Exogenous low-frequency magnetic fields can induce electrical (eddy) currents. Nevertheless, for effective induction, structures larger than single cells are required. Candidate structures are, therefore, the blood system and cells that are interconnected via gap junctions allowing for the formation of large induction loops. It can be estimated, that a flux density of at least 1 mT is necessary to effect biological functions in the brain or of the heart. Static and low-frequency fields may deflect moving charges by the Lorentz force. However, ions and charged compounds can only be significantly influenced at flux densities higher than 10^6 T. The inverse interaction, current induction in a nerve or blood vessel crossing magnetic field lines, may cause nerve excitations when the flux density exceeds 10 mT.

Magnetic fields can influence the spins of unpaired electrons, for example, of organic-label molecules, and nuclei with a spin different from zero, for example, of hydrogen. To orientate the spins, typically static-magnetic fields of 50 mT to 6 T, and 340 mT to 1.25 T are applied in nuclear magnetic resonance (NMR) for medical diagnostics and electron spin resonance (ESR), respectively. The field introduces an energy difference for the two possible spin orientations. The transition from the low-energy orientation to the higher one can be induced by resonant absorption of a radio-frequency field in the MHz to GHz range with a frequency corresponding to the energy difference. Either the absorption or emission of the radio-frequency field induced by the relaxation of the spin distribution is detected in the methods.

Static and low-frequency magnetic fields have been shown to influence chemical reactions which involve radical-pair intermediate states in electron transfer processes. The lifetime of triplet–singlet interconversions in such reactions have been altered at magnetic flux densities of 1 mT and beyond. This mechanism may as well apply to biochemical reactions. For the interaction of magnetic fields with biological processes, other mechanisms such as cyclotron resonance in protein channels and ion parametric resonance in macromolecules have also been proposed, but could not be verified.

Electrodynamics: Continuous Media

A C Eringen, Princeton University, Littleton, CO, USA

Introduction

Electromagnetic (E-M) interactions with material bodies give rise to a large number of interesting phenomena. E-M loads (forces, couples, and energy) applied to material bodies produce mechanical effects (deformation, stress, strain, and heat). For example, under an applied electric field, an elastic solid deforms (develops stress). This is known as "electrostriction." This is a nonlinear phenomenon. There is a parallel effect under magnetic fields, called "magnetostriction." A thin rod or plate subjected to a sufficiently large magnetic field will buckle. Under E-M fields, a body may produce heat (pyroelectric and pyromagnetic effects). E-M fields also produce torques. Conversely, mechanical deformations produce E-M fields. A deforming dielectric produces electric polarization, known as "piezoelectricity." Thus, E-M and mechanical fields are intertwined to produce many "cross effects."

Electrodynamics of continua is essentially nonlinear in nature. This stems from the fact that E-M loads are nonlinear in E-M fields and bodies may undergo large deformations and motions, producing nonlinear accelerations and finite strains. However, in many cases, linear theories can be constructed under some restrictions. In the case of piezoelectricity, the linear theory has been successful. But, in the case of magnetohydrodynamics (MHD), the joule dissipation remains finite and accelerations contain convective nonlinear terms relevant to turbulent motions.

Electromagnetic continua is not the sum (superposition) of the E-M theory and the mechanical theory of continuous media. It is an interconnected, nonlinear composition of both.

The E-M theory of continuous media is based on three fundamental notions: (1) balance laws; (2) thermodynamics of irreversible processes; and (3) constitutive equations. Balance laws are fundamental macroscopic equations governing E-M and mechanical fields. They are valid for any type of media (solids, crystals, metals, bones, fluids, polymers, blood, oil, air, etc.) irrespective of their constitutions. Associated with each balance law, there is a jump condition across a discontinuity surface σ, which may be sweeping the body with its own velocity. When σ is considered to coincide with the surface of the body, jump conditions become boundary conditions. Jump

conditions are also fundamental to the discussion of shock waves.

Material properties are brought into play through the constitutive equations. These are phenomenological relations among the response functions (dependent variables) and the independent variables. These may be called the "cause and effect relations." The response functions are the dependent variables that enter the expression of the energy balance law. The independent variables are the ones that make a given material able to respond, producing effects in the material. Both sets of variables must be frame independent (objective) and admissible by the second law of irreversible thermodynamics. Generally, different materials require different constitutive equations. For example, constitutive equations of E-M elastic solids and those of E-M viscous fluids are different. While, by means of the irreversible thermodynamics and objectivity, unified, all-inclusive constitutive equations can be constructed, for most complex materials, these are neither of practical use nor helpful in understanding the physics of the field. In this article, constitutive equations are obtained for E-M elastic solids, magnetoelasticity, E-M viscous fluids, and MHD. The method presented here for the construction of the constitutive equations can be used for other classes of more complex materials, for example, memory-dependent materials, materials with microstructures, and nonlocal continua. For these, the reader is referred to the references cited in the "Further reading" section.

Once constitutive equations are constructed, by combining these equations with the balance laws, the field equations are obtained. The field equations are, generally, partial differential equations (PDEs) that must be solved under appropriate boundary and initial conditions to determine the response of the body. In this article, example solutions are presented to demonstrate the theories of E-M elastic solids and E-M viscous fluids.

Balance Laws

A tensor is called frame-independent (objective), if it transforms as a tensor under the rigid motions of the frame-of-reference, that is, under the transformations:

$$\bar{\boldsymbol{x}} = \boldsymbol{Q}(t)\boldsymbol{x} + \boldsymbol{b}(t), \qquad \boldsymbol{Q}\boldsymbol{Q}^{\mathrm{T}} = \boldsymbol{Q}^{\mathrm{T}}\boldsymbol{Q} = \boldsymbol{1}, \quad \det \boldsymbol{Q} = 1, \quad \bar{t} = t - t_0 \qquad [1]$$

where $\boldsymbol{Q}(t)$ is the time-dependent orthogonal group, $\boldsymbol{b}(t)$ is an arbitrary translation, and t_0 is a shift of time. The superscript T denotes the transpose. For constants $\boldsymbol{Q}$ and $\boldsymbol{b}$, invariance under [1] denotes the Galilean invariance.

Local balance laws can be obtained by using the invariance of the global (integral) energy balance law under transformation [1] of the frame-of-reference $\boldsymbol{x}$. It is well known that the E-M balance laws are invariant under the Lorentz group, but the mechanical balance laws are not. The E-M and mechanical balance laws considered here are Galilean invariant. E-M balance laws (Maxwell's equations) in a fixed laboratory frame R_{F}, in the Heviside–Lorentz system, are expressed by

Gauss's law

$$\boldsymbol{\nabla} \cdot \boldsymbol{D} = q_e \quad \text{in } V \qquad [2a]$$

$$\boldsymbol{n} \cdot [[\boldsymbol{D}]] = w_e \quad \text{on } \sigma \qquad [2b]$$

Faraday's law

$$\boldsymbol{\nabla} \times \boldsymbol{E} + \frac{1}{c}\frac{\partial \boldsymbol{B}}{\partial t} = 0 \quad \text{in } V \qquad [3a]$$

$$\boldsymbol{n} \times \left[\left[\boldsymbol{E} + \frac{\boldsymbol{v}}{c} \times \boldsymbol{B}\right]\right] = 0 \quad \text{on } \sigma \qquad [3b]$$

Absence of free magnetic poles

$$\boldsymbol{\nabla} \cdot \boldsymbol{B} = 0 \quad \text{in } V \qquad [4a]$$

$$\boldsymbol{n} \cdot [[\boldsymbol{B}]] = 0 \quad \text{on } \sigma \qquad [4b]$$

Ampere's law

$$\boldsymbol{\nabla} \times \boldsymbol{H} - \frac{1}{c}\frac{\partial \boldsymbol{D}}{\partial t} = \frac{1}{c}\boldsymbol{J} \quad \text{in } V \qquad [5a]$$

$$\boldsymbol{n} \times \left[\left[\boldsymbol{H} - \frac{1}{c}\boldsymbol{v} \times \boldsymbol{D}\right]\right] = 0 \quad \text{on } \sigma \qquad [5b]$$

The law of conservation of charge is obtained by taking the divergence of eqn [5a] and using eqn [2a]:

$$\frac{\partial q_e}{\partial t} + \boldsymbol{\nabla} \cdot \boldsymbol{J} = 0 \quad \text{in } V \qquad [6a]$$

$$\boldsymbol{n} \cdot [[\boldsymbol{J} - q_e \boldsymbol{v}]] = 0 \quad \text{on } \sigma \qquad [6b]$$

where double brackets denote the jump conditions at the discontinuity surface σ. A superposed dot or D/Dt denotes the material time derivative, for example,

$$v_{k,l} = \frac{\partial v_k}{\partial x_l}, \qquad \dot{\rho} = \mathrm{D}\rho/\mathrm{D}t = \frac{\partial \rho}{\partial t} + \rho_{,k} v_k$$

where, and throughout, repeated indices denote summation over (1, 2, 3). Indices following a comma denote the partial derivatives with respect to the Cartesian coordinates.

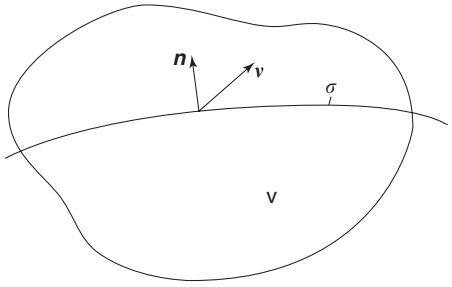

Figure 1 Discontinuity surface σ sweeping body.

In these equations, $\boldsymbol{D}, \boldsymbol{E}, \boldsymbol{B}, \boldsymbol{H}, \boldsymbol{J}, q_e, w_e$, and c are, respectively, the dielectric displacement vector, electric field vector, magnetic induction vector, magnetic field vector, current vector, volume charge density, surface charge density, and the speed of light in a vacuum. In each of eqns [2] to [6], the first set, marked by an "a" (e.g., [2a]), is valid in the volume of the body, V; and the second set, marked by a "b" (e.g., [2b]), is valid on the discontinuity surface σ, which may be sweeping V with its own velocity $\boldsymbol{v}$ in the direction of the unit normal $\boldsymbol{n}$ of σ (**Figure 1**).

$\boldsymbol{D}$ and $\boldsymbol{B}$ are decomposed as

$$\boldsymbol{D} = \boldsymbol{E} + \boldsymbol{P}, \qquad \boldsymbol{B} = \boldsymbol{H} + \boldsymbol{M} \tag{7}$$

where $\boldsymbol{P}$ and $\boldsymbol{M}$ are, respectively, polarization and magnetization vectors. They originate from the presence of the material.

For deformable bodies, it is necessary to express the E-M fields in a reference frame, R_M, co-moving with a material point of the body. These are expressed in terms of the fields in the fixed reference frame by

$$\begin{aligned}
\mathscr{E} &= \boldsymbol{E} + \frac{1}{c}\boldsymbol{v} \times \boldsymbol{B}, \qquad \mathscr{M} = \boldsymbol{M} + \frac{1}{c}\boldsymbol{v} \times \boldsymbol{P}, \\
\mathscr{J} &= \boldsymbol{J} - q_e \boldsymbol{v}, \qquad \mathscr{B} = \boldsymbol{B} - \frac{1}{c}\boldsymbol{v} \times \boldsymbol{E}, \\
\mathscr{H} &= \boldsymbol{H} - \frac{1}{c}\boldsymbol{v} \times \boldsymbol{D}
\end{aligned} \tag{8}$$

where, $\boldsymbol{v}$ is the velocity of the material point. The E-M force $\boldsymbol{F}^E$, couple $\boldsymbol{C}^E$, the power W^E, E-M stress tensor $\boldsymbol{t}^E_{kl}$, E-M momentum $\boldsymbol{G}$, and Poynting vector $\mathscr{S}$, are given by

$$\begin{aligned}
\boldsymbol{F}^E &= q_e \mathscr{E} + \frac{1}{c}(\mathscr{J} + \check{\boldsymbol{P}}) \times \boldsymbol{B} + (\boldsymbol{P} \cdot \boldsymbol{\nabla})\mathscr{E} \\
&\quad + (\boldsymbol{\nabla}\boldsymbol{B}) \cdot \mathscr{M} \\
\boldsymbol{C}^E &= \boldsymbol{P} \times \mathscr{E} + \mathscr{M} \times \boldsymbol{B} \\
W^E &= \boldsymbol{F}^E \cdot \boldsymbol{v} + \rho \mathscr{E} \cdot (\boldsymbol{P}/\rho)^{\cdot} - \mathscr{M} \cdot \dot{\boldsymbol{B}} + \mathscr{J} \cdot \mathscr{E} \\
\boldsymbol{t}^E &= \boldsymbol{P} \otimes \mathscr{E} - \boldsymbol{B} \otimes \mathscr{M} + \boldsymbol{E} \otimes \boldsymbol{E} + \boldsymbol{B} \otimes \boldsymbol{B} \\
&\quad - \tfrac{1}{2}(E^2 + B^2 - 2\mathscr{M} \cdot \boldsymbol{B})\boldsymbol{1} \\
\boldsymbol{G} &= \frac{1}{c}\boldsymbol{E} \times \boldsymbol{B}, \quad \mathscr{S} = c\mathscr{E} \times \mathscr{H}
\end{aligned} \tag{9}$$

where $\check{\boldsymbol{P}}$ is the displacement current, defined by

$$\check{\boldsymbol{P}} = \dot{\boldsymbol{P}} - (\boldsymbol{P} \cdot \boldsymbol{\nabla})\boldsymbol{v} + \boldsymbol{P}\boldsymbol{\nabla} \cdot \boldsymbol{v} \tag{10}$$

These expressions are obtained by statistical mechanical methods, from the atomic Maxwell–Lorentz equations, applied to a stable atomic particle (molecule).

Mechanical Balance Laws

Conservation of mass

$$\dot{\rho} + \rho \boldsymbol{\nabla} \cdot \boldsymbol{v} = 0 \quad \text{in } V \tag{11a}$$

$$[[\rho(\boldsymbol{v} - \boldsymbol{v})]] \cdot \boldsymbol{n} = 0 \quad \text{on } \sigma \tag{11b}$$

Balance of momentum

$$t_{kl,k} + \rho(f_l - \dot{v}_l) + F^E_l = 0 \quad \text{in } V \tag{12a}$$

$$[[\rho v_l(v_k - v_k) - t_{kl} - t^E_{kl} - v_k G_l]]n_k = 0 \quad \text{on } \sigma \tag{12b}$$

Balance of moment of momentum

$$\varepsilon_{klm} t_{lm} + C^E_k = 0 \quad \text{in } V \tag{13}$$

Balance of energy

$$\begin{aligned}
&-\rho\dot{\varepsilon} + t_{kl}v_{l,k} + \boldsymbol{\nabla} \cdot \boldsymbol{q} + \rho h + \rho \mathscr{E} \cdot (\boldsymbol{P}/\rho)^{\cdot} \\
&\quad - \mathscr{M} \cdot \dot{\boldsymbol{B}} + \mathscr{J} \cdot \mathscr{E} = 0 \quad \text{in } V
\end{aligned} \tag{14a}$$

$$\begin{aligned}
&[[\{\rho(\varepsilon + \tfrac{1}{2}\rho v^2) + \tfrac{1}{2}(E^2 + B^2)\}(v_k - v_k) \\
&\quad -(t_{kl} + t^E_{kl} + v_k G_l)v_l - q_k + \mathscr{S}_k]]n_k = 0 \quad \text{on } \sigma
\end{aligned} \tag{14b}$$

where ρ, t_{kl}, f_l, ε, $\boldsymbol{q}$, and h are, respectively, mass density, the stress tensor, the body force density, the internal energy density, heat vector, and the heat input. ε_{klm} is the permutation symbol.

The second law of thermodynamics

$$\rho\dot{\eta} - \boldsymbol{\nabla} \cdot (\boldsymbol{q}/\theta) - \rho h/\theta \geqslant 0 \quad \text{in } V \tag{15a}$$

$$[[\rho\eta(\boldsymbol{v} - \boldsymbol{v}) - \boldsymbol{q}/\theta]] \cdot \boldsymbol{n} \geqslant \boldsymbol{0} \quad \text{on } \sigma \tag{15b}$$

where η and θ are, respectively, the entropy density and the absolute temperature.

Introducing the generalized Helmholtz's free energy, defined by

$$\psi = \varepsilon - \theta\eta - \rho^{-1}\boldsymbol{P} \cdot \mathscr{E} \tag{16}$$

into eqn [14a], and eliminating h from eqn [15a] by means of eqn [14a] gives

$$-\rho(\dot{\psi}+\eta\dot{\theta})+t_{kl}v_{l,k}+\frac{1}{\theta}\boldsymbol{q}\cdot\boldsymbol{\nabla}\theta - \boldsymbol{P}\cdot\frac{\mathrm{D}\mathscr{E}}{\mathrm{D}t}-\mathscr{M}\cdot\dot{\boldsymbol{B}}+\mathscr{J}\cdot\mathscr{E}\geqslant 0 \qquad [17]$$

This is the Clausius–Duhem (C–D) inequality which is fundamental to the construction of the constitutive equations.

E-M Thermoelastic Solids

Elastic solids deform under E-M fields and acquire stress. Conversely, applied mechanical loads produce E-M fields and electric current.

An elastic solid, at the natural state (free of all fields and undeformed and unstressed), occupies a volume V in the three-dimensional Euclidean space E^3. A material point $\boldsymbol{X}$ in V, under external loads, moves to a spacial point $\boldsymbol{x}$, at time t. The motion is expressed by

$$\boldsymbol{x}=\boldsymbol{x}(\boldsymbol{X},t)\quad\text{or}\quad x_k=x_k(X_K,t),\quad k,K=1,2,3 \qquad [18]$$

which is assumed to have the unique inverse:

$$\boldsymbol{X}=\boldsymbol{X}(\boldsymbol{x},t)\quad\text{or}\quad X_K=X_K(x_k,t) \qquad [19]$$

where X_K and x_k are, respectively, Cartesian coordinates of a material point in the material (Lagrangian) frame $\boldsymbol{X}$, and the spacial (Eulerian) frame $\boldsymbol{x}$. Deformation tensor C_{KL} and Lagrangian strain tensor E_{KL} in R_L and corresponding Eulerian tensors c_{kl}, e_{kl} in R_E are defined by

$$C_{KL}=x_{k,K}x_{k,L}=\delta_{KL}+2E_{KL}$$
$$c_{kl}=X_{K,k}X_{K,l}=\delta_{kl}-2e_{kl} \qquad [20]$$

Introducing the displacement vector by $\boldsymbol{u}=\boldsymbol{U}=\boldsymbol{x}-\boldsymbol{X}$, E_{KL} and e_{kl} are expressed as

$$E_{KL}=\tfrac{1}{2}(U_{K,L}+U_{L,K}+U_{M,K}U_{M,L})$$
$$e_{kl}=\tfrac{1}{2}(u_{k,l}+u_{l,k}-u_{m,k}u_{m,l}) \qquad [21]$$

Constitutive equations for E-M elastic solids are constructed with the help of a C–D inequality expressed in material coordinates X_K. This is necessary because specification of the boundary conditions in the spatial (current) configuration is not possible in the nonlinear theory, since the boundary of the current configuration is not known, *a priori*. From eqn [13] and the second of eqn [9], it can be seen that t_{kl} is not a symmetric tensor. A symmetric stress tensor $\bar{t}_{kl}$ and deformation tensor d_{kl} are introduced by

$$t_{kl}=\bar{t}_{kl}-P_k\mathscr{E}_l-\mathscr{M}_kB_l$$
$$d_{kl}=\tfrac{1}{2}(v_{k,l}+v_{l,k}) \qquad [22]$$

Spatial (Eulerian) tensors t_{kl}, q_k, P_k, $\mathscr{M}_k$, $\mathscr{J}_k$, and e_{kl} are related to their counterparts in material (Lagrangian) tensors by

$$\bar{t}_{kl}=\frac{\rho}{\rho_0}\bar{T}_{KL}x_{k,K}x_{l,L}$$
$$(q_k,\mathscr{E}_k,B_k)=(\mathscr{E}_K,B_K)X_{K,k}$$
$$(P_k,\mathscr{M}_k,\mathscr{J}_k)=\frac{\rho}{\rho_0}(Q_K,\Pi_K,\mathscr{M}_K,\mathscr{J}_K)x_{k,K} \qquad [23]$$
$$\dot{E}_{kl}=d_{kl}x_{k,K}x_{l,L}$$
$$\rho_0/\rho=\det x_{k,K}$$

where ρ_0 is the mass density at the natural state. With these, the C–D inequality [17] becomes

$$-\rho_0(\dot{\Psi}+\eta\dot{\theta})+\bar{T}_{KL}\dot{E}_{KL}+\frac{1}{\theta}Q_K\theta_{,K} - \Pi_K\frac{\mathrm{D}\mathscr{E}_K}{\mathrm{D}t}-\mathscr{M}_K\dot{B}_K+\mathscr{J}_K\mathscr{E}_K\geqslant 0 \qquad [24]$$

This inequality is linear in $\dot{\theta}$, $\dot{E}_{KL}$, $\mathrm{D}\mathscr{E}_k/\mathrm{D}t$, and $\dot{B}_K$, and it cannot be maintained in one sign unless

$$\eta=-\frac{\partial\Psi}{\partial\theta},\quad \bar{\boldsymbol{T}}=\rho_0\frac{\partial\Psi}{\partial\boldsymbol{E}}$$
$$\Pi=-\rho_0\frac{\partial\Psi}{\partial\mathscr{E}},\quad \mathscr{M}=-\rho_0\frac{\partial\Psi}{\partial\boldsymbol{B}} \qquad [25]$$

and

$$\frac{1}{\theta}Q_K\theta_{,K}+\mathscr{J}_K\mathscr{E}_K\geqslant 0 \qquad [26]$$

The general solution of this inequality is given by

$$\boldsymbol{Q}=\frac{\partial\Phi}{\partial(\boldsymbol{\nabla}\theta/\theta)}+\boldsymbol{U}_Q,\quad \mathscr{J}=\frac{\partial\Phi}{\partial\mathscr{E}}+\boldsymbol{U}_{\mathscr{J}} \qquad [27]$$

where constitutive residuals $\boldsymbol{U}_q$ and $\boldsymbol{U}_{\mathscr{J}}$ are subject to

$$\boldsymbol{U}_Q\cdot\frac{\nabla\theta}{\theta}+\boldsymbol{U}_{\mathscr{J}}\cdot\mathscr{E}=0 \qquad [28]$$

ψ is a function of $\Omega=(\theta,E_{KL},\mathscr{E}_K,B_K)$, Φ is a function of $\omega=(\boldsymbol{\nabla}\theta/\theta,\mathscr{E}_K)$ and the set Ω. The internal energy density ε and the dissipation potential Φ are required to be positive semidefinite, that is,

$$\varepsilon\geqslant 0,\quad \Phi(\Omega,\omega)\geqslant 0,\quad \Phi(0,\omega)=0 \qquad [29]$$

Expressions [25] and [27] are the most general constitutive equations of E-M elastic solids. Eulerian expressions can be obtained by substituting [25] and [27] into [23].

When the functions ψ and Φ are expressed in terms of their variables, and residuals selected to obey [28], the constitutive equations [25] and [27] take explicit forms. For example, ψ and Φ may be expressed as polynomials of any order in terms of their variables, to construct nonlinear constitutive equations that may be necessary when strong fields are applied to materials.

The balance laws [11a], [12a], and [14a] can be expressed in terms of the material (Lagrangian) fields by means of [23]:

$$\rho_0/\rho = \det(x_{k,K}) \qquad [30]$$

$$(\bar{T}_{KL}x_{k,L})_{,K} + \rho_0(f_k - \dot{v}_k) + F_k^E = 0 \qquad [31]$$

$$-\rho_0\theta\dot{\eta} + Q_{K,K} + \rho h + \mathscr{J}_K\mathscr{E}_K = 0 \qquad [32]$$

This permits the field equations to be obtained directly, by substituting [25] and [27] into [31] and [32].

Among various order theories, the linear theory is the most widely used in practical applications (e.g., piezoelectricity). In the linear theory, in [23], $x_{k,K}$ and $X_{K,k}$ become Dirac delta functions, and the distinction between Eulerian and Lagrangian representations disappears. Moreover, the constitutive residuals are also discarded. In this case, it proves more convenient to express constitutive equations in Eulerian forms.

By setting $\theta = T_0 + T$, where T is a temperature change from a constant ambient temperature $T_0 \gg 0$, $|T| < \theta$, and absorbing T_0 into the material moduli of Ψ and Φ, Ψ and Φ are expressed by second-degree polynomials:

$$\begin{aligned}\rho_0\Psi = &-\tfrac{1}{2}\rho_0\gamma T^2 - T(p_k\mathscr{E}_k + m_kB_k + \beta_{kl}e_{kl})\\ &+ a_{lmk}e_{lm}\mathscr{E}_k + b_{klm}e_{kl}B_m + \tfrac{1}{2}\lambda_{klmn}e_{kl}e_{mn}\\ &- \tfrac{1}{2}\chi^E_{kl}\mathscr{E}_k\mathscr{E}_l + \tfrac{1}{2}\chi^B_{kl}B_kB_l - h_{kl}\mathscr{E}_kB_l\end{aligned} \qquad [33]$$

$$\Phi = \tfrac{1}{2}\sigma_{kl}\mathscr{E}_k\mathscr{E}_l + \tau_{kl}\mathscr{E}_kT_{,l} + \tfrac{1}{2}\kappa_{kl}T_{,k}T_{,l} \qquad [34]$$

Generally, all material moduli γ, p_k, m_k, β_{kl}, a_{lmk}, b_{klm}, λ_{klmn}, χ^E_{kl}, χ^B_{kl}, h_{kl}, σ_{kl}, τ_{kl}, and κ_k depend on temperature and density.

Linear constitutive equations of E-M thermoelastic solids follow from [25] and [27]:

$$\begin{aligned}\eta &= \gamma T + \rho_0^{-1}(p_k\mathscr{E}_k + m_kB_k + \beta_{kl}e_{kl})\\ t_{kl} &= -\beta_{kl}T + \lambda_{klmn}e_{mn} + a_{klm}\mathscr{E}_m + b_{klm}B_m\\ P_k &= p_kT + \chi^E_{kl}\mathscr{E}_l - a_{lmk}e_{lm} + h_{kl}B_l\\ \mathscr{M}_k &= m_kT - \chi^B_{kl}B_l - b_{lmk}e_{lm} + h_{lk}\mathscr{E}_l\\ q_k &= \kappa_{kl}T_{,l} + \tau_{kl}\mathscr{E}_l + e(\boldsymbol{E}\times\boldsymbol{\nabla}T)_k\\ \mathscr{J}_k &= \sigma_{kl}\mathscr{E}_l + \tau_{kl}T_{,l} + h(\boldsymbol{E}\times\boldsymbol{B})_k\end{aligned} \qquad [35]$$

With these, upon using [16], the energy balance law [14a] is reduced to

$$-\rho_0T\dot{\eta} + \boldsymbol{\nabla}\cdot\boldsymbol{q} + \mathscr{J}\cdot\mathscr{E} + \rho_0h = 0 \qquad [36]$$

In order to obtain the field equations, by means of [7] to [10], and [35], $\boldsymbol{D}$, $\boldsymbol{H}$, $\boldsymbol{F}^E$, and [35] are expressed in terms of $\boldsymbol{E}$, $\boldsymbol{B}$, and $\boldsymbol{J}$, then substituted into Maxwell's equations, [12a] and [36].

The physical meaning of various moduli in [35] are γ – heat capacity, p_k – pyroelectric moduli, m_k – pyromagnetic moduli, β_{kl} – thermal stress moduli, λ_{klmn} – elastic moduli, a_{klm} – piezoelectric moduli, b_{klm} – piezomagnetic moduli, χ^E_{kl} – dielectric susceptibility, h_{kl} – magnetic polarizability, χ^B_{kl} – magnetic susceptibility, κ_{kl} – heat transfer moduli, σ_{kl} – electric conductivity, τ_{kl} – Peltier moduli for heat, Seebeck moduli for current, e – Righi – Leduc effect, and h – Hall effect. In linear theory, $e = h = 0$.

Constitutive eqns [35] contain some terms that may not be allowed. With the reversal of time (e.g., reversal of electronic spin), $\mathscr{M}_k$ and B_k change signs (i.e., they are time antisymmetric); all other fields are time symmetric. Consequently, the material symmetry group (magnetic group) must produce the same sign on both sides of the eqns [35]. Those that do not produce the same sign are not allowed. For example, pyroelectricity, represented by p_k, does not vanish in only ten noncentrosymmetric magnetic point groups: 1, 2, m, 2mm, 3, 3m, 4, 4mm, 6, 6mm. There is also a contribution to pyroelectricity from the thermal expansion (the secondary pyroelectricity). Similarly, piezoelectricity, represented by a_{klm}, exists in only 20 noncentrosymmetric groups. The one remaining noncentrosymmetric class, denoted by O (*Shönflies*) excludes piezoelectricity. Piezomagnetism (b_{klm}) exists in 11 groups. In centrosymmetric materials, piezoelectricity and piezomagnetism do not exist. Earlier, some authors, erroneously assuming that all crystals are time symmetric, concluded that pyromagnetism and piezomagnetism are forbidden effects.

This effect was observed in the antiferromagnetic crystals CoF_2 and MnF_2.

Materials are classified as dielectrics, diamagnetics, if conduction is absent and E-M fields cause polarization or magnetization. They are called ferromagnetic, if magnetization exists in the absence of the magnetic fields. Materials with positive susceptibility are called paramagnetic, and those that display electric polarization in the absence of applied electric fields are called ferroelectrics. Examples of dielectrics (also called insulators) are glasses and ceramics. Iron is a ferromagnet. Ceramic magnets are ferrites.

For experimental values of piezoelectric constants, the reader is referred to the "Further reading" section.

Some references employ the inversion of [35], e.g., expressions of e_{kl} in terms of (t_{kl}, P_k, $\mathscr{M}_k$, and T).

For isotropic elastic solids, the odd order tensor moduli vanish and the even order moduli become isotropic. Also, because of the time-antisymmetries of $\boldsymbol{B}$ and $\mathscr{M}$, h_{kl}, a_{klm}, b_{klm}, a_k, p_k, and m_k are not admissible, reducing [35] to

$$\begin{aligned} \eta &= (\gamma T + \rho_0^{-1}\beta \mathrm{tr}\, \boldsymbol{e}) \\ t_{kl} &= (-\beta T + \lambda_e \mathrm{tr}\, \boldsymbol{e})\delta_{kl} + 2\mu_e e_{kl} \\ \boldsymbol{P} &= (\varepsilon - 1)\mathscr{E} \\ \mathscr{M} &= (1 - \mu^{-1})\boldsymbol{B} \\ \boldsymbol{q} &= \tau\mathscr{E} + \kappa\boldsymbol{\nabla}T + e\boldsymbol{E}\times\boldsymbol{\nabla}T \\ \mathscr{J} &= \sigma\mathscr{E} + \tau\boldsymbol{\nabla}T + h\boldsymbol{E}\times\boldsymbol{B} \end{aligned} \quad [37]$$

where ε and μ given by

$$\varepsilon = 1 + \chi^E, \qquad \mu = (1 + \chi^B)^{-1} \quad [38]$$

are, respectively, called dielectric permeability and magnetic permeability.

It is simple to show that the internal energy ε and Φ will be positive-semidefinite, if and only if

$$\begin{aligned} &\gamma \geqslant 0,\ 3\lambda_e + 2\mu_e \geqslant 0,\ \mu_e \geqslant 0,\ \chi^E \geqslant 0, \\ &\chi^B \geqslant 0,\ \sigma \geqslant 0,\ \sigma\kappa - \tau^2 \geqslant 0 \end{aligned} \quad [39]$$

Linear-field equations of isotropic E-M thermoelastic solids are then given by

$$\begin{aligned} &-\beta\boldsymbol{\nabla}T + (\lambda_e + 2\mu_e)\boldsymbol{\nabla}\boldsymbol{\nabla}\cdot\boldsymbol{u} - \mu_e\boldsymbol{\nabla}\times\boldsymbol{\nabla}\times\boldsymbol{u} \\ &\quad + \rho_0(\boldsymbol{f} - \ddot{\boldsymbol{u}}) + \boldsymbol{F}^E = \boldsymbol{0} \end{aligned} \quad [40]$$

$$-\rho_0 T\dot{\eta} + \boldsymbol{\nabla}\cdot\boldsymbol{q} + \mathscr{J}\cdot\mathscr{E} + \rho_0 h = 0 \quad [41]$$

$$\begin{aligned} \boldsymbol{\nabla}\cdot\left(\varepsilon\boldsymbol{E} + \frac{\varepsilon - 1}{c}\boldsymbol{v}\times\boldsymbol{B}\right) &= q_e \\ \boldsymbol{\nabla}\times\boldsymbol{E} + \frac{1}{c}\frac{\partial\boldsymbol{B}}{\partial t} = \boldsymbol{0}, \quad \boldsymbol{\nabla}\cdot\boldsymbol{B} &= 0 \end{aligned} \quad [42]$$

$$\begin{aligned} &\boldsymbol{\nabla}\times\left(\mu^{-1}\boldsymbol{B} + \frac{\varepsilon - 1}{c}\boldsymbol{v}\times\boldsymbol{E}\right) - \frac{1}{c}\frac{\partial(\varepsilon\boldsymbol{E})}{\partial t} \\ &\quad - \frac{1}{c}(q_e\boldsymbol{v} + \sigma\mathscr{E} + \tau\boldsymbol{\nabla}T + h\boldsymbol{E}\times\boldsymbol{B}) = 0 \end{aligned} \quad [43]$$

$$\frac{\partial q_e}{\partial t} + \boldsymbol{\nabla}\cdot(q_e\boldsymbol{v} + \sigma\boldsymbol{E} + \tau\boldsymbol{\nabla}T + h\boldsymbol{E}\times\boldsymbol{B}) = 0 \quad [44]$$

where η, t_{kl}, $\boldsymbol{q}$, and $\mathscr{J}$ are given by eqn [37] and $\boldsymbol{F}^E$ by eqn [9].

Magnetoelasticity

The theory of magnetoelasticity is concerned with the deformation and magnetic behavior of nonferrous materials. For these materials, the effects of charge, displacement current, and polarization can be neglected. For simplicity, here, the isotropic bodies are considered. In this case, [43] reduces to

$$\boldsymbol{\nabla}\times\boldsymbol{H} - \frac{1}{c}\left[\sigma\left(\boldsymbol{E} + \frac{\mu}{c}\boldsymbol{v}\times\boldsymbol{H}\right) + \tau\boldsymbol{\nabla}T\right] = 0 \quad [45]$$

Curl of [45], upon the using the second of eqn [42], gives

$$\begin{aligned} &v_H\boldsymbol{\nabla}\times\boldsymbol{\nabla}\times\boldsymbol{H} + \frac{\partial\boldsymbol{H}}{\partial t} - \boldsymbol{\nabla}\times(\dot{\boldsymbol{u}}\times\boldsymbol{H}) = \boldsymbol{0}, \\ &v_H = c^2/\sigma\mu \end{aligned} \quad [46]$$

Substituting the simplified expression of $\boldsymbol{F}^E$, given by [9] after neglecting q_e, $\boldsymbol{P}$, and $\breve{\boldsymbol{P}}$ into [12a] leads to

$$\begin{aligned} &(\lambda_e + 2\mu_e)\boldsymbol{\nabla}\boldsymbol{\nabla}\cdot\boldsymbol{u} - \mu_e\boldsymbol{\nabla}\times\boldsymbol{\nabla}\times\boldsymbol{u} - \beta\boldsymbol{\nabla}T \\ &\quad + \mu_1(\boldsymbol{\nabla}\times\boldsymbol{H})\times\boldsymbol{H} + \rho(\boldsymbol{f} - \ddot{\boldsymbol{u}}) = \boldsymbol{0} \end{aligned} \quad [47]$$

Substituting constitutive eqns [37] into energy eqn [41], one obtains

$$\begin{aligned} &-\rho_0\gamma T_0\dot{T} - \beta T_0\boldsymbol{\nabla}\cdot\dot{\boldsymbol{u}} + \kappa_E\nabla^2 T \\ &\quad + (c^2/\sigma)(\boldsymbol{\nabla}\times\boldsymbol{H})\cdot(\boldsymbol{\nabla}\times\boldsymbol{H}) \\ &\quad - (c\tau/\sigma)(\boldsymbol{\nabla}\times\boldsymbol{H})\cdot\boldsymbol{\nabla}T + \rho h = 0 \end{aligned} \quad [48]$$

where

$$\mu_1 = \mu(2 - \mu), \qquad \kappa_E = \kappa - \tau^2/\sigma \quad [49]$$

Equations [46] to [48] are the field equations of magnetoelasticity. The solution of these equations under appropriate boundary and initial conditions determines $\boldsymbol{u}(x,t)$, $\boldsymbol{H}(\boldsymbol{x},t)$, and $T(\boldsymbol{x},t)$. Note that these equations are nonlinear. By linearizing [46] to [48] about a constant bias field H_0, the coupling of elastic waves with magnetic systems can be studied. These couplings are used to measure the dispersion of the elastic waves, and the coupling between the lattice and magnetic degrees of freedom.

The industrial applications of magnetic devices are many: ferrites are used in TV and sound amplifiers, computer disks, recorders, speakers, engines, and superconducting trains. Magnetostrictive transducers are used to convert E-M radiation into elastic waves and magnetoelastic delay lines.

Dissipative and Nonlocal Media

In many materials, the memory of the E-M fields and the stress tensor represents significant factors in terms of the outcome. Internal friction causes dissipation of energy. For such media, it is necessary to include the memory effects. For the conduction of high frequency and short wavelengths, nonlocality plays an important

role. In these cases, the constitutive equations involve the nonlocal effects of space and time.

Nonlocal constitutive equations in space–time generalize the Maxwell theory:

$$D_k(\boldsymbol{x},t) = \int_{-\infty}^{t} \mathrm{d}t' \int_V \varepsilon_{kl}(\boldsymbol{x}',\boldsymbol{x},t',t) \times E_l(x',t')\ \mathrm{d}v' \qquad [50]$$

where ε_{kl} is a nonlocal dielectric permeability tensor. Similar nonlocal constitutive equations exist for $\boldsymbol{B}(\boldsymbol{x},t)$ and t_{kl}, q_k, and $\mathscr{J}_k$. These permit the introduction of frequency and wave number dependents, nonlocal material moduli, such as dielectric and magnetic permeabilities $\varepsilon_{kl}(\boldsymbol{k},\omega)$, $\mu_{kl}(\boldsymbol{k},\omega)$.

The nonlocal theory provides rich grounds to discuss a variety of E-M phenomena, with realistic models, for example, media with absorption, polariton, gyroscopic media, and superconductivity.

Constitutive Equations of Rigid Solids

Rigid bodies do not deform, that is, stress and strain vanish:

$$T_{KL} = E_{KL} = 0, \quad \boldsymbol{Q} = \boldsymbol{q}, \quad \mathscr{E} = \boldsymbol{E}, \quad \mathscr{M} = \boldsymbol{M} \qquad [51]$$

Consequently, the constitutive equations of rigid solids can be obtained from those of the elastic solid by using [51].

E-M fields propagate in a vacuum as well. For a vacuum, the constitutive equations are of the form

$$\boldsymbol{D} = \varepsilon_0 \boldsymbol{E}, \qquad \boldsymbol{B} = \mu_0 \boldsymbol{H} \qquad [52]$$

where the vacuum dielectric permeability ε_0 and the vacuum magnetic permeability μ_0 are dimensional constants related to the speed of light $c = (\varepsilon_0\mu_0)^{1/2}$, as predicted by the solution of Maxwell's equations. This, then, explained that light is an electromagnetic wave, a crowning achievement of the Maxwell theory. Thus, the hypothetical concept of ether (whose vibrations, historically, were considered to produce light) vanished from physics.

For an account on macroscopic electrodynamics of rigid bodies, the reader is referred to the "Further reading" section. The discussion of electrodynamics on the atomic scale requires a quantum mechanical approach.

Nonlinear E-M Theory

Discussion of nonlinear optics, electrostriction, magnetostriction, ferroelectrics, ferromagnetics, and other nonlinear phenomena requires the establishment of the nonlinear constitutive equations. These are usually obtained by expressing ψ and Φ as polynomials of a higher degree than 2, in their independent variables. The degrees of $\boldsymbol{E}$, $\mathscr{E}$, $\boldsymbol{B}$, and $\boldsymbol{\nabla}\theta/\theta$ depend on the accuracy desired. In the case of ferromagnetic materials, to represent the inner structure, a director is also necessary.

Electrostriction and Magnetostriction

Under strong E-M fields, elastic solids deform, developing stress. This is known as E-M striction. This is a nonlinear phenomena. For simplicity, as an example, consider simple nonlinear expressions for ε and Φ to demonstrate the electrostrictive effect:

$$2\rho_0\Psi = -\rho_0\gamma\theta^2 - 2\beta\theta\,\mathrm{tr}\,\boldsymbol{E} + \lambda(\mathrm{tr}\,\boldsymbol{E})^2 + 2\mu\,\mathrm{tr}\,\boldsymbol{E}^2 - [\chi^E + \alpha(\mathrm{tr}\,\boldsymbol{E})^2]\mathscr{E}\cdot\mathscr{E} \qquad [53]$$

$$\rho_0\varepsilon = \rho_0\gamma\theta^2 + \tfrac{1}{2}\lambda(\mathrm{tr}\,\boldsymbol{E})^2 + \mu\,\mathrm{tr}\,\boldsymbol{E}^2 + \tfrac{1}{2}[\chi^E + \alpha(\mathrm{tr}\,\boldsymbol{E})^2]\mathscr{E}\cdot\mathscr{E} \qquad [54]$$

$$2\Phi = [\sigma + \sigma^E(\mathrm{tr}\,\boldsymbol{E})^2]\mathscr{E}\cdot\mathscr{E} + 2[\tau + \tau^E(\mathrm{tr}\,\boldsymbol{E})^2]\mathscr{E}\cdot\frac{\boldsymbol{\nabla}\theta}{\theta} + [\kappa + \kappa^E(\mathrm{tr}\,\boldsymbol{E})^2]\frac{\boldsymbol{\nabla}\theta\cdot\boldsymbol{\nabla}\theta}{\theta^2} \qquad [55]$$

where γ, λ, μ, β, α, χ^E, σ, σ^E, τ, τ^E, κ, and κ^E are the material moduli. It can be seen that restrictions $\varepsilon \geqslant 0$ and $\Phi \geqslant 0$ are fulfilled, if and only if

$$(\gamma, \chi^E, \alpha, \sigma, \sigma^E) \geqslant 0, \qquad 3\lambda + 2\mu \geqslant 0, \quad \mu \geqslant 0, \qquad \sigma\kappa - \tau^2 \geqslant 0, \qquad \sigma^E\kappa^E - (\tau^E)^2 \geqslant 0 \qquad [56]$$

Constitutive equations follow from [25] and [27], upon using [53] and [55]:

$$\begin{aligned} \eta &= \gamma\theta + \rho_0^{-1}\beta\,\mathrm{tr}\,\boldsymbol{E} \\ T_{KL} &= [-\beta\theta + (\lambda - \alpha\mathscr{E}\cdot\mathscr{E})\mathrm{tr}\,\boldsymbol{E}]\boldsymbol{\delta}_{KL} + 2\mu E_{KL} \\ \Pi_K &= [\chi^E + \alpha(\mathrm{tr}\,\boldsymbol{E})^2]\mathscr{E}_K \\ \mathscr{J} &= [\sigma + \sigma^E(\mathrm{tr}\,\boldsymbol{E})^2]\mathscr{E} + [\tau + \tau^E(\mathrm{tr}\,\boldsymbol{E})^2]\frac{\boldsymbol{\nabla}\theta}{\theta} + h\boldsymbol{E}\times\boldsymbol{B} \\ \boldsymbol{Q} &= [\kappa + \kappa^E(\mathrm{tr}\,\boldsymbol{E})^2]\frac{\boldsymbol{\nabla}\theta}{\theta} + [\tau + \tau^E(\mathrm{tr}\,\boldsymbol{E})^2]\mathscr{E} + e\boldsymbol{E}\times\boldsymbol{\nabla}\theta \end{aligned} \qquad [57]$$

It is observed that the electric field produces stress. If pressure is defined by

$$p = -\tfrac{1}{3}T_{KK} = \beta\theta + [\alpha\mathscr{E}\cdot\mathscr{E} - \lambda - \tfrac{2}{3}\mu]\mathrm{tr}\,\boldsymbol{E} \qquad [58]$$

the volume of the body will change under this pressure. Electrical contribution to the pressure is given by $\alpha\mathscr{E}\cdot\mathscr{E}$. Conversely, the strain field causes polarization.

Parallel to this, magnetostriction may be illustrated similarly.

E-M Viscous Fluids

The interaction of E-M fields and fluids is observed in magnetohydrodynamics, plasma physics, sun flares, atmospheric physics, ferrofluids, electrohydrodynamics, and electrogas dynamic energy converters. Fluids do not possess natural states. Thermodynamics of fluids can be discussed by means of the spacial form [17] of the C–D inequality. The response functions (dependent variable set Z) and the independent variable set Y are given by the collections:

$$\begin{aligned} Z &= (\psi, \eta, t_{kl}, q_k, P_k, \mathscr{M}_k, \mathscr{J}_k) \\ Y &= (\rho, \theta, d_{kl}, \nabla\theta/\theta, \mathscr{E}_k, B_k) \end{aligned} \qquad [59]$$

All these quantities are objective (frame independent). Stress tensor t_{kl}, given by [22], is expressed as a sum of the static and dynamic parts, denoted, respectively, by the left-hand indices R and D:

$$t_{kl} = {}_R\,\bar{t}_{kl} + {}_D\,\bar{t}_{kl} - P_k\mathscr{E}_l - \mathscr{M}_k B_l \qquad [60]$$

The free energy ψ and dissipation potential Φ, for the linear theory, are quadratic forms expressed by the invariants of $\mathscr{E}$, $\boldsymbol{B}$ for ψ and $\boldsymbol{d}$, $\mathscr{E}$, $\nabla\theta/\theta$ for Φ:

$$\begin{aligned} \rho_0\psi &= \rho_0\Psi_0(\rho,\theta) - \tfrac{1}{2}\chi^E\mathscr{E}\cdot\mathscr{E} + \tfrac{1}{2}\chi^B\boldsymbol{B}\cdot\boldsymbol{B} \\ \Phi &= \tfrac{1}{2}\lambda_v(\operatorname{tr}\boldsymbol{d})^2 + \mu_v\operatorname{tr}\boldsymbol{d}^2 + \frac{1}{2}\kappa\frac{\nabla\theta\cdot\nabla\theta}{\theta^2} \\ &\quad + \frac{1}{2}\sigma\mathscr{E}\cdot\mathscr{E} + \tau\frac{\mathscr{E}\cdot\nabla\theta}{\theta} \end{aligned} \qquad [61]$$

The linear constitutive equations for E-M thermoviscous fluids follow from these:

$$\begin{aligned} &\eta = -\frac{\partial\Psi_0}{\partial T}, \quad t_{kl} = (-\pi + \lambda_v d_{rr})\delta_{kl} + 2\mu_v d_{kl}, \\ &\pi = \rho^2\frac{\partial\Psi_0}{\partial\rho} \\ &\boldsymbol{P} = \chi^E\mathscr{E}, \quad \mathscr{M} = -\chi^B\boldsymbol{B}, \\ &\boldsymbol{q} = \kappa\nabla T + \tau\mathscr{E}, \quad \mathscr{J} = \sigma\mathscr{E} + \tau\nabla T \end{aligned} \qquad [62]$$

where π is the thermodynamic pressure and (λ_v,μ_v) and κ are, respectively, the viscosities and heat conduction coefficient. σ is the conductivity and τ represents the current generated by the temperature gradient and the heat generated by the electric field. The field equations are obtained by substituting [62] into balance laws:

$$\nabla\cdot\left[(1+\chi^E)\boldsymbol{E} + \frac{1}{c}\chi^E\boldsymbol{v}\times\boldsymbol{B}\right] = q_e \qquad [63]$$

$$\nabla\times\boldsymbol{E} + \frac{1}{c}\frac{\partial\boldsymbol{B}}{\partial t} = 0 \qquad [64]$$

$$\nabla\cdot\boldsymbol{B} = 0 \qquad [65]$$

$$\begin{aligned} &\nabla\times\left[(1+\chi^B)\boldsymbol{B} + \frac{\chi^E}{c}\boldsymbol{v}\times\boldsymbol{E}\right] - \frac{1}{c}\frac{\partial[(1+\chi^E)\boldsymbol{E}]}{\partial t} \\ &\quad - \frac{1}{c}\left[q_e\boldsymbol{v} + \sigma\left(\boldsymbol{E} + \frac{1}{c}\boldsymbol{v}\times\boldsymbol{B}\right) + \tau\nabla T\right] = 0 \end{aligned} \qquad [66]$$

$$\dot\rho + \rho\nabla\cdot\boldsymbol{v} = 0 \qquad [67]$$

$$\begin{aligned} &-\nabla\pi + (\lambda_v + 2\mu_v)\nabla\nabla\cdot\boldsymbol{v} - \mu_v\nabla\times\nabla\times\boldsymbol{v} + \rho(\boldsymbol{f} - \dot{\boldsymbol{v}}) \\ &\quad + q_e\boldsymbol{E} + \frac{1}{c}[q_e\boldsymbol{v} + \sigma\boldsymbol{E} + \tau\nabla T + \chi^E\dot{\boldsymbol{E}} - \chi^E(\boldsymbol{E}\cdot\nabla)\boldsymbol{v} \\ &\quad + \chi^E\boldsymbol{E}\nabla\cdot\boldsymbol{v}]\times\boldsymbol{B} + \chi^E\left(\boldsymbol{E} + \frac{1}{c}(\boldsymbol{v}\times\boldsymbol{B})\right)\cdot\nabla\boldsymbol{E} \\ &\quad + \frac{1}{c}\chi^E\boldsymbol{E}\cdot\nabla(\boldsymbol{v}\times\boldsymbol{B}) - \chi^B(\nabla\boldsymbol{B})\cdot\boldsymbol{B} = 0 \end{aligned} \qquad [68]$$

$$\begin{aligned} &-C\dot T - G\nabla\cdot\boldsymbol{v} + \lambda_v(\operatorname{tr}\boldsymbol{d})^2 + 2\mu_v\operatorname{tr}\boldsymbol{d}^2 \\ &\quad + \nabla\cdot\left[\kappa\nabla T + \tau(\boldsymbol{E} + c^{-1}\boldsymbol{v}\times\boldsymbol{B})\right] \\ &\quad + (\sigma\boldsymbol{E} + \boldsymbol{\tau}\nabla T)\cdot\left(\boldsymbol{E} + \frac{1}{c}\boldsymbol{v}\times\boldsymbol{B}\right) \\ &\quad + \rho h = 0 \end{aligned} \qquad [69]$$

where

$$C = -\rho T\frac{\partial^2\Psi_0}{\partial T^2}\Big|_0, \qquad G = \rho^2 T\frac{\partial\Psi}{\partial\rho\partial T}\Big|_0 \qquad [70]$$

Magnetohydrodynamic Approximation

In MHD the motion is nonrelativistic, that is, $v/c \ll 1$, $\chi^E \ll 1$, so that $\boldsymbol{B} = \mu\boldsymbol{H}$, $\mu = (1+\chi^B)^{-1}$. Displacement current $\partial\boldsymbol{D}/\partial t$ is negligible. Also, in the expression $\boldsymbol{F}^E$, terms containing $\breve{\boldsymbol{P}}$ and $\boldsymbol{P}$ are neglected. With this, $\boldsymbol{F}^E$ is reduced to

$$\begin{aligned} \boldsymbol{F}^E &= -\nabla(\mu_1 H^2/2) + \mu(\boldsymbol{H}\cdot\nabla)\boldsymbol{H}, \\ \mu_1 &= 2\mu - \mu^2 \end{aligned} \qquad [71]$$

With these simplifications, and taking the curl of [66], the field equations of magnetohydrodynamics

follow from [66] to [69]:

$$\dot{\rho} + \rho \nabla \cdot \boldsymbol{v} = 0 \qquad [72]$$

$$-\eta^B \nabla \times \nabla \times \boldsymbol{B} + \nabla \times (\boldsymbol{v} \times \boldsymbol{B}) - \frac{\partial \boldsymbol{B}}{\partial t} = 0, \quad \eta^B = c^2/\sigma\mu \qquad [73]$$

$$-\nabla\left(\pi - \frac{\mu - 1}{2\mu}B^2\right) + (\lambda_v + 2\mu_v)\nabla\nabla \cdot \boldsymbol{v} - \mu_v \nabla \times \nabla \times \boldsymbol{v} + \rho(\boldsymbol{f} - \dot{\boldsymbol{v}}) + \frac{1}{\mu}(\nabla \times \boldsymbol{B}) \times \boldsymbol{B} = 0 \qquad [74]$$

$$-C\dot{T} - G\nabla \cdot \boldsymbol{v} + \lambda_v (\mathrm{tr}\, \boldsymbol{d})^2 + 2\mu_v \mathrm{tr}\, \boldsymbol{d}^2 + \left(\kappa - \frac{\tau^2}{\sigma}\right)\nabla^2 T + \frac{c^2}{\mu^2 \sigma}(\nabla \times \boldsymbol{B})^2 - \frac{\tau c}{\sigma\mu}\nabla T \cdot (\nabla \times \boldsymbol{B}) + \rho h = 0 \qquad [75]$$

In the following sections, three example problems in the E-M theory of continuous media are discussed.

