal equilibrium position at zero temperature. The set $\mathscr{L}$ of atomic positions is thus a discrete subset of the space $\mathbb{R}^d$ (d is the dimension of the material). $\mathscr{L}$ is called uniformly discrete whenever the minimum distance between any two distinct points of $\mathscr{L}$ is positive. $\mathscr{L}$ is called relatively dense whenever there is a radius R large enough so that any ball of radius R meets $\mathscr{L}$ on at least one point. A set is Delone if it is both uniformly discrete and relatively dense. A Delone set is repetitive if, given any finite patch p (namely, a finite set of the form $p = \mathscr{L} \cap B$, where B is some open ball), and any small length $\varepsilon > 0$, there is a radius $R_p > 0$ such that any ball of radius R_p contains a translated copy of p modulo, an error smaller than ε. A Delone set has finite type if the set of vectors joining two of its points is itself discrete (this latter set is denoted by $\mathscr{L} - \mathscr{L}$). Lastly, a Meyer set is a Delone set such that the family $\mathscr{L} - \mathscr{L}$ of vectors joining two of its points is itself a Delone set.

Examples:

1. Throwing points randomly in space with a fixed density (Poisson's law) gives a discrete set which, with probability 1, is neither uniformly discrete nor relatively dense.
2. Randomly throwing impurities on sites of a silicon perfect diamond lattice gives a uniformly discrete set which, with probability 1, is not relatively dense. Other materials like zeolithes may have their atoms distributed on a fractal uniformly discrete but nonrelatively dense set.
3. In the ideal limit of zero temperature, most solids have their atoms distributed on a Delone set. But amorphous ones, such as glass or silicon, are neither of finite type nor are they repetitive because their two-point correlation function falls off quickly at a large distance. Perfect crystals and quasicrystals are described by a finite type repetitive Delone set.

4. Typical examples of Meyer sets are provided by crystals or quasicrystals (see **Figure 2**). These are the sets with a point-like diffraction pattern and no diffuse part.

If the solid is homogeneous, $\mathscr{L}$ and $\mathscr{L}+a$ have similar global properties. However, an observer sees only a finite sample in practice, namely, he sees only what happens in a bounded window $\Lambda\subset\mathbb{R}^d$. A sequence of translated $\mathscr{L}_n=\mathscr{L}+a_n$ converges to the discrete set $\mathscr{L}_\infty$ if and only if, for any bounded window Λ, the family $\mathscr{L}_n\cap\Lambda$ of points of $\mathscr{L}_n$ contained in Λ converges to $\mathscr{L}_\infty\cap\Lambda$. The Hull Ω of $\mathscr{L}$ is defined as the family of limit points of translated $\mathscr{L}$. By construction, any point $\omega\in\Omega$ corresponds to a set $\mathscr{L}_\omega$ obtained as the limit of a subsequence of translated $\mathscr{L}$. It can be proved that, as soon as $\mathscr{L}$ is uniformly discrete, Ω is a compact and metrizable set. Metrizability means that the topology defined above can be described through a metric. An example of such metric (it is not the only one) is the following: the distance $d(\omega,\omega')$ between the points ω,ω' of the Hull is the smallest number $\varepsilon>0$, such that $\mathscr{L}_\omega$ and $\mathscr{L}_{\omega'}$ coincide in the ball centered at the origin of radius $1/\varepsilon$ modulo, an error of ε. Compactness means that given any $\varepsilon>0$, there is a finite set $\{a_1,\ldots,a_d\}$ of vectors $\mathbb{R}^d$, such that any ω is within the distance ε of at least one of the $\mathscr{L}+a_i$'s. Hence in a ball of radius $1/\varepsilon$, $\mathscr{L}_\omega$ looks like $\mathscr{L}+a_i$ modulo, an error smaller than ε. In other words, compactness is a way of expressing that $\mathscr{L}$ describes a homogeneous solid. In particular, the minimum distance between distinct points in $\mathscr{L}_\omega$ is at least equal to the one in $\mathscr{L}$. Moreover the properties of being Delone, finite type, repetitive, or Meyer are inherited by all the $\mathscr{L}_\omega$s.

In addition, if $a\in\mathbb{R}^d$ is a vector in space, then $\mathscr{L}_\omega+a$ also belongs to the Hull, thus defining a point denoted by $T^a\omega$. It can be shown that the map $(a,\omega)\mapsto T^a\omega$ is continuous and satisfies $T^{a+a'}\omega=T^a(T^{a'}\omega)$ while $T^0\omega=\omega$, hence giving a topological action of the translation group on the Hull. Therefore, $(\Omega,\mathbb{R}^d,T)$ is a topological dynamical system.

To build the Hull it is convenient to use the canonical transversal Ξ, defined as the set of points ω in the Hull such that the set $\mathscr{L}_\omega$ contains the origin $0\in\mathbb{R}^d$ (see **Figure 3**). Starting from a point in Ξ and translating it, it takes a minimum distance between two points in $\mathscr{L}$ at least to have $0\in\mathscr{L}_\omega+a$ again. So, $\mathscr{L}_\omega$ can be seen as the trace of Ξ in the orbit of ω. Since such an orbit can be seen as the space $\mathbb{R}^d$ in which the solid is living and since the points of $\mathscr{L}_\omega$ are the positions of atoms, Ξ represents the position of the atom in the Hull. This is why Ξ is also called (especially in quasicrystallography) the atomic surface.

For periodic materials, the Hull is the d-torus obtained by identifying points in spaces that differ by a vector of the period group (the Bravais lattice). The transversal is the (finite) set of atoms of the unit cell. For quasicrystals, the Hull is a torus of higher dimension in which the physical space $\mathbb{R}^d$ has

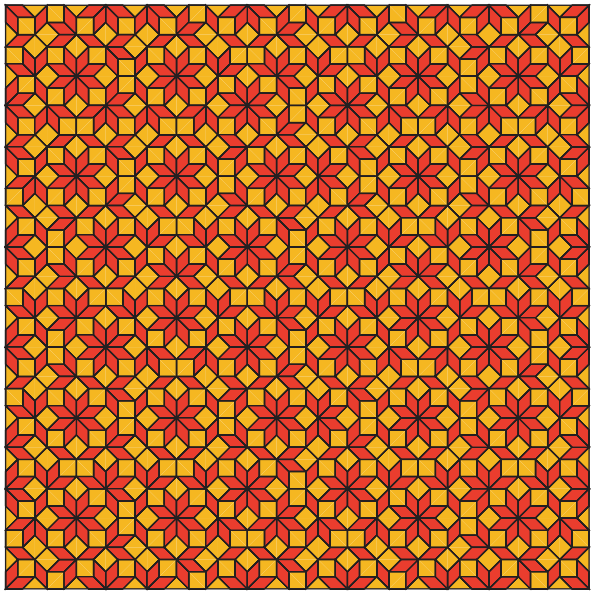

Figure 2 A Meyer set: the Ammann–Beenker tiling.

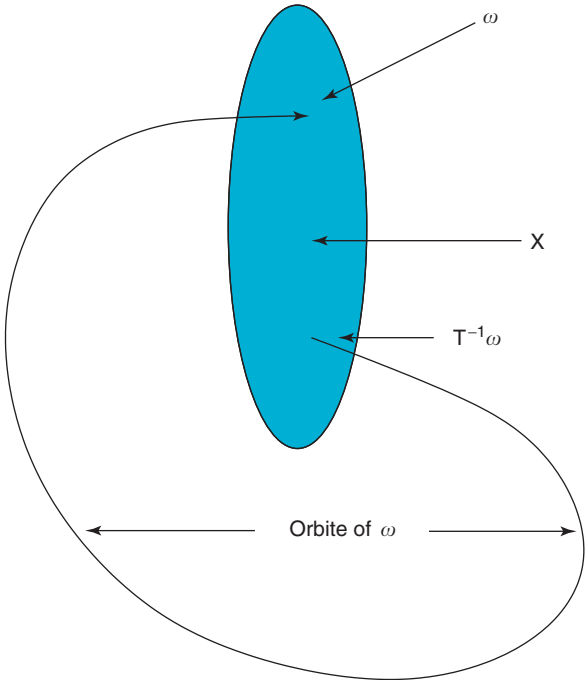

Figure 3 Schematic view of the atomic surface.

irrational slopes. Moreover, the Hull has the topology of a Cantor set, in the direction perpendicular to the physical space (see **Figure 4**).

Noncommutative Brillouin Zone

The description of dynamical degrees of freedom (electrons, holes, phonons) cannot be done through the Bloch theory since the translation invariance is broken. However, any observable describing them can be given by a covariant operator, namely, a family $A = (A_\omega)_{\omega\in\Omega}$ of self-adjoint bounded operators acting on the Hilbert space $\mathscr{H}$ of quantum states, such that: (1) $T(a)A_\omega T(a)^{-1} = A_{T^a\omega}$ if $T(a)$ is the translation operator by $a\in\mathbb{R}^d$ acting on $\mathscr{H}$, and (2) for any quantum state $|\psi\rangle$ the map $\omega\mapsto A_\omega|\psi\rangle$ is continuous (strong continuity). If the material is periodic, all such observables are matrix-valued functions over the Brillouin zone. Hence, the algebra of observables is the noncommutative analog of the space of continuous functions on the Brillouin zone, leading to the notion of Noncommutative Brillouin Zone (NCBZ). Such functions can be integrated: if $\mathbb{P}$ is an $\mathbb{R}^d$ invariant probability measure on the Hull, then $\mathscr{T}_\mathbb{P}(A)$ is defined as the average of the diagonal matrix elements of A_ω and is equal to the trace per unit volume of A. The map $A\mapsto\mathscr{T}_\mathbb{P}(A)$ is linear, positive (namely, $\mathscr{T}_\mathbb{P}(A^*A)\geqslant 0$), and tracial namely $\mathscr{T}_\mathbb{P}(AB) = \mathscr{T}_\mathbb{P}(BA)$. It is the noncommutative analog of the integral over the NCBZ. In addition, if $\boldsymbol{R} = (R_1, \ldots, R_d)$ is the position operator, then $\boldsymbol{\nabla}A = \imath[\boldsymbol{R}, A]$ gives a family of d commuting derivations (namely, $\boldsymbol{\nabla} = (\partial_1, \ldots, \partial_d)$ is linear and obeys the Leibniz rule $\boldsymbol{\nabla}(AB) = \boldsymbol{\nabla}(A)B + A\boldsymbol{\nabla}(B)$) generalizing the derivatives with reference to the quasimomentum in the NCBZ. Depending upon the degrees of freedom (electrons, holes with spin or spinless, or phonons), this algebra of observables is represented in various Hilbert spaces. Most formulas found in textbooks, valid for periodic crystals, extend in a similar way to aperiodic materials provided the integral over quasimomenta is replaced by $\mathscr{T}_\mathbb{P}$, and the derivatives $\boldsymbol{\nabla}_k$ by $\boldsymbol{\nabla}$.

In the independent particle approximation, the electron or holes are described by a Hamiltonian $H = (H_\omega)_{\omega\in\Omega}$ coming from a Schrödinger operator. The simplest example, for spinless electrons, acts on $\mathscr{H} = L^2(\mathbb{R}^d)$ and is given by

$$H_\omega = -\frac{\hbar^2}{2m}\Delta + \sum_{a\in\mathfrak{A}}\sum_{r\in\mathscr{L}_\omega^a} v_a(\boldsymbol{R}-\boldsymbol{r})$$

where $\mathfrak{A}$ is a finite set labeling various species of atoms, $\mathscr{L}_\omega^a$ represents the set of positions for the atoms of species $a\in\mathfrak{A}$, and v_a is the atomic pseudopotential created by atoms of species a acting on the charge carrier. In the tight-binding representation, the Hamiltonian becomes a matrix indexed by the atomic sites and the corresponding atomic species, acting on $\mathscr{H}_\omega = \ell^2(\mathscr{L}_\omega)$, of the form

$$\langle x, a|H_\omega|y, b\rangle = h_{ab}(T^{-x}\omega, y-x),$$
$$a, b\in\mathfrak{A},\ x\in\mathscr{L}_\omega^a,\ y\in\mathscr{L}_\omega^b$$

where h is some continuous matrix-valued function on the set Γ of pairs (ω, x) such that ω belongs to the transversal, and $x\in\mathscr{L}_\omega$.

In the harmonic approximation, phonons are described by the creation and annihilation operators of bosons attached to each atomic site with a polarization

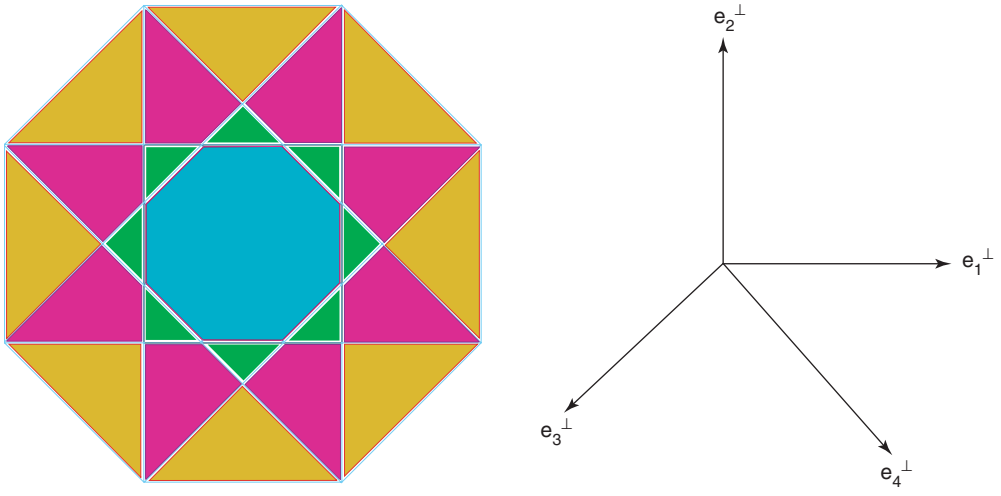

Figure 4 The atomic surface (canonical transversal) of the Ammann–Beenker tiling.

index, $a_{\omega,x;a}$, $a^\dagger_{\omega,x;a}$ such that $\left[a_{\omega,x;a}, a^\dagger_{\omega,y;b}\right] = \delta_{ab}\delta_{xy}\mathbf{1}$ whenever $(\omega, x) \in \Gamma$ and a,b are the polarization index (usually varying from 1 to d, if d is the dimension). Then the phonon Hamiltonian, restricted to a finite volume Λ, acts on the boson Fock space of $\ell^2(\mathscr{L}_\omega)$ and is given by

$$H^{(\mathrm{ph})}_{\omega;\Lambda} = \sum_{x,y \in \mathscr{L}_\omega \cap \Lambda} \hbar\kappa_{ab}(T^{-x}\omega, y-x) a^\dagger_{\omega,x;a} a_{\omega,y;b} + W_{\omega;\Lambda}$$

where W represents the anharmonic contributions. Here κ can be seen as the matrix elements of a covariant operator $K = (K_\omega)_{\omega\in\Omega}$. The eigenvalues of K are the square of the vibrational mode frequencies allowed to propagate through the solid.

The charge carrier DOS $\mathscr{N}(\Delta)$, in an energy interval Δ, is defined as the number of eigenstates of the charge carrier Hamiltonian describing the charge carrier motions per unit volume with energy within Δ. Similarly, the vibrational density of states (VDOS) in some frequency interval Δ is the number of phonon modes with frequency within Δ. The Shubin formula shows that they are given by

$$\mathscr{N}_{\mathbb{P}}(\Delta) = \mathscr{T}_{\mathbb{P}}(\chi_\Delta(H)) \text{ (charge carriers)},$$
$$\mathscr{N}_{\mathbb{P}}(\Delta) = \mathscr{T}_{\mathbb{P}}(\chi_\Delta(K^{1/2})) \text{ (phonons)},$$

where $\chi_\Delta(E) = 1$ if $E \in \Delta$ and 0 otherwise. A useful example of a formula expressed with this formalism is the Kubo formula for the electric conductivity in the relaxation time approximation (RTA) given by

$$\text{Kubo's formula}$$
$$\sigma_{ij} = \frac{e^2}{\hbar}\mathscr{T}_{\mathbb{P}}\left(\partial_f\left(\frac{1}{1+\mathrm{e}^{\beta(H-\mu)}}\right) \times \frac{1}{\hbar/\tau_{\mathrm{rel}} + \mathfrak{Q}_{\mathrm{H}} - \imath\hbar\tilde{\omega}}(\partial_i H)\right) \qquad [1]$$

where H is the one-particle Hamiltonian, $\mathfrak{Q}_{\mathrm{H}} = \imath[H, \cdot]$, $\beta = 1/k_{\mathrm{B}}T$ is the inverse temperature (k_{B} is Boltzmann's constant), $\tilde{\omega}$ is the current frequency, τ_{rel} is the inelastic collision time, μ is the chemical potential fixed by the charge carrier density n_{el} as

$$n_{\mathrm{el}} = \mathscr{T}_{\mathbb{P}}\left(\frac{1}{1+\mathrm{e}^{\beta(H-\mu)}}\right) = \int_{-\infty}^{+\infty} \mathrm{d}\mathscr{N}_{\mathbb{P}}(E)\frac{1}{1+\mathrm{e}^{\beta(E-\mu)}}$$

Exponents

The main difference between periodic and aperiodic solids can be seen in the electron energy spectrum or in the phonon vibrational spectrum (at least for short wavelength). The band spectrum can be a Cantor set, at least in 1D or near the groundstate if the dimension is higher. The electrons can be localized (Anderson localization) or can have an exotic long-distance behavior. The phonon spectrum is likely to have a large low energy optical band exhibiting quantum chaos. Various scaling exponents classify such a behavior. The spectral exponents are associated with the DOS, VDOS or with the local density of states (LDOS). The diffusion exponents are associated with the motion of a typical wave packet in space.

The DOS (or VDOS) regularity is characterized by its behavior as the size $|\Delta|$ of the energy or frequency interval goes to zero, namely $\mathscr{N}(\Delta) \sim |\Delta|^d$. Such a definition is ambiguous and, even in computer simulations, difficulties in interpreting results can be overwhelming. The symbol $\sim$ should then be defined as follows: if $f(\varepsilon)$ is a positive decreasing function of $0 < \varepsilon < 1$ (or $1 < \varepsilon < \infty$) then

$$\alpha^\bigstar = \lim_{\varepsilon\downarrow 0} \bigstar \frac{\ln f(\varepsilon)}{\ln \varepsilon}, \quad \text{denoted by } f \overset{\varepsilon\downarrow 0}{\sim} \varepsilon^{\alpha^\bigstar}$$

where $\bigstar$ stands for sup (or $+$) or inf (or $-$), and similarly if $\varepsilon \uparrow \infty$. Therefore, the DOS-exponent (and similarly for the VDOS) is defined by

$$\mathscr{N}_{\mathbb{P}}([E-\varepsilon, E+\varepsilon]) \overset{\varepsilon\downarrow 0}{\sim} \varepsilon^{d^\bigstar_{\mathrm{DOS}}(E)}$$

The LDOS, also called the spectral measure, is defined as follows: if $H = (H_\omega)_{\omega\in\Omega}$ is the one-particle Hamiltonian for the charge carriers, the LDOS $\mu_{\omega,\phi}$ relative to the quantum state $|\phi\rangle$ and its spectral exponent $d^\pm_{\omega,\phi}(E)$ are defined by

$$\mu_{\omega,\phi}([E-\delta, E+\delta]) := \int_{E-\delta}^{E+\delta} \mathrm{d}\mu_{\omega,\phi} = \frac{1}{\pi}\Im m \int_{E-\delta}^{E+\delta} \mathrm{d}E' \times \langle\phi|(E' - \imath 0^+ - H_\omega)^{-1}|\phi\rangle \overset{\delta\downarrow 0}{\sim} \delta^{d^\bigstar_{\omega,\phi}(E)}$$

Whenever Δ is an interval of energy and if $\bigstar = \sup$ (resp. inf), $d^\bigstar_{\omega,\phi}(\Delta)$ will be infimum (resp. supremum) over $\Delta' \subset \Delta$ of the supremum (resp. infimum) over $E \notin \Delta'$ of $d^\bigstar_{\omega,\phi}(E)$'s where $\int_{\Delta'} \mathrm{d}\mu_{\omega,\phi} = 0$. Then $d^{\bigstar,\pm}_{\omega}(\Delta)$ will be the supremum (resp. infimum) over the state $|\phi\rangle$ of the $d^\bigstar_{\omega,\phi}(\Delta)$'s. It turns out that $d^{\bigstar,\pm}_{\omega}(\Delta)$ is independent of ω with probability 1 and the common value is called $d^{\bigstar,\pm}_{\mathrm{LDOS}}(\Delta)$. In all cases

$$d^{-,\pm}_{\mathrm{LDOS}}(\Delta) \leqslant d^{-}_{\mathrm{DOS}}(\Delta)$$

The LDOS is absolutely continuous (ac) on an interval Δ, whenever for almost all $E \in \Delta$ there is $0 < C(E) < \infty$ such that $\mu_{\omega,\phi}([E-\delta, E+\delta]) \leqslant C(E)\delta$.

Then, the Radon–Nikodym theorem implies the existence of an integrable function F such that $\mu_{\omega,\phi}(\mathrm{d}E) = F(E)\mathrm{d}E$. (Here, $\mathrm{d}E$ is called the Lebesgue measure.) In such a case, $d^{\star}_{\omega,\phi}(E) = 1$ on Δ so that $d^{\star}_{\omega,\phi}(\Delta) = 1$. The LDOS is pure point (pp) on Δ if it can be written as a sum of Dirac measures $\mu_{\omega,\phi}(\mathrm{d}E) = \sum_i \delta(E - E_i)\mathrm{d}E$. In such a case, the E_i are eigenvalues and $d^{\star}_{\omega,\phi}(E_i) = 0$ on Δ, implying $d^{\star}_{\omega,\phi}(\Delta) = 0$. The LDOS is singular continuous (sc) if $\mu_{\omega,\phi}([E-\delta, E+\delta])\downarrow 0$ as $\delta\downarrow 0$ for all $E\in\Delta$, and if there is almost no $E\in\Delta$ for which $\mu_{\omega,\phi}([E-\delta, E+\delta]) \leqslant C(E)\delta$ with $0 < C(E) < \infty$. In particular, if $0 < d^{\star}_{\omega,\phi}(\Delta) < 1$, then the LDOS is sc on Δ.

A charge carrier moving in the solid is a quantum wave interfering with itself after colliding with atomic nuclei. The resulting effect of too many reflections is a slowing down of its motion so that the distance it goes after time t behaves like

$$r(t) \overset{t\uparrow+\infty}{\sim} t^{\overline{\beta}}$$

where $\overline{\beta}$ is called a diffusion exponent. As in the case of spectral exponents, there are many ways of defining $\overline{\beta}$. If $\boldsymbol{R}$ is the position operator for the charge carriers, then $\boldsymbol{R}(t) = \mathrm{e}^{\imath tH/\hbar}\boldsymbol{R}\mathrm{e}^{-\imath tH/\hbar}$ denotes the position after time t, and $|\boldsymbol{R}(t) - \boldsymbol{R}|$ is the distance that the particle goes during this time. To measure it, it is convenient to select particles having energy in some interval Δ and prepared in the quantum state located at the origin of space, denoted by $|0\rangle$. Since the system is not translation invariant, it is better to average over the choice of the origin (using $\mathbb{P}$). To avoid meaningless time oscillations, it is also convenient to average over time too, leading to the following formula

$$\begin{aligned}(L_{\Delta,q}(t))^q &= \int_{-t}^{+t} \frac{\mathrm{d}s}{2t} \int_X \mathrm{d}\mathbb{P}_{tr}(\omega) \\ &\quad \times \langle 0|\Pi_{\omega,\Delta}|\boldsymbol{R}_\omega(s) - \boldsymbol{R}|^q \Pi_{\omega,\Delta}|0\rangle \sim^{t\uparrow\infty} t^{q\overline{\beta}^{\star}_q(\Delta)}\end{aligned}$$

where $\Pi_{\omega,\Delta}$ projects on eigenvalues of H_ω located in Δ. The extra parameter q gives information about the distribution of distances in the initial state.

The diffusion exponents permit one to classify the motion of the charge carriers (or of the phonon modes) according to their values. In a periodic crystal, it is known that $\overline{\beta}^{\star}_q(\Delta) = 1$ for all q's because the motion is ballistic. On the other hand, in an Anderson insulator, where all states are localized, $\overline{\beta}^{\star}_q(\Delta) = 0$. In general, $0 \leqslant \overline{\beta}^{\star}_q(\Delta) \leqslant 1$ and $\overline{\beta}^{\star}_q(\Delta)$ increases with q. The value $q = 2$ is special and is amenable to experimental measurements. There are situations for which $\overline{\beta}_2 = 1/2$, in particular, in weakly disordered systems or if quantum chaos occurs: this is quantum diffusion. It is important to notice that such a diffusion is not due to some loss of information, but the net result of quantum interferences in a complex environment. The motion is called sub-ballistic if $1/2 < \overline{\beta}_2 < 1$ and subdiffusive if $0 < \overline{\beta}_2 < 1/2$.

These exponents are related by the Guarneri inequality

Guarneri's bound

$$\beta^{\star}_q(\Delta) d \geqslant d^{\star}_{\mathrm{LDOS}}(\Delta) \qquad [2]$$

Thus, in dimension $d = 1$, the ac spectrum implies (quasi) ballistic motion. In higher dimension, for any $\varepsilon > 0$, it is possible to find models of Hamiltonians with an ac-spectrum and diffusion exponent smaller than $1/d + \varepsilon$. In particular, the ac-spectrum is compatible with the quantum diffusion for $d \geqslant 2$.

Conductivity

One of the most striking consequences of the previous scaling analysis is the behavior of the conductivity at low temperature. The classical Drude formula asserts that the conductivity of a metal is given by

$$\sigma = \frac{e^2 n_{\mathrm{el}} \tau_{\mathrm{rel}}}{m^*} \overset{\tau_{\mathrm{rel}}\uparrow\infty}{\sim} \tau_{\mathrm{rel}}$$

where m^* is the effective mass of the charge carriers, and τ_{rel} the typical relaxation time for collisions. In view of the RTA Kubo formula [1], the scaling analysis leads to the anomalous Drude formula

$$\sigma \overset{\tau_{\mathrm{rel}}\uparrow\infty}{\sim} \tau_{\mathrm{rel}}^{2\beta_{\mathrm{F}}-1}$$

where $\beta_{\mathrm{F}} = \overline{\beta}^{\star}_2(E_{\mathrm{F}})$ is the diffusion exponent for $q = 2$ at the Fermi level E_{F}. The inelastic relaxation time increases as the temperature goes to zero so that (1) if the motion is ballistic or sub-ballistic, then the solid behaves like a conductor, (2) if the motion is diffusive, then there is a residual conductivity at zero temperature, (3) if the motion is subdiffusive, the solid behaves like an insulator. In the former case (metallic), the addition laws for conductivity show that if several relaxation mechanisms coexist, the one with the shortest relaxation time will dominate (Mathiessen rules). On the contrary, in the latter case (insulating) the one with the longer relaxation time will dominate. In most situations, the dominant dissipative mechanisms come from the phonon–electron collisions in two possible forms: (1) direct collisions leading to the Bloch law $\tau_{\mathrm{rel}} \sim T^{-5}$ as $T\downarrow 0$ (2) electron–electron interactions through the lattice (BCS term) leading to the Landau

Fermi liquid theory with $\tau_{\mathrm{rel}} \sim T^{-2}$. While in the metallic case the Fermi liquid theory applies, the Bloch law dominates in the insulating case leading to $\sigma \sim T^{5(1-2\beta_{\mathrm{F}})}$. If, as computer simulations suggest for $3D$-quasicrystals, $0.35 < \beta\ \mathrm{F} < 0.40$, it provides a mechanism for the results shown in **Figure 1** (AlPdRe-compound).

Another striking numerical observation is that at a small energy scale and for a finite volume, the level spacing distribution of eigenvalues for quasicrystalline lattices follows the Wigner–Dyson law: some quantum chaos occurs, namely the effective Hamiltonian behaves like a random matrix. Such a feature is likely to be universal in aperiodic media. If so, analysis provided for weakly disordered systems should apply, subsequently leading to a quantum diffusive regime at small energy or long timescales and, consequently, producing a residual conductivity at low temperature as shown for the AlPdMn-compound in **Figure 1**. But it might be an artifact of the finite volume. However, following an argument by Thouless, used in disordered systems, it follows that: (1) the time it takes for the particle with diffusion exponent $\overline{\beta}$ to reach the boundary of a sample of size L is $t_{\mathrm{Th}} \sim L^{1/\overline{\beta}}$ (called the Thouless time), (2) the time it takes for the particle to realize that the spectrum is actually discrete due to the finite volume is given by the Heisenberg principle $t_{\mathrm{H}} \Delta E \approx \hbar$ where $\Delta E \sim L^{-d}$ is the average level spacing, so that $t_{\mathrm{H}} \sim L^{d}$ (called the Heisenberg time). If $\overline{\beta} > 1/d$, then the particle reaches the boundary too fast and therefore it will dominantly see the effect of the finite volume, namely of the Wigner–Dyson level spacing distribution. If, on the other hand $\overline{\beta} < 1/d$, the particle never has the time to reach the boundary so that it behaves as if only the subdiffusion was allowed. Hence

$$\beta_{\mathrm{F}} < \frac{1}{d} \Rightarrow \sigma \overset{T \downarrow 0}{\sim} T^{\gamma}, \quad \beta_{\mathrm{F}} > \frac{1}{d} \Rightarrow \sigma \overset{T \downarrow 0}{\sim} \sigma_0 > 0$$

The Guarneri inequality [2] predicts an sc-spectrum near the Fermi level in the former case, while the latter is compatible with the ac-spectrum if $d > 2$. It is reasonable to expect that a slight change in the hopping parameters of the effective tight-binding Hamiltonian between atomic sites due to chemical constraints (e.g., by changing Mn into Re) might produce such a drastic change in behavior in **Figure 1**.

Devices for Telecommunications

M Sugawara and N Hara, University of Tokyo, Meguro-ku, Japan

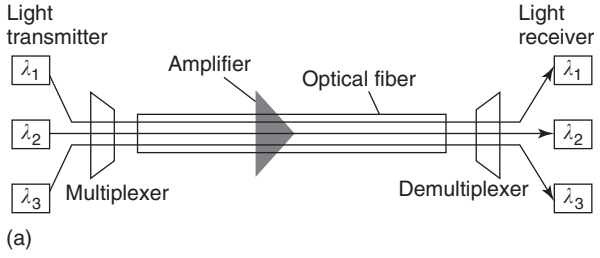
Introduction

The recent global spread of telecommunication networks is due to the advent of optical-fiber and wireless communication technologies. These technologies continue to develop to meet the explosive demand for data traffic on the Internet. In a ubiquitous society, where anyone can access the Internet anywhere at any time, diverse modes of services via various types of devices for connecting to the network are right across the corner.

The optical-fiber communication system basically consists of optical-fiber cables, light transmitters, amplifiers, and light receivers as illustrated in **Figure 1a**. Light transmitters convert electrical signals to optical signals with different wavelengths for different services. Optical signals propagate through the optical fiber to receivers at destinations, being amplified in the case of long fiber span over several tens of kilometers. The receivers reconvert the optical signals to electrical signals for data transmission to be accomplished. The multiplexing technology that uses many wavelengths in the same fiber increases the total transmission bandwidth, and is called wavelength division multiplexing (WDM). In 1996, the total bandwidth of $1.1\,\mathrm{Tb\,s^{-1}}$ was accomplished for a 150-km transmission by using 55 wavelengths with a spacing of 0.6 nm at $20\,\mathrm{Gb\,s^{-1}}$ per wavelength.

Wireless communication systems provide a variety of services such as cellular phones, wireless local area networks (WLAN), electric toll collection system (ETC), satellite communication, fixed wireless access (FWA), and automotive radar as shown in **Figure 1b**. Their progress is due to the development of high-performance transmitters as well as low-noise receivers in the frequency range of 1–100 GHz. A variety of high-speed transistors with output power of 0.01–500 W based on compound and silicon semiconductors play a significant role in this development.

This article explains structures and operation principles of major optical and electrical devices for telecommunications.



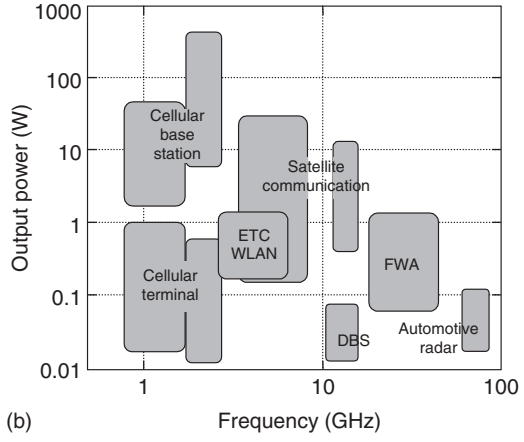


Figure 1 (a) WDM optical-fiber communication system. (b) Requirements for transistors in wireless communication system.

Optical Fiber

Optical fibers are transporting media of high-speed optical signals. Fibers have diverse properties superior to copper cables such as immunity to electromagnetic fields, anti-corrosion, low transmission loss of less than $0.2\,\mathrm{dB\,km^{-1}}$, and extremely broad bandwidth of 40 THz per single fiber. **Figure 2** shows (1) the structure of an optical fiber and (2) the internal light propagation. The fiber consists of the core, the clad surrounding the core, and resinous coating. The fiber cable used in long-haul communication consists of a bundle of optical fibers. A fiber is made by vertically drawing a cylindrical preform made of ultrapure silica in which dopants such as

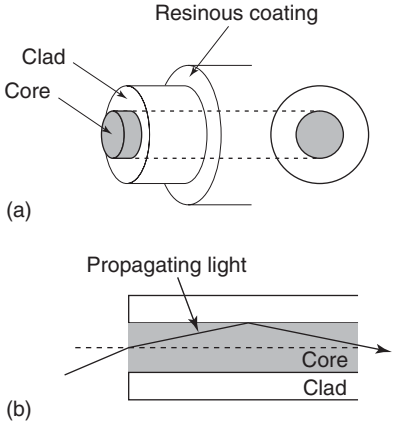

Figure 2 (a) Structure of optical fiber. (b) Internal light propagation.

GeO_2 and B_2O_3 are added in a controlled manner to adjust the refractive index profile of the fiber. The refractive index is increased by GeO_2 and decreased by B_2O_3. The diameter of the clad is 125 μm. The refractive index of the core is slightly larger than that of the clad, so that light entering the core propagates through the optical fiber by repeating the total reflection at the core–clad boundary.

There are two types of fibers with different core diameters for different applications. Fibers with a core diameter of $\sim$50 μm are known as multimode fibers, whereas fibers with a core diameter of $\sim$10 μm are known as single-mode fibers. Modes mean different electromagnetic-field profiles in the cross section of fibers, which can be calculated based on the Maxwell equations under appropriate boundary conditions of the electromagnetic fields. Multimode fibers have an advantage of easy installation owing to their large core diameter, and are used for LANs with fiber spans of less than $\sim$2 km. Their fiber span is limited by the distortion of optical signals due to intermode dispersion, that is, the difference in the group velocity of light pulses between modes. Single-mode fibers are suitable for long-span and high-speed transmission.

Loss, wavelength dispersion, and optical nonlinearity are primary factors that limit the optical-signal transmission performance of fibers. Single-mode fibers have two low-attenuation windows; one $\sim$1.3 μm with a loss of 0.3–0.4 dB km^{-1}, and the other $\sim$1.55 μm with a loss of 0.15–0.2 dB km^{-1}. The wavelength dependence of the dielectric constant of fiber materials causes wavelength dispersion of the light propagation constant, which is called "material dispersion." Another wavelength dispersion is "structural dispersion," which depends on the cross-sectional refractive-index profile of the fiber. The wavelength dispersion results in the broadening of short optical pulses and their interference with former and subsequent pulses to limit the fiber span. Conventional fibers have zero-dispersion point $\sim$1.3 μm. The optical nonlinear effects such as four-wave mixing, cross-phase modulation, and self-phase modulation cause the degradation of the signal-to-noise ratio, wavelength chirping, pulse broadening, and cross talk between different wavelength channels.

Semiconductor Laser

Semiconductor lasers work as standard light transmitters in the optical-fiber communication systems, owing to their small size of 0.2–1 mm length as well as their diverse excellent performances such as the capability of direct modulation up to 10–40 GHz, low-power consumption, single wavelength light, and high output power up to 1 W.

Figure 3a shows the structure of a semiconductor laser. The active region works as a light source via the electron–hole recombination due to spontaneous emission, and as the optical gain medium to amplify light due to stimulated emission. The active region is sandwiched by wide-gap *p*-type and *n*-type cladding layers. This semiconductor layer structure is called a double heterostructure, which effectively confines electrons and holes in the active region due to the well-like energy potential profile as well as light due to the refractive index profile with the active-region index larger than the clad index. The light waveguide is formed in the direction parallel to the layer. The facets on both sides work as optical mirrors to form a cavity for the light propagating in the waveguide. The light partly transmitting through the mirrors is the output. Quantum-well structures consisting of alternating ultrathin semiconductor lasers are widely used as the active region. Semiconductor nanocrystals called quantum dots are being developed for next-generation lasers.

When semiconductor lasers are operated, the forward bias is applied to the *pn* junction to inject electrons and holes into the conduction and valence bands of the active region, respectively, as seen in the band structure of **Figure 3b**. Then, the population inversion is realized where the number of electrons in the conduction band is larger than that of the valence band. Part of the spontaneous emission light emitted by the recombination between electrons and holes goes into the cavity mode, and goes back and forth in the cavity being amplified. When the optical gain balances the total loss, lasing oscillation starts.

Figure 3c shows the output light power versus injected current. Lasing starts at a threshold current to balance the gain and loss of light. The output power rises above the threshold current, where the conversion efficiency from the electrical to optical power reaches up to several tens percent. By directly modulating the injection current as shown in **Figure 3c**, the laser can output digital bit patterns with a variety of information. For long fiber span transmission, distributed feedback (DFB) lasers are used to enable stabilized single-light wavelength, where periodical refractive index distribution is made inside the cavity by an internal grating. Light-signal modulation is also possible by modulating the continuous output of a laser by an external light modulator.

Light Amplifiers

For very long fiber spans of tens of kilometers away, the optical signal may be so attenuated and distorted

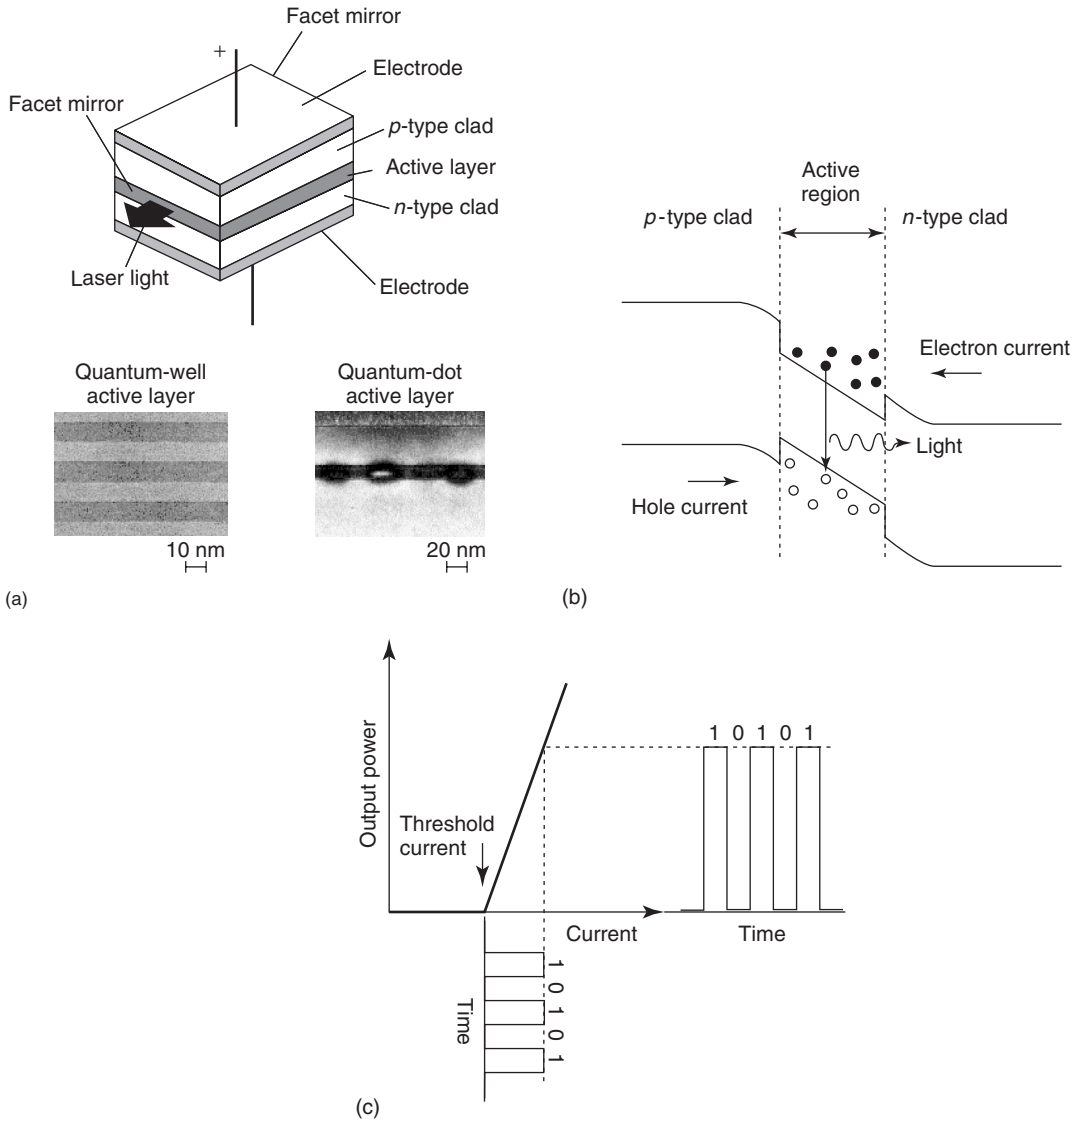

Figure 3 (a) Structure of semiconductor laser. (b) Band diagram under forward bias. (c) Output light power vs. injected current.

that it should be regenerated periodically to reach destinations. The regeneration includes reamplification to recover the signal power, reshaping to reduce noise and distortion, and retiming to reduce the timing jitter, and is called 3R regeneration from their initials. In optical communication networks, there are two types of regenerators: OEO regenerators and optical amplifiers. OEO regenerators receive a modulated optical signal by the photodetector, transform it to an electric signal of the same bit-rate with its timing recovered, amplify it, and then convert the electric signal back to the optical signal of the same modulation bit-rate by the laser. Optical amplifiers recover the optical signal power by the same mechanism as used in the laser; as the light goes through the gain media, its intensity is amplified due to the stimulated emission via the electron–hole recombination. Since only the signal power is recovered, this is a 1R regeneration. Optical amplifiers amplify simultaneously multiple optical signals, each of which is on a different wavelength and within an optical gain bandwidth of the amplifier. This is a significant advantage over the OEO regenerator, which led to the development of the WDM system of **Figure 1a**.

There are two types of optical amplifiers: fiber-type amplifiers (**Figure 4a**) and semiconductor optical amplifiers (SOAs) (**Figure 4b**). The most widely used fiber-type amplifier is the erbium-doped fiber amplifier (EDFA), which mainly consists of the erbium-doped fiber (EDF), pump laser, and coupler as shown in **Figure 4a**. The pump-laser light is coupled to the EDF to excite erbium atoms to generate gain. The optical signals pass through the EDF being amplified. The advantages of the EDFA are high gain, negligible

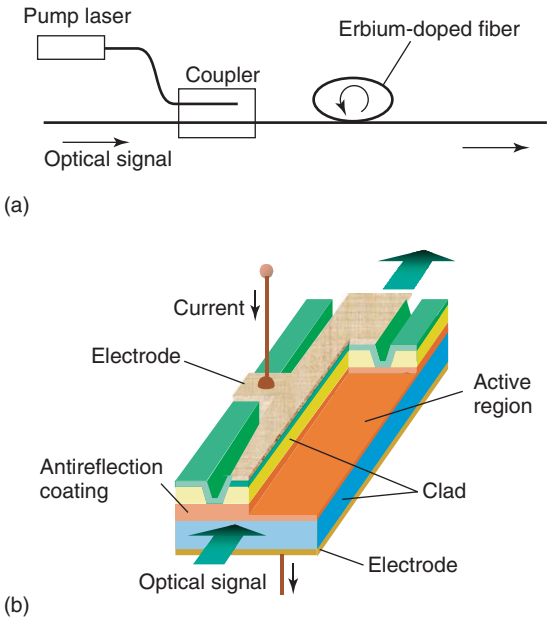

Figure 4 (a) Fiber-type amplifier. (b) Semiconductor optical amplifier.

pattern effect, low noise figure, low cross talk between different channels to enable multichannel amplification. The SOA has a structure similar to the semiconductor laser as shown in **Figure 4b**. By applying forward bias to the *pn* junction, carriers are injected to the active region, causing population inversion to generate gain. The antireflection coating is done on both sides of the facet. The optical signal enters the SOA from one side, propagates the waveguide being amplified, and comes from the other side. The advantages of SOAs are their compactness, low cost, capability of integration with other semiconductor devices, wide gain bandwidth of 50–100 nm, and their easy tunability. Their disadvantages are low saturation power and cross talk between different wavelength channels due to optical nonlinearity. SOAs with quantum dots in their active region are being studied intensively in order to increase the saturation power and realize broader gain bandwidth, so as to enable multi-wavelength amplification with negligible cross talk.

Photodetectors

Photodetectors with sufficiently high-speed response over GHz are positive intrinsic negative (PIN) photodiodes and avalanche photodiodes (APDs).