Piezoelectric Waves

t_{kl} and P_k, given by eqn [35], with $T = 0$, $\boldsymbol{B} = 0$, in R_F are written as

$$t_{kl} = \tfrac{1}{2}\lambda_{klmn}(u_{m,n} + u_{n,m}) + a_{klm}E_m \qquad [76]$$

$$P_k = -\tfrac{1}{2}a_{lmk}(u_{l,m} + u_{m,l}) + \chi^E_{kl}E_l \qquad [77]$$

A plane dielectric elastic wave propagating in the direction of a unit vector $\boldsymbol{n}$ may be represented by

$$G(\boldsymbol{n} \cdot \boldsymbol{x} \pm c_0 t), \quad \boldsymbol{u} = \boldsymbol{u}(\boldsymbol{n} \cdot \boldsymbol{x} \pm c_0 t) \qquad [78]$$

where c_0 is the phase velocity of the wave. The electric potential ϕ is introduced as

$$\boldsymbol{E} = -\nabla\phi \qquad [79]$$

Substituting [76]–[79], into balance laws [2a] and [12a], with $q_e = 0$ and $f_k = 0$,

$$\epsilon_{kl}\phi'' n_k n_l + a_{lmk}u''_l n_m n_k = 0 \qquad [80]$$

$$\lambda_{klmn}u''_m n_n n_k - a_{klm}\phi'' n_m n_k - \rho c_0^2 u''_l = 0 \qquad [81]$$

Eliminating ϕ'' from [81] by means of [80] yields

$$(A_{lm} - \rho c_0^2 \delta_{lm})u''_m = 0 \qquad [82]$$

where

$$A_{lm} = \bar{\lambda}_{klmn} n_k n_n, \quad \bar{\lambda}_{klmn} = \lambda_{klmn} + (\varepsilon_{ij} n_i n_j)^{-1} a_{kln}\, a_{mpq} n_p n_q \qquad [83]$$

Since A_{lm} is a symmetric tensor, whose proper numbers are real, the three roots of

$$\det(A_{lm} - \rho c_0^2 \delta_{lm}) = 0 \qquad [84]$$

are distinct, and the acoustical axes $\boldsymbol{u}''/|\boldsymbol{u}''|$ form an orthogonal triad at a point on the wave surface. c_0^2 must be positive. Thus, for a real wave to propagate in every direction, the acoustical tensor A_{lm} must be positive-definite. It can be shown that the necessary and sufficient condition for this is the strong ellipticity of the piezoelectrically stiffened stiffness tensor, that is,

$$\bar{\lambda}_{klmn} A_l A_n B_k B_m \geqslant 0 \qquad [85]$$

for arbitrary vectors $\boldsymbol{A}$ and $\boldsymbol{B}$. From this discussion, it is clear that the material symmetry regulations for the moduli $\lambda_{klmn}, \alpha_{klm}$, and ϵ_{kl} are important to the outcome.

Piezoelectricity has many industrial applications. A few of them include air bag sensors, audible alarms, keyless entry, computers, speakers, dialysis equipment, sonar, guidance systems, and hydrophones.

Magnetohydrodynamic Poiseulle Flow

An incompressible, electrically conducting fluid with constant viscosity μ_v and constant electrical conductivity σ flows between two parallel straight insulated walls, in the direction of x_1, parallel to the walls. The applied constant magnetic field H_0 is in the x_2-direction, normal to the walls. Flow is steady and two dimensional. Introducing nondimensional variables

$$x = \frac{x_1}{L}, \quad y = \frac{x_2}{L}, \quad v(y) = \frac{v_1}{V}, \quad v_2 = v_3 = 0$$
$$H(y) = \frac{H_1}{H_0}, \quad H_2 = H_0, \qquad [86]$$
$$H_3 = 0, \quad p_0 = p/\rho_0 V^2$$

where p is the unknown pressure, and L and V are, respectively, a characteristic length and a characteristic velocity, the equations of motion follow from [73] and [74]. Heat conduction is neglected:

$$\frac{\partial v}{\partial y} + \frac{1}{R_\mathrm{B}}\frac{\mathrm{d}^2 H}{\mathrm{d}y^2} = 0 \qquad [87]$$

$$\frac{1}{R}\frac{\mathrm{d}^2 v}{\mathrm{d}y^2} + \frac{1}{A^2}\frac{\mathrm{d}H}{\mathrm{d}y} = \frac{\partial p_0}{\partial x} \qquad [88]$$

$$\frac{1}{A^2}H\frac{\mathrm{d}H}{\mathrm{d}y} = -\frac{\mathrm{d}p_0}{\mathrm{d}y} \qquad [89]$$

where R, R_B, and A are, respectively, the Reynolds number, the magnetic Reynolds number, and the Alfvén number, defined by

$$R = \rho_0 VL/\mu_\nu, \quad R_B = VL/\eta^B,$$
$$A = (\rho V^2/\mu_\nu H_0^2)^{1/2} \qquad [90]$$

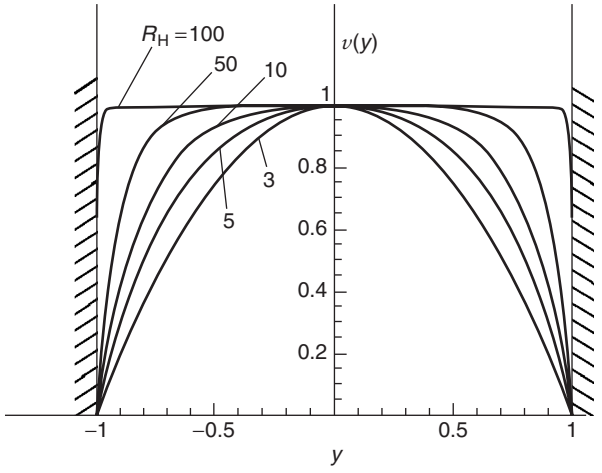

Figure 2 Velocity profile across channel for $R_H = 3, 5, 10, 50, 100$.

Boundary conditions are

$$v(\pm 1) = 0, \quad v(0) = 1,$$
$$H(\pm 1) = 0 \quad \text{(insulated walls)} \qquad [91]$$

The solution of these equations is

$$\begin{aligned} v &= [\cosh R_H - \cosh(R_H y)]/(\cosh(R_H - 1) \\ H(y) &= (R_B/R_H) \\ &\quad \times [\sinh(R_H y) - y \sinh R_H]/(\cosh R_H - 1) \\ p_0 &= -\tfrac{1}{2} A^{-2} H^2(y) + Gx + \bar{p} \end{aligned} \qquad [92]$$

where $R_H = (RR_B/A^2)^{1/2}$ is the Hartmann number and

$$G = (R_H/R)(\cosh R_H - 1)^{-1} \sinh R_H \qquad [93]$$

and $\bar{p}$ are constants. G is the pressure gradient and $\bar{p}$ is the pressure at $x = 0$. As R_H tends to zero, the velocity profile becomes a classical parabolic (Poiseulle) velocity profile

$$v = 1 - y^2 \qquad [94]$$

In the limit $R_H \to \infty$, $v = 1$ everywhere, except $y = \pm 1$, that is, the velocity profile is flat, quickly vanishing at the walls. The velocity profile and magnetic field profile, for various values of R_H, are shown in **Figures 2** and **3**, respectively.

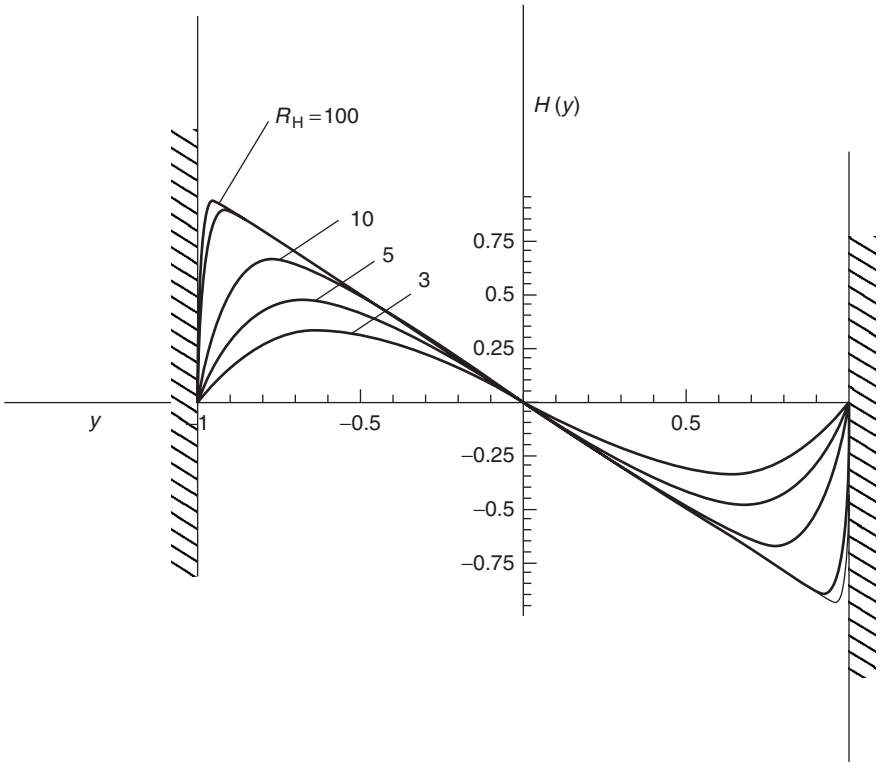

Figure 3 Magnetic field profile for $R_H = 3, 5, 10, 50, 100$.

Φ	dissipation potential ($\mathrm{V^2\,m^{-2}\,s^{-1}}$)
ψ, Ψ	Helmholtz' free energy ($\mathrm{m^2\,s^{-2}}$)

Electrodynamics: Quantum Electrodynamics

G Scharf, Universität Zürich, Zürich, Switzerland

Introduction

Quantum electrodynamics (QED) is the quantum counterpart of classical (Maxwell's) electrodynamics in two ways. First, the electromagnetic field is quantized. This is necessary if one considers high enough frequencies or certain aspects of the interaction between radiation and matter (spontaneous emission). Second, the charged particles which are the sources of the electromagnetic fields have to be described by their correct relativistic equations of motion: the Klein–Gordon (KG) equation for integer spin and the Dirac equation for spin 1/2, in particular for electrons. This is necessary if the kinetic energy of the particles is comparable with their rest energy mc^2, or if the fine structure of the atomic spectra plays a role. However, the KG and Dirac equations are one-particle equations which have no consistent physical interpretation, because the energy is unbounded from below.

The correct procedure is to consider the KG and Dirac equations as field equations for the scalar or electron-positron field, respectively, and to quantize them (second quantization). Second quantization is the method to transform an unphysical single-particle theory into a physical many-particle theory. As such it plays a crucial role in solid-state theory, too. For this reason, the next section starts with a general discussion of second quantization. In the section "Quantized electron–positron and electromagnetic fields," this method is applied to the quantization of the free Dirac and electromagnetic fields. The interaction is introduced in the section "Causal perturbation theory," in the framework of the S-matrix theory. The S-matrix is constructed by the causal perturbation theory which avoids the nasty problems with ultraviolet divergences completely. In the last section, a review of results and an outlook to more complicated (non-Abelian) gauge theories are given of which QED is a part.

Second Quantization

Let $\mathscr{H}$ be the one-particle Hilbert space, for example, $L^2(\mathbb{R}^3)$ in case of a spinless particle. Then the n-particle space is given by the tensor product $\mathscr{H}_n^{\pm} = S_n^{\pm}\mathscr{H}^{\otimes n}$, where S_n^+ is the symmetrization operator in case of integer spin (bosons) and S_n^- the antisymmetrization operator in case of spin 1/2 (fermions). In order to describe all multiparticle states simultaneously, one introduces the Fock space

$$\mathscr{F}^{\pm} = \bigoplus_{n=0}^{\infty} \mathscr{H}_n^{\pm}$$

where the one-dimensional space $\mathscr{H}_0$ consists of the vacuum Ω. An element of $\mathscr{F}$ is an infinite sequence of states $\Phi = (\varphi_0, \varphi_1, \dots)$ with $\varphi_n \in \mathscr{H}_n$.

All operators in Fock space can be defined with the help of emission (or creation) and absorption (or annihilation) operators. The emission operator $a^+(f)$ adds a particle with wave function $f \in \mathscr{H}_1^{\pm}$ to all components φ_n in Φ:

$$a^+(f)\Omega = f$$

$$(a^+(f)\Phi)_n = \sqrt{n}S_n^{\pm}(f \otimes \varphi_{n-1}), \quad n = 1, 2, \dots$$

The absorption operator $a(f)$ is just the adjoint of $a^+(f)$. These operators are often written in distributional form in x-space or momentum space, for example,

$$a^+(f) = \int \mathrm{d}^3k\, a^+(\boldsymbol{k}) f(\boldsymbol{k})$$

Then, for the (distributional) field operators

$$(a^+(\boldsymbol{k})\Phi)_n(\boldsymbol{k}_1, \dots, \boldsymbol{k}) = \sqrt{n}S_n^{\pm}(\delta(\boldsymbol{k} - \boldsymbol{k}_1)\varphi_{n-1}(\boldsymbol{k}_2, \dots, \boldsymbol{k}_n))$$

$$(a(\boldsymbol{k})\Phi)_n(\boldsymbol{k}_1, \dots, \boldsymbol{k}) = \sqrt{n+1}\varphi_{n+1}(\boldsymbol{k}, \boldsymbol{k}_1, \dots, \boldsymbol{k}_n)$$

and $a(\boldsymbol{k})\Omega = 0$.

The most important properties of these operators are their commutation relations in case of bosons or their anticommutation relations in case of fermions

$$\begin{aligned} [a(f), a^+(g)]_{\mp} &= (f, g)_1 \\ [a(f), a(g)]_{\mp} &= 0 = [a(f)^+, a^+(g)]_{\mp} \end{aligned} \qquad [1]$$

where $(\cdot\,,\,\cdot)_1$ is the scalar product in the one-particle space. For the field operators, this gives the simple anticommutation relations

$$[a(\boldsymbol{k}), a^+(\boldsymbol{k}')]_{\mp} = \delta(\boldsymbol{k} - \boldsymbol{k}') \qquad [2]$$

and zero otherwise. For fermions, this implies that $a^+(f)a^+(f) = 0$, that is, two particles cannot be in the same state f (exclusion principle). Any operator in Fock space can be expressed by emission and absorption operators in the so-called normally (or

Wick) ordered form, for example,

$$\boldsymbol{H} = \int \mathrm{d}^3k\, a^+(\boldsymbol{k})H(\boldsymbol{k})a(\boldsymbol{k})$$

Normally ordered means that all absorption operators stand to the right of all emission operators.

In condensed matter physics, the occupation number representation is very popular. One chooses a basis f_k in $\mathscr{H}_1$ and the corresponding tensor basis

$$S_n^{\pm} f_{k_1} \otimes \cdots \otimes f_{k_n} \qquad [3]$$

in $\mathscr{H}_n$. To fix the sign in eqn [3] in case of fermions, one orders the factors with increasing indices $k_1 \leqslant k_2 \leqslant \cdots \leqslant k_n$. If n_i is the number of k's which are equal to i, that is, the number of particles in the state f_i, then an orthonormal basis in $\mathscr{H}_n$ is given by

$$|n_1, n_2, \ldots\rangle = \sqrt{\frac{n!}{n_1!n_2!\ldots}} S_n^{\pm} f_{k_1} \otimes \cdots \otimes f_{k_n} \qquad \sum_{i=1}^{\infty} n_i = n \qquad [4]$$

The occupation numbers n_i assume all values $0, 1, 2, \ldots$ in case of bosons, but only 0, 1 for fermions. The emission operator $a_k^+ = a^+(f_k)$ can be written as

$$(a_k^{\pm}\Phi)_n = \sqrt{n_k + 1}\, |n_1, \ldots n_k + 1, \ldots\rangle$$

in case of bosons and the absorption operator is given by

$$(a_k\Phi)_n = \sqrt{n_k}\, |n_1, \ldots n_k - 1, \ldots\rangle$$

For fermions, one has to be careful with the sign.

Quantized Electron–Positron and Electromagnetic Fields

Free relativistic electrons are described by the Dirac equation

$$\mathrm{i}\hbar\gamma^\mu \partial_\mu \psi(x) = mc\psi(x) \qquad [5]$$

Here, the relativistic notation: $\mu = 0, 1, 2, 3$, $x = (x^\mu) = (ct, x^1, x^2, x^3)$, $\partial_\mu = \partial/\partial x^\mu$ is used. γ^μ are four 4×4 matrices satisfying

$$\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2g^{\mu\nu}$$

where $g^{\mu\nu} = \mathrm{diag}\{1, -1, -1, -1\}$. Furthermore, it is convenient to assume the following property under the Hermitian conjugation:

$$\gamma^{\mu +} = \gamma^0\gamma^\mu\gamma^0 \qquad [6]$$

The solution $\psi(x)$ of eqn [5] is a four-component object, a Dirac spinor, which has a well-defined behavior under the Lorentz transformation $x' = \Lambda x$ such that the Dirac equation [5] holds in any frame of reference.

The general solution of eqn [5] is best written as a Fourier integral

$$\psi(x) = (2\pi)^{-3/2} \int \mathrm{d}^3p [b_s(\boldsymbol{p})u_s(\boldsymbol{p})\mathrm{e}^{-\mathrm{i}px} + \mathrm{d}_s(\boldsymbol{p})^+ v_s(\boldsymbol{p})\mathrm{e}^{\mathrm{i}px}] \qquad [7]$$

Here, $px = p^0x^0 - \boldsymbol{p}\boldsymbol{x}$ with $p^0 = E = \sqrt{\boldsymbol{p}^2 + m^2}$, $(c = 1)$ and the u and v spinors are solutions of the linear algebraic equations

$$(p_\mu\gamma^\mu - m)u_s(\boldsymbol{p}) = 0$$

$$(p_\mu\gamma^\mu + m)v_s(\boldsymbol{p}) = 0$$

They are labeled by the polarization index $s = 1, 2$ and normalized by

$$u_s^+(\boldsymbol{p})u_{s'}(\boldsymbol{p}) = \delta_{ss'} = v_s^+(\boldsymbol{p})v_{s'}(\boldsymbol{p})$$

and orthogonal $u_s^+(\boldsymbol{p})v_s(-\boldsymbol{p}) = 0$.

The quantized Dirac field has the same form [7] where $b_s(\boldsymbol{p})$ are absorption operators of electrons and $d_s(\boldsymbol{p})^+$ emission operators of positrons, respectively. According to the last section, they satisfy anticommutation relations

$$\{b_s(\boldsymbol{p}), b_{s'}(\boldsymbol{p}')^+\} = \delta_{ss'}\delta^3(\boldsymbol{p} - \boldsymbol{p}') = \{d_s(\boldsymbol{p})^+, d_{s'}(\boldsymbol{p}')\} \qquad [8]$$

All other anticommutators vanish. This gives the following anticommutation rule for the total electron positron field [7] and the adjoint $\bar{\psi}(x) = \psi(x)^+\gamma^0$

$$\{\psi(x), \bar{\psi}(x)\} = -\mathrm{i}S(x - y) = (\gamma^\mu\partial_\mu^x - \mathrm{i}m)D(x - y) \qquad [9]$$

where

$$D(x) = \frac{\mathrm{i}}{(2\pi)^3} \int \mathrm{d}^4p\, \delta(p^2 - m^2)\mathrm{sgn}\, p^0 \mathrm{e}^{-\mathrm{i}px} \qquad [10]$$

is the Jordan–Pauli distribution. It has a causal support, that means it vanishes for spacelike x: $x^2 < 0$.

The first term in eqn [7] is called the absorption part $\psi^{(-)}$ (the misleading notion "positive frequency"

part is avoided), the second term is the emission part $\psi^{(+)}$. The anticommutator

$$\{\psi^{(-)}(x), \bar{\psi}^{(+)}(x)\} = -\mathrm{i}S^{(+)}(x-y) = (\gamma^\mu \partial^x_\mu - \mathrm{i}m)D^{(+)}(x-y) \quad [11]$$

where $D^{(+)}$ has the same form as eqn [9] with $\mathrm{sgn}(p^0)$ substituted by $\Theta(p^0)$ (here the meaning of positive frequency part is clear). The adjoint relation involves the negative frequency part $D^{(-)}$ with $-\Theta(-p^0)$ instead of $\mathrm{sgn}(p^0)$.

Consider the quantization of the electromagnetic field. Here, one has to quantize the four-vector potential $A^\mu(x)$, which satisfies the wave equation $\Box A^\mu(x) = 0$. Starting again from a classical solution

$$A^\mu(x) = (2\pi)^{-3/2} \int \frac{\mathrm{d}^3 k}{\sqrt{2\omega}} (a^\mu(\boldsymbol{k})\mathrm{e}^{-\mathrm{i}kx} + a^\mu(\boldsymbol{k})^* \mathrm{e}^{\mathrm{i}kx}) \quad [12]$$

where $\omega = k^0 = |\boldsymbol{k}|$. To consider the $a^\mu(\boldsymbol{k})$ as absorption operators in a photon Fock space with positive definite metric, the (bosonic) commutation relations are

$$[a^\mu(\boldsymbol{k}), a^\nu(\boldsymbol{k}')^+] = \begin{cases} \delta(\boldsymbol{k}-\boldsymbol{k}') & \text{for } \mu = \nu \\ 0 & \text{for } \mu \neq \nu \end{cases}$$

However, Lorentz covariance forces one to change the meaning of the conjugation in eqn [12] for the scalar component: $a^0(\boldsymbol{k})^* = -a^0(\boldsymbol{k})^+$. This makes A^0 a skew-adjoint operator instead of a self-adjoint one, but this is harmless because scalar photons are unphysical degrees of freedom. From eqn [12], one finds the covariant commutation rule

$$[A^\mu(x), A^\nu(y)] = g^{\mu\nu}\mathrm{i}D_0(x-y) \quad [13]$$

where D_0 is the Jordan–Pauli distribution [10] for mass zero.

It is well known that the radiation field has only two transverse physical degrees of freedom. Consequently, besides the scalar photons there are unphysical longitudinal ones which are generated by emission operators

$$a_{||}(\boldsymbol{k})^+ = \frac{k_j}{\omega} a^j(\boldsymbol{k})$$

The total Fock space is a direct sum of a physical subspace and the rest. Only states in the physical subspace can appear as incoming and outgoing states in scattering processes. However, the unphysical degrees of freedom contribute to the interaction. This is the typical situation in quantum gauge theories.

Causal Perturbation Theory

Most experimental information in QED is contained in the S-matrix, which until now is only defined by its perturbation series

$$S(g) = 1 + \sum_{n=1}^{\infty} \frac{1}{n!} \int \mathrm{d}^4 x_1 \ldots \mathrm{d}^4 x_n T_n(x_1, \ldots, x_n) \times g(x_1) \ldots g(x_n) \quad [14]$$

Here $g(x)$ is a Schwartz test function which cuts off the long-range part of the interaction and, therefore, serves as an infrared regulator. To compute observable quantities, one usually performs the limit $g \to e$, where e is the coupling constant which is equal to the unit of charge (assuming $\hbar = 1,\ c = 1$). The T_n are the chronological (or time-ordered) products which are expressed by the free asymptotic fields constructed in the last section. It is not necessary to consider interacting fields, if one is only interested in the S-matrix. In QED the first order is given by

$$T_1(x) = ie : \bar{\psi}(x)\gamma^\mu \psi(x) : A_\mu(x) \quad [15]$$

The double dots mean normal ordering which is essential, otherwise the product of field operators at the same space-time point x is not well defined.

The higher orders $n \geqslant 2$ can be constructed inductively from T_1 on the basis of a few basic axioms for the T_n (Bogoliubov axioms). The axioms express symmetry of T_n in $x_1, \ldots, x_n$, Lorentz and translation invariance and, most importantly, causality. Causality means that T_n factorizes

$$T_n(x_1, \ldots, x_n) = T_m(x_1, \ldots, x_m) \times T_{n-m}(x_{m+1}, \ldots, x_n) \quad [16]$$

if all $x_1, \ldots, x_m$ have time coordinates greater than all $x_{m+1}, \ldots, x_n$ in some Lorentz frame. To see the strength of this property, the construction of T_2 is shown explicitly. With the unknown T_2, consider the difference

$$T_2(x_1, x_2) - T_1(x_1)T_1(x_2) = A_2(x_1, x_2)$$

For $x_1^0 > x_2^0$, this distribution vanishes by causality (advanced distribution), similarly

$$T_2(x_2, x_1) - T_1(x_2)T_1(x_1) = R_2(x_1, x_2) \quad [17]$$

vanishes for $x_1^0 < x_2^0$ (retarded distribution). In the difference

$$D_2(x_1, x_2) = R_2 - A_2 = T_1(x_1)T_1(x_2) - T_1(x_2)T_1(x_1) \quad [18]$$

the unknown T_2 drops out, so this distribution can be computed from the first order. Since the supports of the advanced and retarded distributions have only the plane $x_1^0 = x_2^0$ in common, the splitting of D_2 at this plane gives R_2 and A_2 separately. Then T_2 is obtained from eqn [17], for example. The situation is even simpler. The commutator eqn [18] has causal support, that is, inside the double cone $(x_1 - x_2)^2 \geqslant 0$, because it involves commutators of free fields which all have causal support. Therefore, the two supports intersect in the vertex of this double cone, only, which makes the distribution splitting much simpler. In fact, the splitting which preserves the singular order of the distribution D_2 is unique up to a distribution with point support which is a sum of the derivatives of $\delta(x_1 - x_2)$, if the singular order is $\geqslant 0$.

The above construction goes through in all orders. It goes back to Epstein and Glaser (1973) and has the big advantage that all quantities are well defined, such that no ultraviolet divergences appear. The latter have plagued quantum field theorists for decades and have even been taken as a motivation to abandon the quantum field theory completely and study the string theory. On the other hand, it is pretty clear that if one starts from well-defined quantities (free fields) and makes well-defined operations only, then no divergences can appear. In the following, it is shown for the second order of QED.

To compute the causal distribution D_2 [18], one has to multiply two factors T_1 [15]. The result can be written in normally ordered form by using Wick's theorem, which for two factors simply reads:

$$A_1 A_2 = :A_1 A_2: + :\overbrace{A_1 A_2}: + \cdots \qquad [19]$$

Here the pairing symbol denotes a contraction, that is a commutator (in the case of Bose fields) or an anticommutator (in the case of Fermi fields) between the absorption and emission parts of the two contracted field operators. In QED, only the following three contractions appear:

$$\overbrace{\psi_a(x)\bar{\psi}_b(y)} = \{\psi_a^{(-)}(x), \bar{\psi}_b^{(+)}(y)\} = \frac{1}{\mathrm{i}} S_{ab}^{(+)}(x-y)$$

$$\overbrace{\bar{\psi}_a(x)\psi_b(y)} = \{\bar{\psi}_a^{(-)}(x), \psi_b^{(+)}(y)\} = \frac{1}{\mathrm{i}} S_{ba}^{(-)}(y-x)$$

$$\overbrace{A_\mu(x)A_\nu(y)} = [A_\mu^{(-)}(x), A_\nu^{(+)}(y)] = g_{\mu\nu}\mathrm{i}D_0^{(-)}(x-y)$$

The dots in eqn [19] mean the sum of all possible contractions, there can be more than one contraction between A_1 and A_2. The individual terms in eqn [19] are often represented by graphs. For the photon field operator in eqn [15], one draws a wavy line and for ψ and $\bar{\psi}$ a normal line; all three lines meet at the vertex x. For the second order, one takes two such vertices and connects as many lines as there are contractions. The uncontracted field operators remain as external lines, they represent incoming and outgoing particles in the scattering process. One obtains second-order graphs as shown in **Figure 1**.

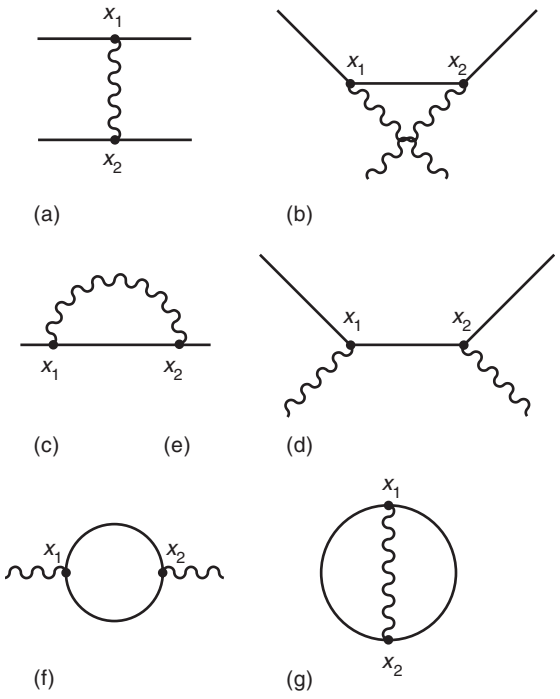

Figure 1 Second-order graphs corresponding to the terms ((a)–(g)) in eqn [20].

The corresponding analytical expression [18] is given by

$$D_2(x_1, x_2)$$

$$= e^2 \gamma_{ab}^\mu \gamma_{cd}^\nu \{: \bar{\psi}_a(x_1)\psi_b(x_1)\bar{\psi}_c(x_2)\psi_d(x_2): g_{\mu\nu}\mathrm{i}$$
$$[D_0^{(+)}(x_2 - x_1) - D_0^{(+)}(x_1 - x_2)] \qquad [20a]$$

$$- :\psi_b(x_1)\bar{\psi}_c(x_2)::A_\mu(x_1)A_\nu(x_2):$$
$$\times \frac{1}{\mathrm{i}}[S_{da}^{(+)}(x_2 - x_1) + S_{da}^{(-)}(x_2 - x_1)] \qquad [20b]$$

$$- :\psi_b(x_1)\bar{\psi}_c(x_2):[S_{da}^{(+)}(x_2 - x_1)D_0^{(+)}(x_2 - x_1)$$
$$+ S_{da}^{(-)}(x_2 - x_1)D_0^{(+)}(x_1 - x_2)]g_{\mu\nu} \qquad [20c]$$

$$- :\bar{\psi}_a(x_1)\psi_d(x_2)::A_\mu(x_1)A_\nu(x_2):$$
$$\times \frac{1}{\mathrm{i}}[S_{bc}^{(-)}(x_1 - x_2) + S_{bc}^{(+)}(x_1 - x_2)] \qquad [20d]$$

$$- :\bar{\psi}_a(x_1)\psi_d(x_2):[S_{bc}^{(-)}(x_1 - x_2)D_0^{(+)}(x_2 - x_1)$$
$$+ S_{bc}^{(+)}(x_1 - x_2)D_0^{(+)}(x_1 - x_2)]g_{\mu\nu} \qquad [20e]$$

$$+ : A_\mu(x_1)A_\nu(x_2) : [-S^{(-)}_{bc}(x_1-x_2)S^{(+)}_{da}(x_2-x_1) + S^{(+)}_{bc}(x_1-x_2)S^{(-)}_{da}(x_2-x_1)] \quad [20f]$$

$$+\frac{1}{\mathrm{i}}g_{\mu\nu}[S^{(-)}_{bc}(x_1-x_2)S^{(+)}_{da}(x_2-x_1)D^{(+)}_0(x_2-x_1) - S^{(+)}_{bc}(x_1-x_2)S^{(-)}_{da}(x_2-x_1)D^{(+)}_0(x_1-x_2)]\} \quad [20g]$$

the numbering indicates the corresponding graph in **Figure 1**.

The graphs with only one contraction (tree graphs) can be simply computed. For example, the bracket in (a) is equal to the Jordan–Pauli distribution $-D_0$ [10]. The splitting into retarded and advanced part is trivial by multiplying with $\Theta(x_1^0 - x_2^0)$. Then the retarded distribution R_2 is proportional to $D_0^{\mathrm{ret}}(x_1 - x_2)$ and the total chronological product proportional to the Feynman propagator

$$D_0^{\mathrm{ret}}(x_1-x_2) + D_0^{(+)}(x_1-x_2) = D_0^{\mathrm{F}}(x_1-x_2) \quad [21]$$

according to eqn [17]. This simple procedure leads to the Feynman rules, where each internal line is represented by a Feynman propagator. But this method does not work for loop graphs. Here the distribution splitting must be done more carefully, otherwise one gets the famous ultraviolet divergences.

For example, for the vacuum polarization graph eqn [20f] we get

$$D_2^{(6)}(x_1,x_2) = -e^2\mathrm{Tr}[\gamma^\mu S^{(-)}(y)\gamma^\nu S^{(+)}(-y) - \gamma^\mu S^{(+)}(y)\gamma^\nu S^{(-)}(-y)] : A_\mu(x_1)A_\nu(x_2) : \quad [22]$$

with $y = x_1 - x_2$. The trace herein has the form $P_1^{\mu\nu}(y) - P_1^{\mu\nu}(-y)$, where $P_1^{\mu\nu}$ is best calculated in momentum space

$$\hat{P}_1^{\mu\nu}(k) = -e^2(2\pi)^{-4}\left(\frac{k^\mu k^\nu}{k^2} - g^{\mu\nu}\right)\hat{d}_1(k) \quad [23]$$

with

$$\hat{d}(k) = \hat{d}_1(k) - \hat{d}_1(-k) = \frac{2\pi}{3}(k^2+2m^2)\sqrt{1-\frac{4m^2}{k^2}} \times \Theta(k^2-4m^2)\,\mathrm{sgn}(k_0) \quad [24]$$

This causal distribution has a singular order $\omega = 2$, then its retarded part is given by the dispersion integral

$$\hat{r}(k) = \frac{\mathrm{i}}{2\pi}\int_{-\infty}^{+\infty}\mathrm{d}t\frac{\hat{d}(tk)}{(t-\mathrm{i}0)^{\omega+1}(1-t+\mathrm{i}0)} \quad [25]$$

This integral is finite and leads to the 'renormalized' vacuum polarization tensor directly. If one does not determine the singular order correctly, the dispersion integral is ultraviolet divergent.

Results

There are two condensed matter systems which are relevant for QED because they give very precise values of the fundamental constants of nature: (1) the AC Josephson effect and (2) the quantum Hall effect. In (1), one applies a DC voltage V across the barrier of a superconducting junction and gets an alternating current of frequency $\nu = 2\,\mathrm{eV}\,h^{-1}$. In (2), one measures the Hall resistance R_H of a two-dimensional electron gas in a strong perpendicular magnetic field. R_H has discrete values

$$R_\mathrm{H} = \frac{h}{ne^2}, \quad n = 1, 2, \ldots$$

which directly give the dimensionless fine structure constant

$$\alpha = \frac{\mu_0 c e^2}{2h}, \quad \mu_0 = 4\pi\cdot 10^{-7}\,\mathrm{Hm}^{-1}$$

The fine structure constant got its name from the bound-state energies E_{nj} of the Dirac equation with a Coulomb potential Ze^2/r:

$$E_{nj} = mc^2\left[1+\frac{(Z\alpha)^2}{(n-\beta)^2}\right]^{-1/2}$$

where n is the principal quantum number, j the total angular momentum and

$$\beta = j + \tfrac{1}{2} - \sqrt{(j+\tfrac{1}{2})^2 - (Z\alpha)^2}$$

It is difficult to obtain a precise value for α from this formula because various corrections must be taken into account. One of the biggest and well calculable by QED is the vacuum-polarization correction of the Coulomb potential. It is the main contribution to the splitting of the $2S_{1/2} - 2P_{1/2}$ states, the so-called Lamb shift.

The most accurate value of α comes from the spin magnetic moment of the electron $\mu = g\mu_\mathrm{B}$, where $\mu_\mathrm{B} = e\hbar/2mc$ is Bohr's magneton and g the dimensionless g value. The Dirac equation gives $g = 2$. The difference $a = g - 2$ has been calculated in QED to better than 1 ppb by now; the result is

$$a = \frac{\alpha}{2\pi} - 0.328478965\ldots\left(\frac{\alpha}{\pi}\right)^2 + 1.181241456\ldots\left(\frac{\alpha}{\pi}\right)^3 - 1.5098(384)\left(\frac{\alpha}{\pi}\right)^4 + 4.393(27)\cdot 10^{-12}$$

The terms up to α^3 are known analytically; the α^3-term was calculated only in 1996 by Laporta and Remeddi. The α^4 term requires evaluation of 891 four-loop diagrams, one only has numerical estimates for them. The experimental value a_e for the electron has been measured to about 4 ppb. The theoretical value for the muon is less accurate because corrections due to strong and weak interactions are necessary.

In high-energy particle physics, only low-order QED results are needed. The most important scattering processes are the following: electron–electron (Møeller) scattering, electron–positron (Bhabba) scattering, photon–electron (Compton) scattering, pair production and annihilation, and the processes with muons. However, as the center of mass energy is in the GeV region, weak and strong interactions have to be taken into consideration. In fact, QED is part of a bigger theory which is now called the standard model. It has grown out of QED and is, in contrast to QED, a non-Abelian gauge theory. For the sake of completeness, its basic ideas are given.

Instead of one gauge field $A^\mu(x)$, one has $N=12$ (photon, $W^\pm$, Z and 8 gluons) denoted by $A^\mu_a(x)$, $a=1,\ldots,N$. On these asymptotic free fields, one defines a gauge variation generated by a gauge charge Q

$$[Q, A^\mu_a(x)] = \mathrm{i}\partial^\mu u_a(x)$$

The $u_a(x)$ are fermionic ghost fields. In contrast to QED, the non-Abelian gauge fields have self-coupling. Its form $T_1(x)$ is uniquely determined by quantum gauge invariance:

$$[Q, T_1(x)] = \mathrm{i}\partial_\mu T_1^\mu(x) \qquad [26]$$

The resulting coupling is of the form

$$T_1(x) = \mathrm{i}g f_{abc} : A_{\mu a}(x) A_{\nu b}(x) \partial^\mu A^\mu_c(x) : + \cdots$$

where f_{abc} are structure constants of a Lie algebra, and the dots represent couplings to ghost fields and additional fields in the theory which are all determined by gauge invariance. The above coupling is called Yang–Mills coupling. It has been found that all interactions in nature, including gravity, are quantum theories in the sense of eqn [26] above.

Electromagnetic Biological Effects

C Marino, ENEA Centro Ricerche Casaccia, Rome, Italy
B Veyret, Université de Bordeaux, Pessac, France

Introduction

Research on biological and health effects of electromagnetic fields (EMFs) has been driven in the last few decades by public concerns about potential detrimental effects. Therapeutic applications have not yet been developed except for microwave hyperthermia.

This article gives a review of the scientific knowledge available on the biological and health effects of EMFs in the two main frequency ranges of concern: the extremely low frequency (ELF, <300 Hz) range mainly at power frequency (50/60 Hz) and the radiofrequency (RF) range, mainly between 300 MHz and 3 GHz, where most sources emit (radio, TV, mobile telephones, wireless networks, etc.) (see **Table 1**).

Explicit distinctions must be made between the concepts of interaction, biological effect, and health hazard, consistent with the criteria used by international bodies when making health assessments: biological effects occur when fields interact to produce responses that may or may not be experienced by people. Deciding whether biological changes have health consequences depends, in part, on whether they are reversible, are within the range for which the

Table 1 Description of frequency ranges

Frequency (Hz)	*Wavelength* (m)	*Description (or radiation name)*
0		Static field
$1–100 \times 10^3$	6×10^6 at 50 Hz	Extremely low frequencies (ELF)
100×10^3–100×10^6	3×10^3–3	Radiofrequencies (RF)
10×10^9	0.03	Microwave (MW)
300×10^{12}	1×10^{-6}	Infrared (IR)
390×10^{12}	760×10^{-9}	Visible red and light
10^{15}	300×10^{-9}	Ultraviolet (UV)
10^{18}	3×10^{-10}	X-ray
10^{21}	3×10^{-13}	γ-ray

Hertz (Hz) = unit of frequency: one cycle per second.
If $f < 300$ GHz (i.e., 3×10^{11} Hz), $hf < 1.2 \times 10^{-3}$ eV → Nonionizing radiation (NIR), where as If $f \geqslant 2.4 \times 10^{15}$ Hz (UV), $hf \geqslant 10$ eV → Ionizing radiation.

body has effective compensation mechanisms, or are likely, taking into account the variability of response among individuals, to lead to unfavorable changes in health. World Health Organization (WHO) defines health as the state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity. Not all biological effects are hazardous; some may be innocuously within the normal range of biological variation and physiological compensation. Others may be beneficial under certain conditions, and the health implications of others may be simply indeterminate. In this article, a health hazard is defined as a biological effect outside the normal range of physiological compensation and adverse to well-being.

It is known that electromagnetic interference with electromedical devices, such as cardiac pacemakers, leads to adverse health consequences, but this article is only concerned with the direct effects of EMFs on living tissues.

Scientific approaches to health risk assessment related to nonionizing EMFs are the same as in the ionizing range, that is, epidemiology, experimental studies on humans, animals, and cells in culture. The experimental protocols are also similar but the choice of exposure systems and biological models are different.

Bioeffects of ELF Fields

Many effects on biological systems exposed to ELF fields have been reported. In the last twenty years, numerous experiments have been performed in laboratories worldwide to assess the biological effects of ELF magnetic and electric fields. This has led to the design and building of several types of exposure systems for *in vitro* and *in vivo* work. The goal is to expose the biological samples (cells or animals) to well-characterized fields under well-defined environmental conditions. Only recently, these have been of sufficient quality to warrant that biological findings were not due to physical artifacts.

In view of the interaction processes of fields with biological organisms (mainly induced electric fields at ELF), the effects of magnetic fields, which penetrate the body, have been the main focus of research projects. In contrast, electric fields at ELF do not penetrate the organism well because of its conductivity. This is not true for direct stimulation of nerves and other excitable cells using electrodes. Electric fields can also induce polarization of the cell membrane leading to specific effects such as electroporation. There have been many improvements in the design of exposure systems in recent years and most of the key parameters described below are well-characterized and controlled. However, standardization of these systems has only been achieved within some of the multicenter research programs.

Many mechanisms have been proposed through which living systems could interact with ELF electric and magnetic fields. However, both laboratory studies and controlled human studies have provided evidence only for electrically based phenomena that occur in the presence of ELF fields and that are present only during exposure to these fields.

Induced electric signals in tissues of the nervous and visual system of animals exposed to ELF electric and magnetic fields can produce effects that lead to field perception. The most notable effect that occurs in humans exposed to fields of moderate intensity is the induction of visual phosphenes. The neuronal circuits of the retina form a part of the central nervous system (CNS) and thus the magneto-phosphene threshold may be taken as a realistic indicator of the threshold value for functional changes induced in other parts of the CNS. Threshold values at 20 Hz were estimated at $\sim 100\,\mathrm{mV\,m^{-1}}$. Direct effects on the peripheral nervous system occur only at relatively high levels of electrical stimulation ($\sim 2\,\mathrm{V\,m^{-1}}$ and with increasing thresholds for frequencies above 1 kHz).

A variety of other potential mechanisms for interaction of ELF electric and magnetic fields with living systems have been proposed, but not demonstrated to produce effects that could significantly perturb normal biological functions. Examples of such interactions are the following: (1) magneto-chemical interactions with charge-transfer reactions which do not appear to influence biochemical pathways such as those involving electron transport, and (2) resonance interactions involving combined static and

ELF fields in specific geometric configurations which have not been shown to have significant biological effects, consistent with predictions based on well-founded physical arguments.

Cellular Models

There is a large and varied body of research literature on the ability of fields to effect changes in cellular models. Overall, the evidence for stimulation of cell division by ELF fields is at best equivocal. There is also no clear evidence that ELF magnetic fields can alter calcium ion homeostasis. Finally, the data on several aspects of intracellular signaling do not consistently support the existence of field effects on these signaling pathways. Furthermore, the types of effects reported, when they have been found, have been of a magnitude that gives little support to the conclusion that they are of consequence for human health.

Animal Models

Overall, a large number of studies have been carried out, principally investigating the possible effects of exposure to ELF electric and magnetic fields, testing many different biological endpoints in a variety of animal species.

With regard to genotoxicity, there is no clear evidence that exposure to ELF magnetic fields presents a hazard. Relatively few animal studies have been carried out, however, and the subject has been more extensively investigated at the cellular level (see above). Similarly, no convincing evidence has been found from experimental studies supporting the hypothesis that exposure to power-frequency magnetic fields increases the risk of cancer.

Many studies of the reproductive and developmental effects of exposure to ELF power-frequency electric and magnetic field effects and visual-display-frequency (VLF) magnetic fields using chick and mammalian species have been carried out. Overall, the data do not support the hypothesis that low-frequency EMF exposures result in reproductive toxicity.

Generally, the evidence for an effect of exposure to power-frequency EMFs on melatonin levels and melatonin-dependent reproductive status is mostly negative in seasonally breeding animals. In addition, no convincing effect on melatonin levels has been observed in a study of nonhuman primates chronically exposed to power-frequency EMFs. The interpretation of the outcome of studies on rat pineal and serum melatonin levels was more problematic: both positive and negative effects were reported in studies without apparent technical or analytical deficits.

With regard to possible effects on other hormones, with the possible exception of transient stress following the onset of ELF electric field exposure at levels significantly above perception thresholds, no consistent effects have been seen in levels of the stress-related hormones of the pituitary–adrenal axis, growth hormones and hormones involved in controlling metabolic activity or those associated with the control of reproduction and sexual development. There is little consistent evidence of any inhibitory effect of ELF EMF exposure to various aspects of the immune system function including those relevant to cancer. In addition, there was no compelling evidence that hematological variables were affected by exposure to ELF fields.

In general, many studies of nervous system functions were either negative, or difficult to interpret because of a weakness in the experimental design or confounding by artifact. However, several studies suggest possible EMF effects on the opioid and cholinergic systems, along with concomitant changes in analgesia, and in the acquisition and performance of spatial memory tasks. Effects on opioid and cholinergic systems should thus be further investigated.

The potential sensitivity of people with epilepsy to EMF exposure is an important factor that should be considered. Exposure of animals to EMFs before testing has been reported to have an inhibitory effect on subsequent tests of epileptic-seizure sensitivity but the type of response was not consistent among different studies. Further investigation needs to be carried out for possible effects during exposure.

There is convincing evidence that ELF electric fields can be perceived by animals, most likely as a result of surface charge effects; threshold values for both rats and baboons lie in the range 5–15 $\mathrm{kV\,m^{-1}}$. Exposures above threshold are sufficient to be mildly aversive and will result in transient arousal but mostly disappear following prolonged exposure.

Human Models

Small inconsistent changes have been described in the circulating levels of leukocytes, but as with animals, the relevance of these changes to human health is not clear. No indication of a clear-cut cytogenetic effect was observed in the blood cells of exposed subjects. The circulating hormone levels in humans, including melatonin, are not adversely affected by exposure to power-frequency electric and/or magnetic fields.

Positive results from studies on the power spectrum of different electroencephalogram (EEG) frequency bands and sleep structure have been

performed at occupational exposure levels higher than general environmental levels.

In the light of cognitive and performance studies that show a large number of positive biological effects, the need for further studies is warranted in order to clarify their significance for human health.

The majority of published cardiovascular changes stay within the range of normal biological variations; however, the study protocols and the results have not been successfully replicated in other laboratories.

As perception of electric or magnetic fields has been reasonably well characterized, skin symptoms, headache, and mood disturbance claimed by working near computer screens or in proximity of other environmental ELF sources have not reliably been linked to any electromagnetic exposure produced by these devices. Also, the studies performed do not indicate any ability of individuals with suspected electromagnetic hypersensitivity to react to any test-field situation, suggesting that other environmental or psychosocial factors should be looked for by people suffering from this pathology.

Conclusion

There is little scientific evidence suggesting that ELF EMF exposures pose a health risk. The strongest evidence for health effects comes from an association observed with childhood leukemia. In contrast, mechanistic studies and animal toxicology data fail to demonstrate any consistent pattern across studies, although sporadic findings of biological effects (including increased cancers in animals) have been reported. The lack of connection between human and experimental data (animal and mechanistic) severely complicates the interpretation of these results.

Radiofrequency Fields

Most of the research activity being devoted to the potential effects of mobile telephony equipment, only experimental findings related to these signals will be given in this section.

Mobile (or cellular) telephony has developed very rapidly over the past ten years. It is now part of the basic equipment of modern life and over 1.3 billion phones are in use worldwide. Concerns about health effects caused by exposure to the microwaves emitted by mobile telephones and base stations have increased over the last few years, becoming a major societal issue in some countries, or at least among part of the population. Stories about health risks from RF radiation (RFR) from mobile phones and base stations have become common in the media over the past five years.

Several systems are used in mobile telephony worldwide, all based on the same principle, that is, "cellular" mapping of the territory. In each cell, a base station emits toward and receives signals from the mobile telephones active in that cell (up to ~ 50). There are, for example, 30 000 base stations in France used by three networks. The carrier frequency varies from 400 to 2100 MHz and the voice or data information is coded digitally either by frequency or phase modulation. Mobile telephones are two-way radio transmitters operating in the 400–2100 MHz frequency range. In the global system for mobile communications (GSM), for example, the peak power emitted is 2 W, but the time-averaged power is always below 1/8 of this value, as power control reduces emission to the lowest level required. About half of the emitted power is absorbed by the user's head, that is, a maximum of 125 mW. Power absorption is expressed as specific absorption rate (SAR) in $\mathrm{W\,kg^{-1}}$.

Major improvements have been achieved in measuring the SAR in liquid phantoms and calculating power distribution in the head using numerical phantoms over the last ten years. Presently, the worst-case SAR associated with the average GSM phone on the market is $\sim 0.5\,\mathrm{W\,kg^{-1}}$, that is, 1/4 of the recommended local-exposure limit value. It is now known with certainty that temperature increase in the brain periphery caused by the waves emitted by mobile telephones does not exceed 0.1°C.

As a result of current changes in usage – increasing use of text and image messages and hands-free kits – mobile telephones are less frequently placed against the ear. This dramatically reduces exposure of the tissues in the head.

GSM base-station antennas have an emitting power of ~ 20 W. They are generally placed on rooftops and the emission beam is disk-shaped. Maximum exposure occurs on the ground, ~ 200 m from the base station and it is almost zero at the bottom of the building or mast on which the antenna is mounted. Exposure of the public to the RFR emitted by base stations is typically 1/10 000 of the recommended limit in terms of incident power. There is a consensus in the scientific community that base stations do not represent a health hazard.

There is much scientific evidence, based on existing research, that warrants limiting exposure to high-level RFR due to the "thermal effects" caused by heating of the tissues at SAR levels that correspond to a temperature elevation of a few degrees. However, this does not occur with mobile telephones. The search is thus for nonthermal effects and most of the research activity has been aimed at defining the thresholds for these effects, with respect to existing exposure guidelines based on acute effects known to be due to heating.

Health risk assessment associated with RFR benefits from a database spanning over 50 years: the WHO and Institute of Electrical and Electronics Engineers (IEEE) databases list ~1300 peer-reviewed publications, from biophysical theoretical analyses to human epidemiological studies. Half of these studies relating to cancer have been overwhelming in finding no evidence that RFR exposure initiates or promotes cancer. More than 350 studies are specifically related to mobile telephony.

Cellular Models

A number of replication studies that addressed some positive findings on enzyme activity, gene expression, and DNA alteration have all proven negative so far. Research is currently very actively investigating possible alterations of heat-shock proteins, seen as potential markers for RFR exposure and/or leading to physiological alterations in cells.

A wide range of short-term, low-level *in vitro* experiments have shown that exposure did not cause cell death, implying that RFR is not a toxic agent. Furthermore, the weight of evidence available at present (induction of DNA strand breaks, chromosome aberrations, micronuclei formation, DNA repair synthesis, sister chromatid exchange, and phenotypic mutation) supports the conclusion that RFR is not genotoxic. However, the synergy of RFR with chemical agents or other physical agents still needs further investigation.

WHO recommendations for short-term projects on cellular systems are: "the expression of stress (heat-shock) proteins in mammalian cells exposed to RF should be studied experimentally to follow-up recently published data. Biologically relevant hypotheses, if supported by experimental data (in particular, if related to the function of the CNS), should be tested to explore the utility of such data in risk assessment."

Animal Models

A large number of animal experiments have been performed over the past forty years, using various frequencies and modulations. It is clear from these data that the vast majority of the reported biological effects are due to heating. These effects result either from a rise in tissue or body temperature exceeding 1°C or in physiological and behavioral responses aimed at minimizing the total heat load.

Major improvements in exposure system design have made it possible to better characterize the SAR within the organism, and allow for either local exposure that mimics mobile telephone use (e.g., loop antenna, carousel) or whole-body exposure related to base stations (e.g., Ferris wheel, reverberation chamber, circular waveguide).

Results on most of the noncancer endpoints have been negative (memory, EEG, hearing, etc.) except for data on the permeability of the blood–brain barrier, which was found to be increased by two research groups but not by several others.

Therefore, most of the major ongoing studies deal with cancer models. All of the long-term bioassays or sensitized studies have given negative results except for one using transgenic mice, genetically modified to increase the background incidence of lymphomas; an increased tumor incidence was found following GSM exposure. No such finding emerged from a recent confirmation study, using a different design. While awaiting the results of a further replication study, there is no convincing evidence from animal investigations that the incidence of lymphomas and other types of tumors is influenced by lifetime daily exposure to mobile telephony RFR.

WHO recommendations for short-term projects on animals are: "Follow-up studies to immune system studies that suggest an effect of RF exposure (i.e., Russian publications from several years ago). Studies to assess the accuracy and reproducibility of published RF effects on the permeability of the blood–brain barrier and other neuropathologies (e.g., dura mater inflammation, dark neurones). Additional studies of the effect of RF exposure on sleep are recommended. More quantitative studies on the effects of heat on the development of the CNS, particularly the cortex, in the embryo and fetus using morphological and functional endpoints."

Human Models

In spite of the obvious limitations of human experiments in terms of endpoints and exposure characterization, several investigations have been performed using various models. Findings have either been negative or difficult to replicate (sleep, EEG, cognitive functions, etc.). Currently, there is no conclusive evidence from human studies of detrimental health effects of mobile telephones.

However, a report from a Dutch laboratory has drawn a lot of attention from the media and the scientific community as it reported minor effects on the well-being and cognitive functions of volunteers exposed to weak base-station signals. This work, which is not yet published, has been heavily criticized but its protocol may serve as the basis of some more refined work. However, it is not directly relevant to mobile telephone exposure.

Clearly, the main issue at present is the potential greater sensitivity of children to mobile telephone

RFR. Their lifetime exposure, the fact that their CNS is still developing, and, possibly, increased RFR absorption in the head, have led to concerns that cannot be easily resolved through laboratory investigations and numerical modeling.

WHO recommendations for short-term projects on humans are: "Replication and extension of the studies which demonstrated effects on sleep. Studies of RF exposure and headaches in a controlled laboratory setting. Studies of memory performance should be expanded to include children."

Health Risk Assessment

The process of health risk assessment by bodies such as International Commission on Non-ionizing Radiation Protection (ICNIRP), IEEE, International Agency for Research on Cancer (IARC), and WHO relies heavily on judging the quality of investigations. As stated above, the quality of exposure systems has greatly improved and can now be considered adequate. The use of well-grounded experimental protocols (sham-exposure, blinding of exposure and biological tests, positive controls) has become generalized. Moreover, it is now a common practice in the field of bioelectromagnetics to ascertain that any positive results are replicated in at least one independent laboratory. In spite of these improvements, it should be noted that only a few top-level biology laboratories have engaged in this type of research, partly due to interferences created by societal and media pressure.

Within its EMF International Project, WHO has reviewed the science and issued research recommendations. The main conclusion from these reviews is that EMF exposures below the limits recommended in the ICNIRP guidelines do not appear to have any known impact on health. However, there are still some key gaps in knowledge, requiring further research to provide definitive health risk assessments: IARC will issue a cancer classification of RFR in 2005, and WHO and ICNIRP's evaluations on RFR and health are due in 2006.

Remaining uncertainties in the science database have led to pressure to introduce precautionary measures until gaps in knowledge are filled. If precautionary measures are introduced to reduce RFR levels, it is recommended that they should be voluntary and that health-based exposure limits be mandated to protect public health.

Conclusion

RFR can cause biological effects when exposure is sufficiently intense: possible injuries include cataracts, skin burns, deep burns, heat exhaustion, and heat stroke. They are mostly due to heating. There have been scattered reports of effect, the nonthermal effects, that do not appear to be due to temperature elevation. None of these effects have been independently replicated, and most have no obvious consequence to human health. Furthermore, there are no known biophysical mechanisms which suggest that such effects could occur.

Following the very rapid development of mobile telephony, a major research effort has been carried out worldwide (tens of millions of euros per year). Europe is most active (UK, Germany, Italy, and Finland, in particular), but many research groups are contributing in Japan, US, and Australasia.

Most governments have addressed the issue of mobile telephony and health, and several international and national expert committees have written accurate summaries of current knowledge (see the "Further reading" section). Their conclusions converge toward an absence of health effects related to mobile telephones, but all encourage continuing research in some areas.

In answer to the question: "mobile telephony: is there evidence of harm?", one must conclude that the weight of scientific evidence does not support health concerns or indicate any health risk from mobile phones in normal use, nor is there any accepted mechanism for potential health effects at the low levels associated with these devices. Findings to date, including epidemiological studies and laboratory studies of animals, exposed both for a short-term and their entire lifetimes, have not provided evidence that exposure causes cancer, or affects biological tissues in a manner that might lead to, or augment, any disease. However, there are still some issues pending, in particular those related to the potentially greater sensitivity of children. The many ongoing research projects should help clarify these issues by the end of 2005.

Electromagnetically Induced Transparency

M Artoni, University of Brescia, Brescia, Italy

Introduction

Three-level atomic and molecular systems coupled to two laser fields exhibit transparency effects that result from the cancellation of absorption at a resonance transition frequency. These effects are deliberately induced by one of the two laser fields upon modifying the medium optical response to the other field. The large degree of transparency in a medium where strong absorption and hence opacity would normally be expected, has then been termed as "electromagnetically induced transparency" (EIT). The effect is a rather subtle one. It relies on atomic states coherence and quantum interference, and the necessary background tools to understand the basic physical ideas behind EIT is presented here. A brief and preliminary discussion of coherent population trapping (CPT), a closely related effect whose observation first raised interest in induced transparency phenomena, is also presented.

From the very beginning EIT has stimulated a considerable amount of work on fundamental issues such as nonlinear optics at low-light levels, photon entanglement and entanglement of atomic ensembles, quantum information processing, quantum information storage, and enhanced acoustooptical effects, just to mention a few. In view of such a significant and rapid advancement, one may conclude by overviewing one of its most relevant aspects and prospects.

Coherence and Population Trapping

Cancellation of absorption due to the coherence between a pair of atomic states and subsequent trapping of the population is perhaps one of the earliest examples of transparency induced in an otherwise absorbing medium. Specifically, the coherent superposition of two atomic states leads, under certain conditions, to trapping of the population in one of the states and hence to transparency. This typically occurs in three-level atomic systems, or at least systems that can be adequately reduced to a three-level configuration when interaction with two electromagnetic fields is considered. A basic configuration leading to the effects of CPT is reported in **Figure 1**.

This phenomenon was first observed in Gozzini's group in Pisa and later in Stroud's group in Rochester. The Pisa group performed experiments that established a coherence between the Zeeman split lower levels of sodium atoms using a multimode laser. They employed a spatially varying magnetic field and observed a series of spatially separated dark lines, originally called "dark resonances," corresponding to the locations where the Zeeman splitting matched the frequency difference between modes of the coupling laser. The other experiment involved, instead, the hyperfine lower levels of atomic sodium and similar findings were observed.

The usual atomic dipole selection rules normally require that two pairs of levels are dipole coupled,

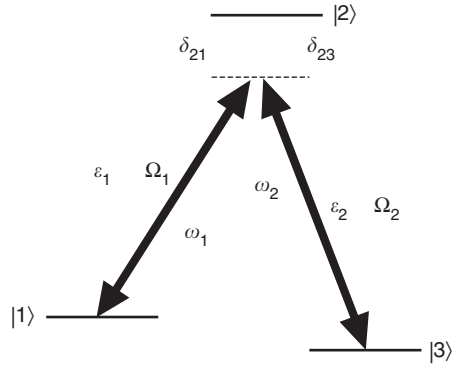

Figure 1 Lambda (Λ) scheme leading to coherent population trapping. The applied fields of amplitude $\mathscr{E}_1$ and $\mathscr{E}_2$ and with frequencies ω_1 and ω_2 need not be in single-photon resonance, but the two-photon resonance condition ($\delta = 0$) should be met as shown in the figure. Field strengths are typically of comparable magnitude ($\Omega_1 \simeq \Omega_2$). The states $|1\rangle$ and $|3\rangle$ are typically Zeeman or hyperfine sublevels of the ground state and are initially populated.

whilst the transition between the third pair is dipole forbidden. The basic scheme in **Figure 1** comprises the states $|1\rangle$, $|2\rangle$, and $|3\rangle$ coupled by two near-resonance laser fields whose strengths are defined in terms of the Rabi frequencies $\Omega_1 = \mu_{12}\mathscr{E}_1/\hbar$ and $\Omega_2 = \mu_{23}\mathscr{E}_2/\hbar$, respectively. Defining the frequency of transitions between states as $\omega_{21} = (E_2 - E_1)/\hbar$, $\omega_{23} = (E_2 - E_3)/\hbar$, and $\omega_{31} = (E_3 - E_1)/\hbar$, one can further introduce the one-photon frequency detunings $\delta_{21} = \omega_{21} - \omega_1$ and $\delta_{23} = \omega_{23} - \omega_2$ as well as the two-photon (Raman) frequency detuning $\delta = (\omega_{21} - \omega_{23}) - (\omega_1 - \omega_2)$.

In a simple treatment, the bare atom Hamiltonian $H_o = \sum_{i=1,3} E_i|i\rangle\langle i|$ should be modified to include the interactions due to the two atom-field couplings to obtain in the dipole approximation a total Hamiltonian of the form,

$$H = H_o + H_I \equiv H_o - \frac{\hbar\Omega_1}{2}|2\rangle\langle 1| - \frac{\hbar\Omega_2}{2}|2\rangle\langle 3| + \text{h.c.} \quad [1]$$

In general, the eigenstates of H turn out to be linear superpositions of the bare atomic states $|1\rangle$, $|2\rangle$, and $|3\rangle$. At exact resonance ($\delta_{21} = \delta_{23} = 0$), two of the eigenstates of H turn out to be symmetric and antisymmetric coherent superpositions of the two lower states of the bare atom basis, namely,

$$|C\rangle = \frac{\Omega_1}{\Omega}|1\rangle + \frac{\Omega_2}{\Omega}|3\rangle$$
$$|NC\rangle = \frac{\Omega_2}{\Omega}|1\rangle - \frac{\Omega_1}{\Omega}|3\rangle \quad [2]$$

where $\Omega = (\Omega_1^2 + \Omega_2^2)^{1/2}$. It should be noted that no component of the bare state $|2\rangle$ appears in these superpositions and that state $|C\rangle$ is coupled to the upper state $|2\rangle$ via the electric-dipole interaction whilst the state $|NC\rangle$ is not. This can easily be seen by evaluating the (dipole) transition matrix element $\langle 2|H_I|NC\rangle$. The two probability amplitudes that are summed to give the whole transition amplitude between $|NC\rangle$ and the atom's upper state $|2\rangle$ have in fact equal and opposite magnitudes. In the present lambda configuration, coherent trapping occurs due to the destructive quantum interference between the probability amplitudes associated with two (dipole) transitions. Conversely, the transition amplitude $\langle 2|H_I|C\rangle$ does not cancel to zero and $|C\rangle$ remains coupled to the upper state $|2\rangle$.

When the steady-state regime has been reached, the state $|NC\rangle$ will acquire all the atom's population under the combined effects of optical pumping from $|C\rangle$ to $|2\rangle$ and spontaneous emission from $|2\rangle$ to $|NC\rangle$. At last, no absorption process will depopulate the state $|NC\rangle$ where all population will remain trapped. The noncoupled state $|NC\rangle$ is often referred to as "dark" state whilst the other state $|C\rangle$, which remains coupled to the fields, is instead referred to as "bright" state.

Electromagnetic Induced Transparency

A highly opaque medium may be rendered almost transparent through EIT. Even in this case, as for CPT, cancellation of absorption relies on a process involving laser-induced coherence and quantum interference between the atomic coherences induced by the electromagnetic fields.

Formally, coherences are identified with the off-diagonal elements of the density matrix ρ. Off-diagonal elements of the density matrix play a critical role in the evolution of an atom coupled to electromagnetic fields. Many calculations on the effects of EIT in three-level systems are, therefore, developed in terms of the density matrix. Besides, this approach naturally lends itself to the inclusion of dampings that cause the decay of populations and coherences. Characteristic configurations for which EIT takes place in three-level atoms interacting with two near-resonance electromagnetic fields are shown in **Figure 2**. Atomic dipole selection rules, for example, in the lambda configuration of **Figure 2**, normally require that $|g\rangle - |e\rangle$ and $|e\rangle - |m\rangle$ transitions be dipole allowed but not the $|g\rangle - |m\rangle$ transition. Often $|m\rangle$ is a metastable state. In the Λ or ladder scheme, $|g\rangle$ is normally the ground state of the atom where the largest part of the population initially resides while states $|e\rangle$ and $|m\rangle$, which remain essentially unpopulated throughout the process, need not be ground state(s).

To understand how EIT works to reduce absorption when two laser fields interact with a three-level atom, for definiteness, the Λ configuration in **Figure 2** is examined. The states $|g\rangle$ and $|e\rangle$ are coupled by a probe field of amplitude $\mathscr{E}_p$ and frequency ω_p while the excited state $|e\rangle$ is coupled to $|m\rangle$ by a coherent field of frequency ω_c and Rabi frequency Ω_c. The one-photon detunings δ_p and δ_c as well as the two-photon (Raman) detuning δ are defined here as in the previous section. The off-diagonal decay rates for the coherences ρ_{eg}, ρ_{em}, and ρ_{gm} are denoted by γ_1, γ_2, and γ_3, respectively. The explicit form of the total Hamiltonian $H = H_0 + H_1 + H_2$ is

$$H_o = \hbar\omega_g|g\rangle\langle g| + \hbar\omega_e|e\rangle\langle e| + \hbar\omega_m|m\rangle\langle m|$$
$$H_1 = -\frac{\mu_{eg}\mathscr{E}_p}{2}e^{-i\omega_p t}|e\rangle\langle g| + \text{h.c.} \quad [3]$$
$$H_2 = -\frac{\hbar\Omega_c}{2}e^{-i\omega_c t}|e\rangle\langle m| + \text{h.c.}$$

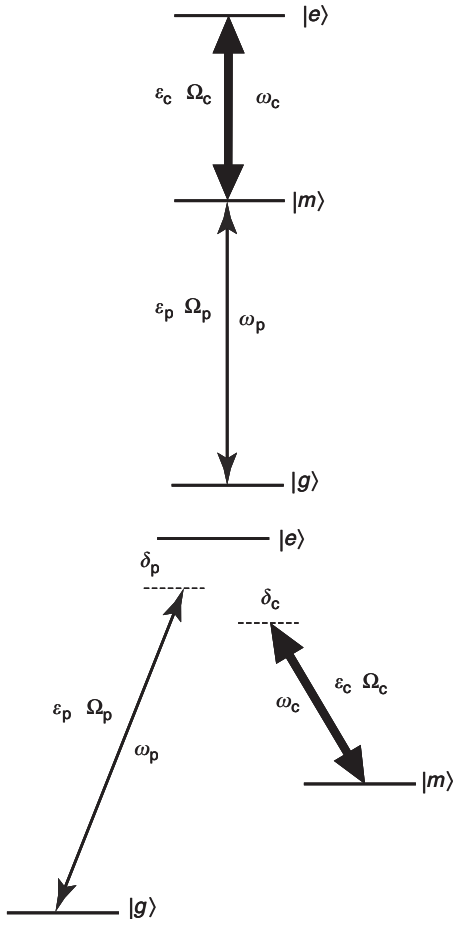

Figure 2 Basic schemes leading to electromagnetic induced transparency (EIT): (upper) a ladder scheme, (lower) a Λ scheme. In the Λ configuration levels, E_m and E_g are commonly almost degenerate. As for coherent population trapping (CPT) the two-photon (Raman) resonance condition should be met, yet the strength of one of the two fields could be appreciably larger than that of the other ($\Omega_c \ll \Omega_p$). State $|3\rangle$ in the Λ scheme need not be a ground state.

From the Liouville equation for the density matrix ρ, one obtains a set of coupled equations connecting the density matrix elements and their temporal derivatives. These equations are generally solved by numerical methods. If a steady-state limit is assumed, however, all time derivatives in the density matrix elements vanish. Under the additional assumption that the coupling field is much stronger than the probe, the former is the only field that must be retained to all orders. In these two limits, one arrives at a simplified form of the coupled density matrix equations and an exact solution can be attained. If initially the atoms are in the ground state $|g\rangle$, that is,

$$\rho_{gg}(0) \simeq 1, \quad \rho_{ee}(0) \simeq 0, \\ \rho_{mm}(0) \simeq 0, \rho_{em}(0) \simeq 0 \qquad [4]$$

the simplified set of coupled equations for a resonant coupling beam ($\delta_c = 0$) reads as

$$\dot{\tilde{\rho}}_{eg}(t) = -(\gamma_1 + i\delta_p)\tilde{\rho}_{eg}(t) + \frac{i\mu_{eg}\mathscr{E}_p}{2\hbar} + \frac{i\Omega_c}{2}\tilde{\rho}_{mg}(t) \qquad [5]$$

$$\dot{\tilde{\rho}}_{mg}(t) = -(\gamma_3 + i\delta_p)\tilde{\rho}_{mg}(t) + \frac{i\Omega_c}{2}\tilde{\rho}_{eg}(t) \qquad [6]$$

where $\delta_p = \omega_{eg} - \omega_p$ denotes the probe-field detuning while the new variables $\tilde{\rho}_{eg} = \rho_{eg}\, e^{i\omega_p t}$ and $\tilde{\rho}_{mg} = \rho_{mg}\, e^{i(\omega_p + \omega_{me})t}$ have been introduced. In the steady-state limit one has from [5] and [6],

$$\rho_{eg} = \frac{\mu_{eg}\mathscr{E}_p(\delta_p - i\gamma_3)}{(\delta_p - i\gamma_3)(\delta_p - i\gamma_1) - \Omega_c^2/4} \qquad [7]$$

The complex steady-state coherence [7] is directly proportional to the probe susceptibility χ_p and hence ρ_{eg} describes the medium optical response to the incident probe and, in particular, its absorption or transparency properties.

The expression for ρ_{eg} contains a number of terms in the various parameters that will lead to cancellation of its value, both real and imaginary parts, when two-photon resonance takes place. In this case, in fact, the real part of [7] is always zero while for appropriately strong coupling beams, or when $\Omega_c^2 \gtrsim \gamma_1\gamma_3$, the imaginary part of eqn [7] is seen to become several orders of magnitude smaller than the value it acquires when the coupling beam is absent, making the medium essentially transparent. It is likewise seen that the Lorentzian-like absorption dip obtained by expanding the imaginary part of eqn [7] around resonance exhibits a width given approximately by Ω_c^2/γ_1. Because there exists an upper bound to the coupling beam Rabi frequency Ω_c for EIT to take place, namely $\Omega_c \lesssim \gamma_1$, it follows that quenching of absorption only takes place over a small bundle of probe frequencies which is appreciably narrower than the natural line width γ_1. Thus, under the two-photon resonance condition and for Ω_c's such that

$$\sqrt{\gamma_1\gamma_3} \lesssim \Omega_c \lesssim \gamma_1 \qquad [8]$$

a probe field can propagate without absorption within a small transparency window, even though it would be strongly absorbed in the absence of the coupling beam.

Within the context of a density matrix formulation, the interference that leads to induced transparency manifests itself in the vanishing of the coherence ρ_{eg}. This stems from the existence of the coherence ρ_{mg} which is coupled to it and which only appears when the coupling laser beam is present. The

contribution from ρ_{mg} to the coherence ρ_{eg} may cancel, in fact, with the direct contribution driving this coherence due to the applied probe field (see eqns [5] and [6]).

The relevant optical response of an EIT medium is described by a linear susceptibility whose form depends, in general, on the presence of the external coupling beam. Imaginary and real parts of the susceptibility at the probe transition frequency ω_p are obtained from the macroscopic polarization $\mathscr{P}(\omega_p) = \varepsilon_o \chi(\omega_p)\mathscr{E}_p$, which can, in turn, be related to the microscopic coherence $\rho(\omega_p)$ at ω_p via the expression $\mathscr{P}(\omega_p) = (N/V)\mu_{eg}\rho(\omega_p)$. Here, N/V is the atoms density in the medium while μ_{eg} is the dipole matrix element associated with the transition. This relation holds for a medium sufficiently dilute that dipole–dipole coupling between atoms can be ignored. Besides, for the relatively large fields used in most EIT experiments, a semiclassical treatment, where the fields are treated classically (i.e., in terms of Maxwell's equations and susceptibilities) and the coherences are treated quantum mechanically with spontaneous decay added as a phenomenological damping, proves adequate. Only when atoms are coupled to cavities modes or when the statistical properties of light are important, a fully quantum approach is indeed required. In the semiclassical limit, the complex probe susceptibility for a resonant coupling beam ($\delta_c = 0$) can be written as,

$$\chi_p = 3\pi \mathscr{N}_p \frac{\Gamma_1(\delta_p - i\gamma_3)}{(\delta_p - i\gamma_3)(\delta_p - i\gamma_1) - \Omega_c^2/4} \qquad [9]$$

where $\mathscr{N}_p$ is the scaled sample average density $N\lambda\!\!\!^{-3}_p/V$ and $\lambda\!\!\!^{-}_p = \lambda_p/2\pi$ is the resonant probe reduced wavelength. The expression [9] depends upon parameters, namely detunings and laser intensities, that can all be directly controlled within an experiment. The real and imaginary parts of the refractive index $n_p \equiv \eta_p + i\kappa_p = \sqrt{1+\chi_p}$ associated with the medium dispersion and absorption, respectively, are plotted in **Figure 3** as a function of the probe detuning δ_p. The absorption vanishes at exact resonance and this is a striking result when compared with the situation in which the coupling field is absent ($\Omega_c = 0$).

Most EIT experiments have concentrated on ensembles of atoms. In these experiments, one measures the transmission of a weak probe in the presence of a strong-coupling field through an otherwise optically opaque medium. A landmark demonstration was performed by the Harris group at Stanford in two atomic systems, namely strontium and lead vapors. In both experiments, narrow-band pulsed laser radiation were used.

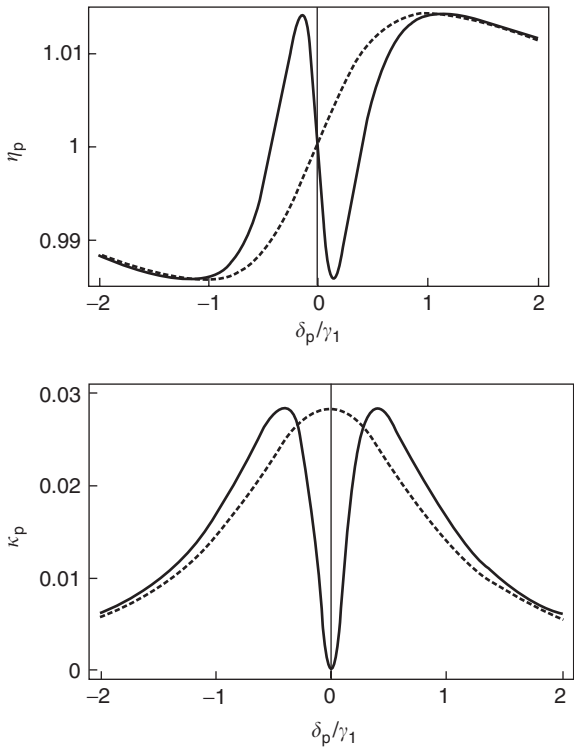

Figure 3 Real (upper) and imaginary (lower) part of the probe refractive index n_p as a function of the normalized probe detuning δ_p/γ_1 in the absence (dashed) and in the presence (solid) of a resonant coupling beam with Rabi frequency $\Omega_c = 0.8\gamma_1$. Due to destructive interference the imaginary part κ_p, associated with medium absorption, vanishes at exact resonance when the coupling field is on. The real part η_p, which determines the medium dispersion, is likewise modified in the presence of the coupling field and acquires a rather steep slope around resonance.

In the Sr experiment, the first to be reported and whose results are shown in **Figure 4**, the atoms are pumped into the $4d5d\,^1D_2$ autoionizing state starting from the $5s5p\,^1D_2$ state via a pulsed probe laser (337.1 nm) spanning the transition that was to be rendered transparent. A coupling laser (570.3 nm) was, instead, applied between this autoionizing state and the metastable bound state $4d5p\,^1D_2$. In the absence of the coupling beam, the probe field excited the system to the state $|2\rangle$, exhibiting strong absorption which made the Sr vapor completely opaque. Transmission, measured as the ratio of the transmitted to the incident intensity, was estimated to be e^{-20} at resonance. When the coupling laser was applied, instead, the resonant transmission increased dramatically to $\sim$40%.

In the Pb experiment, on the other hand, transparency was demonstrated using bound states of a collisionally broadened medium. Here, a ladder configuration was adopted where probe and coupling beams coupled the $6s^2 6p7s\ ^3P_1$ excited state respectively to the $6s^2 6p^2\ ^3P_0$ ground state and the state $6s^2 6p7p^3D_1$. These two experiments serve to

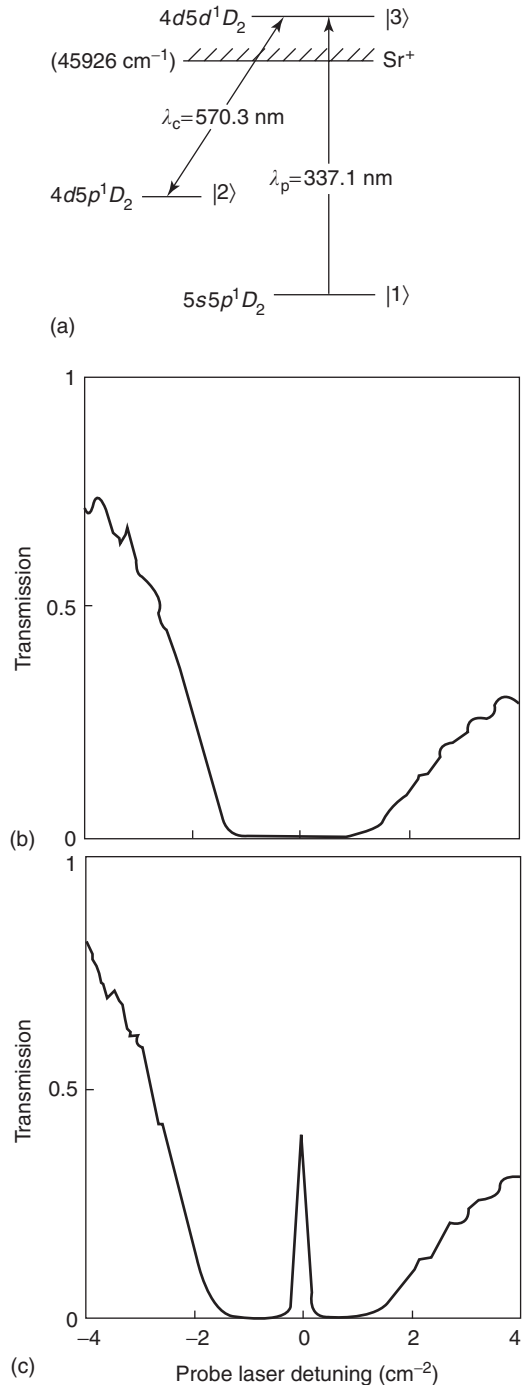

Figure 4 Electromagnetically induced transparency in strontium (Sr) vapors. (a) Sr energy levels and Λ configuration with coupling and probe beam of wavelength λ_c and λ_p, respectively. Transmission vs. probe laser detuning in the absence (b) and in the presence (c) of a coupling beam. Under the conditions of this experiment transmission goes from zero to $\sim$40%.

demonstrate the principle of EIT in three-level atomic systems. They also indicate how EIT can take place when the excited states are either autoionizing or collisionally broadened.

Fast and Slow Light

Along with induced transparency, there is a concomitant modification of the refractive properties of the medium. These are characterized by a very steep variation of the real part η of the medium complex refractive index n with frequency as shown in **Figure 3**. Here, for comparison, η is plotted both in the absence and in the presence of the coupling beam that causes the transparency.

In an ideal EIT regime, the atoms susceptibility vanishes from the light fields and at resonance, and the complex index n remains close to unity throughout the EIT transparency window. The propagation speed c/n of a monochromatic beam of light is then essentially unchanged from its speed c in vacuum. This means that the propagation velocity of the beam phase front in the medium, that is, its phase velocity, is equal to c.

Yet for a light pulse, which contains, instead, several Fourier components at different frequencies, the small variations in the phase velocity that each component experiences in the medium can add up to make an appreciable effect. Components with slightly different speeds get, in fact, out-of-phase with each other, with the net result that the velocity of the pulse envelope, that is, its group velocity, is different from c.

Consider, for instance, the superposition of two monochromatic plane waves of the form $\cos[(\omega_o \pm \delta\omega)\ t - (k_o \pm \delta k)z]$. Addition gives $2\cos[\delta\omega(t - (\delta k/\delta\omega)z)]\cos(\omega_o t - k_o z)$, which is a wave with an amplitude that retains its shape as it propagates with the velocity $\delta\omega/\delta k$. More generally, if it is superposed over many waves whose frequencies and wave numbers are distributed in a small range about the center values ω_o and k_o, one obtains a wave of the form $A(t - z/v_g)\cos(\omega_o t - k_o z)$. The intensity, averaged over a few optical periods, is proportional to $A^2(t - z/v_g)$, which describes a light pulse propagating without change of shape at a group velocity v_g defined as $d\omega/dk$.

Using the relation $k = \omega n/c$ with $n = \eta + i\kappa$, one can, for very small absorptions ($\kappa \ll 1$), express v_g in terms of the real part η of the refractive index and its derivative $d\eta/d\omega$, so that for a given frequency ω one has

$$v_g(\omega) \equiv \frac{d\omega}{dk(\omega)} = \frac{c}{\eta(\omega) + \omega\, d\eta(\omega)/d\omega} \qquad [10]$$

In the presence of EIT, $d\eta(\omega)/d\omega$ is large and positive around resonance as one can see from **Figure 3** and according to [10], very small group velocities can be attained. By substituting the expression [9] into [10], one has indeed at the resonance

frequency ω_o,

$$\frac{v_g^o}{c} \simeq \frac{\Omega_c^2}{6\pi \mathcal{N}_p \gamma_1 \omega_o} \qquad [11]$$

Note that v_g^o depends on the control field intensity, proportional to Ω_c^2, and on the atomic density N/V. Decreasing the control beam power or increasing the atomic density can make v_g^o orders of magnitude smaller than the speed of light c in vacuum.

Evidence for ultraslow light is typically provided by measuring the time delay between a pulse propagating in a medium of given length L, and a twin pulse that has instead propagated in vacuum. The leading edge of a pulse that enters the medium is, in fact, rapidly decelerated while its tail outside the medium still propagates at speed c. As a result, upon entering the medium, the spatial extent of the pulse is compressed (by the ratio c/v_g) and its energy decreased as photons are being expended to establish the coherence between the states $|g\rangle$ and $|m\rangle$, or, in other words, to change the atomic state, with any excess energy carried away by the control field. As the pulse exits the medium, its spatial extent increases again and the atoms return to their original ground state. The pulse as a whole, however, has experienced a peak-shift given approximately by

$$\Delta \simeq L\left(1 - \frac{c}{v_g^o}\right) \qquad [12]$$

with a concomitant pulse delay τ given by Δ/c.

The possibility of manipulating the group velocity in EIT media was first pointed out by Harris. The subject, however, was truly brought to focus by a remarkable experiment of Hau in which an ultracold gas of Na atoms was used to slow light pulses down to few tens of $m\,s^{-1}$. The large pulse delay τ measured in this experiment is reported in **Figure 5** for different experimental conditions. Although the first demonstration of ultraslow light used ultracold gases, shortly thereafter, two groups reported ultraslow light propagation in hot Rb gases. This work was a milestone on the way to making ultraslow light "on the cheap," that is, without expensive cold-atom traps.

Furthermore, it follows from eqn [10], that group velocities can become infinite or even negative when $d\eta(\omega)/d\omega$ is sufficiently negative, that is, when the real part of the refractive index decreases with frequency. Because in the visible, $\eta(\omega)$ normally increases with frequency, the case $d\eta(\omega)/d\omega < 0$, for historical reasons is called anomalous dispersion. Directly from **Figure 3**, one sees that in EIT media $\eta(\omega)$ acquires negative slopes slightly off-resonance. A negative group velocity means that the peak of the pulse emerging from the medium moves faster than the pulse peak that has propagated in vacuum at speed c. This, according to eqn [12], leads to a positive peak shift Δ or delay τ rather than negative ones as obtained in ultraslow light experiments. Such anomalous group velocities can occur without significant pulse distortion. An infinite group velocity, on the other hand, means that the peak of the pulse emerging from the medium occurs at the same time as the peak of the pulse entering the medium as seen again from eqn [12]. The pulse, in other words, appears to cross the medium instantaneously. Superluminal peak velocities have been observed, though with substantial pulse attenuation and pulse compression. Such a superluminal behavior does not contradict relativity as the pulse peak velocity is not, in general, the velocity at which a signal can be transmitted.

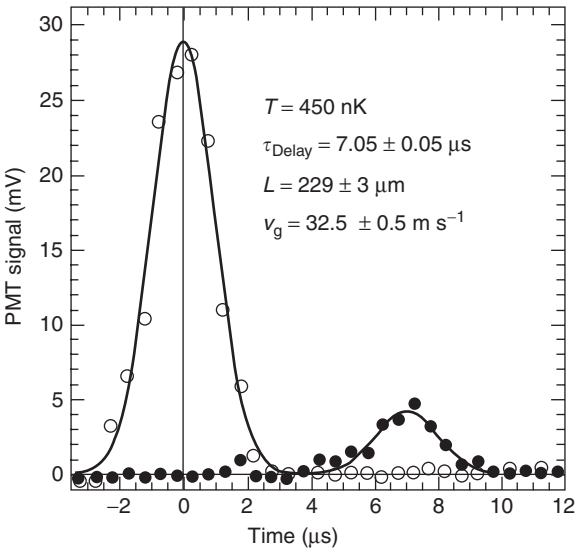

Figure 5 Pulse delay measurement. The front pulse (open circles) is a reference pulse that has propagated in vacuum. The other pulse (filled circles) is delayed by 7.05 μs in a 229-μm-long atom cloud. The corresponding light speed is $32.5\,m\,s^{-1}$. The curves represent Gaussian fits to the measured pulses.

Unlike the pioneering experiments that demonstrated anomalous group velocities of single-photons wave packets carried out nearly a decade ago by Chiao at Berkeley, the anomalous dispersion regime attained by using EIT has been shown to lead to a much larger superluminal effect. Again, these experiments in no way contradict the principle of Einstein causality, that is, the principle that no signal can propagate faster than c.

Slow Light: Some Prospects

Recent advances in quantum information science have led to many interesting new concepts such as

quantum computation and quantum memories. The practical implementation of these concepts involves storing, retrieval, and transporting quantum states between different nodes of a network. Methods for manipulating photons and their quantum information in EIT atomic media have recently been suggested. Photons are indeed the most promising carriers of quantum information: they are fast, robust, and readily available. Atoms, on the other hand, represent reliable and long-lived storage units. These methods essentially consist in trapping single-photon Gaussian pulses in atomic media by adiabatically reducing their group velocity to zero and subsequently releasing them after a suitable interval of time. This represents a reversible technique for coherent transfer of quantum information carried by light pulses to atoms and vice versa.

Photon–photon interaction strength is typically very weak and conventional nonlinear optics requires powerful laser beams tightly focused in nonlinear materials. Ultraslow light pulses in EIT media may experience, however, exceedingly large nonlinearities so that nonlinear optical processes may become efficient even at energy densities as low as a few photons per atomic cross section. Low-light-level nonlinear optics has recently become quite relevant in the context of resonant four-wave mixing, teleportation of atomic ensembles, and production of correlated photon states.

Furthermore, laser pulses slowed down to the speed of sound can produce strong coupling between acoustic waves and the electromagnetic field. This might be employed for efficient multiwave mixing as well as for novel acoustooptical EIT-based devices. Proof-of-principle experiments in support of some of these ideas have already been conducted while others are just underway.

Finally, slow and stopped light can also be attained in solid materials enabling important steps toward many potential applications. Recent attempts have indeed led to the observation of group velocities of the order of few tens of $\mathrm{m\,s^{-1}}$, for example, in ruby crystals either at cryogenic temperatures of few degrees Kelvin or at room temperature.

Electron and Positron Sources

S Tazzari, Università di Roma "Tor Vergata," Rome, Italy
M Ferrario, Laboratori Nazionali di Frascati of Istituto Nazionale di Fisica Nucleare, Rome, Italy

Introduction

A particle source is a device producing particle beams with well-defined and controlled intensity, divergence, mean energy, and energy spread.

Electron beams are used in science and technology to both investigate and modify matter. Applications in science mainly concern material investigation, processing and the study of elementary particle, nuclear and atomic physics. Technological applications cover a vast number of fields, including particle accelerators and lasers, microscopy, microprocessing, communications, medical diagnostics and treatment, welding and machining, and household appliances. Positron beams, more difficult to produce, are almost exclusively used in basic material, nuclear and atomic sciences. Electrons can be directly produced using thermal or field emission processes. Positron beams

are obtained either from radioactive sources, or from primary electron or photon beams via the pair production mechanism.

Particle beams are accelerated by DC or alternating (RF) electric fields, handled and transported using electric or magnetic components equivalent to lenses and prisms. One therefore speaks of beam optics. Because particles are charged, space charge, radiation, and other possible forces between particles, including those mediated by the beam environment, have to be taken into account in addition to optical aberrations.

The main parameters characterizing a particle beam are energy E, energy spread ΔE, momentum ($\boldsymbol{P}$), current (I) and brightness (B). The beam current is defined as $I = qN\,\beta c$, q being the particle charge, βc the particle velocity, and N the number of beam particles. Brightness (see below) is a measure of the current flowing through the unit area and solid angle and ultimately of the current that, for a given energy spread and optics, can be focused onto a spot of a given size: for a given current, the higher the brightness the smaller the spot, down to the diffraction limit. A brief introduction to beam dynamics, given below, is required to precisely define the terminology and relations between the parameters.

Depending on their main application, electron sources can be loosely classified as

- low (DC) current, high brightness, industrially produced guns designed for "micro-applications" such as electron microscopy, material analysis and processing, microlithography, micromachining;
- high average (DC or pulsed) current, moderate brightness "conventional" guns to drive devices such as appliances, power tubes, klystrons, and conventional-type linear accelerators (Linacs);
- high-(pulsed) current, high-brightness, high-voltage "preinjector" sources, usually including additional acceleration stages, for high-energy accelerators, synchrotron radiation sources, and free electron lasers.

Positron sources, devoted to science, are instead best classified into low intensity, radioactive and nuclear sources; and high intensity ones generated via pair production.

Basic Beam Dynamics Elements

The equivalent of the optical axis in a beam optical transport system is the trajectory followed by an ideal reference particle having the nominal beam momentum $\boldsymbol{P}_\mathrm{o}$ and an initial position. The position and momentum of the generic beam particle are defined relative to those of the reference particle and described by a point in the six-dimensional (6D) phase space whose coordinates are (x, p_x, y, p_y, s, p_s). The transverse space and momentum coordinates, x, p_x, y and p_y, as well as p_s, are in general, functions of the longitudinal coordinate s along the trajectory. The reference system is fixed to the reference particle so that the latter always occupies the origin. Introducing the familiar from optics angular coordinates x', y', the prime indicating the derivative with respect to s, the 6D phase space reduces to [x, $\beta\gamma x'$, y, $\beta\gamma y'$, s, p_s], with γ the reference particle Lorentz factor.

Consider an ideal paraxial beam of N noninteracting particles (forces between particles negligibly small), subject only to external conservative forces (no radiation) with constant or slowly varying momentum P_o and p_x, $p_y \ll P_\mathrm{o}$. In this case, the transverse [x,$\beta\gamma x'$, y, $\beta\gamma y'$] and longitudinal [s, p_s] phase space projections become (to first order in the coordinates) uncoupled; it can then be shown (Liouville's theorem) that the volume and area respectively occupied by the beam particles in each of the two projections are constants of motion. From the invariance of the beam occupied area in [s, p_s], it follows that $\Delta E/I$ is a constant of motion. In transverse phase space, consider first a cylindrically symmetric beam with radius r and angular half aperture θ: the occupied phase space volume $(\beta\gamma)^2 \Delta S\, \Delta\Omega \approx \pi^2 (\beta\gamma \cdot r\theta)^2 \equiv \pi^2 \varepsilon_\mathrm{n}^2$, with ΔS the beam cross section and $\Delta\Omega$ the beam subtended solid angle, is invariant and so is the here-defined quantity ε_n called energy-normalized (or reduced) beam emittance. Note that the quantity $\varepsilon = \pi^2 (r\theta)^2$, is the area occupied by the beam in the physical position–angle space. Called physical emittance, it is the relevant quantity in physical space and, because the invariant quantity is $\beta\gamma \cdot r\theta$, it becomes smaller as the beam is accelerated. The normalized brightness is defined as $B_\mathrm{n} = I/\pi^2 \varepsilon_\mathrm{n}^2$ and is seen to be none other but the energy-normalized phase space current density. (Note that brightness is often defined in literature either, incorrectly, as a current density $B = \Delta I/(\Delta S.\Delta\Omega)$, or, correctly, in normalized form, as $B_{\mathrm{n}V} = I/(\Delta S \cdot \Delta\Omega \cdot V)$, qV being the reference particle kinetic energy. $B_{\mathrm{n}V}$ and our adimensional energy dependence definition B_n are related through equation $B_\mathrm{n} = (E_\mathrm{o}/q) \cdot B_{\mathrm{n}V}$, with E_o the particle rest energy.) As expected, the smaller the beam radius and angular aperture, the brighter the beam. More generally, when motions in x and y are uncoupled, the horizontal and vertical normalized emittances, $\beta\gamma \int z'\, \mathrm{d}z \equiv \pi\varepsilon_{\mathrm{n}z}$ (z stands for x or y), defined in the respective (z, p_z) phase space projections, are separately constant. (Here the factor π in the definition of $\varepsilon_{\mathrm{n}z}$ arises from the beam boundary in 2D phase space

being an ellipse when the simple approximation is made of external forces linear in the particle displacements.) The resulting normalized brightness value is $B_n = I/\pi^2\ (\varepsilon_{nx} \cdot \varepsilon_{ny})$. For a Gaussian beam with standard deviations $\sigma_z(s)$ and $\sigma_z'(s)$ (z standing for either x or y), the most used normalized emittance definition is $\varepsilon_{nz} = \beta\gamma\ \sigma_z\sigma_z'$.