The PIN photodiode in **Figure 5** consists of an intrinsic region that is sandwiched by *p*-type and *n*-type wide-gap semiconductor layers, and is operated under the reversed bias. When the light signal comes into the device, it is absorbed in the intrinsic

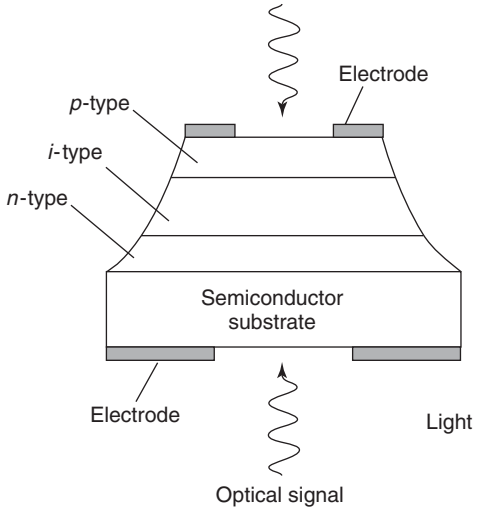

Figure 5 Structure of PIN photodiode.

region to generate electrons in the conduction band and holes in the valence band. The electrons flow toward the *p*-type layer, and the holes toward the *n*-type layer to produce a current pulse with the same duration and shape as the optical signal. The RC time constant determines its frequency response.

The APD is a detector designed to have a strong electric field of $5–6 \times 10^5\,\mathrm{V\,cm^{-1}}$ in the junction region under the reversed bias to enhance the photocurrent response by the impact ionization. When the light signal creates an electron–hole pair by the optical absorption, the electrons and the holes flow in the opposite direction as in the PIN photodiode. Because of the strong electric fields in the junction, the electron gains enough energy to cause secondary electron–hole pairs, which is called impact ionization, resulting in a signal multiplication process.

High-Speed Transistors

The transmitters and receivers in the optical-fiber communication systems include several kinds of transistors. High-speed/high-frequency operation of transistors is indispensable in increasing communication capacity. Transistors which operate at high frequency are also required in wireless communication systems, since the frequency range used in the systems becomes higher and higher. Compound semiconductors, such as GaAs, InP, and related alloy semiconductors, are suitable for high-speed applications due to the high electron velocity. In addition, utilization of heterostructures makes it possible to design the band lineup, and improves high-speed performances of transistors. Presently, Si-based transistors with heterostructures are also candidates for high-speed devices. They have the advantage of being

Figure 6 Schematic diagrams of high-speed transistors.

easily integrated with matured Si process technologies.

There are two types of transistors with different principles of operation: field-effect transistors (FETs) and bipolar junction transistors (BJTs). In FETs, the applied gate bias voltage controls the current flow between the drain and the source. **Figure 6a** shows the schematic cross-sectional view of a metal–semiconductor FET (MESFET), one of the representative high-speed transistors. Unlike Si metal-oxide–semiconductor FETs (MOSFETs), a Schottky barrier gate is employed, because compound semiconductors do not have a stable oxide. The gate bias voltage controls the current flow by modulating the depletion region. MESFETs benefit from the high electron velocity of compound semiconductors. It is possible to further increase the electron velocity by using heterostructures. The schematic cross-sectional view and the conduction band diagram of a high-electron-mobility transistor (HEMT) are shown in **Figures 6b** and **6c**. Electrons from donors in a wider bandgap layer, an electron supply layer, transfer to a narrower bandgap layer, a channel layer. Electrons, therefore, are separate from the ionized donors, and ionized impurity scattering is significantly reduced, which results in high electron mobility. The gate voltage controls the current flow by changing the electron density.

BJTs consist of two *pn*-junctions combined with a thin semiconductor layer, the base layer. Electrons are injected from the emitter into the base; then they diffuse across the base layer, and are swept by the collector. The amount of the injected electrons, which can be changed by the base voltage, controls the current flow. **Figures 6d** and **6e** show the schematic cross-sectional view and the conduction band diagram of a heterojunction bipolar transistor (HBT), which is also a popular high-speed transistor. Employment of the wider gap emitter is a key to improving high-speed characteristics. This enables one to increase the doping density of the base to reduce the base resistance without seriously increasing the amount of holes injected from the base to the emitter.

Diamagnetism

P F de Châtel, New Mexico State University, Las Cruces, NM, USA

Diamagnetic materials do not order magnetically and have a negative susceptibility, which means the magnetization is pointing opposite to the magnetic field. Possibly, there is also a paramagnetic susceptibility. The material is classified as diamagnetic if the sum of the two contributions is negative. Nevertheless, the diamagnetic susceptibility can be determined in both kinds of materials.

Diamagnetism is a very small effect, but all the more puzzling. It entails a response of all known materials to an external magnetic field, which manifests itself in a magnetization opposing that field. It appears thus that the magnetic field generates a magnetic dipole, whose orientation is most unfavorable, being at a maximum of the potential energy as a function of the angle between the magnetic field and the magnetization,

$$E = -\boldsymbol{B}\cdot\boldsymbol{M} = BM > 0$$

There is no simple, intuitive explanation for this paradox. This is not surprising though, considering that our intuition is mostly based on classical physics. The celebrated Bohr–van Leeuwen theorem states that the classical free energy of a system of charged particles moving in a magnetic field is independent of the field. Since the magnetization is proportional to the derivative of the free energy with respect to the field,

$$\boldsymbol{M} = -\frac{1}{V}\frac{\partial F}{\partial \boldsymbol{B}} \qquad [1]$$

this theorem implies that classical physics, in this case classical mechanics combined with classical statistics, cannot account for any field-induced magnetization, be it paramagnetic (aligned along the field) or diamagnetic (opposing). In the case of diamagnetic metals, whose charge carriers behave like free electrons, this conclusion contradicts what one would expect from electrodynamics. Charged classical free particles exposed to a magnetic field move in circles. Lenz's law of induction requires that the current loops represented by the orbiting electrons produce a magnetization opposed to the field which induces the currents; this should result in a diamagnetic response. It is no wonder that Niels Bohr was fascinated by this paradox. His main interest was the stability of atomic orbitals, which also contradicts classical expectation. He has formulated the rule of angular-momentum quantization, which, imposed on the classical treatment, accounted for the observed stable orbitals. As it will be shown below, the same rule, applied in the presence of a magnetic field, gives the correct answer for the diamagnetism of free atoms. The diamagnetism of free electrons cannot be understood in this semiclassical way, here a fully quantum mechanical treatment is needed.

The formal proof of the Bohr–van Leeuwen theorem is rather simple, but conceals the clue to its counterintuitive implication. Indeed, if one writes the free energy, $F = -k_B T \ln Z$, of a system of N identical particles (taking electrons of mass m_e and charge $-e$), the partition function has the form

$$Z = \prod_{i=1}^{N} \int \cdots \int \mathrm{d}\boldsymbol{r}_i\, \mathrm{d}\boldsymbol{p}_i \times \exp(-H(\{\boldsymbol{r}_i\},\{\boldsymbol{p}_i\})/k_B T) \qquad [2]$$

where H is the Hamiltonian, a function of all position vectors $\boldsymbol{r}_i$ and canonical momenta $\boldsymbol{p}_i$. The latter are written as

$$\boldsymbol{p}_i = m_e \boldsymbol{v}_i - e\boldsymbol{A}(\boldsymbol{r}_i)$$

where $\boldsymbol{A}$ is the vector potential describing the magnetic field, which enters the Hamiltonian via the kinetic energy,

$$E_{\mathrm{kin}} = \frac{1}{2} m_e v_i^2 = \frac{1}{2m_e}[\boldsymbol{p}_i + e\boldsymbol{A}(\boldsymbol{r}_i)]^2$$

To prove the independence of Z from $\boldsymbol{A}$, one changes the integration variables $\boldsymbol{p}_i$ to $\boldsymbol{p}'_i = \boldsymbol{p}_i + \boldsymbol{A}(\boldsymbol{r}_i)$ and realizes that this will not change the result of integration, because the shift of the limits of integration, $\pm\infty$, has no effect. The vector potential thus being eliminated from eqn [2], the partition function must be independent of the magnetic field.

To understand the implications of this freedom to shift parameters, it is instructive to carry out the differentiation in eqn [1] for the simple case of a system of N_a identical atoms. If the electron–electron interaction is treated in the mean-field approximation, the N electrons localized on the same atom are described by the Hamiltonian

$$H = \sum_{i=1}^{N} H^{(1)}(\boldsymbol{r}_i, \boldsymbol{p}_i)$$

with

$$H^{(1)}(\boldsymbol{r}, \boldsymbol{p}) = V(r) + [\boldsymbol{p} + e\boldsymbol{A}(\boldsymbol{r})]^2/2m_e \qquad [3]$$

where $V(r)$ is the potential consisting of the potential of the nucleus and of the "other" $N-1$ electrons, the latter contribution being spherically averaged (central-field approximation). The partition function (eqn [2]) becomes then the product of N identical integrals,

$$\begin{aligned} Z &= \left\{ \int\int \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{p} \exp(-H^{(1)}(\boldsymbol{r}, \boldsymbol{p})/k_B T) \right\}^N \\ &= \{Z^{(1)}\}^N \end{aligned}$$

and, consequently, the free energy is a sum of N identical terms, $F = -k_B T N \ln Z^{(1)}$. Choosing the gauge

$$\boldsymbol{A} = -\frac{1}{2}(\boldsymbol{r} \times \boldsymbol{B}) \qquad [4]$$

one obtains

$$\begin{aligned} \boldsymbol{M} &= -\frac{N_a}{V}\frac{\partial F}{\partial \boldsymbol{B}} \\ &= -\frac{N_a}{V}\frac{eN}{2m_e}\int\int \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{p}\, \boldsymbol{r} \times \left[\boldsymbol{p} - \frac{e}{2}(\boldsymbol{r} \times \boldsymbol{B})\right] \\ &\quad \times \frac{\exp(-H^{(1)}(\boldsymbol{r}, \boldsymbol{p})/k_B T)}{Z^{(1)}} \end{aligned} \qquad [5]$$

where N_a is the number of atoms. The result is seen to be proportional to the thermal average of the kinetic angular momentum, $\boldsymbol{r} \times m_e \boldsymbol{v}$. This is not unexpected, because currents, the sources of magnetization, are related to the velocity, not the canonical momentum $\boldsymbol{p}$, of the charge carriers. The same holds for the kinetic energy in the Hamiltonian [3], which appears in the statistical weight factor $\exp(-H^{(1)}/k_B T)$.

Consider now two points in the phase space of a single electron, which are given by the same position vector $\boldsymbol{r}$ and opposite velocities,

$$\begin{aligned} &\boldsymbol{r}_1 = \boldsymbol{r}_2 = \boldsymbol{r} \\ &\boldsymbol{p}_1 - \frac{e}{2}(\boldsymbol{r}_1 \times \boldsymbol{B}(\boldsymbol{r}_1)) = -\left(\boldsymbol{p}_2 - \frac{e}{2}(\boldsymbol{r}_2 \times \boldsymbol{B}(\boldsymbol{r}_2))\right) \end{aligned}$$

The statistical weight factors associated with these two points are identical, whereas the kinetic angular momenta have opposite signs and the same magnitude. Therefore, the sum of their contributions to the integral will vanish. The cancelation would have been more obvious, if $\boldsymbol{p}$ was shifted to $\boldsymbol{p}' = \boldsymbol{p} + (e/2)(\boldsymbol{r} \times \boldsymbol{B}(\boldsymbol{r}))$. In that case, the integrand would have become an odd function of $\boldsymbol{p}'$ resulting obviously in a vanishing $\boldsymbol{M}$. Again, the freedom to shift the canonical momentum at a given value of $\boldsymbol{r}$, which amounts to shifting the canonical angular momentum $\boldsymbol{L} = (\boldsymbol{r} \times \boldsymbol{p})$, turns out to be important in the derivation. As classical mechanics puts no constraints on $\boldsymbol{L}$ and, according to the ergodic theorem underlying classical statistics, a system will visit all possible states of different values of $\boldsymbol{L}$, it is understandable that $\boldsymbol{M}$ has to vanish on average.

These considerations suggest that the classical realm need not be left altogether. It may suffice to impose some constrains on the angular momentum, in the spirit of the Bohr model of atoms, to get sensible results for the magnetization. As a uniform magnetic field along the z-axis, $\boldsymbol{B} = (0, 0, B)$, leaves all rotations around the z-axis as symmetry operations, it is postulated that L_z be limited to the values $m\hbar$, $m = \pm 1, \pm 2, \pm 3, \ldots$. To impose this condition, each integral over the entire six-dimensional $(\boldsymbol{r}, \boldsymbol{p})$ phase space must be replaced by a sum of integrals, each over a subspace P_m containing only $(\boldsymbol{r}, \boldsymbol{p})$ points, for which $(\boldsymbol{r} \times \boldsymbol{p})_z = m\hbar$. In particular,

$$\begin{aligned} Z^{(1)} &= \sum_m \int\int_{P_m} \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{p} \exp(-H^{(1)}(\boldsymbol{r}, \boldsymbol{p})/k_B T) \\ &= \sum_m Z_m^{(1)} \end{aligned}$$

By the definition of the subspace P_m

$$\begin{aligned} &\int\int_{P_m} \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{p} (\boldsymbol{r} \times \boldsymbol{p})_z \exp(-H^{(1)}(\boldsymbol{r}, \boldsymbol{p})/k_B T) \\ &\quad = m\hbar Z_m^{(1)} \end{aligned}$$

so that eqn [5] can be written as

$$M_z = -\frac{N_a}{V}\sum_m \left\{ \frac{eN}{2m_e}\frac{Z_m^{(1)}}{Z^{(1)}}\hbar m + \frac{e^2 N}{4m_e} \langle \rho^2 \rangle_m^{\mathrm{th}} B \right\}$$

where $NZ_m^{(1)}/Z^{(1)} = p_m$ is the thermal occupation probability of the $L_z = m\hbar$ orbit. Introducing the

Bohr magneton, $\mu_B = e\hbar/2m_e$, the first term takes the form $p_m m\mu_B$, which can be recognized as the paramagnetic contribution to the magnetization. In the second term, which makes evidently a negative, diamagnetic contribution to the magnetization, $\langle \rho^2 \rangle_m^{th} = \int\int_{P_m} d\boldsymbol{r}\, d\boldsymbol{p}\, \rho^2 \exp(-H^{(1)}(\boldsymbol{r},\boldsymbol{p})/k_B T)/Z^{(1)}$ is the thermal average of ρ^2 for the same orbit m. Here, it is assumed that the $\boldsymbol{r}$ vector is in the $z = 0$ plane and $|\boldsymbol{r}| = \rho$, constant. It then follows that

$$M_{dia} = -\frac{N_a}{V}\frac{e^2}{4m_e}\sum_m \langle \rho^2 \rangle_m^{th} B$$

In practice, no thermal excitation out of the ground state will occur and $N\langle \rho^2 \rangle_m^{th}$ can be replaced by the average of the squared radii of occupied orbits. Clearly, at this stage the simple Bohr model fails. It would be a tortuous extension to introduce the principal quantum number n on the basis of the Bohr–Sommerfeld model and the angular momentum quantum number ℓ on an *ad hoc* basis. Even so, only for $T = 0$ would the introduction of the Pauli principle suffice to give the correct result. For $T > 0$, Fermi–Dirac statistics should be applied, which is a further step away from classical physics. In a proper quantum mechanical treatment, $(2/3)\langle r^2 \rangle$ enters, instead of $\langle \rho^2 \rangle^{th}$ where $\langle \ldots \rangle$ stands for the expectation value and the factor 2/3 accounts for the difference between the expectation values of $r^2 = x^2 + y^2 + z^2$ and $\rho^2 = x^2 + y^2$. The diamagnetic susceptibility is thus

$$\chi_{dia}^{(Langevin)} = \frac{M_{dia}}{H} = -\frac{N_a}{V}\frac{\mu_0 e^2}{6m_e}\sum_j \langle r_j^2 \rangle \qquad [6]$$

where the summation is over the occupied orbits j on each atom. Langevin's result for atomic diamagnetism was brought to this form by Pauli.

It is remarkable that Planck's constant does not appear in the expression for the diamagnetic susceptibility, whereas the importance of angular-momentum quantization in its derivation is obvious. Also, eqn [6] is an appealing result, as it enables a seemingly classical interpretation in terms of currents i_j, induced on each orbit j. Such currents will generate magnetic moments $m_j = i_j\alpha_j \propto \langle r_j^2 \rangle$, where α_j is the area enclosed by the orbit j. The sign of the moments (opposite to $\boldsymbol{B}$) can be understood in terms of Lenz's law and their magnitudes can be derived from Faraday's law of induction. This derivation, however, invokes well-defined orbits, which are modeled by tiny current loops. Bohr has grafted such orbits onto the classical treatment of particles moving in a potential proportional to r^{-1} and postulated the quantization of angular momentum. Remarkably, this supplement to the classical description was sufficient to understand quantized energy levels and line spectra, as well as diamagnetism.

The validity of eqn [6] turns out to extend beyond the case of atomic orbits. Most notably, it is applicable to ring-shaped molecules, whose structure offers extended orbits. The diamagnetic susceptibility of substances containing such molecules is known to be anisotropic, being larger in magnitude if the magnetic field is applied perpendicular to the plane of the ring-shaped molecules,

$$|\chi_{dia}^{\perp}| > |\chi_{dia}^{\parallel}|$$

The interpretation of this phenomenon in terms of "ring currents" goes beyond the qualitative argument that the induced magnetic moments are maximized in the perpendicular configuration. For benzene, C_6H_6, the anisotropic susceptibility

$$\chi^{an} = \chi_{dia}^{\perp} - \chi_{dia}^{\parallel}$$

is found to be close to what eqn [6] gives. The summation in eqn [6] is to be taken over the six carbon p electrons, which, not being localized in sp^2 hybrid states, are free to move around the molecule:

$$\chi_{benzene}^{an} = -6\frac{A}{V_m}\frac{\mu_0 e^2}{4m_e}\rho^2 = -\frac{A}{V_m}\frac{i_r}{H}\alpha_{hex} \qquad [7]$$

Here, A/V_m is the density of molecules, A being Avogadro's number and $V_m = 89 \times 10^{-6}\,m^3$ the molar volume of benzene, $\rho = 0.139$ nm is the distance from the axis of the molecule to the carbon nuclei and i_r is the total ring current carried by the six delocalized electrons. Pauling has shown in 1936 that the ratio of the anisotropic susceptibility of other, more complicated aromatic hydrocarbons to that of benzene is correctly given by a simple model of conducting networks, assuming that the "resistance" of a carbon–carbon bond is the same in all such molecules. The ultimate success of this model is the correct estimation of the anisotropic susceptibility of graphite. The crystal structure of graphite consists of honeycomb-like layers built of benzene-like units. Assuming that in each hexagonal unit a ring current is induced of the same magnitude as in benzene, one finds that the current of neighboring unit cells cancel and the current density inside the material vanishes. However, the outermost hexagons have two sides with uncompensated currents i_r flowing in a zigzag pattern at 30° from the orientation of the surface. The resulting surface current density is $j_S = i_r \cos 30°/d$, where $d = 0.335$ nm is the interlayer distance in graphite. The surface current density j_S generates a magnetization $M_{graphite} = -j_S = -i_r\sqrt{3}/2d$

inside the sample. This is to be compared with $M_{\text{benzene}} = -(A/V_{\text{m}})\, i_{\text{r}} \alpha_{\text{hex}}$ (cf. eqn [7]), leading to

$$\frac{\chi^{\text{an}}_{\text{graphite}}}{\chi^{\text{an}}_{\text{benzene}}} = \frac{\sqrt{3} V_{\text{m}}}{2A\alpha_{\text{hex}} d} = 7.6 \qquad [8]$$

which is close enough to the experimental value of 6.9, considering the simplicity of the model.

Semiclassical and empirical schemes like the ones used above for free atoms and aromatic compounds, respectively, cannot be applied to the diamagnetic response of conduction electrons in metals. Even the simplest model, the free-electron gas, has been a major challenge, until Landau gave his derivation of what has come to be called Landau diamagnetism. In fact, in most textbooks the Bohr–van Leeuwen theorem is only mentioned in this context, even though its validity is not violated by the presence of atomic or molecular potentials.

The Schrödinger equation was four years old, when Landau (who was twenty-one at the time) solved it for free electrons in the uniform magnetic field (eqn [6]). Instead of the symmetric gauge (eqn [4]), he has chosen

$$\boldsymbol{A} = (0, xB, 0) \qquad [9]$$

which enabled the separation of variables. The resulting differential equation in x was found to be identical with the Schrödinger equation of a harmonic oscillator with a force constant e^2B^2/m_{e}, while the ones in y and z were satisfied by plane-wave solutions. The latter is reasonable for the z dependence, considering that the Lorentz force is perpendicular to $\boldsymbol{B}$, so that the motion along the z axis is free. The density of the eigenstates described by $\mathrm{e}^{\mathrm{i}k_z z}$ is that of a one-dimensional electron gas,

$$\rho(\varepsilon) = \frac{2eB}{\hbar^2}\sqrt{2m_{\text{e}}\varepsilon} \qquad [10]$$

The motion in the (x,y) plane gives a discrete spectrum, with highly degenerate states at the energies

$$\varepsilon_n = \left(n + \frac{1}{2}\right)\frac{\hbar e}{m_{\text{e}}}B \qquad [11]$$

the Landau levels, which correspond to the stationary states of the harmonic oscillator. The resulting total density of states has a spiked structure. A singular contribution of the form [10] begins at each level [11]. These $\rho(\varepsilon - \varepsilon_n)$ contributions stand for the motion in the z direction while the motion in the (x, y) plane corresponds to the nth level of the harmonic oscillator. As to the x- and y-dependence of the wave functions, they are not suggestive of the circular motion resulting from the classical equations of motion for a charged particle subjected to a uniform magnetic field. This may seem to be due to the choice of the asymmetric gauge [9]. However, it is hardly surprising that the classical motion is not implied by the calculation of an effect, which does not occur at all in the classical theory.

The maxima in the density of states at energies separated by $\hbar eB/m_{\text{e}}$ result in a total energy, which is a periodic function of $1/B$. Through eqn [1], a similar periodicity arises in the magnetization, which is the signature of the de Haas–van Alphen effect. In the low-field limit, the same B-dependent total-energy expression yields the diamagnetic susceptibility

$$\chi^{(\text{Landau})}_{\text{dia}} = -\frac{n\mu_{\text{B}}^2}{\varepsilon_{\text{F}}}$$

where n is the electron density and ε_{F} is the Fermi energy. This is seen to be $-1/3$ times the Pauli paramagnetic susceptibility, a relationship, which cannot be expected to be valid for metals in general, but seems to hold for the so-called "simple" metals, for which the nearly free-electron approximation works.

Diamond Anvil Cells

W A Bassett, Cornell University, Ithaca, NY, USA

Introduction

The extraordinary properties of diamond and the very high pressures that can be achieved simply by reducing sample size make the diamond anvil cell (DAC) capable of pressures up to and beyond those existing at the center of the earth. Resistance heating and laser heating can produce temperatures up to and beyond those at the center of the earth. The very simple principle of the DAC allows great versatility of design for accommodating many analytical techniques. Background, development, and applications of the DAC are described in this article.

History and Background

Alvin Van Valkenburg at the National Bureau of Standards (now the National Institute of Science and Technology) reasoned that he could make infrared absorption measurements on a sample under pressure by squeezing the sample between the flat faces of two diamond anvils. He did not know if the faces were perfectly parallel and so he placed his device on the stage of a microscope and looked through the diamonds at the sample. When he saw the sample, he immediately realized that he had something extraordinary. Although the diamonds were in fact not very parallel, he could see that parts of the sample looked different because they were at high pressure (HP); and the diamond anvil cell was born. Visual observation continues to the present as the most important technique used with DACs. Van Valkenburg found that he could solidify water, alcohol, and other liquids by placing them in gaskets formed by drilling holes in metal foils and placing them between the diamond faces. He also found he could see phase transitions in single crystals of calcite and other solids when surrounded by a fluid in a gasket. The National Bureau of Standards group soon found they could examine samples under pressure by X-ray diffraction as well.

Since that time there have been more than a dozen additions to the list of analytical techniques successfully used to study samples at high pressures and temperatures (HPT) in the DAC. These include a variety of applications employing visible light, infrared, X-rays, electrical resistance, and magnetic susceptibility.

Principles of the Diamond Anvil Cell

Diamond has many properties that make it ideal for use as anvils in high-pressure (HP) devices. It is the hardest material known, has elastic moduli with very large values, is transparent to large portions of the electromagnetic spectrum, is a good electric insulator, is an excellent thermal conductor, and is readily available as nearly perfect single crystals. Gem diamonds are available in high-quality, ready-cut shapes close to the most desirable shapes for anvils. Grinding and polishing the culet point on a brilliant-cut faceted diamond is all that is needed to turn it into an anvil face. Although metastable, diamond has a remarkable resistance to change with increased pressure and temperature up to hundreds of GPa and $\sim 1500\,\mathrm{K}$.

Great versatility is possible because the principle of the diamond anvil cell is simple: two diamond anvils driven together with a sample trapped between them (**Figure 1**). Because pressure is defined as force divided by area, it can be increased by increasing force or decreasing area. The DAC clearly benefits from the latter. As analytical techniques have become miniaturized, diamond anvil faces have been reduced to dimensions only microns across while forces continue to be generated by screws, levers, and small hydraulic or pneumatic devices. Because such small anvil faces are needed for generating very high pressures, precise parts with precise motions are essential for maintaining alignment. DACs need good support

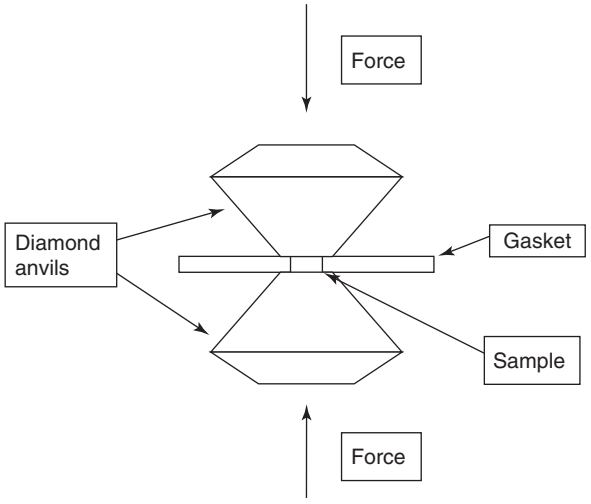

Figure 1 The diamond anvil cell (DAC) consists of two gem diamonds with their culet points ground and polished to form anvil faces. The diamonds are driven together against a sample contained in a gasket consisting of a hole drilled in a foil. This very versatile principle allows a wide variety of configurations depending on the type of analytical technique being applied.

for the anvils, usually a hard material such as tungsten carbide, while providing adequate access for analytical techniques, usually an opening in the support and/or in the plane of the sample. The principle is so simple that DACs can be adapted to the geometric needs of many analytical techniques. As a result, there are numerous DAC designs.

Gaskets play an important role in the many applications of DACs. The properties of gasket materials are crucial and are selected for specific applications. The rheologic properties are usually the most important. However, transparency to X-rays, electrical properties, and chemical properties are important as well. Gasket materials include rhenium, tungsten, iridium, spring steel, inconel, stainless steel, brass, boron–epoxy mixture, aluminum, and beryllium.

Heating a sample in a DAC can be achieved by

1. external resistance heating including use of heaters that surround the whole cell, heaters that surround just the anvils, heaters that surround the seats that the anvils sit on (**Figure 2**), and graphite heaters that are imbedded within the anvils;
2. internal resistance heaters are heaters that are insulated from the anvils and therefore do not heat the anvils to temperatures as high as sample temperature (**Figure 3**). They consist of an electrically conducting sample wire, a metal strip with a hole to receive the sample, or graphite sandwich; and
3. laser heating also heats the sample without heating the anvils (**Figure 4**).

External resistance heating (**Figure 2**) requires careful choice of materials that will resist softening or deformation with temperature change. Because some of the materials, including diamond, readily oxidize at high temperature, an inert or slightly reducing gas is needed to prevent oxidation. The main advantage of external heating is the very constant and uniform temperatures that can be achieved. Pressures can also be held constant when the cell is designed to eliminate or minimize the effects of dimensional changes with temperature. Pneumatic devices and springs that are kept cool are especially important for achieving this. The main disadvantage is the upper limit of 1500 K at which diamond begins to graphitize.

Internal resistance heating (**Figure 3**) has the advantage that it heats only the sample and can, therefore, generate much higher temperatures than can be tolerated by the diamond anvils. The upper limit for internal resistance heating is imposed by the melting point of the resistor. However, that can be very high if Re or W is used.

Laser heating (**Figure 4**) has employed yttrium aluminum garnet (YAG), yttrium lithium fluoride, and CO_2 lasers with their beams focused through the anvils onto the sample. The sample must be thermally insulated from the diamond anvils by a transparent

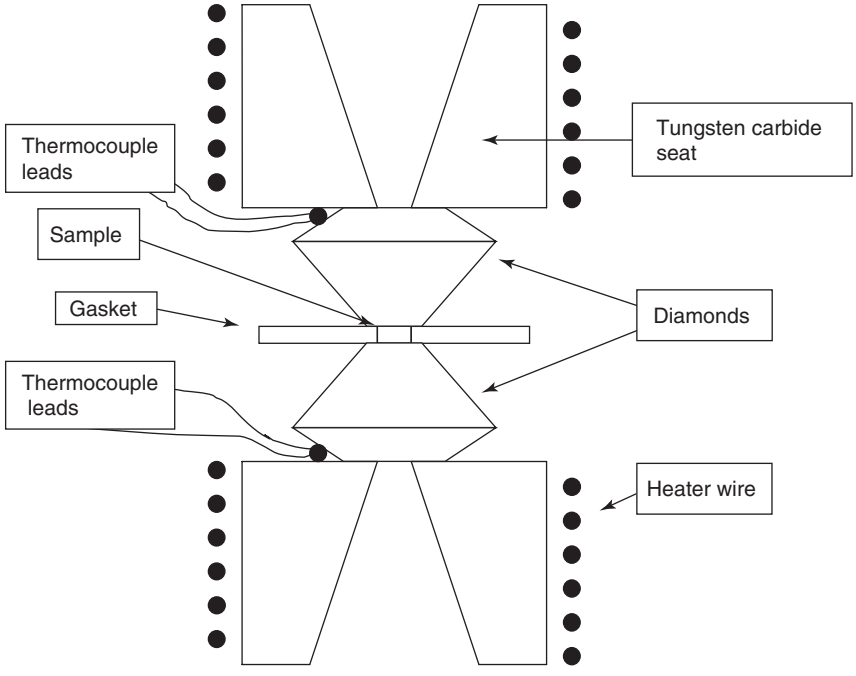

Figure 2 Samples can be heated to 1500 K while under pressure by means of resistance heaters wound around the seats supporting the diamond anvils. Thermocouples placed in contact with the diamond anvils measure temperatures to within a few kelvin. Corrections can be made by observing melting of standard materials in the sample chamber. Access can be through the diamonds or the gasket.

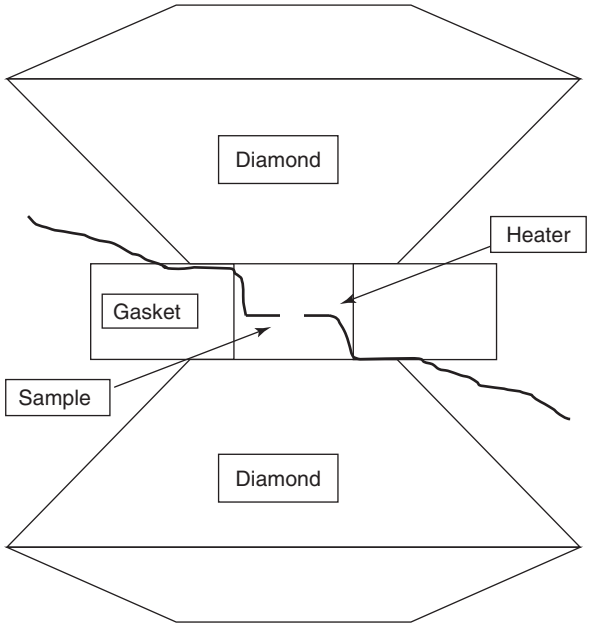

Figure 3 An internal resistance heater, usually constructed from rhenium, can be used to heat a sample to much higher temperatures (3000 K) than the diamonds can tolerate because it is insulated from them. Temperatures are measured by spectroradiometry.

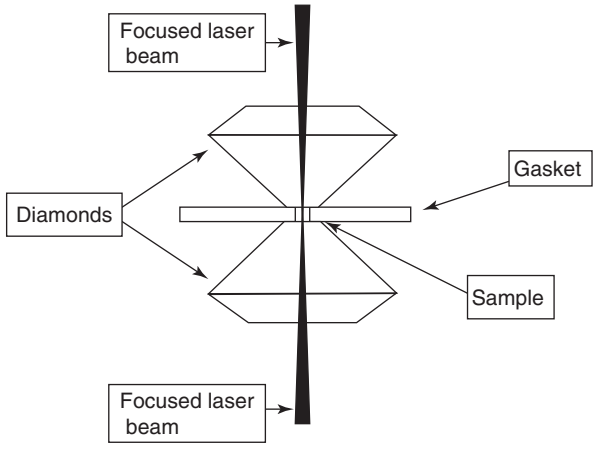

Figure 4 Laser heating can raise the temperatures of samples to several thousands of kelvin. When a laser beam is split and directed to the sample through both anvils, more uniform and constant temperatures can be achieved than heating from one side alone. Temperature gradients within the sample are minimized by using the larger TEM $_{01}$ laser mode and focusing the probing X-ray beam to a very small spot within the heated area.

material, which protects the diamonds and serves as a pressure medium. Although continuous power delivered to both sides of the sample has yielded the best quantitative results, single-side and pulsed laser heating have been used extensively. Temperatures of thousands of kelvin can be achieved, especially if very short pulses are used. Sample design for laser heating is much simpler than for internal resistance heating, but requires a rather large and complex optical system outside of the DAC.

Low temperatures down to that of liquid helium can be achieved by passing cold gases through the DAC or injecting liquid nitrogen or liquid helium directly into the cell and letting it boil there. Another approach has been to completely immerse the DAC into liquid nitrogen or liquid helium.

Pressure Measurement

Accurate methods for determining pressure can be divided into two groups: (1) primary, those that are independent and (2) secondary, those that must be calibrated using a primary pressure scale.

Primary

Force divided by area can provide reliable, accurate pressure measurements but only to pressures far less than what DACs are capable of because of the limitations of the apparatus for making such determinations, usually piston-cylinder devices. Phase transitions such as those in elemental bismuth were used as calibration points for transferring pressure measurements to other types of apparatus in which those same phase transitions could be observed.

One of the most significant advances was Decker's development of an equation of state (EoS) for NaCl from first principles. This could be applied directly when X-ray diffraction was used and NaCl was mixed with the sample in a DAC. Its use for calibrating secondary pressure scales, such as the ruby fluorescent scale, was also very valuable.

Dynamic shock-wave measurements are also an important source of primary pressure determination but rely on corrections when data are converted from high-temperature Hugoniot measurements to isothermal EoS. Nonetheless, dynamic measurements on some metals have provided an important means for calibrating the secondary pressure scales, especially the ruby fluorescence scale, to higher pressures.

Recent primary pressure scales have been based on combining data from direct compression measurement using X-ray diffraction (XRD) and sound velocity measurements, which yield data related to the pressure derivative of compression. From the two sets of data, it is possible to derive completely independent values of pressure as a function of lattice parameters. Brillouin scattering in the DAC and sound interferometry have been used to measure sound velocities.

Secondary

A secondary pressure scale is one that offers an observable change as a function of pressure. There

are many materials which display observable phase transitions at calibrated pressures – Bi, AgI, KCl, and NaCl, to mention a few. One or two of these can be included along with a sample as a pressure indicator. There are many materials whose EoS have been calibrated so that a measurement of their lattice parameters by XRD can be used for determining pressure. Sometimes the sample itself can be used in cases where its EoS is well defined and some other property is being investigated.

The most widely used secondary pressure scale is the ruby fluorescence scale. The R_1 and R_2 emissions from ruby when excited by some higher energy radiation shift monotonously with pressure. The fluorescence is typically excited by an argon ion laser and the emission is analyzed by a grating spectrometer. The positions of the R_1 and R_2 lines in the spectrum provide a convenient and inexpensive method for determining pressure. In addition, the shapes and separation of the R_1 and R_2 lines can be used as indicators of deviatoric stress and pressure gradient. Other fluorescent materials such as Cr:MgO and Sm:YAG have been used as well, but ruby continues to be the most popular.

Raman spectra of diamond show shifts with pressure and can be used as a secondary pressure scale. At lower pressures, diamond particles synthesized from ^{13}C are used to avoid interference from the diamond anvils. At higher pressures, natural diamond can be used.

Temperature Measurement

Temperature measurements in externally heated DACs can be accomplished by placing thermocouples in contact with the diamond anvils. Because diamonds are such good thermal conductors, discrepancies between sample temperature and thermocouple temperature are rarely more than a few degrees celsius even at the highest temperatures. Corrections to thermocouple readings can be determined by observing melting of standard materials such as $NaNO_3$ and NaCl placed in the sample chamber. The same thermocouples used for high-temperature measurements can be used for the low-temperature measurements.

Internal resistance heating and laser heating are utilized in order to achieve temperatures in excess of those that cause damage to the diamond anvils ($\sim$1500 K). The most commonly used method of temperature determination is spectroradiometry, which consists of fitting the spectrum of incandescent light from the hot sample to a blackbody or graybody curve. Steep temperature gradients and unknown emissivities can be sources of error.

Recently, the intensity ratio of stokes and anti-stokes peaks in X-ray Raman spectra has been used to determine temperatures. They were found to be in good agreement with those determined by spectroradiometry.

Pressure Measurement at High Temperatures

Primary

Accurate pressure measurement in samples at high temperature has been an area of much concern. Neither sample pressure (isobaric) nor sample volume (isochoric) can be assumed to remain constant as temperature is changed in most sample configurations. In these cases, an internal calibrant is needed. Decker's EoS for NaCl is a full EoS including the effect of temperature on molar volume and is, therefore, suitable for pressure measurement at high temperature. The full EoS of gold has also been determined and is desirable for samples in which only a small amount of pressure calibrant is wanted or where recrystallization needs to be avoided.

There are two configurations, however, that can greatly reduce or eliminate the effect of temperature on pressure. A very small opaque sample surrounded by a much larger volume of transparent pressure medium can be locally heated by laser and remain nearly isobaric because of the relative sizes. Isochoric conditions can be achieved at relatively low pressures by cycling a sample in a gasket, such as rhenium, to high temperature several times. If forces are not great, the gasket finishes relaxing on about the third cycle and the volume can be shown to remain constant with temperature within experimental error. If the full EoS of the contents is known, as with H_2O, the pressure can be calculated from the temperature. This approach has been especially valuable in fluid studies where the pressure is allowed to develop as a result of heating.

Secondary

Attempts to use ruby and Sm:YAG to measure pressure at high temperature have been less than satisfactory. The fluorescence emission from ruby fades with temperature and the emissions from Sm:YAG are complex to follow.

There are several rapidly-running reversible phase transitions that have been calibrated, for example, $BaTiO_3$, $PbTiO_3$, $Pb_3(PO_4)_2$, and α–β transition in quartz. These have specific trajectories in P–T space and, therefore, are not useful for determining pressure at just any location in the P–T space. They are, however, very useful for calibrating fluid EoS described above. Re and other metals have been calibrated for pressure measurement at very high temperatures using XRD.

Analytical Methods

Visual observation is the easiest and most useful method for studying a sample in a DAC. It requires only using a microscope to look at it through the diamond anvils. Visual observation is valuable for not only alignment and centering but can be used to observe phase transitions, coexistence of phases, and optical properties. Phase diagrams can be developed by observing phases as P and T are changed.

XRD of samples under pressure in DACs has been one of the most important applications of DACs. Angle dispersion X-ray diffraction (ADXD) using monochromatic radiation and energy-dispersion X-ray diffraction (EDXD) using white radiation are both used, usually by passing an X-ray beam through one anvil to the sample and collecting scattered X-rays through the other anvil (**Figure 5**). X-rays that pass through a transparent gasket can also be collected (**Figure 6**). Both polycrystalline and single-crystal samples can be studied. The advent of synchrotron radiation (SR) with its high intensities, very smooth white spectrum, and excellent collimation has reduced exposure times by orders of magnitude while improving resolution and offering a greater variety of configurations. Improved solid-state detectors have also played a major role.

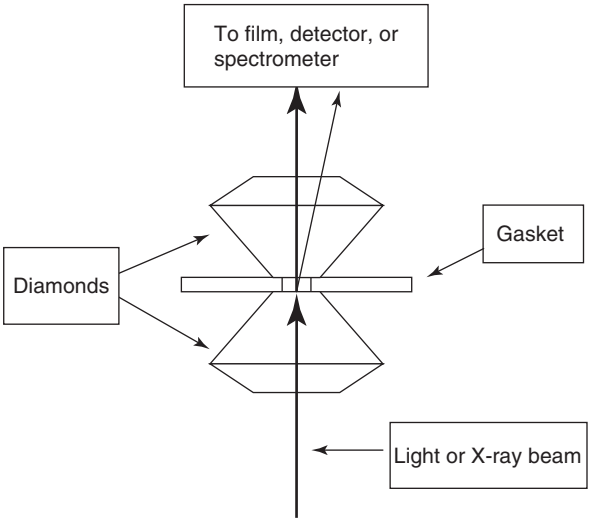

Figure 5 The most commonly used configuration is to pass electromagnetic radiation though one diamond anvil to the sample and to observe or analyze the radiation emerging through the other diamond anvil.

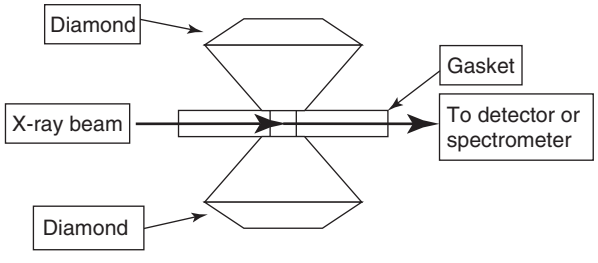

Figure 6 Gasket materials transparent to X-rays such as beryllium and boron–epoxy mixture allow incident X-rays to enter through one side of the gasket and scattered X-rays to be collected through the other side.

Emitted visible light from a sample in a DAC can be spectrally analyzed. Fluorescence emission may be excited by X-rays, ultraviolet light, or visible light of shorter wavelength. The trajectory of an X-ray beam as it passes through a fluorescent diamond can be located visually by emission of visible light. The ruby method for determining pressure depends on the excitation of fluorescent emission in small ruby chips included in a sample. Incandescent light from a hot sample contained in a DAC can be spectrally analyzed and fit to a blackbody curve to determine the temperature. Sample fluorescence has been an important source of fundamental information, especially for studying the effect of pressure and temperature on organic compounds. Lasers are favored for stimulating fluorescence because of their high intensity and because they make it possible to pinpoint parts of the sample.

Absorption spectra of light passing through a sample (**Figure 5**) as well as spectra of reflected light (**Figure 7**) provide useful information about bonding and band gap changes as a function of pressure and temperature. Imaging can allow selected portions of a sample to be analyzed.

Infrared (IR) absorption spectroscopy requires carefully selected diamonds (usually type II) to be transparent over the desired range of IR-active frequencies. IR absorption at high pressure has been especially important for understanding the effects of pressure and temperature on organic materials.

Raman scattering has been a very important analytical technique for HPT samples. Light scattered from the sample can be analyzed to determine Raman-active

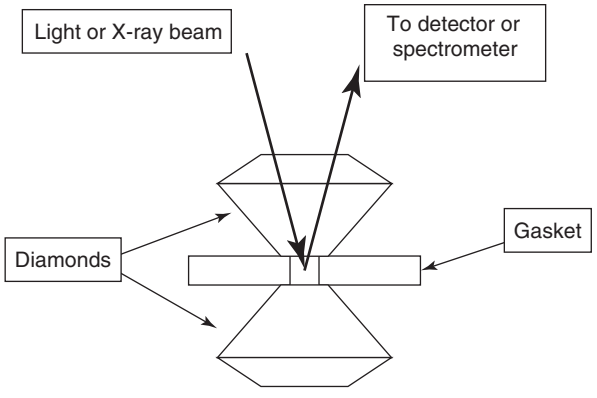

Figure 7 Observation and analysis of radiation scattered back through the same diamond it entered provide an important source of information for many types of studies.

vibrational frequencies. Vibrational frequencies are an important source of information for identifying phases, examining bonding, and studying the relationships between vibration frequencies and phase transitions. Hyper-Raman spectroscopy employs a three-photon process and can detect not only far IR vibrational frequencies but can also detect frequencies ("silent" modes) that are not normally IR or Raman active.

Brillouin scattering has been an important source of information on the effects of P and T on the elastic properties of single-crystal samples. A light beam from a laser, usually an Ar^+ laser, is directed through one of the diamond anvils onto an oriented single-crystal sample in a DAC. Light scattered by interaction with phonons in the sample contains frequency shifts (usually smaller than in Raman) that can be used to calculate the velocities of the phonons. If the anvil faces exactly bisect a 90° angle between the incident beam and scattered light, no corrections need to be made for the refractive index of the sample, medium, and anvils (**Figure 8**). These phonon velocities, in turn, can be used to determine the effects of P and T on elastic moduli.

Impulsive stimulated scattering (ISS) is another technique that yields information about sound velocities and elastic moduli. Sound waves in the ISS method are generated within the sample by means of laser radiation. Laser light from a different source is Bragg reflected from these sound waves. Its intensity fluctuation can then be used to determine sound velocities.

X-ray spectroscopy (XRS) which includes emission, absorption, and scattering is now the area of most active development of new techniques and applications in HPT research. X-ray emission spectroscopy (XES) consists of analyzing spectra of radiation excited by an incident X-ray beam as it passes out through the anvils (**Figures 5** and **7**) or the gasket (**Figure 6**). Laser-machined diamond anvils and very transparent gaskets are two modifications that now make it possible to analyze all elements heavier than Ca. While elemental analysis is the most important application, newly developed sub-eV energy resolution makes it possible to show a line shape which can be used to provide valuable information on filled electronic states as well as valence and magnetic states such as high-spin to low-spin transition in Fe.

X-ray absorption spectroscopy (XAS) consists of analyzing the spectra of photons absorbed when their energies exceed the excitation energy of deep-core electrons. Laser-drilled holes in the diamond anvils (**Figure 9**) can reduce the amount of diamond in the beam to 0.3 mm. In these DACs, X-ray absorption fine structure (XAFS) spectra down to 4 keV permit analyses of the K edges of elements as light as Sc as well as L edges of rare-earth elements. Near-edge X-ray absorption fine structure (XANES) provides information on the symmetry-projected conduction band density of states (DOS), while the extended X-ray absorption fine structure (EXAFS) provides local structure information. These element-specific probes are able to reveal electronic and structural changes that take place at HPT conditions. Intensity loss due to Bragg reflections as an X-ray beam passes through the diamond anvils causes unwanted sharp peaks. However, these

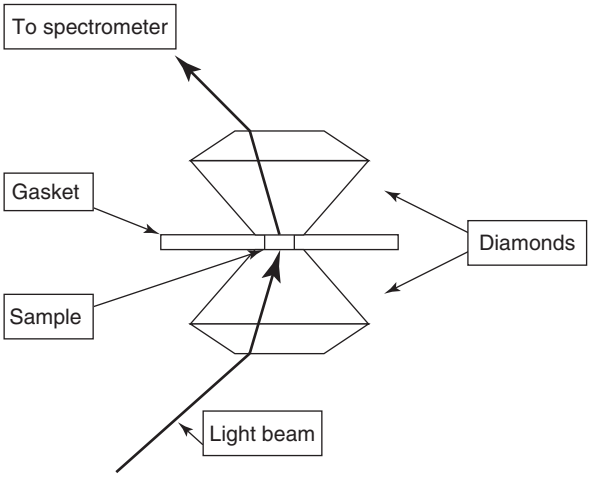

Figure 8 Brillouin scattering can be used to determine phonon velocities in high-pressure samples without making corrections for refractive indices if the anvil faces bisect the 90° angle between the incident and scattered light rays.

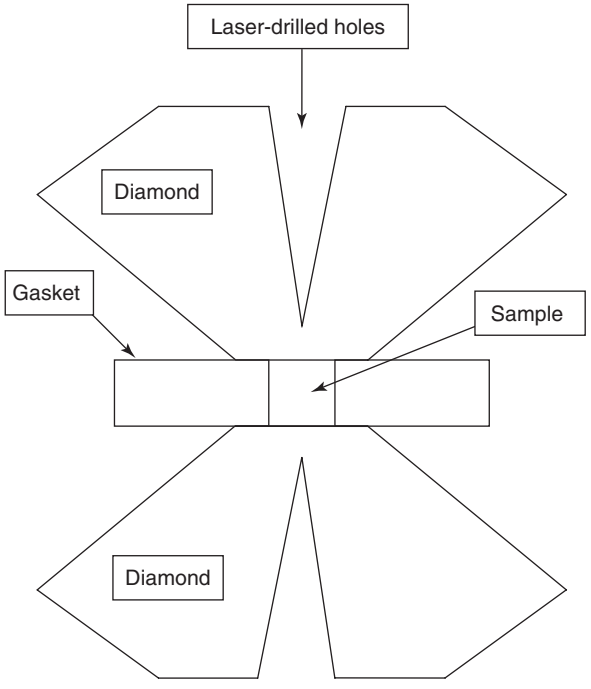

Figure 9 Holes laser-drilled to within 0.15 mm of the anvil face greatly reduce the absorption by diamond allowing X-ray absorption studies to be made at energies down to <4 keV.

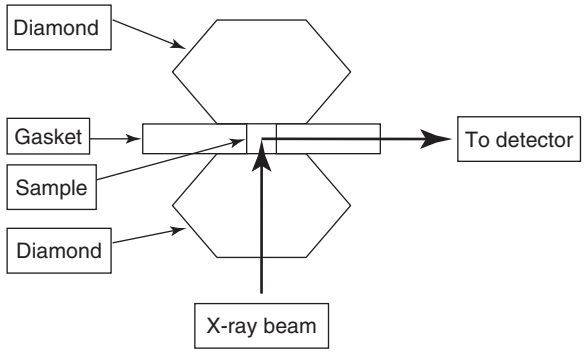

Figure 10 X-ray emission excited by an X-ray beam passing through one of the diamond anvils can pass out through a transparent gasket and be analyzed. Background due to Rayleigh and Compton scattering is minimized when the detector is located at 90° from the X-ray beam in the plane of polarization of an X-ray beam from a synchrotron source.

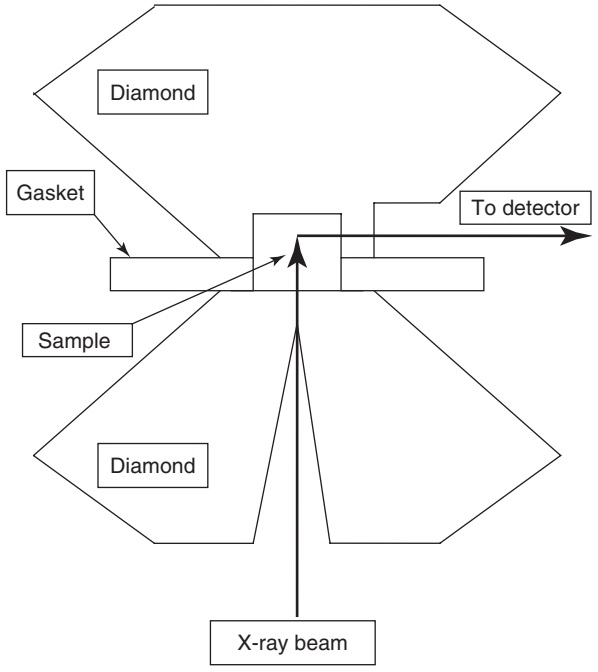

Figure 11 X-ray emission excited by an X-ray beam passing through one of the diamond anvils can pass out through the side of the other diamond anvil to be analyzed. Using a diamond with a laser-drilled hole for one anvil and a diamond with a thin-walled recess for the other greatly reduces absorption to permit high-pressure–temperature studies down to energies of 4 keV and less.

can be shifted by changing the orientation of the DAC slightly. An alternative and very successful way of obtaining absorption spectra is by measuring the intensity of fluorescence emission at the energy of one of the emission peaks while the energy of the incident beam is scanned over the absorption edge being studied. X-rays emerging through an X-ray transparent gasket (**Figure 10**) or side of one of the anvils (**Figure 11**) are collected and analyzed. The signal-to-noise ratio is much improved with this method.

Nuclear resonance X-ray spectroscopy (NRXS), also known as Mössbauer spectroscopy, deals with exceedingly narrow absorption peaks resulting from nuclear transitions. NRXS uses an in-line high-resolution monochromator (HRM) on an SR beam capable of narrowing the photon energy and fine-tuning the monochromatic X-ray beam with meV resolution. Avalanche photodiodes (APD) are used to collect signals from nuclear resonance absorption, and reject all other signals.

Inelastic X-ray spectroscopy (IXS) represents a major breakthrough for high-pressure research. As in Raman spectroscopy, the energies of the events being probed appear as differences in the energies of incident and scattered X-rays. For this reason, IXS is sometimes referred to as X-ray Raman spectroscopy. This principle makes it possible for experimenters to select X-ray energies that are high enough to easily penetrate diamond anvils and/or low-Z gaskets while probing low-energy phenomena. Recent advances in focusing of X-rays onto samples as small as 0.01 mm and dramatic improvements in monochromators and analyzers to achieve sub-eV resolution have opened the way for these techniques to be applied to investigations of a wide variety of low-energy events at HPT conditions. IXS comprises several techniques which yield different types of information. They are X-ray inelastic near-edge spectroscopy (XINES), electronic inelastic X-ray scattering (EIXS), resonant inelastic X-ray scattering (RIXS), nuclear resonant inelastic X-ray scattering (NRIXS), and phonon inelastic X-ray scattering (PIXS).

X-ray inelastic near-edge spectroscopy (XINES) is capable of making measurements that yield the same information as XANES on near core-electron absorption edge features. The principle is similar to that of electron energy loss spectroscopy (EELS). These techniques provide information about the nature of chemical bonding. Spectral features are particularly pronounced and the information particularly important for the very light elements. It is only since the development of XINES that such measurements can be made at HPT conditions because the low-energy X-ray and electron beams needed for XANES and EELS are completely blocked by any of the pressure vessels. Successful observations have been made on second-row elements from Li (56 eV) to O (543 eV) at high pressures. This opens a wide new field of near K-edge spectroscopy of the very light elements.

Electronic inelastic X-ray scattering (EIXS), which is very similar to XINES in principle and instrumentation, can be used to investigate the drastic effect that pressure can have on the energy and dispersion of electronic bands. The IXS principle makes it

possible to use a 10 keV X-ray beam for excitation and a monochromator capable of 0.3–1 eV resolution to probe high-energy electronic phenomena, including electronic band structure, Fermi surface, excitons, plasmons, and their dispersions at HP.

In resonant inelastic X-ray spectroscopy (RIXS) experiments, both incident and scattered X-ray energies need to be scanned. Of particular interest is the investigation of phase transitions driven by electron correlation effects that occur in transition elements and rare-earth elements and their compounds at high pressures.

Nuclear resonant inelastic X-ray scattering (NRIXS) utilizes inelastic scattering to collect nuclear resonance or Mössbauer spectra. An APD directly downstream of the sample collects nuclear resonant forward scattering (NRFS) spectra which provide a precise determination of the hyperfine interaction parameter and Lamb–Mössbauer factor. APDs surrounding the sample collect NRIXS spectra. Isotopes that exhibit a nuclear resonant Mössbauer effect, for example ^{57}Fe, offer an extraordinary opportunity to make phonon DOS measurements on samples containing them, measurements that provide valuable information on dynamic, thermodynamic, and elastic properties.

PIXS requires detecting a very weak sample signal in the presence of a very strong background signal, especially when a HP vessel contains the sample. New novel HRMs which are being developed will improve the feasibility of making nonresonant PIXS measurements at high pressure. Such measurements would be a valuable source of information on phonon dynamics in highly compressed materials, information important for understanding vibrational thermodynamic properties, elasticity, and phase transition mechanisms.

Electrical resistance has been measured on samples as a function of pressure and at high temperature in DACs. For these experiments, fine electric leads are connected to the sample and four-lead systems have been employed for the most quantitative measurements. A particularly novel approach, dubbed designer diamonds, has employed diamonds in which the leads are imbedded in the anvils by vapor depositing single-crystal diamond over the leads.

Magnetic measurements have been made in DACs constructed of nonmagnetic materials such as beryllium–copper. Coils for generating and picking up signals are placed as close to the sample as possible.

Sound velocity measurements have been made by three important methods, Brillouin scattering, impulse stimulated scattering, and interferometry of GHz acoustic signals. The first two of these use interactions between photons and phonons while the third generates GHz sound by a transducer and uses interferometry of the acoustic signals to measure travel time in a crystal only $\sim$0.1 mm across. Sound velocities are then calculated.

Gamma rays emitted by a radioactive sample in a DAC have been counted and the effect of pressure on the decay rate measured. Pressure has been shown to increase the decay rate of ^{7}Be in an electron-capture process.

Conclusions

Diamond anvil cells combined with many analytical techniques are a valuable source of information on fundamental properties of solids including crystal structures, equations of state, and nature of bonding. Encapsulation of fluids in gaskets has made it possible to learn about structures and properties of fluids, hydrothermal studies, properties of melts, interactions between fluids and solids, and other phase relationships. DACs have contributed to the search for superhard materials. Our knowledge of the planets has benefited from information about the physical properties of materials that form them. In the biological sciences, efforts are being directed to biological questions. These include organic chemistry, macromolecular studies, and microorganisms under pressure. Some of the methods described above are only now beginning to be applied to important questions. Future research with DACs is certain to yield important new results in all of the sciences.

Dielectric Function

J Petzelt and I Rychetský, Institute of Physics of Academy of Sciences of the Czech Republic, Prague, Czech Republic

Definition and General Properties

Electromagnetic field in a condensed matter medium is described by Maxwell equations containing charge densities $\rho(\boldsymbol{r},t)$ and currents of electrons and ions in the medium. Dependence of charge density on the macroscopic electric field (averaged over local field variations due to the discreet atomic structure) constitutes a material relation characteristic for the material. The charge density can be expressed by means of the dipole moment vector per unit volume (polarization) $\boldsymbol{P}$ or by the electrical displacement vector $\boldsymbol{D}$:

$$\rho = -\mathrm{div}\,\boldsymbol{P}, \quad \boldsymbol{D} = \varepsilon_0\boldsymbol{E} + \boldsymbol{P} = \varepsilon_0\chi\boldsymbol{E}$$

where ε_0 is the permittivity of vacuum and χ is the linear dielectric susceptibility tensor. Applying generally spatial and time-dependent electric field $\boldsymbol{E}(\boldsymbol{r},t)$, the polarization vector in the linear approximation is

$$P_i(\boldsymbol{r},t) = \varepsilon_0 \int_{-\infty}^{t} \mathrm{d}t' \int \mathrm{d}\boldsymbol{r}'\chi_{ij}(\boldsymbol{r}-\boldsymbol{r}', t-t')E_j(\boldsymbol{r}', t')$$

and may depend on the spatial surrounding (nonlocal response) and history of $\boldsymbol{E}$ (for causality reasons only on previous times). Assuming space and time homogeneity, the dependences are only on the differences $\boldsymbol{R}=\boldsymbol{r}-\boldsymbol{r}'$ and $\tau = t - t'$. Defining the time and spatial Fourier transform of the field $E_i(\omega,\boldsymbol{k}) = \int_{-\infty}^{\infty} \mathrm{d}t \int \mathrm{d}\boldsymbol{r}\, E_i(\boldsymbol{r},t)\, \mathrm{e}^{\mathrm{i}(\omega t - \boldsymbol{k}\boldsymbol{r})}$, the Fourier components (i.e., plane waves) of polarization and electric displacement are $P_i(\omega,\boldsymbol{k}) = \varepsilon_0\chi_{ij}(\omega,\boldsymbol{k})E_j(\omega,\boldsymbol{k})$ and $D_i(\omega,\boldsymbol{k}) = \varepsilon_0\varepsilon_{ij}(\omega,\boldsymbol{k})E_j(\omega,\boldsymbol{k})$, where the linear dielectric function (relative dielectric permittivity or dielectric constant) $\varepsilon_{ij}(\omega,\boldsymbol{k}) = \delta_{ij} + \chi_{ij}(\omega,\boldsymbol{k})$ and susceptibility $\chi_{ij}(\omega,\boldsymbol{k})$ are complex functions of the real $\boldsymbol{k}$-vector and frequency:

$$\varepsilon_{ij}(\omega,\boldsymbol{k}) = \delta_{ij} + \int_0^{\infty} \mathrm{d}\tau \int \mathrm{d}\boldsymbol{R}\ \chi_{ij}(\boldsymbol{R},\tau)\mathrm{e}^{\mathrm{i}(\omega\tau - \boldsymbol{k}\boldsymbol{R})}$$

The dielectric function describes the linear relation between $\boldsymbol{D}$ and the macroscopic electric field $\boldsymbol{E}$.

The frequency and $\boldsymbol{k}$-vector can be mathematically considered as complex quantities. Since the fields are real, the dielectric function fulfills the relation $\varepsilon_{ij}(\boldsymbol{k},\omega) = \varepsilon_{ij}(-\boldsymbol{k}^*, -\omega^*)^*$ or, for real ω and $\boldsymbol{k}$, $\varepsilon_{ij}(\boldsymbol{k},\omega) = \varepsilon_{ij}(-\boldsymbol{k}, -\omega)^*$. In nongyrotropic (i.e., without optical activity) media where $\varepsilon_{ij}(\omega,\boldsymbol{k}) = \varepsilon_{ij}(\omega,-\boldsymbol{k})$, the dielectric function tensor is symmetric, $\varepsilon_{ij}(\omega,\boldsymbol{k}) = \varepsilon_{ji}(\omega,\boldsymbol{k})$. If the wave vector obeys the constraint $ak = \pi a/\lambda \ll 1$, where a is of the order of the characteristic system inhomogeneities (in crystals the interatomic distances), the dielectric function can be expanded in ak:

$$\varepsilon_{ij}(\omega,k) = \varepsilon_{ij}(\omega) + O((ak)^2) \approx \varepsilon_{ij}(\omega)$$

Neglecting the second term on the right-hand side, it is assumed that the response is local so that the spatial dispersion effects are neglected. Then only the frequency dependence has to be considered:

$$\varepsilon_{ij}(\omega) = \delta_{ij} + \int_0^{\infty} \mathrm{d}\tau\ \chi_{ij}(\tau)\mathrm{e}^{\mathrm{i}\omega\tau}$$

In most cases of practical interest, for macroscopically homogeneous media, this approximation is well justified and further discussion is limited to this case.

The complex dielectric function has the real and imaginary part, $\varepsilon_{ij}(\omega) = \varepsilon'_{ij}(\omega) + \mathrm{i}\varepsilon''_{ij}(\omega)$, which are even and odd functions of real ω, respectively:

$$\varepsilon'_{ij}(\omega) = \varepsilon'_{ij}(-\omega), \quad \varepsilon''_{ij}(\omega) = -\varepsilon''_{ij}(-\omega)$$

In the case of capacitors, the real part describes its capacity and the imaginary part determines the rate of losses of the radiation energy, which in the isotropic case is

$$Q = \tfrac{1}{2}\varepsilon_0|E(\omega)|^2\omega\varepsilon''(\omega)$$

In the case of electromagnetic waves, the real part describes the change of the wavelength compared to that in vacuum ($\lambda \propto 1/\sqrt{\varepsilon'}$) and the imaginary part its absorption (attenuation).

Instead of dielectric function, the AC electric conductivity tensor $\varepsilon_{ij}(\omega) = \mathrm{i}\sigma_{ij}(\omega)/\varepsilon_0\omega$ can be equivalently used. Along the principal axes of the dielectric tensor in nonmagnetic media where the magnetic permeability $\mu = 1$, the complex index of refraction $\hat{n}(\omega) = \sqrt{\varepsilon(\omega)} = n(\omega) + \mathrm{i}\kappa(\omega)$ is also frequently used to describe the dielectric response at optical frequencies. Here n is the real refractive index and κ index of absorption (characterizing the wave attenuation factor within one wavelength).

Kramers–Kronig Relations

The causality principle provides analyticity of $\varepsilon_{ij}(\omega)$ in the upper complex half-plane (in the lower half-plane $\varepsilon_{ij}(\omega)$ has singularities, mostly simple poles)

and results in Kramers–Kronig dispersion relations:

$$\varepsilon'_{ij}(\omega) - \delta_{ij} = \frac{2}{\pi} \boldsymbol{P} \int_0^{+\infty} \frac{x\varepsilon''_{ij}(x)}{x^2 - \omega^2}\, \mathrm{d}x$$

$$\varepsilon''_{ij}(\omega) - \frac{\sigma_{ij}(0)}{\varepsilon_0 \omega} = -\frac{2\omega}{\pi} \boldsymbol{P} \int_0^{+\infty} \frac{\varepsilon'_{ij}(x) - \delta_{ij}}{x^2 - \omega^2}\, \mathrm{d}x$$

Checking the validity of Kramers–Kronig relations is an important issue for experimentalists measuring independently the real and imaginary part of the dielectric response, even in a somewhat limited frequency range.

Sum Rules

The finite charges in the medium of interest result in the so-called sum rule for oscillator strengths (*f*-sum rule):

$$\int_0^{\infty} \omega\varepsilon''_{ij}(\omega)\, \mathrm{d}\omega = \delta_{ij} \frac{\pi}{2} \omega_{\mathrm{p}}^2, \quad \omega_{\mathrm{p}}^2 = \frac{Ne^2}{m\varepsilon_0}$$

$$\int_0^{\infty} \varepsilon'_{ij}(\omega)\, \mathrm{d}\omega = \delta_{ij} - \frac{2\pi^2}{\varepsilon_0} \sigma_{ij}(0)$$

where N is the density of charges, e and m their mass (assuming for simplicity only one type of charges of uniform density). These sum rules are of practical importance when discussing temperature or pressure dependences of the dielectric function, which undergoes pronounced changes (e.g., metal-insulator and superconductive phase transitions), since the total charge in the system is conserved.

Fluctuation–Dissipation Theorem

Dielectric function is closely related to thermal fluctuations of the polarization characterized by the autocorrelation function $\langle \delta P_i(t) \delta P_j(0) \rangle$, the Fourier component of which

$$S_{ij}(\omega) = \int_{-\infty}^{+\infty} \langle \delta P_i(t) \delta P_j(0) \rangle\, \mathrm{e}^{\mathrm{i}\omega t}\, \mathrm{d}t$$

is called spectral density function. This function is proportional to dynamic structure factor measured in inelastic neutron scattering experiments and to inelastic light scattering (Raman and Brillouin) cross section. The fluctuation–dissipation theorem relates this function to dielectric losses:

$$\varepsilon_0 \varepsilon''_{ij}(\omega) = \frac{1}{2\hbar}\left(1 - \mathrm{e}^{-\hbar\omega/kT}\right) S_{ij}(\omega) \approx \frac{\omega}{2kT} S_{ij}(\omega)$$

where the last approximation is valid in the classical high-temperature limit $kT \gg \hbar\omega$.

Polaritons

Dielectric function $\varepsilon(\omega, \boldsymbol{k})$ describes the dielectric response to the plane-wave electric field $E(\omega, \boldsymbol{k})\mathrm{e}^{-\mathrm{i}(\omega t - \boldsymbol{kr})}$, which can be, in principle, realized for arbitrary values of ω, $\boldsymbol{k}$ by using appropriate external electric charges and currents. When one limits to propagating electromagnetic waves in macroscopically homogeneous media, the values ω, $\boldsymbol{k}$ become mutually dependent. For example, for transverse waves $\boldsymbol{E} \perp \boldsymbol{k}$ which propagate along the optical axes, $k(\omega)^2 = (\omega^2/c^2)\varepsilon(\omega)$. Such waves, whose propagation is characterized by a complex wave vector, characterize mixed electromagnetic and lattice vibrational (phonon) or electron excitations called polaritons. Knowing the complex dielectric function, polariton dispersion branches are fully determined.

Physical Mechanisms and Models of Dielectric Dispersion

Dielectric function provides direct and important information about the polarization mechanisms in the medium. In all systems, the dominant dispersion and absorption mechanism in the high-frequency optic range (visible and/or ultraviolet) is caused by electronic excitations (transitions from populated to empty electron levels). Since these transitions involve the whole Brillouin zone, there are no simple phenomenological models used for the description of this dispersion. Instead, microscopic calculations based on the known or calculated electron band structure are normally used and compared with the experiment.

In the infrared range, the dominating dispersion and absorption mechanism in dielectrics is lattice vibrations (one-phonon absorption). Only polar phonons connected with the dipole moment fluctuations in the $\boldsymbol{E}$ direction, that is, transverse phonons whose eigenvectors have polar vector symmetry are infrared active. Their dielectric response can be well described by that of damped harmonic oscillators. Assuming s infrared active (i.e., polar) modes, the dielectric function in approximation which neglects the mutual coupling among the oscillators is a simple sum of individual oscillator responses:

$$\varepsilon(\omega) = \varepsilon(\infty) + \sum_{j=1}^{s} \frac{\omega_{pj}^2}{\omega_{TOj}^2 - \omega^2 - \mathrm{i}\gamma_{TOj}\omega}$$

where $\varepsilon(\infty)$, ω_{pj}^2, ω_{TOj}, γ_{TOj} are the high-frequency (optic) permittivity due to electronic transitions, oscillator strength, square root of the force constant, and damping of the jth transverse optical phonon mode, respectively. A more general function frequently used particularly for fitting the experimental

infrared reflectivity is the so-called factorized form of the dielectric function:

$$\varepsilon(\omega) = \varepsilon(\infty) \prod_{j=1}^{s} \frac{\omega_{\mathrm{LO}j}^2 - \omega^2 - \mathrm{i}\gamma_{\mathrm{LO}j}\omega}{\omega_{\mathrm{TO}j}^2 - \omega^2 - \mathrm{i}\gamma_{\mathrm{TO}j}\omega}$$

where the frequencies and dampings of longitudinal optical phonons are introduced explicitly. All the parameters are real positive numbers. For finite damping, the transverse and longitudinal eigenfrequencies correspond to complex poles and zeros of the dielectric function, respectively. Only in the limit of small dampings, these eigenfrequencies approach the corresponding ω_{TO} and ω_{LO} frequencies. In the static limit $\omega = 0$, the factorized dielectric function yields the generalized Lyddane–Sachs–Teller relation. It shows that high values of the static permittivity can be reached particularly by low ω_{TO} frequencies. This is the case of displacive ferroelectrics, where the Curie–Weiss divergence $\varepsilon = C/(T - T_{\mathrm{C}})$ is achieved by softening of the soft phonon mode $\omega_{\mathrm{TO}}^2(\mathrm{soft}) \propto T - T_{\mathrm{C}}$ (Cochran law).

In highly conducting materials (metals), the lattice response is screened by free charges (electrons) and their absorption dominates in the whole infrared range. It can be usually well described by the simple Drude response:

$$\varepsilon(\omega) = \varepsilon(\infty) - \frac{\omega_{\mathrm{p}}^2}{\omega(\omega + \mathrm{i}\gamma)}$$

It is the response of a damped harmonic oscillator for zero force constant. The zero of this dielectric function is called screened plasma frequency (plasmon eigenfrequency) and characterizes longitudinal oscillations of the free carrier plasma density. Notice that unlike the case of oscillators, contribution of the Drude term to the static permittivity is negative.

Below the lattice absorption range, no polarization (absorption) mechanism exists in an ideal nonpiezoelectric dielectric crystal. In piezoelectric crystals the coupling between polar optic and acoustic waves activates the acoustic waves in a finite sample, which introduces additional dielectric resonances, typically in the MHz frequency range, whose frequencies are, however, dependent on sample size and shape.

However, structural disorder and strong lattice anharmonicities or all kinds of movable charged defects usually induce further dispersion in the microwave and lower frequency range. Such dispersion is as a rule of relaxation type, the simplest model being the Debye relaxation:

$$\varepsilon(\omega) - \varepsilon(\infty) = \frac{\omega_{\mathrm{p}}^2}{\omega_0^2 - \mathrm{i}\gamma\omega} = \frac{\Delta\varepsilon}{1 - \mathrm{i}\tau\omega}$$

where $\tau = \gamma/\omega_0^2$ and $\Delta\varepsilon = \omega_{\mathrm{p}}^2/\omega_0^2$ are relaxation time and dielectric strength, respectively. It is seen that in the low-frequency range $\omega \leqslant 1/\tau$, this function approaches that of the oscillator with frequency ω_0 and damping γ. If the oscillator is overdamped (pure imaginary eigenfrequency for $\gamma \geqslant 2\omega_0$), the dielectric losses are peaked approximately at ω_0^2/γ like the Debye relaxation. This frequency characterizes the dynamics of the defects or hopping frequency of the localized charges. In more complex cases, distribution of Debye relaxations have to be used to fit the broadband dielectric spectra. In these cases, frequently appearing, for example, in polymers, much effort was exerted to study the universal dispersion laws which rule the tails of the broad loss peaks. However, till now no generally accepted picture has been achieved.

The simplest model which yields the Debye dispersion in solids is hopping of charges over a potential barrier E_{a} much higher than the thermal energy kT. If the charges do not interact, the temperature dependence is described by the Arrhenius law $\tau = \tau_\infty \exp(E_{\mathrm{a}}/kT)$. If the charges interact, the effective barrier for hopping increases on cooling and the temperature law is usually modified either to Vogel–Fulcher law $\tau = \tau_\infty \exp(E_{\mathrm{a}}/k(T - T_{\mathrm{g}}))$, or to critical slowing-down $\tau \propto 1/(T - T_{\mathrm{C}})$. Here, T_{g} is the glass transition temperature and T_{C} the critical temperature (connected, e.g., with an order–disorder ferroelectric transition) where the relaxation time tends to infinity. In the latter case, the systems order below T_{C} and the relaxation vanishes. In the former case, the long-range order is prohibited by some frustration due to structural disorder so that the disorder remains frozen down to low temperatures (glass phase). Near and below T_{g}, the Vogel–Fulcher law gradually changes into the Arrhenius law and the relaxation broadens and weakens on cooling.

Dielectric Constant of Various Dielectrics

The static permittivity (dielectric constant) of homogeneous solids may acquire values reaching from ~ 2 up to the order of 10^4. Materials from both ends of this broad spectrum are required for contemporary microelectronic applications: low-permittivity materials such as organosilicate films for advanced on-chip interconnects, and high-permittivity materials such as capacitors, tunable ferroelectric films or low-loss ceramics for microwave passive elements in communication systems. As discussed above, the permittivity value is determined by several always-positive contributions in the dielectric spectra. In low-permittivity materials, both electronic and vibrational contributions are very weak, which is typical for weak bonding among nonpolar molecules in organic substances. In high-permittivity materials, mostly the vibrational contribution of strong and

low-frequency polar modes dominates, since the electronic contribution ε_∞ is always relatively small due to high frequencies of the electronic transitions. Also the order–disorder ferroelectrics may reach high permittivity values close to T_C, but these are usually of no practical use because of strong temperature dependences of ε' and high losses. The most perspective high-permittivity materials are the so-called relaxor ferroelectrics (special type of structurally disordered ferroelectrics), where only a short-range polar ordering is reached and the dominant dielectric dispersion is due to the high-frequency dynamics of the polar nanoclusters.

Effective Dielectric Function

In the case of macroscopically or mesoscopically inhomogeneous media (e.g., composites, ceramics, and films with granular structure), the standard experimental techniques are unable to determine the bulk dielectric functions of individual constituents. Instead, the so-called effective dielectric function can be determined. If the probing electric field is homogeneous on the scale of inhomogeneities and the boundaries between different homogeneous regions are sharp, effective medium approximation can be used for calculation of the effective dielectric function. For example, for a two-component composite of spherical particles with dielectric function $\varepsilon_1(\omega)$, $\varepsilon_2(\omega)$ and volume fraction f, $1-f$, respectively, the effective dielectric function $\varepsilon_{\text{eff}}(\omega)$ is given by

$$f\frac{\varepsilon_1-\varepsilon_{\text{eff}}}{\varepsilon_1+2\varepsilon_{\text{eff}}}+(1-f)\frac{\varepsilon_2-\varepsilon_{\text{eff}}}{\varepsilon_2+2\varepsilon_{\text{eff}}}=0$$

This expression holds as long as the probing AC field is homogeneous within individual particles, that is, up to the infrared range if the particle size is $\sim 1\,\mu$m. If the difference between permittivities of both components is pronounced, particularly strong changes in $\varepsilon_{\text{eff}}(\omega)$ (including effective polar mode frequencies) appear near the percolation thresholds of both components, which in the latter model appear for $f = 1/3$ and $2/3$. In ceramics and films, the percolation threshold of the bulk grain properties cannot be reached (each grain is separated from its neighbors by the grain boundary with different dielectric properties) and therefore, the effective dielectric spectra are often strongly influenced by grain boundaries. For example, combining semiconducting grains with insulating boundaries can lead to effective giant permittivities (values up to $\sim 10^6$ were actually observed) with strong dielectric relaxations at low or medium frequencies, which are absent in the response of both bulk components.

Diffusionless Transformations

H Ledbetter, A Saxena, and A Migliori, Los Alamos National Laboratory, Los Alamos, NM, USA

Introduction

Several topics on diffusionless phase transformations are briefly described. All solid-state phase transformations fall into two groups: diffusional and nondiffusional. The first involves thermally activated noncorrelated atomic jumps from one lattice position to another. The second (focused here) possesses several descriptors: diffusionless, displacive, nonreconstructive, coordinated-shear, military, and martensitic. Because martensite represents the prototypical diffusionless phase transformation, martensitic

and diffusionless are used nearly synonymously. Diffusionless transformations occur in nearly every material type: metals, alloys, ceramics, minerals, rare-gas solids, polymers, and (perhaps) biological systems. Although diffusionless, these transformations can occur at high temperatures.

The following topics are considered: energy relationships; vibration modes, phonons, and entropy; Landau theory, including microstructure and soft modes; elastic-inclusion theory. All these topics relate to the thermodynamic free energy. Free-energy differences among phases provide the driving force for a transformation from one phase to another.

Energy Relationships

For a first-order phase transformation, **Figure 1** summarizes the essential thermodynamics. The usual three energy functions relate by

$$F = E - TS \qquad [1]$$

where F denotes the Helmholtz free energy, E internal energy, T temperature, S entropy. A phase transformation occurs when $\Delta F = F^{(2)} - F^{(1)} = 0$, or $\Delta E = T\Delta S$. Often, ΔE is approximately temperature independent. (In a Debye model, ΔE is exactly temperature independent if $\Theta_D^{(2)} = \Theta_D^{(1)}$, where Θ_D denotes the Debye temperature.) Thus, a phase transformation occurs when the $T\Delta S$ term equals the ΔE term. Various *ab initio* methods exist for calculating ΔE. Here, *ab initio* means that no solid-state properties enter the calculation, only atomic properties do. Such calculations yield the basic solid-state cohesive properties: atomic volume, binding energy, compressibility.

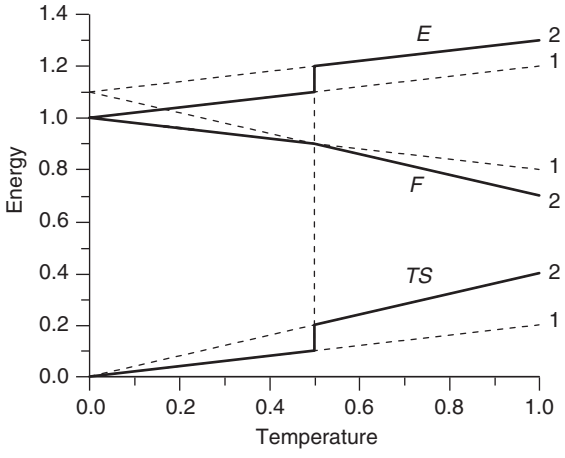

Figure 1 For a first-order phase transformation, schematic temperature dependence of three thermodynamic functions: internal energy E, Helmholtz free energy F, and entropy S. Numerals 1 and 2 denote low-temperature and high-temperature phases.

The Planck–Einstein oscillator model is the simplest model that captures most of the essential features of the thermodynamic functions. (At low temperatures, this model predicts a wrong specific-heat/temperature relationship.) This harmonic-oscillator model yields the following relationships:

$$(E - E_0)/3RT = x/(e^x - 1) \qquad [2]$$

$$S/3R = x/(e^x - 1) - \ln(1 - e^{-x}) \qquad [3]$$

$$(F - E_0)3RT = -\ln(1 - e^{-x}) \qquad [4]$$

$$C_V/3R = x^2 e^x/(e^x - 1)^2 \qquad [5]$$

where R denotes the universal gas constant, emphasizing the relationship between crystalline-solid and perfect-gas-model thermodynamics. The variable x denotes Θ_E/T, Θ_E being the Einstein temperature, where $\Theta_E = (3/4)\Theta_D$. Subscript zero denotes zero-temperature values. **Figure 2** shows the temperature dependence of these four functions. Both the $S(T)$ curve and the $F(T)$ curve show a strong correspondence to the bulk modulus (reciprocal compressibility) temperature dependence. (Cautionary note: Based on a harmonic model, these E–S–F relationships apply

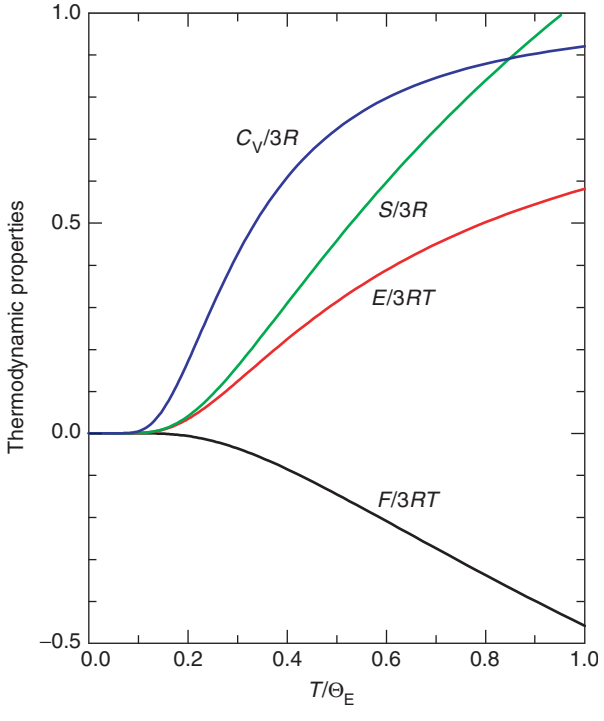

Figure 2 Based on a Planck–Einstein oscillator model, temperature dependence of four thermodynamic functions: specific heat C_V, entropy S, internal energy $E - E_0$, and Helmholtz free energy $F - E_0$. Note that while C_V and S represent absolute values, E and F represent values relative to zero temperature.

at temperatures below the melting temperature, near which strong anharmonic lattice vibrations may occur.) Among these three functions, only entropy vanishes at zero temperature because of the third law of thermodynamics. Some physical properties also vanish at zero temperature, for example, constant-volume specific heat

$$C_V(\approx C_P) = \int_0^T (S/T)\mathrm{d}T = -T(\partial^2 F/\partial T^2)_V \quad [6]$$

thermal expansivity

$$\beta = (1/V)(\mathrm{d}V/\mathrm{d}T)_P = -(1/B_T)(\partial^2 F/\partial T \partial V)_{V,T} \quad [7]$$

bulk-modulus (reciprocal compressibility) temperature derivative

$$(\partial B/\partial T) = \partial/\partial T(\partial^2 F/\partial V^2)_P \quad [8]$$

where B_T denotes the isothermal bulk modulus

$$B_T = (1/V)(\partial^2 F/\partial V^2)_T \quad [9]$$

These properties – B, β, C_V – provide useful probes of the phase transformation. (Caution: changes in these properties at first-order phase transformations differ dramatically from their changes at second-order phase transformations.) Interestingly, all three of these properties interrelate simply with the Gruneisen parameter: $\gamma = B_T\beta V/C_V = B_S\beta V/C_P$.

At a first-order phase transformation, discontinuities occur in the free-energy first derivatives, thus changes in entropy and volume:

$$S = -(\partial F/\partial T)_V \quad [10]$$

$$V = (\partial G/\partial P)_T \quad [11]$$

where $G = F + PV$ denotes the Gibbs free energy.

At low temperatures, tens of degrees, instead of the simple Planck–Einstein model, an improved model is needed, such as Debye's, which yields particularly simple low-temperature expressions for the thermodynamic functions:

$$S = AT^3 \quad [12]$$

$$E = E_0 + (3/4)ST^3 \quad [13]$$

$$F = E_0 - (1/4)ST^3 \quad [14]$$

where $A = 4\pi^4 k_B/5\Theta_D^3$. In simple harmonic models the characteristic temperature Θ_D determines all the thermodynamic functions together with their pressure, temperature, and volume derivatives.

The phase-transformation latent heat is

$$\Delta H = \Delta E + P\Delta V = T\Delta S \quad [15]$$

where $H = E + PV$ denotes enthalpy. Usually, the $P\Delta V$ term is small compared with ΔE. Latent heat is positive, that is, the system absorbs thermal energy during warming through a first-order phase transformation.

Vibration Modes, Phonons, Entropy

The fundamental electronic structure of a homogeneous solid determines all its properties. However, it is not currently possible to perform an *ab initio* electronic-structure calculation at finite temperature with an accuracy adequate to explain structural phase transitions. To simplify the general problem, it is useful to separate the Helmholtz free energy into four parts:

$$F = F_L + F_H + F_E + F_A \quad [16]$$

where F_L denotes the static lattice energy for electrons and ions in position on the lattice and in the ground state at zero temperature, F_H the harmonic phonon free energy, F_E the free energy of thermally excited electronic states, and F_A a lumped term including such anharmonic effects as phonon–phonon and electron–phonon interactions. At higher temperatures, F_H dominates. In metals, at lower temperatures, F_E dominates.

Consider a string of masses (atoms), a distance a apart and connected by springs (bonds) of stiffness c as shown in **Figure 3**. Looking at one of the masses, it is found that stretching the springs to the left or right of that mass produces an acceleration (Newton's force law $f = ma$) such that

$$m\frac{\mathrm{d}^2 u_i}{\mathrm{d}t^2} = -c(u_i - u_{i-1}) + c(u_{i+1} - u_i) \quad [17]$$

Equation [17] can be solved to find that there are many different vibrational frequencies with different wavelengths. For each angular frequency ω, the

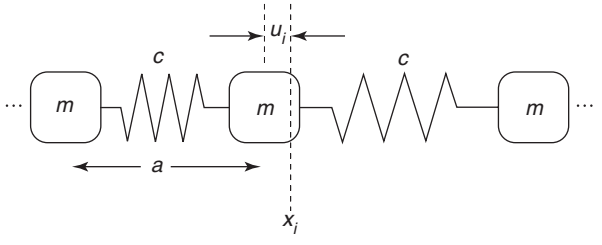

Figure 3 Simple one-dimensional mass/spring lattice.

displacements $u_i(t)$ are

$$u_i(t) = u_{i0}e^{i(kx_i - \omega t)} \quad \text{and} \quad k = \frac{2\pi}{\lambda}$$
$$\text{then } \omega = \sqrt{\frac{2c}{m}} \sin ka = s \sin ka \qquad [18]$$

Here λ denotes wavelength and s sound velocity. Considering that the full $\omega(k)$ dispersion curves describe an ensemble of simple harmonic oscillators, entropy can be computed for each element of the ensemble. For any individual vibration mode, the partition function can be used to compute its entropy. Remembering that the energies of each harmonic oscillator or normal mode i are equally spaced such that $E_i = (n + 1/2)\hbar\omega_i$, the average number of quanta per normal mode (or allowed vibration) is found to be

$$\bar{n}_i = \frac{1}{Z}\sum_{n=0}^{\infty} n \exp[-(n + 1/2)\hbar\omega_t/k_B T] = \frac{1}{e^{\hbar\omega_i/k_B T} - 1}$$
$$\text{If } k_B T \gg \hbar\omega_i \quad \text{then} \quad \bar{n}_i \approx \frac{k_B T}{\hbar\omega_i} \qquad [19]$$

Here the partition function Z is used to compute the expectation value of the quantum number. Similarly, expressions can be obtained for energy $\bar{E}_i$, free energy F_i, and entropy S_i, where

$$\bar{E}_i = \hbar\omega_i(\bar{n}_i + 1/2) \qquad [20]$$

$$F_i = -k_B T \ln Z \quad \text{and} \quad Z = \frac{1}{e^{\hbar\omega_i/2k_B T} - e^{-\hbar\omega_i/2k_B T}} \qquad [21]$$

$$TS_i = \bar{E}_i - F_i. \text{ If } k_B T \gg \hbar\omega_{\max}, \quad \text{then} \quad TS_i \approx k_B T(1 + \ln \bar{n}_i) \qquad [22]$$

where $\omega_{\max}$ denotes the highest frequency in the highest phonon branch. Computing the entropy of the entire system requires a three-dimensional average.

Differences between the phonon specific heat calculated from the full elastic tensor and that obtained by measurements is a key indicator of the importance of electronic and other nonphonon effects. At temperatures $k_B T \gg \Theta_{\max}$, where all the phonon modes populate fully, a different characteristic temperature Θ_0 (average of $\ln(\omega_i)$) is needed where

$$TS \approx 3Nk_B T[1 + \ln(T/\Theta_0)] \qquad [23]$$

Note that Θ_0 does not equal to Θ_D. Equation [23] describes the total vibrational entropy of a solid of N atoms at high temperatures, and can be calculated from the sound speed at all wavelengths and in all directions if optical modes can be neglected.

An Illustration: Plutonium

The simple approach outlined above, especially in the high-temperature limit, can establish quickly whether a theoretical model is sufficiently robust. This is illustrated by considering Pu, a mysterious metal, with at least five zero-pressure stable phases shown in **Figure 4**. The δ' b.c.t. phase is omitted as being thermodynamically unjustified. Electronic-structure calculations predict with reasonable certainty the low-temperature phases, but find that the two higher-temperature phases, f.c.c δ and b.c.c ε, are local energy saddle points and hence unstable.

One should not expect zero-temperature electronic-structure calculations (band-structure) to predict anything about such an elastically soft metal as Pu at elevated temperatures because the entropic contributions to the free energy will be unusually large. Remembering that such calculations assume zero temperature, results are only for the energy, not the free energy. In many other systems where Θ_D or other phonon averages are near or above room temperature (that is, relatively high), the free energy F is expected to include a much smaller fractional contribution from the entropy (see eqns [3] and [14].) In Pu, Θ_D is low because Pu has a very low $C' = (C_{11} - C_{12})/2$ shear modulus and very low bulk modulus $B = (C_{11} + 2C_{12})/3$, so that entropy is expected to play a much stronger role than in other f.c.c. metals. Failure to include the 740 meV/atom entropic contribution to the free energy at 750 K, the lower bound of the f.c.c. phase is doomed to failure in attempting to understand Pu's higher-temperature phase stability. For Pu, very likely, electronic-structure details do not stabilize the high-temperature crystal structures; vibrational entropy does.