When dealing with nonideal, irregular beam shapes and current densities, it becomes useful to introduce the rms (or average) normalized beam emittances

$$\pi\varepsilon_{nz}^{(rms)}(s) = \sqrt{\langle z^2 \rangle \langle (\beta\gamma \cdot z')^2 \rangle - \langle z \cdot \beta\gamma z' \rangle^2}$$

To define the actual "beam stay clear" envelope in either physical transverse space projection, most authors use the expression $4\pi\varepsilon_{nz}^{(rms)}$, the resulting rms beam brightness being $B_n^{(rms)} = I/(16 \cdot \pi^2\ \varepsilon_{nx}^{(rms)}\ \varepsilon_{ny}^{(rms)})$.

Note finally that when in real life one has to deal with nonlinear optical elements and internal forces, the rms normalized emittances are no longer invariant. They will, in general, depend on the beam local current density, tending to blow up during beam acceleration and transport, thereby spoiling $B_n^{(rms)}$ (see **Figure 4**). A great amount of theoretical and experimental work has been and is, therefore, devoted to methods and techniques to minimize the final output brightness deterioration particularly of high-current sources. Last, keeping the beam energy spread small is also important particularly to reduce chromatic aberrations; the ratio of $B_n^{(rms)}$ to the beam relative momentum (energy) spread $\Delta p/P_o$, called rms normalized spectral brightness or brilliance, B_{nS}, quantifies this aspect.

Electron Sources

General

The typical e^- source (electron gun) consists of a cathode, the primary emitter of low-energy (few eV) electrons, and of a system to accelerate the electrons and shape them into a paraxial beam. Emission from the cathode material is basically obtained lowering the material work function by either heating or by means of external electric fields or photoelectrically. The most common cathodes are metal filament or disk-shaped thermionic emitters. Field effect and photoelectric cathodes are used for special applications.

Electron Sources for Micro-Applications

The main requirement for microscopy type applications is highest space resolution in the plane of the object to be examined or processed, and consequently, highest source brightness and brilliance. Micromachining and semiconductor processing put rather more emphasis on high-power density and scanning capabilities, requiring higher source currents and somewhat lower brightness. The first element of a micro-application-type source is a "needle" cathode (**Figure 1**) producing a cylindrical symmetry beam. An accelerating and focusing column, comprising one or more electrodes and electrostatic or magnetic lenses, collects the cathode-emitted electrons and focuses them into the sample to be examined or processed. Cathode tip diameters down to the sub-μm range are used, a size limiting the maximum extracted current to typically a few tens of μA. Further, collimation down to a few nA (effective current) takes place in the column allowing for very small normalized emittances ($\varepsilon_{nz} \approx 10^{-8}$–$10^{-11}$ m rad) and nanometer size spots at the sample. The resulting normalized brightness can exceed 10^{12} A $(m^{-2}\,rad)^{-2}$ with energy spread in the 10^{-5} range. Electrons are extracted from the cathode by either thermionic emission from heating it to ≈2000–2800 K, or by cold field emission (CFE) in an electrostatic field strong enough for electrons to "tunnel" through the surface barrier at room temperature. A third technique (Schottky emission) combines thermo and field emission allowing for lowering of the operating temperature to ≈1700 K. A low operating temperature makes for longer cathode lifetime and higher brightness since beam emittance is ultimately determined by the thermal motion of the extracted electrons. With a cylindrical cathode of radius r, the thermal contribution to the normalized emittance is approximately $\varepsilon_{th}^2 \approx r^2 \cdot K_B T/E_o$, K_B being the Boltzmann constant and T the absolute cathode temperature. CFE cathodes can therefore ultimately produce the smallest emittance, but, at extracted

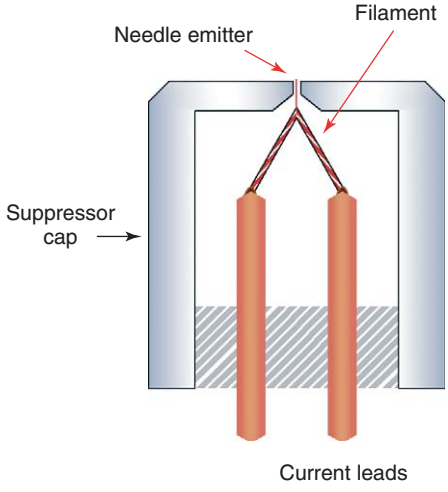

Figure 1 Schottky type cathode cross section.

Table 1 Cathodes for micro-applications: order of magnitude parameters for various cathode materials

Main parameters	*W*	LaB_6	*Cold field*	*Schottky*	*Carbon nanotubes*
Effective source size (nm)	$\geqslant 10^4$	$\geqslant 10^3$	3	10	3
Operating temperature (K)	2800	2000	300	1800	300
Useful current (nA)	1000	1000	1	10	
Normalized brightness ($A\,m^{-2}\,rad^{-2}$)	10^{10}	10^{11}	$>10^{13}$	10^{13}	10^{14}
Invariant emittance (m rad)	10^{-9}	5×10^{-9}	5×10^{-12}	10^{-11}	
Energy spread (eV)	1.0	1.0	0.5	0.5	0.3

current values comparable to those of the other two types, their lifetime is shorter. Schottky cathodes are therefore the most popular solution for highest resolution and brilliance, associated with a long lifetime.

Cathode materials vary from metal (mainly W) filaments to single crystals of various metals or of low work-function composites such as LaB_6. A typical Schottky cathode arrangement is shown in **Figure 1**: the few μm-radius single-crystal tip, mounted on a hairpin filament that heats it to the desired temperature, protrudes through a hole in a negatively biased shield (Wehnelt cap) so that only electrons emitted from the very tip can enter the column. In the column the beam is further collimated, accelerated to energies from a few hundred eV to a few tens of keV (typically ≈ 25 keV) and focused down into the sample to be studied or processed.

Schottky cathodes made of carbon nanotube bundles are also under development: very high brightness has been demonstrated in test stands.

A typical order of magnitude performance of micro-application-type sources equipped with different kinds of cathodes is presented in **Table 1**.

Conventional-Type Electron Guns

Electron guns covered in this section are used to drive a great variety of devices such as power tubes, klystrons, and linear accelerators for industrial, medical, and scientific applications. The emphasis being on high current, ease of operation, lifetime and price, they are mostly rugged thermionic cathode DC guns of the diode or triode (gridded) type. The gun voltage and current specifications vary widely, depending on the application, from the $\approx$50–100 kV/$\approx$10 A of Linac guns to the $\approx$100–1000 kV/$\approx$100–1000 A of the highest power klystron guns.

Common cathodes consist of a high melting-point metal disk coated with a low work-function material and indirectly heated by a filament. The extracted current density $J_T = A\,T^2 e^{-(W/K_B T)}$ is a function of temperature and of the material work function, W. The most used material is Ba or Sr oxide coated tungsten having a work function of $\approx$1.6 eV, compared to 4.5 eV of pure tungsten, and capable of 10–20 $A\,cm^{-2}$ at temperatures of $\approx$1500 K. Because in a high-temperature and high-voltage environment the coating tends to be removed rather rapidly by desorption, sputtering, and evaporation, dispenser cathodes have been developed made of porous tungsten impregnated with oxide which slowly diffuses towards the cathode surface, continuously replacing the removed material. Operated in good vacuum ($\leqslant 10^{-7}$ hPa) and at current densities $\approx 5\,A\,cm^{-2}$, a dispenser cathode can typically reach useful lifetimes of $\sim$40 000 h. The gun operates ideally in the space-charge limited Child–Langmuir regime: a voltage applied to Pierce geometry electrodes (**Figure 2**) provides the radial focusing required to form the cathode-emitted particles into an ideally laminar flow beam. Laminarity ensures a constant current density emission at the cathode, lowest emittance, and highest brightness. Normalized emittance and brightness values lie typically in the $\varepsilon_n^2 \sim 10^{-3}$–$10^{-5}\,A\,m^{-2}\,rad^{-2}$ and $B_n \sim 10^8$–$10^{11}\,A\,m^{-2}\,rad^{-2}$ range, respectively.

The relation between applied voltage and extracted current is $I = P^* V^{3/2}$, P being a constant,

characteristic of the device, called perveance. Its measurement unit is the perv$\equiv 1\,A/V^{3/2}$. Highest brightness values are obtained with perveance values of less than 1 μperv because above it, space-charge forces make it increasingly difficult to produce laminar beams. For very high peak and average currents more complicated gun designs are therefore needed, using annular beams or multiple beam (cathode) devices (**Figure 3**). Multiple-beam klystron guns having several large cathodes (up to $\approx 100\,\mathrm{cm}^2$) and operating at $\leqslant 2.5\,\mathrm{A\,cm}^{-2}$ s are being developed for applications aimed at MW average power with 10^5 h lifetimes. The various cathode beams are combined after acceleration so as to minimize space-charge effects.

Pulsed beam configurations are obtained by various methods, such as pulsing either the anode or the grid voltage, or periodically sweeping the continuous beam across a collimator (chopping), or by imposing a periodic longitudinal velocity chirp on the beam in such a way as to make particles bunch together in a following field-free region (drift space) of appropriate length (velocity bunching). The main parameters of a typical S-band Linac gun and of DC and pulsed high-power klystron guns are listed in **Table 2**.

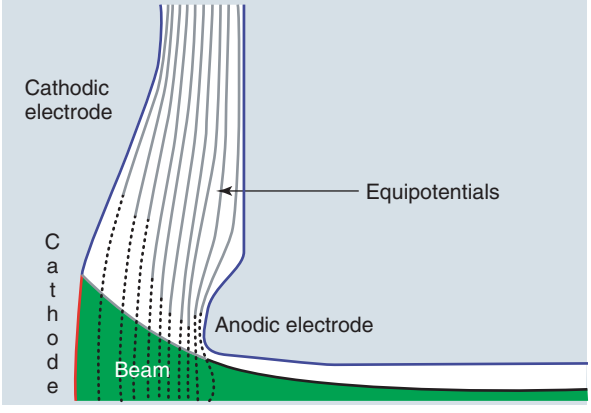

Figure 3 Pierce-type geometry scheme (upper half of cross section shown).

Electron Preinjectors

To drive free electron laser (FEL)-based, fully coherent, short-wavelength (X-ray) sources and to implement techniques such as laser and plasma acceleration for a future generation of compact electron accelerators requires the most demanding beam parameters: $\varepsilon_{nr} < 1$ μm rad, $(\Delta E/E) < 0.1\%$, $B_{nr} \sim 10^{15}$ A (m rad)$^{-2}$, $\tau \approx ps$ and peak bunch current $\hat{I}_b \sim$ kA. (Such specifications are beyond those at present routinely obtainable. Physics and technology of generating and transporting very high brightness, intense beams are therefore being actively researched and developed worldwide and advancing very fast.) Next generation colliders for particle physics also need a similar source performance and, in addition, high bunch charge, polarized, ribbon-shaped beams.

Preinjector systems (so-called because they are normally only the first part of the injector to the final accelerator) have been developed to approach the above listed specifications, consisting of a high-energy gun and of a number of auxiliary components. A several MeV electron gun is the first component needed to accelerate the source-emitted electrons as fast as possible to relativistic energies to minimize space-charge force effects, scaling like $1/\gamma^2$, which tend to blow the beam emittance up. It can be shown, by ideally slicing up the bunch like a loaf, that the emittance at the gun output has a fan-like structure in phase space (**Figure 4a**) due to space-charge forces being stronger on slices near the bunch center than on tail ones. Each bunch slice thus contributes one of the ribs of the fan, and the rms normalized emittance of the whole fan becomes much larger than that of any individual slice. The fraction of the fan-like blow-up caused by the linear components of the space-charge force can be taken out (compensated) by adding a solenoid at the gun exit followed by a drift space, and by additional accelerating sections and by proper shaping the bunch-charge distribution (should ideally be uniform). How the scheme works is seen in the simulation whose results are presented in **Figures 4** and **5**. The simulation follows a uniform charge distribution through

Table 2 Parameters of typical power thermionic electron guns: for an S-band linear accelerator injector and for power klystron tubes

Electron guns	*V* (KV)	*I* (A)	*Perv.* (μperv)	$\langle W \rangle$ (kW)	T_M (μs)	*Rep rate* (Hz)
S-band linac	100	10	0.3	1.0	10	50–60
High power	100	20	0.6	1000		DC
	500	210	0.6	1	1.5	10
	535	700	2.0	35	3	60
	800	4000	0.9	8	1	5

V: gun voltage; *I*: av. beam pulse current; $\langle W \rangle$: average beam power; T_M: pulse duration.

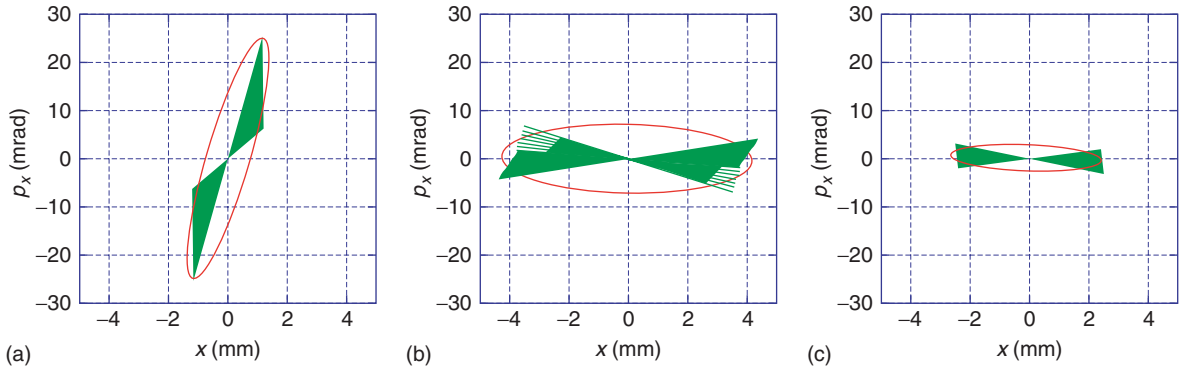

Figure 4 Fan-like beam footprint in the (x, p_x) phase plane at: (a) the gun exit; (b) the solenoid exit; (c) the drift space point where a first minimum is obtained. The beam-stay-clear footprint is shown as an ellipse whose area is four times the computed rms normalized fan area, $\pi\varepsilon_n^{(rms)}$.

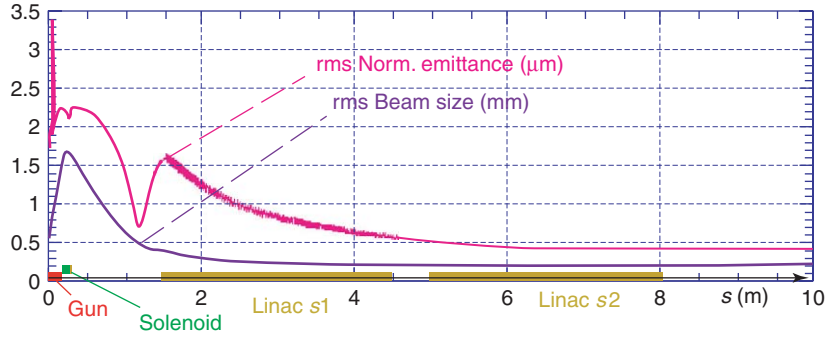

Figure 5 Computed rms normalized emittance and rms horizontal envelope evolution in the preinjector. The emittance is taken through a minimum at $s = 1.5$ m by the compensating solenoid and the following drift space. It then starts increasing again and is damped back in the next two accelerating Linac sections.

from cathode to the end of such a space-charge compensated preinjector whose two-Linac sections provide acceleration to 150 MeV.

Figure 4a shows the beam phase-space footprint at the gun output, and its beam-stay-clear equivalent ellipse having four times the area of the fan-like rms distribution. **Figures 4b** and **4c** show how the compensating solenoid and the following drift space reduce the footprint. A further reduction of the rms emittance in the final accelerating sections is shown in **Figure 5**. The end ε_n value is essentially due to thermal contributions and to nonlinear space charge force components only.

Peak-normalized brightness values measured at state-of-the-art preinjector installations are shown in **Figure 6**. Normalized emittances in the 2–4 μm rad range are routinely obtained today at peak bunch currents up to $\hat{I}_b \sim 50 - 100$ A.

To raise the peak bunch current, preinjectors are being developed using the preinjector additional accelerating sections to reduce the bunch length also: energy-chirping of the moderately relativistic (≈ 5 MeV) bunch produced by the gun and injection into the following accelerator sections far off the RF

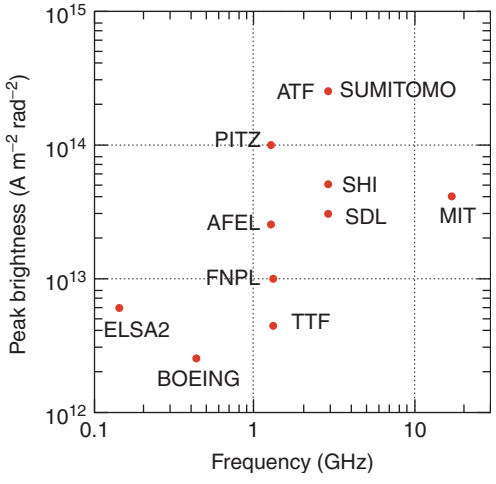

Figure 6 Peak normalized brightness of state-of-the-art preinjectors, mostly operating at L-, S-, or K-band frequencies with bunch charges of ≈ 1 nC. Emittances are in the 2–4 μm rad range.

field crest produces a velocity bunching so that the bunch itself is simultaneously compressed and accelerated. Focusing solenoids are added around the accelerating sections to prevent an emittance blow-up.

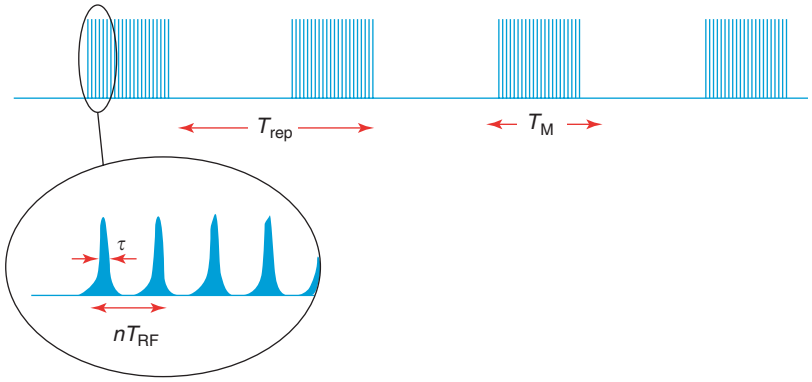

Figure 7 Time structure of a resonant pulsed linear accelerator. T_M long macropulses repeat with period T_{rep}. The microstructure repetition period is (equal to or) multiple of the accelerating field period T_{RF}.

Concerning the beam time structure, preinjectors generate bunch trains whose typical configuration is shown in **Figure 7**: a train of (macro) pulses, each containing a train of short bunches. The macropulse duration T_M and repetition frequency, $1/T_{rep}$, are usually determined by the allowed average power consumption of the particle source and of the accelerator. Duty factors range from $\sim 10^{-5}$ to $\sim 10^{-1}$. The bunch repetition frequency in the macropulse is a subharmonic of the accelerating field frequency $1/T_{RF}$, which also determines the initial bunch duration, τ.

Preinjector high-voltage guns in operation are basically of two types. The first consists of a normal thermionic DC gun followed by a high frequency, standing or traveling wave-accelerating structure. The second (RF gun), simpler and more compact, combines gun and accelerating structure in one by directly embedding the cathode in a standing-wave RF cavity. A $\approx$50–100 MV m^{-1} peak RF field in the $\approx$10 cm long cavity provides very fast acceleration to several MeV, thereby minimizing the effect of the defocusing space charge forces. The cathode of either type gun can be either thermionic or a photocathode from which electrons are photoelectrically extracted by illuminating it with a laser beam.

Schematic diagrams of RF gun structures are shown in **Figures 8a** and **8b**, one mounting a thermionic cathode, the other a photocathode.

The main asset of thermionic, metallic cathodes is stability of the emitted current and long lifetime. Drawing from micro-applications technology single crystal, mm-diameter LaB_6 cathodes are being proposed to achieve a high current with emittance values at the thermal limit. The required bunch microstructure must be produced by chopping or velocity-bunching their continuous macropulse current.

With photocathodes, the beam microstructure can be directly generated by modulating the drive laser pulse length, shape, spot size, and intensity on a pulse-to-pulse basis. On the other hand, stabilising to percent accuracy, the extracted current, which depends on the pulse-to-pulse stability of the high-power high-repetition rate driving laser, is more difficult. Nevertheless, because they offer much higher extracted current densities than thermionic devices, photocathodes are today's choice for high-peak current, bright-beam applications.

Photocathode materials such as Cu and Mg, to be illuminated with UV light, can operate in pressures of $\sim 10^{-7}$ hPa, have low, albeit constant, quantum efficiencies (QE) in the 10^{-3}–10^{-4} range. Alkali (Cs, K, Rb, RbCs) telluride semiconductor devices, illuminated with 4.5 eV UV light, require ultrahigh vacuum ($\approx 10^{-9}$ hPa) but have high efficiency and long lifetime: Cs_2Te photocathodes have been routinely operated in accelerators with initial QE of $\approx$10%, gradually dropping to a few percent over many months of useful lifetime.

Negative electron affinity (NEA) photocathodes have the advantage of operating at longer laser wavelengths. Illuminated with polarized light, NEA-GaAs devices can also produce 80–90% polarized beams; they are being developed aiming at ps long, $\approx$1 nC bunches with $\varepsilon_n \approx 5 \times 10^{-5}$ m rad. For acceptable quantum efficiency lifetime though, they must operate in $\sim 10^{-11}$ hPa vacuum, a specification not easy to meet with high-frequency RF guns because of the intrinsic low pumping conductance of the RF structure. Preinjectors equipped with easier-to-evacuate DC guns, low-frequency (larger iris) RF guns or open RF gun structures of the "plane wave transformer" type are therefore also being developed. Other photoemitters such as diamond-based, ferroelectric ceramic, and nanostructured carbon cathodes are also being studied. Parameters of the most commonly used photocathode materials are collected in **Table 3**.

Table 3 Parameters of various photocathode materials

Material	*Quantum efficiency* (*QE*)	*Lifetime*	*Required vacuum* (hPa)	*Laser wavelength* (nm)
Cu	2×10^{-4}	Years	10^{-7}	260
Mg	2×10^{-3}	years	10^{-7}	260
Alkali Antimonide	0.05	days	10^{-10}	532
Alkali Telluride	0.1	>1 year	10^{-9}	260
NEA-GaAs	0.05	weeks	10^{-11}	780

Gun developments include RF devices capable of generating bright, continuous microbunch trains for applications requiring the highest possible average current such as CW operation of superconducting linear accelerators.

New types of preinjectors are also being studied, such as high-brightness devices, promising to directly generate 100 fs, 0.1 nC bunches with peak currents up to $\approx 10^3$ A, by integrating the gun into the preinjector high-energy accelerating section. A photocathode is mounted only a few mm away from the back wall of a Linac section serving as anode. By generating GV m^{-1}, sub-ps pulses across the mm wide cathode-to-anode gap, photoelectrons are accelerated to several MeV in a few fs and directly injected into the preinjector final acceleration section, so that essentially no space-charge-induced emittance blow-up is expected.

More exotic schemes are being investigated for applications to further future laser–plasma accelerators. As an example, an "all-optical" electron source for a laser-driven plasma wake-field accelerator is claimed to be capable of GV cm^{-1} electric fields, micrometer spot sizes, femtosecond-long bunches, and GA cm^{-2} current densities. The scheme foresees a first-drive laser creating a plasma wake by ionizing a confined gas to below its self-trapping threshold (free electrons oscillating around ions). The transverse ponderomotive force of a second (injection) laser pulse, shining orthogonal to the first, then imparts to the plasma electrons an extra kick in the wave direction so as to inject them into the plasma wake-field with the correct phase to be trapped and accelerated.

Positron Sources

Positron Production

Positron beams are produced either by β-radioactive sources or via pair production by photons. Photons are normally obtained either from neutron-induced nuclear reactions such as $^{113}\mathrm{Cd}(n,\gamma)^{114}\mathrm{Cd}$ or from electron-induced electromagnetic showers in solid targets. Radioactive and nuclear e^+ sources are mainly used to produce low intensity, quasi-monochromatic positron beams in the <1 eV to $\sim$MeV range, used in materials science for surface and bulk investigations. Radioactive sources are relatively inexpensive and suited for low-energy laboratory installations, while neutron-induced production requires reactor-grade slow n beams. For high intensities, primary high-energy electron or γ-ray beams must be used.

Radioactive and Nuclear e^+ Sources

The most popular radioactive source is the ^{22}Na isotope which decays, according to the diagram of **Figure 9a**, with 2.6 years half-life. One of its advantages is that the fast γ-ray accompanying the decay can be used to perform e^+ annihilation lifetime measurements. Positrons are emitted with a very large energy spread $\sim$200 keV, extending to 540 keV. A common method to produce a beam with the desired energy and a narrow energy spread is to first thermalize the decay positrons in a system of tungsten vanes, from which they emerge with energy of $\sim$0–2 eV, and then re-accelerate them. Using electrostatic acceleration, continuous positron beams with typical DC current values of a few pA, energies up to several MeV, and relative energy spreads of $\sim 10^{-4}$ can be obtained that, for microprobe-type applications, can be focused to spot sizes of a few μm. Higher intensities, up to $\approx$100 pA can be obtained from other, less easily handled sources such as ^{64}Cu.

The design of a much higher intensity e^+ source based on the $^{113}Cd(n,\gamma)$ ^{114}Cd neutron capture reaction is schematically shown in **Figure 9b**. Slow neutrons from a reactor are captured in a Cd blanket, each capture event producing a cascade of γ-rays. The high-energy photons are then converted into e^+ e^- pairs in a set of Pt absorbers that also serve to slow the positrons down. A system of electrical lenses and solenoids finally collects the slow particles in a continuous beam with design intensity of up to ~ 10 nA. Reactors are, in principle, capable of orders of magnitude higher e^+ production rates but only over much larger target volumes, which makes it difficult to collect the particles in a compact beam.

High-Intensity e^+ Sources

High-intensity positron beams are obtained by letting primary, high-energy, intense e^- beams shower in a converter, the shower photons producing the positrons via pair production, or by directly hitting the converter with a photon beam. The relatively low energy, large emittance, large energy spread e^+ positron beam out of the converter is captured in a system of magnetic lenses surrounding the converter, followed by an accelerating structure.

The converter thickness for maximum e^+ yield depends on the nature and energy of the primary. The number of photons in an e^- initiated shower increases approximately proportional to the primary electron energy (E_e) for $E_e \geqslant 1$ GeV, while the thickness yielding the maximum collectable e^+/photon ratio increases proportional to $\approx \ln(E_e)$. At $E_e \sim 1$ GeV, it is $\approx 3\,X_o$ (X_o being the converter material radiation length $\propto 1/Z^2$) and the e^+ effective source radius at the converter exit, which affects the positron collection efficiency, is $\approx 0.3\ X_o$ neglecting the contribution from the primary beam emittance. The positron energy spectrum exiting the optimum target thickness peaks at around a few MeV tailing out at a few tens of MeV, almost independently of the primary energy. A typical yield figure, when collecting $\approx$2–20 MeV positrons, is $\sim 5 \times 10^{-2}$ positrons per incident electron and per GeV of the primary beam.

The overall source intensity is ultimately limited by the target material sustainable peak and average thermal stresses from local, sudden temperature peaks due to the energy deposited in the converter by sub-μs electron bunches over very small volumes. Materials with short X_o, high-mechanical strength and high-melting point are thus favored, the most used being tungsten (^{74}W). Specific energy deposition in a ^{74}W converter can typically not exceed a few tens of J g^{-1}. For very high intensity e^+ sources, cooled rotating converters are used. Liquid metal converters are also being studied. Large amounts of radiation and residual activity produced in the target surroundings require strict maintenance and personnel protection measures.

Higher positron beam intensities can be produced using primary intense, bright, photon beams, such as can be obtained from free electron lasers or from high-energy e^- beams spontaneously radiating in an undulator magnet. High-power laser beams Thompson back-scattered from a multi-GeV electron beam are also candidates being studied to produce high-energy photon beams.

Because the photon pair production cross section saturates at ≈ 1 GeV, where the positron yield per photon peaks at approximately $0.3\,X_o$, low Z, high-heat capacity converter materials (typically ^{22}Ti) can be used, offering less multiple scattering and correspondingly higher collection efficiency, less energy deposition per collected e^+, and therefore, higher allowed deposited energy density. In addition, more than 40% linear or circular-polarized positrons can be obtained by using polarized primary photons.

Finally, it has recently been shown that the periodic atomic potential inside a single crystal converter can act like a very short period undulator magnet and that the positron yield from electrons or photons incident at glancing angle to the crystal axis can be two to three times larger than from an amorphous converter.

Nomenclature

B, B_n	brightness, normalized brightness
c	speed of light
e	electron charge
e^-, e^+	electron, positron
E	energy
E_o	particle rest energy
E_e	electron energy
I	beam current
I_b, $\hat{I}_b$	bunch current, peak bunch current
m_o	particle rest mass
N	number of particles
$\boldsymbol{P}$, $\boldsymbol{P}_o$	momentum, nominal beam momentum
q	charge
Q	quality factor
s	longitudinal coordinate
v	velocity
V	voltage
W	work function
x, y	horizontal, vertical coordinates
X_o	radiation length
z	z stands for either x or y
Z	atomic number
β	reduced velocity v/c
γ	Lorentz factor
$\Delta\boldsymbol{P}$	relative momentum deviation $\boldsymbol{P}-\boldsymbol{P}_o$
ε, ε_n, ε_{th}	emittance, normalized emittance, thermal emittance
τ	bunch duration

Electron Gas (Theory)

M P Tosi, Scuola Normale Superiore, Pisa, Italy

Introduction

The homogeneous gas of electrons (also known as jellium) is the most important basic model in the physics of condensed matter. It was introduced by Drude in 1900 to account for the electromagnetic properties of plasmas and was used by the pioneers of quantum mechanics in the early 1930s to model the sea of interacting valence electrons in a metal. The valence electrons are the outer electrons of an atom and determine how it interacts with its surroundings, but in a metal they are released by the atoms into a collective state. In the early studies, the ions of the crystalline lattice in the metal were smeared into a rigid uniform background of positive charge, which exactly balances the negative charge associated with the distribution of outer electrons. More generally, through the development of density-functional theory the electron gas has become the basic reference system in most calculations of electronic structure not only for metallic or insulating solids and liquids, but also often applied to describe the electronic structure and the cohesion of atomic-scale systems up to biomolecules.

In metals the density of valence (or conduction) electrons is high enough that many of their properties can be understood in terms of a picture in which they move almost independently of each other, forming a paramagnetic fluid made of equal numbers of up and down spins. The success of this single-electron picture of metals rests on the work carried out in the 1950s by Landau in developing the theory of Fermi liquids. But with decreasing density the potential energy associated with the Coulomb interactions between the electrons grows to dominate over their kinetic energy and ultimately at very low density the electron gas freezes into the "Wigner crystal," in which the electrons become localized on lattice sites. This behavior is just the opposite of what happens with classical systems, where it is high density that favors a lattice structure. It is also believed that crystallization of the electron gas in the jellium model is preceded, in an intermediate range of density, by the stabilization of a spin-polarized state in which the spins spontaneously align into a ferromagnetic state of order. This possibility was already foreseen by Bloch in 1929, within the context of the Hartree–Fock approximation. This theoretical framework, when widened to include man-made semiconductor devices in which the electronic carriers are constrained to move in a plane (as in a quantum well) or on a line (as in a quantum wire) or under three-dimensional confinement (as in a quantum dot), provides much of the basic understanding that is necessary for modern condensed matter physics and nanotechnology.

It is appropriate to note at this point, before embarking on a more detailed presentation of the issues indicated above, that especially over the last few decades some more exotic properties of the valence-electron gas have come to the fore. These developments really started with the idea of Cooper pairs in the BCS theory of superconductivity in metals and have been stimulated by discoveries of novel materials, such as the cuprate high-T_c superconductors and other oxides, or of novel physical effects such as the Kondo scattering against magnetic impurities or the fractional quantum Hall effect. The quantum theory of solids is now no longer confined to the electron as the quasiparticle of a Fermi liquid, but in special situations reconstructs the system of valence electrons to produce quasiparticles that may behave like fragments of an electron, such as composite fermions, composite bosons, or holons and spinons.

Ideal Fermi Gas and Fermi Liquid Theory

Conduction electrons in normal metals under ordinary laboratory conditions form a highly degenerate Fermi fluid, in which the mean interparticle spacing a is a small fraction of the characteristic de Broglie wavelength $\lambda = h/p_{dB}$ (here h is Planck's constant and p_{dB} is the momentum of a particle of mass m having kinetic energy equal to the thermal energy $k_B T$, with k_B the Boltzmann constant and T the temperature). If for the moment one neglects all interactions, one can write the energy levels E of the gas in terms of the single-particle kinetic energies ε_k and of the number n_k of electrons in a single-particle state at energy ε_k, $E = \sum_k n_k \varepsilon_k$. Here k is a label specifying the momentum and the spin of each electron. The Pauli exclusion principle restricts the values that n_k may take for particles of half-integer spin to $n_k = 0$ or 1.

A cell of volume h^3 in phase space can thus contain at most two electrons with opposite spins, so that in the ground state at $T = 0$ the electrons must have a spread of momenta in a range up to a maximum momentum p_F (the "Fermi momentum"). For N electrons with up and down spins inside a volume V and defining $k_F = p_F/\hbar$, one can write the density $n = N/V$ as $n = k_F^3/3\pi^2$. The wave number k_F is the radius of a spherical surface in wave number space (the "Fermi surface") and the energy of an electron with momentum corresponding to the Fermi surface is the Fermi energy ε_F. This also is the lowest energy with which one may add a further electron to the gas (i.e., ε_F is the chemical potential of the gas at $T = 0$) and evidently increases with the electron density, since $k_F = (3\pi^2 n)^{1/3}$.

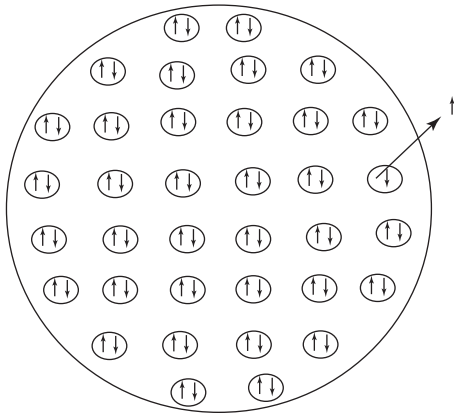

Figure 1 Schematic representation of a section of the Fermi sphere for a paramagnetic electron gas, showing also a process of excitation of an electron–hole pair.

The notion of a Fermi sphere allows a vivid picture of ground state and excitations in a normal Fermi fluid. At $T = 0$, the single-particle states inside the Fermi sphere are fully occupied by the fermions and the states outside it are empty. The momentum distribution (i.e., the occupation number of an electron state of given momentum and spin) thus takes a discontinuous change from 1 to 0 as the momentum crosses the Fermi surface. Thermal excitations at finite temperature bring fermions from states inside to states outside the Fermi surface, leaving "holes" behind and lowering the chemical potential of the gas (see the schematic picture in **Figure 1**).

It is somewhat surprising that a number of properties of normal metals are observed to behave as predicted by the ideal Fermi-gas model, in view of the electron–electron and electron–ion interactions that may be expected to lead to substantial departures from ideality. In particular, the electronic contribution to the specific heat of a metal increases linearly with temperature and the paramagnetic spin susceptibility is independent of temperature, both quantities being proportional to the density ν_F of electronic states at the Fermi surface. The explanation of these behaviors has been given by Landau: he assumed that in a Fermi liquid the net effect of the interactions would be to "dress" a particle excited out of the ground state with a cloud of surrounding particles, building up what is termed a quasiparticle. Once one deals with quasiparticles rather than with "bare" electrons, the excitations of the fluid can be described as an almost ideal gas of quasiparticles. A crucial point in Landau's theory is that the quasiparticles obey Fermi statistics, so that at low temperature the low-lying excited states in terms of the excitation of quasiparticles across the Fermi surface can be described. The correct behaviors of the electronic specific heat and spin susceptibility follow at once.

There is, however, one major difference to be emphasized between quasiparticles and bare particles, that is a quasiparticle carries a renormalized effective mass from the backflow that through its interactions it induces in the surrounding fluid as it tears through it. This implies a shift in the density of states at the Fermi surface and hence in the absolute values of the thermodynamic properties of the interacting electron gas relative to the ideal Fermi gas. The spin susceptibility is enhanced by a further factor which favors the alignment of the spins of neighboring electrons into a parallel configuration (see below).

Exchange Effects and Hartree–Fock Theory

As a start to a calculation of the ground-state energy of the interacting electron gas, one might ask what is the distribution of electron pairs in the ideal Fermi gas as a function of their relative distance r. The pair distribution function, that is written in general as $g(r)$, is defined by setting equal to the quantity $ng(r)(4\pi r^2 \mathrm{d}r)$ the average number of electrons that lie within a spherical shell centered on an electron and having radius r and thickness dr. For the electron gas with equal numbers of up and down spins it can be written as $g(r) = [g_{\uparrow\uparrow}(r) + g_{\uparrow\downarrow}(r)]/2$, the average of the values for pairs of electrons with parallel spins and antiparallel spins.

Whereas $g(r) = 1$ in a classical ideal gas, the probability of finding two electrons with the same spin at a distance r vanishes exactly as $r \to 0$. This property derives from the symmetry imposed by the Pauli exclusion principle, according to which the wave function of a Fermi fluid changes sign under the operation of exchange of two identical fermions. That is, the many-body wave function of the electron gas has a node at the mid-point between each pair of parallel-spin electrons. The property $g_{\uparrow\uparrow}(0) = 0$ is an exact result and implies that each electron of given spin induces a local depletion of the density of electrons with the same spin.

If we bear in mind that the Coulomb interactions between electrons are repulsive, it is seen that the presence of the "Pauli hole" that was introduced above is accompanied by a gain in potential energy of the electron gas. Exchange effects keep apart electrons with parallel spins and therefore reduce on average the Coulomb repulsive energy of parallel-spin pairs. This consequence of the Pauli principle is for the electron gas the analog of the so-called Hund rule for the electronic structure of atoms, according to which there is on total energy grounds a preference for the state of maximum total spin. As seen in more detail below, this same effect favors the alignment of the spins of neighboring electrons in the interacting electron gas and stabilizes a spin-polarized state at strong coupling.

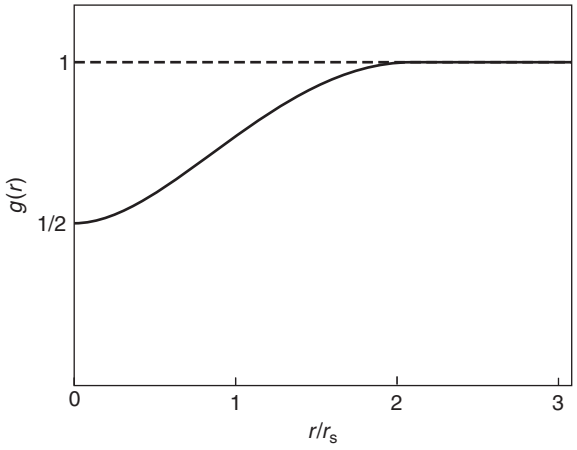

Figure 2 The Pauli hole surrounding an electron of given spin in the ideal Fermi gas.

In the ideal Fermi gas $g(r)$ takes the expression

$$g_{\mathrm{ideal}}(r) = 1 - \tfrac{9}{2}\,[j_1(k_{\mathrm{F}}r)/(k_{\mathrm{F}}r)]^2$$

where $j_1(x) = (\sin x - x\cos x)/x^2$ is a spherical Bessel function. The shape of this function, which describes the Pauli hole in the ideal Fermi gas, is shown in **Figure 2**. Of course, no correlations exist at this level between pairs of electrons with antiparallel spins, that is, $g_{\uparrow\downarrow}(r) = 1$.

The expression for $g_{\mathrm{ideal}}(r)$ can be used to evaluate the ground-state energy in first-order perturbation theory. This calculation corresponds to the energy of the electron gas in the Hartree–Fock approximation, since by translational symmetry the self-consistent Hartree–Fock single-particle orbitals must be the plane-wave orbitals of the ideal gas. The result is

$$\begin{aligned} E_{\mathrm{g}}^{\mathrm{HF}}(r_{\mathrm{s}}) &= \left(\frac{3}{5\alpha^2 r_{\mathrm{s}}^2} - \frac{3}{2\pi\alpha r_{\mathrm{s}}}\right)\mathrm{Ryd} \\ &\cong \left(\frac{2.21}{r_{\mathrm{s}}^2} - \frac{0.916}{r_{\mathrm{s}}}\right)\mathrm{Ryd} \end{aligned}$$

per electron, with $\alpha = (9\pi/4)^{-1/3}$ and in units of the Rydberg ($1\,\mathrm{Ryd} = e^2/(2a_{\mathrm{B}})$ with $a_{\mathrm{B}} = \hbar^2/(me^2)$ being the Bohr radius). Here, the density parameter r_{s} by the definition $4\pi(r_{\mathrm{s}}a_{\mathrm{B}})^3/3 = n^{-1}$ is introduced, that is, r_{s} represents the mean distance between neighboring electrons in units of the Bohr radius. The two terms in $E_{\mathrm{g}}^{\mathrm{HF}}(r_{\mathrm{s}})$ are the average kinetic energy and the average potential energy per electron, respectively, and their ratio is evidently proportional to $1/r_{\mathrm{s}}$. This shows that the role of the electron–electron

interactions becomes progressively more important as r_s increases – that is, as the density of the electron gas decreases.

Coulomb Correlations: Screening and Plasmons

It has been already remarked that no correlations between antiparallel spins are present in the ideal Fermi gas. Further depletion of the local electron density around each electron arises when the Coulomb repulsive interactions are switched on and allowed to modify the many-body wave function. The main effect is that the motions of opposite-spin electrons start to be correlated, since pairs of electrons with parallel spins are already kept apart by the Pauli principle.

Figure 3 shows the "Pauli–Coulomb hole" at increasing values of the coupling strength r_s. A property of this function is that the total local depletion of electron density around the electron at the origin corresponds to taking away exactly one electron from its neighborhood. This is a microscopic manifestation of Faraday's law, according to which an electric field cannot penetrate in the depth of a conductor. The bare electrical potential generated by each electron is on average completely screened by a local rearrangement of the other electrons, and the effective potential that an electron creates decays to zero over a microscopic distance. The notion of screening provides the microscopic basis for the Landau quasiparticles.

The screening effect has both static and dynamic manifestations. Considering first the screening of a static foreign charge, its bare potential is screened in Fourier transform by an electronic dielectric function $\varepsilon(q)$ which depends on wave number. The Thomas–Fermi theory yields $\varepsilon(q) = 1 + (q\lambda_{TF})^{-2}$ where $\lambda_{TF} = \sqrt{(\pi\hbar^2/4mk_Fe^2)}$ is the Thomas–Fermi screening length. In fact, the presence of the Fermi surface induces microscopic "Friedel oscillations" of wavelength π/k_F in the local electron density. The electron density $n(r)$ at a distance r from the foreign charge is asymptotically described by the expression

$$n(r) - n \propto \cos(2k_F r + \phi)/r^3$$

This result should be contrasted with the monotonic decay of the screened potential in a classical plasma, as found for instance in the Debye–Hückel theory of electrolytic solutions. Instead the effective potential created by an ion inserted in the electron gas, as well as the effective potential with which each electron interacts with the other electrons, are oscillating functions of distance showing both repulsive and attractive regions. These properties have crucial consequences for the electron theory of metals and for the electronic systems of interest in nanotechnology.

With regard to dynamical screening, an argument given by Langmuir in 1928 shows that the electron plasma can be driven into harmonic oscillation at the

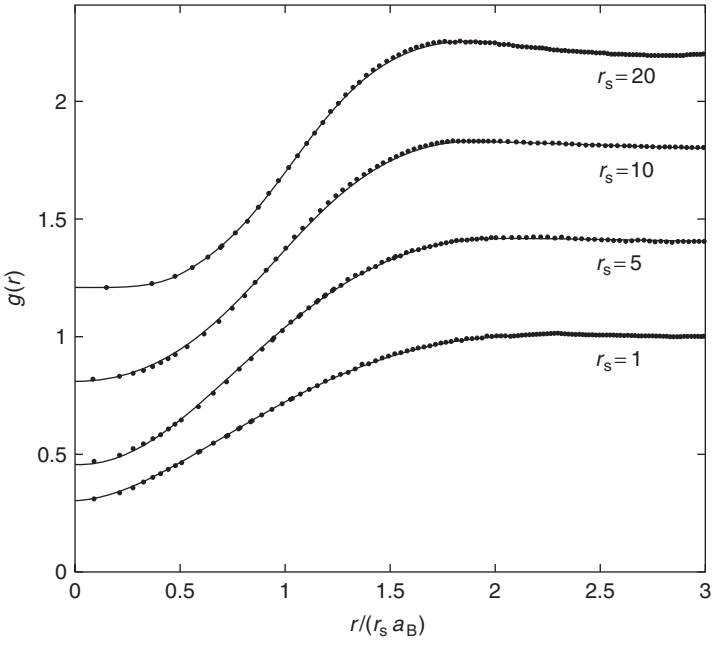

Figure 3 The Pauli–Coulomb hole in the interacting electron gas at various values of the coupling strength r_s: a comparison between theory (full curves) and quantum Monte Carlo data (dots). The values of $g(r)$ at $r_s = 5$, 10, and 20 have been rigidly shifted upwards for clarity by 0.4, 0.8, and 1.2.

"plasma frequency"

$$\omega_p = \sqrt{4\pi ne^2/m}$$

Such "plasmon excitations" are observed in inelastic scattering experiments on metals, using either a beam of fast electrons (in an EEL (electron energy loss) experiment) or a beam of X-rays.

Hubbard Model and the Para–Ferro Quantum Phase Transition

A simple way to illustrate the role of short-range correlations in driving the formation of order in the spins is provided by the model Hamiltonian introduced by Hubbard in 1963. The Hubbard model adds to the kinetic energy term a point-like repulsive interaction of magnitude U between two electrons with antiparallel spins whenever they meet on the same site. Considering here just the case of "itinerant" (nearly free) electrons, this interaction favors the alignment of the spins of neighboring electrons: the spin susceptibility in a constant magnetic field is enhanced by a factor $(1 - Uv_F/2)^{-1}$ relative to the Pauli value for the ideal Fermi gas (recall that v_F is the density of electron states on the Fermi surface).

Therefore, if U is increased in a continuous manner, it is found that the static spin susceptibility diverges when U attains the value $2/v_F$, and this corresponds to an instability of the paramagnetic state against the formation of a translationally invariant state of spin order. That is, the interacting electron gas stabilizes itself by a transition to a state having incipient ferromagnetic order. This "quantum phase transition" has been seen in quantum Monte Carlo studies carried out by Ceperley and Alder in 1980 and may correspond to the observation of magnetic (spin) polarization reported by Young *et al.* in 1999 for a dilute electron gas created in calcium hexaboride by doping with lanthanum. Of course, the electrons move in this system inside an ionic lattice, so that their states involve an additional quantum number which is absent in the electron gas model. Such "band effects" increase the effective mass of the electrons and hence the value of v_F, enhancing the natural tendency of the electron spins to align.