Landau Theory

The focus now is on a particular class of group–subgroup materials known as ferroelastic martensites. Ferroelastics are a subclass of materials known as ferroics, which also include ferromagnetic and ferroelectric materials. The term martensite refers to a diffusionless first-order phase transition that can be described in terms of one (or several successive) shear deformation(s) from a parent to a product phase. The transition results in a characteristic lamellar microstructure resulting from transformation twinning or an equivalent lattice-invariant deformation. The morphology and kinetics of the transition are dominated by the strain energy. Ferroelasticity is defined by the existence of two or more stable orientation states of a crystal that correspond to different arrangements of the atoms, but are structurally

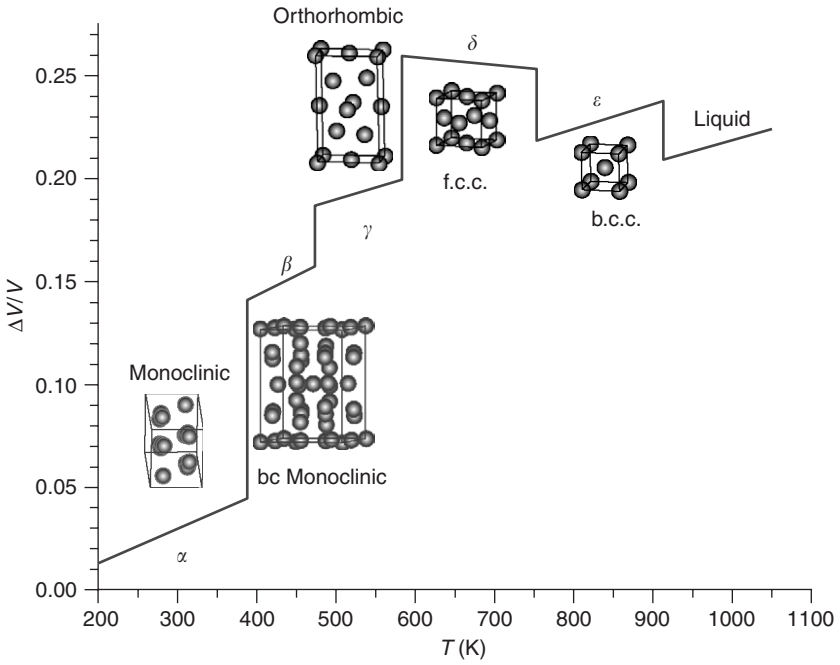

Figure 4 Measured volume changes and crystal structures of Pu at zero pressure.

identical, or enantiomorphous. Also, in the absence of mechanical stress, these orientation states are degenerate in energy.

Salient features of ferroelastic crystals include mechanical hysteresis and mechanically (reversibly) switchable domain patterns. Usually, ferroelasticity occurs as a result of a phase transition from a nonferroelastic high-symmetry "prototype" phase and is associated with the softening of a prototype-phase elastic constant with decreasing temperature or increasing pressure. Because the ferroelastic transition is usually weakly first order, or second order, it can be described to a good approximation by the Landau theory with spontaneous strain as the order parameter. Depending on whether the spontaneous strain, which describes the deviation of a given ferroelastic orientation state from the prototype phase, is the primary or secondary order parameter, the low-symmetry phase is called a proper or an improper ferroelastic, respectively. Although martensites are proper ferroelastics, examples of improper ferroelastics include ferroelectrics and magnetoelastics.

A few materials (either metals or alloy systems) are both martensitic and ferroelastic and show a shape-memory effect. They are characterized by high-mobility twin boundaries and often show precursor structures (such as tweed and modulated phases) above the transition. Furthermore, these materials show a small Bain strain, elastic shear-modulus softening, and a weak-to-moderate first-order transition. Some examples include $In_{(1-x)}Tl_x$, FePd, CuZn, CuAlZn, CuAlNi, AgCd, AuCd, $CuAuZn_2$, NiTi, and NiAl.

In many of these transitions, intracell distortion modes (or shuffles) can couple to the strain either as a primary or secondary order parameter. NiTi and titanium represent two such cases with technological importance. Other examples include actinide alloys: the shape-memory alloy UNb_6 and Ga-stabilized δ-Pu.

Landau-Theory Thermodynamics

To understand the thermodynamics of the phase transformation and the phase diagram, consider the Helmholtz free energy. The Landau free energy (LFE) is a symmetry-allowed polynomial expansion in the order parameter that characterizes the transformation, for example, strain tensor components and/or (intra-unit-cell) shuffle modes. A minimization of the LFE with the order-parameter components leads to conditions that give the phase diagram. Derivatives of the LFE with respect to temperature, pressure, and other relevant thermodynamic variables provide information about the specific heat, entropy, susceptibility, and so on. To study domain walls between different orientational variants (such as twin boundaries) or different shuffle states (such as antiphase boundaries), symmetry-allowed strain-gradient terms or shuffle-gradient terms must be added to the Landau free energy. These gradient terms are called Ginzburg terms and the augmented free energy is

referred to as the Ginzburg–Landau free energy (GLFE). Variation of the GLFE with respect to the order-parameter components leads to Euler–Lagrange equations whose solutions leads to the microstructure.

Symmetry-adapted strains are defined as a function of the Lagrangean strain-tensor components (for cubic symmetry) ε_{ij}:

$$\begin{aligned} e_1 &= \frac{1}{\sqrt{3}}(\varepsilon_{xx}+\varepsilon_{yy}+\varepsilon_{zz}), \quad e_2 = \frac{1}{\sqrt{2}}(\varepsilon_{xx}-\varepsilon_{yy}), \\ e_3 &= \frac{1}{\sqrt{6}}(\varepsilon_{xx}+\varepsilon_{yy}-2\varepsilon_{zz}), \quad e_4 = \varepsilon_{xy}, \\ e_5 &= \varepsilon_{yz}, \quad e_6 = \varepsilon_{xz} \end{aligned} \qquad [24]$$

As an example, the Landau part of the elastic free energy for a cubic-tetragonal transition (for example, in FePd) in terms of the symmetry-adapted strain components is

$$\begin{aligned} F(e_2,e_3) =& \frac{A}{2}(e_2^2+e_3^2)+\frac{B}{3}(e_2^3-3e_2e_3^2) \\ &+\frac{C}{4}(e_2^2+e_3^2)^2+\frac{A_1}{2}e_1^2 \\ &+\frac{A_4}{2}(e_4^2+e_5^2+e_6^2) \end{aligned} \qquad [25]$$

Here, A, B, C denote second-order, third-order, fourth-order elastic constants, respectively; A_1 and A_4 denote bulk and shear moduli; e_2, e_3 denote order-parameter deviatoric-strain components. The non-order-parameter dilatation e_1 and shear strains e_4, e_5, e_6 are included to harmonic order. For domain walls (twinning) and microstructure, this free energy must be augmented by symmetry-allowed gradients of e_2, e_3. Coefficients in the GLFE are determined from a combination of experimental structural (lattice-parameter variation as a function of temperature or pressure), vibrational (e.g., phonon-dispersion curves along different high-symmetry directions), and various thermodynamic quantities (entropy, specific heat, elastic constants, and so on). Lacking sufficient experimental quantities, then electronic-structure calculations and molecular-dynamics simulations (using appropriate atomistic potentials) can provide the relevant information to determine some or all of the GLFE coefficients.

For simple phase transitions (for example, two-dimensional square-to-rectangle, or those involving a one-component order parameter), the GLFE can be written by inspection (from the parent-phase symmetry). However, in general, the GLFE must be determined by group-theoretic means, now readily available for all 230 crystallographic space groups.

Microstructure

For modeling the phase-transformation microstructure, there exist several related approaches: (1) GLFE-based as described above, (2) phase-field model in which strain variables couple in a symmetry-allowed manner to the morphological variables, and (3) sharp-interface models used by applied mathematicians.

Natural-order parameters in the GLFE are strain-tensor components. However, until recent years, researchers simulated the microstructure in a displacement variable by rewriting the free energy in displacement variables. This procedure leads to the microstructure without providing direct physical insight into its evolution. A natural way to gain insight is to work in strain variables only. However, if lattice integrity is maintained during the phase transformation, that is, no dislocation (or topological defect) generation is allowed, then one must obey the St. Venant elastic-compatibility constraints because various strain-tensor components are derived from the displacement field and they are not all independent. This can be achieved by minimizing the free energy with compatibility constraints treated with Lagrangean multipliers. This procedure leads to an anisotropic long-range interaction between the order-parameter strain components. This interaction (or compatibility potential) provides direct insight into the domain-wall orientations and various aspects of the general microstructure.

Mathematically, the elastic compatibility condition on the geometrically linear strain tensor $\overleftrightarrow{e}$ is given by

$$\boldsymbol{\nabla} \times (\boldsymbol{\nabla} \times \overleftrightarrow{e}) = 0 \qquad [26]$$

This represents one two-dimensional equation connecting the three components of the symmetric strain tensor. In three dimensions, two sets of three equations are needed, each connecting the six components of the symmetric strain tensor. For periodic boundary conditions in Fourier space, it becomes an algebraic equation, easily incorporated as a constraint.

The concept of elastic compatibility in a monocrystal can be generalized readily to polycrystals by defining the strain-tensor components in a global reference frame. By adding a stress term (bilinear in strain) to the free energy, one can compute the stress–strain constitutive response in the presence of a microstructure for both monocrystals and polycrystals and compare the recoverable strain upon cycling. Grain rotation and grain boundaries play an important role when polycrystals are subject to external stress. Similarly, calculation of the constitutive response can be generalized to improper ferroelastic materials such as those driven by shuffle modes, ferroelectrics, and magnetoelastics.

Finally, elasticity at the nanoscale can differ from macroscopic continuum elasticity. In this case, one must go beyond the usual elastic-tensor components and include intra-unit-cell deformation modes.

Dynamics and Simulations

The overdamped (or relaxational) dynamics can be used in simulations to obtain equilibrium microstructure: $\dot{e} = -(1/A')\delta(F + F^c)/\delta e$. Here, A' denotes a friction coefficient and F^c a long-range contribution arising from elastic compatibility. However, if the evolution of an initial nonequilibrium structure to the equilibrium state is important, one can use inertial strain dynamics with appropriate dissipation terms included in the free energy. The strain dynamics for the order-parameter strain-tensor components ε_l is given by

$$\rho_0 \ddot{\varepsilon}_l = \frac{c_l^2}{4} \vec{\nabla}^2 \left[\frac{\delta(F + F^c)}{\delta \varepsilon_l} + \frac{\delta(R + R^c)}{\delta \dot{\varepsilon}_l} \right] \qquad [27]$$

where ρ_0 denotes mass density, c_l a symmetry-specific constant, and $R = (A_l'/2)\dot{\varepsilon}_l^2$ denotes Rayleigh dissipation and R^c the contribution to dissipation arising from elastic compatibility. Overdots indicate time derivatives.

Some martensites show strain modulation (or tweed precursors) above the phase transition. These are attributed to disorder such as compositional fluctuations. They can be modeled and simulated by including symmetry-allowed coupling of strain to compositional fluctuations in the free energy. Some martensites exhibit supermodulated phases (for example 5R, 7R, 9R), which can be modeled within the Landau theory in terms of a particular phonon softening (and its harmonics) and coupling to the transformation shear.

Soft Modes

In the Landau phase-transition theory, the free energy F is expanded in some order-parameter Q. In particular, for a second-order (or continuous) transition with transition temperature T_c,

$$F(Q) = \frac{a}{2}(T - T_c)Q^2 + \frac{b}{4}Q^4 \qquad [28]$$

Q can be viewed as the atomic displacement in a mode pattern that takes the crystal from a higher-symmetry phase to a lower-symmetry phase. For small displacements, the Q^2 coefficient is effectively the spring constant for such a mode with frequency ω_0:

$$m\omega_0^2 = a(T - T_c) \qquad [29]$$

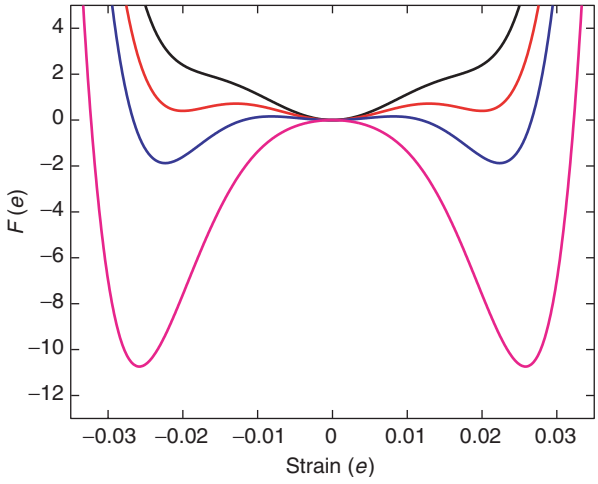

Figure 5 For a first-order phase transition, Helmholtz free energy F as a function of strain e (eqn [30] with representative parameters). The transition occurs at temperature T_c, at which the three energy minima become degenerate. Curves from top to bottom represent decreasing temperatures.

As $T \to T_c$, the phase transition is equivalent to the mode frequency $\omega_0 \to 0$. Thus arises the soft-mode concept, that is, the lattice becomes dynamically unstable; equivalently, the restoring force for the displacement in this mode vanishes. Such instabilities occur in many materials. $SrTiO_3$ provides a paradigm example. Structural phase transitions, martensites in particular, are first-order phase transitions; thus, they do not show complete mode softening at the transition temperature. The free energy in terms of a strain-tensor component is (**Figure 5**)

$$F = \frac{a}{2}(T - T_c)e^2 + \frac{b}{2}e^4 + \frac{c}{6}e^6 \qquad [30]$$

For $b < 0$, there is a discontinuous transition when $F(0) = F(e_0)$, where e_0 denotes the strain at the transition, corresponding to the two symmetric degenerate minima of $F(e)$. Because the curvature of F at $e = 0$ and at $e = e_0$ is upward and finite, the mode frequencies in both phases are nonzero; thus, the lattice is dynamically stable in both phases. However, the lattice is thermodynamically unstable. This instability is assisted by transfer of thermal energy from all other degrees of freedom in the material to move over the barrier between $e = 0$ and $e = e_0$ (**Figure 5**). Both the relevant elastic constant and the anomalous phonon soften only partially. Complete mode softening is not required.

Elastic-Inclusion Theory

The question of elastic-strain energy of an inclusion in a homogeneous matrix is old and general. It

connects not only with diffusionless phase transformations, but with many other familiar solid-state phenomena such as precipitation and twinning. A general inclusion shape poses a practically nonsolvable problem. But mathematical solutions exist for ellipsoid-shape inclusions. Ellipsoids include a surprisingly wide variety of observed cases. They range from thin disks ($c/a \ll 1$), through spheres ($c/a = 1$), to needles ($c/a \gg 1$). In 1957, Eshelby solved the general ellipsoid-inclusion/matrix elastic-energy problem.

Here, the computation of the elastic energy of a thin-disk inclusion in a homogeneous matrix is considered. This geometry corresponds to most martensites, bainites, mechanical twins, and planar precipitates. This geometry can possess zero-strain energy, unlike spheres and needles, which always show finite strain energy. Zero-strain energy arises for certain special disk orientations that lie in a plane called the "habit" plane, the austenite–martensite interface.

The backbone of the computations is the solution for the stress in, and elastic energy of, an arbitrary-orientation inclusion containing a transformation strain (eigenstrain) embedded in an anisotropic matrix. Considering an isotropic inclusion in an isotropic matrix, Eshelby laid the firm foundation for this computation. The stress in an inclusion having the same elastic constants C_{ijkl} as the matrix and with a uniform transformation strain ε_{ij}^T can be expressed as

$$\sigma_{ij} = C_{ijkl}(\varepsilon_{kl} - \varepsilon_{kl}^T) \qquad [31]$$

The total strain is

$$\varepsilon_{kl} = S_{klmn}\varepsilon_{mn}^T \qquad [32]$$

Here, S_{klmn} denotes the well-known (and tabulated) Eshelby tensor, a function only of C_{ijkl} and the inclusion shape. For ellipsoidal inclusions with semiaxes a_i, S_{klmn} can be expressed in terms of a surface integral over the unit sphere:

$$S_{klmn} = \frac{1}{8\pi} C_{pqmn} \int_{-1}^{1} \int_{0}^{2\pi} [G_{kplq}(\bar{\xi}) + G_{lpkq}(\bar{\xi})] \mathrm{d}\Theta \mathrm{d}\zeta_3 \qquad [33]$$

Here, $G_{ijkl}(\bar{\xi}) = \bar{\xi}_k \bar{\xi}_l N_{ij}(\bar{\xi})/D(\bar{\xi})$, $\bar{\xi}_\alpha = \xi_\alpha/a_\alpha$ (no sum on α), $\bar{\varsigma}_1 = (1 - \varsigma_3^{-2})^{1/2} \cos\Theta$, and $\bar{\varsigma}_2 = (1 - \varsigma_3^{-2})^{1/2} \sin\Theta$. Also, $D(\bar{\xi}) = \in_{mnl} K_{m1} K_{n2} K_{l3}$, $N_{ij}(\bar{\xi}) = (1/2) \in_{ijk} K_{lm} K_{ln}$, and $K_{ik}(\bar{\xi}) = C_{ijkl}\xi_j\xi_l$. Equation [33] is valid in a coordinate system aligned with the principal axes of the ellipsoidal inclusion. If the inclusion is spheroidal ($a_1 = a_2$), then its shape can be described solely in terms of the aspect ratio $\alpha = a_3/a_1$. The Eshelby tensor S_{klmn} simplifies considerably in the thin-disk limit ($\alpha \to 0$).

When the inclusion possesses anisotropic elastic constants C_{ijkl}^* that differ from those of the matrix, stress can be calculated by using Eshelby's equivalent-inclusion concept:

$$\sigma_{ij} = C_{ijkl}^*(\varepsilon_{kl} - \varepsilon_{kl}^T) = C_{ijkl}(\varepsilon_{kl} - \varepsilon_{kl}^T - \varepsilon_{kl}^*) \qquad [34]$$

The two terms on the right-hand side constitute an equivalency relationship that enables the inclusion with elastic constants C_{ijkl}^* to be simulated by an inclusion with elastic constants C_{ijkl}, but also containing a fictitious transformation strain ε_{ij}^*. In this case, one obtains ε_{ij} by the relationship $\varepsilon_{kl} = S_{klmn}(\varepsilon_{mn}^T + \varepsilon_{mn}^*)$.

A fundamental result obtained by Eshelby is that for the elastic-strain energy of an inclusion/matrix system:

$$E = -\frac{1}{2}\int_{\mathrm{inc}} \sigma_{ij}\varepsilon_{ij}^T \mathrm{d}V = -\frac{1}{2} V_{\mathrm{inc}} \sigma_{ij}\varepsilon_{ij}^T \qquad [35]$$

Integration is over the inclusion volume V_{inc}. The stress used in eqn [35] is computed either from eqn [31] or [34], depending on whether the inclusion elastic constants differ from the matrix elastic constants.

In general, computing the elastic-strain energy proceeds by first computing ε_{ij}^T based on the inclusion and matrix crystal structures. One then uses eqn [31] or [34] to compute the stress in the transformed inclusion, the stress caused by ε_{ij}^T. One then computes the energy from eqn [35]. One determines the minimum-energy orientation by specifying a habit-plane orientation (hkl), transforming the elastic-stiffness tensor to a coordinate system aligned with (hkl), and doing the energy computation. The preferred habit plane corresponds to that with minimum energy. With the assumption of a thin-disk inclusion, the calculation simplifies. In some cases, one can obtain explicit closed-form solutions.

As an example, the much-studied thin-disk martensite plates formed in an Fe-31Ni alloy is considered, an f.c.c.–b.c.c. transformation where the lattice-invariant deformation is twinning. Wayman's well-known book considered this alloy using both the Wechsler–Lieberman–Read and Bowles–Mackenzie approaches. **Figure 6** shows the main result of the inclusion-theory analysis described here.

After the habit plane is calculated, other phase-transformation features follow more easily. These features include magnitude of the lattice-invariant deformation (such as twinning), magnitude and direction of the macroscopic shape change, and orientation relationship.

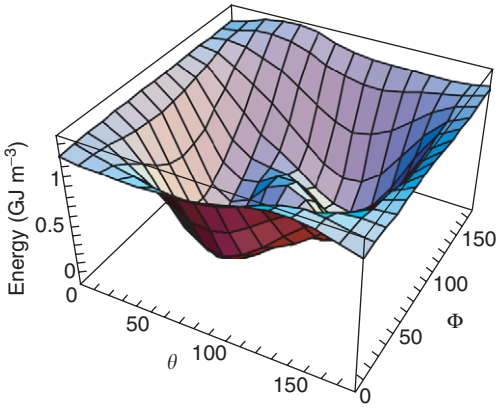

Figure 6 For an Fe-31Ni alloy, calculated elastic-strain energy vs. Θ, Φ rotation angles. The two minima correspond to two habit-plane variants. For this thin-disk-morphology case, the minima represent zero elastic-strain energy. Altogether, 24 variants occur: $(\pm h, \pm k, \pm l)$.

For the thin-disk zero-elastic-strain case, the inclusion theory gives results identical to those predicted by the invariant-plane-strain (i.p.s.) theories. But the inclusion theory allows one to move far beyond the i.p.s. theories. As examples, one can consider the following: (1) different inclusion-matrix elastic constants, (2) anisotropic elastic constants, (3) various shapes (disks, spheres, needles), (4) alternative pure distortions (such as the Bain strain), (5) various twinning systems, (6) anisotropic interface distortions, and (7) applied-stress effects.

Dislocations

V Vitek, University of Pennsylvania, Philadelphia, PA, USA

Introduction

Dislocations are the line defects found in all crystalline materials. They are important in many branches of condensed matter physics, but most significantly they are defects, the motion of which produces plastic flow. The notion of dislocations has two starting points. First, the dislocation was introduced as an elastic singularity by considering the deformation of a body occupying a multiply connected region of space. Second, dislocations were introduced into crystal physics by Taylor, Orowan, and Polanyi in the context of analysis of the large discrepancy between the theoretical and experimental strength of crystals. These two approaches became almost immediately intertwined since the crystal dislocations are sources of long-ranged elastic stresses and strains that can be examined in the continuum framework. In fact, the bulk of the dislocation theory employs the continuum elasticity when analyzing a broad variety of dislocation phenomena encountered in plastically deforming crystals. The most comprehensive monographs devoted to the dislocation theory are books of Friedel, Nabarro, and Hirth and Lothe. An excellent simple introduction to this topic is the book by Hull and Bacon.

In this article, the crystallographic concept of dislocations is explained, the relation between dislocation movement and plastic strain is shown, the concept of the force acting on a dislocation due to externally applied stress is introduced, and the most important aspects of dislocation energetics and properties related to the long-ranged elastic fields are summarized. Then the dislocation nucleation and multiplication which is the most important ingredient

in understanding of the plastic deformation, and brittle-to-ductile transition is discussed. Finally, the properties that relate to the atomic structure of materials are paid attention to; in particular, the significance of dislocation dissociation and the dislocation core structure is elucidated.

Principal Characteristics of Dislocations

A dislocation line in a continuum is obtained by cutting the material along any surface that terminates on this line, giving the two cut surfaces a relative displacement and joining them again together. Suppose the cut is made along a planar surface terminating in a straight line, and that this line and the normal to the surface define an orthonormal coordinate system. Fixed vector translations of the cut surfaces parallel, respectively, to the three axes of this system define the three basic types of dislocation. When the displacement is parallel to the line, the result is a screw dislocation. The other two translations, both perpendicular to the line, produce (equivalent) edge dislocations; if the displacement is perpendicular to the cut, a material needs to be removed or added to rejoin the two surfaces. (Three more types of "dislocation," in which the two parts of the continuum on each side of the cut are given a relative rotation before rejoining, can be introduced. The line singularities of this type are called disclinations. These line defects play important role, for example, in liquid crystals but they are not the subjects of this article.) A straight dislocation of general mixed character is obtained when the fixed translation of the cut surfaces has components both parallel and perpendicular to the line. A curved dislocation in a plane or in three dimensions may be introduced in the same way with the surface of the cut (generally nonplanar) terminating on the curve. Since the dislocation line has been introduced as the edge of a surface, it can either terminate on external surfaces or internally by closing on itself and forming a loop. Alternatively, it may meet other dislocation lines at points where at least three dislocations meet and total sum of their Burgers vectors is zero; such points are called dislocation nodes. However, the dislocation line can never end abruptly inside the body.

The principal characteristics of a dislocation are the relative displacement of the two cut surfaces and the line terminating the cut. The former defines the Burgers vector of the dislocation and the latter the dislocation direction, the surface over which the cut has been made has no significance. In the continuum, the dislocation is defined mathematically by the relation $\oint \mathrm{d}\boldsymbol{u} = \boldsymbol{b}$, where $\boldsymbol{u}$ is the displacement vector, $\boldsymbol{b}$ the Burgers vector, and the integral is along any circuit encompassing the dislocation line; for circuits not encircling the dislocation $\oint \mathrm{d}\boldsymbol{u} = 0$. This relation is then the main boundary condition when determining within the elasticity theory, the displacement, strain, and stress fields associated with a dislocation.

Dislocations defined in the continuum have exact analogs in crystals. If the same virtual process of introducing a dislocation is employed in crystals then if the cut surfaces are to rejoin without introducing a fault along the cut, the translation vector, that is, the Burgers vector, must be a repeat vector of the Bravais lattice. A formal definition of the Burgers vector, analogous to the above path integral, invokes the concept of corresponding paths in the real crystal and a defect-free reference crystal. If a closed circuit, consisting of the same number of equivalent atoms to atom steps, is made either in the real or the reference crystal, the corresponding path in the other crystal will not, in general, be closed, and the closure failure is defined as the net Burgers vector of the dislocation lines that thread through the circuit in the real crystal.

The density of dislocations present in a body of material, ρ, is defined as the total length of dislocations per unit volume (dimension m^{-2}). The plastic strain, $\varepsilon^{\mathrm{pl}}$, which is produced if these dislocations move, on average, a distance $\bar{d}$, is $\varepsilon^{\mathrm{pl}} = \rho b \bar{d}$, where b is the magnitude of the Burgers vector of the dislocations.

Elastic Fields and Energy Associated with Dislocations

In a continuum the dislocation defined above is a line singularity invoking a long-ranged elastic field. The details of the evaluation of the strain and stress fields in the framework of linear isotropic and anisotropic elasticity can be found, for example, in the books by Nabanna and co-workers. In the case of straight dislocations their stress and strain fields decrease as d^{-1}, where d is the distance from the dislocation line. These fields have a complex angular dependence for a fixed distance from the dislocation line. Formally, both the stress and strain diverge at the dislocation line but physically this means that there is a region, centered at the dislocation line, in which the linear elasticity does not apply. This region, the dimensions of which are of the order of the lattice spacing in crystalline materials, is called the dislocation core and it can only be fully accounted for within atomic level models of dislocations. This is discussed in more detail later in this article. The stress and strain fields of a dislocation loop decrease

far away from its center as d^{-2}, similarly as the field of a dislocation dipole formed by two dislocations of opposite Burgers vectors.

The elastic energy associated with the long-range stress and strain fields of a straight dislocation is

$$E_{\mathrm{el}}^{\mathrm{sl}} = \frac{Kb^2}{4\pi}\ln\left(\frac{R}{r_{\mathrm{o}}}\right)$$

where R is the radius of a cylinder centered on the dislocation line and r_{o} is the core radius. K is a constant depending on the elastic moduli and orientation of the dislocation line. (In the isotropic case, $K = [\mu/(1-\nu)](1-\nu\cos^2\theta)$ where μ is the shear modulus, ν is the Poisson ratio, and θ is the angle between the dislocation line and the Burgers vector.) This energy diverges as $R \to \infty$ and thus depends on the size of the crystal, but it is generally assumed that when a material contains many dislocations of opposite signs, their stress fields cancel at about half of the average dislocation separation and R is identified with this distance. The elastic energy of dislocation loops is always finite and depends logarithmically on their size. For example, in an elastically isotropic medium, the energy of a glissile planar circular loop of radius r (the Burgers vector lies in the plane of the loop) is

$$E_{\mathrm{el}}^{\mathrm{loop}} = 2\pi r\frac{\mu b^2}{4\pi(1-\upsilon)}\left[\ln\left(\frac{8r}{r_{\mathrm{o}}}\right) - 1\right]$$

It is noteworthy that this energy can be interpreted as the energy per unit length of the dislocation times the length of the dislocation loop $2\pi r$. This suggests that the increase of the energy of a dislocation ΔE, associated with an increase of its length Δl, can be written as $\Delta E = \tau\Delta l$, where τ is the energy of the dislocation per unit length. In general, τ will be different for different dislocation shapes, but when the curvature of the dislocation line is small, and this concept is usually restricted to this situation, τ is well approximated as the energy per unit length of a straight dislocation. It is generally dependent on the orientation of the dislocation line, but in many analyses it has been approximated by a constant of the order of $\mu b^2/2$. Since $\tau = \Delta E/\Delta l$, it also has the meaning of a line tension, in analogy with the behavior of a taut string, and this approach to evaluation of the energy change with the change in dislocation length is called the line tension approximation. (Since the energy of the dislocation depends on the angle θ between the dislocation line and its Burgers vector, a more rigorous expression for the line tension is $\tau = E + \partial^2 E/\partial\theta^2$, analogously as in the case of anisotropic surface tension. This is not essential when using isotropic elasticity when τ is always positive and $\tau \approx E$ is a good approximation. However, in highly anisotropic crystals the more rigorously determined line tension may even become negative for certain orientations. In this case, the dislocations decrease their energy by increasing their length and changing orientation. This has been observed, for example, in β-brass.)

Forces on Dislocations and Interaction between Dislocations

According to the Colonnetti principle there is no elastic interaction between internal and external stresses, that is, the response of a medium to external loading is the same whether it is self-stressed or not. However, if the source of internal stresses is displaced, the external stress may be doing work. This is what happens in the case of a dislocation. Its motion induces the relative displacement of two parts of the body by the Burgers vector within the region swept by the dislocation. One may consider an element of the dislocation line $\Delta\boldsymbol{l}$ that is displaced by a vector $\Delta\boldsymbol{r}$ in a body subject to an external stress σ_{ij}^{e}. The area within which the material has been displaced by the Burgers vector is $\Delta S = |\Delta\boldsymbol{r} \times \Delta\boldsymbol{l}|$ and the unit vector normal to this surface has components $n_j = \varepsilon_{jlk}\Delta r_l \Delta l_k/\Delta S$ (Einstein summation convention is used). When displacing the material the external stress produced work $\Delta W = -\sigma_{ij}^{\mathrm{e}} n_j b_i \Delta S = -\sigma_{ij}^{\mathrm{e}} b_i \varepsilon_{jlk}\Delta r_l \Delta l_k$. This can be expressed alternatively as $\Delta W = F_l \Delta r_l |\Delta\boldsymbol{l}|$ with

$$F_l = \varepsilon_{ljk}\sigma_{ij}^{\mathrm{e}} b_i \varsigma_k$$

where ς_k is the k component of the unit vector parallel to the dislocation line. This expression can be interpreted such that F_l is the l component of the force, called the Peach–Koehler force, by which the stress σ_{ij}^{e} acts on the dislocation per unit length. The physical meaning of this force is that $F_l \Delta r_l$ is the work done when the dislocation of unit length is displaced by $\Delta\boldsymbol{r}$, produced by the stress σ_{ij}^{e} that is doing work when the material is being displaced by the Burgers vector in the area swept by the dislocation. For example, in the case of an edge dislocation parallel to the axis x_3 and the Burgers vector b parallel to the axis x_1, $F_1 = \sigma_{12}^{\mathrm{e}} b$ and $F_2 = -\sigma_{11}^{\mathrm{e}} b$. The component F_1 and thus the shear stress σ_{12}^{e} drive the glide in the slip plane x_1x_3, and the component F_2 and thus the tensile stress σ_{11}^{e} drive the climb perpendicular to the slip plane.

When using the Peach–Koehler formula, it is immaterial whether σ_{ij}^{e} is an externally imposed stress field or the stress arising from another internal source of stresses. Thus, if σ_{ij}^{e} is identified with the

stress associated with another dislocation, this formula determines the force between the two dislocations. The interaction energy between two dislocations marked, respectively (1) and (2), separated by a distance r, can then be evaluated as the work done when the dislocation (2) is brought in from a distance R, against the force $F^{(1-2)}$ exerted on dislocation (2) by the dislocation (1). This force obviously decreases as $1/r$. The interaction energy per unit length of the dislocations is then $E^{\text{int}}_{(1-2)} = -\int_R^r F^{(1-2)}\,\mathrm{d}r$. This interaction energy, proportional to $\ln(R/r)$, could also be evaluated as the part of the elastic energy corresponding to the cross terms between the stress and strain fields of dislocations (1) and (2), respectively. Similarly, elastic interaction between dislocations and other defects inducing internal stresses, such as inclusions, cracks, stress inducing point defects, is determined.

Dislocation Multiplication

Consider first the homogeneous nucleation of a circular glissile dislocation loop. The energy of such loop as a function of its radius is given above. The work done by the shear stress σ parallel to the Burgers vector acting in the plane of the loop during the growth of the loop is $\sigma b\pi r^2$. If the loop is to form and grow spontaneously, this work has to exceed its elastic energy already at the stage when the loop radius is only slightly larger than the radius of the core. Consider, for example, that this has to occur when $r = 2r_o$. The condition for spontaneous formation of the loops is then $\sigma = \mu b/(4\pi(1-\upsilon)r_o)\,(\ln 16 - 1)$. Since $r_o \approx b$, the stress needed for the dislocation nucleation is (taking $\nu = 1/3$) $\sigma \approx 0.2\mu$, which is of the same order of magnitude as the ideal shear strength of materials. This is a very high stress, and in most metallic, covalent, and even in ionic materials the plastic flow and intensive dislocation multiplication occur at stresses three to five orders of magnitude lower. Thus, homogeneous nucleation of individual dislocation loops cannot be the usual mechanism of dislocation nucleation. However, a collective homogeneous nucleation at finite temperatures by the mechanism akin to the Kosterlitz–Thouless transition is a possibility albeit not yet unequivocally proven.

An alternative heterogeneous mechanism, known as the Frank–Read source, requires stresses much lower than the ideal shear strength of the material. This process of generation of dislocations is shown schematically in **Figure 1**. A dislocation lying in a glide plane is pinned at two points (marked by bold dots), for example owing to intersection with dislocations in different glide planes. If these points are fixed, the dislocation can bow out under the action of a shear stress and adopt the successive configurations shown in (**Figure 1b–1f**). Eventually the two segments of opposite sign meet (**Figure 1e**), mutually annihilate, and a closed dislocation loop is produced (**Figure 1f**). A line segment between the pinning points remains available to repeat the whole process. The bowing out of the dislocation is opposed by the line tension of the dislocation that pulls the dislocation back by the force (per unit length) equal to $\tau\kappa$, where κ is the curvature of the line. In the isotropic case, the curvature is the largest when the dislocation forms the half-circle of radius d, where $2d$ is the separation of the pinning points (**Figure 1c**). Thus,

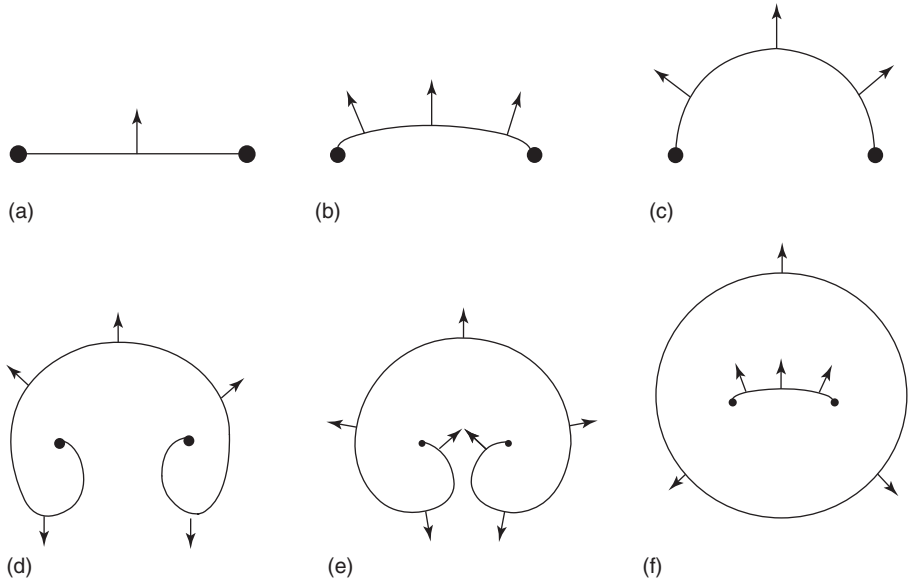

Figure 1 Successive stages in the operation of a double-needed Frank–Read dislocation source.

the condition for the onset of the operation of the Frank–Read source is $\sigma b = \tau/d$. Taking $\tau = \mu b^2/2$, the stress needed for the operation of the source is $\sigma = \mu b/2d$. Since d may be three or four orders of magnitude larger than b, this leads to a stress that is several orders of magnitude lower than the ideal shear strength of the material, in agreement with experimental observations. Hence, Frank–Read-type dislocation sources, the geometrical configurations of which may be more complex than that in **Figure 1**, represent the principal mechanism of dislocation multiplication during deformation. Nevertheless, homogeneous dislocation nucleation may still occur in the case where no sources are available. However, the stresses then reach the level of the ideal shear strength. This occurs, for example, in nanoindentation.

Dislocation Dissociation and Stacking Faults

A vital characteristic of dislocations in crystalline materials is their possible dissociation into partial dislocations with Burgers vectors smaller than the lattice vector. Such dislocation splitting can occur if the displacements corresponding to the Burgers vectors of the partials lead to the formation of metastable planar faults which then connect the partials. The reason for the splitting is, of course, the decrease of the dislocation energy when it is divided into dislocations with smaller Burgers vectors. For example, if the dislocation with the Burgers vector $\boldsymbol{b}$ splits into two partials with Burgers vectors $\boldsymbol{b}_1$ and $\boldsymbol{b}_2$, such that $\boldsymbol{b} = \boldsymbol{b}_1 + \boldsymbol{b}_2$ and the angle between the vectors $\boldsymbol{b}_1$ and $\boldsymbol{b}_2$ is acute, then $b^2 > b_1^2 + b_2^2$. Since the elastic energy of a dislocation is proportional to the square of its Burgers vector, the self-energy of the total dislocation is larger than that of two partials. This is the basis of the so-called b^2 criterion for estimation whether a dissociation is energetically favorable. However, to determine the energy balance precisely, one has to consider also the interaction energy between partials and the energy of the planar fault formed between them. A simple example is splitting of $1/2\langle 1\,1\,0\rangle$ dislocations into two Shockley partials with the Burgers vectors $1/6\langle 1\,1\,2\rangle$ on $\{1\,1\,1\}$ planes. The planar fault formed by the $1/6\langle 1\,1\,2\rangle$ displacement is an intrinsic stacking fault. The stacking of $\{1\,1\,1\}$ planes in an ideal face-centered cubic (f.c.c.) lattice can be described as a repeat sequence …ABCABCABC… and the $1/6\langle 1\,1\,2\rangle$ displacement between layers B and C produces the stacking sequence …ABCAB|ABCABC…; this corresponds to the stacking fault marked by |.

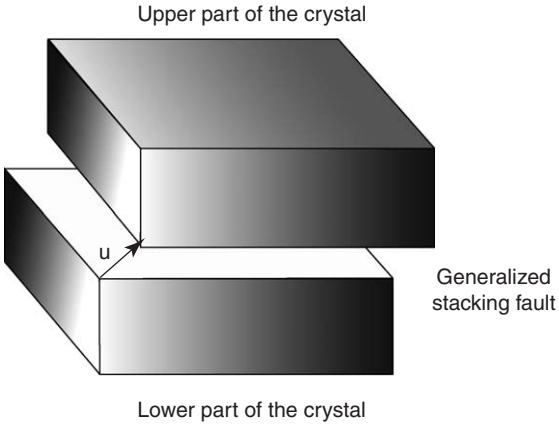

Figure 2 Formation of the generalized stacking fault.

In general, stacking-fault-like defects can be very conveniently analyzed using the notion of γ-surfaces (Stacking-fault-like defects include not only stacking faults but also other planar defects such as antiphase domain boundaries and complex stacking faults encountered in ordered alloys and compounds). To introduce the idea of γ-surfaces, a generalized stacking fault is defined first: imagine that the crystal is cut along a given crystallographic plane and the upper part displaced with respect to the lower part by a vector $\boldsymbol{u}$, parallel to the plane of the cut, as shown in **Figure 2**. The fault created in this way is called the "generalized stacking fault" and it is not, in general, metastable. The energy of such fault, $\gamma(\boldsymbol{u})$, can be evaluated using atomistic methods and/or density-functional theory based approaches; relaxation perpendicular to the fault has to be carried in such calculations. Repeating this procedure for various vectors $\boldsymbol{u}$ within the repeat cell of the given crystal plane, an energy–displacement surface can be constructed, commonly called the γ-surface. The local minima on this surface determine the displacement vectors of all possible metastable stacking-fault-like defects, and the values of γ at these minima are the energies of these faults.

Symmetry arguments can be utilized to assess the general shape of these surfaces. If a mirror plane of the perfect lattice perpendicular to the plane of the generalized stacking fault passes through the point corresponding to a displacement $\boldsymbol{u}$, the first derivative of the γ-surface along the normal to this mirror plane vanishes owing to the mirror symmetry. This implies that the γ-surface will possess extrema (minima, maxima, or inflexions) for those displacements, for which there are at least two nonparallel mirror planes of the perfect lattice perpendicular to the fault. Whether any of these extrema corresponds to minima, and thus to metastable faults, can often be ascertained by considering the change in the

nearest neighbor configuration produced by the corresponding displacement. Hence, the symmetry-dictated metastable stacking-fault-like defects can be ascertained on a crystal plane by analyzing its symmetry. Such faults are then common to all materials with a given crystal structure. The intrinsic stacking faults in f.c.c. crystals are symmetry-dictated since three mirror planes of the {1 0 1} type pass through the points that correspond to the displacements $1/6\langle 1\,1\,2\rangle$. However, other minima than those associated with symmetry-dictated extrema may exist in any particular material. These cannot be anticipated on crystallographic grounds, and their existence depends on the details of atomic interactions and can only be revealed by calculations of the γ-surface.

The primary significance of the dislocation dissociation is that it determines uniquely the slip planes, identified with the planes of splitting and corresponding stacking-fault-like defects, and, consequently, the operative slip systems. The fact that {1 1 1} planes are the slip planes in f.c.c. materials is a typical example. As discussed above, metastable stacking faults always exist on these planes and since their energy is in many cases relatively low, dislocations split in {1 1 1} planes and are confined to them.

Dislocation Cores

It has already been mentioned above that every crystal dislocation possesses a core region in which the linear elasticity does not apply and the structure and properties of the core can only be fully understood when the atomic structure is adequately accounted for. When a dislocation glides, its core undergoes changes that are the source of an intrinsic lattice friction. This friction is periodic with the period of the crystallographic direction in which the dislocation moves. The applied stress needed to overcome this friction at 0 K temperature is called the Peierls stress and the corresponding periodic energy barrier is called the Peierls barrier.

In general, the dislocation core structure can be described in terms of the relative displacements of atoms in the core region. These displacements are usually not distributed isotropically but are confined to certain crystallographic planes. Two distinct types of dislocation cores have been found, depending on the mode of the distribution of significant atomic displacements. When the core displacements are confined to a single crystallographic plane, the core is planar (a more complex planar core, called zonal, may be spread into several parallel crystallographic planes of the same type). Dislocations with such cores usually glide easily in the planes of the core spreading and their Peierls stress is commonly low. In contrast, if the core displacements spread into several nonparallel planes of the zone of the dislocation line, the core is nonplanar, extended spatially. The glide planes of dislocations with such cores are often not defined uniquely, their Peierls stress is high, and their glide well below the melting temperature is enabled by thermal activation over the Peierls barriers.

A planar dislocation core can be regarded as a continuous distribution of dislocations in the plane of the core spreading. The reason for the core extension is the decrease of the dislocation energy when it is redistributed into dislocations with smaller Burgers vectors. Such approach to the analysis of the dislocation core is the basis of the Peierls–Nabarro model. If the coordinate system in the plane of the core spreading is chosen such that the axes x_1 and x_2 are parallel and perpendicular to the dislocation line, respectively, the corresponding density of continuous distribution of dislocations has two components: $\rho_\alpha = \partial u_\alpha/\partial x_2 \ (\alpha = 1, 2)$, where u_α is the α-component of the displacement vector $\boldsymbol{u}$ in the x_1, x_2 plane. Owing to the dislocation distribution, the displacement $\boldsymbol{u}$ increases gradually in the direction x_2 from zero to the Burgers vector so that $\int_{-\infty}^{+\infty} \rho_\alpha \, dx_2 = b_\alpha$, where b_α is the corresponding component of the Burgers vector. In the continuum approximation, the elastic energy of such dislocation distribution can be expressed as the interaction energy of the dislocation distribution with itself:

$$E_{\mathrm{el}} = \sum_{\alpha,\beta=1}^{2} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} K_{\alpha\beta}\rho_\alpha\rho_\beta \ln(|x_2 - x_2'|)\, dx_2\, dx_2'$$

where $K_{\alpha\beta}$ are constants depending on the elastic moduli and orientation of the dislocation line. On the atomic scale, the displacement across the plane of the core spreading causes a disregistry that leads to an energy increase. The displacement $\boldsymbol{u}$ produces locally a generalized stacking fault, and in the local approximation the energy associated with the disregistry can be approximated as

$$E_\gamma = \int_{-\infty}^{+\infty} \gamma(\boldsymbol{u})\, dx_2$$

where $\gamma(\boldsymbol{u})$ is the energy of the γ-surface for the displacement $\boldsymbol{u}$. The continuous distribution of dislocations describing the core structure is then found by the functional minimization of the total energy $E_{\mathrm{tot}} = E_{\mathrm{el}} + E_\gamma$ with respect to the displacement $\boldsymbol{u}$. When the displacement vector is always parallel to the Burgers vector, the Euler equation corresponding to the condition $\delta E_{\mathrm{tot}} = 0$ leads to the well-known

Peierls equation

$$K\int_{-\infty}^{+\infty}\frac{1}{x_2-x_2'}\frac{\mathrm{d}u}{\mathrm{d}x_2'}\,\mathrm{d}x_2'=-\frac{\partial\gamma}{\partial u}$$

where u is the displacement in the direction of the Burgers vector and K is a constant depending on the elastic moduli and orientation of the dislocation line; in the isotropic elasticity K is given earlier. In the original Peierls–Nabarro model, $\partial\gamma/\partial u$ was taken as a sinusoidal function and the Peierls equation then has an analytical solution

$$u=\frac{b}{2\pi}\tan^{-1}\left(\frac{x_2}{\zeta}\right)$$

where 2ζ measures the width of the core (for $-\zeta<x_2<\zeta$, the disregistry is greater than half its maximum value) and it is proportional to the separation of the crystal planes into which the core spreads. The Peierls stress evaluated in the framework of this model is

$$\tau_{\mathrm{P}}=\frac{2\mu}{\alpha}\exp(-4\pi\zeta/b)$$

where μ is the shear modulus and α a constant of the order of 1. This stress is very small even when the core is very narrow; for example, if $\zeta=b$, $\tau_{\mathrm{P}}\approx10^{-5}\mu$. This is a general characteristic of the planar cores and this is the reason why in f.c.c. metals, in which dislocations possess planar cores, the Peierls stress is practically negligible.