Wigner Crystallization

It has been already remarked that as the dimensionless electron spacing r_s increases (i.e., as the electron density decreases) the kinetic energy is becoming less and less important relative to the potential energy associated with the Coulomb repulsions. In the 1930s Wigner had noticed that an optimal value is obtained for the potential energy of jellium if the electrons are placed on the sites of a body-centered cubic lattice structure. Localization of the electrons raises their kinetic energy and an electron crystal may become favored only at very low density, where the potential energy becomes dominant. Of course, in the crystal the electrons are not strictly localized on the lattice sites but execute vibrational motions around them. Strong anharmonicity and high concentrations of lattice defects will be present in this quantum crystal near melting.

The problem of "Wigner crystallization" has become a classic in many-body physics, from both the theoretical and the experimental point of view. Quantum Monte Carlo studies have indicated that the ground state of three-dimensional (3D) jellium, after undergoing a continuous transition from a paramagnetic fluid to a fully spin-ordered ferromagnetic fluid, undergoes a first-order transition to a ferromagnetic crystal at $r_s \approx 65$. Similar studies of 2D jellium indicate a first-order transition from a paramagnetic to a ferromagnetic fluid followed by crystallization into a triangular lattice at $r_s \approx 35$. The search for Wigner crystallization in the laboratory has been addressed to quasi-2D assemblies of electronic carriers, mostly in man-made semiconductor structures.

The first unambiguous observation of Wigner crystallization was reported by Grimes and Adams in 1979 for electrons floating on top of a substrate of liquid ^{4}He in a quasi-classical regime. Metal–insulator transitions have subsequently been reported in quasi-2D systems of carriers subject to very strong magnetic fields in the fractional quantum Hall effect regime or in the presence of disorder and also in high-purity quasi-2D samples having exceptionally high carrier mobility.

Electron Gas in Reduced Dimensionalities

As it has been already seen in the introduction to this article, electron gases in reduced dimensionalities present strong fundamental interest and high technological relevance. A general consequence of reducing the dimensionality is an increasing role of the electron–electron correlations at each given value of the adimensional coupling strength r_s. This is ultimately a consequence of the modified topology of the electronic motions as the electrons are constrained to move in a plane or along a line or inside a quantum dot. This profoundly modifies the excitation spectrum of the ideal Fermi gas and enhances its susceptibility to any perturbation.

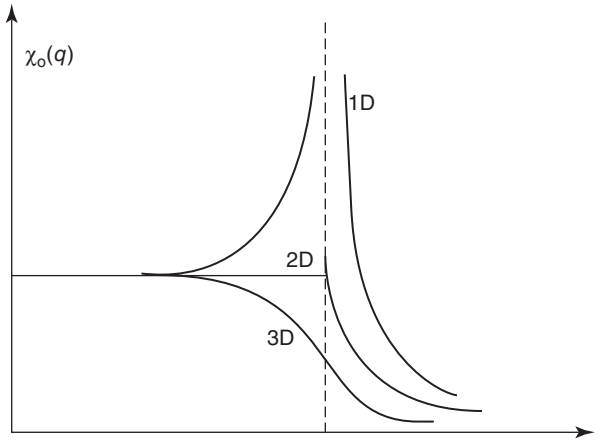

Figure 4 Static susceptibility of the Fermi gas in dimensionalities 1D, 2D, and 3D, as a function of wave number q; the vertical dashes show the position $q = 2k_F$.

Consider in particular a system in which the conduction electrons are restricted to move along a line. The Fermi surface reduces to two planes located at $k = \pm k_F$ and only forward or backward scattering processes are allowed. The susceptibility of the 1D Fermi gas to a static electrical potential varying along the line with a wave number q becomes

$$\chi_o(q) = -(2m/\pi\hbar^2 q)\ln\left|\frac{q+2k_F}{q-2k_F}\right|$$

This function presents a logarithmic divergence at $q = \pm 2k_F$, which can drive the "Peierls distortion" when the Coulomb repulsions are switched on: for example, a monoatomic 1D conductor with a half-filled conduction band (one electron per atom) may gain electronic energy by a lattice distortion opening a gap at the Fermi level through the formation of dimers.

The sketch shown in **Figure 4** illustrates the dependence of $\chi_o(q)$ on dimensionality. In all cases there is a singularity at $q = \pm 2k_F$, whose character depends on dimensionality: from a logarithmic divergence in the derivative of $\chi_o(q)$ in 3D, to a discontinuity in the derivative of $\chi_o(q)$ in 2D, and to a logarithmic divergence in $\chi_o(q)$ in 1D as seen above.

In conclusion, for conduction electrons in reduced dimensionalities (D = 1 and also in some 2D tight-binding-like models) a "Luttinger liquid" state may be induced by the electron–electron interactions. A Luttinger liquid differs from a normal Fermi liquid in two respects, that is (a) the discontinuity in the momentum distribution across the Fermi surface is replaced by another type of nonanalytic behavior, and (b) spin–charge separation occurs.

Electron Spin Resonance

A-L Barra, Grenoble High Magnetic Field Laboratory, Grenoble, France
A K Hassan, Bruker Biospin AG, Fallanden, Switzerland

Introduction

Since its discovery in 1945 by Zavoisky, the electron spin resonance (ESR) technique is now commonly used in fields ranging from biology to solid-state physics and materials science. ESR, also known as electron paramagnetic resonance (EPR), is a spectroscopic method used to study the systems possessing a permanent magnetic moment of electronic origin. Most of these systems belong to the class of paramagnets, but the same experimental setup can be used for the study of ferro- and antiferromagnets. The states of magnetic materials and their corresponding properties are discussed elsewhere in this encyclopedia. The special cases of ferro- and antiferromagnets, corresponding to ferromagnetic resonance (FMR) and antiferromagnetic resonance (AFMR), respectively, is, however, not treated here.

The paramagnetic systems which have been studied extensively include free radicals, paramagnetic metal complexes (especially transition metals or rare-earth compounds), semiconductors (impurities, defects, etc.), and excited triplet states of molecules. Another important branch of ESR spectroscopy relies on the use of spin labeling, where free radicals are used to study diamagnetic hosts. As their magnetic moments are influenced by their local environment, the analysis of their ESR spectrum can give structural information such as the local symmetry, the nature of the environment, and the electronic distribution.

Usually, the ESR spectrum is obtained by irradiating the system under study at a fixed frequency and varying the applied external magnetic field until the resonance condition is fulfilled. The position of the resonance, its intensity, its lineshape, and line width are the characteristic features of the spectrum. An exact treatment of the ESR phenomenon requires the use of quantum mechanics, as the electronic magnetic moment is related to the electronic spin. However, a preliminary description can be obtained from a classical approach.

Phenomenological Approach

The magnetic moment $\boldsymbol{M}$ is related to the angular momentum $\boldsymbol{J}$ by the equation $\boldsymbol{M} = -\gamma \boldsymbol{J}$, where γ is the gyromagnetic ratio and $\boldsymbol{J}$ is in units of $\hbar$. When an external magnetic induction $\boldsymbol{B}_0$ is applied to the magnetic moment $\boldsymbol{M}$, it induces a torque $\boldsymbol{\Gamma} = \boldsymbol{M} \times \boldsymbol{B}_0$ so that the resulting equation of motion for the system is $\mathrm{d}\boldsymbol{J}/\mathrm{d}t = \boldsymbol{\Gamma}$ or $\mathrm{d}\boldsymbol{M}/\mathrm{d}t = -\gamma \boldsymbol{M} \times \boldsymbol{B}_0$. This describes the precession of the magnetic moment around the applied magnetic induction (**Figure 1**), with an angular frequency $\omega_0 = \gamma B_0$ for completely isolated magnetic moments. In order to take into account the interaction of the magnetic moments with the surroundings, a relaxation term has to be added which is assumed to be exponential. Let $\boldsymbol{M}_0$ be the equilibrium value of $\boldsymbol{M}$; it is parallel to $\boldsymbol{B}_0$ which is chosen to be along z. Two different relaxation times, the spin–lattice relaxation time T_1 (along the z-direction) and the spin–spin relaxation time T_2 (perpendicular to the z-direction), are introduced to describe the relaxation processes. T_1 corresponds to the energy transfer between the magnetic moments and the lattice via phonons, whereas T_2 describes the vanishing of the transverse components, a result of the growing incoherence in the perpendicular plane.

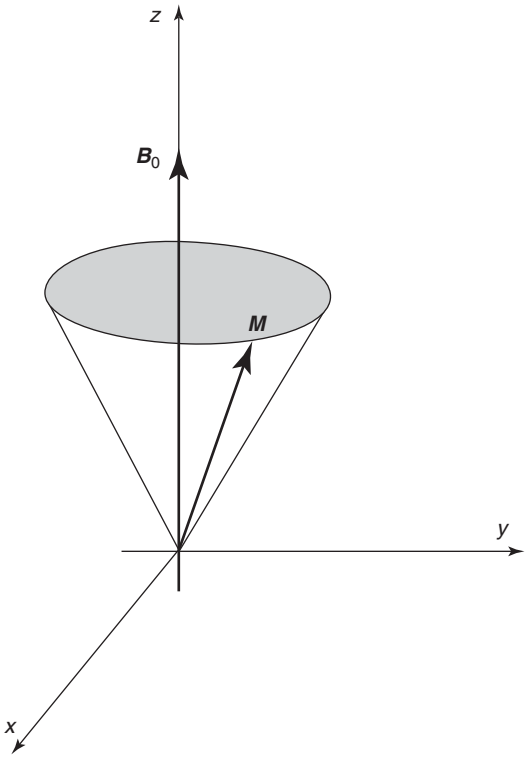

Figure 1 Magnetization precession about the applied magnetic induction $\boldsymbol{B}_0$.

Bloch Equations

When performing an ESR experiment, an oscillating magnetic induction $\boldsymbol{B}_1(t)$ is superimposed to the static

induction $\boldsymbol{B}_0$, with $\boldsymbol{B}_1$ perpendicular to $\boldsymbol{B}_0$ and $B_1 \ll B_0$. The oscillating induction usually has a linear polarization, which can be decomposed into the sum of two opposite circular polarizations. However, only one of these two circular components acts on the magnetic moment, so the other one can be neglected. Then the Bloch equations describing the evolution of a magnetic moment in the presence of static and oscillating external magnetic induction are obtained:

$$\frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t} = -\gamma \boldsymbol{M} \times \boldsymbol{B} - \begin{bmatrix} M_x/T_2 \\ M_y/T_2 \\ (M_z - M_0)/T_1 \end{bmatrix}$$

$$= -\gamma \boldsymbol{M} \times \begin{bmatrix} B_1 \cos(\omega t) \\ B_1 \sin(\omega t) \\ B_0 \end{bmatrix} - \begin{bmatrix} M_x/T_2 \\ M_y/T_2 \\ (M_z - M_0)/T_1 \end{bmatrix}$$

At this stage, it is easier to consider the evolution of the system in the rotating frame instead of the laboratory frame. The rotating frame is a Cartesian frame (x^r, y^r, z^r) whose z^r-axis coincides with the z-axis of the laboratory frame, whereas the x^r- and y^r-axis rotate around z at ω so that $\boldsymbol{B}_1$ is stationary in this frame. The x^r-axis is chosen along $\boldsymbol{B}_1$. The transformed Bloch equations describe the evolution of the magnetic moment $\boldsymbol{M}^r$ in the rotating frame:

$$\frac{\mathrm{d}\boldsymbol{M}^r}{\mathrm{d}t} = -\gamma \boldsymbol{M}^r \times \begin{bmatrix} B_1 \\ 0 \\ B_0 - \omega/\gamma \end{bmatrix} - \begin{bmatrix} M_x^r/T_2 \\ M_y^r/T_2 \\ (M_z - M_0)/T_1 \end{bmatrix}$$

The effective magnetic induction along the z-axis is reduced to $B_0 - \omega/\gamma = \Delta\omega/\gamma$, which vanishes for the resonance condition $\omega = \omega_0$. At resonance, the system sees only $\boldsymbol{B}_1$ in the rotating frame and precesses around this induction with an angular frequency $\omega_1 = \gamma B_1$.

Solution of the Bloch Equations

The steady-state solution of the Bloch equations, which describes correctly the system for time duration t that is large with respect to T_1 and T_2, is obtained easily in the rotating frame:

$$M_x^r = \frac{\omega_1 \Delta\omega T_2^2}{1 + (T_2\Delta\omega)^2 + \omega_1^2 T_1 T_2} M_0$$

$$M_y^r = \frac{-\omega_1 T_2}{1 + (T_2\Delta\omega)^2 + \omega_1^2 T_1 T_2} M_0$$

$$M_z^r = M_z = \left(1 - \frac{\omega_1^2 T_1 T_2}{1 + (T_2\Delta\omega)^2 + \omega_1^2 T_1 T_2}\right) M_0$$

where M_x^r is the response of the system in-phase with respect to $\boldsymbol{B}_1$, and M_y^r is the out-of-phase response.

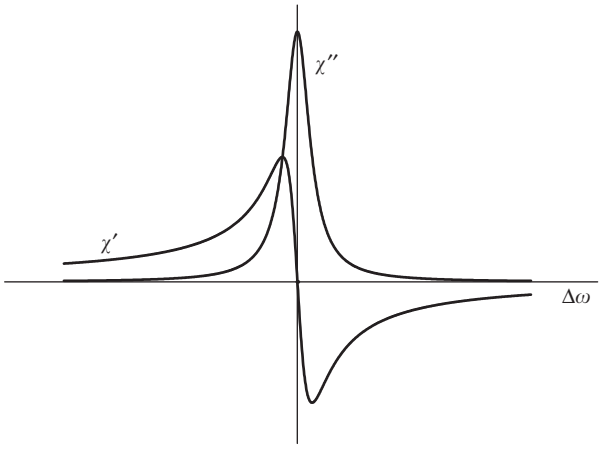

Figure 2 In-phase (χ') and out-of-phase (χ'') components of the dynamic magnetic susceptibility, as a function of the angular frequency deviation $\Delta\omega$.

These two components are associated to the dynamic susceptibility $\chi = \chi' - \mathrm{i}\chi''$ at the angular frequency ω. As $M = \chi H = \chi B/\mu_0$ (in the case where the relative permeability equals 1), and under nonsaturating conditions $(\omega_1^2 T_1 T_2 \ll 1)$,

$$\chi' = \frac{\Delta\omega\omega_0 T_2^2}{1 + (\Delta\omega T_2)^2}\,\chi_0$$

$$\chi'' = \frac{\omega_0 T_2}{1 + (\Delta\omega T_2)^2}\,\chi_0$$

where $\chi_0 = \mu_0 M_0/B_0$ is the static magnetic susceptibility. χ'' represents the power absorption and has a Lorentzian lineshape (**Figure 2**) with a half-width at half height equal to $1/T_2$, whereas χ' is the dispersion of the resonance.

Zeeman Interaction

Basis for a Free Electron

The classical picture given by the Bloch equations allows one to visualize the magnetic resonance phenomenon. However, as ESR deals with the electronic spin, it is necessary to perform a quantum mechanical treatment. The description with the Bloch equations then corresponds to the evolution of the medium value of the magnetic moment, that is, the evolution of the magnetization.

When an electron with spin 1/2 is placed in an external magnetic induction $\boldsymbol{B}_0$ applied along the z-direction, the degeneracy of the two energy levels corresponding to the two possible spin projections ($\pm 1/2$) is lifted (**Figure 3**). This is the Zeeman interaction described by the spin Hamiltonian: $H_S = -\boldsymbol{\mu} \cdot \boldsymbol{B}_0 = \gamma\hbar B_0 S_z = g_e \mu_B B_0 S_z$, where g_e the Landé factor for a free electron, is proportional to the variation of the

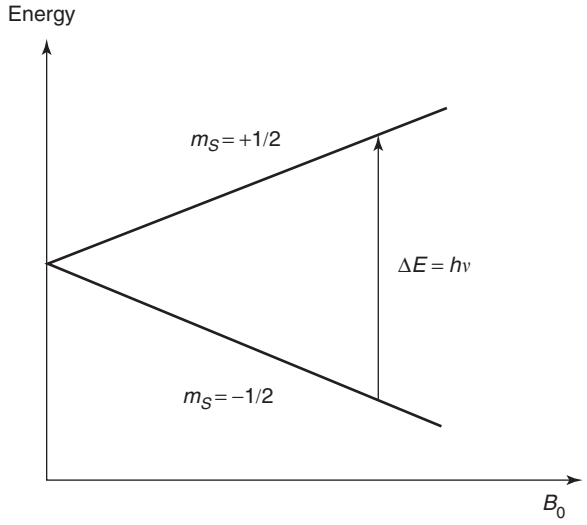

Figure 3 Zeeman effect on the energy levels for a spin $S = 1/2$.

energy levels with the applied induction; for a free electron, $g_e = 2.0023$. It is not equal to 2, as would be expected from a simple approach, due to relativistic corrections. $\mu_B = e\hbar/2m$ is the Bohr magneton, with e the absolute value of the charge, m the mass of the electron, and $\hbar$ the reduced Planck constant. S_z is the dimensionless spin projection operator along the z-direction. The eigenvectors of H_S are the eigenvectors of S_z, $|m_S = \pm 1/2\rangle$, with the corresponding eigenvalues: $E_\pm = \pm(1/2)g_e\mu_B B_0$. Thus, the resonance condition is $h\nu = E_+ - E_- = g_e\mu_B B_0$, where ν is the frequency of the exciting radiation.

Besides the resonance condition, there also exists an important selection rule resulting from the fact that the photon possesses only two spin polarizations, ± 1 (in units of $\hbar$). The conservation of the total angular momentum implies the selection rule for the paramagnetic system: $\Delta m_S = \pm 1$. Such a rule is valid when one uses a "standard" spectrometer, for which the exciting light propagates with its oscillating magnetic induction $\boldsymbol{B}_1$ perpendicular to the main magnetic induction $\boldsymbol{B}_0$.

General Case

Up to now, when looking for the resonance phenomenon only the Zeeman interaction of a free electron with the external induction has been considered. However, a spin also feels the internal magnetic field created by the system it is embedded in. As a result, its resonance will give direct information on this internal field and thus on the spin environment. A very important feature of ESR spectroscopy is to provide local properties of the system and not global ones, as does the magnetic susceptibility. This comes from the spatial dependence of the interactions creating the internal magnetic field, which decrease rapidly with increasing distances (e.g., the magnetic dipole–dipole interactions decrease like $1/r^3$). The contributions to the internal field can be divided into two classes: the ones induced by the external field and thus proportional to it, and the others which are independent of the applied field and correspond to permanent properties of the system.

The first class of interactions is taken into account within the formalism of the Landé factor, g. This means that instead of considering a total induction $\boldsymbol{B} = (1 + \alpha)\boldsymbol{B}_0$ acting on the system, the effect of the induced term is introduced via a Landé factor differing from the free electron value: $H_S = g_e\mu_B \boldsymbol{S} \cdot (\boldsymbol{B}_0 + \alpha\boldsymbol{B}_0) = g\mu_B \boldsymbol{S} \cdot \boldsymbol{B}_0$ with $g = (1 + \alpha)g_e$. In the general case of a spin 1/2 embedded in a low symmetry environment, g will transform to a second-rank matrix $\boldsymbol{g}$, not necessarily symmetric. In its principal axes (x, y, z), the $\boldsymbol{g}$-matrix reduces to

$$\begin{pmatrix} g_x & 0 & 0 \\ 0 & g_y & 0 \\ 0 & 0 & g_z \end{pmatrix}$$

and an external induction $\boldsymbol{B}_0$ can be expressed as

$$\begin{pmatrix} B_0 \sin\vartheta \cos\varphi \\ B_0 \sin\vartheta \sin\varphi \\ B_0 \cos\vartheta \end{pmatrix}$$

so that the Zeeman interaction leads to

$$\begin{aligned} E_\pm &= \pm\tfrac{1}{2} \\ &\quad \times \sqrt{g_x^2 \sin^2\vartheta \cos^2\varphi + g_y^2 \sin^2\vartheta \sin^2\varphi + g_z^2 \cos^2\vartheta} \\ &\quad \times \mu_B B_0 \\ &= \pm\tfrac{1}{2}\, g\mu_B B_0 \end{aligned}$$

From this equation, it can be seen that the g^2 value for each field orientation is found on an ellipsoid having g_x^2, g_y^2, and g_z^2 as principal values (**Figure 4**).

Three different cases should be distinguished depending on their symmetry: cubic symmetry, axial, anisotropy and rhombic symmetry. It is the local symmetry at the unpaired electron position that has to be taken into account and not the crystal symmetry. In the case of cubic symmetry, the three principal values of the $\boldsymbol{g}$-matrix are equal to each other: $g_x = g_y = g_z$; the ellipsoid reduces to a sphere. Thus, the resonance position will be the same for any orientation of the applied external induction. The powder spectrum of such a system, in which all the possible orientations of the external induction are present with the same

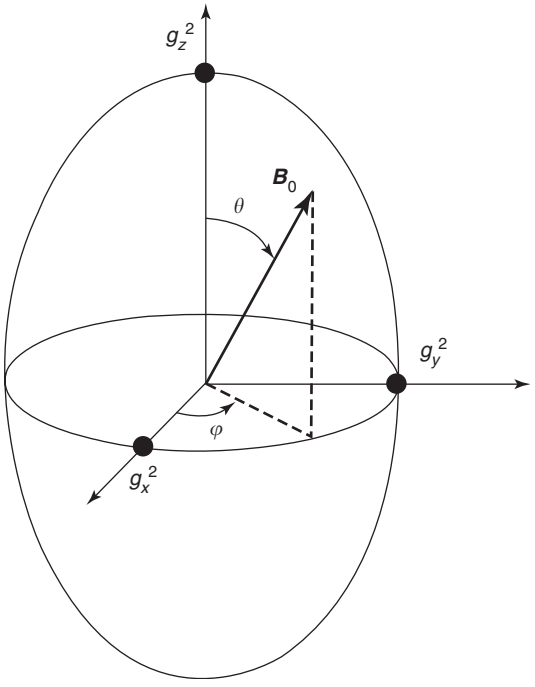

Figure 4 g^2 ellipsoid and definition of the angles θ and φ.

probability, consists of a single symmetric line, the same that one would obtain for a single crystal.

In the case of axial symmetry, the principal values are reduced to two independent values, $g_{||}$ and $g_{\perp}$, with $g_{\perp}$ doubly degenerate. The ellipsoid associated to such a system has a cylindrical symmetry. Such a case is encountered when the axis of symmetry has a symmetry higher than twofold. Then, for all the magnetic induction directions perpendicular to the symmetry axis, the resonance position will be the same; however, it changes when the angle between the external field and the axis of symmetry varies. When studying a powder sample, the resonance spectrum will have the shape shown in **Figure 5a** if $g_{||} < g_{\perp}$, and in **Figure 5b** if $g_{||} > g_{\perp}$.

In the case of rhombic symmetry, there are three different principal values and this is reflected on the ellipsoid corresponding to it (**Figure 4**). This is observed not only when the system has no symmetry elements at all but also if there are only twofold axes or inversion centers or mirrors as local symmetry elements. Then, any rotation of the external field will result in a variation of the resonance position. The shape of the spectrum obtained from a powder sample is shown in **Figure 6**.

Field-Independent Interactions

Besides the ***g***-matrix, the other important properties, which can be obtained from ESR spectroscopy, of a paramagnetic system are field independent. Here, the two most important properties, resulting from the interactions giving rise to the hyperfine and fine structures, are addressed.

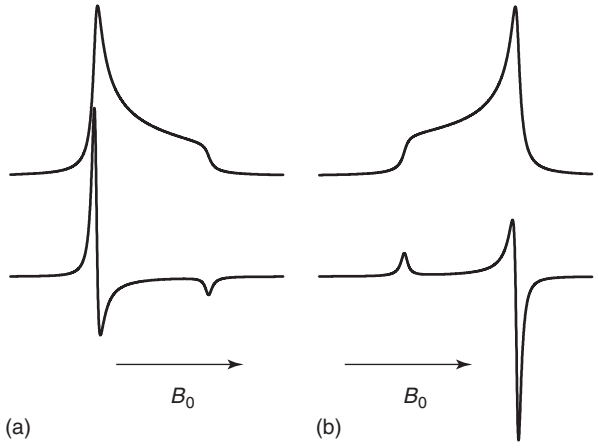

Figure 5 Powder spectrum (up: absorption and down: derivative) for an axially symmetric $S = 1/2$ system. (*a*) $g_{||} < g_{\perp}$; (*b*) $g_{||} > g_{\perp}$.

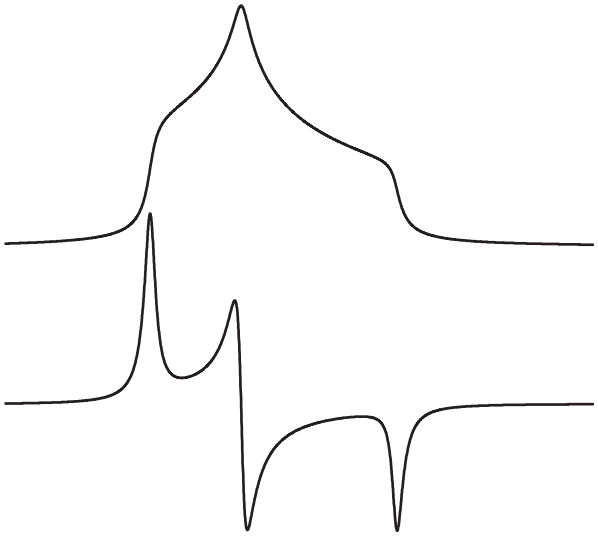

Figure 6 Powder spectrum (up: absorption and down: derivative) for a totally rhombic $S = 1/2$ system.

Hyperfine Interaction

The hyperfine structure results from the interaction of an electronic spin $\boldsymbol{S}$ with the neighboring nuclei possessing a nonzero nuclear spin $\boldsymbol{I}$. Its analysis yields very important information on the system under study, such as the determination of the chemical elements surrounding the electronic spin or the spin density of the electronic wave function. The hyperfine interaction is described by the Hamiltonian: $H_{\mathrm{hf}} = \boldsymbol{S} \cdot \bar{a} \cdot \boldsymbol{I}$, where $\bar{a}$ is the hyperfine tensor. The

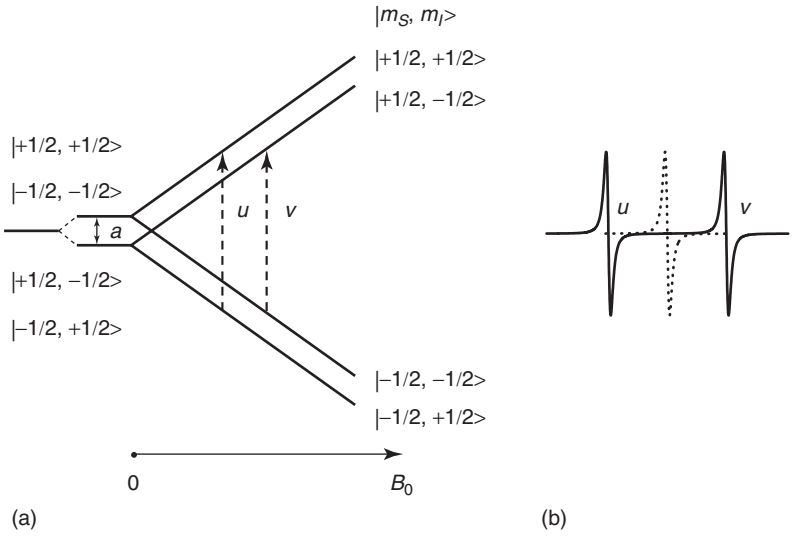

Figure 7 (a) Energy levels of a system with $S = I = 1/2$, showing first the split induced by an isotropic hyperfine interaction a. In zero field, there are two levels doubly degenerated split by the hyperfine interaction. Then the degeneracy removal from the application of the magnetic induction is shown, together with the two expected ESR transitions (labeled u and v). (b) ESR spectrum for an $S = I = 1/2$ system. The dotted line represents the resonance position for $a = 0$.

hyperfine interaction splits each of the electronic Zeeman levels into $2I+1$ levels, depending on the relative orientation of both spins, as illustrated in **Figure 7a** for $S = I = 1/2$. The existence of a hyperfine interaction adds a new selection rule for observing an ESR transition: $\Delta m_I = 0$.

There are two contributions to the hyperfine tensor: the first comes from the magnetic moments associated to the electronic and nuclear angular momenta ($\boldsymbol{S}$ and $\boldsymbol{I}$), which interact with each other via the well-known magnetic dipolar interaction. For a distance vector $\boldsymbol{r}$ between them, and neglecting the g-anisotropies, the effective Hamiltonian is

$$H_{\mathrm{dip}}(\boldsymbol{r}) = -\frac{\mu_0}{4\pi} g\mu_{\mathrm{B}} g_{\mathrm{n}} \beta_{\mathrm{n}} \left[\frac{\boldsymbol{S}\cdot\boldsymbol{I}}{r^3} - \frac{3(\boldsymbol{S}\cdot\boldsymbol{r})(\boldsymbol{I}\cdot\boldsymbol{r})}{r^5}\right]$$

where g_n and β_n are the nuclear g-factor and magneton, respectively, and μ_0 the permeability of vacuum. The dipolar contribution to the hyperfine tensor is then obtained by averaging the electron probability distribution resulting from the electronic wave function. The second contribution comes from the contact or Fermi interaction, when the dipolar treatment breaks down. It is directly proportional to the electronic spin density at the nucleus, and thus concerns electrons with wave functions containing s-type orbitals, which have a nonzero probability density at the nucleus. The symmetry of these orbitals implies that the contact interaction is isotropic. On the other hand, the dipolar interaction, being a traceless interaction, gives no isotropic term and is responsible for the anisotropic part of the hyperfine tensor.

Here, the hyperfine interaction is illustrated in the simplest case of a spin $S = 1/2$ interacting with a nuclear spin $I = 1/2$, but this treatment can be generalized to spins (S as well as I) of higher multiplicity, and considering isotropic values both for the Zeeman and the hyperfine interactions. Choosing the z-axis along the applied magnetic induction $\boldsymbol{B}_0$, and in the limit where the resulting Zeeman effect is much larger than the hyperfine interaction, the Hamiltonian describing the system reduces to $H = g\mu_{\mathrm{B}} B_0 S_z + a S_z I_z$. For the sake of simplicity, the nuclear Zeeman interaction is neglected. The eigenvectors are then $|m_S = \pm 1/2; m_I = \pm 1/2\rangle$ with the corresponding eigenvalues $E(m_S, m_I) = g\mu_{\mathrm{B}} B_0 m_S + a m_S m_I$. There exist four different energy levels (**Figure 7a**) between which two ESR transitions can be observed (**Figure 7b**) separated by $|a|/(g\mu_{\mathrm{B}})$. The center of these lines corresponds to the resonance position of the system in the absence of hyperfine interaction. A nice illustration of the simple case ($S = I = 1/2$) is found with the example (classical system) of n-type silicon doped with phosphorus, Si : P. When the doping level is low enough ($n < 10^{18}\,\mathrm{cm}^{-3}$), the phosphorus atoms can be treated as isolated. Two resonance lines are observed at low temperatures with a splitting of 42 G (**Figure 8**), as a result of the hyperfine coupling of the donor electron spin and the phosphorus nuclear spin (^{31}P with 100% natural abundance).

It should be pointed out that an ESR study cannot determine the sign of the hyperfine parameter. It can be inferred from theoretical considerations or, from the experimental point of view, by using a double-resonance method (such as electron nuclear double

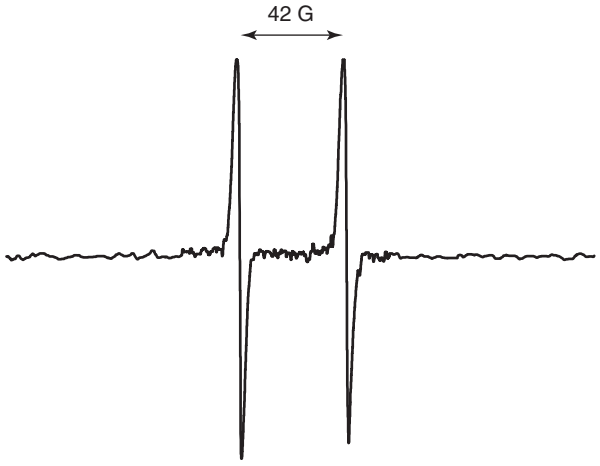

Figure 8 Low-temperature ESR spectrum of an Si : P sample (donor concentration 10^{16}) showing the double line expected from the hyperfine interaction between the ^{31}P nuclear spin $I = 1/2$ and the donor electron spin $S = 1/2$, with a hyperfine constant $a = 42$ G.

resonance (ENDOR)). ENDOR is indeed a very powerful method when dealing with complex systems with several nuclear spins interacting with the unpaired electrons, also because it allows one to take advantage of the different gyromagnetic factors of nuclei.

Fine Structure

When the system under study possesses more than one unpaired electron, the interactions between these electrons have to be taken into account. Examples of such systems are triplet-state molecules (either in the fundamental or in the excited state), biradicals and mostly systems containing transition metal or rare-earth ions. Besides the Coulomb interaction, which contributes to the energy difference (described by the exchange interaction) between levels having a different spin S and which will be ignored here, the electron–electron interaction leads to new terms in the spin Hamiltonian. These are the fine structure terms which may appear when the electronic spin is larger than 1/2. Among these terms only the second order term, the lowest possible order, is treated here.

There exist two different mechanisms giving rise to the fine structure term. One results from the magnetic dipolar interactions between the individual electronic spins $\boldsymbol{S}_1$, and $\boldsymbol{S}_2$, and is described in a way similar to the magnetic dipolar contribution to the hyperfine tensor by

$$H_{\mathrm{dip}}(\boldsymbol{r}) = \frac{\mu_0}{4\pi} g^2 \mu_{\mathrm{B}}^2 \left\{ \frac{\boldsymbol{S}_1 \cdot \boldsymbol{S}_2}{r^3} - \frac{3(\boldsymbol{S}_1 \cdot \boldsymbol{r})(\boldsymbol{S}_2 \cdot \boldsymbol{r})}{r^5} \right\}$$

and neglecting the g-factor anisotropy, for the sake of simplicity. Integrating over the electron coordinates, it is then possible to derive the magnetic dipolar contribution to the fine structure, which is described by a Hamiltonian of the form $H_{\mathrm{f}}^{\mathrm{dip}} = \boldsymbol{S} \cdot \bar{D}_{\mathrm{dip}} \cdot \boldsymbol{S}$.

The other contribution involves the spin–orbit coupling and is usually considered within a perturbation treatment using either the crystal field interaction model or the more sophisticated ligand field approach to take into account the effect of the surrounding atoms. Here, only a simple approach giving the basic ideas is underlined. The unperturbed Hamiltonian H_0 corresponds to the electronic kinetic energy and the Coulomb interaction between the charged particles (nuclei and electrons). The perturbation Hamiltonian involves the effect of the surrounding atoms (crystal field), the spin–orbit and the Zeeman interactions. Depending on their respective strength, the effect of the crystal field is treated before or after the spin–orbit interaction. Consider the simplest case where the spin–orbit and the Zeeman interactions are the smallest contributing terms. The corresponding perturbation Hamiltonian can then be written as $H_{\mathrm{p}} = H_{\mathrm{SO}} + H_{\mathrm{Z}} = \lambda \boldsymbol{L} \cdot \boldsymbol{S} + \mu_{\mathrm{B}}(\boldsymbol{L} + g_{\mathrm{e}}\boldsymbol{S}) \cdot \boldsymbol{B}_0$, with λ the spin–orbit coupling constant and g_{e} the free electron Landé factor. In the hypothesis of an orbitally nondegenerate ground state $|0, m_S\rangle$ (here $|0\rangle$ represents the spatial part of the eigenvector), there is no energy correction to the first order of perturbation and all the $|m_S\rangle$ levels are degenerate in the absence of the external field. In the second order of perturbation, the energy correction has the form

$$E^{(2)}_{0,m_S} = \sum_{n \neq 0} \frac{\langle 0, m_S | (\mu_{\mathrm{B}}\boldsymbol{B} + \lambda \boldsymbol{S}) \cdot \boldsymbol{L} + g_{\mathrm{e}}\mu_{\mathrm{B}} \boldsymbol{B} \cdot \boldsymbol{S} | n, m'_S \rangle \langle n, m'_S | (\mu_{\mathrm{B}}\boldsymbol{B} + \lambda \boldsymbol{S}) \cdot \boldsymbol{L} + g_{\mathrm{e}}\mu_{\mathrm{B}} \boldsymbol{B} \cdot \boldsymbol{S} | 0, m_S \rangle}{E_0 - E_n}$$

with E_0 and E_n the eigenvalues of the unperturbed Hamiltonian corresponding to the states $|0\rangle$ and $|n\rangle$, respectively. Since it has no orbital operator, the term $g_{\mathrm{e}}\mu_{\mathrm{B}}\boldsymbol{B} \cdot \boldsymbol{S}$ vanishes. The other term can be factorized into two parts, one involving the orbital variables and the other involving only the spin variables. By introducing a matrix

$$\bar{\Lambda} = \sum_{n \neq 0} \frac{\langle 0 | \boldsymbol{L} | n \rangle \langle n | \boldsymbol{L} | 0 \rangle}{E_0 - E_n}$$

the energy correction can be associated to the effective spin Hamiltonian, $H^{\text{eff}} = \mu_B \boldsymbol{B} \cdot \bar{g} \cdot \boldsymbol{S} + \lambda^2 \boldsymbol{S} \cdot \bar{\Lambda} \cdot \boldsymbol{S}$, with $\bar{g} = g_e \bar{1} + 2\lambda\bar{\Lambda}$ where $\bar{1}$ is the unit matrix. This Zeeman term explains the origin of the *g*-anisotropy and, more generally, how the *g*-values can differ from the free electron *g*-factor. The second term of the effective Hamiltonian gives the spin–orbit contribution to the fine structure, so that in this simple case, $\bar{D}_{SO} = \lambda^2 \bar{\Lambda}$.

While the dipolar contribution to $\bar{D}$ is traceless, there is no such constraint for the one involving the spin–orbit effect. However, this isotropic part only contributes to a global energy shift of the whole *S* multiplet and can simply be omitted here (it gives no spectroscopic contribution). Thus, the general expression for the fine structure interaction up to the second order is $H_f = H_f^{dip} + H_f^{SO} = \boldsymbol{S} \cdot \bar{D} \cdot \boldsymbol{S}$, with D_x, D_y, and D_z the principal values of the $\bar{D}$ tensor. $\bar{D}$ is called the zero-field splitting (ZFS) tensor, as it leads to an energy difference between the different m_S levels of the *S* multiplet in the absence of a magnetic field (**Figure 9**). As $\bar{D}$ is traceless, $D_x + D_y + D_z = 0$, the three principal values reduce to only two independent parameters, *D* and *E*, defined by $D = 3D_z/2$, $E = (D_x - D_y)/2$. D_z is chosen to be the largest absolute principal value ($|D_z| > |D_x|$ and $|D_z| > |D_y|$) which results in $-1/3 \leqslant E/D \leqslant 1/3$. Thus, the fine structure term can be written as $H_f = D(S_z^2 - S(S+1)/3) + E(S_x^2 - S_y^2)$. *D* characterizes the axial anisotropy, whereas *E* describes its rhombicity ($E = 0$ for a system with axial symmetry).

The above Hamiltonian applies for all systems with spin $S > 1/2$. However, with respect to ESR spectroscopy, it is worth noting the difference between integer and half-integer spin systems associated to the fine structure. For a half-integer spin *S*, time reversal invariance implies that the levels corresponding to the same absolute value of the spin projection are degenerate ($E(m_S) = E(-m_S)$) in the absence of an external magnetic field. They form the so-called Kramer's doublets. In zero field, the existence of a zero-field splitting will induce an energy gap between the levels $|\pm 1/2\rangle$, $|\pm 3/2\rangle$, …. As the energy level $|\pm 1/2\rangle$ is at least doubly degenerate and will split with the applied magnetic field, half-integer spin systems should, in principle, always give rise to a signal (at any ESR frequency). For an integer spin *S*, there is no such restriction on the splitting of the multiplet and all the $|m_S\rangle$ levels can differ in energy in zero magnetic field, depending on the local symmetry of the system. As a result, the observation of an ESR signal is no more guaranteed for integer spin systems but depends on the spectrometer (frequency and available magnetic field range). This has led to the denomination "ESR silent" spin systems (**Figure 9b**), in order to describe integer spin systems giving no signal essentially in X-band ESR (9 GHz). However, using frequencies high enough to overcome the splitting should allow one to obtain a spectrum.

Finally, another property of $S > 1/2$ spin systems worth mentioning is the possibility to observe the so-called forbidden transitions. At high field, when the

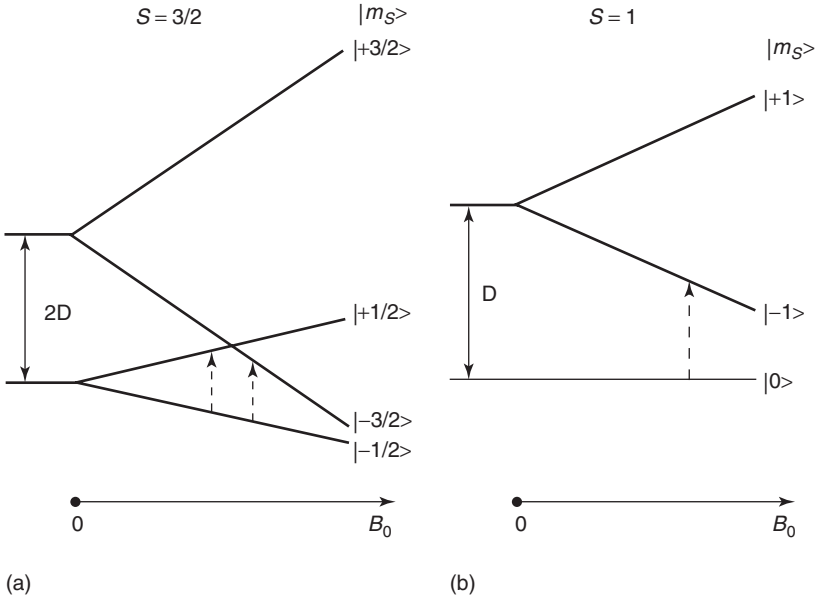

Figure 9 (a) Energy levels of an $S = 3/2$ system with axial symmetry, and their Zeeman splitting for a magnetic induction applied along the *z*-axis. (b) Idem for an $S = 1$ system. The dotted arrows depict the allowed ESR transitions.

Zeeman interaction dominates with respect to the field independent interactions, the field direction defines the quantization axis and the eigenvectors of the system are the corresponding $|m_S\rangle$ levels. Then the selection rule $\Delta m_S = \pm 1$ holds for a spectrometer operating in the perpendicular configuration. At low field, the eigenvectors are still labeled with the same $|m_S\rangle$; however, they are no more pure levels as the other interactions become comparable to, or larger than, the Zeeman term. In general, the quantization axis will not coincide with the field direction and it will be possible to observe "forbidden transitions," that is, transitions corresponding to $\Delta m_S \neq \pm 1$ with m_S defined by the field direction. For instance, for spin $S = 1$, an additional half-field signal is observed. Even if they are called "forbidden," these transitions are observed because they are actually allowed. They play an important role because, when dealing with powders, they often give rise to intense signals as they are relatively isotropic.

High-Frequency ESR

A recent evolution in ESR spectroscopy is the use of higher magnetic fields and frequencies. Usually, ESR is considered high field when performed in magnetic fields beyond the electromagnets range, that is, for fields higher than 2 T and for an exciting frequency higher than 60 GHz. The reasons for using higher fields and higher frequencies may vary. One reason is obviously the increased Zeeman interaction. Using higher fields can help in separating signals with slightly different g-values and resolving small g-anisotropies. Starting from the resonant condition $h\nu = g\mu_B B$, the separation between two lines associated with two different g-factors, g_1 and g_2, is given by

$$\Delta B = B_1 - B_2 = \frac{h\nu}{\mu_B}\left(\frac{1}{g_1} - \frac{1}{g_2}\right)$$

Thus, increasing the field, and consequently the frequency, increases the separation of the lines linearly, and leads to an increased resolution as long as the line width does not change.

Another main interest of using higher frequencies concerns spin systems with $S > 1/2$. High frequencies allow one to overcome large zero-field splittings and to observe transitions inaccessible with a lower-frequency excitation, especially in the case of integer spin systems (there are no more "EPR silent" systems). This characteristic has been used for the study of simple systems, such as mononuclear or binuclear species, for instance, single ion complexes with high spin Mn(III) ($S = 2$)or Ni(II) ($S = 1$). It has also proven very important for unraveling the striking properties of more complex compounds known as molecular spin clusters. These are molecules containing several spins, most often arising in metal ions, coupled together. Among the huge variety of these systems, a particularly attractive class is the one composed of single-molecule magnets (SMMs), in which the spin clusters behave like superparamagnets (showing, for instance, a hysteresis in the magnetization curve). SMMs are obtained for molecules with a large ground spin state associated to an Ising-type magnetic anisotropy, as observed for an octanuclear Fe(III) cluster (**Figure 10**, inset) which has an $S = 10$ ground state associated to a ZFS of $-0.2\,\mathrm{cm}^{-1}$. A single-crystal spectrum obtained on this system, at 230 GHz and 35 K with the field oriented along the principal x-axis of the SMM, illustrates the benefits of high-frequency EPR in the study of spin clusters, and more generally of systems with large ZFS (**Figure 10**). Besides the impurity signal in the center, the spectrum shows a regular pattern of 20 lines (the expected $2S$ transitions of the $S = 10$ multiplet). The distance between the lines allows one to determine the ZFS along the recording direction, as ZFS is proportional to this distance. The intensity pattern is not symmetric with respect to the center of the spectrum, because the intensity of the lines also depends on the thermal population of the spin levels.

Finally, another important property of high-frequency ESR is the possibility to reduce second-order effects, which make the spectra difficult to interpret, with the increase of the Zeeman term. More generally, when it is not possible to reach the high-field limit, operating at several frequencies allows one to distinguish the interactions independent of the magnetic field from the Zeeman term, thus obtaining a complete picture of the system under study.

Technical Aspects

Standard Spectrometer

Even if many different ESR spectrometers have been constructed, the most frequently encountered one is the cw X-band ESR spectrometer (see **Table 1** for a review of the most used bands), operating with the standard elements shown in **Figure 11**.

The 9 GHz microwaves, conveying the exciting magnetic field, are generated by a klystron. The sample is mounted in a resonant cavity placed at the center of the electromagnet generating the main magnetic field. A small coil is inserted in the main magnet, and produces a small (with respect to the line width) modulating field superimposed to the main field, resulting in the observation of a derivative signal. The microwaves reflected by the cavity are

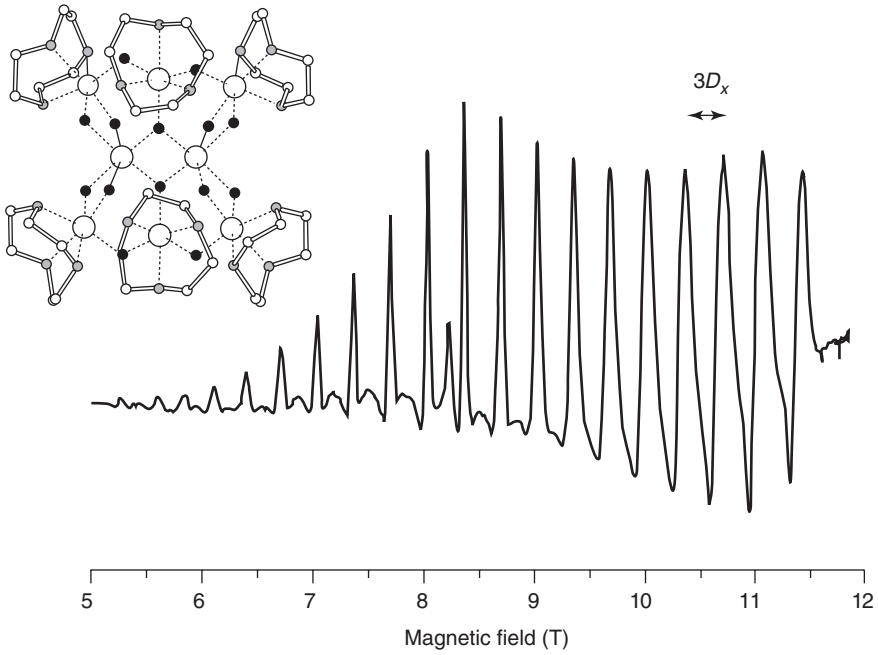

Figure 10 Inset: Schematic view of the molecular structure of the Fe_8 cluster, $[Fe_8O_2(OH)_{12}(tacn)_6]Br_8 \cdot 9H_2O$ where tacn = 1,4,7-triazacyclononane. The oxygen atoms are shown in black, nitrogen atoms in gray, carbon atoms in white (small circles) and the large white circles denote Fe(III) ions. Main: Single-crystal ESR spectrum of Fe_8 recorded at 35 K and 230 GHz along the principal axis *x*. The signals are regularly spaced, with a separation of $3D_x$, as expected when close to the high field limit. The intensity of each line results from the interplay between the transition probability and the thermal population of the involved levels. The small signal in the center of the spectrum (8.2 T) is due to an impurity.