The nonplanar cores can be divided into two classes: crosslip and climb cores. In the former case, the core displacements lie in the planes of core spreading, whereas in the latter case, they possess components perpendicular to the planes of spreading. Climb cores are less common and are usually formed at high temperatures by a climb process. The best-known example of the crosslip core is the core of the 1/2 $\langle1\,1\,1\rangle$ screw dislocations in body-centered cubic (b.c.c.) metals that is spread into three $\{1\,1\,0\}$ planes intersecting along the $\langle1\,1\,1\rangle$ direction. **Figure 3** shows two alternate structures of such core. The core shown in **Figure 3a** is spread asymmetrically into the $(\bar{1}\,0\,1)$, $(0\,\bar{1}\,1)$, and $(\bar{1}\,1\,0)$ planes that belong to the [1 1 1] zone and is not invariant with respect to the $[1\,0\,\bar{1}]$ diad and another energetically equivalent configuration, related by this symmetry, operation exists. The core in **Figure 3b** is invariant with respect to the $[1\,0\,\bar{1}]$ diad. These core structures were found by atomistic calculations employing (1) central-force many-body potentials and (2) a tight binding and/or density-functional theory based approach, respectively. Atomistic calculations employing appropriate descriptions of atomic interactions are the principal tool for investigations of such cores since direct observations are often outside the limits of experimental techniques. The example presented here shows that the structure of such cores is not determined solely by the crystal structure but may vary from material to material even when they crystallize in the same structure. The Peierls stress of dislocations with these cores is commonly several orders of magnitude higher than that of dislocations with planar cores. Furthermore, the movement of the dislocations is frequently affected not just by the shear

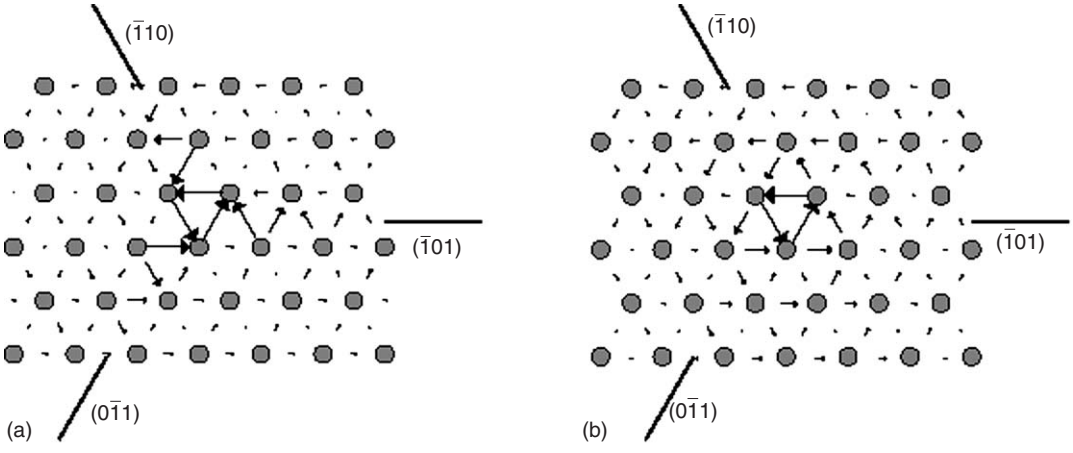

Figure 3 Two alternate core structures of the 1/2 [1 1 1] screw dislocation depicted using differential displacement maps. The atomic arrangement is shown in the projection perpendicular to the direction of the dislocation line ([1 1 1]) and circles represent atoms within one period. The [1 1 1] (screw) component of the relative displacement of the neighboring atoms produced by the dislocation is represented by an arrow between them. The length of the arrows is proportional to the magnitude of these components. The arrows, which indicate out-of-plane displacements, are always drawn along the line connecting neighboring atoms and their length is normalized such that it is equal to the separation of these atoms in the projection when the magnitude of their relative displacement is equal to |1/6 [1 1 1]|.

stress parallel to the Burgers vector in the slip plane but by other stress components. Thus, the deformation behavior of materials with nonplanar dislocation cores may be very complex, often displaying unusual orientation dependencies and breakdown of the Schmid law. The nonplanar dislocation cores are the more common the more complex is the crystal structure, and thus these cores are more prevalent than planar cores. In this respect, f.c.c. materials (and also some hexagonal close-packed (h.c.p.) materials with basal slip) in which the dislocations possess planar cores and, consequently, the Peierls stress is very low, are a special case rather than a prototype for more complex structures.

Additional complex features of the dislocation core structures arise in covalent crystals where the breaking and/or readjustment of the bonds in the core region may be responsible for a high lattice friction stress, and in ionic solids where the cores can be charged which then strongly affects the dislocation mobility. Such dislocation cores affect not only the plastic behavior but also electronic and/or optical properties of covalently bonded semiconductors and ionically bonded ceramic materials.

Disorder and Localization Theory

E N Economou, University of Crete, Greece

Introduction

A plane electronic wave, $\exp(i\boldsymbol{k}\cdot\boldsymbol{r})$, impinging upon a local potential, $v(|\boldsymbol{r}-\boldsymbol{r}_n|)$, centered at $\boldsymbol{r}_n$, is scattered, thus giving rise to a spherical wave of the form $f(\theta,\phi)\exp(i\boldsymbol{k}\cdot\boldsymbol{r})/r$ as $r\to\infty$. The scattering amplitude, f, is related to the differential $d\sigma/d\Omega(=|f(\theta,\phi)|^2)$, and the total scattering cross section, σ. The total scattering cross section, $\sigma=\int|f|^2\,d\Omega$, gives essentially the part of the area of the incoming wave front intercepted by the scattering potential. For transport properties, the relevant cross section is $\sigma_t=\int(1-\cos\theta)|f|^2\,d\Omega$.

An electron propagating within a solid or liquid is subject to many local scattering potentials stemming from the atoms comprising the solid or liquid, and giving rise to a total scattering potential $V(\boldsymbol{r})=\sum_n v(|\boldsymbol{r}-\boldsymbol{r}_n|)$. The response of electrons to $V(\boldsymbol{r})$ is of central importance in understanding and controlling the mechanical, electrical, magnetic, and optical properties of materials.

Identical and periodically placed scatterers allow a systematic constructive interference of the scattered waves, which to a great extent, compensates the effects of the scattering. As a result, a periodic potential, $V(\boldsymbol{r})$, produces plane-wave-like solutions, called Bloch waves, of the form $u_{kj}(\boldsymbol{r})\exp[i(\boldsymbol{k}\cdot\boldsymbol{r}-\omega_{kj}t)]$, associated with bands of allowed values of ω_{kj}; u_{kj} is a periodic function of $\boldsymbol{r}$ with the same period as $V(\boldsymbol{r})$. Gaps in the spectrum also appear because of systematic destructive interference (another effect of

periodicity) and/or well-separated atomic or molecular levels giving rise to nonoverlapping bands.

"Classical" Treatment of Disorder

In actual solids, there are always static, chemical and, structural deviations from periodicity, located randomly within the solid; in other words, there is always disorder. The thermal vibrations of atoms (or ions), although dynamical in nature, can be treated for fast processes and high temperatures as additional sources of static disorder. However, at low temperatures, lattice vibrations and other dynamical processes lead to inelastic scatterings, which are clearly distinct from the elastic scatterings considered up to now; these inelastic scatterings are responsible for an energy uncertainty, ΔE, which in turn defines an inelastic dephasing time $\tau_\phi \sim \hbar/\Delta E$; for $t \gtrsim \tau_\phi$, the phase is randomized.

Disorder is crucial in determining important transport properties, such as electrical and thermal conductivities, magnetoresistances, photoconductivities, and metal–insulator transitions. Under normal conditions, the main role of disorder is to change the propagation of electrons (or more generally, of whatever carriers) from ballistic to diffusive; the latter involves a new characteristic quantity, the so-called transport mean free path, l, which is connected to the diffusion length $L_D = (D\tau)^{1/2}$ by the relation $L_D = l/\sqrt{d}$. D is the diffusion coefficient, $\tau = l/v$, v is the carrier velocity, and d is the space dimensionality. The transport mean free path, for low concentration, $n_s = N_s/V$, of scatterers is related to the transport cross section σ_{ti} of each scatterer by the relation

$$\frac{1}{l} = \frac{1}{V}\sum_{i=1}^{N_s} \sigma_{ti} \qquad [1]$$

which means that over a length l, the N_s scatterers within the volume $V = Sl$ will intercept the whole cross section, S, of the incoming wave (i.e., $S = \sum_i \sigma_{ti}$).

The summation of σ_{ti}s in eqn [1] implies that interference effects have been omitted; thus the term "classical" in the title of this subsection. Actually, a scattered wave from one scatterer can be scattered again by other scatterers; this is especially true when the σ_{ti}s are large and their concentration, n_s, is high. All these single and multiple scattered waves can, in principle, interfere with one another, possibly modifying the basic result in eqn [1]. The argument in support of eqn [1] is that constructive and destructive interference more or less cancel each other as a result of the interfering waves having random phase differences (associated with the random positions and phase shifts of the scatterers).

Weak Disorder and the Role of Interferences

Consider an electron initially ($t = 0$) at the point $\boldsymbol{r}$. The probability density amplitude, $A(t)$, to again find the electron at $\boldsymbol{r}$, after time t, is given by $A(t) = \sum_v A_v(t)$, where the sum is over all directed path integrals, $A_v = \exp[(i/\hbar)\int_0^t L(\boldsymbol{r}_v(t'))\,dt']$, starting and ending at $\boldsymbol{r}$. The probability density, $dP(t)/d^3r$, to find the electron at $\boldsymbol{r}$ after time t is $dP/d^3r = |A(t)|^2 = \sum_v |A_v(t)|^2 + \sum_{v\neq\mu} A_v(t)A_\mu^*(t)$. Omitting the last double sum on the basis of random phases is equivalent to the approximation leading to eqn [1]. However, not all terms with $\mu \neq v$ have random phases; indeed, for each path $\mu = \bar{v}$, where $\bar{v}$ is the same as path v but run in the opposite direction, $A_\mu = A_{\bar{v}} = A_v$ (the last equality stems from time-reversal symmetry), and consequently $\sum_{v\neq\mu} A_v A_\mu^* = \sum_v A_v A_{\bar{v}}^* + \sum_{\mu\neq v,\bar{v}} A_v A_\mu^*$. Thus, making the reasonable assumption that $\sum_{\mu\neq v,\bar{v}} A_v A_\mu^*$ is really zero because of random phases, one may come to the conclusion that dP/d^3r is twice as big as the classical diffusion would predict, since $\sum_v A_v A_{\bar{v}}^* = \sum_v |A_v|^2$. Actually, $dP(t)/d^3r$ is less than twice as large because the equality $A_{\bar{v}} = A_v$ is not valid for very long paths, whose length far exceeds the inelastic dephasing length $L_\phi \equiv (D\tau_\phi)^{1/2}$; for such long paths, repeated inelastic scattering destroys the phase equality of $A_{\bar{v}}$ and A_v. In any case, the conclusion is that interference effects make quantum diffusion slower than classical diffusion, and lead to a decrease of the diffusion coefficient and the electrical conductivity. This decrease is proportional to the integral $\int dt \sum_v A_v A_{\bar{v}}^*$.

The latter can be estimated by taking into account that the paths which contribute are inside a tube of cross section λ^2 (or λ^{d-1} for a d-dimensional system, where λ is the wavelength) around the classical trajectory. Furthermore, the probability of returning is directly related to the probability of self-intersection of this orbital tube. Within time dt, the wave would move by $v\,dt$ and would sweep a volume $dV = \lambda^{d-1} v\,dt$; hence, the probability of self-intersection during the time interval dt, after time t has elapsed, is equal to the ratio of the volume $dV = \lambda^{d-1} v\,dt$ over the total volume swept up to t; the latter is of the order of $L_D^d = (Dt)^{d/2}$. Hence, the probability of self-intersection at any time between $t = \tau$ and $t = \tau_\phi$ is proportional to $\int_\tau^{\tau_\phi} dt \lambda^{d-1} v/(Dt)^{d/2}$. The elastic collision time, $\tau = l/v$, has been set as the lower limit because, for $t \ll \tau$, the motion is ballistic and the probability of self-intersection is zero; the inelastic dephasing time τ_ϕ is the upper limit since for $t \gtrsim \tau_\phi$,

the phase equality of A_v and $A_{\bar{v}}$ is lost. Notice that at high temperatures, where $\tau_\phi \approx \tau$, the quantum corrections are negligible. On the other hand, for low temperatures, where $\tau_\phi \gg \tau$, there is an appreciable increase in the probability, p, of returning to the initial point and consequently an appreciable correction, $\delta\sigma = \sigma - \sigma_0$, to the classical conductivity, σ_0, as a result of interference effects:

$$\delta\sigma \sim -p \sim 1 - \left(\frac{\tau_\phi}{\tau}\right)^{1/2} \approx -\left(\frac{\tau_\phi}{\tau}\right)^{1/2} = -\frac{L_\phi}{L_D} \text{ (1D systems)} \quad [2a]$$

$$\delta\sigma \sim -p \sim -\frac{\lambda}{L_D}\ln\frac{\tau_\phi}{\tau} = -\frac{2\lambda}{L_D}\ln\frac{L_\phi}{L_D} \text{ (2D systems)} \quad [2b]$$

$$\delta\sigma \sim -p \sim -\frac{\lambda^2}{L_D^2}\left[1 - \left(\frac{\tau}{\tau_\phi}\right)^{1/2}\right] = -\frac{\lambda^2}{L_D^2}\left(1 - \frac{L_D}{L_\phi}\right) \approx 0 \text{ (3D systems)} \quad [2c]$$

The above formulas are valid when the disorder is weak, so that $|\delta\sigma|$ is considerably smaller than σ_0, since otherwise, one could end up with negative conductivity $\sigma = \sigma_0 + \delta\sigma$. The condition $|\delta\sigma| \ll \sigma_0$ implies that $\lambda \ll L_D$, which in turn means that under the present conditions, $\delta\sigma$ is negligible for 3D systems. On the other hand, for 1D and 2D systems, $\delta\sigma$ can become appreciable when $L_\phi \gg L_D$; furthermore, since τ_ϕ is proportional to T^{-1} for 2D and $T^{-2/3}$ for 1D systems, and for very low temperatures, T, it follows that σ for $d = 1$ and $d = 2$ decreases with decreasing T. Such a T-dependence suggests an insulating behavior as $T \to 0$K, and consequently, the nonexistence of one- and two-dimensional metallic behavior. In other words, the possibility is raised that in 1D and 2D systems, as $L_\phi \to \infty$, the conductivity may become zero, no matter how weak the disorder is. The possibility of $\sigma \to 0$ as $L_\phi \to \infty$ may be realized even in 3D systems when the disorder is strong enough, so that $\lambda \gtrsim L_D$. This question is taken up again in the next subsection, in which formulas [2a]–[2c] are generalized to the strong disorder case.

This subsection is concluded by pointing out that the presence of a magnetic field, $\boldsymbol{B}$, breaks the time-reversal symmetry, and as a result, breaks the equality $A_v = A_{\bar{v}}$, and consequently, reduces the magnitude of $|\delta\sigma|$, and thus, tends to restore the classical behavior. Actually, the magnetic field adds a term $q\boldsymbol{A}\cdot\boldsymbol{v}$ to the Lagrangian, where q is the charge of carriers ($-e$ for electrons), and $\boldsymbol{A}$ is the vector potential such that $\boldsymbol{B} = \nabla \times \boldsymbol{A}$. So the closed path integrals, A_v, $A_{\bar{v}}$, in the presence of $\boldsymbol{B}$, acquire an extra phase, that is $A_v = A_{v0}\exp(i\phi_v)$, $A_{\bar{v}} = A_{v0}\exp(-i\phi_v)$, where $\phi_v = q\Phi_v/\hbar$, and Φ_v is the magnetic flux through the closed path. As a result $A_v A_{\bar{v}}^* + A_{\bar{v}} A_{\bar{v}}^* = 2|A_{v0}|^2\cos(2\phi_v)$, instead of $2|A_{v0}|^2$ as in the case $\boldsymbol{B} = 0$. This implies a periodic variation of the conductance as a function of the applied magnetic field if Φ_v is a constant independent of v. Indeed, this phenomenon has been observed in cylindrical tubes of cross section S with very thin walls, and with the magnetic field parallel to the axis of the tube. The configuration is such that $\Phi_v = nBS$, where $n = 1, 2, \ldots$. Because L_ϕ^2 is not much larger than S, the dominant contribution comes from $n = 1$ and the conductance, G, varies as $\delta G \sim \cos(2eBS/\hbar)$; this is the so-called $h/2e$ Aharonov–Bohm effect. In ring configurations, such as in **Figure 1c**, where the conduction paths are between diametrically opposite points, the variation of the conductance, δG, is proportional to $\cos(eBS/\hbar)$; this is the so-called h/e Aharonov–Bohm effect. Notice that the Aharonov–Bohm effects can provide an operational definition of the length L_ϕ, since for lengths $L \gtrsim L_\phi$, the characteristic conductance oscillations gradually disappear. In thin wires, such as in **Figures 1d** and **1e**, the oscillatory magnetic field dependence of the conductance is more complicated as shown in **Figure 2**. It must be pointed out that these oscillations are reproducible (for the same system) and that their size is universal and $\sim e^2/\pi\hbar$. Furthermore, the conductance in the system of **Figure 1d** is different from that in the system of **Figure 1e**, in spite of the classical current carrying paths being identical in the two configurations; this shows the wave nature of electronic propagation, the non-negligible role of interference effects associated with the existence of the ring in **Figure 1e**, and the nonlocal nature of the current–electric field relation.

Disorder, Density of States, and Wave Functions

Three-Dimensional systems

In **Figure 3a**, the density of states (DOS) of a band associated with the s-level of identical atoms placed periodically in a simple cubic lattice is shown; the bandwidth is $12|V_2|$, where V_2 is the matrix element transferring electrons between two neighboring atoms. Disorder is introduced (**Figures 3b–3d**) by assuming that the s-levels of atoms are independent random variables possessing a Gaussian distribution of standard deviation w. The effects of the disorder are the following: (1) The analytical singularities

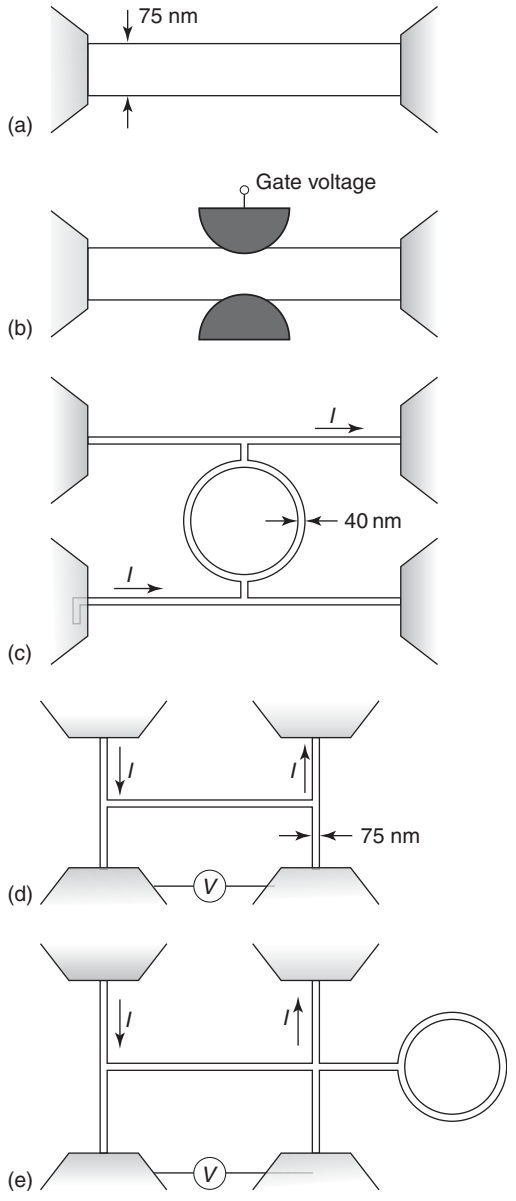

Figure 1 Various mesoscopic wires. (a) Simple quantum wire. (b) The gate voltage, V_G, creates a restriction which gradually, by changing V_G, leads to the 1D limit. (c) Four probe ring configuration which splits the current to the two semicircular paths. (d, e) Four probe configurations differing by the presence of the ring in case (e). The cross sections of the wires are $\sim 10^3\,\text{nm}^2$, and their length $\sim \mu\text{m}$.

shown in **Figure 3a** disappear. (2) The bandwidth increases as the band edges $\pm E_B^{(0)}$ move to new positions $\pm E_B$, where $E_B - E_B^{(0)} = c_1 w^2/|V_2|$ ($c_1 \approx 0.25$ in the present case). (3) Besides this widening of the band, tails in the DOS, $\rho(E)$, appear which are of exponential nature, $\rho(E) \sim \exp(-|E|/E_0)$ for $E_B \lesssim |E|$, where $E_0 = c_2 w^2/|V_2|$ ($c_2 \approx 0.12$ in the present case); these tails give rise to tails in the optical absorption of semiconductors for $\hbar\omega$ less than the gap (Urbach tails). (4) Two characteristic energies, $\pm E_c$, termed mobility edges, appear at which the nature of the eigenstates changes from propagating (or extended) to nonpropagating (or localized, shaded regions in **Figures 3b–3d**). The localized eigenstates are trapped either around a cluster of atoms or around a single atom whose *s*-energy level is much different than the average. For low disorder ($w \lesssim 2.5|V_2|$), the mobility edges follow the band edges closely, $|E_B| - |E_c| \sim w^4/|V_2|^3$. As the disorder increases, the mobility edges start moving toward the center of the band, and eventually they merge together making all eigenstates of the band localized; this is known as the Anderson transition (in the present case, this transition occurs when $w \simeq 6.2|V_2|$).

For weak disorders (e.g., **Figure 3b**), the states near the center of the band are quasi-Bloch characterized by the band index, j, the wave vector, $\boldsymbol{k}$, and the mean free path, which is connected to the phase $\phi(\boldsymbol{r})$ of the eigenfunction through the relation $\langle \exp[i\phi(\boldsymbol{r}) - i\phi(0)] \rangle = \exp(-r/2l')$, where the symbol $\langle\ \rangle$ denotes the average value over all random variables. The mean free path l' satisfies eqn [1] with σ_i instead of σ_{ti}. As one moves from the center of the band toward the mobility edges, the amplitude of the eigenstates develops ever increasing fluctuations, both in magnitude and spatial extent up to a maximum length, ξ; for distances, r, such that $a \ll r \lesssim \xi$, the eigenfunctions exhibit a statistically self-similar, fractal, behavior (a is the lattice spacing). As $|E| \to |E_c|$, ξ blows up, $\xi \to A/(|E_c| - |E|)^\gamma$, where γ has been estimated to be 1.58 (in the absence of a magnetic field) and 1.43 (in the presence of a magnetic field). On the localized sides of the spectrum, the eigenfunctions, $\psi(\boldsymbol{r})$, decay exponentially on the average, that is, $\langle |\psi(\boldsymbol{r})| \rangle_g \sim \exp(-r/L_c)$, as $r \to \infty$, where $\langle |\psi(\boldsymbol{r})| \rangle_g \equiv \exp[\langle \ln|\psi(\boldsymbol{r})| \rangle]$, and L_c is the so-called localization length. For distances, r, such that $a \ll r \lesssim L_c$, the eigenfunctions exhibit fluctuations of statistically self-similar, fractal nature. As $|E| \to |E_c|$, L_c blows up: $L_c \to A'/(|E| - |E_c|)^\gamma$.

The contribution of a band to the conductivity, $\sigma(T)$, is given by $\sigma(T) = \int dE \sigma(E,T)(-\partial f/\partial E)$, where $f(E)$ is the Fermi–Dirac distribution, $\sigma(E,T)$ is proportional to the DOS $\rho(E)$ and the mobility $\mu(E)$ at E. The conductivity $\sigma(E,T)$ for a finite cube of length L at $T = 0\,\text{K}$ is given by

$$\sigma(E,0) = \frac{e^2}{\hbar}\left(\frac{0.066}{\xi} + \frac{A_1}{L}\right) \qquad [3]$$

for E in the extended region (A_1 is ~ 0.05), $\sigma(E,0) \sim \exp(-2L/L_c)$ in the localized regime, and for $L_c \ll L$. Actually, L, besides the length of the specimen, can be of any number of upper cut-off lengths such as L_ϕ or $R_B = (\hbar c/eB)^{1/2}$, the cyclotron

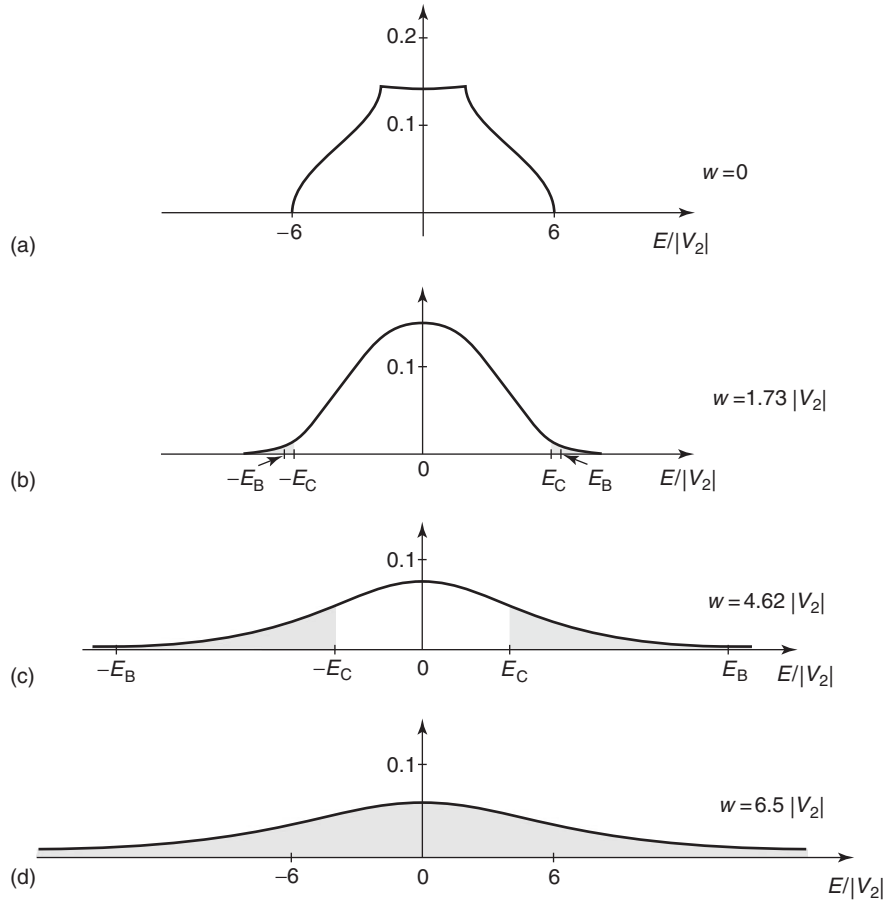

Figure 3 The density of states (DOS) of a band associated with the *s*-level of atoms placed periodically in a simple cubic lattice. The *s*-level of each atom is an independent random variable of Gaussian probability distribution with zero-average value and standard deviation equal to w, which goes from zero (case (a)) to $6.5|V_2|$ (case (d)). The bandwidth at $w = 0$ is $12|V_2|$. Shaded regions correspond to localized eigenstates.

radius in the presence of a magnetic field, or $L_\omega = (D/\omega)^{1/2}$, the diffusion length in the presence of an AC field of frequency ω, etc. In the presence of all these upper cut-off lengths, L in the above formulas should be replaced by an effective length, $\tilde{L}$, probably of the form $\tilde{L}^{-2} = c_1 L^{-2} + c_2 L_\phi^{-2} + c_3 L_\omega^{-2} + c_4 R_B^{-2} + \cdots$, where the weights c_i are of the order of unity.

Two-Dimensional Systems

2D systems, such as very thin films or electrons trapped at the interface of Si/SiO_2 or $GaAs/Al_xGa_{1-x}As$,

are borderline as far as localization properties are concerned. In the absence of magnetic forces, all eigenstates are localized, no matter how weak the disorder is (exceptions do exist). In the presence of magnetic forces, the situation is qualitatively similar to that shown in **Figure 3b–3d** with an extremely narrow region of extended states at the center of the band. This picture has been employed to interpret the so-called integral quantum hall effect (IQHE), where as the Fermi level moves in the localized regime, the Hall resistance does not change until it enters the extended regime and a rather abrupt step is exhibited.

In the absence of magnetic forces, the localization length at E is related to the mean free path $l(E) : L_c(E) \simeq 2.7l(E)\exp[S(E)l(E)/4]$, where $S(E)$ is the length of the line in $\boldsymbol{k}$-space satisfying the equation $E_k = E$. The conductivity $\sigma(E,0)$ is given by an approximate interpolation formula involving $\tilde{L}$ and L_c as well as a length $r_0 \simeq c'l$. In the limit $\tilde{L} \ll L_c$,

$$\sigma \approx \sigma_0 - \frac{e^2}{\pi^2\hbar}\ln\frac{\tilde{L}}{r_0} \qquad [4]$$

while for $L_c \ll \tilde{L}$, $\sigma = (2\sigma_0\tilde{L}/L_c)\exp(-2\tilde{L}/L_c)$. Equation [4] is similar to eqn [2b] and is known as a weak localization correction. For $\tilde{L} \simeq R_B$, eqn [4] gives $\Delta\sigma \equiv \sigma(B) - \sigma(0) = (e^2/2\pi^2\hbar)\ln[1 + (eL_\phi^2 B/1.78\hbar c)]$, that is a negative magnetoresistance, $\Delta R/R \simeq -\Delta\sigma/\sigma$, as shown in **Figure 4**. For $L \simeq L_\phi \sim T^{-1/2}$, the above formulas for the conductivity show that $\sigma \to 0$ as $T \to 0$ K. Notice, however, that electron–electron interactions produce a similar temperature dependence. Nevertheless, recent experiments at very low temperatures, in very clean interfaces $GaAs/Al_xGa_{1-x}As$ or Si/SiO_2, have shown that $\sigma(T)$ stops decreasing and starts increasing with decreasing temperatures.

One-Dimensional and Quasi-One-Dimensional Systems

For 1D systems, such as the one shown in **Figure 1b**, all eigenstates are localized, no matter how small the disorder is (exceptions do exist); the localization length is proportional to the mean free path, $L_c = cl$, where the coefficient c equals 4 for not-so-strong a disorder. The conductivity, σ, is given by $\sigma = (e^2\tilde{L}/\pi\hbar)/[\exp(2\tilde{L}/L_c) - 1]$. Thus in the limit $\tilde{L} \ll L_c$, $\sigma = (e^2L_c/2\pi\hbar) - (e^2\tilde{L}/2\pi\hbar)$; the first term gives the classical result $\sigma = 2e^2l/\pi\hbar$, since $L_c = 4l$, while the second is linear in $\tilde{L}$ as in eqn [2a]. Taking into account that the conductance G in 1D equals to $\sigma/\tilde{L}$ and that the geometrically averaged transmission coefficient, T, equals to $\exp(-2\tilde{L}/L_c)$, the formula for σ can be recast as $G = (e^2/\pi\hbar)T/(1 - T)$. However, a direct calculation of G gives $G = (e^2/\pi\hbar)T$. This discrepancy is due to the fact that the first formula gives the conductance of the wire *per se* without taking into account the two contact resistances $2R_c = \pi\hbar/e^2$, and it requires a four-probe measurement for its determination; on the contrary, the result $G = (e^2/\pi\hbar)T$ is the outcome of a two-probe measurement and it includes the contact resistances, so that $1/G = 2R_c + R_w = (\pi\hbar/e^2) + (\pi\hbar/e^2)[(1 - T)/T] = (\pi\hbar/e^2)/T$. In the presence of M coupled parallel to 1D channels in the limit where $\tilde{L} \ll l$ and $T \simeq 1$, the two-probe measurement will give $G = (e^2/\pi\hbar)M$ in agreement with the experimental results in **Figure 5**. The importance of the above formulas lies in their

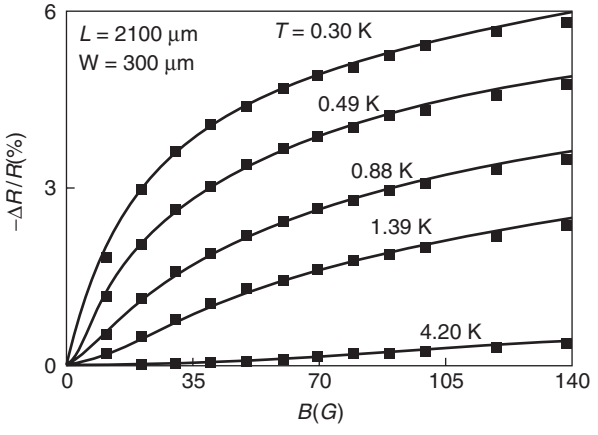

Figure 4 Experimental data (solid squares) and theoretical results (continuous lines) for the relative magnetoresistance $-\Delta R/R$, in a two-dimensional sample of electronic concentration $n = 1.6 \times 10^{11}$ cm^{-2} and mobility $\mu = 27\,000$ cm^2 V^{-1} s^{-1} (Reproduced from Choi KK *et al.* (1987) Dephasing time and one-dimensional localization of two-dimensional electrons in $GaAs/Al_xGa_1 - xAs$ heterostructures. *Physical Review B* 36: 7751.)

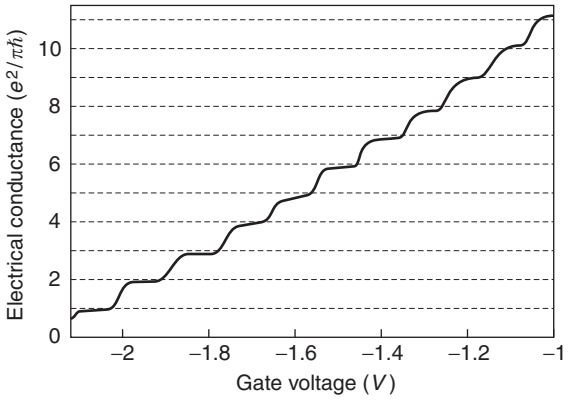

Figure 5 The electrical conductance of the configuration shown in Figure 1b vs. the gate voltage, V_g. The step-like dependence on V_g according to the formula $G = (e^2/\pi\hbar)M$, $M = 1, 2, \ldots$, is shown. For $V_g < -2V$, the 1D limit $M = 1$ has been reached (Reproduced from van Wees BJ *et al.* (1988) Quantized conductance of point contacts in a two-dimensional electron gas. *Physical Review Letters* 60: 848.)

capability to be generalized to a multiterminal system; each terminal, i, is in contact with a reservoir at electrochemical potential $\mu_i = -|e|V_i$, and feeds the system with a net current I_i

$$I_i = \frac{e^2}{\pi\hbar}\sum_i T_{i\leftarrow j}(V_i - V_j) \qquad [5]$$

Equation [5] is very useful in treating many mesoscopic systems, such as quantum dots exhibiting the phenomenon Coulomb blockade.

Justifying the Localization Picture

Several theoretical/numerical methods have been employed to obtain the various localization quantities such as L_c, ξ, E_c, $\delta\sigma$, etc.

Level Statistics

Localized eigenstates belonging to neighboring energy levels of a very large system are, in general, far away from one another and hence, they have negligible overlap and as a result, negligible level repulsion. On the contrary, extended eigenstates always overlap, and thus always exhibit level repulsion. Hence, the probability distribution of the separation of two consecutive energy levels (which can be obtained numerically) is quite different for localized and extended eigenstates. This difference is an efficient way for determining regions of localized and extended states.

Transfer Matrix Techniques

A transfer matrix, t_{12}, propagates the general solution of the wave equation from point x_1 to point x_2 along 1D and quasi-1D systems. By multiplying transfer matrices, $t_{0L} = t_{12}t_{23}\ldots t_{NL}$, the solution at one end $(x = 0)$ can be connected to the solution at the other end $(x = L)$. For disordered quasi-1D systems, the eigenvalues of t_{0L} come in pairs $(\mu_i, \bar{\mu}_i)$, such that $\mu_i \to \exp(L/L_{ci})$ and $\bar{\mu}_i \to \exp(-L/L_{ci})$ as $L \to \infty$, where $\pm L_{ci}^{-1}$ are the so-called Lyapunov exponents. The longest L_{ci}, L_c, determines the transmission coefficient, T, of the quasi-1D system of length L as $T = (-2L/L_c)$. By considering quasi-1D strips of M coupled channels arranged in a plane, or wires of square cross section with M^2 channels, $L_c(M)$ can be determined numerically; by employing a scaling property, the limit $M \to \infty$ can be taken, which determines L_c for the 2D case ($L_c = \lim L_c(M)$ as $M \to \infty$), and both L_c (when $L_c(M)$ converges as $M \to \infty$) and ξ (when $L_c(M) \sim M^2/\xi$) for the 3D case.

Scaling Approach

In the model considered in **Figure 3**, the only relevant parameter is the dimensionless ratio $w/|V_2|$. Then a cluster of p neighboring atoms of length $L_1 = p^{1/d}a$ (where a is the lattice spacing) is examined and one may attempt to define a single dimensionless ratio, Q_1, which would play for the cluster the same role as $w/|V_2|$ plays for each atom. By repeating the rescaling n times, where n eventually approaches infinity, one finds that $Q_n = (\hbar/e^2)G$, where G is the conductance of a d-dimensional "cube" of linear dimension $L = p^{n/d}a$. Since $Q_n \equiv Q(L)$ is the only relevant parameter, the occurrence or not of localization depends on whether $Q(L)$ tends to infinity or to zero respectively, as $L \to \infty$. To find this limit, the logarithmic derivative $\beta = \mathrm{d}\ln Q/\mathrm{d}\ln L$, which depends on the parameter Q, is defined. In the limit $Q \to \infty$, the classical behavior is approached, which gives that $Q \sim G \sim L^{d-2}$; hence $\beta \to d - 2$, that is, negative for $d < 2$ and positive for $d > 2$. Assuming that β is a monotonically increasing function of Q, one can conclude that in the limit $L \to \infty$, $G \to 0$ for $d < 2$. For $d > 2$, $G \to \infty$ as $L \to \infty$ (in the region $\beta > 0$), and $G \to 0$ as $L \to \infty$ (in the region $\beta < 0$).

Potential Well Analogy

More sophisticated approximate analytical approaches for the calculation of σ permit one, under certain conditions, to map the localization question to that of an effective d-dimensional potential well (in the absence of magnetic forces) of depth $V_0(E) \sim [\sigma_0(E)]^{-1}[l(E)]^{-d}$ and linear extent $a \sim l(E)$. If this effective potential well sustains a bound state of decay length $L_c(E)$, then the states at E are localized with localization length equal to $L_c(E)$. If the effective potential well exhibits a resonance in the cross section at $E_r(E)$, then the eigenstates at E are extended with a length ξ given by $E_r(E) = \hbar^2/2m\xi^2(E)$, $\xi \gg l$. Using the fact that a potential well, no matter how shallow, always sustains a bound state for $d \leqslant 2$, while it must exceed a critical value of V_0a^2 to sustain a bound state for $d = 3$, the basic picture presented before is recaptured, before including the expressions for the localization length in 1D and 2D systems. Furthermore, by employing the critical value of V_0a^2, one finds that localized states appear in 3D systems, when the product $lk \lesssim 0.85$ or $l/\lambda \lesssim 0.14$; this is the so-called Ioffe–Regel criterion.

Classical Wave Localization

In addition to the work of electronic localization presented above, the question of classical localization has received attention. This interest is due partly to the fact that classical waves, such as electromagnetic or acoustic/elastic, being subject to destructive

interference and hence to the possibility of localization, can serve as a model system for testing the theory of Anderson localization of electrons experimentally in a clean way, without the complication of strong inelastic scattering and other effects of electron–electron and electron–phonon interactions. On the other hand, it is harder to localize classical waves, mainly due to the fact that at low frequencies, the effects of disorder tend to be wiped out, whereas electrons at low energies are trapped very effectively, even by a weak random potential.

To see this, consider the simple scalar wave equation, $\nabla^2 u + (\omega^2/c^2)u = 0$, where the velocity, $c(\boldsymbol{r})$, in the medium varies from point to point between a maximum, c_M, and a minimum, c_m, value. Compare this equation with Schrödinger's equation in the presence of a potential $V(\boldsymbol{r})$ which varies between V_M and V_m. The two equations are mathematically equivalent if one makes the following correspondences:

$$\frac{\omega^2}{c_M^2} \leftrightarrow \frac{2m}{\hbar^2}(E - V_M) \qquad [6a]$$

$$\omega^2\left(\frac{1}{c_M^2} - \frac{1}{c(\boldsymbol{r})^2}\right) \leftrightarrow \frac{2m}{\hbar^2}[V(\boldsymbol{r}) - V_M] \qquad [6b]$$

Equation [6a] implies that classical waves correspond to electronic waves, but for energy above the maximum value of the potential; eqn [6b] shows that the scattering producing fluctuations in the classical wave case are multiplied by ω^2, and thus are fully ineffective for low frequencies. The conclusion is that classical waves can only be localized, if at all, at intermediate frequencies. The analogies between the classical and quantum problems indeed lead to many cross fertilizations, since solutions obtained in one field can be carried over to the other. However, considerable care has to be exercised in transforming the results of the theory of localization of electrons to the case of classical waves. The most important difference is that for classical waves, the equivalent of the particle number is not conserved. The quantity conserved here is the energy, leading to a diffusion behavior of the energy density. Another difference is that the scattering potential is frequency dependent as shown in eqn [6]. As a consequence, the energy transport velocity entering the diffusion coefficient for a strongly disordered system may be appreciably renormalized, and, as a result, diffusion coefficients can be quite small even far from the localization transition. In particular, the low values experimentally obtained for the diffusion coefficient, $D = v_E l/3$, are caused by extremely small values of the energy transport velocity, v_E, and not necessarily by the small values of l, which would signify strong localization. It is well understood that low values of v_E for classical waves are due to the Mie resonances of the scatterers. Near resonances, a lot of energy is temporarily stored inside the dielectric scatterer or, equivalently, the wave spends a lot of time (dwell time) inside the dielectric scatterer.

The outstanding problem in classical wave localization is to find the optimal conditions for its realization. It has been suggested that an intermediate frequency window of localized states separates the low-frequency extended states, characterized by Rayleigh scattering, from the high-frequency extended states, described by geometric optics. Theories based on weak scattering limit and on the coherent potential approximation (CPA) predict frequency intervals within which localization should be observed. These predictions are based on extrapolation of results obtained in the weak disorder regime. Wiersma *et al.*, in 1997, reported experiments at the near-infrared in GaAs powders, where the transmission coefficient, T, was measured in the extended, critical, and localized regimes. In the critical regime, T should vary with the inverse of the square of the sample thickness and in the localized regime, it should vary exponentially with the thickness. F Scheffold *et al.*, in 1999, argued that the results can be interpreted on the basis of the classical diffusion theory if absorption is included. One way to separate the effects of absorption and localization is to measure fluctuations of the transmission T, in addition to more conventional transport properties. This can be done easier at microwave frequencies, where one can measure both the amplitude and the phase of the electric field.

To facilitate the solution of the classical wave localization problem, it was proposed to construct first a periodic medium which, hopefully, will produce a spectral gap, and then by a disordering process, to create tails of localized states in this gap. The first part of this proposal produced much more than what one was looking for initially: it led to the creation of the so-called photonic (and phononic) band gap (PBG) artificial materials, and to the emergence of a new technological field.

Disordered Magnetic Systems

P Nordblad, Uppsala University, Uppsala, Sweden

Introduction

Disordered magnetic systems, when defined widely, comprises the whole field of applied magnetic materials – ranging from the extremely soft permalloy to the hardest permanent magnet as well as the physics of model systems of strongly disordered magnetic materials, spin glasses, and random-field Ising systems.

Magnetic ordering requires that the electron system forms local or itinerant magnetic moments and that there is interaction between these moments. Such interacting magnetic moments will eventually, as the temperature is lowered, become correlated and in certain cases form a long-ranged ordered phase at a critical temperature. The simplest magnetic order in crystalline systems arises when the leading interaction is ferromagnetic and there is only one type of magnetic ions in the material. The low-temperature phase then shows a regular pattern with the magnetic moments all aligned in parallel. Magnetic disorder in an ideal system of this type is enforced by thermal energy, and above the critical ordering temperature, a random paramagnetic phase forms. However, intrinsic quenched disorder, due to lattice dislocations, impurities, and other defects, always appears in a real magnetic system, also in the magnetically ordered phase. This kind of disorder is the key to the macroscopic magnetic properties of an ordered ferromagnet. The disorder and the microstructure of the system then determine if a weakly anisotropic magnet becomes a good soft ferromagnet or if a strongly anisotropic system attains applicable permanent magnetic properties. It is thus disorder, on nano- and micrometer length scales, that governs the quality of applied magnetic materials, whether soft or hard.