Table 1 Main ESR frequencies and corresponding band denomination

Band	*Wavelength* (cm)	*Frequency* (GHz)	*Resonance* ($g = 2$)(T)
L	19	1.5	0.05
S	9.5	3	0.11
X	3	9.5	0.34
Q	0.8	35	1.3
W	0.3	95	3.4

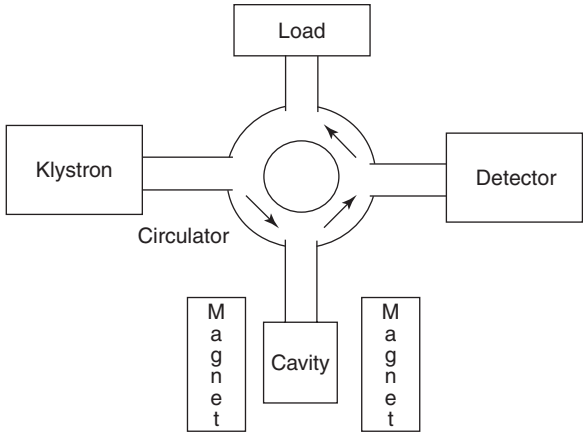

Figure 11 Block diagram showing the main components of an ESR spectrometer.

then directed to a diode detector, associated to a lock-in (detecting the first derivative signal). The parasitic microwaves reflected from the detector are directed to a load which absorbs them. A circulator is used to direct the microwaves from one part to the other.

Pulsed Techniques

Since the early 1970s, important technical advances have led to a renewal of ESR spectroscopy. One of the changes as already mentioned, deals with the development of spectrometers using higher magnetic fields and higher frequencies, whereas the other is the introduction of pulsed methods. Both of these techniques have developed enough to become, at least partially, commercially available. While NMR switched to pulsed operation and looked for higher fields very early, a similar development was not possible for ESR mostly due to the higher frequencies involved in ESR spectroscopy and, for pulsed ESR, the short relaxation times of paramagnetic species.

Basically, pulsed ESR relies on the use of short (typically ~ 1 ns) and powerful (typically $\sim 10^4$ W) microwave pulses to modify the spin distribution and relies on the detection of the time evolution of the perturbed system (free induction decay). Then, the Fourier transformation of the time response gives

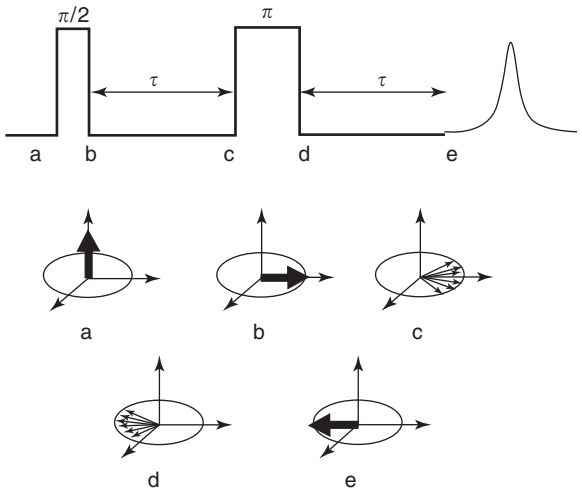

Figure 12 Echo experiment. Upper part showing a two pulse sequence and the echo signal. Lower part showing the corresponding magnetization evolution.

the frequency spectrum. Another important feature of pulsed operation is that the main magnetic field is no more swept; conversely, the microwave field becomes time dependent (pulsed). These experiments give access to time-dependent properties of the system under study, such as relaxation times. The basic experiment, already proposed in the 1960s by Mims, is a simple spin echo measurement (**Figure 12**) and has led to a specialized branch called electron spin echo spectroscopy. Another very important pulsed technique for ESR is known as the electron spin echo envelope modulation (ESEEM; also developed by Mims in 1965), which deals with the nuclear spins coupled to the paramagnetic center. Several pulse sequences have now been developed for ESEEM. More generally, in the same way NMR evolved, more and more pulse sequences are being implemented. Clearly, ESR is turning to Fourier transform ESR, even if it is still very far from the status of NMR where almost only FT-NMR exists.

Electronic Structure (Theory): Atoms

V M Ramaglia, Università degli Studi di Napoli "Federico II," Naples, Italy

Introduction

The analysis of the spectrum of the hydrogen atom has been the starting point of the development of quantum mechanics at the beginning of the twentieth century. The calculation of the energy eigenvalues and of the corresponding eigenfunctions of this one-electron system is simple enough both in nonrelativistic and in relativistic quantum mechanics. When the number of the electrons in the atom increases, an exact solution, such as for the hydrogen atom, is no more possible. A multielectron atom is a many-body system in which the electron–electron interactions together with the fermionic nature of the electrons as identical particles play a fundamental role. It is necessary to introduce some approximations. The majority of these approximations use a spherical self-consistent mean field $V_c(r)$ that includes, in an average way, all the interactions (mainly the electron–electron and electron–nucleus interactions) and in which the electrons move as independent particles. The electrons, being fermions of spin $\hbar/2$, obey the Pauli principle, and this circumstance,

as it will be shown later, allows one to justify the structure of the periodic table of the elements, that is the most important regularity property of the electronic structure of atoms.

The study of the helium atom, which has only two electrons, demonstrates the goodness of the mean-field approach because it provides a very good agreement with experiments from both a qualitative and a quantitative point of view. The choice of a suitable central mean potential depending on the atomic number Z provides a description of the periodic table of the elements. The most important ways to achieve $V_c(r)$ are the Thomas–Fermi, the Hartree, and the Hartree–Fock methods.

To improve this approximation, the nonspherical part of the electron–electron interaction has to be taken into account. The effect of this residual electrostatic interaction can be estimated as a perturbation on the Slater determinants containing the single-particle states of $V_c(r)$. The residual electrostatic interaction mixes these determinants, yielding states with a total angular momentum L and with a total spin S (the orbital angular momentum l and the spin s of the single electrons are no more good quantum numbers).

The spin–orbit coupling gives the fine structure of the levels (multiplets) that are also characterized by the total angular momentum $\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S}$, so that the stationary states of the atom are eigenstates of $\boldsymbol{J}^2$, $\boldsymbol{L}^2$, $\boldsymbol{S}^2$, J_z. The knowledge of the multiplets structure allows the interpretation of the complex spectra of many-electron atoms also in the presence of electrical and magnetical fields.

The Helium Atom

The Hamiltonian of the two electrons that includes only the electrostatic interactions after the separation of the center-of-mass motion, is

$$H = \sum_{i=1}^{2}\left(-\frac{\hbar^2\nabla_{r_i}^2}{2\mu} - \frac{Ze^2}{r_i}\right) + \frac{e^2}{|\boldsymbol{r}_1 - \boldsymbol{r}_2|} - \frac{\hbar^2}{M}\nabla_{r_1}\cdot\nabla_{r_2} \qquad [1]$$

The nucleus, in the origin, has mass M and charge $+Ze$, the electrons have the reduced mass $\mu = Mm/(m+M)$ (m is the electronic mass), positions $\boldsymbol{r}_1$, $\boldsymbol{r}_2$ and charge $-e$. In eqn [1], the terms $\hbar^2\nabla^2/2\mu$ are the kinetic energies of the relative electronic motion; the electron–electron interaction $e^2/|\boldsymbol{r}_1 - \boldsymbol{r}_2|$ screens the external Coulomb nuclear potential $-Ze^2/r$. The last term in eqn [1] represents the mass polarization term which, in the first approximation, will be neglected.

A mean spherical field $V_c(r)$ can be obtained by substituting Z with an effective charge Z_{eff}. This charge is estimated within a variational approach using, for the ground state, the trial wave function

$$\psi(r_1, r_2) = \frac{1}{\pi a^3}\,\mathrm{e}^{-(r_1+r_2)/a}\chi_{00}(1,2)$$

where the single-particle ground state of the potential $-Z_{\text{eff}}e^2/r$ appears ($a = \hbar^2/Z_{\text{eff}}me^2$). Here, $\chi_{00}(1, 2)$ is the singlet spin wave function of the total spin $\boldsymbol{S}$. The addition of two 1/2 spins gives a singlet state $S = 0$, $M_s = 0$ and a triplet state $S = 1$, $M_S = 0, \pm 1$

$$\begin{aligned}
&\chi_{00}(1,2) = \tfrac{1}{\sqrt{2}}(\alpha(1)\beta(2) - \beta(1)\alpha(2))\\
&\chi_{10}(1,2) = \tfrac{1}{\sqrt{2}}(\alpha(1)\beta(2) + \beta(1)\alpha(2))\\
&\chi_{11}(1,2) = \alpha(1)\alpha(2), \qquad \chi_{1-1}(1,2) = \beta(1)\beta(2)
\end{aligned} \qquad [2]$$

where α is the spin-up state, β the spin-down state, while the numbers 1 and 2 distinguish the electrons. The fermionic wave function is totally antisymmetric, having a spatial part symmetric (exchanging the coordinates) and a spin part antisymmetric (exchanging the spins). The minimization of the energy provides the following effective charge:

$$Z_{\text{eff}} = Z - \tfrac{5}{16} \qquad [3]$$

In **Table 1**, the ground-state energies calculated with the variational method are compared with those estimated from experiments for three different two-electron systems (He, Li^+, and Be^{2+}). As it can be seen, the central-field approximation overestimates the electron–electron repulsion.

An improvement has been obtained by Hylleraas and Kinoshita using trial wave functions (depending on $r_1 + r_2$, $r_1 - r_2$, and $|\boldsymbol{r}_1 - \boldsymbol{r}_2|$), that take into account the correlation between the electrons. The density probability of such wave functions is no more the product of two independent functions of r_1 and r_2. When the mass polarization, the relativistic, and the radiative effects are included, the agreement between theory and experiment is within the experimental error, as **Table 2** shows.

The independent-particle scheme applies to the excited states too. The lowest-lying excited states

Table 1 Values of the ground-state energy of two-electron He atom and ions in eV. Z is the atomic number, E_0 the energy without the electron–electron interaction (with only the Coulomb field of the nucleus), E_{var} the variational estimate (with $Z_{\text{eff}} = Z - 5/16$), and E_{exper} the experimental value

	Z	E_0	E_{var}	E_{exper}

correspond to the couple of single-particle states:

$$\psi_{100}(\boldsymbol{r}),\ \psi_{nlm}(\boldsymbol{r}) \qquad [4]$$

where n is the principal quantum number, $l(l+1)\hbar^2$ is the eigenvalue of the orbital angular momentum operator $\boldsymbol{l}^2$, $m\hbar$ the eigenvalue of the operator l_z. Now, a two-independent-particle state (totally antisymmetric) can have either the singlet or the triplet spin part

$$\begin{aligned}\Phi^+_{nlm} &= \tfrac{1}{\sqrt{2}}(\psi_{100}(\boldsymbol{r}_1)\psi_{nlm}(\boldsymbol{r}_2) \\ &\quad + \psi_{100}(\boldsymbol{r}_2)\psi_{nlm}(\boldsymbol{r}_1))\chi_{00} \\ \Phi^-_{nlmM_S} &= \tfrac{1}{\sqrt{2}}(\psi_{100}(\boldsymbol{r}_1)\psi_{nlm}(\boldsymbol{r}_2) \\ &\quad - \psi_{100}(\boldsymbol{r}_2)\psi_{nlm}(\boldsymbol{r}_1))\chi_1 M_S\end{aligned} \qquad [5]$$

Starting from the Coulomb nuclear potential $-Ze^2/r$, these states have the energy eigenvalues

$$E_n = -\frac{Z^2e^2}{2a_0}\left(1+\frac{1}{n^2}\right), \quad a_0 = \frac{\hbar^2}{me^2} \qquad [6]$$

on which the electron–electron interaction e^2/r_{12} has to be included. The degeneracy with respect to l and between triplet and singlet states is removed with the energy shifts

$$\begin{aligned}\varepsilon^\pm_{nl} &= \int \mathrm{d}^3r_1 \int \mathrm{d}^3r_2 |\psi_{100}(\boldsymbol{r}_1)|^2 |\psi_{nlm}(\boldsymbol{r}_2)|^2 \frac{e^2}{r_{12}} \\ &\quad \pm \int \mathrm{d}^3r_1 \int \mathrm{d}^3r_2 \psi^*_{100}(\boldsymbol{r}_1)\psi^*_{nlm}(\boldsymbol{r}_2) \\ &\quad \times \psi_{100}(\boldsymbol{r}_2)\psi_{nlm}(\boldsymbol{r}_1)\frac{e^2}{r_{12}} \\ &= I_{nl} \pm K_{nl}\end{aligned} \qquad [7]$$

where the signs + and − are relative to singlet and triplet states, respectively.

The first integral is called the Coulomb (or direct) integral. It represents the Coulomb interaction between the charge distributions of the two electrons. The integral K is known as the exchange integral and does not have a classical analog. Since the Coulomb integral is positive and being in the general case $K_{nl} > 0$, it turns out that a spin triplet state has a lower energy than the corresponding spin singlet state with the same n and l quantum numbers. Although the Hamiltonian does not contain spin-dependent terms, the purely electrostatic electron–electron interaction removes the spin degeneracy. The exchange term is much stronger than the spin-dependent terms arising from relativistic effects, such as the spin–orbit interaction. In fact, as Heisenberg first observed, the exchange term is strong enough to keep the electron spins aligned in certain solids, giving rise to the phenomenon of ferromagnetism.

Figure 1 shows the splitting of the unperturbed helium level for $n = 2$. In the electric dipole approximation, the transitions between the singlet states and the triplet states are forbidden and the most intense helium spectral lines belong to two independent families and apparently two different kinds of helium exist: the orthohelium (with $S = 1$) and parahelium (with $S = 0$).

When $n \to \infty$, then I_{nl} and K_{nl} go to zero and the first ionization limit of two-electron atoms (ions) is reached on the energy $E_\infty = -Z^2e^2/2a_0$ (see eqn [6]). The crude approximation of noninteracting electrons yields, for higher-energy excited bound states with n, $n' > 1$, the levels

$$E_{nn'} = -\frac{Z^2e^2}{2a_0}\left(\frac{1}{n'^2}+\frac{1}{n^2}\right) > E_\infty \qquad [8]$$

These levels are degenerate with the continuous energy spectrum of the ion starting from E_∞. The electron–electron interaction induces radiationless transition between the bound state and the scattering state. These doubly excited states are called autoionizing states because they can de-excite losing one of the electrons. The phenomenon of autoionization is known as the Auger effect. Not only helium-like

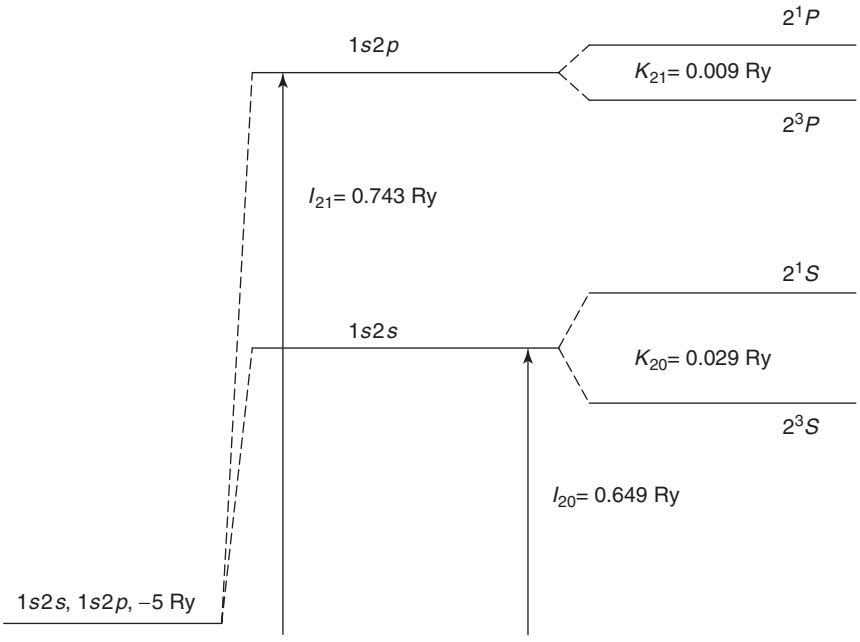

Figure 1 Splitting of the first unperturbed excited state $n=2$ of the He by the electron–electron interaction. The Coulomb and exchange integrals are given in Rydberg (1 Ry = 27.2116 eV).

(ions) but all atoms or ions with two or more electrons have such autoionizing states.

The Periodic Table of the Elements

The Hamiltonian of an atom with Z electrons without relativistic spin-dependent terms and external fields is

$$H = \sum_{i=1}^{Z}\left(\frac{p_i^2}{2m} - \frac{Ze^2}{r_i}\right) + \frac{1}{2}\sum_{i=1}^{Z}\sum_{j(\neq i)=1}^{Z}\frac{e^2}{|\boldsymbol{r}_i - \boldsymbol{r}_j|} \quad [9]$$

The ground state and the first excited states can be described using a mean central field $V_c(r)$, in which the electrons move as independent particles. In this approximation

$$H \simeq H_c = \sum_{i=1}^{Z}\left(\frac{p_i^2}{2m} - V_c(r_i)\right) \quad [10]$$

and the overall effect of the electrons is to screen the Coulomb nuclear field more and more increasing the distance from the nucleus: near the nucleus $V_c(r)$ is of the form $-Ze^2/r$ and very far from it, $V_c(r) \simeq -e^2/r$. The screening can be represented by an effective charge depending on the distance r and the spherical mean field is no more Coulombian

$$V_c(r) = -Z_{\text{eff}}(r)e^2/r \quad [11]$$

The eigenstates of H_c are the Slater determinants $Z \times Z$ that can be formed with the single-particle states $|nlm_l m_s\rangle$ which are eigenstates of $p^2/2m + V_c(r)$, of the orbital momentum operators $\boldsymbol{l}^2$, l_z, and of spin z-component σ_z. The single-particle energy levels e_{nl} have a $2(2l+1)$ degeneracy $(-l<m_l<l,\ m_s = \pm 1/2)$. The central potential V_c changes with the atomic number Z but the order in the levels sequence e_{nl} is nearly the same for all the atoms and it is shown in **Table 3**.

The total energy is the sum of the individual energy levels and the Pauli principle allows the occupancy with only one electron of the state $|nlm_l m_s\rangle$. The distribution of the electrons with respect to the quantum numbers n and l is called the electron configuration. The states with the same n and l form a subshell, the subshells with the same n form a ;shell. The ground state of an atom has a configuration with filled (closed) subshells, each containing $n_i = 2(2l+1)$ electrons and an open subshell with $n<n_i$ electrons (called equivalent). A subshell has a degeneracy:

$$d_i = \frac{n_i!}{n!(n_i - n)!}$$

the closed subshells have $d_i = 1$.

As an example, the ground state of the carbon atom $Z=6$ has the configuration $1s^2 2s^2 2p^2$. The subshells $1s$, $2s$ are nondegenerate while the subshell $2p$ has a degeneracy:

$$\frac{6!}{2!4!} = 15$$

The total degeneracy of the ground state is $1 \times 1 \times 15 = 15$.

Table 3 The ordering of the single-particle energies of each subshell. The energy increases from bottom to top. The levels enclosed in the square brackets have very similar energies and their order can change by varying the atomic number Z

The last tightly bound electrons, which are in the subshell of the highest energy, and are in an insufficient number to form another closed subshell, are called valence electrons. They are responsible for the bondings between the atoms in the molecules.

All the information that is needed to discuss the electronic structure and the "building up" (aufbau) of atoms is on hand now.

The list of the elements begins with hydrogen that has an ionization potential of 13.6 eV. The next element is helium that has the largest ionization potential (24.59 eV). The configuration $1s^2$ corresponds to the closed shell $n = 1$. There are no valence electrons and helium is the first inert rare gas. The third element is lithium (the first alkali atom) with the ground-state configuration $1s^2 2s^1$. If the screening of the closed $n = 1$ shell were perfect, the ionization potential would be $13.6/4 = 3.4$ eV ($Z_{\text{eff}} = 1$); but the electron–electron potential reduces Z_{eff} and rises the ionization potential to 5.39 eV. Berillium has a configuration $1s^2 2s^2$. The ionization potenial is larger (9.32 eV) because of the increase of the nuclear charge. The subshell $2p$ is progressively filled starting from boron ($Z = 5$) up to neon ($Z = 10$), for which the shell $n = 2$ is full. Neon is the second inert rare gas for which the ionization potential is increased up to 21.56 eV. From $Z = 11$ (sodium, the second alkali atom) to $Z = 18$ (argon, the second rare gas), the subshells $3s$ and $3p$ are progressively filled. The filling of the shell $n = 3$ is interrupted at $Z = 19$ (potassium, third alkali element) because the level $4s$ is lower in energy than the $3d$ level that starts to be filled after the $4s$ from scandium ($Z = 21$) to zinc ($Z = 30$). There is a competition between the levels $4s$ and $3d$ that are very close in energy and the filling is not so regular as for the elements with lower atomic numbers. The elements with an incomplete $3d$ subshell belong to the first transition or iron group. The higher incomplete subshells of chromium ($Z = 24$) correspond to the state $[\text{Ar}]4s^1 3d^5$ ([Ar] stands for the noble gas argon configuration $1s^2 2s^2 3s^2 3p^6$) that is energetically more favorable to the $[\text{Ar}]4s^2 3d^4$ configuration. The high number of valence electrons allows the very rich class of molecules that can be formed with chromium. The filling competition between the subshells $5s$ and $4d$ characterizes the second transition or palladium group (from $Z = 39$ (yttrium) to $Z = 48$ (cadmium)), and the third transition or platinum group (from $Z = 71$ to $Z = 80$ (mercury)) corresponds to the irregular filling of the states $6s$ and $5d$. The list of elements ends with the actinides beginning from $Z = 89$ (actinium) in which a competition occurs between $5f$ and $6d$ states. The $Z = 103$ (lawrencium) is the element with the largest atomic number because the actinides are radioactive elements with highly unstable nuclei that decay by spontaneous fission into lighter elements.

The list of the elements can be organized in a table by arranging the elements with similar outer subshells in columns. All the alkali metals have a single weakly bound electron in a subshell s ($2s$ Li, $3s$ Na, $4s$ K, and so on). All the halogens (F, Cl, Br, I) have a subshell p^5 lacking only one electron. The alkalis and the halogens have high chemical reactivities because they can reach more stable energetic arrangements, losing or acquiring an electron in such a way as to form completely filled subshells. The last column of the table contains the rare gases (He, Ne, Ar, Kr, Xe, and Rn).

The recurrences of similar chemical properties led Mendeleev in 1869, long time before the existence of the electrons and the nuclei were known, to classify the elements in the periodic table. He placed elements with similar chemical properties in the same column. The chemical properties change progressively along the rows, which are called periods. There are seven periods and each of the periods begins with an alkali element and ends with a noble gas atom, except for the seventh period, which is incomplete.

The ionization potential increases along a period and has a sudden drop passing from a noble gas to the alkali of the next period (**Figure 2**).

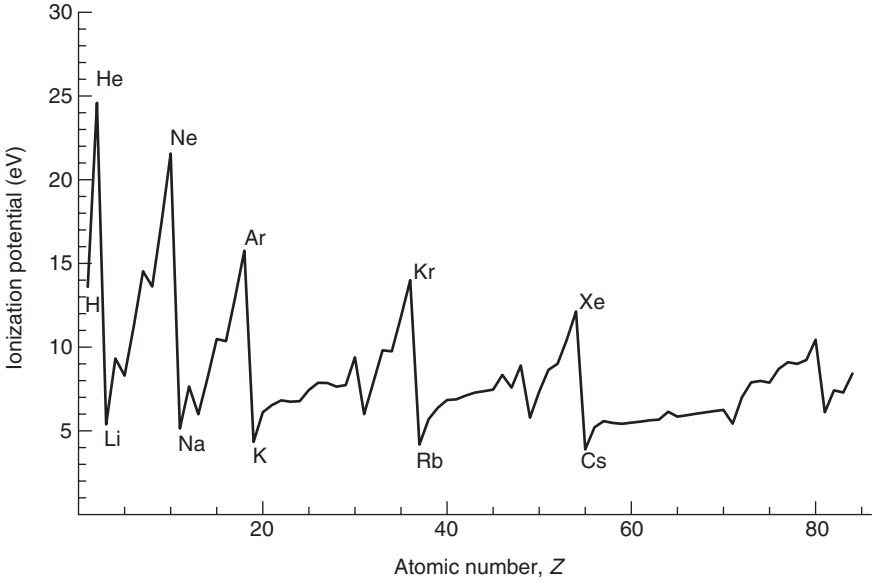

Figure 2 The first ionization potential against the atomic number.

Beyond the Central-Field Approximation

There are two main corrections to the approximate Hamiltonian H_c. The first one is the correlation due to the electron–electron interaction

$$\begin{aligned} H_1 &= H - H_c \\ &= -\sum_i \frac{(Z - Z_{\text{eff}}(r_i))e^2}{r_i} + \frac{1}{2}\sum_{i,j(j\neq i)} \frac{e^2}{r_{ij}} \\ r_{ij} &= |\boldsymbol{r}_i - \boldsymbol{r}_j| \end{aligned} \qquad [12]$$

that is called the residual electrostatic interaction and is no more spherically symmetric. The second correction is the spin–orbit term that, within the central field approximation, is

$$\begin{aligned} H_2 &= \sum_i \xi(r_i)\boldsymbol{l}_i \cdot \boldsymbol{s}_i \\ \xi(r_i) &= \frac{1}{2mc^2}\frac{1}{r_i}\frac{\mathrm{d}V_c(r_i)}{\mathrm{d}r_i} \end{aligned} \qquad [13]$$

If the spin–orbit coupling terms are neglected, the effect of the residual electrostatic interaction can be evaluated treating H_1 as a perturbation on H_c. The ground state and the first excited states of H_c are strongly degenerate and the levels of H can be obtained by diagonalizing H_1 in the subspace S_0 of the lowest eigenvalue E_0 of H_c. As an example, the subspace S_0 of the ground state of the carbon atom contains 15 Slater 6×6 determinants formed with the four states of the two closed subshell $1s^2$ and $2s^2$ and two states of the incomplete $2p$ subshell, namely,

$$\left|-1, \tfrac{1}{2}\right\rangle,\ \left|-1, -\tfrac{1}{2}\right\rangle,\ \left|0, \tfrac{1}{2}\right\rangle,$$
$$\left|0, -\tfrac{1}{2}\right\rangle,\ \left|1, \tfrac{1}{2}\right\rangle,\ \left|1, -\tfrac{1}{2}\right\rangle$$

where the first number is the eigenvalue of l_z, the second one that of s_z (in units $\hbar$). The subspace S_0 is called a multiplet. The multiplet is spanned by the eigenvalues of the angular orbital momenta $\boldsymbol{l}_i$ and of the spins $\boldsymbol{s}_i$ of the single-particle levels of the central potential $V_c(r)$. If the overall electron–electron interaction is taken into account, only the total angular momentum $\boldsymbol{L} = \sum \boldsymbol{l}_i$ commutes with H, while the single angular orbital momenta are not conserved (H is invariant only under overall rotations). The perturbation H_1 is diagonal in the multiplet basis $\{\boldsymbol{L}^2, L_z, \boldsymbol{S}^2, S_z\}$ whose vectors $|\alpha LSM_LM_S\rangle$ are eigenvectors of the total orbital momentum and the total spin, and the quantum number α labels the different vectors having the same total angular momentum and total spin. The use of this basis, that has the symmetries of the total Hamiltonian H, greatly simplifies the diagonalization of H_1

$$\begin{aligned} &\left\langle \alpha' L' S' M_L' M_S' | H_1 | \alpha L S M_L M_S \right\rangle \\ &\quad = \delta_{LL'}\delta_{SS'}\delta_{M_L M_L'}\delta_{M_S M_S'} V_{\alpha\alpha'}^{(LS)} \end{aligned} \qquad [14]$$

and one needs only to diagonalize the matrices $V_{\alpha\alpha'}^{(LS)}$ corresponding to each pair of quantum numbers LS. The complete electron–electron interaction does not remove the degeneracy with respect to M_L and M_S because H_1 has an overall spherical symmetry and it

does not have a preferential direction. The levels LS (generally denoted as ${}^{2S+1}C$, C being the capital letter S for $L=0$, P for $L=1$, D for $L=2,\ldots$) are left by the residual electrostatic interaction with a $(2L+1)(2S+1)$ degeneracy.

The vectors $|\gamma LSM_LM_S\rangle$ can be constructed by summing up the single orbital momenta $\boldsymbol{l}_i$, and the single spins $\boldsymbol{s}_i$. The Slater determinants spanning the subspace $\boldsymbol{S}_0$ have to be mixed with each other to form the eigenstates of the basis $\{\boldsymbol{L}^2, L_z, \boldsymbol{S}^2, S_z\}$. The antisymmetry of the wave function forbids some values of L and S compatible with the single-particle angular momenta addition. Returning to the example of the carbon atom ground state and setting aside the Pauli principle, the addition of the single-particle angular momenta of two $2p$ electrons gives the following spectral terms:

$$^3S, ^3P, ^3D, ^1S, ^1P, ^1D$$

that have an overall degeneracy of $3\times 1+3\times 3+3\times 5+1\times 1+1\times 3+1\times 5=36=6\times 6$, while only 15 states are available. It turns out that the terms of this list satisfying the Pauli principle are

$$^3P, ^1S, ^1D$$

as the triplet- and the singlet-spin states are, respectively, symmetrical and antisymmetrical in the exchange of the spins, and as the states S and D, and P are, respectively, symmetrical and antisymmetrical in the interchange of the orbital variables. The number of linearly independent antisymmetrical states is $9+1+5=15$, just the number of the Slater determinants in $\boldsymbol{S}_0$.

Although the perturbation H_1 does not depend on the spin S, the perturbed levels depend on S via the exchange integrals introduced by the two-body operator H_1, such as those that appear in the excited levels of the helium. The repulsive electron–electron interaction decreases with the mutual distance of the electrons, that is, when the orbital part of the wave function becomes more antisymmetrical. The spin part of the wave function is more symmetrical for larger S and, therefore, the orbital part is more antisymmetrical for larger S. The levels of a given configuration are in the order of decreasing total spin (Hund's rule). In the ground state of the carbon atom, the lowest level is the triplet one ^3P, followed first by the singlet ^1D and then by ^1S. These two levels have the same spin multiplicity, but ^1D has an higher orbital momentum and in this state the electrons are farther away and the repulsive effect of electron–electron interaction on it is less.

Subshells that contain the same number of occupied or empty states (holes in the filled subshell) are equivalent to one another. It can be seen that the two subshells with k and $4l+2-k$ equivalent electrons have the same LS terms, so the perturbative corrections due to H_1 are the same.

The addition of the spin–orbit coupling H_2 to the electrostatic correction H_1 gives a less symmetric perturbative correction to H_c: H_1+H_2 commutes with $\boldsymbol{J}=\boldsymbol{L}+\boldsymbol{S}$, but neither with $\boldsymbol{L}$ nor with $\boldsymbol{S}$. The relative importance of H_2 increases rapidly with Z. In the light and medium atoms $|H_1|\gg|H_2|$; in heavier atoms (starting from Pb), $|H_1|$ and $|H_2|$ are of the same order of magnitude. In the first case, H_2 is treated as a small perturbation on LS levels. This scheme is called Russel–Saunders coupling or LS coupling. First, H_1 removes the degeneracy of the linear combinations of Slater determinants corresponding to the values of $\boldsymbol{L}=\sum \boldsymbol{l}_i$ and of $\boldsymbol{S}=\sum \boldsymbol{s}_i$ allowed by the Pauli principle. Then, H_2 gives a different energy eigenvalue to each possible value of J ($J=L+S, L+S-1,\ldots, |L-S|$) with a residual degeneracy of order $(2J+1)$.

The other scheme relatively simple is the jj coupling, where $|H_2|\gg|H_1|$. The Slater determinants are formed using single-particle states perturbed by a spin–orbit interaction on V_c: first, the orbital angular momentum $\boldsymbol{l}_i$ is coupled with the spin $\boldsymbol{s}_i$ as $\boldsymbol{j}_i=\boldsymbol{l}_i+\boldsymbol{s}_i$ by H_2, then H_1 removes the degeneracy between the allowed values of $\boldsymbol{J}=\sum \boldsymbol{j}_i$. The level structure of the ground state of the heavier atoms is intermediate between those given by LS and jj coupling.

It turns out that the matrix elements in the subspace of a level (αLS) with a degeneracy of the order $(2L+1)(2S+1)$ are the same as those of the operator $\gamma(\alpha, L, S)\ \boldsymbol{L}\cdot\boldsymbol{S}$, where $\gamma(\alpha, L, S)$ is a constant characteristic of the unperturbed level:

$$\begin{aligned}&\langle \alpha LSM_LM_S|H_2|\alpha LSM'_LM'_S\rangle \\ &\quad=\gamma\langle \alpha LSM_LM_S|\boldsymbol{L}\cdot\boldsymbol{S}|\alpha LSM'_LM'_S\rangle\end{aligned} \qquad [15]$$

This relationship between the matrix elements of $\sum_i \boldsymbol{l}_i\cdot\boldsymbol{s}_i$ and $L\cdot\boldsymbol{S}$ is proved in the quantum mechanics theory of angular momentum by the Wigner–Eckart theorem. The constant γ is proportional to the average value of $\xi(r)$ on the radial orbital part common to all the single-particle states spanning the subspace of the level. The spin–orbit correction on a closed subshell is null (for this level, $L=S=M_L=M_S=0$). While H_2 is not diagonal in the representation $\{\alpha LSM_LM_S\}$, as $L_xS_x+L_yS_y+L_zS_z$ does not commute with L_z and S_z, it becomes diagonal in the equivalent representation $\{\alpha LSJM_J\}$. Since

$$\boldsymbol{J}^2=\boldsymbol{L}^2+\boldsymbol{S}^2+2L\cdot\boldsymbol{S}=\tfrac{1}{2}(\boldsymbol{J}^2-\boldsymbol{L}^2+\boldsymbol{S}^2) \qquad [16]$$

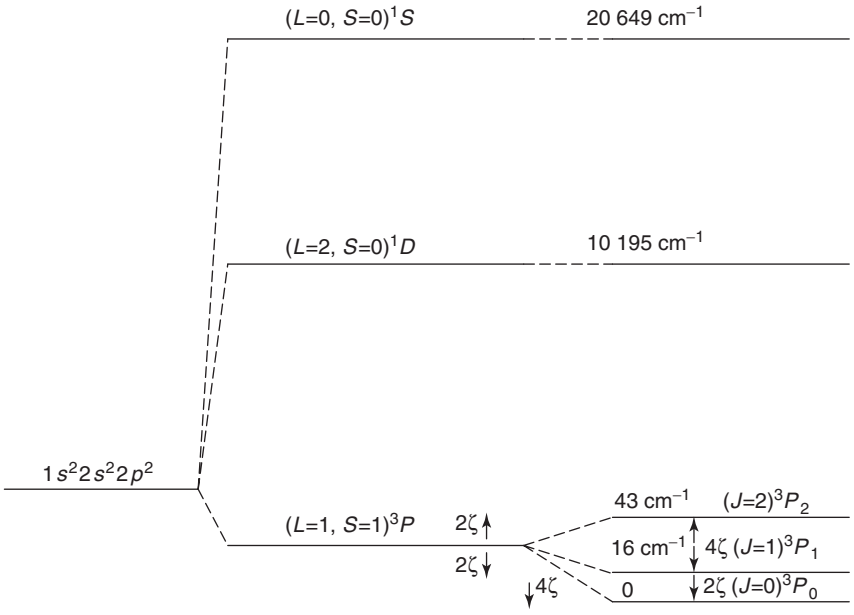

Figure 3 Splitting of the ground-state configuration of the carbon atom due to electrostatic residual interaction and to the spin–orbit coupling. Here $\zeta = \gamma(\alpha, L, S)\hbar^2/2$. The numbers near the levels (in cm^{-1}) are the experimental values of the energy levels. The Landè interval rule is approximately satisfied. The separation between $^3P_0$ and $^3P_1$ gives a value of $\zeta = 8\,cm^{-1}$ and the energy of $^3P_2$, above the ground state $^3P_0$, foreseen by the interval rule is of $6 \times 8 = 48\,cm^{-1}$, a little larger than the measured value of $43\,cm^{-1}$.

one has

$$\begin{aligned}&\left\langle \alpha LSJM_J | H_2 | \alpha LSJM'_J \right\rangle \\ &\quad = \tfrac{1}{2}\gamma\hbar^2(J(J+1) - L(L+1) - S(S+1)) \\ &\quad = E(J)\end{aligned} \qquad [17]$$

and the unperturbed level αLS splits into as many levels as the possible values of $J(= L+S, \ldots, |L-S|)$. The degeneracy of these levels is of the order $(2J+1)$ (**Figure 3**).

The energy separation between adjacent levels $E(J)$ and $E(J-1)$ is proportional to J:

$$\begin{aligned}E(J) - E(J-1) = \tfrac{1}{2}\gamma\hbar^2[&J(J+1) - L(L+1) \\ &- S(S+1) - J(J-1) \\ &+ L(L+1) + S(S+1)] \\ = \gamma\hbar^2 J\end{aligned} \qquad [18]$$

This result is known as the Landè interval rule and is well satisfied experimentally for Z large enough, when among the overall magnetic interactions between the angular momenta

$$a_{ij}\boldsymbol{l}_i \cdot \boldsymbol{s}_j,\ b_{ij}\boldsymbol{l}_i \cdot \boldsymbol{l}_j,\ c_{ij}\boldsymbol{s}_i \cdot \boldsymbol{s}_j$$

only the diagonal terms a_{ii} dominate all the others. For a single open subshell that is less than half-filled, the constant γ is positive and the lowest energy value has the smallest possible value of J. These multiplets are called regular. On the other hand, multiplets that are more than half-filled have $\gamma < 0$, the order with J is turned upside down and they are called inverted. Regular and inverted multiplets have opposite spin–orbit corrections

$$\begin{aligned}&\left| \sum_{k \in \text{filled states}} \boldsymbol{l}_k \cdot \boldsymbol{s}_k \right| \\ &\quad = \left| \left(\sum_{k \in \text{all shell}} - \sum_{k \in \text{empty states}} \right) \boldsymbol{l}_k \cdot \boldsymbol{s}_k \right| \\ &\quad = -\left| \sum_{k \in \text{empty states}} \boldsymbol{l}_k \cdot \boldsymbol{s}_k \right|\end{aligned} \qquad [19]$$

being

$$\left| \sum_{k \in \text{all shell}} \boldsymbol{l}_k \cdot \boldsymbol{s}_k \right| = 0 \qquad [20]$$

When the subshell is just half-filled, there is no multiplet splitting.

Electronic Structure (Theory): Molecules

R Righini, University of Florence, Florence, Italy

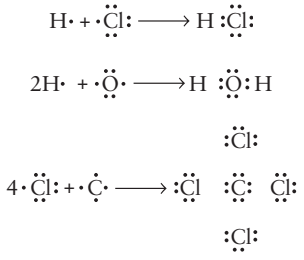
Introduction

In this article, some of the most popular and simple empirical theories of electronic structure and chemical bonding are described. The quantum mechanical treatment is then introduced in a qualitative way, with reference to valence bond and molecular orbital theories. A more detailed description of a quantitative evaluation of molecular properties is also presented.

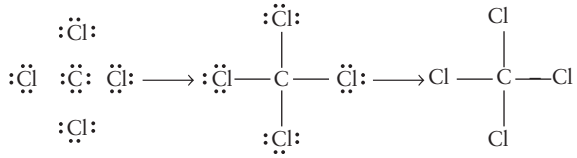
Lewis Theory of Bonding

The description of the electronic structure of molecules in terms of the bonds connecting the constituting atoms is a natural consequence of basic chemical concepts. Historically, the Lewis theory represents the first systematization of the matter.

The basic idea is that chemical bonds are made by sharing one electron pair between two atoms. Thus, the electronic structure of some simple molecules can be represented (each dot represents one electron) as



The bonding electron pairs are generally indicated by a dash (the bond), while the nonbonding pairs (lone pairs) are often omitted:



In a similar way, the Lewis theory describes the formation of double and triple bonds:

In these examples, all the atoms belonging to the first row of the periodic table satisfy, the octet rule, with the exception of hydrogen, that is, they form bonds in such a way that each atom is surrounded by eight electrons. This is, in fact, the most stable electronic configuration, the so-called closed shell configuration characteristic of the noble gas atoms.

Electron Pairs and Molecular Geometry

The Lewis picture of chemical bonding and molecular structure does not account at all for the molecular shape. This is, of course, a fundamental aspect of the molecular electronic structure: it can be introduced along the same phenomenological line as that of the Lewis theory, by using the concept of valence shell electron pair repulsion (VSEPR). This approach provides a simple and efficient tool for rationalizing and predicting the geometry of molecules, starting from their Lewis electronic structure. The VSEPR method is based on a set of simple and essentially empirical rules, with the main assumption that the geometry of a molecule depends only upon the electron–electron interactions. The main points are:

- Atoms in a molecule are bound by bonding electron pairs; multiple bonds consist of more than one set of bonding pairs. The electron pairs not involved in bonds are called lone pairs.
- The general criterion for organizing bonding pairs and lone pairs around any atom in a molecule is that of minimum mutual interaction between electron pairs. This rule comes from the simple and intuitive idea that negatively charged electrons repel each other.

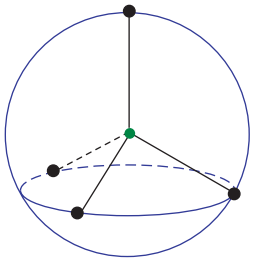
Applying the method requires that the single, double, and triple bonds binding the atoms in the molecule and the lone pairs are first determined on the basis of the Lewis theory. VSEPR then provides the criteria for positioning the bonds in space.

It can be directly and easily applied to molecules containing a central atom and just single bonds, but it can be easily extended to less simple structures.

Elementary geometrical considerations, based on the idea of maximizing the interpair angular distances around the central atom, give the following geometries for the disposition of n electron pairs (disregarding whether bonding pairs or lone pairs):

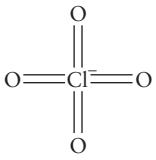
Electron pairs	*Geometry*
2	Linear
3	Trigonal
4	Tetrahedral
5	Trigonal bipyramidal
6	Octahedral

The method fully accounts for the structure of a molecule such as methane CH_4, in which all the H–$\hat{C}$–H angles equal the tetrahedral angle of 109.5°.



Also, the geometry of ammonia NH_3 is correctly predicted (the same as for methane, with one bond replaced by the lone pair sitting on the nitrogen atom). However, the experimental H–$\hat{N}$–H angle in ammonia does not coincide with the tetrahedral angle (107° instead of 109.5°). In order to complete the picture, a further VSEPR rule is introduced, stating that lone pairs require more space than bonding pairs.

In the VSEPR method double and triple bonds are treated, from a geometrical point of view, as single bonds. For instance, the Lewis structure of the perchlorate ion ClO_4^- is



The theory correctly predicts, for this ion, a tetrahedral structure (**Figure 1**), the same that would have been obtained if all the bonds were single bonds.

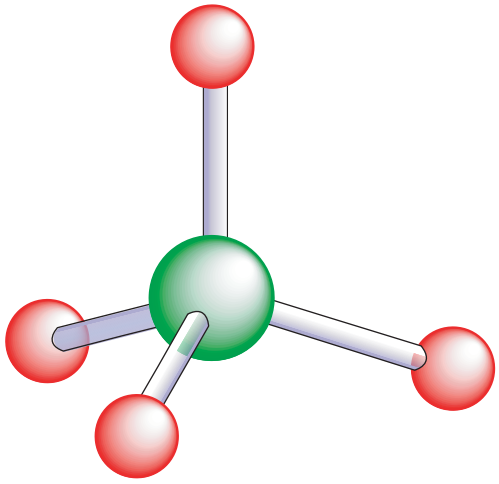


Figure 1 The tetrahedral structure of perchlorate ion.

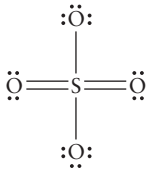
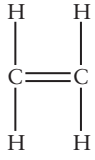
According to VSEPR rules, the same is true in cases where both single and double bonds are present, such as in the sulphate ion SO_4^{2-}, whose Lewis structure is

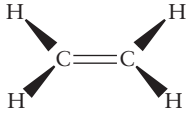


Also in this case, a tetrahedral geometry is correctly predicted.

VSEPR can also be applied to molecules without a central atom: for instance, ethylene C_2H_4 has the Lewis structure



Each carbon atom is surrounded by three bonds (two single bonds and one double bond). The model predicts that the bonds are distributed around each carbon atom according to a trigonal geometry. The overall shape of the molecule is then



with 120° angles between the bonds. Strictly speaking, the planar structure of ethylene molecule cannot be inferred from these simple arguments: its justification requires concepts concerning the nature of the double bonds that can be better understood in the quantum mechanical picture (*vide infra*). This is just one of the limitations of the VSEPR method. It has been already noticed that only approximated values are predicted

for the bond angles; in addition, the method does not tell anything about the length of the bonds. The strength of the method is its simplicity, but it clearly lacks a sound theoretical basis that can justify the overall picture and provide quantitative estimates.

Quantum Mechanical Description of Molecular Electronic Structure

The proper treatment of the electronic structure of atoms and molecules requires adopting the fully quantum mechanical approach. For a molecule, one has to consider a collection of n electrons and N nuclei interacting through the Coulomb potential. The quantum treatment requires that the Schrödinger equation

$$H\Psi = E\Psi$$

for the full system is solved, with the Hamiltonian H containing the kinetic and potential energy of all the electrons and nuclei. In principle then, the eigenfunction Ψ explicitly depends on both electronic and nuclear coordinates.

Here comes the main assumption common to all the generally adopted quantum treatments for molecules: the Born–Oppenheimer approximation. It derives from considering that, since the mass of the nuclei is much larger than that of the electrons, the nuclear coordinates can be considered fixed in the timescale typical of the very fast electronic motions. This assumption allows one to consider just an electronic Hamiltonian H_{el}, which does not contain the kinetic energy of the nuclei. In other words, the positions of nuclei are considered fixed, and the electronic Schrödinger equation $H_{el}\Psi_{el} = E\Psi_{el}$ is solved for the given nuclear geometry. By choosing different sets of nuclear positions, it is possible to follow the dependence of the electronic structure and energy on the nuclear coordinates.

The orbital description of the electronic structure of molecules follows the scheme already adopted for atoms. In the orbital approximation, each electron is assumed as independently described by a wave function, consisting of the product of a function ϕ depending on the spatial coordinates of the electron and of a spin function. The overall wave function of the molecule is then given by the product of the spin-orbitals, that is, of the one-electron wave functions, including the spin functions:

$$\Psi = \phi_1(1)\phi_2(2)\ldots\phi_n(n) \times \text{spin function}$$

There are two main approaches to the quantum mechanical description of the molecular electronic structure: the valence bond (VB) theory and the molecular orbital (MO) theory. Both were formulated in 1927; many of the most common and intuitive concepts of chemical bonding can be found in the VB theory, but the MO theory became more and more popular during the years, being definitely better suited for quantitative estimates of the molecular properties.

Valence Bond Theory

The VB theory can be seen as the translation, in quantum mechanical language, of the basic Lewis ideas on chemical bonding. The basic assumption is that of considering a molecule as formed by atomic "cores" (i.e., atomic nuclei surrounded by inner electrons) and valence (outer) electrons, which are responsible for the formation of chemical bonds. The starting point is the orbital description of the electronic structure of atoms: bonding in molecules occurs via the overlap of two half-filled orbitals of the atoms taking part in the bond formation.

In the case of the hydrogen molecule H_2, there are two nuclei a and b, and two electrons 1 and 2: one possible structure (ϕ_1) is that electron 1 is assigned to nucleus a (in the atomic orbital $1s_a$) and electron 2 to nucleus b (in the atomic orbital $1s_b$). Since the electrons are indistinguishable, the opposite assignment (ϕ_2) is also equally probable. A good wave function (Ψ) for the system is then the linear combination of the two structures ϕ_1 and ϕ_2:

$$\phi_1 = 1s_a(1)1s_b(2), \quad \phi_2 = 1s_a(2)1s_b(1)$$
$$\Psi = c_1\phi_1 + c_2\phi_2$$

By introducing this wave function in the Schrödinger equation, one obtains the two solutions $\Psi_+ = N_+(\phi_1 + \phi_2)$ and $\Psi_- = N_-(\phi_1 - \phi_2)$, where $N_\pm$ is a normalization factor. The corresponding energies are

$$E_+ = \frac{Q + J}{1 + S}, \quad E_- = \frac{Q - +J}{1 - S}$$

where Q is the Coulomb integral $\langle \phi_1|H|\phi_1 \rangle$, J is the exchange integral $\langle \phi_1|H|\phi_2 \rangle$, and S is the overlap given by the integral $S = \langle 1s_a(1)|1s_b(1) \rangle \langle 1s_a(2)|1s_b(2) \rangle$.

The overlap of the $1s$ orbitals to give the H–H bond is shown in **Figure 2**.

The $\Psi_\pm$ functions depend only on the spatial electronic coordinates: the complete wave function is obtained by multiplying the Ψ functions by the appropriate spin function. For the two electrons, there are four possible spin functions:

$$\alpha(1)\alpha(2)$$
$$\beta(1)\beta(2)$$
$$1/\sqrt{2}(\alpha(1)\beta(2) + \alpha(2)\beta(1))$$
$$1/\sqrt{2}(\alpha(1)\beta(2) - \alpha(2)\beta(1))$$

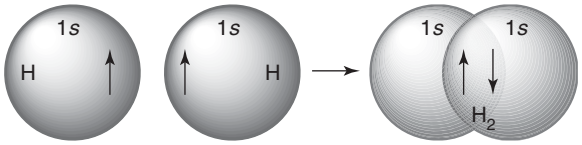


Figure 2 The H–H bond if formed by the overlap of the 1*s* atomic orbitals of hydrogen.

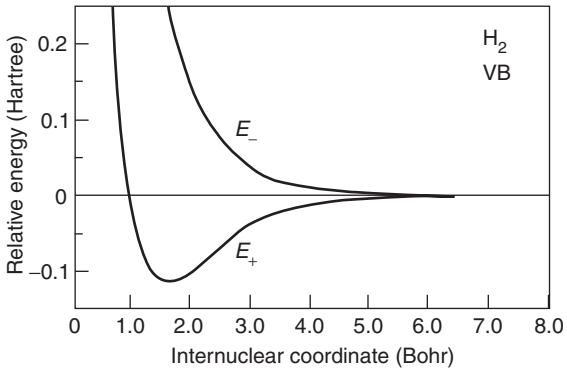

Figure 3 The Ψ_+ wave function corresponds to the bound state of molecular hydrogen: the corresponding energy E_+ has a minimum at the equilibrium internuclear distance. Ψ_- instead is a dissociative state: the E_- energy has no minimum.

The Pauli principle requires that the overall wave function is antisymmetric for the exchange of the coordinates of the electrons. Ψ_+ is clearly symmetric, and can only be multiplied by the antisymmetric spin function (the last one): its spin multiplicity is 1, and Ψ_+ corresponds to the singlet state of the bound atoms. The antysimmetric Ψ_- can be multiplied by any of the other three symmetric spin functions: the corresponding triply degenerate state is a triplet state.

Following the Born–Oppenheimer approximation, the Schrödinger equation can be solved for different interatomic distances; the results for the energies are given in **Figure 3**. Evidently Ψ_+ corresponds to the ground state of the molecule: its (monodimensional) energy surface has a minimum corresponding to the stable molecular structure. E_-, instead, has no minimum, and the corresponding Ψ_- wave function describes a dissociative state.

In the case of atoms with higher atomic number, bonding involves higher orbitals: fluorine for instance, has the atomic structure F: $(1s)^2(2s)^2(2p)^5$; the electrons in the 1*s* and 2*s* orbitals are part of the atomic core; four of the five 2*p* electrons form two nonbonding pairs that occupy two 2*p* orbitals. The third 2*p* orbital contains one unpaired electron, which is available for bonding. The bonding to H to form the hydrogen fluoride HF can be depicted as the overlap of the 1*s* orbital of hydrogen and the 2*p* orbital of fluorine containing one electron (**Figure 4**). In a similar way, the two collinear 2*p* orbitals of two

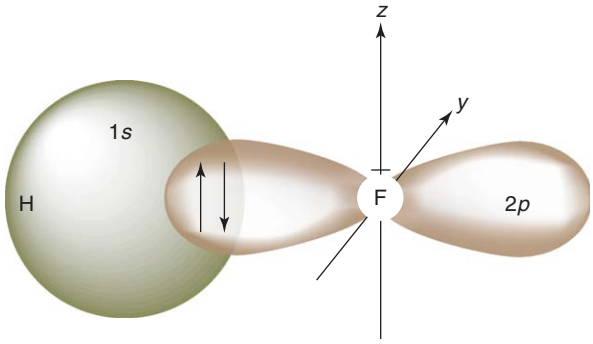

Figure 4 1*s* orbital of hydrogen and one 2*p* orbital of fluorine overlap to accommodate the bonding pair of hydrogen fluoride HF.

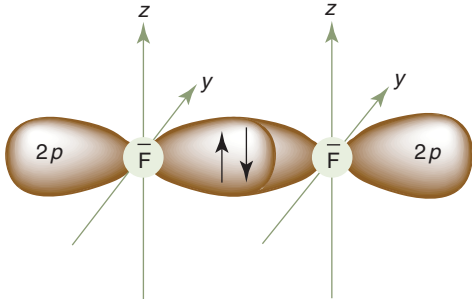

Figure 5 The F–F bond of molecular fluorine F_2 is formed by the overlap of two collinear 2*p* atomic orbitals.

fluorine atoms overlap to accommodate the bonding pair of the F_2 molecule (**Figure 5**).

Hybrid Orbitals

The *p* orbitals being mutually orthogonal, it is evident that the VB picture needs some improvement, in order to account for the trigonal, tetrahedral, octahedral, etc., molecular structures observed experimentally and predicted by the VSEPR method (**Figure 6**). This can be done by introducing the concept of orbital hybridization: the carbon atom provides a good example.

The electronic configuration of the carbon atom is $(1s)^2(2s)^2(2p)^2$; the 1*s* electrons are core electrons and do not take part in bond formation. The four valence electrons are distributed among the available orbitals according to

2*s*	$2p_x$	$2p_y$	$2p_z$
↓↑	↑	↑	

In this configuration, carbon has only two electrons available for pairing. Thus only two bonds are possible. This is obviously in contrast with the existence of compounds such as methane CH_4. The VB solution

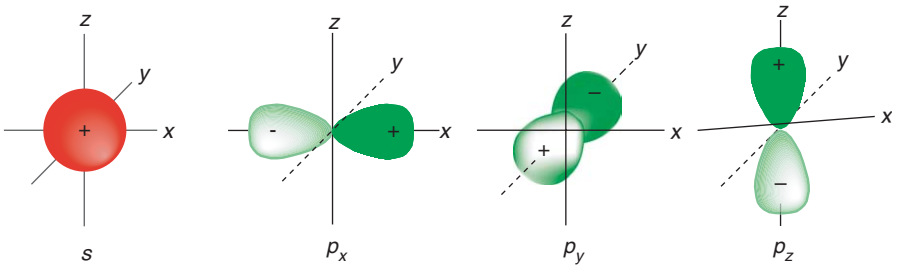

Figure 6 The 2*s* and the three orthogonal 2*p* atomic orbitals.

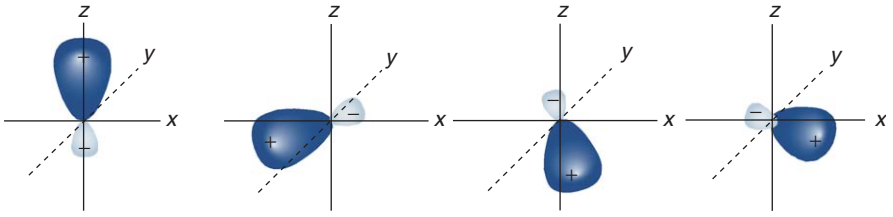

Figure 7 The four hybrid orbitals of sp^3 type, generated by the mixing of the atomic orbitals of **Figure 6**, are directed in the tetrahedral directions.

to this inconsistency is the introduction of hybrid orbitals. The 2*s* and the three 2*p* wave functions mix together yielding four iso-energetic hybrid orbitals of the sp^3 type:

sp^3 orbitals

↑	↑	↑	↑

The sp^3 orbitals are directed along the tetrahedral directions, and each one is occupied by one unpaired valence electron (**Figure 7**). The overlap of the sp^3 hybrid orbitals with the 1*s* orbital of hydrogen leads to the formation of the molecule of methane (**Figure 8**).

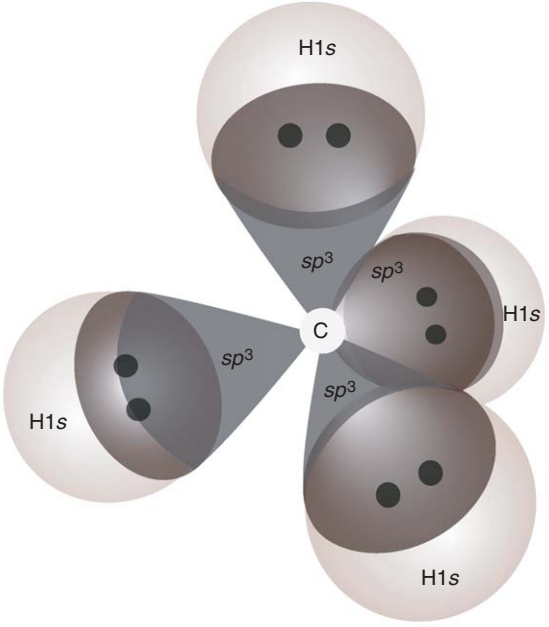

Figure 8 In the VB theory, the tetrahedral geometry of methane CH_4 is attributed to the formation of four *s* bonds involving the sp^3 hybrid orbitals of methane.

σ and π Bonds

In all the bonds considered above, the electron density has a cylindrical symmetry around the line connecting the two bound atoms. Bonds of this type are named σ bonds. There is also a different way of having two atomic orbitals overlapped. Two *p* orbitals, for instance, may overlap sideways, forming a π bond (**Figure 9**).

A good example again comes from the carbon atom. Starting from its electron configuration $(1s)^2(2s)^2(2p)^2$, if two of the three 2*p* orbitals are hybridized with 2*s*, three sp^2 hybrid orbitals are generated, whose lobes are coplanar (with angles of 120°) and directed along the trigonal directions:

2*s*	$2p_x$	$2p_y$	$2p_z$	→	sp^2 orbitals				$2p_z$
↓↑	↑	↑			↑	↑	↑	↑	↑

The three sp^2 hybrid orbitals are used to form three σ bonds per carbon atom in the *xy* plane. This is the case of ethylene C_2H_4 in **Figure 10**.

The remaining $2p_z$ orbitals, orthogonal to the σ bond plane, overlap sideways, giving rise to a bond of π character between the two carbon atoms (**Figure 11**).

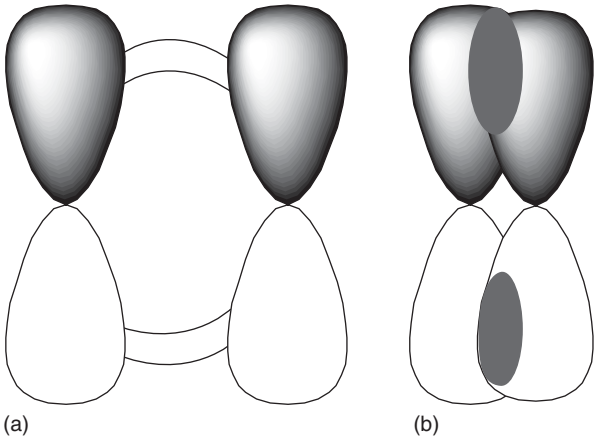

Figure 9 Two 2*p* orbitals overlap sideways to form π bond.

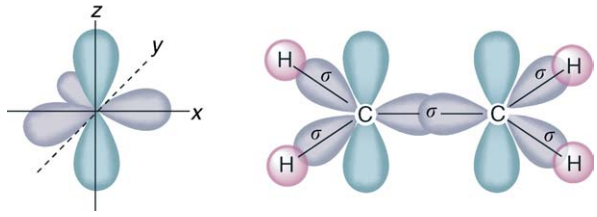

Figure 10 On the left: the sp^2 hybrid orbitals, obtained from 2*s* and two 2*p* atomic orbitals. On the right: the sp^2 hybrid orbitals participate in the formation of the σ type bonds of ethylene molecule.

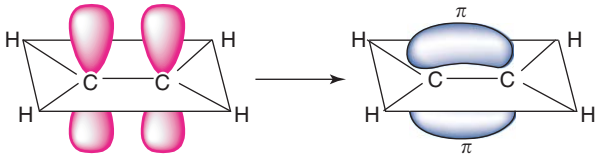

Figure 11 The π bond between the carbon atoms participates in the formation of the double C=C bond of ethylene. Its geometrical constraints force the molecule to assume a planar configuration.

The π bond is characterized by two lobes separated by a nodal plane (the *xy* plane) where the electron density is zero. It is evident that the two CH_2 groups must be coplanar so that the double bond C=C may be set up.

The VB theory translates the most basic concepts of chemical bonding in the language of quantum mechanics; it has been very successful in providing support to essentially empirical theories, such as, the Lewis theory and VSEPR, and has established a large part of the language that chemists use in describing the properties of chemical bonds. The very fast development of computers, however, demonstrated severe limits of the VB approach in applications where quantitative estimates are required: accurate calculations of molecular energies, of excited state structures and dissociation energies, of molecular multipole moments, polarizability, etc, are especially for large molecules, practically not possible in the VB framework. The alternative quantum mechanical approach, the MO theory, acquired more and more popularity for its easy implementation in computer programs: it is now practically the only method in use in the quantum chemistry community.

Molecular Orbital Theory

Differently from the VB theory, the MO theory does not base its treatment on the formation of bonds between the atoms of a molecule. Its goal is, instead, that of describing the distribution of electrons around the atomic nuclei that represent the backbone of the molecule. Each electron is then described by a wave function (the molecular orbital), extended over all the nuclei. The Born–Oppenheimer approximation, allowing for a separation of the timescales of the electron and nuclear motion, is at the basis of the treatment. The Schrödinger equation cannot be solved exactly for polyelectronic molecules: the MO theory employs approximate methods to solve the problem.

The most simple molecule to start with is the hydrogen molecular ion H_2^+. Its electronic Hamiltonian is

$$H = -\frac{1}{2}\nabla^2 - \frac{1}{r_a} - \frac{1}{r_b}$$

where the first term on the right-hand side is the kinetic energy, and the other two terms are the potential energy of the electron in the field of the two nuclei *a* and *b*.

This monoelectronic system is the only molecule for which the Schrödinger equation can be solved exactly; however, it is useful to consider its approximate treatment, since it provides the general scheme for describing the electronic structure of more complex molecules.

The first step is that of choosing a convenient form for the zero-order approximate wave function. It is easily acceptable in the MO spirit, that this function should correspond to the electron "belonging" both to nucleus *a* and to nucleus *b*: a simple form is $\phi = c_a 1s_a + c_b 1s_b$, where only the 1*s* atomic orbitals have been considered. This choice for the basic MO function takes the name of linear combination of atomic orbitals (LCAO); it is a frequent choice, although absolutely not the only one possible.

Minimization of the energy provides the values for the coefficients c_a and c_b, and the resulting orbitals are

$$\phi_1 = N_+(1s_a + 1s_b), \quad \phi_2 = N_-(1s_a(1) - 1s_b(2))$$

($N_\pm$ are normalization factors)

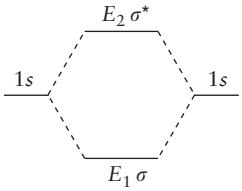
with corresponding energies

$$E_1 = \frac{H_{aa} + H_{ab}}{1 + S_{ab}}, \qquad E_2 = \frac{H_{aa} - H_{ab}}{1 - S_{ab}}$$

with the definition of the integrals

$$H_{ab} = \langle 1s_a | H | 1s_b \rangle, \qquad S_{ab} = \langle 1s_a | 1s_b \rangle$$

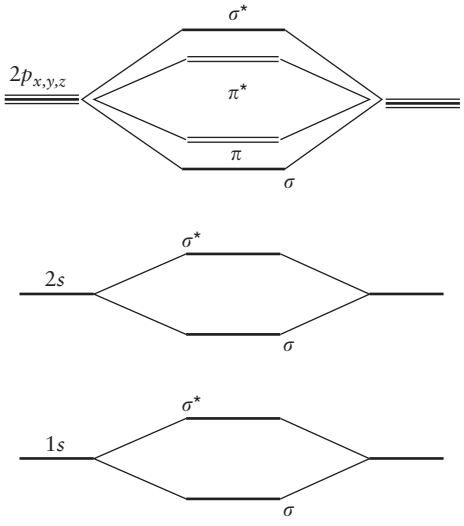
H_{ab} has a negative sign, so that the two VB energy levels are



The shape of the two molecular orbitals is shown in **Figure 12**.

The MO with energy lower than the two 1*s* atomic orbitals is said to be a bonding orbital; the one with higher energy is the antibonding orbital. Both MOs are cylindrically symmetric around the line connecting the bound atoms: they are σ molecular orbitals.

The mechanism of generating molecular orbitals can be extended to the combination of higher energy atomic orbitals 2*s*, 2*p*, etc. If *x* is the internuclear direction, the molecular energy level scheme produced from 1*s*, 2*s*, and 2*p* orbital is



The combination of the $2p_x$ atomic orbitals produces two σ MOs; the $2p_y$ and $2p_z$ atomic orbitals combine sideways, giving rise to two doubly degenerate π orbitals (**Figure 13**).

The extension of the method to the hydrogen molecule H_2 is immediate. With the Hartree assumption, the global electronic molecular wave function is the product of two one-electron wave functions, each one describing one electron in the $\sigma 1s$ bonding orbital:

$$\Psi = \sigma 1s(1)\sigma 1s(2)$$

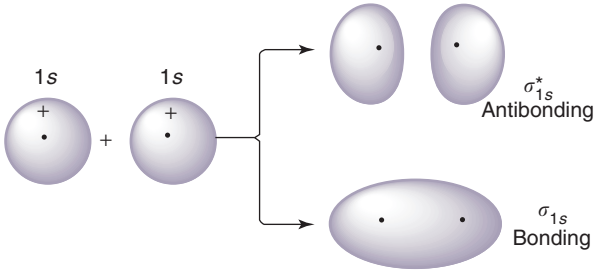


Figure 12 Bonding and antibonding molecular orbitals of H_2^+ molecular ion.

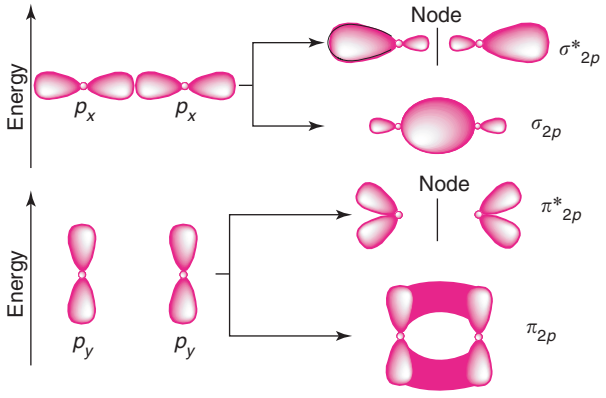

Figure 13 Bonding and antibonding molecular orbitals obtained by linear combination of 2*p* atomic orbitals. Upper figure: σ-type orbitals generated by two collinear 2*p* atomic orbitals; lower figure: π-type orbitals generated by two parallel 2*p* atomic orbitals.

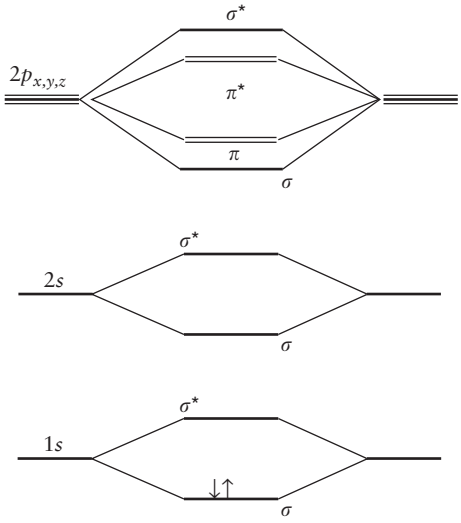
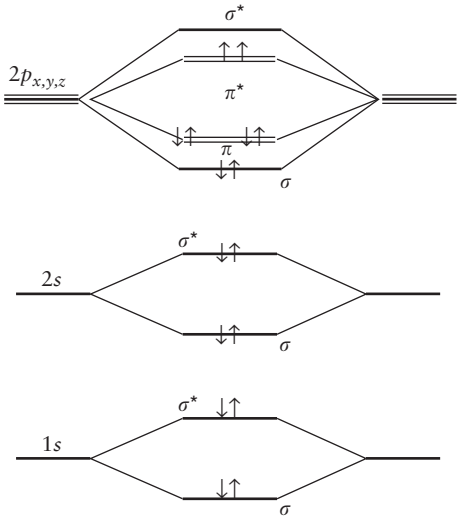
The scheme of molecular orbitals developed for H_2^+ can be extended, in a qualitative way, to other diatomic molecules. Following the same procedure used for atoms, the sequence of molecular orbitals can be filled with the electrons provided by the atoms of the molecule: thus, for molecular hydrogen, one has just two electrons to allocate in the available orbitals; the ground state configuration is then



Similar to atoms, an aufbau principle holds for molecular orbitals also: the levels are filled in an increasing order of energy, respecting the Hund's rule (maximum multiplicity favored) and the Pauli principle (two electrons cannot be described by the same spin–orbital).

For instance, an oxygen atom has eight electrons: there are 16 electrons to be placed in the molecular orbitals given above. The distribution of the electrons in the MO is



The electronic configuration of molecular oxygen is then $(\sigma 1s)^2(\sigma^* 1s)^2(\sigma 2s)^2(\sigma^* 2s)^2(\sigma 2p)^2(\pi 2p)^4(\pi^* 2p)^2$. Note that the two electrons in the highest occupied doubly degenerate π^* orbital have parallel spins (as required by Hund's rule): the ground state of oxygen is then a triplet state, and the molecule is paramagnetic.

From the electronic configuration comes the definition of the bond order: it is defined as one half the number of electrons in bonding orbitals minus the number of electrons in antibonding orbitals. The bond order in an oxygen molecule is then 2.

The MO approach has been particularly successful in explaining the structure of a class of organic molecules called conjugated molecules. These are planar organic molecules consisting of a framework of carbon atoms joined by alternating single and double bonds. A typical example is benzene C_6H_6 (**Figure 14**). The six carbon atoms are at the vertices of a planar hexagon in the *xy* plane; each carbon is bound to two neighbor carbons and to one hydrogen (not shown). The planar structure originates from σ bonds involving the $2p_x$ and $2p_y$ atomic orbitals. The three double bonds in the above figure are due to π orbitals obtained by the linear combination of the $2p_z$ orbitals, orthogonal to the molecular plane.

In reality, all six C–C bonds in benzene are identical (the two bonding schemes in **Figure 14a** are equally probable) and possess properties intermediate between those for single and double bonds. The electron pairs forming the π bonds are not localized between specific carbon atoms but are delocalized over the whole ring (**Figure 14b**). A simple adaptation of the MO theory, called Hückel theory, which takes the σ bonds for granted and describes the π MOs as linear combinations of the $2p_z$ atomic orbitals on each carbon atom, provides a very good explanation of the properties of conjugated molecules.

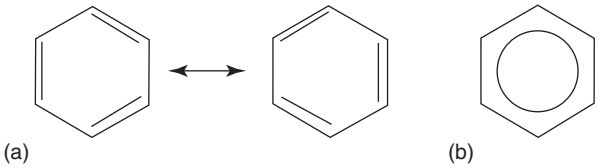


Figure 14 The actual structure of benzene molecule "resonates" between the two structures in (a). The delocalization of the three double bonds is often represented as shown in (b).

The shape of the six MOs, obtained by combining the six $2p_z$ carbon orbitals in the Hückel approximation together with the distribution of the six $2p_z$ electrons in the energy levels, is given in **Figure 15**. The three occupied MOs are bonding orbitals; no electron occupies the antibonding orbitals. The π contribution to the bond order for the six C–C bonds is then 1/2.

The highest occupied molecular orbital (HOMO), and the lowest unoccupied molecular orbital (LUMO) are widely used acronyms indicating the so-called frontier orbitals. In general, the energy difference of the two, and their energy separation from the relative zero-energy determine many spectroscopic and chemical properties of molecules.

The above discussion is very useful for understanding many aspects of the electronic structure of molecules, but is essentially qualitative. For a quantitative treatment, the full electronic Hamiltonian of the molecule must be considered, the necessary approximations introduced, and the solutions at different levels of accuracy discussed and compared.

Molecular hydrogen is the simplest case: the exact electronic Hamiltonian for H_2 is

$$H = -1/2\nabla_1^2 - 1/2\nabla_2^2 - \frac{1}{r_{a1}} - \frac{1}{r_{a2}} - \frac{1}{r_{b1}} - \frac{1}{r_{b2}} + \frac{1}{r_{12}}$$

that can be written as the sum of two one-electron Hamiltonians plus the electron–electron interaction terms $1/r_{12}$, which makes the exact solution of the Schrödinger equation impossible:

$$H = H_1^o + H_2^o + \frac{1}{r_{12}}$$

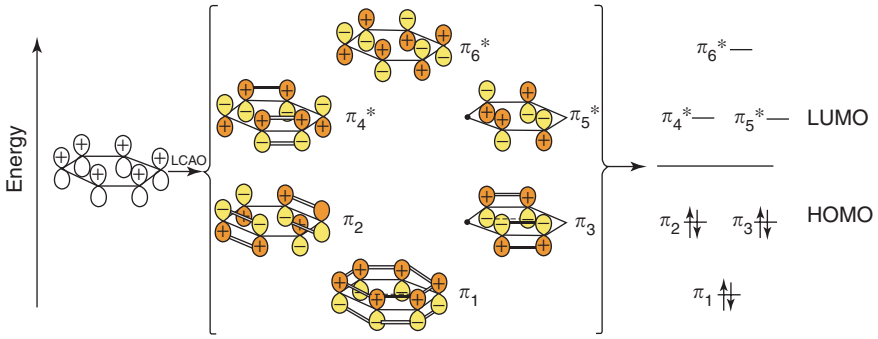

Figure 15 The π molecular orbitals of benzene as described in the Hückel picture. On the right hand side of the figure, the orbital energy levels and their occupancy by the $2p_z$ electrons are shown.

With the Hartree assumption, and following the example of H_2^+, the general form of the molecular wave function is the product of two one-electron orbitals and of an antisymmetric spin function

$$\Phi = \sigma_g 1s(1)\sigma_g 1s(2)\frac{1}{\sqrt{2}}[\alpha(1)\beta(2) - \alpha(2)\beta(1)]$$

With the LCAO assumption, its spatial part is

$$\Phi = N[1s_a(1) + 1s_b(1)][1s_a(2) + 1s_b(2)]$$

The approximate solution is obtained by minimization of the variational integral

$$\langle \Phi|H|\Phi \rangle = 2E_1 + \langle \Phi|1/r_{12}|\Phi \rangle$$

The evaluation of the integral on the right-hand side is the main obstacle. The Hartree–Fock method provides an approximate solution to the problem: it transforms the n-dimensional problem (for a molecule with n electrons) in the solution of n one-electron eigenvalue equations of the type

$$f\phi_i = \varepsilon_i \phi_i$$

where f is the Fock operator, an effective one-electron operator, which includes the mean field generated by all the $n-1$ electrons and acting on electron i.

The ϕ_i functions are generally expressed as a combination of basis functions

$$\phi_i = \sum_s \chi_s c_{si}$$

The basis functions may be atomic orbitals (for the LCAO method), or may have other functional forms (Gaussian, for instance). Generally, a larger number of basis functions ensures a higher accuracy for the results of the calculation. However, the solution of Fock equations requires the evaluation of a large number of integrals involving the basis functions; this poses a practical limitation to the size of the basis set, specially for large molecules. The full Hartree–Fock method, where all the integrals are calculated is named *ab initio* Hartree–Fock method. From it, a number of approximate methods have been developed, in which all or part of the integrals are not explicitly calculated, but are treated as semi-empirical parameters. Methods known with acronyms, such as CNDO, MNDO, MINDO, etc. are widely used, because their computational cost is very low, while providing satisfactory results in many cases.

Electron Correlation

Ab initio Hartree–Fock calculations, nowadays, can be very accurate and reliable, even for large molecules. In addition to the ground electronic structure and energy, knowledge can be gained of the molecular excited states, of the dissociation energies, of the molecular multipoles, and polarizability; the vibrational and electronic spectra can be calculated. There is, however, an important point missing in the Hartree–Fock approach, namely the electron correlation. The Coulomb repulsion between electrons makes them "avoid" each other at any time: this effect is not fully accounted for by the mean-field interelectronic potential adopted in the Hartree–Fock method. Configuration interaction (CI) is one of the most general ways to improve upon the Hartree–Fock theory by taking into account the correlations between electron motions.

The wave function for the ground electronic configuration of the molecule thus includes contributions of the wave functions corresponding to excited configurations. Even for small systems, their number is enormously large. Generally, the CI expansion is limited to the singly and doubly excited configurations, but also with this restriction the method is not applicable to large molecules.

A different approach to electron correlation has become very popular in recent years: the second-order

Møller–Plesset perturbation theory (MP2). The Hartree–Fock Hamiltonian is the unperturbed operator $H^{(0)}$; the perturbation operator $H^{(1)}$ is the difference between the Hartree–Fock and the exact Hamiltonian. The first nonzero term of the perturbation expansion is the second-order correction to the energy $E^{(2)}$; it corresponds to including the contribution of an electron pair excitation, that is, it accounts for the correlation energy between electron pairs. MP2 leads to a simple and tractable expression for the correlation energy that can be easily implemented in computer programs, with satisfactory results for large molecules also.

Density-Functional Theory

An alternative approach to solving the problem of the electronic structure of molecules, which is becoming more and more popular, is the one known as the density-functional theory (DFT). The method is particularly suited for computer implementation, and, most of all, it allows one to include the electron correlation effects in a much simpler and less costly way.

The theory is based on the Hohenberg–Kohn theorem, stating that any molecular property can be expressed in terms of the electron density $\rho(x, y, z)$. Kohn–Sham then demonstrated that the ground-state energy of an n-electrons molecule is expressed in terms of the one-electron density $\rho(1)$ as

$$E_0 = -\frac{1}{2}\sum_{i=1}^{n} \langle \psi_i(1)|\nabla_i^2|\psi_i(1)\rangle - \sum_{\alpha}\int \frac{Z_\alpha \rho(1)}{r_{1\alpha}}\,\mathrm{d}v_1 + \frac{1}{2}\int\int \frac{\rho(1)\rho(2)}{r_{12}}\,\mathrm{d}v_1\mathrm{d}v_2 + E_{\mathrm{xc}}[\rho]$$

where ψ_i are the Kohn–Sham orbitals, Z_α is the nuclear charge, and E_{xc} is the so-called exchange–correlation energy; ρ is a function, then $E_{\mathrm{xc}}[\rho]$ is a functional of the electron density.

In a broad sense, it can be included in the family of the molecular orbital techniques: the Kohn–Sham orbitals are, in fact, obtained by solving equations formally similar to the Fock equations:

$$F_{\mathrm{KS}}(1)\psi_i(1) = \varepsilon_{i,\mathrm{KS}}\psi_i(1)$$

The Kohn–Sham operator contains (like the Fock operator) a mean-field potential term that is expressed as a function of the exchange–correlation energy $E_{\mathrm{xc}}[\rho]$. One important difference is that the electronic correlation contribution can be included from the beginning in $E_{\mathrm{xc}}[\rho]$. In contrast to the Hartree–Fock method, the calculations performed in the DFT do not need any further improvement to include electron correlation, with a remarkable saving of computer time. In spite of the formal similarities, DFT substantially differs from the MO treatment: the latter, in fact, optimizes the results by improving the approximate wave function. DFT, instead, is oriented toward improving the quality of the approximate Hamiltonian, which is eventually solved exactly.

The main drawback of DFT is that the form of the $E_{\mathrm{xc}}[\rho]$ functional cannot be known *a priori*; many efforts have been devoted to formulate convenient forms for this functional, and different "recipes" are now available that have shown a very good heuristic power. The popularity of the method has been growing fast: DFT is now at the basis of *ab initio* treatments of complex systems. For instance, the implementation of DFT techniques made it possible to perform molecular dynamics simulations calculating the forces from first principles: electronic properties of molecules and condensed phases, reaction mechanisms in solution, and structure and dynamics of biomolecules and biological systems (enzymes, for instance) can be investigated at *ab initio* accuracy level.

Electronic Structure Calculations: Plane-Wave Methods

M L Cohen, University of California at Berkeley, Berkeley, CA, USA

Introduction

Understanding the electronic structure of solids is basic to explaining and predicting solid-state properties, but what is an appropriate description of electronic states in solids?

Although it is clear that solids are made of atoms and that one can think of the gas-to-liquid-to-solid transitions as a process in which atoms just get closer together, the electronic properties of solids often differ significantly from what one would expect from a collection of isolated atoms. In cases where the interactions between the atoms are weak, as in the case of rare gas solids, it is reasonable to consider these interactions as perturbations of atomic states. However, when atoms are close to each other in a solid, sometimes they can give up their outermost electrons easily, and it is even possible to end up with a sea of nearly free electrons. In fact, a nearly free-electron model is appropriate for metals such as the alkali metals, aluminum, and many others.

It is also fortunate and useful that this nearly free-electron model applies to a wider class of solids when a few modifications are added. A totally free electron is described by a plane-wave wave function. Hence, if one assumes that the electrons describing a metal behave as if they are nearly free, then a plane-wave position-dependent wave function $\Psi(\boldsymbol{r})$ confined to a box of volume Ω, having a wave vector $\boldsymbol{k}$ which can be written as

$$\psi(\boldsymbol{r}) = \frac{1}{\sqrt{\Omega}} \, e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$$

may be a good starting point for describing the electrons in metals such as sodium. If one examines the resulting electronic density corresponding to a plane-wave wave function, it is constant since it is proportional to $\psi^*(\boldsymbol{r})\psi(\boldsymbol{r})$. Therefore, the collection of atoms with localized wave function on each atomic site and peaked electronic density yields a valence electron density which is vastly different.

What about bonds? For example, covalent bonds arise because electrons tend to concentrate in certain regions between atoms. Can the bonds and charge modulation known to exist in metals and especially in covalent semiconductors be described using plane waves as a starting point? The answer is yes for a broad class of solids. A plane wave is a solution to Schrödinger's equation when the electron–ion and electron–electron potentials are zero. However, when these potentials are included (and if they are not too strong and if the electrons are not strongly correlated), a perturbative scheme can be used to modify the free-electron picture, and this is the "nearly free-electron model" which is described in many textbooks. However, more generally, Schrödinger's equation is solved by diagonalizing a Hamiltonian matrix with appropriate potentials and a basis set composed of plane waves to describe the wave function.

What about alternatives to the nearly free-electron model? The opposite approach to using plane waves is the utilization of atomic wave functions for the basis set. There are tight-binding methods where linearized combinations of atomic orbitals form the basis. This description is also very useful especially when the solid-state wave functions are not too different from the atomic wave functions forming them. If done correctly with sufficient orbitals in the basis set, both the above methods work and are useful.

In the following discussion, the plane-wave basis is featured. In particular, a pseudopotential-density functional approach is described which has been applied successfully to a large number of solids, clusters, nanostructures, and molecules.

The Standard Model of Solids

In **Figure 1**, a schematic picture of a solid is presented where the nuclei and core electrons for the atoms are represented as positive cores and the stripped-off valence electrons are contributed to the electron sea which flows through the periodic array of cores. In this model, the solid system is viewed as having two types of particles: cores and valence electrons. The interaction between the positive cores is taken to be a standard Coulomb interaction describable by Madelung sums. The electron–core and electron–electron

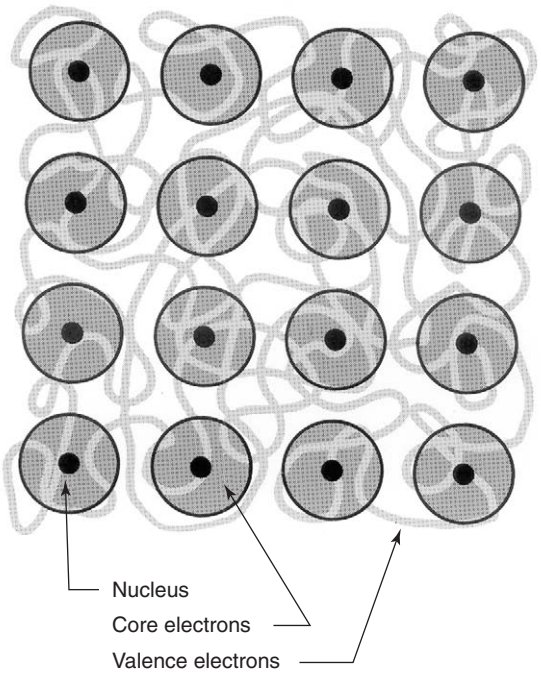

Figure 1 Schematic view of a solid with positive cores at fixed lattice positions in a periodic array and a sea of relatively free valence electrons moving through the lattice.

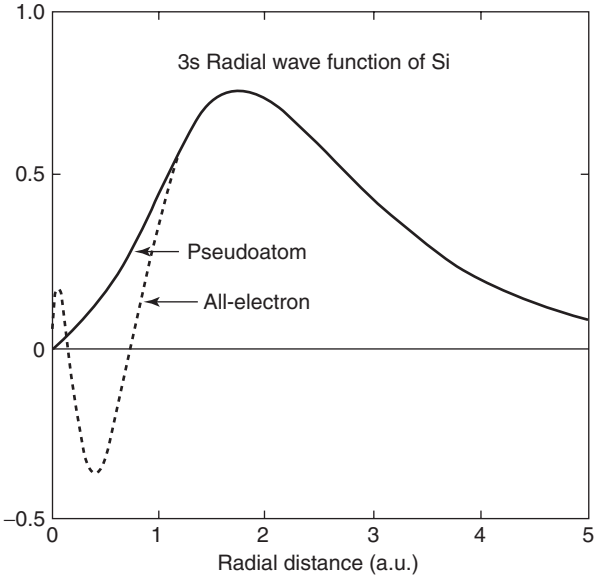

Figure 2 The solid line represents the Si 3*s* pseudo-wave-function resulting from the use of a pseudopotential. The dashed line results from an "all electron" calculation.

interactions are essential inputs to this model. As mentioned above, the form of the standard model of solids, represented by **Figure 1**, which is focused here, will model the electron–core interaction using pseudopotentials and the electron–electron interaction using the density-functional theory – in particular, the local density approximation (LDA).

Pseudopotentials

Arguments for the use and/or appropriateness of a weak electron–core potential have been made since the 1930s. In 1934, Fermi constructed a pseudopotential to describe highly excited electronic states of alkali atoms. His weak potential was designed to yield an accurate description of the outer portions of the wave function and to avoid the more difficult calculation of the properties of the oscillations of the wave function near the core. This would require a strong potential. Since solid-state effects are dominated by the outer portions of atomic wave functions, this is a viable approach for constructing pseudopotentials for solids. As shown in **Figure 2**, a "pseudoatom" wave function is generated which is identical to an "all-electron" 3*s* radial wave function for Si away from the core and smooth near the core. The weak pseudopotential which produced the pseudoatom wave function can be computed from first principles using only the atomic number as input. There are many schemes available for producing these *ab initio* pseudopotentials, which in principle can be constructed for all atoms.

The electron–electron interactions can be approximated using the electronic density. This density-functional approach represents the Hartree and exchange-correlation potentials as functionals of the electronic density. Hence, a self-consistent calculation can be done with a plane-wave basis set, pseudopotentials, and the LDA to density-functional theory. The calculated electronic density can be used to produce LDA potentials which in turn can produce updated wave functions and subsequently, new LDA potentials. This scheme and variants using pseudopotentials and plane waves are often referred to as the "plane-wave pseudopotential method" (PWPM). In general, the method has been extremely successful for determining the electronic structure and many other properties of solids.

Although most modern pseudopotential calculations use *ab initio* pseudopotentials of the type described above, the pseudopotential method went through a semi-empirical stage of development where experimental input was used to generate a potential representing the total valence electron potential (electron–core plus electron–electron). This approach, called the empirical pseudopotential method (EPM), used plane waves and a few Fourier coefficients of the potential which were fit to experimental data. In addition to explaining the origin of the optical structure in the visible and UV in terms of interband electronic transitions and many other properties of solids,

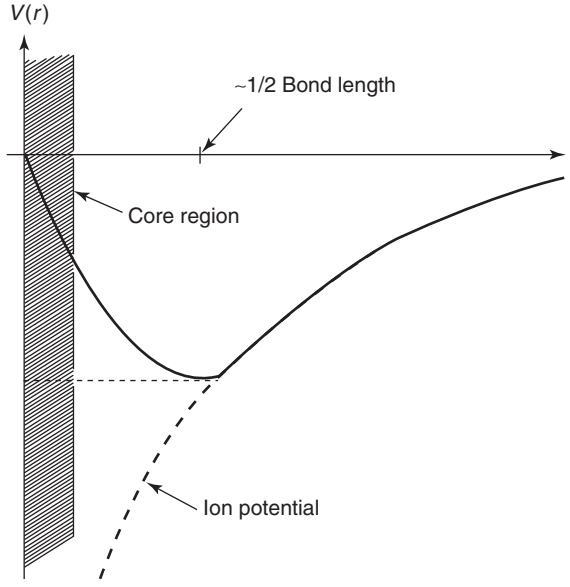

Figure 3 Schematic drawing of a pseudopotential (solid curve) compared to a Coulomb ion potential (dashed line).

the EPM set the stage for the first-principles methods and the standard model.

A schematic real space potential is illustrated in **Figure 3**. The strong ionic Coulomb potential is "cut off" in the core region. The physical origin of the cancelation of the ionic potential in the core region was attributed by Phillips and Kleinman to a repulsive potential arising because of the Pauli exclusion principle preventing the valence electrons from occupying core states. The result is again a weak net potential describable by a few Fourier form factors and a wave function which can be expanded in a plane-wave basis set. Usually, three pseudopotential form factors per atom gave highly accurate electronic band structures.

The EPM was the first successful plane-wave method for real materials with applications to metals, semiconductors, and insulators. Dozens of band structures and optical response functions were calculated with high precision for the first time. The optical spectra of semiconductors were interpreted in terms of critical points in the electronic band structure, and when the wave functions were used to compute the electronic density, the covalent and ionic bonds were pictorially displayed – again for the first time.

In **Figure 4**, a plot of the predicted electronic density for Si is displayed and compared with results based on subsequent X-ray studies. In addition to the striking agreement between theory and experiment, these plots reveal the nature of the covalent bond. It is particularly satisfying to see the local build-up of charge in the Si–Si bond region even though the basis

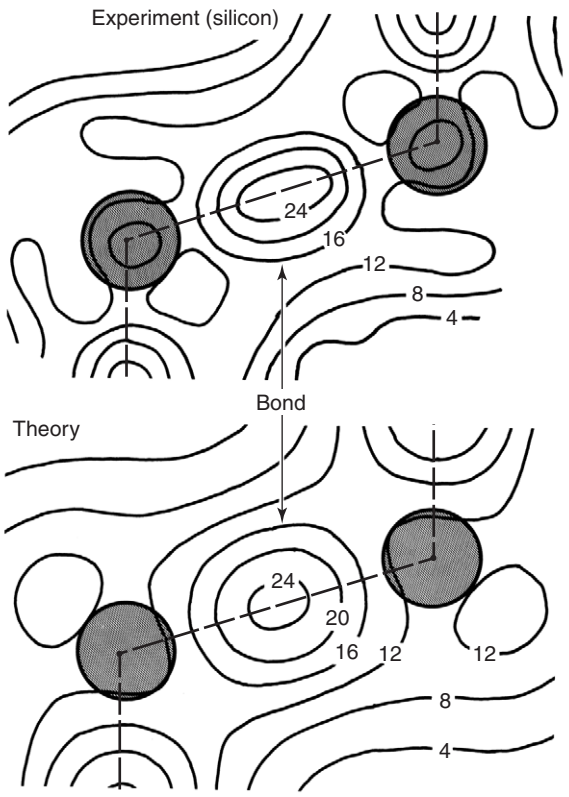

Figure 4 Valence electron density for silicon. The contour spacings are in units of electrons per unit cell volume. The shaded disks represent atomic cores.

set is composed of plane waves which yield a constant density before the potential is "turned on." There is no prior prejudice for this pile-up of charge in the bond region built into the basis set.

Total Energy Calculations and Structural Properties

The EPM calculations were constructed to deal with bulk crystals which were not terminated. Standard techniques, described in textbooks, use periodic boundary conditions to avoid having surfaces or interfaces. The EPM pseudopotential $V(\boldsymbol{r})$ has the periodicity of the lattice so it could be expressed as an expansion using reciprocal lattice vectors $\boldsymbol{G}$:

$$V(\boldsymbol{r}) = \sum_{\boldsymbol{G}} S(\boldsymbol{G}) V(\boldsymbol{G}) \mathrm{e}^{\mathrm{i}\boldsymbol{G}.\boldsymbol{r}}$$

where $S(\boldsymbol{G})$ is the structure factor that locates the atoms relative to a lattice point. It is the form factors $V(\boldsymbol{G})$ which are fit to experiment in the EPM scheme.

In order to deal with surfaces and interfaces, one has to allow charge to redistribute at a surface or interface and break translational invariance. To do

this, the EPM evolved into a scheme where the electron–core and the electron–electron potentials were separated. As in modern calculations, the electron–core potential is referred to as the "pseudopotential" and the electron–electron potential was expressed in terms of the density. In early calculations, the Slater and Wigner approximations were used. This allowed the charge density to readjust to a surface or interface and because of self-consistency, so did the potentials. The surface or interface was modeled by introducing a supercell which contained the geometric configuration of interest. For example, a (1 1 1) Si surface was modeled using a slab containing 12 atomic layers separated from the next slab by an equivalent space with no atoms. The surface of the slab represented the surface of the Si crystal and self-consistency required the rearrangement of the electronic density to correspond to the new geometry. **Figure 5** shows this rearrangement of electron density on an ideal Si (1 1 1) surface in one of the first calculations done with this method. Later calculations used supercells to examine Schottky barriers, heterojunctions, and reconstructions at surfaces and interfaces.

The evolution of the use of the LDA was straightforward since in this approach the electron–electron potentials are expressed as functionals of the electron density. Hence, surfaces, interfaces, and localized configurations in general could be dealt with using supercells and by letting the charge density adjust to the geometric constraints. The use of the PWPM and the LDA also allowed the exploration of other solid-state properties.

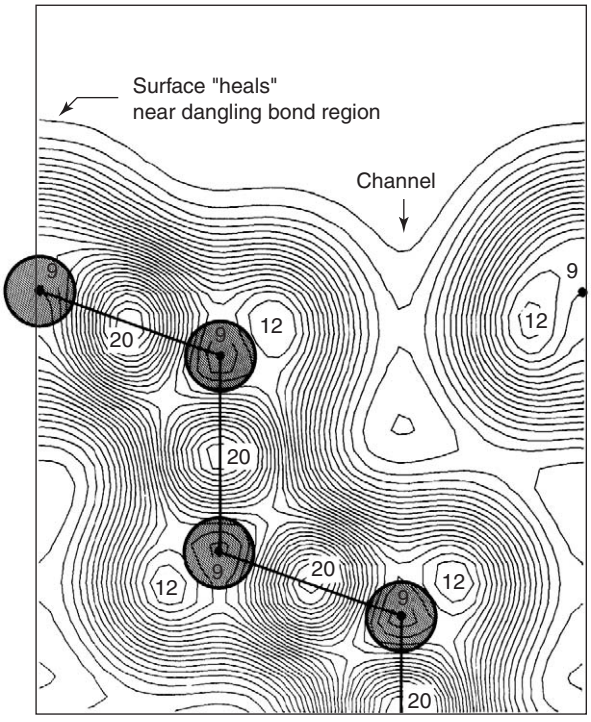

Figure 5 Valence electron density for the ideal Si (1 1 1) surface. Contours are plotted in the perpendicular (1 1 0) plane with units corresponding to one electron per primitive cell. The shaded disks represent atomic cores.

Important applications became possible once a scheme was developed to calculate the total structural energy E_S of the solids for given configurations of the atomic cores. Once E_S is evaluated for a series of candidate structures, a comparison of their structural energies immediately reveals the lowest energy structure for the group. At a given volume, this lowest energy structure would be the most stable structure if all possible structures are considered. Since it is not possible to test all structures, a limitation on this method is the possible omission of the most stable structure. However, in practice, it has often been possible to choose the most likely structures, and the success rate of the PWPM is high for predicting new structures and structural properties. Because E_S depends on volume (or lattice separations), changes induced by pressure can cause solid–solid phase transitions where crystal structures can change. Therefore, calculations of the dependence of E_S on volume can predict transition pressures and volumes for the structural phase changes. Similar calculations for lattice constant changes caused by strains or alloying can yield elastic constants and even vibrational spectra.

Using the standard model with cores and valence electrons as illustrated in **Figure 1**, the total structural energy of the solid can be expressed as

$$E_S = E^{cc} + E^{ec} + E_k^e + E_c^{ee} + E_x^{ee}$$

and all the energy components can be evaluated using the PWPM. The core–core Coulomb energy E^{cc} can be calculated from point–ion sums as discussed earlier, E^{ec} is evaluated using the pseudopotential, and both the Hartree (Coulomb) electron–electron energy E_c^{ee} and the exchange-correlation energy E_x^{ee} can be approximated using the electron density. The electron kinetic energy E_k^e is obtained once the wave function is computed. Therefore, with pseudopotentials and the LDA approximation, the total energy E_S and many ground-state properties can be determined for different structural configurations.