Models

A random distribution of the atomic magnetic elements in alloys and compounds introduces strong disorder and deviations from a regular interaction pattern. The interaction between the magnetic constituents becomes random in size and, in some cases, also in sign. This causes the appearance of new magnetic phases and phenomena. An interacting magnetic Ising system can be described by its spin Hamiltonian

$$H = -\sum_{i,j} J_{i,j} S_i S_j \qquad [1]$$

where $J_{i,j}$ is the exchange interaction strength between spin S_i and spin S_j: spins that in an Ising system point either up or down. A random-exchange ferromagnet is described if all $J_{i,j}$ are positive but of different magnitude, and a spin glass is described if the sign of $J_{i,j}$ varies but the mean value is zero. Equation [1] can be used to describe systems of any dimensionality and any range of interaction. Another important class of disordered magnetic Ising systems is the random field system

$$H = -\sum_{i,j} J_{i,j} S_i S_j + \sum_i h_i S_i \qquad [2]$$

where $J_{i,j}$ are positive interaction constants and h_i is a local field of random size and sign with zero mean that acts on spin number S_i. This system does not have an experimental realization, but a dilute Ising antiferromagnet in an applied homogeneous magnetic field has been shown to describe an equivalent problem:

$$H = -\sum_{i,j} J \varepsilon_i \varepsilon_j S_i S_j + H_a \sum_i \varepsilon_i S_i \qquad [3]$$

where J is a negative exchange interaction constant, and ε_i is 1 if site i is occupied by a magnetic ion, and 0 if the site contains a nonmagnetic element. H_a represents a homogeneous applied magnetic field, and the equation shows that the random field is proportional to this field and thus arbitrarily tunable.

Spin Glasses

An alloy with magnetic ions randomly dispersed in a nonmagnetic host metal forms an archetypical spin glass material at low magnetic ion concentrations. The interaction in the system is random in size and sign due to the Ruderman–Kittel–Kasaya–Yoshida (RKKY) nature of the interaction in a metal. The RKKY-interaction is mediated by the conduction electrons, and is oscillatory in size and decays with the cube of the distance between the magnetic constituents. The signature and the initial cause of interest in this type of dilute magnetic alloys was the observation of a cusp in the in-phase component of the AC-susceptibility by Cannella and Mydosh in the early 1970s. This finding was a clear indication of a phase transition to a new kind of magnetic order, and this phase, later named the spin glass phase, has been found to have surprising magnetic properties and has created a theoretical problem of much greater complexity than what only the occurrence of a cusp in the AC susceptibility promises. Spin glasses provide a useful introduction to the physics of strongly disordered magnetic systems, in general, and are therefore described in some detail below.

A spin glass problem can be defined using eqn [1] by setting the spatial dimension of the system as well as the distribution and range of the interaction $J_{i,j}$. In the Sherrington–Kirkpatrick (SK) model, the sum is taken over all pairs (i,j) of N spins, and a Gaussian distribution of $J_{i,j}$ with zero mean is used. The famous Parisi solution of this problem using replica symmetry breaking (RSB) forms one school of models describing spin glasses: the RSB or mean-field picture. An alternative model to describe finite dimensional systems is the droplet picture, which is based on the scaling hypothesis and yields a spin glass with properties, remarkably different in parts than the mean-field predictions. A main difference concerns the nature of the spin glass in a magnetic field, where the droplet picture prescribes that there is no equilibrium spin glass phase, whereas the RSB model yields a phase line in the field-temperature (H–T) plane (the Almeida–Thouless line) that separates the paramagnetic from the spin glass phase. Alternatively, in zero magnetic fields, both models anticipate a low-temperature phase with relaxation processes that lasts over exceedingly wide timescales and a nonstationary nature of a system that has been quenched to a temperature below its spin glass temperature (T_g).

There is an extensive literature on the static and dynamic magnetic properties of three-dimensional spin glass materials as observed in experiments and Monte Carlo (MC) simulations on three-dimensional Ising spin glass models. A clear empirical picture as to the magnetic properties of spin glasses can be extracted from this literature. The behavior is, however, complex and has allowed interpretations in terms of both the RSB and the droplet scaling model or combinations of the two pictures.

It is firmly established that there is a second-order phase transition to a low-temperature spin glass phase in the zero field. This transition is evidenced from the dynamics through analyses of the critical slowing down on approaching the phase transition temperature (spin glass temperature) and from the static susceptibility through a divergence of the nonlinear susceptibility on approaching T_g. In **Figure 1**, AC-susceptibility data at different frequencies measured on the Ising spin glass $Fe_{0.5}Mn_{0.5}TiO_3$ are shown; the original spin glass signature, a (frequency-dependent) cusp in the AC susceptibility is clearly seen. The temperature dependence of the relaxation time τ, that can be derived from the frequency dependence of the cusp (or freezing) temperature T_f, obeys critical slowing down and implies a phase transition with a relaxation time that diverges according to critical slowing down: $\tau = \tau_0 t^{-z\nu}$, where τ_0 is an atomic relaxation time $\sim 10^{-13}$ s, $z\nu \approx 10$ is the dynamic critical exponent, and t is the reduced

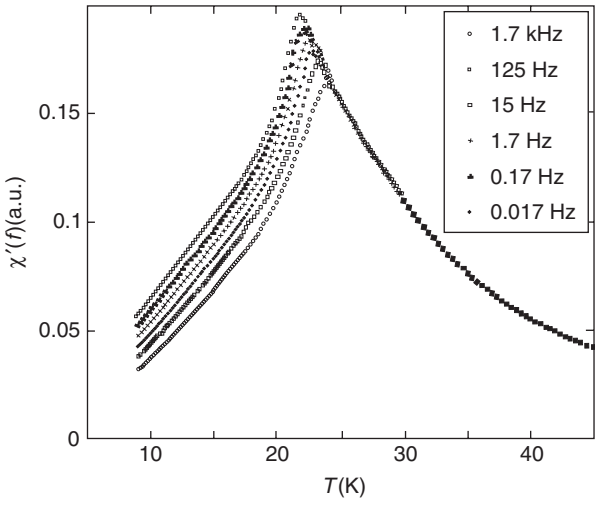

Figure 1 The AC susceptibility, $\chi'(f,T)$, measured along the c-axis of the Ising spin glass, $Fe_{0.5}Mn_{0.5}TiO_3$. The frequency (f) of the weak AC field is indicated in the figure. (Data from the theses of Mattsson J (1994) Uppsala University and Jonsson T (1998) Uppsala University.)

temperature, $t = T/T_{g-1}$. Critical slowing down and the existence of a low-temperature spin glass phase have been convincingly established from experiments and simulations on three-dimensional Ising spin glasses. This is one side of the phase-transition problem; a key question, which distinguishes the RSB- and droplet-model predictions, is whether the phase transition persists in an applied magnetic field or not. This seemingly simple question has not been easy to answer from either experiments or simulations. However, analyses of the in-field dynamics of the Ising spin glass $Fe_{0.5}Mn_{0.5}TiO_3$ show that the slowing down of the relaxation time is significantly altered in an applied field compared to the zero field and suggest that there is no phase transition in a magnetic field in a three-dimensional Ising spin glass.

The response of a spin glass to the application of a weak magnetic field in the spin glass phase extends from the atomic relaxation time (τ_0) to exceedingly long times well beyond the timescale of any experimental probe. That is, in common with other glassy systems, the relaxation times are exceedingly long in the low-temperature phase. Also, in common with other glasses, the low-temperature spin glass falls out of equilibrium as the system is cooled through the spin glass transition temperature. Once the system is kept at constant temperature in the low-temperature phase, it spontaneously and continuously reorganizes the spin structure – the system ages! Aging has a very characteristic influence on the response function of spin glasses. The relaxation of the magnetization $M(t)$ attains an inflection point at an observation time (t) of the order of the wait time (t_w) at constant temperature before the weak magnetic field was applied in a plot of $M(t)$ versus $\log(t)$. **Figure 2a** shows the relaxation of the magnetization $M(t)$ of an Ag(11 at.% Mn) spin glass measured after the different wait times indicated in the figure; also plotted in the figure is the relaxation rate, $S(t) = \partial M(t)/h\partial \log(t)$, that

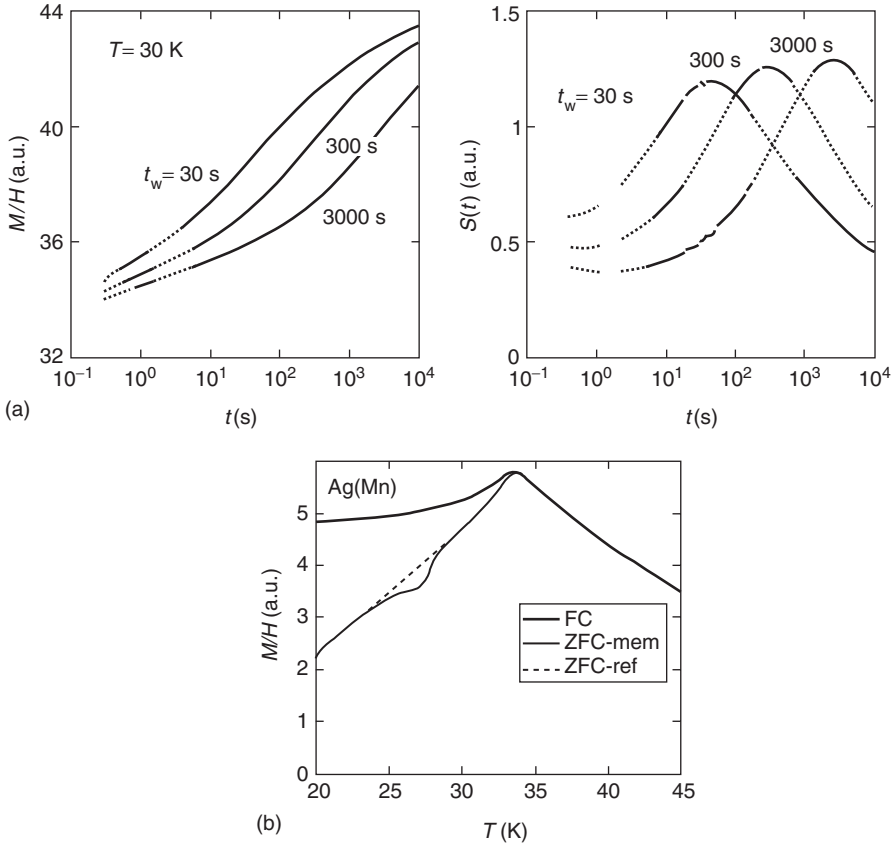

Figure 2 (a) The left figure shows the relaxation of the ZFC magnetization $M(t)$ of the spin glass Ag(11 at.% Mn) at $T = 30$ K. The magnetization has been measured after different wait times at the measurement temperature as indicated in the figure. The right figure shows the relaxation rate $S(t) = \partial M(t)/h\partial \log(t)$ of the magnetization relaxation curves. $T_g \approx 32$ K, $h = 40$ A m^{-1}. (Data from the thesis of Jönsson P (2002) Uppsala University.) (b) ZFC and FC magnetization vs. temperature ($M(T)/H$) for the spin glass Ag(11 at.% Mn). The curve labeled ZFC-ref shows the ZFC-magnetization measured after continuous cooling to low temperature, whereas the curve labeled ZFC-mem shows the corresponding curve measured after the sample has been kept at 27 K for 10^4 s during otherwise continuous cooling. $H = 8$ A m^{-1}. (Data from the thesis of Mathieu R (2002) Uppsala University.)

is, the local slope of the relaxation curves; this quantity exhibits a pronounced maximum at an observation time equal to the wait time. Results from MC simulations of the dynamics of three-dimensional Ising spin glass models yield similar results and confirm the existence of an aging phenomenon. The main conclusion from the aging (nonequilibrium) behavior is that the spin glass continuously evolves toward an equilibrium state at constant temperature in the spin glass phase and that this equilibrium state is different at different temperatures (the system appears chaotic).

An additional and remarkable feature of the nonequilibrium spin glass phase is that it incorporates a memory phenomenon. This phenomenon is most simply revealed by measurements according to a standard protocol to investigate the temperature dependence and irreversibility of the magnetization through the phase-transition temperature of a magnetic system. The zero-field-cooled (ZFC) and field-cooled (FC) magnetization, which are measured by cooling the sample in zero field, apply a weak field at a low temperature and record the magnetization (ZFC) while continuously heating the system to a temperature above T_g and then recool the magnetization in the applied field while recording the magnetization (FC). Such magnetization curves are shown for the archetypical spin glass Ag(11 at.% Mn) in **Figure 2b**. In addition, the figure shows a magnetization curve where the cooling of the sample has been interrupted for some hours at 27 K, and after reaching the low temperature, the magnetization was recorded on continuous heating in the same way as the ZFC-reference curve. This ZFC-mem curve shows a pronounced dip at the temperature for the stop. The system keeps a memory of the cooling history – and the memory is recalled when recording the ZFC magnetization on reheating the spin glass. The observed dip in the ZFC-mem curve is reminiscent of the aging that occurs in the system when it is kept at constant temperature, which results in a slower relaxation with increasing age of the system as was illustrated in **Figure 2a**. The memory-aging behavior are manifestations of some crucial concepts – aging, rejuvenation, and chaos – that characterize the spin glass phase and are of key importance for the modeling of spin glasses.

Spin glass behavior is not only confined to the model systems with atomic magnetic moments described above; there are several other disordered magnetic systems that have been found to show spin-glass-like magnetic behavior, for example, interacting magnetic nanoparticle systems, granular magnetic systems, some manganites and coboltites, and certain high-temperature superconductors.

Re-Entrant Spin Glasses

A spin glass is formed when there is disorder and frustration due to an equal amount of positive and negative interactions in the system, that is, the mean value of the interactions is close to zero. Such systems can simply be modeled by using an equal amount of interactions of the same magnitude $\pm J$ in the system or by using a Gaussian distribution of the interactions with zero mean. If the random interactions have a nonzero mean value, ferro $(+)$ or antiferromagnetic $(-)$, the system can show re-entrant behavior. The system first orders according to the dominant interaction at a high temperature and forms a long-ranged ordered random ferromagnetic or antiferromagnetic phase. However, on further lowering the temperature, the system seems to re-enter into a disordered phase, a spin glass phase. Re-entrant systems are quite common; they appear, for example, at higher concentration of magnetic atoms in dilute magnetic alloys and amorphous metals. Re-entrant ferromagnets show some remarkable properties: both the re-entrant spin glass phase and the long-range ordered phase show an aging phenomenon, and on cooling into the low-temperature spin glass phase, the ferromagnetic long-range order seems to persist although macroscopic AC-susceptibility data indicate critical slowing down and a true re-entrance into a spin glass phase. Many unanswered questions remain as to the physics of re-entrant magnetic systems.

The Random-Field Ising Model

A random-field Ising system is described by eqn [2]. The properties of that Hamiltonian have been extensively studied theoretically and by simulations and have been found to show a behavior that is very different from a random exchange or pure ferromagnetic system with respect to critical exponents, critical dimensions, and magnetic properties. Experimentally, there is no real material that provides local random fields as prescribed by the random-field Ising model. However, the random-field Hamiltonian is mapped by a dilute antiferromagnet in a homogeneous magnetic field: eqn [3] above – and such materials are readily fabricated in single crystalline form and provide systems that allow a continuously tunable strength of the random field only by varying the strength of an applied homogeneous magnetic field. A major part of the experimental work on three-dimensional random-field magnetic systems has been performed on the model Ising antiferromagnetic system FeF_2 diluted with nonmagnetic zinc atoms: $Fe_{1-x}Zn_xF_2$. The study of random-field systems is made more complicated by nonequilibrium effects that

appear when the system is cooled to low temperatures and hinder the system to reach thermodynamic equilibrium. A quite consistent picture as to some thermodynamic equilibrium properties of random-field systems of different spatial dimensionality has, however, been empirically attained.

The two-dimensional Ising system forms a low-temperature ordered phase via a second-order phase transition, the only second-order phase transition that has been given an exact solution (Onsager). This transition is, both in theory and experiments, found to be destroyed by finite random fields, that is, the lower critical dimension of the random-field Ising system is 2 or larger. In 3d random-field Ising systems, after many years of experimental and theoretical controversies, it has been confirmed that the second-order phase transition survives in random fields, and both theory and experiments agree that the lower critical dimension is equal to 2. The critical exponents describing the asymptotic behavior at the phase transition are significantly different from those of the pure three-dimensional Ising and also different from the random-exchange Ising model values.

Nonequilibrium effects appear as the random-field system is cooled into the ordered phase; these effects give rise to domain states and relaxation phenomena that are not yet fully satisfactorily described by theory and experiments. However, a quite high level of empirical understanding of the physics of random-field Ising model systems has been realized by combining results from macroscopic (susceptibility, magnetization, and specific heat) measurements with those from microscopic probes (neutron scattering and X-ray scattering experiments).

Amorphous Magnetic Systems

Crystallographically disordered materials with an exchange interaction strength that is dependent on the distance between the magnetic entities would naturally form disordered magnetic systems that mimic a random exchange or more complicated model system. A realization of such systems is amorphous metals fabricated by rapid quenching methods and stabilized by introducing glass-forming elements in the melt. Magnetic metallic glasses were first fabricated in the late 1960s and early 1970s and have provided excellent model systems for disordered magnetic systems and the influence of random exchange on the magnetic properties. There are outstanding possibilities to tailor materials using the rapid-quenching method, since almost any composition of different metals can be mixed without a need to consider phase segregation or consult complicated phase diagrams. It was earlier found that amorphous magnetic metals can form a variety of magnetic structures ranging from simple ferromagnets to complex ferrimagnetic spiral structures and spin glasses. However, a huge challenge and obstacle for the theoretical description of these metals is, of course, the lack of a periodic lattice as a backbone for the description of the electronic structure.

Amorphous metals are trapped in a metastable state and the structure has to be stabilized against crystallization, which severely limits the possible production processes. However, an important part of the interest in amorphous magnetic metals is due to their potential as magnetic materials in many applications. The possibility of fabricating materials with marginal magnetocrystalline anisotropy, very low magnetostriction, and high resistivity compared to their crystalline counterparts promises materials with excellent soft magnetic properties for medium- and high-frequency applications. Soft amorphous magnetic metal systems have also found important applications in, for example, small-scale transformers, motors, and generators. The rapid-quenching method does not only allow amorphous metals to form, it also yields possibilities of fabricating nanocrystalline systems. These systems, at certain microstructure sizes, form extremely hard magnetic materials with exceedingly high coercivity (which are useful building blocks for good permanent magnets), whereas under other compositions and nanocrystalline sizes, provide materials with excellent soft magnetic properties.

Magnetic Materials

Disorder is the physical parameter that governs extrinsic magnetic properties, such as coercivity, remanence, and energy product, of an intrinsically ferromagnetic or ferrimagnetic material. The producer of magnetic materials is thus forced to understand disorder to be able to effectively design and fabricate both soft and hard magnetic materials. It is, in fact, the ability to master disorder and find new material combinations that underlies the fast improvement of the technical performance that magnetic materials have been subjected to during the last few decades. Maybe, the prime example of such progress is found in the rapidly increasing areal storage density in magnetic information-storage media.

Summary

Theoretical and experimental studies of disordered magnetic model systems, such as the Ising spin glass and the random-field Ising model, have provided new insights and understanding of the influence of disorder on the properties of not only magnetic but also

other physical systems. In addition, the models and methods that have been developed in this research have found applications in many different fields of science that deal with complex and disordered systems. Examples are found in the physics of ordinary glasses and in optimization problems as well as in studies of stock markets and descriptions of social systems.

Disordered Solids and Glasses, Electronic Structure of

S R Elliott, University of Cambridge, Cambridge, UK

Introduction

In this article, the term "electronic structure" is taken to mean a description of the details of the solution, in its totality, of the Schrödinger equation for electrons in solids. Two quantities characterize the Schrödinger eigenequation solution, namely the eigenvalue (or electron energy, E) and eigenvector (or electron wave function, $\psi(\boldsymbol{r})$).

In the simple case of electron states in perfect single-crystalline materials, that is, those considered in most textbooks on the electronic theory of solids, the term electronic structure is often restricted to a description solely of the electronic energy since, for translationally periodic systems, the electronic states themselves always have the same character and generic functional form. The electronic wave function is always spatially extended throughout the volume of the crystalline sample, and has the functional form of the "Bloch" function, that is, a product of a spatially extended plane-wave state and a function, $u_{\boldsymbol{k}}(\boldsymbol{r})$, having the periodicity of the underlying crystal lattice:

$$\psi_{\boldsymbol{k}}(\boldsymbol{r}) = u_{\boldsymbol{k}}(\boldsymbol{r})\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} \qquad [1]$$

where $\boldsymbol{k}$ is the (quantized) wave vector of the plane-wave component, and is used as a label for the eigenstate. (This is not the case for disordered systems, as will be seen.)

Thus, for perfect single crystals, the electronic structure, characteristic of a particular material, is taken to refer to either the four-dimensional (4D) quantity, the electronic band structure, $E(\boldsymbol{k})$, or its 2D derivative, the electronic density of states (EDOS), $g(E)$, where generally

$$g(E) = \sum_i \delta(E - E_i) \qquad [2]$$

The EDOS in this representation is simply a sum of Dirac delta functions at all allowed, quantized electron-energy eigenvalues, E_i; it is the number of electron states at a particular energy in unit energy interval, and $g(E)$, therefore, has the units of inverse

energy. Alternatively, for a single crystal, the EDOS can be obtained as a surface integral in $\boldsymbol{k}$-space over the Brillouin zone of a constant-energy surface S_E of the electronic band structure, that is,

$$D(E) = \frac{2}{(2\pi)^3} \int_{E(\boldsymbol{k})=\text{const}} \frac{\mathrm{d}S_\mathrm{E}}{\nabla_k E} \qquad [3]$$

Here, $D(E) = g(E)/V$, where V is the volume of the sample, and hence this form of the EDOS has units of inverse energy times volume.

One special feature of the EDOS of crystalline solids is the presence of van Hove singularities, that is, sharp features in the density of states corresponding to flat regions of the band structure, for which $\nabla_k E = 0$ (cf. eqn [3]), that is, regions where there are a large number of electron states with different $\boldsymbol{k}$-values in a very small energy interval.

It will be seen that the introduction of disorder in a solid can have dramatic effects on the above simple picture of electron states in single-crystal materials.

Nature of Disorder

The translational periodicity characteristic of perfect single crystals can be disrupted in a number of ways. Although, in a given disordered material, a glass for instance, several different types of disorder may occur together, nevertheless it is instructive to consider such possible forms of disorder separately. Perhaps, the simplest form is substitutional disorder in which a different type of atom is substituted for another in the crystalline lattice of the host material. The simplest example of substitutional disorder is the inclusion of one type of atom in the structure consisting entirely of another type, for example, the electrical dopants, *n*-type phosphorus or *p*-type boron, in crystalline silicon (**Figure 1a**). A related substitutional defect is the so-called antisite defect, for example, in a binary crystalline compound, AB, where only heteropolar (A–B) bonding occurs in the completely ordered case. The replacement of an A atom, for example, by a B atom leads to the formation of homopolar (B–B in this case) nearest-neighbor bonds (**Figure 1b**). A related defect is the atomic vacancy, where an atom is missing at a lattice-related site (**Figure 1c**). This type of disorder involves point (or zero-dimensional) defects.

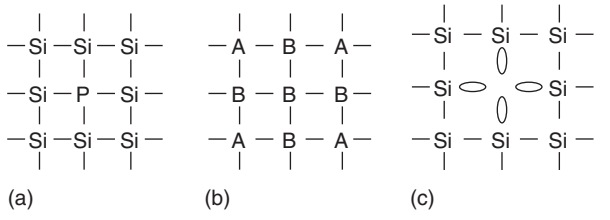

Figure 1 Schematic illustration of different types of substitutional disorder associated with point defects in solid (crystalline) materials: (a) a phosphorus donor atom in crystalline silicon; (b) an antisite defect in a binary crystal, AB; and (c) an atomic vacancy (e.g., in crystalline silicon, showing four dangling-bond orbitals pointing into the vacancy).

A somewhat related 2D defect is the so-called antiphase boundary in a binary crystal, AB, where an entire plane of atoms is missing (i.e., a stacking fault exists): in this case, like atoms face each other across the antiphase boundary (**Figure 2**).

Another type of disorder prevalent in crystalline materials is positional disorder, characteristic of vibrational motion: atoms are instantaneously displaced randomly from their equilibrium, lattice-related crystallographic sites, according to a Gaussian (normal) distribution in the case of thermal vibrational disorder (**Figure 3**). Positional disorder in crystals due to vibrational motion is dynamic in nature: the time-averaged atomic positions are simply the equilibrium, lattice-related sites. However, for the case of noncrystalline (e.g., amorphous or glassy) materials, the positional disorder is static in nature, that is, the equilibrium atomic positions do not correspond to a crystalline lattice.

What really distinguishes an amorphous material from its crystalline counterpart, however, is the presence of topological disorder, for example, involving the presence of noncrystalline ring orders in (covalent) network materials (**Figure 4**). In this case, the disorder is more profound, and there is no simple displacement relationship between noncrystalline and crystalline structures, as there is for positional disorder, for example.

The presence of topological disorder also permits the existence of other types of defective structures,

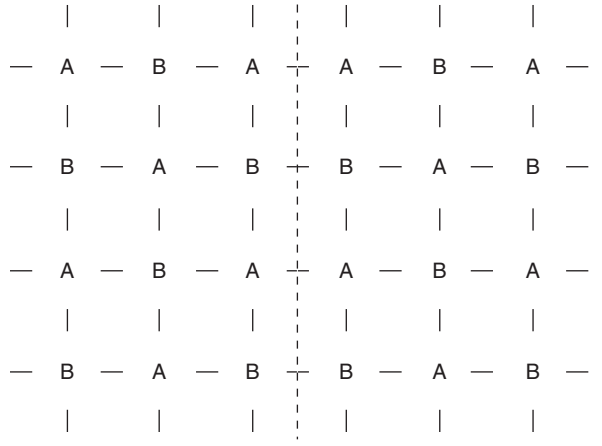

Figure 2 Schematic illustration of a two-dimensional stacking fault (missing layer) or antiphase boundary (dashed line) in a binary crystal, AB.

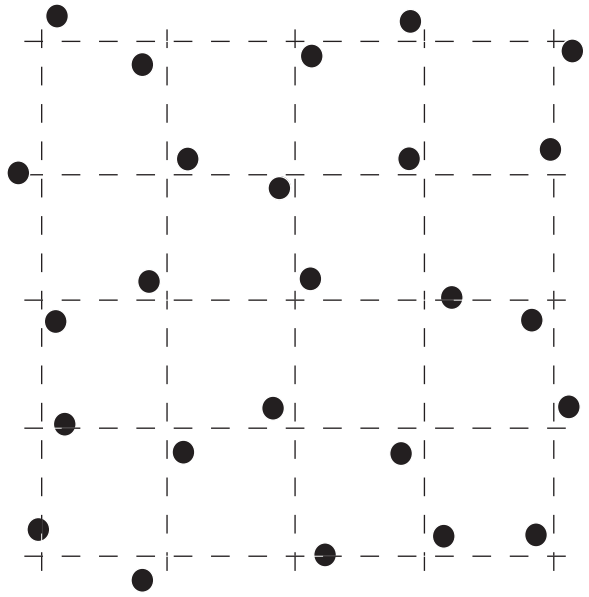

Figure 3 Schematic illustration of positional (e.g., vibrational) disorder.

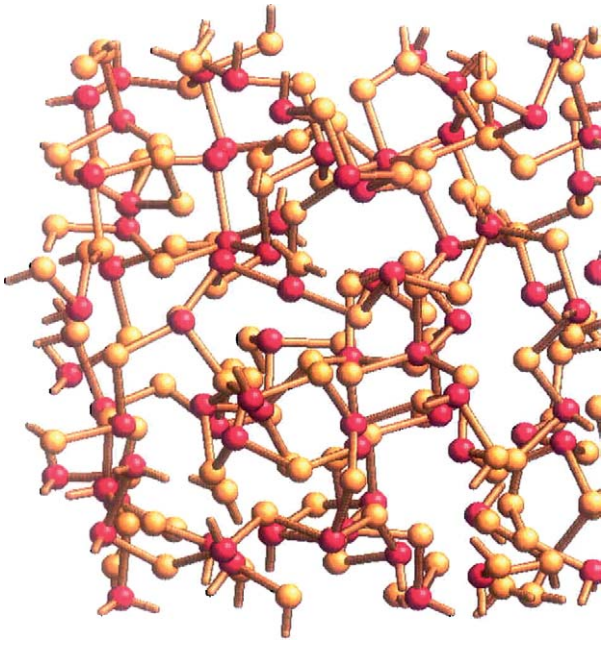

Figure 4 Illustration of topological disorder in a computer-simulated model of amorphous As_2S_3, created by *ab initio* molecular dynamics: As atoms are colored pink and S atoms are yellow. (S Simdyankin and SR Elliott, unpublished data.)

unique to the amorphous phase and not found in the crystalline state. For instance, in materials with strongly directed covalent bonds, isolated dangling-bond (under-coordinated) coordination defects can occur instead of the clusters of dangling bonds that always occur at the site of atomic vacancies in crystals of such materials, for example, the four (unreconstructed) dangling bonds pointing into the vacancy in the tetrahedral crystalline material, c-Si (**Figure 1c**). In addition, isolated homopolar-bond defects can occur in amorphous compound materials (where in the stoichiometric composition, only heteropolar bonds would otherwise be expected), instead of the clusters of homopolar-bond defects that exist around an antisite defect (**Figure 1b**) or along an antiphase boundary (**Figure 2**) in the corresponding crystalline materials.

Effects of Disorder on the Electronic Structure

General Aspects

In the case of a perfect crystal, the allowed values of the quantized electron wave vector, $\boldsymbol{k}$, are set by the periodicity of the lattice: for example, for a 1D crystal with a unit-cell parameter a, and with N atoms in the sample, there are correspondingly N discrete $\boldsymbol{k}$-states, equally spread in $k(=|\boldsymbol{k}|)$ in the first Brillouin zone, that is, for the range of $\boldsymbol{k}$-values $-\pi/a < k < \pi/a$. Each electron eigenvalue (energy) is associated with a particular $\boldsymbol{k}$-value, which shows that the electronic band structure, $E(\boldsymbol{k})$, is a well-defined quantity (see **Figure 5**).

The presence of a single defect (or a surface) is sufficient to break the infinitely ranged translational invariance characteristic of ideal single crystals. In the case of a disordered material with no translational periodicity, there is no crystalline unit cell and hence the electron wave vector becomes an ill-defined quantity and no longer is useful as a label for electron states. Although at low electron energies corresponding to small k (the electron wavelength being long compared to characteristic atomic-structural distances, for example, the nearest-neighbor bond length), the uncertainty in k is rather small, it rapidly increases with increasing energy (**Figure 5**). In other words, the electron wave function for a disordered material can no longer be expressed in terms of a single plane wave, characterized by one particular $\boldsymbol{k}$-value, as in the case for Bloch states in single-crystalline materials (eqn [1]). Instead, in a disordered material, electronic wave functions can be regarded as comprising an increasing number of Fourier components with increasing energy.

In the light of the above discussion, evidently the electronic band structure, $E(\boldsymbol{k})$, is not an appropriate description of electron states for disordered materials. However, since the electron energy remains a well-defined quantity, even in the presence of strong disorder, the EDOS (as defined as a sum of delta functions by eqn [2], but not in terms of the band

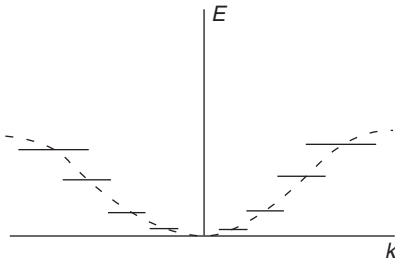

Figure 5 Schematic illustration of a one-dimensional electronic band structure for a 1D crystal (dashed line) and an amorphous solid (solid lines, illustrating the uncertainty in electron wave vector $\boldsymbol{k}$ for a given eigenenergy).

structure, eqn [3]) remains a valid form of description for the electron states of disordered materials.

The Electronic Density of States

The effect of disorder on the EDOS is varied: some changes are striking, others are more subtle. Perhaps, the most striking effect of the loss of translational symmetry is in the destruction (broadening) of the van Hove singularities in the EDOS that are a signature of the presence of flat electron-energy surfaces in $\boldsymbol{k}$-space, characteristic of crystals (see **Figure 6**).

However, van Hove singularities apart, the EDOS of many amorphous materials is often similar to that of their crystalline counterparts (see **Figure 6** for the case of silicon). This is particularly true for covalently bonded semiconductors/insulators, where the similarity in the electronic structure arises from marked similarities in the short-range atomic structural order between the two phases. In the case of amorphous and crystalline silicon, for example, the short-range structural motif is the $SiSi_4$ tetrahedron in both cases: the average nearest-neighbor bond length and bond angle are practically the same, although the amorphous phase is characterized by having an $\sim \pm 10\%$ variation in bond angle from the average tetrahedral value, $\theta = 109°28'$. (The translational periodicity of the crystalline phase is destroyed in the amorphous material, not so much by this bond-angle disorder as by the disorder in dihedral angles, that is, the angle of twist between pairs of corner-sharing connected tetrahedra.)

The reason for the overall similarity in EDOS between amorphous and crystalline states, for example, of silicon, can be seen from a simple tight-binding description of the origin of the electron states, and the similarity in the short-range order in both cases. Only two types of local electronic interactions are assumed to be operative, namely a nearest-neighbor intersite interaction, V_2, between orbitals emanating from pairs of nearest-neighbor atoms and forming

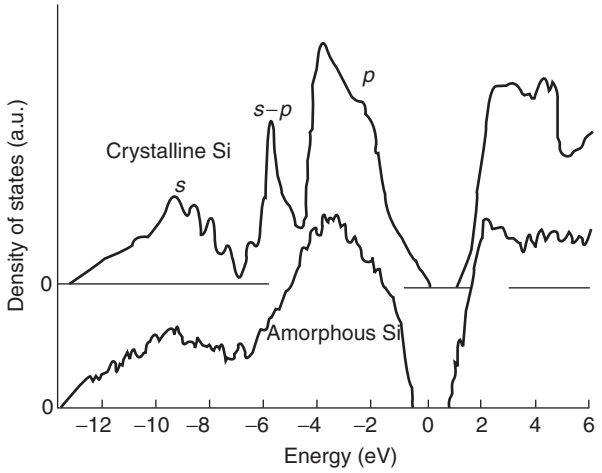

Figure 6 Calculated EDOS for amorphous and crystalline silicon, for a 216 atom model. (Reproduced with permission from Street RA (1991) *Hydrogenated Amorphous Silicon*. Cambridge: Cambridge University Press.)

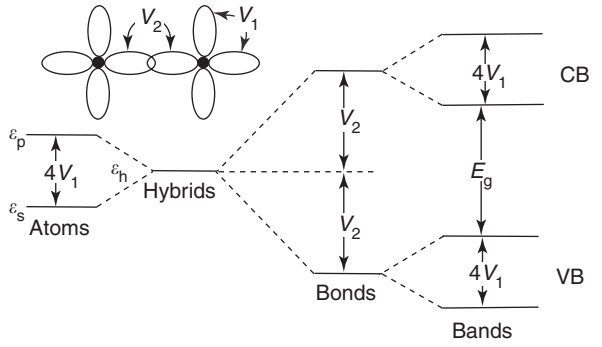

Figure 7 Illustration of the origin of the bandgap between valence and conduction bands for a tetrahedrally coordinated material, such as silicon. The successive sections show the atomic *s*- and *p*-levels, the sp^3-hybrid level, the bonding–antibonding splitting resulting from the intersite electron interaction, V_2, and the formation of bands resulting from the intrasite interaction, V_1. The origins of the interactions V_1 and V_2 are shown in the inset.

common bonds, and an intrasite interaction, V_1 between orbitals emanating from the same atom (**Figure 7**). In the case of silicon, for example, atomic *s*- and *p*-orbitals hybridize to give the sp^3-hybrid basis orbitals. The intersite interaction, V_2, is responsible for a gap of magnitude $2V_2$ occurring between occupied and unoccupied electron states (i.e., the bonding–antibonding splitting). The intrasite interaction, V_1, in this model, is responsible for the broadening of bonding and antibonding levels into, respectively, the valence and conduction bands, each of width $4V_1$ (**Figure 7**), since it couples orbitals together in such a way that, together with the intersite interaction, an electron may hop from any given orbital on one atom to any other orbital on any other atom, thereby becoming delocalized (extended)

throughout the sample volume. It should be noted that both V_1 and V_2 are negative quantities. In this model, a bandgap occurs between filled valence and empty conduction bands as long as the bonding–antibonding splitting is sufficiently large to overcome the opposing effect of the band broadening, that is, for

$$|V_2| > 2|V_1| \qquad [4]$$

and the bandgap, therefore, has the value

$$E_g = 2|V_2 - 2V_1| \qquad [5]$$

Since the average nearest-neighbor bond lengths and angles in amorphous and crystalline silicon are very similar, the magnitude of the electron-hopping interactions V_1 and V_2 are also expected to be very similar, and hence, for example, the width and shape of the valence band, and the magnitude of the bandgap between valence and conduction bands, is expected to be very similar for the two phases (see **Figure 6** for the case of Si).

However, subtle changes in the EDOS can be caused by disorder. Since the bandwidth in this tight-binding picture is governed by the intrasite interaction, V_1, and this interaction (as well as the degree of orbital hybridization) depends on the angle, θ, between (hybrid) orbitals at a site (**Figure 7**), the fluctuations in θ will lead correspondingly to variations in the bandwidth, that is, a tailing of states at the band edges into the gap region (see **Figure 8**). It appears, on the basis of experimental data, that these band tails in amorphous semiconductors generally have an exponential energy dependence:

$$g(E) = \frac{N_0}{E_0} \exp(E/E_0) \qquad [6]$$

where N_0 is the total number of tail states, and E_0 is the energy decay parameter.

Substitutional disorder, for example, phosphorus donor dopants in silicon, that is, Si:P (**Figure 1a**), also gives rise to electron states lying outside the bands of the perfect crystal; in the case of Si:P, these are donor levels just below the conduction-band edge. (Acceptor states associated with substitutional acceptors, for example, boron in silicon, Si:B, correspondingly lie just above the valence-band edge.) Substitutional defects comprising atoms having a greater electronegativity

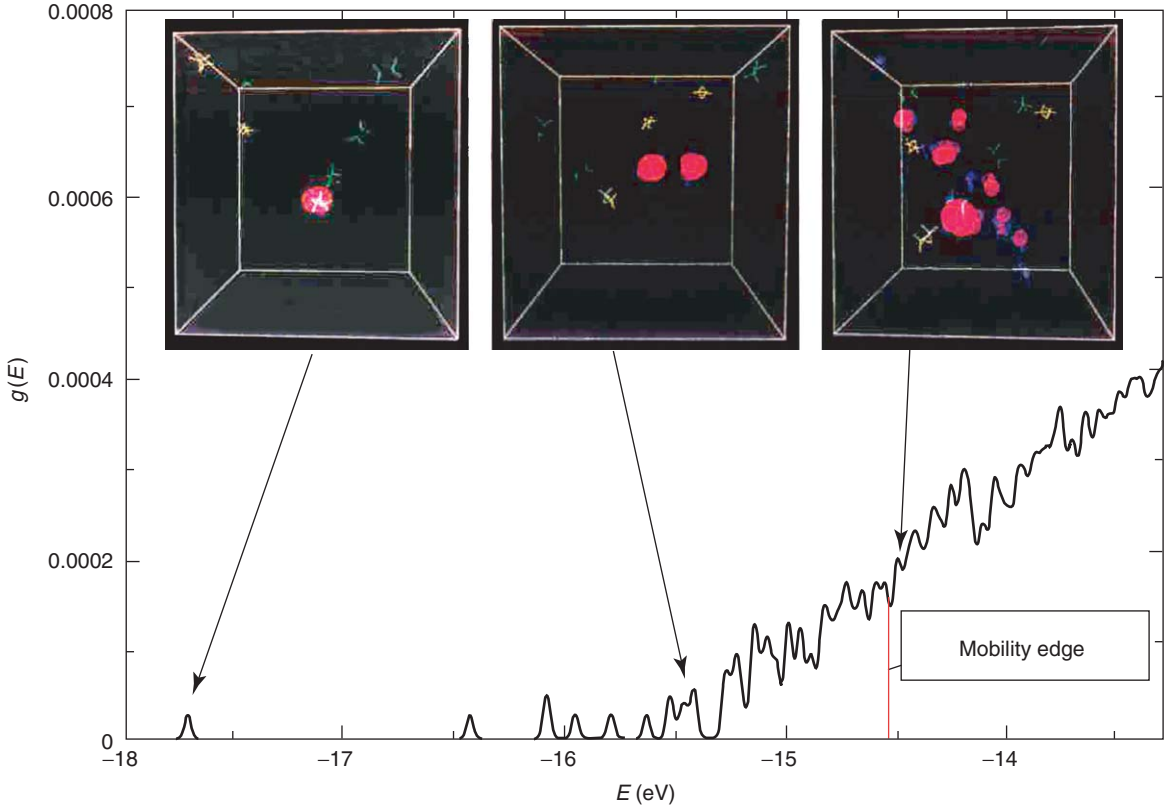

Figure 8 The density of states for the (lower-energy) valence-band tail calculated for a model of amorphous silicon, showing the computed position of the LD transition. Visualizations of three representative localized electron eigenstates are also shown: a highly localized near-mid-gap state associated with a dangling bond; a localized tail state and a critical state at the LD transition, each showing constituent island states, the number of which increase on approaching the LD transition. (J Ludlam and SR Elliott, unpublished data.)

difference with the atoms in the host material correspondingly give rise to electron states lying deeper within the bandgap.

Although relatively small levels of disorder, for example, bond-angle deviations in covalent amorphous semiconductors, produce relatively small changes in the EDOS, that is, moderate band tailing into the bandgap, larger degrees of disorder can cause correspondingly larger changes in the EDOS. For instance, electron states associated with gross instances of disorder (e.g., coordination defects such as dangling bonds in amorphous network materials) have energy levels deeper in the bandgap than the bond-angle-fluctuation-induced band tails. The reason why (singly occupied) dangling-bond orbitals should have an electron energy lying near midgap in the case of a-Si can be seen from the simple tight-binding hybrid–orbital picture illustrated in **Figure 7**: the dangling-bond orbital is a nonbonding state and hence should lie at the level corresponding to that of the sp^3-hybrids (i.e., at midgap in this model). Such singly occupied, electrically neutral dangling-bond defects in silicon can be represented by the symbol Si_3^0, where the subscript denotes the coordination number at the defect, and the superscript denotes the electrical charge state of the defect. Such Si_3^0 defects are electron-spin resonance (ESR) active because of the unpaired electron spin in the dangling-bond orbital.

Not all dangling-bond defects in amorphous semiconductors are paramagnetic, as they are in a-Si or a-Ge, however. In chalcogenide glasses, which contain the chalcogen (C) elements, S, Se, or Te, alloyed with neighboring elements (e.g., As, Ge, Sb, and B), bond reconstruction can make electron pairing at dangling-bond defects energetically favorable. An electron, transferred between two C_1^0 paramagnetic chalcogen dangling-bond defects to create a C_1^+, C_1^- defect pair, can be energetically stabilized by the formation of a dative bond between the empty p-orbital on C_1^+ and the filled nonbonding, lone-pair p–π orbital on a neighboring, normally bonded chalcogen (i.e., C_2^0), thereby forming an over-coordinated defect, C_3^+, with the overall defect reaction being

$$2C_2^0 \rightarrow C_3^+ + C_1^- \qquad [7]$$

The so-called valence-alternation pair (VAP) of defects, C_3^+, C_1^-, is spin-paired and hence diamagnetic, and has energy levels closer to the band edges than the near mid-gap position of C_1^0.

The Electronic Wave Function

Disorder in a material can cause a qualitative change in the nature of the electron wave functions compared with the Bloch form (eqn [1]) characteristic of perfectly crystalline solids. Instead of all wave functions being spatially extended (delocalized) as in the case of single crystals, the presence of disorder can cause some electron states instead to become spatially localized: the envelope of the magnitude of the wave function then decays exponentially with distance away from the center of localization (or the site of maximum magnitude of the electron charge density, $\rho_e(r)$, or $|\psi(r)|^2$) as

$$\psi(r) = Ae^{-\alpha r} \qquad [8]$$

where α^{-1} is the localization length.

An isolated substitutional impurity, for example, a P donor in c-Si (**Figure 1a**), also shows clearly the disorder-induced localized nature of the associated electron wave function: the isolated donor state can be represented reasonably accurately by a 1s-like hydrogenic orbital having an exponential envelope, the extra donor electron being bound to the positively charged P^+ donor atom by the Coulomb interaction, screened by the dielectric constant of the Si host, resulting in the effective Bohr radius of the electron orbit (equivalent to the localization length) being several tens of unit-cell lengths in size.

The isolated dangling-bond electron state lying near mid-gap in topologically disordered amorphous semiconductors is more strongly exponentially localized, with the localization length being comparable to the nearest-neighbor bond length, $\alpha^{-1} \cong r_1$. It is generally true that, the deeper the energy level of an electron state in the bandgap, away from the valence- or conduction-band edges, the stronger the degree of spatial localization (i.e., the smaller the value of α^{-1}) of the associated electron wave function.

A remarkable feature of the nature of electron states in disordered materials, such as amorphous solids, is that there are critical energies in the tails of the bands, at which the character of the eigenstates changes from being spatially extended (but non-Bloch-like, and having a dispersion of $\boldsymbol{k}$-values), for states nearer the band center, to being spatially (exponentially) localized, for states nearer the gap. The localization length, α^{-1}, of the envelope of the localized states diverges at the localization–delocalization (LD) transition. **Figure 8** shows this LD transition energy, sometimes called the (electron) mobility edge, because the electron transport changes there from being high-mobility diffusive for extended states to being low mobility involving thermal hopping for localized states, calculated for a structural model of a-Si with a realistic tight-binding electron-interaction Hamiltonian. Also shown in this figure are visualizations of the computed localized electron wave function for different representative energies in

the gap and the band tail. A dangling-bond state deep in the bandgap is very strongly localized at a coordination defect, the localized wave function consisting of a single region of charge density having an exponential envelope. However, localized electron states in the band tail, especially with energies approaching the LD transition, do not consist of single uniform regions of charge density with ever-increasing localization length, α^{-1}. Instead, discrete "islands" of charge density occur within the overall exponential envelope of the localized wave function; these individual islands are also exponentially localized, but their localization length, α_I^{-1}, increases only very gradually, and the number of islands also increases significantly, as their energy moves toward the LD transition. The electron eigenstate at the LD transition itself is a multifractal state consisting of a dense collection of the individual island states (see **Figure 8**).

Conclusions

The effects of disorder on electron states in solids are fourfold: (1) the electron wave vector is no longer a good quantum number, (2) sharp features in the density of states are destroyed, (3) bands broaden, creating band tails having an exponential energy dependence, and (4) electron states in band tails and in the bandgap region, lying below a critical energy and corresponding to very disordered sites, are exponentially spatially localized.

Nomenclature

a	unit-cell parameter
C_i^{α}	chalcogen atom with atomic coordination i $(=1-3)$ and electric charge $\alpha(-,0,+)$
$D(E)$	EDOS (per energy per volume) $= g(E)/V$
E	electron energy
E_g	bandgap energy
$g(E)$	electronic density of states (per energy) $= D(E) \times V$
k	electron wave vector magnitude
$\boldsymbol{k}$	electron wave vector
$\boldsymbol{r}$	real space position vector
S_E	constant-energy surface of electron states in $\boldsymbol{k}$-space
$u_k(r)$	function having periodicity of crystal lattice (in Bloch function)
V	volume
V_1	intrasite electron interaction
V_2	intersite electron interaction
α	inverse localization length of envelope of a localized state
α_I	inverse localization length of island state within a localized state
$\delta(E)$	Dirac delta function (of energy)
$\nabla_k E$	gradient of electron energy with respect to wave vector
θ	bond angle
$\rho_e(r)$	electron charge density
$\psi(\boldsymbol{r})$	electron wave function

DNA and RNA, Biophysical Aspects

M D Frank-Kamenetskii, Boston University, Boston, MA, USA

Introduction

DNA and RNA together are known as nucleic acids. Their full names are deoxyribonucleic acid and ribonucleic acid, respectively. They play a crucial role in all living organisms because they are the key molecules responsible for storage, duplication, and realization of genetic information. They are both heteropolymeric molecules consisting of residues (nucleotides) of four types. Four RNA nucleotides are shown in **Figure 1**. They consist of the phosphate group, sugar (called ribose) (these two elements are identical for all four nucleotides), and nitrous bases,

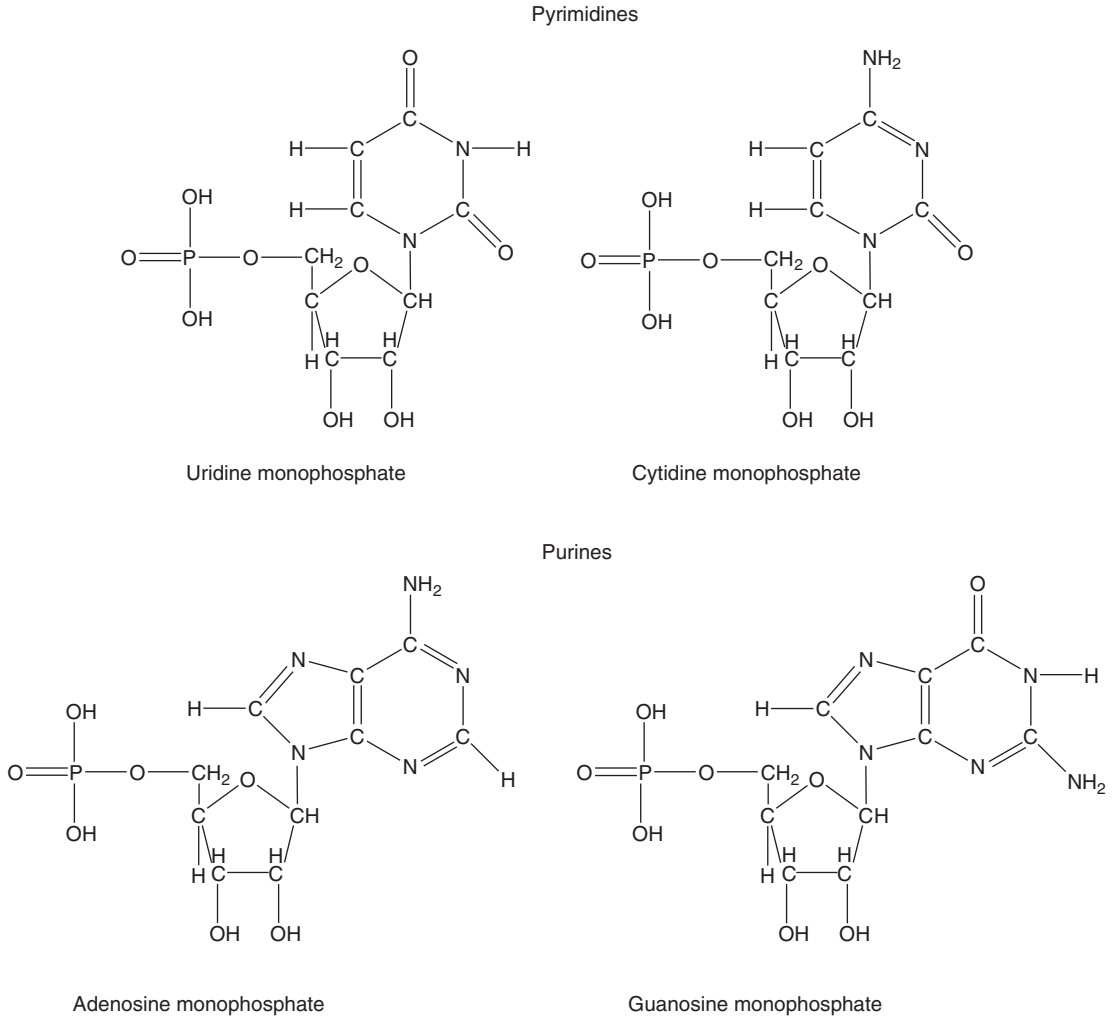

Figure 1 Chemical formulas of residues of RNA, i.e., of nucleotides. At the top are the pyrimidine nucleotides (U and C), and below, the purine nucleotides (A and G). Nucleotides within DNA differ in that, instead of the right-hand lower OH group, they simply have H. In addition, DNA, instead of the uridine nucleotide, includes the thymidine nucleotide whose top C–H group in the ring is replaced by the C–CH_3 group.

which determine the type of the nucleotide. DNA nucleotides are very similar to RNA nucleotides. The main difference is that the right-handed OH group in sugar is replaced with just H (making deoxyribose). Three bases (A, G, and C) are the same for DNA and RNA. Only the fourth base is different: instead of uracil (U), DNA carries thymine (T) (see **Figure 2**). The DNA chain is shown in **Figure 3**.

In living nature, as is observed today, DNA plays the most important role because genetic information is stored and duplicated in the form of DNA in all living cells and organisms without any exceptions. Only in some viruses, which are not living creatures because they cannot reproduce themselves outside cells, is genetic information carried in the form of RNA molecules. A notable class of such viruses is retroviruses, which include many cancer-inducing viruses as well as HIV, the AIDS virus.

A genetic message is "written down" in the form of a continuous text consisting of four letters (DNA nucleotides A, G, T, and C). This continuous text, however, is subdivided, in its biological meaning, into sections. The most significant sections are genes, parts of DNA, which carry information about the amino acid sequence of proteins. Whereas DNA stores and duplicates genetic information, RNA plays a key role in its realization, that is, in the process of synthesis of a protein molecule in accordance with the nucleotide sequence of the corresponding gene.

This process consists of two major steps. First an RNA copy of the gene is made with the help of a special enzyme, RNA polymerase. The process is called transcription and the RNA copy of the gene is

called messenger RNA (mRNA). The mRNA is an exact copy of the gene, in which all thymines (T) are replaced with uracils (U). In the second step, called translation, mRNA is used as a template for protein synthesis in a special cell machinery, the ribosome. Ribosome is a complex aggregate of special ribosomal RNA (rRNA) and a number of proteins. It translates the nucleic acid text into amino acid language. In so doing, it uses a special dictionary, the genetic code. In the process of translation, a very important class of additional small RNA molecules plays a crucial role. These RNA molecules consist of about hundred nucleotides and are called transfer RNA (tRNA).

In this article, an overview of the present knowledge of physical structures of nucleic acids is provided. The most important structural transitions, such as DNA melting and B–Z transition, are explained. Special attention is paid to the topological properties of DNA, which play a significant role in its functioning within the cell. Theoretical models, which are most popular in the field of biophysics of DNA and RNA are also overviewed. Recently emerged areas of DNA and RNA biophysics, such as single-molecule experiments and DNA/RNA nanostructures are also considered.

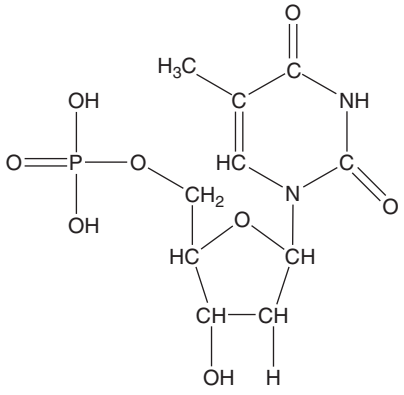

Figure 2 Thymidine monophosphate is a thymine nucleotide that is part of DNA. The remaining three DNA nucleotides have similar structure, but each has a nitrous base of its own (the top group). These three bases (adenine, guanine, and cytosine) are identical in DNA and RNA (see **Figure 1**).

Structures of DNA and RNA

Traditionally, the structural versatility of nucleic acids had been considered as much narrower than that of proteins. This viewpoint fitted well "the division of power" between nucleic acids and proteins in present-day living creatures. The major function of nucleic acids is to store and reproduce genetic information while proteins perform an innumerable variety of reactions within the cell and are also its main construction blocks. The discovery of ribozymes (RNA molecules capable of catalytic functions) and of the remarkable versatility of the RNA structure completely changed the attitude toward the pivotal question of which type of major biopolymers, proteins or nucleic acids, had been the prebiotic molecule, forefather of the living cell. Earlier, everybody believed that only protein could fulfill this function. Now, the common view is that this should be the RNA molecule (the RNA World concept).

However, in the present-day cell, RNA plays an important but mostly an auxiliary role. The central player is DNA.

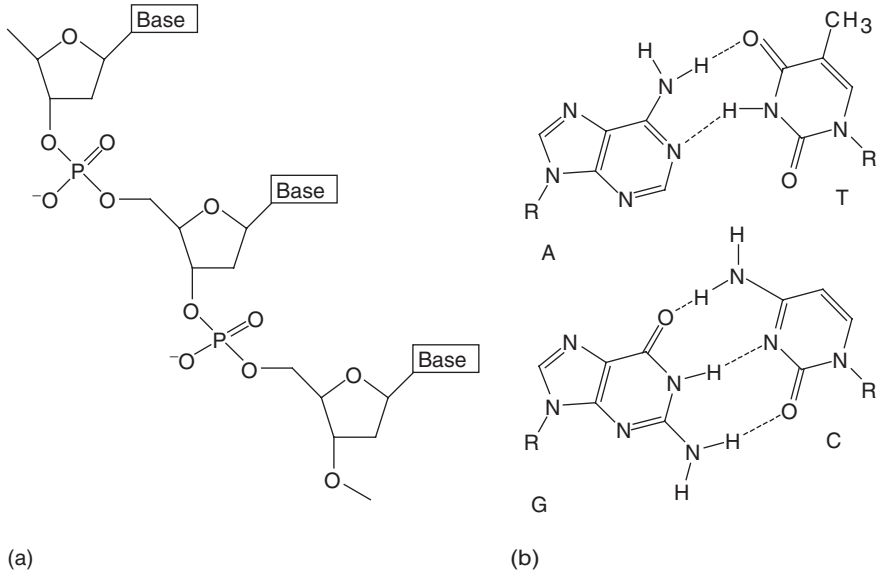

Figure 3 (a) The DNA single strand and (b) the Watson–Crick complementary base pairs.

Major Helical Structures of DNA

In spite of enormous versatility of living creatures, and, accordingly, variability of genetic texts which DNA molecules in different organisms carry, they all have virtually an identical physical spatial structure: the double-helical B form discovered by Watson and Crick in 1953. Sequences of the two strands of the double helix obey the complementary principle. This principle is the most important law in the field of nucleic acids, and, probably, the most important law of living nature. It declares that in the double helix, A always opposes T and vice versa, whereas G always opposes C and vice versa.

B-DNA It (see **Figure 4a**) consists of two helically twisted sugar-phosphate backbones stuffed with base pairs of two types, AT and GC. The helix is right-handed with 10 bp per turn. The base pairs are isomorphous (see **Figure 3**): the distances between glycosidic bonds, which attach bases to sugar, are virtually identical for AT and GC pairs. Due to this isomorphism, the regular double helix is formed for an arbitrary sequence of nucleotides and the fact that DNA should form a double helix imposes no limitations on DNA texts. The surface of the double helix is by no means cylindrical. It has two very distinct grooves: the major groove and the minor groove. These grooves are extremely important for DNA functioning because in the cell, numerous proteins recognize specific sites on the DNA via binding with the grooves.

Each nucleotide has direction: if one treats sugar as a ring lying in the plane, then the CH_2 group will be above the plane (see **Figure 1**). This carbon is designated as 5′ whereas the carbon atom connecting the sugar to the next nucleotide in the polynucleotide chain is designated as 3′. In the DNA double helix, the two strands have opposite directions.

In B-DNA, base pairs are planar and perpendicular to the axis of the double helix.

Under normal conditions in solution, often referred to as "physiological" (neutral pH, room temperature, ~200 mM NaCl), DNA adopts the B form. All available data indicate that the same is true for the totality of DNA within the cell. It does not exclude, however, the possibility that separate stretches of DNA carrying special nucleotide sequences would adopt other conformations.

B′-DNA Up to now only one such conformation has been demonstrated, beyond any doubts, to exist under physiological conditions. When three or more A residues in one strand (and, accordingly, T's in the other DNA strand) are met, they adopt the B′ form. In many respects, the B′ form is similar to the classical B form. There are two main differences: base pairs in B′-DNA are not planar (they form a kind of propeller with the propeller twist of 20°) and the minor groove in B′-DNA is twice as narrow as in B-DNA.

A-DNA Similar to B-DNA, the A form can be adopted by an arbitrary sequence of nucleotides. As in B-DNA, the two complementary strands in A-DNA are antiparallel and form right-handed helices. Normal DNA undergoes transition from the B to A form under drying. In A-DNA, the base pairs are planar but their planes form a considerable angle with the axis of the double helix. In so doing, the base pairs shift from the center of the duplex forming a channel in the center.

Z-DNA It presents the most striking example of how different from the B form the DNA double helix can be (**Figure 4b**). Although in Z-DNA the complementary strands are antiparallel as in B-DNA, unlike in B-DNA they form left-handed, rather than right-handed, helices. There are many other dramatic differences between Z- and B-DNA.

Not any sequence can adopt the Z form. To adopt the Z form, the regular alternation of purines (A or G) and pyrimidines (T or C) along one strand is strongly preferred. However, even this is not enough for Z-DNA to be formed under physiological conditions. Nevertheless, Z-DNA can be adopted by DNA stretches in cell due to DNA supercoiling (see below). The biological significance of Z-DNA, however, remains to be elucidated.

ps-DNA The complementary strands in DNA duplex can be parallel. Such parallel-stranded (ps) DNA is formed most readily if both strands carry only adenines and thymines and their sequence excludes formation of the ordinary antiparallel duplex. If these requirements are met, the parallel duplex is formed under quite normal conditions. It is right-handed but the AT pairs are not regular Watson–Crick ones, but rather so-called reverse Watson–Crick.

Some other sequences also can adopt parallel duplexes. For instance, at acidic conditions two strands carrying only C residues form parallel duplex consisting of hemiprotonated CC^+ base pairs (see the section "Quadruplexes"). However, any possible biological role of psDNA remains obscure.

RNA Structure

Quite naturally, similarity between DNA and RNA in their chemical nature entails significant similarity in structures they adopt. RNA can also form the double helix with complementary base pairs AU and

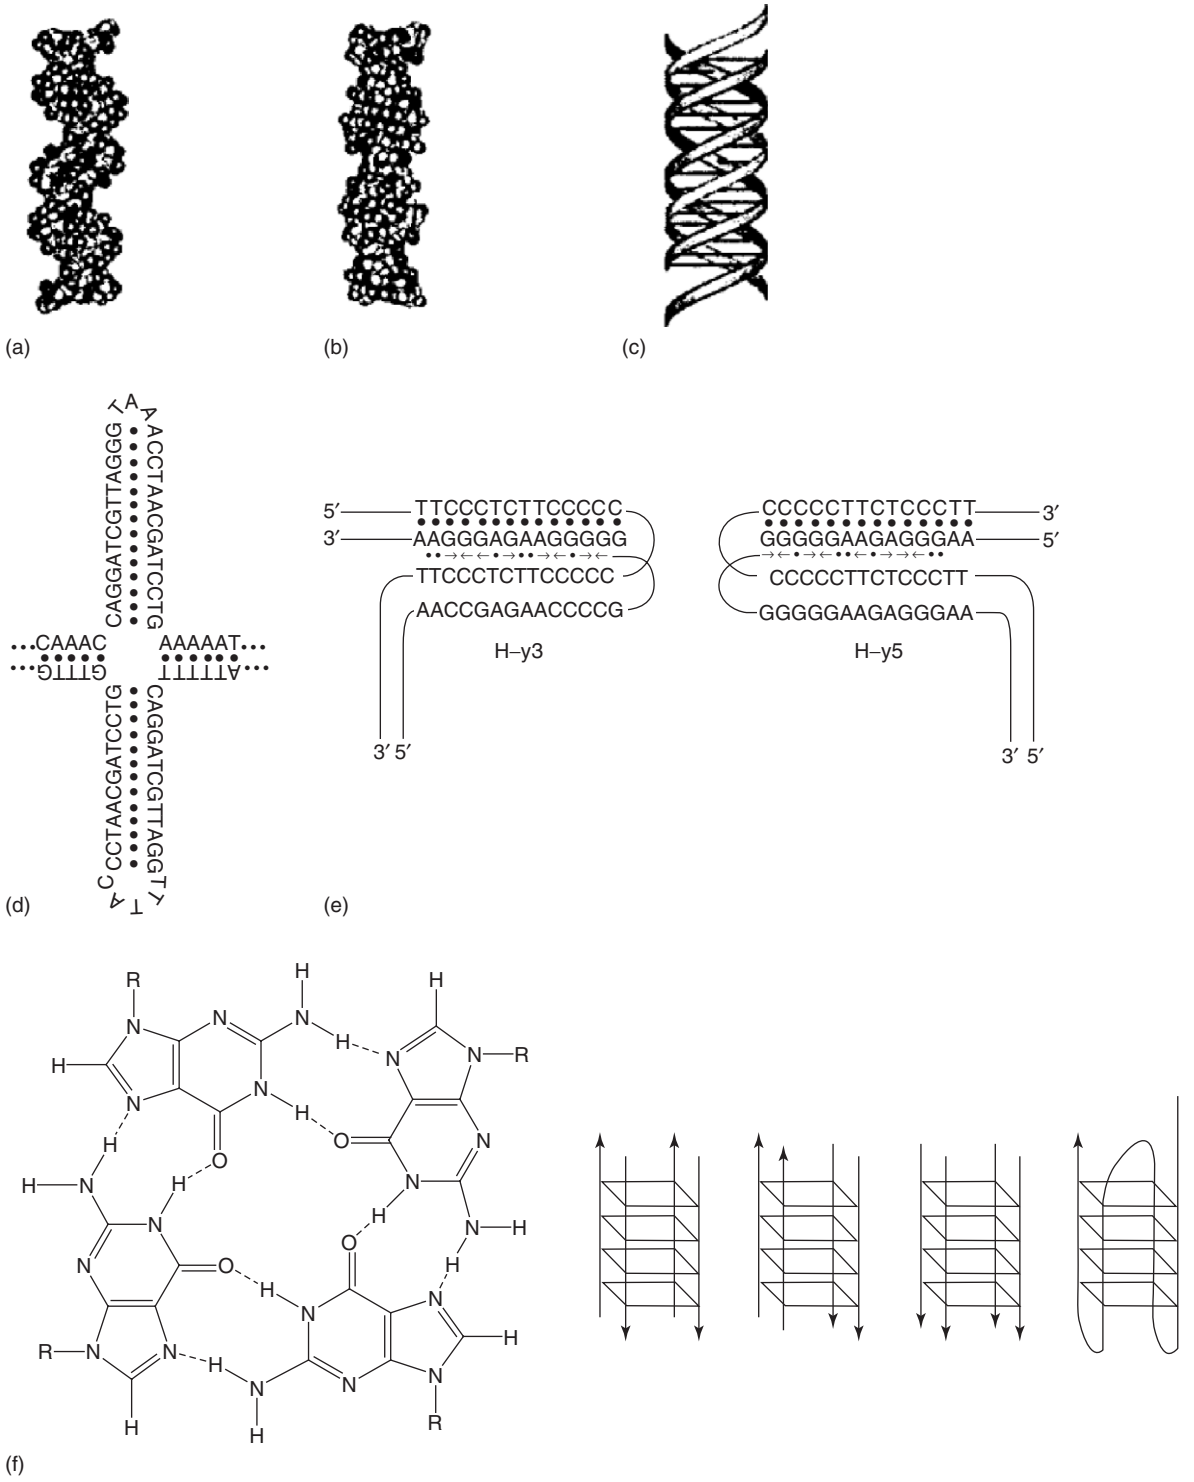

Figure 4 Schematics of (a) B-DNA and some unusual structures of DNA: (b) Z-DNA, (c) intermolecular triplex, (d) cruciform, (e) H-DNA, (f) G-quadruplex and its various folding modes.

GC. However, the major RNA duplex conformation remains A-form rather than B-form.

In general, due to bulkier OH group in the sugar ring, the versatility of RNA duplexes is rather narrower than those of DNA.

In a cell, different types of RNA molecules (mRNA, rRNA, tRNA, etc.) exist as single strands. Of course, these strands are not unfolded, but fold into complex spatial structures. Mutually complementary stretches of the same molecules form numerous short duplexes,

which are a major structural motif of RNA molecules. Single-stranded regions form loops of different types. Sometimes very complex folding patterns, called pseudoknots, are met.

Spatial structure plays an important role in RNA functioning. For instance, rRNA organized in complex spatial structure forms a scaffolding to which numerous ribosomal proteins attach to form the functional ribosome. The elucidation of the full 3D structure of the ribosome by X-ray crystallography has been one of the major achievements of biophysics and structural biology. Spatial structure at tRNA molecules are specially designed to permit them to fulfill the central role in the realization of the genetic code. One part of tRNA carries the anticodon, a trinucleotide complementary to a codon (a trinucleotide corresponding to one amino acid in the genetic code), whereas the amino acid, which corresponds to the codon in the genetic code, is attached to one terminus of the molecule.

DNA Topology

DNA very often operates within the cell in the form of a closed circular molecule in which both strands form closed circles (**Figure 5**). The physical properties and physiological behavior of closed circular (cc) DNA are different in many respects from those of linear DNA molecules. These differences stem from the fact that ccDNA acquires, as compared to linear DNA, a new fundamental feature, topology. There are two levels of DNA topology.

Knots of DNA

The double helix, as a whole, may form a simple circle (i.e., a trivial knot) or be knotted (see **Figure 6**).

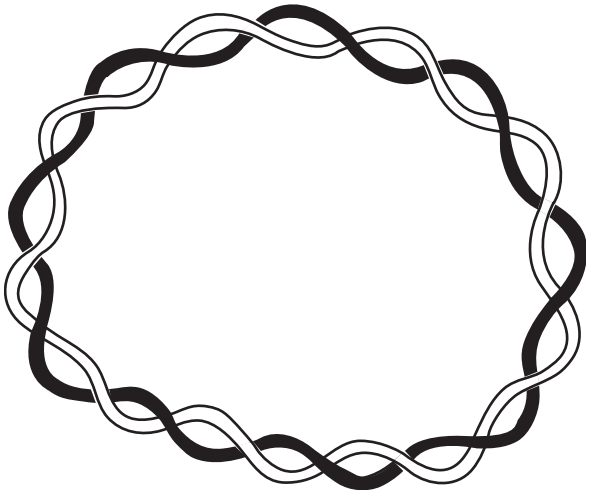

Figure 5 In a ccDNA, two complementary strands form a linkage of a high order.

Knotting of DNA may be conducted by random closure of linear molecules with "cohesive" ends (mutually complementary single-stranded overhangs). There are also different enzymes which do the job. The most important class of such enzymes is known as DNA topoisomerases II. The type of knot is the topological invariant, that is, it cannot be changed (converted to another type of knot) without breakage of both DNA strands. As a result, identical ccDNA molecules belonging to different knot types may be separated in gel.

DNA Supercoiling

The two complementary strands in ccDNA are topologically linked with one another (see **Figure 5**). The degree of linkage, which is designated as *Lk*, the DNA linking number, is a topological invariant, which cannot be changed with any deformations of the DNA strands without strand breaks. The *Lk* value is easily calculated as the number of times one strand pierces the surface placed on the other strand. If N is the number of base pairs in DNA and γ_o is the

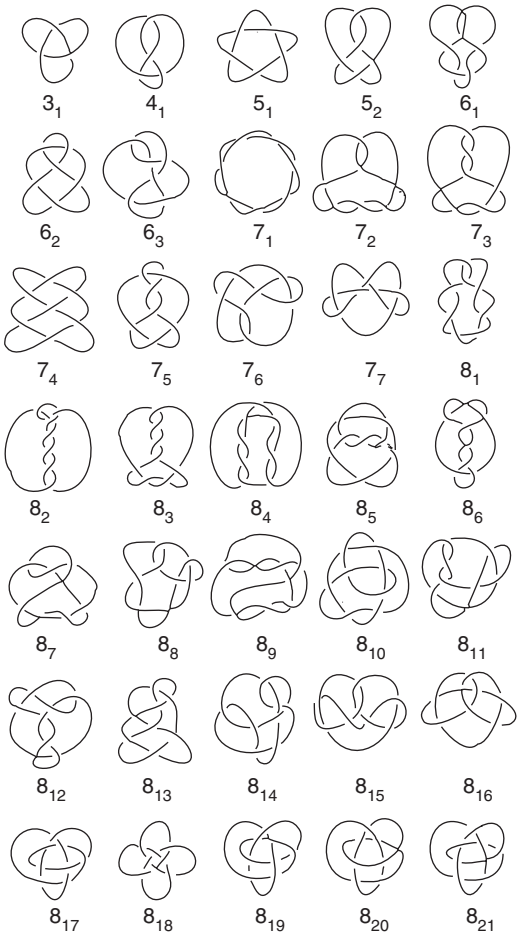

Figure 6 Knots.

number of base pairs per one turn of the double helix under given ambient conditions, then the difference:

$$\tau = Lk - N/\gamma_o \qquad [1]$$

is the number of superhelical turns in ccDNA under given conditions. If $\tau \neq 0$, then ccDNA cannot form a planar ring with the helical twist corresponding the γ_o value. Either the helical twist should change or the DNA molecule as a whole should writhe in space. Actually, with $\tau \neq 0$ both things happen: the DNA adopts the writhe, and its twist changes. The distribution of energy associated with DNA supercoiling (i.e., with $\tau \neq 0$) between twist and writhe is determined by the torsional and bending rigidities, which have been measured with good accuracy. Supercoiling is also significantly affected by replication and transcription. DNA topology plays an extremely important role in DNA functioning.

Structural Transitions and Unusual Structures

If negative supercoiling in ccDNA becomes too high, the bending and torsional degrees of freedom may become insufficient to accommodate the superhelical energy. Under these circumstances, the integrity of the DNA double helix breaks down at its most "weak" sites. These sites, which have the potential to adopt structures significantly different from B-DNA, can undergo structural transitions into unusual (non-B-DNA) structures.

DNA Melting

On heating or under superhelical stress, the DNA complementary strands separate forming single-stranded loops. In case of linear duplex molecules, the process ends up, at sufficiently high temperature, with complete separation of the two strands. The process has been studied comprehensively both experimentally and theoretically and is known as DNA melting (the terms denaturation or helix-coil transition also exist in literature). AT pairs have significantly lower stability than GC pairs.

With increasing temperature, long DNA sections melt out. Melting of each such section is a cooperative, all-or-none phenomenon. However, melting of a long enough molecule becomes a series of such cooperative processes, each occurring at its own temperature (**Figure 7**). Roughly speaking, sections more enriched with GC pairs melt out at higher temperatures. Thus, DNA melting is not a classical phase transition because two different "phases," helical and melted, coexist with each other in one and the same molecule.

When two mutually complementary single-stranded DNA molecules are mixed, the process reverse to melting occurs. It is called renaturation, annealing or hybridization.

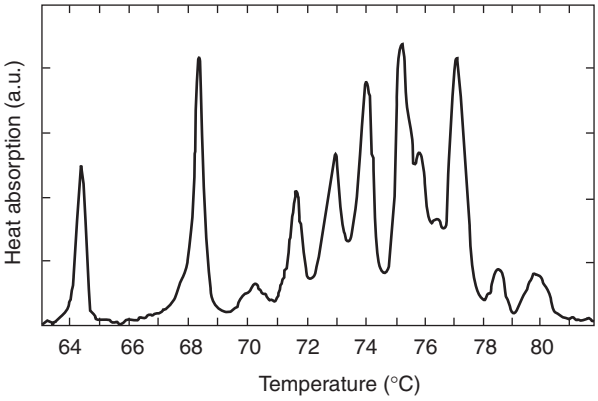

Figure 7 Melting of DNA. This curve is also often called the differential melting curve. The curve was obtained for DNA that has the code name of ColE1 and contains ~6500 nucleotide pairs.

DNA melting is an exceptionally important phenomenon. It occurs in the cell when DNA replicates and when DNA polymerase "reads" the mRNA copy of the gene. Cycles of melting and annealing are utilized in the PCR machines, the most remarkable tools of the current biotechnology revolution.

B–Z Transition

Negative supercoiling favors the formation of Z-DNA most because, in this case, the maximal release of superhelical stress per 1 bp adopting a non-B-DNA structure is achieved. As a result, although under physiological conditions the Z form is energetically very unfavorable as compared with B-DNA, it is easily adopted in negatively supercoiled DNA by appropriate DNA sequences (with alternating purines and pyrimidines).

Cruciforms

Another structure readily formed under negative supercoiling is cruciform, which requires palindromic regions (see **Figure 4d**). To form cruciform, a palindromic region should be long enough. For example, 6 bp long palindromes recognized by restriction enzymes do not form cruciforms under any conditions.

Triplexes

Intramolecular triplex or H-DNA forms a special class of unusual structures, which are adopted under superhelical stress by sequences carrying purines (A and G) in one strand and pyrimidines (T and C) in the other, that is, homopurine–homopyrimidine sequences. The major element of H-DNA is triplex formed by a half of the insert adopting the H form and by one of two strands of the second half of the

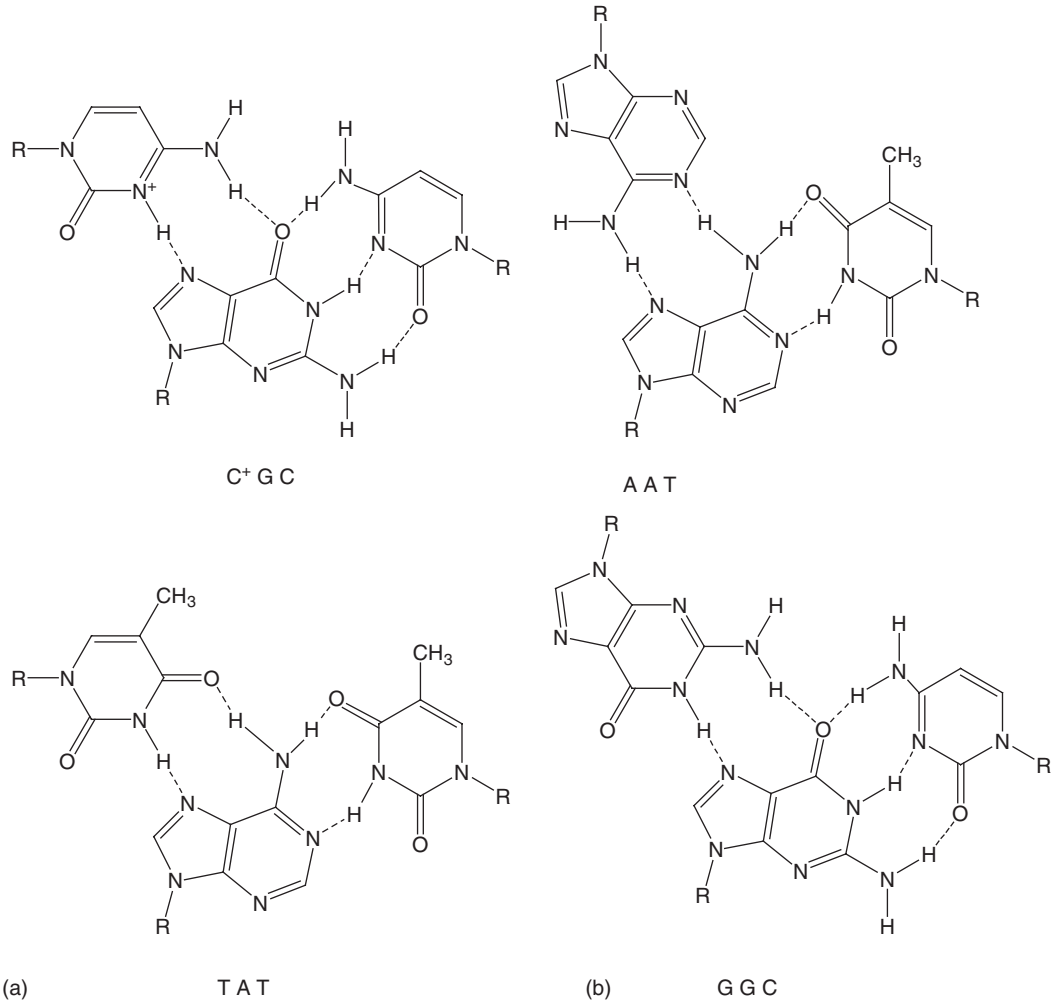

Figure 8 The structure of (a) pyrimidine (TAT and C^+GC), and (b) purine (AAT and GGC) base triads of which the DNA triple helix is made.

insert (**Figure 4e**). Two major classes of triplexes are known: pyrimidine–purine–pyrimidine (PyPuPy) and pyrimidine–purine–purine (PyPuPu). **Figure 8** shows the canonical base-triads entering these triplexes.

Always two isomeric forms of H-DNA are possible, which are designated as H-y3, H-y5, H-r3, and H-r5 depending on which kind of triplex is formed and which half of the insert forms the triplex (see **Figure 4e**).

Discovery of H-DNA stimulated studies of intermolecular triplexes, which may be formed between homopurine–homopyrimidine regions of duplex DNA and corresponding pyrimidine or purine oligonucleotides (**Figure 4c**).

Quadruplexes

Of all nucleotides, guanines are most versatile in forming different structures. They may form GG pairs but the most stable structure, which is formed in the presence of monovalent cations (especially potassium), is G4 quadruplex (see **Figure 4f**). G-quadruplexes may exist in a variety of modifications: all-parallel, all-antiparallel, and others. As a result, G-quadruplexes are easily formed both inter- and intramolecularly, again with a variety of modifications. A remarkable variety of quadruplex structure was discovered for protonated cytosines. This structure, called i-motif, consists of two pairs of parallel stranded duplexes consisting of hemiprotonated CC^+ base pairs. In the final structure, two duplexes and mutually antiparallel and CC^+ base pairs from one ps duplex alternate with CC^+ base pairs from the other ps duplex. The structure is stable only at acidic pH because protonation is necessary.

Bent DNA

For an arbitrary sequence, the minimum energy conformation of the DNA double helix corresponds to the straight DNA axis. However, there is a notable exception to this rule. If three or more A nucleotides

are located in a row in one of the DNA strands, the corresponding regions adopt the B′ structure. As a result, the DNA axis experiences a bend of 20° in such a region. DNA bending plays an important role in DNA functioning.

RNA Unusual Structures

Most DNA unusual structures have their analogs in the RNA world. Specifically, formation of triplexes was first demonstrated for artificial RNA chains. Solitary RNA base-triads are often met in tRNA structures. Triplexes are formed by mixed DNA–RNA hybrids and some of them are rather stable.

However, in general, studies of RNA unusual structures lag behind corresponding DNA structures because methods to study unusual structures are much better developed in the case of DNA than in the case of RNA.

Nanostructures and Nanodevices from DNA and RNA

One of the most rapidly developing areas in DNA and RNA biophysics consists in using the remarkable ability of nucleic acid to self-assembly for creation of nanostructures and nanodevices. In so doing, virtually all unusual structures described above are extensively used: triplexes, quadruplexes, Z-DNA, etc., as well as the duplex. Specifically, a family of topological and pseudotopological nanostuctures has been assembled as is shown in **Figures 9a–9c**. An example of a nanodevice (nanoactuator) is shown in **Figure 9d**. By adding specially designed single-stranded DNA chains, the nanoactuator is transformed from the relaxed form shown in **Figure 9d** to a straightened form in which the A strand is extended into a straight double helix.

Biophysical Methods to Study DNA and RNA

The whole arsenal of methods, which is traditionally used to study molecular structure, is applied to DNA and RNA. A leading position is occupied by X-ray crystallography, which provided us with a knowledge of details of the atomic structure of DNA and RNA. X-ray crystallography made it possible to solve the structure of the nucleosome, the main building block of chromosomes consisting of DNA and hystone proteins, and of a major cellular machinery, ribosome, consisting of RNA and many proteins. The next method is proton NMR, which is especially valuable when biological molecules resist crystallization, a not uncommon problem with nucleic acids. An enormous body of data on the structure of DNA triplexes, quadruplexes, and various ribozymes was delivered by NMR. Electron microscopy (EM), crio-EM and atomic force microscopy (AFM) have become indispensable in studying the DNA and its complexes with proteins. All kinds of spectroscopy methods, UV, IR, Raman, and CD are very useful in studying conformational transitions in DNA and RNA. A special role is played by various fluorescence methods, which find more and more applications not only in biophysical studies, but also in biotechnology. Below, specific methods, which have been specially developed in the field of DNA and RNA biophysics are discussed.

Theoretical Models

As in the study of any important physical object, a number of simplified theoretical models of nucleic acids exist, different models being used to analyze different properties. **Figure 10** presents schematics of some of these models.

The DNA double helix may be treated as an isotropic elastic rod (**Figure 10a**). In the framework of this model, the DNA molecule is described by only three parameters: bending, torsional rigidities, and the diameter. The model has proved to be extremely useful for analyzing hydrodynamics and other properties of linear DNA, when it behaves as a usual polymeric molecule. It has also provided a comprehensive theoretical treatment of DNA topology of both levels: knotting and supercoiling. More recently, the model has been extensively used for quantitative analysis of the force-extension curves for DNA in single-molecule experiments (see below).

A quite different, but also very successful, model treats the DNA double helix as consisting of base pairs of two types: closed and open (**Figure 10b**). This is the helix-coil model, which explains all major features of DNA melting quantitatively.

The polyelectrolyte model (**Figure 10c**) treats DNA itself just as a charged cylinder but allows for mobile counter-ions surrounding the double helix.

To predict the RNA structure, a simplified model of RNA folding is widely used (**Figure 10d**).

Gel Electrophoresis

Gel electrophoresis is a simple technique, introduced in the early 1970s, which truly revolutionized the biophysical studies of DNA and RNA and, subsequently, the whole field of molecular biology. All developments in this field in the past 30 years are connected, directly or indirectly, with the gel electrophoresis method. Gel electrophoresis has pushed aside ultracentrifugation as the method to separate nucleic acids.

Gel electrophoresis differs from electrophoresis in solution only in the nature of the medium in which molecules are separated in the electric field. In case of gel electrophoresis the medium is the gel, a polymer network. The most popular in the field of nucleic acids are gels made of polyacrylamide or agarose. Originally, the great advantage of gels in the separation of nucleic acids was discovered purely empirically. The understanding came later after some ideas of De Grennes P-J were borrowed from polymer physics, namely the notion of reptation of polymer molecules. Gel electrophoresis is indispensable in all methods of DNA sequencing which have revolutionized the entire field of biology. The DNA sequencing techniques have been developed to perfection, based on different conceptual approaches. The most fertile approach proved to be that of Sanger who developed a method of DNA sequencing, which uses enzymes working on DNA.

Single-Molecule Experiments with DNA and RNA

In recent years, remarkable progress in the application of the single-molecule techniques to DNA and RNA studies has been achieved. There are many different formats for single-molecule experiments.

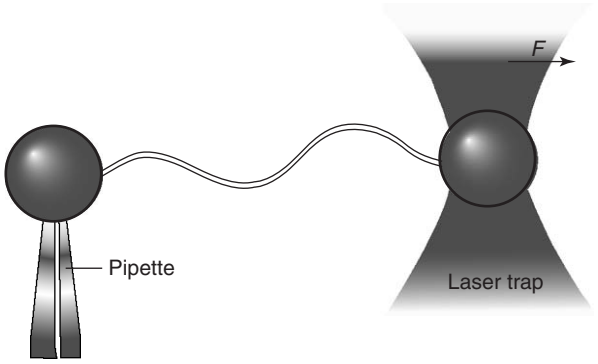

Figure 11 Stretching a single DNA molecule with optical tweezers.

For example, a DNA molecule consisting of about 50 kbp is attached via one terminus to a pipette tip equipped with a streptavidin-covered polymer bead. Streptavidin is a protein, which binds very strongly to a small molecule, biotin. The DNA terminus is covalently tagged with biotin to be attached to the streptavidin-covered bead. The other terminus is also attached to the polymer bead, but the bead is not fixed. Then, optical tweezers are used to drag the free bead with the DNA attached to it. As a result, a single DNA molecule can be stretched in a fully controllable manner and the force created in the process can be accurately measured (see **Figure 11**).

These experiments have allowed, for the first time, measurement of the force–extension curves of ds and ss DNAs and comparison of the curves with theoretical predictions. One of the important directions of these studies include isothermal melting of DNA and RNA duplexes under the external force. The influence of the force on the performance of major enzymes working on DNA and RNA (DNA and RNA polymerases) has also been studied. A very important feature of single-molecule experiments consists in the fact that they introduce a new variable on which DNA and RNA structure critically depend, the external force.

E

Effective Masses

A L Wasserman, Oregon State University, Corvallis, OR, USA

Introduction

Electrons in condensed matter interact strongly with their environment. This environment generally consists of a crystalline lattice, phonons, other electrons and an assortment of localized "defect" potentials, as well as applied external fields. As a result of these interactions, free, single particle energies ε_0, where

$$\varepsilon_0(\boldsymbol{k}) = \frac{\hbar^2 k^2}{2m} \qquad [1]$$

with $\boldsymbol{k}$ the electron wave vector and m the "bare" electron mass, are usually altered in significant ways, which can include simple energy shifts as well as imparting finite lifetimes to the single particle states.

It is often possible and convenient, both for experimentalists and theoreticians, to regard the particles plus interactions as a new fermionic entity, referred to as a "quasiparticle" with energy

$$\varepsilon(\boldsymbol{k}) = \frac{\hbar^2 k^2}{2m_{\text{eff}}} \qquad [2]$$

where an effective mass m_{eff} can parametrize important features of the interacting environment. There is, in fact, a considerable range of experimental phenomena whose results are usefully parametrized in this surprisingly simple way. The extent to which some (or any) of them relate to first-principles microscopic interactions are briefly surveyed here.

In an attempt to bring some uniformity to the calculation and interpretation of effective masses, one can present a general approach to the problem by deriving a single formulation for effective mass calculations. This formulation is first adapted to semiconductor and insulator problems where effective mass parameters are attributed, in the first order, to interactions with the periodic lattice and, in particular, to electrons whose occupation is confined to the edges of the conduction and valence bands. The formulation is then modified for dense Fermi systems in which particle behavior at the Fermi surface is the crucial determinant of electronic properties, including effective masses.

Consequences of Interactions

A general expression which describes the effects of interactions is

$$\varepsilon(\boldsymbol{k}) = \varepsilon_0(\boldsymbol{k}) + \Gamma[\boldsymbol{k}, \varepsilon(\boldsymbol{k})] \qquad [3]$$

where $\varepsilon(\boldsymbol{k})$ is the fully interaction-modified "quasiparticle" energy, $\varepsilon_0(\boldsymbol{k})$ is the noninteracting energy, as given in eqn [1], and $\Gamma[\boldsymbol{k}, \varepsilon(\boldsymbol{k})]$ is the quantitative consequence of all the environmental perturbations to the free electron system. It should be noted that Γ depends on the wave vector $\boldsymbol{k}$, but may also depend, self-consistently, on $\varepsilon(\boldsymbol{k})$, the quasiparticle energy of the state itself. Moreover, $\Gamma[\boldsymbol{k}, \varepsilon(\boldsymbol{k})]$ is, in general, a complex quantity:

$$\Gamma[\boldsymbol{k}, \varepsilon(\boldsymbol{k})] = \Delta[\boldsymbol{k}, \varepsilon(\boldsymbol{k})] + \mathrm{i}\gamma[\boldsymbol{k}, \varepsilon(\boldsymbol{k})] \qquad [4]$$

the imaginary part usually being responsible for quasiparticle lifetime effects. Although $\gamma \neq 0$ is often the case, this possibility does not explicitly contribute to the following discussion. The apparent abstractness of eqns [3] and [4] notwithstanding, one finds that a quasiparticle effective mass m_{eff} is a useful and intuitive concept.

An Effective Mass Formulation

In formulating the general case for an effective mass theory which can embrace simple interactions, such as band structure in semiconductors, as well as phonons and the more subtle electron–electron interactions, one begins with eqns [3] and [4] and assumes that the imaginary part $\gamma[\boldsymbol{k}, \varepsilon(\boldsymbol{k})]$ has a negligible effect in determining m_{eff}.

The initial step in obtaining an explicit form for the "quasiparticle" energy $\varepsilon(\boldsymbol{k})$ is most simply done

by applying Newton's iterative method to eqn [3], which is first rewritten in the form

$$\varepsilon(\boldsymbol{k}) - \varepsilon_0 - \Delta[\boldsymbol{k}, \varepsilon(\boldsymbol{k})] = 0 \qquad [5]$$

Newton's method consists of first expanding eqn [5] to linear order about some initial value $\varepsilon^{(0)}$ (which will be chosen below) to give

$$\varepsilon^{(0)} - \varepsilon_0(\boldsymbol{k}) - \Delta(\boldsymbol{k}, \varepsilon^{(0)}) + \left[1 - \frac{\partial\Delta(\boldsymbol{k}, \varepsilon)}{\partial\varepsilon}\right]_{\varepsilon=\varepsilon^{(0)}} [\varepsilon(\boldsymbol{k}) - \varepsilon^{(0)}] = 0 \qquad [6]$$

Now solving for ε, one finds

$$\varepsilon(\boldsymbol{k}) = \varepsilon^{(0)} - \frac{[\varepsilon^{(0)} - \varepsilon_0(\boldsymbol{k}) - \Delta(\boldsymbol{k}, \varepsilon^{(0)})]}{[1 - (\partial\Delta(\boldsymbol{k}, \varepsilon)/\partial\varepsilon)]_{\varepsilon=\varepsilon^{(0)}}} \qquad [7]$$

Temporarily assuming, for simplicity, that $\boldsymbol{k}$ is a scalar and expanding to the first order in k^2 about $k = 0$, one has

$$\varepsilon(\boldsymbol{k}) = \varepsilon^{(0)} - \frac{[\varepsilon^{(0)} - \varepsilon_0(k) - \Delta(0, \varepsilon^{(0)}) - (\partial\Delta(k, \varepsilon^{(0)})/\partial(k^2))|_{k=0} k^2]}{[1 - (\partial\Delta(0, \varepsilon)/\partial\varepsilon)]_{\varepsilon=\varepsilon^{(0)}}} \qquad [8]$$

Finally, starting the iterations from $\varepsilon^{(0)} = 0$, after a single iteration one obtains

$$\varepsilon(k) = \frac{[\varepsilon_0(k) + \Delta(0,0) + (\partial\Delta(k,0)/\partial(k^2))|_{k=0} k^2]}{[1 - \partial\Delta(0,\varepsilon)/\partial\varepsilon]_{\varepsilon=0}} \qquad [9]$$

Assuming the constant energy shift $\Delta(0,0) = 0$ and from the above equation $\varepsilon_0(\boldsymbol{k}) = \hbar^2 k^2/2m$, one can obtain

$$\varepsilon(k) = \frac{\hbar^2}{2m}\left\{\frac{1 + (2m/\hbar^2)[\partial\Delta(k,0)/\partial(k^2)]_{k=0}}{(1 - (\partial\Delta(0,\varepsilon)/\partial\varepsilon))_{\varepsilon=0}}\right\} k^2 \qquad [10]$$

Therefore, an effective mass can be defined by

$$\frac{m}{m_{\text{eff}}} = \left\{\frac{1 + (2m/\hbar^2)[\partial\Delta(k,0)/\partial(k^2)]_{k=0}}{(1 - (\partial\Delta(0,\varepsilon)/\partial\varepsilon))_{\varepsilon=0}}\right\} \qquad [11]$$

In the case that k is not a scalar, one should expand instead to the second order and similarly find an effective mass tensor

$$\left(\frac{m}{m_{\text{eff}}}\right)_{\mu\nu} = \left\{\frac{\delta_{\mu\nu} + (m/\hbar^2)[\partial^2\Delta(\boldsymbol{k},0)/\partial k_\mu \partial k_\nu]_{k=0}}{(1 - (\partial\Delta(0,\varepsilon)/\partial\varepsilon))_{\varepsilon=0}}\right\} \qquad [12]$$

In the general semiconductor band case,

$$\varepsilon_0(\boldsymbol{k}) + \Delta(\boldsymbol{k}, \omega) \rightarrow E(\boldsymbol{k}, 0) \qquad [13]$$

where $E(\boldsymbol{k})$ is the band dispersion relation and the $\boldsymbol{k}$-expansion of eqn [8] is taken about any band extremal point $\boldsymbol{k}_m$ (the Fermi gas case is discussed below). Once the relevant perturbing terms are known, eqn [11] or [12] may be straightforwardly applied.

Band-Structure Effective Mass

The most common application of effective mass theories is in parametrizing the features of a band structure. This is especially practical in semiconductors and insulators where most experimental features arise from electron occupation near the extremal points of band maxima (valence bands) and band minima (conduction bands). In the energy band approximation, it is first noted that $\partial\Delta(0,\varepsilon)/\partial\varepsilon = 0$. Recasting eqn [12] to reflect the energy band approximation (see eqn [13]), one obtains

$$\left(\frac{1}{m_{\text{eff}}}\right)_{\mu\nu} = \frac{1}{\hbar^2}\left[\frac{\partial^2 E(\boldsymbol{k}, 0)}{\partial k_\mu \partial k_\nu}\right]_{\boldsymbol{k}=\boldsymbol{k}_m} \qquad [14]$$

where $E(\boldsymbol{k},0)$ is the electron energy band dispersion relation and $\boldsymbol{k}_m$ are wave vectors of any conduction-band minima or valence-band maxima. Since the derivative in eqn [14] is related to the "curvature" of the dispersion relation, bands of large curvature correspond to small effective masses (light "quasiparticles") while flatter bands, that is, bands with small curvature, are "heavier" quasiparticles. Moreover, since valence bands have maxima at $\boldsymbol{k}_m$, their curvature will have negative values and, therefore, be quasiparticles with negative effective masses. This inadmissible condition is resolved by assigning to these quasiparticles a positive charge, referring to them as holes and thereby restoring proper signs to transport properties.

Effective Mass of a Degenerate Fermi System

In the case of a degenerate Fermi system, Fermi–Dirac statistics usually restrict dominant behavior to those electrons at the Fermi surface where $\boldsymbol{k}_F$, the Fermi wave vector, is neither a band maximum nor a minimum. Therefore, the noninteracting energy band relation $\varepsilon_0(\boldsymbol{k})$ is expressed as an expansion about $k = k_F$. Since k_F is not an extremal point, one can obtain an expression which has a term linear in $(k - k_F)$:

$$\varepsilon_0(k) = \varepsilon_0(k_F) + \frac{\hbar^2 k_F}{m}(k - k_F) + \cdots \qquad [15]$$

Similarly, eqn [7] is expanded about $k = k_F$ instead of $k = 0$ giving, to linear order,

$$\varepsilon(k) = \varepsilon^{(0)} - \{[1 - (\partial\Delta(k_F, \varepsilon)/\partial\varepsilon)]_{\varepsilon=\varepsilon^{(0)}}\}^{-1}[\varepsilon^{(0)} - \varepsilon_0(k_F) - \Delta(k_F, \varepsilon^{(0)}) - (\hbar^2 k_F/m)([1 + (m/\hbar^2 k_F) \times (\partial\Delta(k, \varepsilon^{(0)})/\partial k)|_{k=k_F}](k - k_F) + \cdots] \quad [16]$$

Iterating once again, starting with $\varepsilon^{(0)} = 0$, one obtains

$$\varepsilon(k) = \{[1 - (\partial\Delta(k_F, \varepsilon)/\partial\varepsilon)]_{\varepsilon=0}\}^{-1}[\varepsilon_0(k_F) + \Delta(k_F, \varepsilon^{(0)}) + (\hbar^2 k_F/m)[1 + (m/\hbar^2 k_F) \times (\partial\Delta(k, \varepsilon^{(0)})/\partial k)|_{k=k_F}](k - k_F) + \cdots] \quad [17]$$

Comparing this result with eqn [15], an expression for an effective mass is given by

$$\frac{1}{m_{\text{eff}}} = \left[\frac{1}{m} + \frac{1}{\hbar^2 k_F}\frac{\partial\Delta(k, \varepsilon^{(0)})}{\partial k}\bigg|_{k=k_F}\right] \times \left\{\left[1 - \frac{\partial\Delta(k_F, \varepsilon)}{\partial\varepsilon}\right]_{\varepsilon=0}\right\}^{-1} \quad [18]$$

In the case where the band structure is of dominant interest in interpreting an effective mass, one can write (see eqn [14])

$$\frac{1}{m_{\text{eff}}} = \left[\frac{1}{\hbar^2 k_F}\frac{\partial E(k, 0)}{\partial k}\bigg|_{k=k_F}\right]\left\{\left[1 - \frac{\partial\Delta(k_F, \varepsilon)}{\partial\varepsilon}\right]_{\varepsilon=0}\right\}^{-1} \quad [19]$$

which is inversely proportional to the "slope" of $E(k,0)$, the electron dispersion at the Fermi surface. Here, $\Delta(k_F, \varepsilon)$ represents all perturbing terms beyond the band approximation (phonons, etc.). This should be compared to the semiconductor case in which proportionality to the inverse "curvature" at the band extrema determines the effective mass.

Electron Correlations: Hartree–Fock

The simplest case for calculating an effective mass arising from electron–electron interactions is to consider the contribution to $\Gamma[\boldsymbol{k}, \varepsilon(\boldsymbol{k})]$ in the Hartree–Fock approximation. The widely known Hartree–Fock result has only a real part

$$\Delta(k, 0) = -\frac{\hbar^2 e^2 k_F}{2\pi}\left[2 + \frac{(k_F^2 - k^2)}{k k_F}\ln\left|\frac{k + k_F}{k - k_F}\right|\right] \quad [20]$$

This approximation, although far from an adequate picture of electrons in metals, provides an example to which one can apply eqn [18]. Differentiating eqn [20] as required gives the nonsensical result:

$$m_{\text{eff}} = 0 \quad [21]$$

which can be interpreted as an indication of just how flawed the Hartree–Fock approximation is for the degenerate Fermi gas.

In the case of exotic heavy fermion alloys, for example, CeB_6, $CeCu_2$, which have effective masses 10–100 times those of bare electron masses, the mixture of strong on-site *f*-state correlations and hybridization between *s*-states and *f*-states requires a description in terms of strongly hybridized bands. These hybridized bands have extremely large "slopes" at the Fermi surface due to the large *f*-state interactions having forced open a small energy gap just above the Fermi energy. This results in flattening the occupied conduction band to an almost horizontal conformation at k_F, so that according to eqn [19], an unusually large effective mass is to be expected.

Density-of-States Effective Mass

Although optical experiments are capable of probing a band structure with considerable detail and can even determine effective mass tensor components, thermodynamic experiments (e.g., specific heat) do not have this capability. For example, the low-temperature specific heat in Fermi systems is linear in temperature (its signature):

$$C_V = \frac{\pi^2}{3}k_B^2 \mathscr{D}(E_F)T \quad [22]$$

and proportional to $\mathscr{D}(E_F)$, the "density of electronic states" at the Fermi energy E_F, where T is temperature in K and k_B is the Boltzmann constant. The density of states is able to make no distinctions about the detailed geometry of the electron energy bands and thereby presents an effective mass interpretation which, at best, averages the mass tensor components in a specific way.

The density of electronic states is determined by "sifting" through all the electrons in a band and counting those that have a particular energy. The sifting and counting process is repeated for all bands. This process is succinctly described by the expression

$$\mathscr{D}(\varepsilon) = 2\sum_{\boldsymbol{k}}\delta[\varepsilon - E(\boldsymbol{k})] \quad [23]$$

Note how the Dirac δ-function combs through the band electrons and registers a count when it encounters one with energy ε. It then continues to

comb and count. The factor of 2 accounts for spin degeneracy. This is the simple meaning of the density of states.

Now, to see how the effective mass enters into the density of states, evaluate eqn [23] for a single, simple isotropic band such as represented by eqn [2]. Using the fact that in three dimensions

$$\sum_{\boldsymbol{k}} \rightarrow \frac{V}{(2\pi)^3}\int_0^{2\pi} \mathrm{d}\phi \int_0^{\pi} \mathrm{d}\theta \sin\theta \int_0^{\infty} \mathrm{d}k\, k^2 \qquad [24]$$

eqn [23] becomes

$$\mathscr{D}_{\mathrm{c}}(\varepsilon) = \frac{2V}{(2\pi)^3}\int_0^{2\pi} \mathrm{d}\phi \int_0^{\pi} \mathrm{d}\theta \sin\theta \int_0^{\infty} \mathrm{d}k \times k^2 \delta\left[\varepsilon - \left(E_{\gamma \mathrm{c}} + \frac{\hbar^2 k^2}{2m_{\mathrm{eff}}}\right)\right] \qquad [25]$$

for the choice of an isotropic conduction band in an effective mass approximation,

$$E_{\mathrm{c}}(\boldsymbol{k}, 0) = E_{\gamma \mathrm{c}} + \frac{\hbar^2 k^2}{2m_{\mathrm{eff}}} \qquad [26]$$

where $E_{\gamma \mathrm{c}}$ is a bandgap energy.

Using the Dirac identity

$$\delta[f(k)] = \sum_{k_{\mathrm{R}}} \frac{\delta(k - k_{\mathrm{R}})}{\left[\left|\frac{\partial f(k)}{\partial k}\right|_{k=k_{\mathrm{R}}}\right]} \qquad [27]$$

where the values of k_{R} are determined by the solutions of $f(k_{\mathrm{R}}) = 0$, one gets the density of states per unit volume:

$$\frac{\mathscr{D}_{\mathrm{c}}(\varepsilon)}{V} = \frac{m_{\mathrm{eff}}^{3/2}\sqrt{2}}{\pi^2\hbar^3}\sqrt{\varepsilon - E_{\gamma \mathrm{c}}}, \quad \varepsilon > E_{\gamma \mathrm{c}} \qquad [28]$$

This isotropic case does not, of course, expose any of the averaging that will take place in the anisotropic case. To understand better what kind of averaging this is, the ellipsoidal band case is taken as

$$E(\boldsymbol{k}) = E_{\gamma} + \frac{\hbar^2}{2}\left(\frac{k_x^2 + k_y^2}{m_{\perp}} + \frac{k_z^2}{m_{\mathrm{II}}}\right) \qquad [29]$$

Following eqn [23] but this time integrating in cylindrical coordinates, one gets, for a conduction band,

$$\frac{\mathscr{D}_{\mathrm{c}}(\varepsilon)}{V} = \frac{(m_{\perp} m_{\perp} m_{\mathrm{II}})^{1/3}\sqrt{2}}{\pi^2\hbar^3}\sqrt{\varepsilon - E_{\gamma \mathrm{c}}}, \quad \varepsilon > E_{\gamma \mathrm{c}} \qquad [30]$$

which defines the averaging of effective mass tensor components imposed by the density-of-states effective mass. For an ellipsoidal valence band, one obtains

$$\frac{\mathscr{D}_{v}(\varepsilon)}{V} = \sqrt{2}\frac{(m_{\perp} m_{\perp} m_{\mathrm{II}})^{1/3}}{\pi^2\hbar^3}\sqrt{-\varepsilon}, \quad \varepsilon < 0 \qquad [31]$$

It is now interesting to note that the thermodynamic implication of the Hartree–Fock result of eqn [23] is that C_V (Hartree–Fock) $= 0$, which continues to point to the inadequacy of that approximation.

Electron–Phonon Interactions

After explicitly evaluating the density of states for an isotropic band structure, the constant volume specific heat for a Fermi gas, eqn [22], becomes

$$C_V = \frac{k_{\mathrm{B}}^2 m_{\mathrm{eff}} k_{\mathrm{F}}}{\hbar^2} T \qquad [32]$$

As is well known, measured specific heats generally exceed the free electron values even for simple metals in the alkali series, which have nearly free electron bands. By determining an effective mass which arises from electron–phonon interactions, it can be seen that a fraction of this excess specific heat can be attributed to electron–phonon interactions. One can use eqns [11] and [12] to explore this case by referring to the well-known result that for electron–phonon interactions in a Fermi gas,

$$\Delta_{\mathrm{e-p}}(k_{\mathrm{F}}, \varepsilon) = -\lambda\varepsilon \qquad [33]$$

where ε is the self-consistent "quasiparticle" energy that is generally characteristic of $\Delta(\boldsymbol{k}, \varepsilon)$ and

$$\lambda = 2\int_0^{\infty} \mathrm{d}\omega \frac{\alpha^2(\omega) F(\omega)}{\omega} \qquad [34]$$

is a measure of the electron–phonon coupling strength, with $\alpha^2(\omega)$ the electron–phonon coupling function and $F(\omega)$ the phonon density of states.

Returning to eqn [18] (ignoring band structure effects),

$$\varepsilon(k) = \frac{\varepsilon_0(k_{\mathrm{F}})}{[1 - (\partial\Delta_{\mathrm{e-p}}(k_{\mathrm{F}}, \varepsilon)/\partial\varepsilon)]_{\varepsilon=0}} = \frac{\hbar^2 k_{\mathrm{F}}^2}{2m(1+\lambda)} \qquad [35]$$

so that an electron–phonon enhanced effective mass may be identified as

$$m_{\mathrm{eff}} = m(1+\lambda) \qquad [36]$$

Other Effective Mass Parametrizations

An effective mass is used to parametrize interacting electron behavior in other measurements. For example,

1. Electrical conductivity

$$\sigma = \frac{ne^2\tau}{m_{\text{eff}}} \qquad [37]$$

   where τ is a transport relaxation time.
2. The theory of excitons and interband optical absorption, in which a reduced effective mass μ is defined:

$$\frac{1}{\mu} = \frac{1}{m_{\text{eff,c}}} + \frac{1}{m_{\text{eff,h}}} \qquad [38]$$

   in order to parametrize the excitonic Rydberg states. Here, $m_{\text{eff,c}}$ is a conduction band effective mass and $m_{\text{eff,h}}$ is a valence band effective mass.
3. The de Haas–van Alphen magneto-oscillations, where the temperature-dependent amplitude of the rth harmonic $r = 1, 2, \ldots$, is

$$A_r = \left\{ \sinh\left[\frac{2\pi^2 r k_{\text{B}} m_{\text{eff}} T}{ehB} \right] \right\}^{-1} \qquad [39]$$

The de Haas–van Alphen effective mass is almost identical to the density-of-states effective mass which appears in the specific heat:

$$m_{\text{eff}}(C_V) = m(1 + \lambda_{\text{e-p}} + \cdots) \qquad [40]$$

except that the de Haas effective mass refers to only one extremal areal slice of the Fermi surface perpendicular to the magnetic field direction, whereas the specific heat effective mass is averaged over the entire Fermi surface.

There are experiments for which some kind of effective mass description seems appropriate, but for which there is no rigorously applicable or meaningful theory. For example, the plasma frequency

$$\omega_{\text{p}}^2 = \frac{ne^2}{m_{\text{eff}}\varepsilon_0} \qquad [41]$$

which can be determined from optical or electron stopping power experiments (and a Hall measurement to determine the carrier concentration n) is parametrized by an effective mass. But the plasma frequency is a collective excitation of all available mobile electrons so that effective mass calculations of the type described above have little relevance. In those cases, phenomenology rules.

Comparing effective masses from different types of experiments may have to be done with great care and with the knowledge of the theoretical origins of the parameter in each specific case.

Electric and Magnetic Fields in Cells and Tissues

J Gimsa and L Haberland, Universität Rostock, Rostock, Germany

Introduction

Electromagnetic phenomena play an important role at all hierarchical and structural levels of biological organisms, and even in interactions among organisms and their orientation within the biosphere. Electromagnetic fields in cells and tissues may be inherent to the biological system or the result of natural or man-made exposure to such fields. Fields may interact with electrically passive or active biological structures. In both cases, the response by specific mechanisms will depend on field frequency and intensity. Whereas external fields may range from electrostatic fields up to Gamma-irradiation, the generation of fields in cells is limited in frequency range and intensity. The frequencies of physiologically generated electromagnetic fields range from 0 Hz for static (DC) fields up to light frequencies for fluorescence effects driven by captured photons or ATP, as is the case with lightning bugs.

In this article, the electric and magnetic properties of biological matter for frequencies ranging from DC up to GHz are considered. The main focus is on electric phenomena, since the interaction with magnetic fields is usually weak for the generally low-magnetic susceptibility of biological matter. Impedance and AC electrokinetic techniques as methods that apply fields for exploring the passive properties of tissues and suspended cells are also considered. To focus on tissues and cells, specific mechanisms discussed in relation to speculations of possible harmful effects of electromagnetic fields are not considered. Neither are fields beyond GHz in the far infrared or visible light range considered.

Mechanisms and Frequencies of Field Generation and Interaction

At the atomic and molecular levels, static electric fields associated with ions and dipole molecules are important for intermolecular forces. At the next higher structural level, static fields are found in electric double layers, such as at the interfaces of membranes with aqueous electrolytes. Whereas these fields are part of the thermodynamic (electrochemical) equilibrium at the interface, the (nonequilibrium) physiological transmembrane potential of living cells is built up by ATP-driven ion pump proteins. Other nonequilibrium processes are found in electrorheological effects as motion of fluids in or around cells and tissues, and in the deformation of tissue leading to a piezoeffect, as in bones, for instance. Even though the transmembrane potential cannot usually be measured in the external medium, in some cases, static fields can be detected around single cells or even organisms, for example, the DC potentials between various parts of an animal body or of plants. In lesions, wound potentials are found.

Cell excitation, as in nerve and muscle cells, is based on active electric cell properties. Voltage-gated, ion-channel proteins play a key role in the generation of membrane-potential spikes. Spike frequencies reach the kHz range. In excitable tissues, such as the brain, the so-called "field potentials," superimposed potentials generated by a great number of cells, are found. Such potentials are detected, for example, in medical diagnostics in electromyograms, electrocardiograms, or electroencephalograms (EMG, ECG, or EEG). Between limbs, ECG potentials of several mV are detected.

Even though mechanical oscillations in the lower radio-frequency range are common for ultrasound orientation of animals, the emission of electromagnetic fields by biological systems in the radio-frequency range is unknown. Nevertheless, the hair cells of the inner ears of these animals or the sound-detecting cells in insects must, of course, be capable of electrically processing these frequencies.

Beyond the radio-frequency range, spectroscopic methods detect molecular properties. In the microwave and far infrared regions, energy transitions (the absorption and emission of energy quanta) are particularly related to the rotation of molecules. Oscillations inherent to the molecules possess higher energies and are subsequently detected in the near infrared range. The highest energies are associated with the electrons of the molecules. The corresponding energy transitions are mediated by the quanta of the visible and ultraviolet optical ranges.

It is generally believed that molecular oscillations are not synchronous and thus generate localized fields of low strength. Nevertheless, these fields mediate inter- and intra-molecular interaction forces (van der Waals forces). Since physiological energy is steadily degraded by chemical reactions which leads to warming, living organisms radiate electromagnetic energy of the infrared-frequency range into the environment.

The exploration of the properties of biological matter has always been connected to medical and

biotech applications of electromagnetic fields. For the response of cells to electric fields, both the passive properties of the different media as well as the active properties of various membrane proteins, such as ion pumps and exchangers, are of importance. The patch-clamp technique has revolutionized the exploration of protein channels, another class of membrane proteins. Muscle and nerve stimulations as well as hyperthermia are well established in medical therapy. Electric cell transfection by foreign DNA and the production of hybridoma cells by fusion are based on membrane poration by high-induced transmembrane potentials. New biotech applications such as the development of a lab-on-chip technology are based on a combination of single-cell techniques and AC-electrokinetics.

Passive Electric Properties of Biological Matter

An electric field E passing through a medium is weakened by a factor that is given by the absolute value of its relative permittivity $|\varepsilon^*|$. The electric displacement D^* is constant:

$$D^* = \varepsilon^* \varepsilon_0 E \qquad [1]$$

ε_0 stands for the permittivity of vacuum. The asterisk denotes complex parameters. For such parameters, a phase shift may appear in between the exciting field or voltage and the resulting displacement or current. As a result, the material parameters, for example, ε^*, consist of a real (ε'-in-phase) and an imaginary (ε''-out-of-phase) part. The capacitance of a medium with a relative permittivity ε^* that is located in between two parallel electrodes of distance d and area A is

$$C^* = \frac{1}{\varepsilon^* \varepsilon_0} \frac{A}{d} \qquad [2]$$

For thin films, such as membranes, an area specific capacitance $C_m = C/A$ can be defined. When C_m values are given in the literature, in most cases, a possible frequency dependence is neglected. Often the passive electric properties of biological matter are described by its impedance Z^* that is the generalized, frequency-dependent resistance:

$$Z^* = \frac{1}{\sigma^*} \frac{d}{A} \qquad [3]$$

describes the impedance of a medium with a specific conductivity σ^* that is located in between two parallel electrodes of distance d and area A. In the simplest case, the medium is homogeneous and isotropic like aqueous electrolytes. In contrast, biological tissue is structured, for example, by cell membranes. This compartmentalization is the reason for structural dispersions.

Dispersions

The impedance of biological material is characterized by a variety of characteristic frequency-dependent changes. These changes are based on the fact that permittivity contributions of certain relaxation processes, which follow the external field at lower frequencies, disperse at higher ones. Consequently, the permittivity of biological material drops by several orders of magnitude over some frequency decades. A permittivity drop at a given frequency corresponds to a certain conductivity increase, since the field-induced movement of bound charges can no longer be distinguished from the movement of charges, such as ions, that are already free to move at DC.

The aim of the research was to assign the measured dispersions to certain biological structures on different hierarchical levels and to classify the contributing processes. For classification, two different approaches were chosen – the dispersions were either sorted according to their physical nature, for example, as Maxwell–Wagner and Debye dispersions, or according to the frequency range where they occur. While Maxwell–Wagner dispersions are based on the structuration of the material, Debye dispersions are related to the orientation of molecular dipoles. A classification according to frequencies yielded a scaling where the dispersions with increasing frequencies were assigned to the α-, β-, and γ-range (**Figure 1**). It was assumed that well-defined processes are responsible in a certain dispersion range.

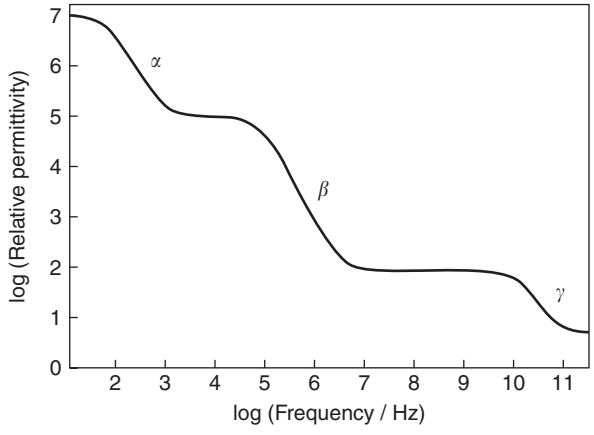

Figure 1 Schematic frequency dependence of the relative permittivity of tissue or cell suspensions according to H P Schwan (1957) Electrical properties of tissue and cell suspensions. In: Lawrence JH and Tobias CA (eds.) *Advances in Biological and Medical Physics*, pp. 147–209. New York: Academic Press.

Despite their low frequencies, analysis of α-dispersions in the sub-1 kHz frequency range is especially difficult. Many different processes may overlap, including such processes as electrode processes, hydrodynamic relaxation of electroosmotically induced convections within the measuring chamber and around the cells, membrane channels, cell orientation and deformation, as well as cell electrophoresis. The difficulty is that these phenomena are hard to separate, and concurrently influence suspension medium and cells (**Figure 2**).

In tissues and cell suspensions, the major contributions of the β-dispersion stem from structural polarizations as those of the cytoplasmic membrane or of internal membrane systems, as well as the polarization of the cytoplasm. It is to be noted that membrane and cytoplasmic dispersions are of different qualities. Whereas membrane dispersions are based on the capacitive bridging of the thin membrane film, the cytoplasmic dispersions mediate the switching from a field distribution, according to the conductivities, to a distribution according to the permittivities of the bulk

Structural level "theory"	Sketch of structure	Dispersing effect

Figure 2 Polarization processes based on various biological structures. The size of the polarized structures and the physical nature of the dispersion processes determine their characteristic times and frequency dependencies. The first column summarizes the structural levels and theoretical approaches for describing dispersion processes. The sketches in the second column present examples for processes that are designated in the third column.

media. The structural dispersions may be influenced by the dispersion of other processes, such as the surface conductance or dipole relaxation of large molecules. In cellular systems, protein dispersions usually occurring around 1 MHz are masked by the structural membrane dispersions.

In the γ-range above 100 MHz, quick dissociation–association relaxation or Debye dispersions of small molecules or charged groups must be expected. The dielectric properties of proteins are believed to be important for their physiological function such as protein-protein association or the interaction with charged ligands. Dispersions between 200 MHz and 10 GHz were assigned to bound water and small molecules (δ-dispersion). Dispersion over 10 GHz can mainly be assigned to free water.

Properties of Aqueous Media

Aqueous Electrolytes

The intracellular space and the cytoplasm can be considered to be aqueous solutions of ions and organic molecules. Up to GHz frequencies, their properties are often simplified to those of aqueous electrolytes that can be described by frequency-independent specific conductivities and permittivities. For electrolytes, the conductivity σ and permittivity ε are based on ionic conduction and the permittivity of water, respectively. Whereas the permittivity of water of 80 at 18°C shows a slight decrease with temperature and ion concentration, the conductivity may vary by orders of magnitude. For solutions of one salt, it can be calculated from salt concentration and equivalent conductivity. These relations are more complex for mixed solutions. Accordingly, the complex specific conductivity σ^* consists of the frequency-independent contribution of ion conduction and frequency-dependent displacement currents based on the water permittivity

$$\sigma^* = \sigma + \mathrm{j}\omega\,\varepsilon\,\varepsilon_0 \qquad [4]$$

where ω and j stand for the circular frequency of the field and $\sqrt{(-1)}$, respectively. After introduction of eqn [4], eqn [3] describes a system that consists of a resistor (for the ion current) in parallel to a capacitor (for the displacement current). Accordingly, the impedance of the medium steadily decreases with frequency.

Cytosolic Proteins

The cytoplasm of most cells is extremely rich in proteins influencing the electric properties. Proteins reduce the water concentration resulting in a reduced ion mobility and conductivity. The reduction factor may be higher than 2 in red blood cells. A second contribution comes from the proteins themselves. Because of their high dipole moments, they are the cause for extraordinary high permittivities at low frequencies. Nevertheless, their bulky structure is incapable of following the orientation force of an external field beyond a certain frequency. This is the reason for dielectric dispersions, that is, the decrease of ε by the dielectric decrement, and a corresponding increase in σ, which are typically in the frequency range $\sim$1 MHz. The dispersion in pure protein suspensions can be considered to be Debye dispersions which were extensively investigated. In tissues and cell suspensions, protein dispersions are masked by structural dispersions. Therefore, dispersions of cytoplasmic proteins were predominantly investigated after cell lysis or in cell-free suspensions.

Passive Membrane Properties

Area Specific Capacitance

Membranes are known to be inhomogeneous and anisotropic. For a membrane, solely composed of a lipid double layer, a specific capacitance of $\sim 7.5 \times 10^{-3}\,\mathrm{F\,m^{-2}}$ can be estimated. Nevertheless, biological membranes are rich in membrane spanning proteins. Thus, protein and lipid areas form a parallel circuit of two capacitors, resulting in a specific capacitance of about $10^{-2}\,\mathrm{F\,m^{-2}}$ at frequencies below 1 MHz. Accordingly, protein regions present areas of higher specific capacitance. The various regions of the membrane, that is, bound water layers, lipid headgroup regions, the hydrophobic lipid chain regions as well as the orthogonal segments formed by transmembrane proteins, will exhibit a different frequency-dependent dielectric behavior. The glycocalix surface layer made up by charge-carrying polysaccharides that are bound to membrane lipids and proteins is of special importance for the α-dispersion.

Lipid Region

The lipid regions of membranes have an overall thickness of 4–5 nm with roughly 0.8 nm at each side being occupied by the headgroups. The hydrophilic headgroup regions contain the strong P–N dipoles, the ester bonds of the fatty acids and the glycerol backbones. Together with the associated water molecules, dipole potentials as high as 240 mV (positive at the membrane surface) are generated. In normal direction, the relative permittivity drops from $\sim$78 in the bulk water to $\sim$2 in the fatty acid chain

region. The permittivity of approximately 30 in the headgroup region disperses with a decrement of ~28. In a tangential direction, experimental and theoretical results hint on relative permittivities as high as 300 to 400 with a dispersion that is related to the in-plane orientation of the headgroups. For both orientations, dispersion occurs ~50 MHz resulting in a high-frequency permittivity of ~2. Due to its low permittivity already at low frequencies, the fatty acid chain region is highly hydrophobic, forming the major energetic barrier for the permeation of ions and small polar molecules.

Membrane Proteins

Intercalation of proteins in the membrane relies on a microenvironment of specific dielectric properties. Nonpolar amino acids form the protein surface where it is exposed to the lipid chain region. Highly polar protein groups as loops and tails of the polypeptide chains are exposed to aqueous surfaces. They possess a higher degree of molecular freedom suggesting higher permittivities. The peptide bonds of the membrane part of most proteins are very rigid. Their highly restricted mobility results in a low permittivity. Up to low kHz frequencies, the protein mediated ion transport is also of importance for electric protein properties.

Bound Water

The thickness of the bound water layers is ~0.5 nm, with 11–16 water molecules per lipid. About 4 water molecules per lipid are tightly bound and strongly oriented. More distant water molecules show a smoothly decreasing orientation profile. The average permittivity of the bound water layer is ~60. The dispersion frequency will depend on the binding strength with higher frequencies for lower binding strengths.

Impedance and AC-Electrokinetic Phenomena

Impedance experiments provided the first proof for the existence of biological membranes. Impedance experiments analyze the frequency-dependent electric response to an applied field to explore dielectric properties of tissues and cells. The electric response is based on the polarization of the sample structures, like suspended cells. Single-cell polarization may lead to orienting, deforming, moving, or rotating in AC-electrokinetics. The different motions depend on the different spatial properties of the field determining its interaction with the polarized cell. The frequency dependence of each effect is related to the frequency dependence of the polarizability of the various constituents of the cell. All effects are exploited in cell characterization methods: electroorientation, electrodeformation, dielectrophoresis, and electrorotation. For modeling the effects, the induced-cell dipole moment is obtained by integrating over the local fields of all subcellular structures in the cell volume. As in the case of impedance, models for multishell spherical, cylindrical, and ellipsoidal geometries are readily available.

Generally, the force experienced by the cell is related to the induced dipole moment which is the volume integral of the polarization of the cell. For an ellipsoidal cell with confocal layers, for each field frequency, a Maxwellian equivalent body can be found that exhibits the same complex dipole moment m^*. The equivalent body has homogeneous medium properties and a constant local field. The induced dipole moment reduces to

$$m^* = (m_x \;\; m_y \;\; m_z) = \varepsilon_0 \varepsilon_e V f^*_{CM} E \qquad [5]$$

Its frequency-dependent part is described by the Clausius–Mossotti factor f^*_{CM}. The x-component of f^*_{CM} is given by

$$f^*_{CMx} = \frac{\varepsilon^*_i - \varepsilon^*_e}{\varepsilon^*_e + (\varepsilon^*_i - \varepsilon^*_e) n_x} \qquad [6]$$

The permittivities of the external and internal media are marked by indices e and i, respectively. n_x is the depolarizing factor in x-direction. Depending on the ellipsoidal shape, n_x can vary from 0 to 1. n_x is 1/3 for a sphere since the sum of the three factors along the three principal axes is unity.

AC-electrokinetic methods yield similar information as does impedance, though with a higher resolution. A rotating field induces a dipole moment which rotates at the angular frequency of the external field. A spatial phase shift of the external field vector and the induced dipole moment, caused by any dispersion process, gives rise to a torque generating individual cell rotation. For example, the membrane dispersion generates a cell-typical electrorotation peak. Interestingly, the torque and therefore cell rotation is at maximum if relaxation time of the dispersion process and external field frequency match ($\omega = \omega_c$, see below). For their high-resolution, dielectric single cell methods are of special value for cell characterization and the determination of the field distribution at the subcellular level. All AC-electrokinetic phenomena can also be used for cell or molecule

manipulation. They form the basis for the lab-on-chip technology.

The Induced Transmembrane Potential ($\Delta\phi$)

Electric cell transfection and cell fusion are routine biotech applications based on membrane poration by high-induced $\Delta\phi$. For poration, DC or AC fields have to be applied for a sufficiently long time or at a sufficiently low frequency, respectively. Pore induction is a strongly nonlinear process mimicking a "critical" transmembrane voltage of $\sim 1\,\mathrm{V}$ corresponding to $\sim 200\,\mathrm{MV\,m^{-1}}$ in the lipid phase. $\Delta\phi$ is proportional to the external field strength and depends on cell size, shape, orientation, and electric cell properties.

Physicists deal with the potential induced on the surface to describe the dependence of the local field deviation on the shape of the bodies or cavities. H Fricke was the first to apply the physical knowledge on the depolarizing factors of ellipsoidal bodies or cavities to express the induced transmembrane voltage $\Delta\phi$. For an ellipsoidal cell with semi-axes a, b, and c at the pole of a semi-axis, a $\Delta\phi$ for a cell of the general ellipsoidal shape is given by

$$\Delta\phi = \frac{1}{1-n} aE = a_i aE \qquad [7]$$

E, a, n, and a_i stand for the external field strength, the length of the semi-axis oriented in field direction, the depolarizing factor along semi-axis a, and the relative influential radius, respectively. The equation applies for the DC steady state and a cell with zero-membrane conductance. The parameter "influential radius" ($a_i^* a$) depends solely on the shape of the ellipsoidal body. For a vacuum body, it describes the distance of the symmetry plane of the body to that equipotential plane in the absence of the body that is touching the pole in its presence.

For a sphere, $a = b = c$, and $n = 1/3$ leading to the well-known expression: $\Delta\phi = 1.5rE$. For axisymmetric cells $a = b$. The symmetry axis is c. For such spheroidal cells limited in shape by an infinitely thin disk and an infinitely long cylinder, respectively, the shape dependence can be sufficiently good, described by

$$\Delta\phi = \frac{a+2c}{a+c} aE \qquad [8]$$

and

$$\Delta\phi = \frac{a+2c}{2} E \qquad [9]$$

for a field oriented in a-direction and c-direction, respectively. At higher frequencies, the membrane impedance decreases by capacitive bridging. The characteristic frequency ω_c at which the induced potential is decreased by $-3\,\mathrm{dB}$ is given by

$$\omega_c = \frac{1}{aC_m}\left(\frac{\sigma_e\sigma_i}{\sigma_e + (a_i - 1)\sigma_i} + ag\right) \qquad [10]$$

σ_i, σ_e, and g stand for the internal and external conductivities, and the area-specific membrane conductance in $\mathrm{S\,m^{-2}}$. The complete equation for $\Delta\phi$ at a pole of an ellipsoidal cell is

$$\Delta\phi = \frac{a_i a}{\left(1 + ag\left(\frac{1}{\sigma_i} + \frac{a_i - 1}{\sigma_e}\right)\right)\sqrt{1 + \frac{\omega^2}{\omega_c^2}}} E \qquad [11]$$

with ω standing for the field frequency. Assuming a superposition of the $\Delta\phi$ and the physiological $\Delta\psi$ (see below), is the simplest way to explain the asymmetry in cell poration often found after dielectric membrane breakdown.

Absorption

An exposed system is only influenced by that part of the electromagnetic field energy that is absorbed (principle of Grotthus and Draper). For this reason, research on the impact of electromagnetic fields must focus on the mechanisms of absorption and the identification of the absorbing structures. Generally, the energy input into a given volume is described by Ohmic heating that is proportional to the square of the local field strength and the effective, specific conductivity of a certain medium. Magnetic absorption processes, also those based on quantum effects, such as on the spins of unpaired (radical-) electrons, can usually be neglected. Dispersions lead to subcellular field redistributions. Up to GHz-range frequencies, the local field distribution and thus local absorption greatly depend on the geometric structure and compartmentalization of a cell.

The local power dissipation (Ohmic heating) per volume element P/V in an AC-field is not directly proportional to the applied field but depends on the effective local field E_{eff}

$$\frac{P}{V} = \sigma E_{\mathrm{eff}}^2 \qquad [12]$$

The equation suggests that the power dissipation is described by a frequency-independent specific-DC conductivity. In practice, the specific conductivity of structured media increases with frequency in correspondence to the permittivity decline given in **Figure 1**.

Considerations show that the field strength in the external medium and thus absorption in the vicinity of the cell strongly depends on field frequency even for the simple single-shell geometry. The picture dramatically deviates from the classic one when assuming more realistic membrane and cytoplasmic properties based on their molecular structure. It suggests a possible role of the membrane in field absorption even at frequencies far above the membrane-dispersion frequency.

The Physiological Transmembrane Potential ($\Delta\Psi$)

Nerve excitation or muscle activity generate AC fields of the Hz and kHz ranges. The physiological transmembrane potential $\Delta\Psi$ is of special importance for this phenomenon. $\Delta\Psi$ generation is based on the special electric properties of biological membranes. $\Delta\Psi$ is defined as the difference of the potentials of the internal (index i) and external (index e) bulk media:

$$\Delta\Psi = \Psi_i - \Psi_e \qquad [13]$$

Because of the surface potentials at the two membrane sides, fixed charges in the glycocalix and the dipole potentials of the lipid headgroups, the actual potential difference across the lipid phase of the membrane may strongly deviate from the $\Delta\Psi$. At specialized membranes such as the thylakoid membranes of plant chloroplasts, $\Delta\Psi$ may be higher than $-200\,\text{mV}$. Accordingly, the field strengths across the membrane under physiological conditions may be well above $10\,\text{MV}\,\text{m}^{-1}$. The membrane properties allow for the storage and transformation of electrochemical energy into chemical energy such as ATP, or in electrical energy as in nerve excitation or the electrical organs of fishes. $\Delta\Psi$ for resting neurons or muscle cells are in the range of -100 to $-40\,\text{mV}$. Action potentials are typically in the range of 30 to 80 mV.

In excitable cells of vertebrate species, sodium and potassium ions are actively pumped outwardly and inwardly, respectively, leading to a roughly inverse distribution for the two ion species. In resting cells, the membrane permeability for potassium is much higher than for sodium. Consequently, $\Delta\Psi$ is determined by the potassium distribution. Since its concentration is much higher in the cytoplasm, random diffusion across the membrane via potassium channels leads to a net potassium loss and a negative charging of the cytoplasm. Nerve cells are rich in voltage-gated ion-channel proteins. The transition from resting to action potential is driven by a sequential change in the membrane permeabilities for sodium ions and potassium ions. The relations are described by the Goldman equation:

$$\Delta\Psi = \frac{RT}{F}\ln\frac{P_{Cl}a^{i}_{Cl} + P_{K}a^{e}_{K} + P_{Na}a^{e}_{Na}}{P_{Cl}a^{e}_{Cl} + P_{K}a^{i}_{K} + P_{Na}a^{i}_{Na}} \qquad [14]$$

R, T, F, P, and a stand for the gas constant, the absolute temperature, the Faraday constant, permeability, and ion activity, respectively. Indices i, e, Na, K, and Cl designate internal and external bulk media, as well as the ion species sodium, potassium, and chloride, respectively. Please note that for $P_K \gg P_{Na},\ P_{Cl}$ and $P_{Na} \gg P_K,\ P_{Cl}$, the Goldman equation reduces to the Nernst equations for potassium and sodium, respectively. A feedback loop where the local membrane field alters the ion permeabilities of voltage-gated ion-channel proteins is the basis for the propagation of cell excitation, for example, along the axon of a nerve cell.

Passive Magnetic Properties of Biological Matter

In analogy to the electric field, a static magnetic field of strength H causes a magnetic induction B of

$$B = \mu\mu_0 H \qquad [15]$$

where μ_0 and μ are the magnetic field constant and the relative permeability of the material, respectively. Since the permeabilities of biological matter are very close to unity, it is reasonable to list susceptibilities $\chi = \mu - 1$ (**Table 1**)

The low magnetic susceptibility is the reason for the very weak interaction of static magnetic fields with biological matter. Most biological cells and tissues are diamagnetic ($\chi < 0$). Paramagnetic ($\chi > 0$) deoxygenated red blood cells are an exception.

The high structuration of biological tissues and cells is reflected in their magnetic anisotropy $\Delta\chi$, which

Table 1 Magnetic susceptibility of different matter

Material	$\chi/10^{-6}$
Air	0.264
Water	−9.04
Arterial blood	−9.3
Oxygenated red blood cells	−9.03
Deoxygenated red blood cells	3.88
Venous blood	−7.8
Lungs (air-filled to 15%)	−4.2
Muscle	−9.03
Liver	−8.26
Bone	−10
Biogenic Fe_3O_4-crystals	10^{12}

describes the difference in the magnetic susceptibilities parallel and perpendicular to characteristic biological structures. This feature is especially pronounced in lipid membranes that can even be orientated by magnetic fields at flux densities larger than 1 T.

Biogenic magnetites (Fe_3O_4-crystals) are found in magnetostatic bacteria. The susceptibility of these ferromagnetic particles is as large as 10^6. The particles are the major component of magnetosomes, cell organells that are surrounded by a membrane. They enable the bacteria to orientate themselves along the vector of the geomagnetic field. To a lesser extent, biogenic magnetites have also been found in different animals and even in the human brain. Nevertheless, it is still not clear as to whether magnetic fields can interfere with physiological processes in humans. The mechanisms of magnetic orientation of animals are not fully understood, either.

Generation and Effects of Magnetic Fields

Of course, all biological processes which involve charge movement generate endogenous magnetic fields. Such processes are the transmembrane transport of ions or charged compounds as well as ion currents related to signal transduction in nerves and muscles. The displacement of ions and charged particles in the bloodstream or the lymphatic system induces streaming potentials and electric currents. Nevertheless, in no case does the induced magnetic flux densities exceed the pT-range (compared to 20–70 μT of the geomagnetic field). Currently, no hard experimental data are available for the coupling of external with endogenous magnetic fields, subsequently influencing biologically relevant processes.