It is convenient to evaluate the above energy contributions to E_S using expressions for the potentials and energies in reciprocal space. An early application was the examination of the ground-state properties of Si. **Figure 6** contains the results for calculations of E_S as a function of volume for seven candidate structures. The volume is normalized by the experimental volume of the diamond phase at atmospheric pressure. Therefore, when the volume is unity, this

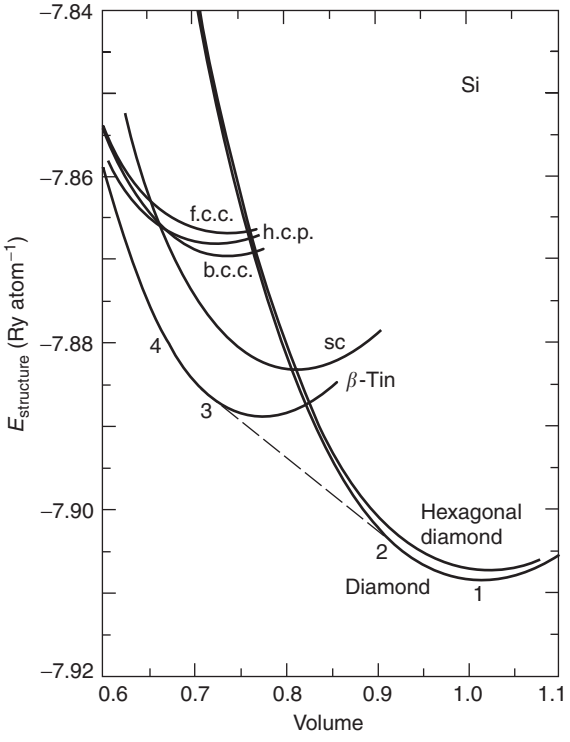

Figure 6 Structural energies for seven structures of Si as a function of volume normalized to the experimental volume at ambient pressure (solid lines). The common tangent represented by the dashed line illustrates the structural transition between the diamond and β-tin structures.

corresponds to ambient pressure and the diamond structure has the lowest energy. As the pressure increases and the volume decreases, it is noted that the hexagonal diamond-structured material is always at a higher energy than the diamond (cubic) structure; therefore, diamond is the more stable phase. At smaller volumes (higher pressures), the β-tin phase has a lower energy than diamond-structured Si, and β-tin is therefore the stable phase. If one views the transition as occurring along the dashed line (**Figure 6**) which is the common tangent between the diamond and β-tin curves, the transition volumes (points 2 and 3) can be evaluated along with the transition pressure which is the slope of the common tangent. These values are all found to be in good agreement with the measured data. In addition, the minimum energy volume for the diamond structure yields a calculation of the equilibrium lattice constant while the curvature of E_S as a function of volume near the minimum energy point yields the bulk modulus or compressibility for Si. In all the calculations, it is assumed that the temperature is zero.

Using the above method, the lattice constants and bulk moduli have been calculated for many solids. Typical accuracies are less than 1% for lattice constants and less than 5% for bulk moduli. Discrepancies between theory and experiment for transition volumes and pressures are normally in the few percent range. In addition, modifications of structures at interfaces and surfaces can also be addressed with this approach. By calculating the changes in energy with movements of specific atoms or by computing Hellmann–Feynman forces, it is possible to determine reconstructions of surfaces and interfaces. In the calculations described above, the only input is the atomic number of the constituent atoms to calculate the pseudopotential and the candidate structure.

Another important application of this method is the determination of vibrational spectra. The method often used within the PWPM is called the "frozen phonon" approach, where the crystal structure is distorted to represent the displaced atoms associated with a particular phonon mode. By comparing the energies of the undistorted and distorted structures or by directly calculating the forces on the atoms, the phonon spectrum can be determined. Here, one needs to input the atomic masses of the constituent atoms as well as their atomic numbers. Again, agreement with experiment is excellent.

Superconductors, Optical Properties, and Novel Materials

A particularly striking success of this approach is its application to superconductivity. The systems considered are expected to be "BCS electron–phonon superconductors." A variation on the frozen phonon method allows a determination of the electron–phonon coupling constants. As described above, the PWPM within the LDA yields ground-state properties with high precision. Since the superconducting transition temperature in the BCS description is extremely sensitive to the strength of the electron–phonon parameter λ and, to a lesser extent, the Coulomb parameter μ^*, it is imperative that the normal-state properties of the material studied be known with high precision. Only a few first-principles calculations of μ^* are available; however, this parameter does not vary a great deal for different materials, and it scales reasonably well with the density of states at the Fermi energy. In contrast, λ can have a much larger variation and therefore the focus for first-principles calculations for superconducting materials has been on the determination of λ.

The enhancement of the effective mass is also related to λ:

$$m^* = m_b(1 + \lambda)$$

where m_b is the band mass calculated without including the electron–phonon interactions. The strong dependence on λ for the superconducting transition temperature, T_c, can be illustrated by equations such

as the McMillan equation which have the generic form

$$T_c = AT_D \exp\left(\frac{1}{\lambda^* - \mu^*}\right)$$

where A is a constant, T_D is the Debye temperature, and $\lambda^* = \lambda/(1+\lambda)$.

The PWPM formulation for the calculation of λ had as its first application a study of high-pressure phases of Si. The results were dramatic because the existence of the two high-pressure solid metallic phases, simple (or primitive) hexagonal (s.h.) and hexagonal close packed (h.c.p.) were predicted by PWPM calculations. In addition to predicting the transition pressures needed to obtain these phases, their electronic, structural, vibrational, and superconducting properties were successfully predicted. The input information was only the atomic number and atomic mass of Si, the candidate structures, and an estimate of μ^*.

Although the PWPM has limited use for highly correlated materials, it is sometimes used as a starting point to obtain the electronic structure before correlation effects, such as a Hubbard U parameter, are considered to estimate the expected changes when correlation is considered. However, when new superconductors are found, it is common to apply the approach described above as a test of whether one is dealing with a conventional superconductor or not. Superconducting doped C_{60} materials, nanotubes, and MgB_2 are good representatives of materials in this category.

The case of MgB_2 serves as an excellent example of what can be done now with the PWPM and Eliashberg theory, which is an extension of the BCS theory. The method yielded the electronic and vibrational properties of MgB_2 and demonstrated that the strongest electron–phonon coupling was associated with a particular phonon mode. By considering phonon anharmonicity and including the anisotropy of the superconducting energy gap which was found to be important when doing the calculation, it was possible to reproduce the experimental data and predict new properties. The results were consistent with the proposal that MgB_2 is a BCS superconductor with electron pairing caused by electron–phonon coupling and that the superconducting energy gap was multivalued. The results for MgB_2 are particularly striking since this PWPM calculation had no experimental input except for the estimate of μ^* and the known structure of MgB_2.

The optical properties of solids are of particular interest when one is describing a method for computing an electronic structure. The interplay between the development of quantum mechanics and the study of atomic optical spectra was extremely important to the evolution of both fields. However, identifying peaks in optical response functions for solids appeared to be a formidable task. Unlike atomic spectra that contained very sharp peaks which could be interpreted in terms of electronic transitions between narrow electronic states, solid-state spectra were broad and featureless.

The challenge remained in essence until the 1960s, and, for the most part, it was the use of the EPM which provided the tools to deal with these spectra, particularly for semiconductors. An important feature is the fact that peaks in optical response functions, such as reflectivity, arise from interband transitions between states where the bands are parallel. For example, if an electron in a valence band n at point $\boldsymbol{k}$ in the Brillouin zone with energy $E_n(\boldsymbol{k})$ is excited to an empty state m with energy $E_m(\boldsymbol{k})$, this requires a photon having energy $\hbar\omega = E_m(\boldsymbol{k}) - E_n(\boldsymbol{k})$. This transition will result in a more prominent structure or "signature" in the reflectivity if the initial occupied and final unoccupied bands are parallel at the point $\boldsymbol{k}$. The condition is $\nabla_{\boldsymbol{k}} E_n(\boldsymbol{k}) = \nabla_{\boldsymbol{k}} E_m(\boldsymbol{k})$, and this is the requirement for a "critical point" to occur in the band structure. It can be shown that this critical point is associated with the structure in the joint density of states between the two bands. This structure, referred to as a Van Hove singularity, in turn, appears in the optical response functions such as the reflectivity or frequency-dependent dielectric function. It was the analysis of these critical points in semiconductor spectra that yielded the energy separations used to fit the pseudopotential form factors for the EPM. A typical result is shown in **Figure 7** where the modulated or derivative reflectivity spectrum of Ge is displayed. Derivative spectroscopy is used to accentuate the Van Hove structures, and the zeros and peaks arise because of the nature of the critical points. As discussed before, the positions of these are related to the energies of the critical points. In **Figure 7**, near the 2 eV region, it is noted that although there is reasonable agreement between theory and experiment for the critical point energies, the magnitudes of the curves differ considerably. This arises because of electron–hole attraction effects which are not included in the calculation. These are discussed later.

Although the transition from the EPM to *ab initio* PWPM applications was fairly straightforward, there were particularly interesting problems associated with the calculations of energy-band separations, the minimum bandgap, optical spectra, and the role of electron–hole effects described above. The most dramatic signal that one could not just apply the LDA and the PWPM to obtain experimental band structures was the fact that researchers using this

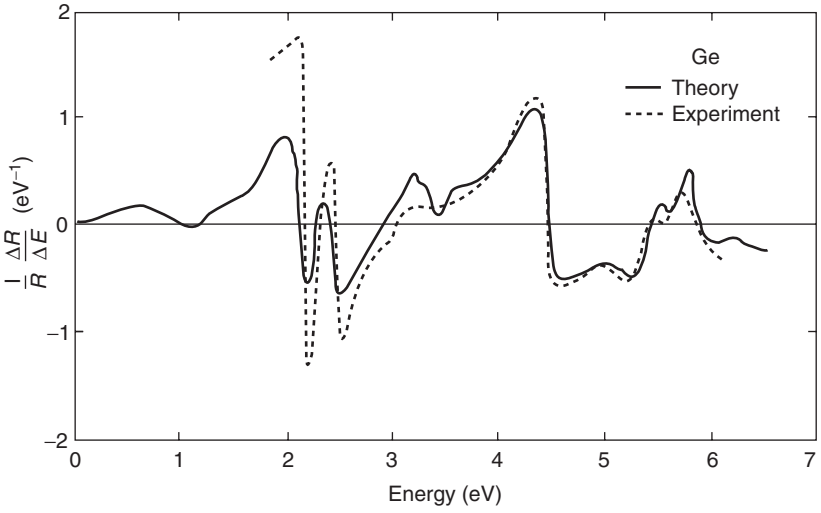

Figure 7 The modulated or derivative reflectivity spectrum for Ge. A comparison is made between the experimental spectrum and the theoretical calculation.

approach were consistently underestimating bandgaps. The specific focus was on Si where the measured and EPM values for the minimum gap were 1.1 eV, while the PWPM–LDA gap was half this value. The EPM was fit to give the correct result, but the *ab initio* method had as its input the LDA, the pseudopotential, and the plane-wave bases. It was soon found that other methods using the LDA gave similar results. Hence, it was concluded that it was the use of the LDA which resulted in calculations which underestimated the bandgap. Since it was emphasized by the inventors of the LDA that, in principle, this approximation should not be applicable for bandgap determination, this result came as no surprise. However, because of the ease of use of the LDA and its success for determining ground-state properties, it was hoped that modifications could be made to standard LDA methods to allow the computation of bandgaps and optical spectra.

A successful practical solution to this dilemma that was often referred to as "the bandgap problem" involved the use of the "GW" method. In this approach, the quasiparticle energies appropriate to excited electron and hole states are calculated starting with LDA calculations. In this scheme, the electron self-energy is computed using the Green's function G and a screened Coulomb potential W. When the resulting self-energy is included in the LDA calculation, the electronic states are renormalized and yield bandgaps in excellent agreement with experiment for a broad class of materials. An analysis of the results of applying the GW method reveals that two important physical features are mainly responsible for the success of the method. First, by using an appropriate dielectric function which includes local field effects, the variations in the charge density arising because of bonding effects are correctly included. Second, the renormalization of the electronic energies because of their interactions with plasmons and electron–hole excitations is included to produce appropriate quasiparticle states produced because of the excitations.

Hence with the inclusion of GW modifications to the LDA, the calculations employing the PWPM can yield bandgaps and band structures in agreement with experiment on a level of accuracy found for the experimentally fit EPM results. In addition, these *ab initio* calculations have been extended further and have addressed the problems of the effects on the optical response functions arising from electron–hole interactions. This problem was raised earlier when discussing the results shown in **Figure 7**. Modifications of spectra of this kind are sometimes referred to as exciton enhancements of oscillator strengths near band edges. However, even when excitons, which are bound states of electron–hole pairs, are not formed, the electron–hole interactions in the excited state can still modify the oscillator strengths and in turn the optical response functions. Applications of the Bethe–Salpeter approach for two-particle interactions to this problem with electron and hole wave functions computed using the PWPM have been successful. At this point, applications of the GW approximation including electron–hole effects have been done for several materials. The computational requirements are somewhat heavy, but the results in all cases tested yield excellent spectra.

A major and important component of condensed matter physics is the research focused on the development of new and novel materials. In the past

two or three decades, new systems have revealed new physical properties, new physics, and important application. Systems such as superlattices, fullerenes, nanotubes, and high-temperature superconductors have broadened the horizons. Often novel materials are complex, structurally or electronically, and they offer new challenges for theoretical methods such as the PWPM. In particular, the number of atoms in a unit cell or supercell is a constraint on this method. Usually, complex materials or configurations of materials can only be modeled with a large number of atoms, and this may require a very large number of plane waves in the basis set. If the electronic structure results in very localized configurations as might be appropriate for complex molecules, again many plane waves may be required. A further and interesting aspect of most novel systems on the nanoscale level is that there are effects of confinement. These effects can be dominant for lower-dimensional or very small structures, and they must be accounted for in the calculational scheme.

A typical example is the case of research on nanocrystals where there have been significant advances in recent years. Here, supercells can be employed along with the PWPM. Other techniques which start out with plane waves have had success. One such approach is to use the EPM to generate Bloch functions for a bulk crystal and then convert these itinerant states into more localized states represented by Wannier functions. If the nanocrystal is then modeled using a potential which is bulk-like inside the nanocrystal and zero outside, the Wannier functions can be used to solve the resulting Hamiltonian appropriate to the nanocrystal. One example of the application of this method is a study of the bandgap of InAs as a function of the nanocrystal radius. The results are in excellent agreement with experiment.

Many applications of the PWPM to C_{60} and nanotubes have appeared in the literature. Electronic structure calculations for C_{60} were used to interpret optical, photoemission, superconducting, and other properties. For nanotubes, the explorations have been even more extensive. For carbon nanotubes, calculations of the properties of semiconductor and metal nanotubes have revealed interesting aspects of their electronic structure for interpreting transport and optical properties. Theoretical predictions of Shottky barrier and heterojunction systems composed of semimetallic and semiconductor nanotubes have been verified. There is even evidence of superconductivity which is consistent with semi-empirical calculations based on PWPM results. No completely *ab initio* calculations of the superconducting properties of fullerenes or nanotubes as in the case of MgB_2 have as yet been done.

A dramatic success of applications of the methods described here to this area is the successful prediction of compound nanotubes. In particular, the prediction of BN nanotubes was verified. In this case, unlike the situation for carbon nanotubes, all BN nanotubes without defects or impurities are semiconducting independent of their "chirality." Theory also suggests that when doped, BN nanotubes will have interesting behavior. An example is the nature of the free electron-like wave function associated with the lowest conduction band for this system. It is predicted that when doped appropriately, the electron density for this state will reside in the center of the BN nanotube. It is expected that this system will resemble a tube with electrons filling its center. Other interesting predictions are that, for BC_2N nanotubes, doping can result in electrons traveling along a spiral path producing effects resembling a nanocoil. For BC_3N, it is expected that each tube will behave as if it were a semiconductor, but a collection of these tubes would be metallic. Although the existence of these predicted compound nanotubes has been established, in general, their transport properties have not been measured, so tests for these unusual predicted properties will have to wait until the appropriate experimental techniques become available.

Conclusion

Summarizing, the history of the use of plane-wave methods for electronic structure calculations has many components. As was discussed, the physical justifications came in different forms, and the development of the techniques required physical interpretation. For example, the major changes in the development of the PWPM were motivated by the desire to answer new questions or to broaden the application of the method. Although the advances in computer hardware had a large effect, the largest impact came from the knowledge gained from doing the calculations. It is important to know what is important, or as Linus Pauling said, "The secret to having good ideas is to have many ideas and the judgment to know which ones should be discarded."

Electronic Structure Calculations: Scattering Methods

J S Faulkner, Florida Atlantic University, Boca Raton, FL, USA

Introduction

Walter Kohn and his collaborators derived the density-functional theory (DFT) that justifies the replacement of the complicated Schrödinger equation for N electrons with simpler equations for the one-electron orbitals:

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + V(\boldsymbol{r})\right]\psi_i(\boldsymbol{r}) = E_i\psi_i(\boldsymbol{r}) \qquad [1]$$

Methods such as the local density approximation (LDA) or the generalized gradient approximation (GGA) are used to generate the effective one-electron potential $V(\boldsymbol{r})$. In all of these approaches, $V(\boldsymbol{r})$ is a functional of the density of the electrons in the system, $\rho(\boldsymbol{r})$, which means that the one-electron equation must be solved self-consistently.

An electronic structure calculation involves finding the eigenvalues and the orbitals from the one-electron equation. Any property of the structure, be it a cluster, a molecule, or a solid, can then be calculated. For example, the charge density is

$$\rho(\boldsymbol{r}) = \sum_{\text{occ.}} \psi_i^*(\boldsymbol{r})\psi_i(\boldsymbol{r}) \qquad [2]$$

and the total energy is

$$E_{\text{total}} = \sum_{\text{occ.}} E_i - \frac{1}{2}\int \frac{\rho(\boldsymbol{r})\rho(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}\,\mathrm{d}\boldsymbol{r}\,\mathrm{d}\boldsymbol{r}' + E_{\text{xc}}[\rho] - \int \frac{\delta E_{\text{xc}}[\rho]}{\delta\rho(\boldsymbol{r})}\rho(\boldsymbol{r})\,\mathrm{d}\boldsymbol{r} \qquad [3]$$

The sums are over all occupied states including spin, and the exchange correlation functional $E_{\text{xc}}[\rho]$ is determined by the particular method used to calculate the effective one-electron potential.

The standard approach to solving the one-electron Schrödinger equation is the Rayleigh–Ritz variational method. The one-electron orbitals are expanded in a complete set of trial functions, and the Schrödinger equation is converted into a set of coupled equations for the expansion coefficients. A problem with the variational method is that all of the core states of the atoms have to be included in the calculation so that the valence-electron orbitals are orthogonal to them. Plane waves are convenient basis functions. The difficulty that these functions cannot be made orthogonal to the core states is circumvented by converting the actual potential into a pseudopotential that has no core states. The pseudopotential method works well for covalent crystals, for example, diamond and silicon, and for simple metals. It is difficult to apply to solids containing transition metals or rare earths because they have too many electrons outside the core, although a class of potentials called soft pseudopotentials has had some success in that area. A completely different method, which was also initiated by Lord Rayleigh, is based on the scattering theory. The orbitals corresponding to a given energy are automatically orthogonal to those for any other energy, so the core levels pose no problem. Another advantage to the multiple-scattering method is that it is the most convenient way to obtain the one-electron Green's function for a solid, which is discussed elsewhere in this encyclopedia.

Scattering Theory

In the Dirac notation, eqn [1] can be written as an inhomogeneous equation, $(E - H_0)|\psi\rangle = V|\psi\rangle$, where H_0 is the kinetic energy operator. The solution of the homogeneous equation is $\varphi(\boldsymbol{r}) = \langle \boldsymbol{r}|\varphi\rangle$, where $(E - H_0)|\varphi\rangle = 0$. A formal solution of the

inhomogeneous equation is the sum of the solution of the homogeneous equation with a particular solution of the inhomogeneous equation $|\psi\rangle = |\varphi\rangle + G_{0+}V|\psi\rangle$, where $G_{0+} = \lim_{\varepsilon\to 0}(E - H_0 + i\varepsilon)^{-1}$. This is the Lippmann–Schwinger equation, and it is the starting point for modern treatments of the scattering theory. The infinitesimal ε avoids the singularity at $E - H_0 = 0$. Letting it approach zero through positive values guarantees the boundary conditions, as will be seen later. Using the identity, $(A-B)^{-1} = A^{-1} + A^{-1}B\,(A-B)^{-1}$, the Lippmann–Schwinger equation can be written in another way,

$$|\psi\rangle = (1 + G_{0+}T)|\varphi\rangle \qquad [4]$$

where the t-matrix is defined by

$$T = V + VG_{0+}V + VG_{0+}VG_{0+}V + \cdots \qquad [5]$$

Suppose the potential V is the sum of N potentials, $V = \sum_{i=1}^{N} v_i$. The physical meaning of this is that it describes the interaction of the electron with a cluster of atoms having nuclei located at positions $\boldsymbol{R}_i$. It is assumed that, in the position representation, the potentials are localized in space and do not overlap, so that $v_i(\boldsymbol{r})v_j(\boldsymbol{r}) = 0$ for $i \neq j$ and all $\boldsymbol{r}$. Define an operator Q_i so that T can be written as a sum

$$T = \sum_{i=1}^{N} Q_i$$

Inserting the expressions for V and T into the definition of T leads to

$$\begin{aligned}\sum_i Q_i &= \sum_i v_i\left(1 + G_{0+}\sum_j Q_j\right)\\ &= \sum_i\left[v_i G_{0+}Q_i + v_i\left(1 + G_{0+}\sum_{j\neq i} Q_j\right)\right]\end{aligned}$$

so

$$Q_i = t_i\left(1 + G_{0+}\sum_{j\neq i} Q_j\right)$$

where $t_i = (1 - v_i G_{0+})^{-1} v_i$. Iterating this equation leads to

$$\begin{aligned}T = &\sum_i t_i + \sum_i t_i G_{0+}\sum_{j\neq i} t_j\\ &+ \sum_i t_i G_{0+}\sum_{j\neq i} t_j G_{0+}\sum_{k\neq j} t_k + \cdots\end{aligned}$$

In terms of the operators Q_i, eqn [4] becomes

$$\begin{aligned}|\psi\rangle &= \left(1 + G_{0+}\sum_{j\neq i} Q_j\right)|\varphi\rangle + G_{0+}Q_i|\varphi\rangle\\ &= |\varphi_i^{\text{in}}\rangle + |\varphi_i^{\text{out}}\rangle\end{aligned}$$

The site i that is chosen to focus on can be any of the sites in the cluster. The incoming wave on this site is taken to be

$$|\varphi_i^{\text{in}}\rangle = \left(1 + G_{0+}\sum_{j\neq i} Q_j\right)|\varphi\rangle = |\varphi\rangle + \sum_{j\neq i}|\varphi_j^{\text{out}}\rangle$$

and the outgoing wave from the site is defined as

$$|\varphi_i^{\text{out}}\rangle = G_{0+}Q_i|\varphi\rangle = G_{0+}t_i|\varphi_i^{\text{in}}\rangle$$

In other words, the first of these equations states that the incoming wave on site i is the sum of the wave coming onto the cluster of scatterers plus the waves scattered out from all of the other scatterers. At first sight, this seems obvious, but one might wonder about the effect of intervening scatterers. It is fundamentally a statement about the superposition of solutions of a linear differential equation. The second equation states that the outgoing wave from a site is obtained from the incoming wave by the solution of a simple scattering problem, which is obvious. To sum up, the fundamental equations of the multiple-scattering theory are

$$\begin{aligned}|\psi\rangle &= |\varphi_i^{\text{in}}\rangle + |\varphi_i^{\text{out}}\rangle\\ |\varphi_i^{\text{in}}\rangle &= |\varphi\rangle + \sum_{j\neq i}^{N}|\varphi_j^{\text{out}}\rangle\\ |\varphi_i^{\text{out}}\rangle &= G_{0+}t_i|\varphi_i^{\text{in}}\rangle\end{aligned} \qquad [6]$$

Using the lowest-level approximation to the t-matrix, $T = \sum_i t_i$, the Lippmann–Schwinger equation can be written as

$$\begin{aligned}\psi_{\boldsymbol{k}}(\boldsymbol{r}) = \varphi_{\boldsymbol{k}}(\boldsymbol{r}') + \sum_{i=1}^{N} e^{i\boldsymbol{k}\cdot\boldsymbol{R}_i}\int G_{0+}(\boldsymbol{r}_i - \boldsymbol{r}_i')\\ \times\ t_i(\boldsymbol{r}_i', \boldsymbol{r}_i'')\varphi_{\boldsymbol{k}}(\boldsymbol{r}_i'')\,d\boldsymbol{r}_i'\,d\boldsymbol{r}_i''\end{aligned}$$

where $\boldsymbol{r}_i = \boldsymbol{r} - \boldsymbol{R}_i$, and $\boldsymbol{R}_i$ is the position of the ith nucleus. The function $t_i(\boldsymbol{r}_i', \boldsymbol{r}_i'')$ is zero outside the range of the potential $v_i(\boldsymbol{r}_i)$, which is a relatively small region surrounding $\boldsymbol{R}_i$. The incoming wave is taken to be a plane wave, which may be written as

$$\begin{aligned}\phi_{\boldsymbol{k}}(\boldsymbol{r}) &= (2\pi)^{-3/2}e^{i\boldsymbol{k}\cdot\boldsymbol{r}}\\ &= e^{i\boldsymbol{k}\cdot\boldsymbol{R}_i}(2\pi)^{-3/2}e^{i\boldsymbol{k}\cdot\boldsymbol{r}_i}\\ &= e^{i\boldsymbol{k}\cdot\boldsymbol{R}_i}\phi_{\boldsymbol{k}}(\boldsymbol{r}_i)\end{aligned}$$

Assuming that $r_i \gg r_i'$, the Green's function can be recast into the form

$$\begin{aligned}G_{0+}(\boldsymbol{r} - \boldsymbol{r}') = G_{0+}(\boldsymbol{r}_i - \boldsymbol{r}_i') &= -\frac{1}{4\pi}\frac{e^{ik|\boldsymbol{r}_i - \boldsymbol{r}_i'|}}{|\boldsymbol{r}_i - \boldsymbol{r}_i'|}\\ &\approx -\frac{1}{4\pi}\frac{e^{ikr_i}}{r_i}e^{-i\boldsymbol{k}_i'\cdot\boldsymbol{r}_i'}\end{aligned}$$

where $\boldsymbol{k}_i' = (\boldsymbol{r}_i/r_i)k$. The solution is then

$$\psi_{\boldsymbol{k}}(\boldsymbol{r}) = \frac{1}{(2\pi)^{3/2}}\left[e^{i\boldsymbol{k}\cdot\boldsymbol{r}} + \sum_{i=1}^{N}\frac{e^{ikr_i}}{r_i}f^i(\boldsymbol{k}_i', \boldsymbol{k})e^{i\boldsymbol{k}\cdot\boldsymbol{R}_i}\right] \quad [7]$$

where

$$\begin{aligned} f^i(\boldsymbol{k}_i', \boldsymbol{k}) &= -\frac{1}{4\pi}\int e^{-i\boldsymbol{k}_i'\cdot\boldsymbol{r}_i'}t^i(\boldsymbol{r}_i, \boldsymbol{r}_i')e^{i\boldsymbol{k}\cdot\boldsymbol{r}_i}\,d\boldsymbol{r}_i\,d\boldsymbol{r}_i' \\ &= -2\pi^2\langle \boldsymbol{k}_i'|t^i|\boldsymbol{k}\rangle \end{aligned} \quad [8]$$

This form of the formula holds for positions $\boldsymbol{r}$ outside the range of any individual potential function. If the solution is to be evaluated only for points outside the cluster of atoms, then $r \gg R_i$ for any i and

$$\psi_{\boldsymbol{k}}(\boldsymbol{r}) = \frac{1}{(2\pi)^{3/2}}\left[e^{i\boldsymbol{k}\cdot\boldsymbol{r}} + \frac{e^{ikr}}{r}\sum_{i=1}^{N} f^i(\boldsymbol{k}', \boldsymbol{k})e^{i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{R}_i}\right] \quad [9]$$

where $\boldsymbol{k}' = (\boldsymbol{r}/r)k$.

The approximations used to derive eqn [9] are obviously very good for a standard X-ray, neutron, or electron diffractometer, where the sample size is of the order of millimeters, while the counter is a sizable fraction of a meter away. If the sample is a monatomic crystal, the scatterers are all identical atoms and they are distributed in a periodic array. It follows that the $f^i(\boldsymbol{k}, \boldsymbol{k}')$ are all the same, and $\sum_{i=1}^{N} e^{i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{R}_i} = N\sum_n \delta(\boldsymbol{k} - \boldsymbol{k}' + \boldsymbol{K}_n)$, where $\boldsymbol{K}_n$ are the reciprocal lattice vectors, which explains the occurrence of Bragg peaks. The application of the multiple-scattering equations to explain diffraction was pioneered by P P Ewald, and the Born approximation:

$$f^i(\boldsymbol{k}', \boldsymbol{k}) = -\frac{1}{4\pi}\int v_i(\boldsymbol{r}_i)\,e^{i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{r}_i}\,d\boldsymbol{r}_i$$

is adequate to describe the weak scattering from the atoms. More complicated effects can be treated by including higher-order terms in the t-matrix.

These multiple scatterings can be used to explain many other scattering experiments, such as the scattering of electrons from molecules, low-energy electron diffraction (LEED) from surfaces of solids, and extended X-ray absorption fine structure (EXAFS). They are also used to describe the propagation of radio waves in inhomogeneous media and the scattering of sound waves from obstacles in water or air. In 1892, Lord Rayleigh introduced the concept that evolved into the multiple-scattering theory in a treatment of the electrical conductivity of a solid with a periodic array of rods embedded in it. Jan Korringa made the conceptual leap that the multiple-scattering equations can also be used to calculate the stationary states of electrons in a solid. The computer power was not adequate to carry out useful calculations with Korringa's equations when they were published in 1947, so they did not get the attention they should have. In 1954, Walter Kohn and Norman Rostoker rederived Korringa's equations using the Kohn variational method. The resulting energy band theory is called the Korringa–Kohn–Rostoker (KKR) method.

Electronic States in Periodic Solids

The picture of a solid that is used in theoretical treatments of the stationary electronic states is an infinite array of atoms that fills all space. This makes it possible to ignore surface states, which are not of interest at this stage. The incoming wave on the cluster $|\varphi\rangle$ may be set equal to zero in the multiple-scattering equations, so eqn [7b] is replaced by

$$|\varphi_i^{\text{in}}\rangle = \sum_{j\neq i}^{\infty}|\varphi_j^{\text{out}}\rangle \quad [10]$$

A simple description of the resulting stationary states is that the electrons scatter from one atom to the other *ad infinitum*, so there is no incoming or outgoing wave.

Since the $v_i(\boldsymbol{r})$ are bounded in space and do not overlap, there is an interstitial region between them within which the potential is a constant, usually taken to be zero, $V(\boldsymbol{r}) = 0$. In the interstitial region, eqn [1] becomes

$$\lfloor \nabla^2 + \alpha^2 \rfloor\psi_i(\boldsymbol{r}) = 0 \quad [11]$$

where $\alpha = \sqrt{2mE}/\hbar$. The solutions of this equation are $Y_{lm}(\vartheta, \varphi)j_l(\alpha r)$ and $Y_{lm}(\vartheta, \varphi)n_l(\alpha r)$, where $Y_{lm}(\vartheta, \varphi)$ is the spherical harmonic, $j_l(\alpha r)$ is a Bessel function, and $n_l(\alpha r)$ is a Neumann function. The incoming wave on site i can thus be written in the position representation

$$\langle \boldsymbol{r}|\varphi_i^{\text{in}}\rangle = \varphi_i^{\text{in}}(\boldsymbol{r}_i) = \sum_{l,m} Y_{lm}(\hat{\boldsymbol{r}}_i)j_l(\alpha r_i)d_{lm}^i$$

where the d_{lm}^i are undetermined coefficients and $\boldsymbol{r}_i = \boldsymbol{r} - \boldsymbol{R}_i$. The unit vector $\hat{\boldsymbol{r}}_i$ defines the angles ϑ and φ in a coordinate system centered on the site of the ith nucleus, $\boldsymbol{R}_i$. The Green's function may be expanded in the interstitial region:

$$\begin{aligned} G_{0+}(\boldsymbol{r} - \boldsymbol{r}') &= -\frac{1}{4\pi}\frac{e^{i\alpha|\boldsymbol{r}_i - \boldsymbol{r}_i'|}}{|\boldsymbol{r}_i - \boldsymbol{r}_i'|} \\ &= -i\alpha\sum_{l',m'} Y_{l',m'}(\hat{\boldsymbol{r}}_i)h_{l'}^+(\alpha r_i)j_{l'}(\alpha r_i')Y_{l',m'}^*(\hat{\boldsymbol{r}}_i') \end{aligned}$$

where $h_l^+ = j_l + in_l$ is the outgoing Hankel function. It follows that eqn [6a] can be written in the position representation:

$$\begin{aligned} \psi(\boldsymbol{r}) = \sum_{l,m}\Bigg[& Y_{lm}(\hat{\boldsymbol{r}}_i)j_l(\alpha r_i) \\ & - i\alpha\sum_{l',m'} Y_{l'm'}(\hat{\boldsymbol{r}}_l)h_{l'}^+(\alpha r_i)t_{l'm',lm}^i(E)\Bigg]\, d_{im}^i \end{aligned} \quad [12]$$

where

$$t^i_{l'm',lm} = \int\int j_{l'}(\alpha r'_i) Y^*_{l',m'}(\hat{\boldsymbol{r}}'_i) t^i(\boldsymbol{r}'_i, \boldsymbol{r}''_i) \times Y_{l,m}(\hat{\boldsymbol{r}}''_i) j_l(\alpha r''_i)\, \mathrm{d}\boldsymbol{r}'_i\, \mathrm{d}\boldsymbol{r}''_i$$

and the outgoing wave can now be identified as

$$\langle \boldsymbol{r} | \varphi^{\text{out}}_i \rangle = \varphi^{\text{out}}_i(\boldsymbol{r}_i) = -\mathrm{i}\alpha \sum_{l,m}\sum_{l',m'} Y_{l',m'}(\hat{\boldsymbol{r}}_i) h^+_{l'}(\alpha r_i)\, t^i_{l'm',lm}(E) d^i_{lm}$$

The content of eqn [10] is that the incoming wave on site i is the sum of the outgoing waves from all of the other sites. The incoming wave is a sum of Bessel functions that are finite for all $\boldsymbol{r}$. The outgoing wave from the site j is infinite at the nuclear position $\boldsymbol{R}_j$, but is finite in the neighborhood of the ith site. The equality can be demonstrated with the help of the mathematical identity:

$$-\mathrm{i}\alpha Y_{l'm'}(\boldsymbol{r}_j) h^+_{l'}(r_j) = \sum_{l,m} Y_{lm}(\boldsymbol{r}_i) j_l(\alpha r_i) g_{lm,l'm'}(E, \boldsymbol{R}_{ij})$$

where the vector $\boldsymbol{R}_{ij}$ is the position of the ith scatterer relative to the jth, $\boldsymbol{R}_{ij} = \boldsymbol{R}_i - \boldsymbol{R}_j$, and

$$g_{lm,l'm'}(E, \boldsymbol{R}_{ij}) = -4\pi i \alpha i^{(l-l')} \sum_{l'',m''} i^{-l''} C^{l''m''}_{lm,l'm'} \times h^+_{l''}(\alpha R_{ij}) Y^*_{l''m''}(\boldsymbol{R}_{ij})$$

The $C^{l''m''}_{lm,l'm'}$ are called Gaunt factors

$$C^{l''m''}_{lm,l'm'} = \int\int Y_{l''m''}(\theta,\phi) Y^*_{lm}(\theta,\phi) Y_{l'm'}(\theta,\phi) \times \sin\theta\, \mathrm{d}\theta\, \mathrm{d}\phi$$

Equation [10] thus leads to a set of homogeneous simultaneous equations that determines the unknown coefficients d^i_{lm}

$$\sum_{j,l''m''} \Big[\delta_{ij}\delta_{lm,l''m''} - (1-\delta_{ij}) \times \sum_{l'm'} g_{lm,l'm'}(E, \boldsymbol{R}_{ij}) t^j_{l'm',l''m''}(E)\Big] d^j_{l''m''} = 0 \quad [13]$$

The eigenvalues of the one-electron equation, eqn [1] for the potential $V(\boldsymbol{r}) = \sum_{i=1}^{\infty} v_i(\boldsymbol{r})$, are the energies for which the determinant of the coefficients in the square bracket in eqn [13] is zero. It is more convenient to deal with a symmetric matrix, and this can be done by defining the coefficients $c^i_{lm} = \sum_{l'm'} t^i_{lm,l'm'}(E) d^i_{l'm'}$. These coefficients satisfy the set of linear equations

$$\sum_{j,l'm'} M^{ij}_{lm,l'm'} c^j_{l'm'} = 0 \quad [14]$$

with the elements of the matrix $\boldsymbol{M}$ being

$$M^{ij}_{lm,l'm'} = m^i_{lm,l'm'}\delta_{ij} - (1-\delta_{ij}) g_{lm,l'm'}(E, \boldsymbol{R}_{ij}) \quad [15]$$

and the $m^i_{lm,l'm'}$ are the elements of the inverse of the t-matrix.

Periodic Solids, One Atom Per Unit Cell

Equations [14] and [15] can, in principle, be used to calculate the electronic states for any solid, but they require that the zeros of an infinitely large matrix must be found. The problem is simplified considerably for periodic solids in which all of the potentials $v_i(\boldsymbol{r}_i)$ are the same, and the nuclear positions $\boldsymbol{R}_i$ form a periodic array. Bloch's theorem holds for such a system because the potential $V(\boldsymbol{r})$ is invariant under the operations of the lattice translation group. Bloch's theorem states that the eigenfunctions of eqn [1] can be indexed by a quantum number $\boldsymbol{k}$, and $\psi_{\boldsymbol{k}}(\boldsymbol{r} + \boldsymbol{R}_i) = \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_i}\psi_{\boldsymbol{k}}(\boldsymbol{r})$. This implies that the coefficients in eqn [14] can be written in terms of coefficients that do not depend on the site, $c^j_{l'm'} = \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_j} c_{l'm'}(\boldsymbol{k})$. Premultiplying eqn [14] by $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_i}$ and summing leads to

$$\sum_{j,l'm'} M_{lm,l'm'}(E, \boldsymbol{k}) c_{l'm'}(\boldsymbol{k}) = 0 \quad [16]$$

where

$$M_{lm,l'm'}(E, \boldsymbol{k}) = m_{lm,l'm'}(E) - A_{lm,l'm'}(E, \boldsymbol{k}) \quad [17]$$

and

$$A_{lm,l'm'}(E, \boldsymbol{k}) = \sum_{j\neq i} \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_{ij}} g_{lm,l'm'}(E, \boldsymbol{R}_{ij}) \quad [18]$$

These are the KKR band theory equations for a periodic crystal with one atom in the unit cell. The Ewald summation process can be used to calculate the structure constants $A_{lm,l'm'}(E, \boldsymbol{k})$. It is easy to prove that the sum in eqn [18] does not depend on i because of the periodicity of the system.

The energy eigenvalues of the periodic solid for a particular $\boldsymbol{k}$, $E_b(\boldsymbol{k})$, are the roots of the equation $\det \boldsymbol{M}(E, \boldsymbol{k}) = 0$. The eigenfunctions are found by solving eqn [16] with $E = E_b(\boldsymbol{k})$. The dimension of these matrix equations is technically infinite, but by ignoring all contributions that correspond to an angular momentum quantum number l greater than $l_{\max}$, they have dimension $(l_{\max}+1)^2$. The justification for this approximation is that the matrix elements of the t-matrix $t_{lm,l'm'}$ are very small when l and l' are greater than $l_{\max}$, and the elements of the inverse matrix $m_{lm,l'm'}$ are very large. The choice of $l_{\max}$ depends on the specific calculation, but $l_{\max} = 3$ can be used in many applications.

Periodic Solids, Several Atoms Per Unit Cell

Periodic solids with several atoms in a unit cell can be treated using the multiple-scattering equations in the form of eqns [14] and [15], but it is convenient to change the notation. The origin of the coordinate system in the mth unit cell is $\boldsymbol{R}_m$, and the positions of the n_c particles in the unit cell are $\boldsymbol{R}_m + \boldsymbol{a}_i$. It is possible to write

$$\sum_{nj,L'} M^{mi,nj}_{L,L'} c^{nj}_{L'} = 0 \qquad [19]$$

with the elements of the matrix $\boldsymbol{M}$ being

$$M^{mi,nj}_{L,L'} = m^{i}_{L,L'}\delta_{mn}\delta_{ij} - (1-\delta_{mn}\delta_{ij})g_{L,L'}(E, \boldsymbol{R}_{mn} + \boldsymbol{a}_{ij}) \qquad [20]$$

where $\boldsymbol{R}_{mn} = \boldsymbol{R}_m - \boldsymbol{R}_n$ and $\boldsymbol{a}_{ij} = \boldsymbol{a}_i - \boldsymbol{a}_j$. In order to simplify the appearance of the equations in the face of the increasing number of indices, the abbreviation L is used for the pair of angular momentum quantum numbers l, m. This crystal is invariant under translations of entire unit cells, not atoms, so the relation between the coefficients due to Bloch's theorem is $c^{nj}_{L'} = \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_n} c^{j}_{L'}(\boldsymbol{k})$. Premultiplying eqn [14] by $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_m}$ and summing leads to

$$\sum_{j=1}^{n_c}\sum_{L'} M^{ij}_{L,L'}(E,\boldsymbol{k}) c^{j}_{L'}(\boldsymbol{k}) = 0 \qquad [21]$$

where

$$M^{ij}_{L,L'}(E,\boldsymbol{k}) = m^{i}_{L,L'}(E)\delta_{ij} - A^{ij}_{L,L'}(E,\boldsymbol{k}) \qquad [22]$$

and

$$A^{ij}_{L,L'}(E,\boldsymbol{k}) = (1-\delta_{ij})g_{L,L'}(E,\boldsymbol{a}_{ij}) + \sum_{m\neq n} \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_{mn}} g_{L,L'}(E, \boldsymbol{R}_{mn} + \boldsymbol{a}_{ij}) \qquad [23]$$

The structure constants, $A^{ij}_{L,L'}(E,\boldsymbol{k})$, are somewhat more complex than those for the monatomic case, but they can also be evaluated with the help of the Ewald summation process. If the contributions to these equations that correspond to angular momentum quantum numbers greater than l_{max} are ignored, the dimension of the matrix equations is $(l_{max}+1)^2 n_c$.

Madelung Energy

The atoms in a crystal with more than one atom per unit cell are typically charged. The exact value for the net charge q_i on the atom at the position $\boldsymbol{R}_m + \boldsymbol{a}_i$ is somewhat arbitrary, depending on the manner in which space is divided up. The sum of the charges in the unit cell must satisfy the neutrality condition, $\sum_{i=1}^{n_c} q_i = 0$. The one-electron potential at the site i is shifted by the Madelung potential V_i, and the proper calculation of these electrostatic shifts is an important part of the band theory calculation. In principle, V_i can be calculated from the usual Coulomb equation from electrostatics

$$V_i = \sum_{j\neq i=1}^{n_c} \frac{q_j}{|\boldsymbol{a}_i - \boldsymbol{a}_j|} + \sum_n \sum_{j=1}^{n_c} \frac{q_j}{|\boldsymbol{a}_i - \boldsymbol{a}_j + \boldsymbol{R}_n|}$$

but this sum is notoriously difficult to converge. In practice, the potential is calculated from the expression

$$V_i = \sum_{j=1}^{n_c} \alpha^{ij}_{M} q_j \qquad [24]$$

where the elements of the Madelung matrix, α^{ij}_{M}, are obtained by a sophisticated mathematical method, such as the Ewald summation process or the fast multipole method.

Electronic States in Nonperiodic Solids Using Supercells

It is often desirable to calculate the electronic structure of systems of atoms that are not arranged periodically. Examples are solids containing impurities or structural defects, liquid metals, amorphous solids, or solid solution alloys. An approach to these problems might be to construct a cluster of N atoms and use the multiple-scattering equations in the form of eqns [14] and [15]. This will not work for a number of reasons. The ratio of near-surface atoms to bulk atoms is so high that surface effects dominate the calculation. Because of the slow convergence of the Coulomb sums, the Madelung potentials in the cluster are quite different from those in a solid.

A way around these difficulties is to reproduce the N-atom cluster periodically to fill all space. This now looks like a periodic solid with N atoms per unit cell, and eqns [21]–[23] can be used to find the electronic structure. Such supercell calculations have been used extensively to treat solids without symmetry.

The eigenvalues $E_b(\boldsymbol{k})$ of the matrix $\boldsymbol{M}(E, \boldsymbol{k})$ from eqn [22] have a k-dependence due to the forced periodicity of the supercell. The error that is introduced is of the order of the bandwidth, $\delta E_b(\boldsymbol{k})$, which can be estimated by taking the difference between the eigenvalues at the Brillouin zone boundary and the center of the zone:

$$\delta E_b(\boldsymbol{k}) = E_b\left(\frac{\pi}{D}\right) - E_b(0) \approx \frac{\partial E_b}{\partial k}\frac{\pi}{D}$$

The way to make the error small is to make D large, where D is a dimension of the supercell and is proportional to $\sqrt[3]{N}$. The algorithms for finding the eigenvalues of any matrix require a number of floating point operations that increases as the cube of the dimension of the matrix. The dimension of the matrix

$\boldsymbol{M}(E, \boldsymbol{k})$ for the supercell is $(l_{\max}+1)^2 N$, so the computer time required to diagonalize the matrix increases as the cube of the dimension, N^3 or D^9. There is thus a competition between the goals of reducing the error in the eigenvalues $\delta E_b(\boldsymbol{k})$ and minimizing the computer time required for the calculation. A solution to this dilemma is to develop order-N methods for which the number of floating point operations increases as N instead of N^3. Two order-N methods based on the multiple-scattering approach are discussed elsewhere in this encyclopedia.

Surface Electronic States

One of the reasons that the solid was assumed to fill all space in the preceding two sections is to focus on the bulk states. There are electronic states in a real solid that are specifically associated with the surface. An understanding of the surface states is important in applications, such as chemical catalysis. The magnetic properties of atoms in the surface region are frequently different from the atoms in the bulk.

The multiple-scattering method can be used to calculate the electronic states associated with surfaces. Consider planes of atoms stretching to infinity in directions perpendicular to the z-direction. The planes that are well separated from the terminal plane at the surface will have the same arrangement of atoms and the same separation from each other as they have in the bulk solid. Closer to the surface, the distance between planes is not the same as the bulk, and the arrangement of atoms in the planes may reconstruct into another arrangement. In any case, there is periodicity in the xy-plane, and hence a 2D Bloch's theorem for each plane.

Perhaps the easiest model to visualize is a slab geometry that starts with a central plane of atoms with the same arrangement as the bulk. Similar planes are placed on either side of the central one, building a slab with symmetry about the central plane and containing an odd number of planes. These slabs are then periodically reproduced in the z-direction, separated by a large distance that contains no atoms. Making use of the symmetry in the xy-planes, the system can be modeled with long, narrow supercells that are a few lattice constants wide in the planar directions but many angstroms long in the z-direction. Equations [21]–[23] can be used to calculate the electronic structure, but the dependence on k_z can be ignored because of the length of the supercell.

After the electronic states have been calculated self-consistently for a given configuration, the atomic positions in the outer planes of atoms are allowed to relax and the calculations are repeated. The Hellmann–Feynman theorem is useful in this step, which leads to a prediction of the spacing between planes and possible reconstruction of surface atoms. Experience has shown that, at least in metals, only the first few planes nearest the surface differ significantly from the bulk.

The multiple scattering equations have been used in other ways to treat surfaces. Instead of periodically reproducing the slabs, a mirror-like scatterer with a planar surface is put outside of the slab on either side to reflect the electrons back in. Another variation is to extend the slab to infinity in the minus z-direction. This is called the layer Korringa, Kohn, Rostoker (LKKR) method, and it is more like the surface on a real solid.

Approximations and Extensions

The Muffin–Tin Approximation

Until recently, the one-electron potentials used in multiple-scattering calculations were approximated by muffin–tin (MT) potentials that are spherically symmetric within bounding spheres centered on the nuclei and are constant outside them. The spheres do not overlap, and a 2D drawing of the function is similar to a pan that is used to cook muffins.

The inverse of the scattering matrix can be written as

$$m^i_{L,L'} = \alpha \sum_{L'} c^i_{LL''} s^i_{L''L'} - i\alpha$$

where the cosine and sine matrices are defined by

$$c^i_{LL'} = \delta_{LL'} - \alpha \int n_l(\alpha r) Y_L(\boldsymbol{r}) v_i(\boldsymbol{r}) \Phi^i_{L'}(E, \boldsymbol{r})\, \mathrm{d}\boldsymbol{r}$$

$$s^i_{LL'} = \alpha \int j_l(\alpha r) Y_L(\boldsymbol{r}) v_i(\boldsymbol{r}) \Phi^i_{L'}(E, \boldsymbol{r})\, \mathrm{d}\boldsymbol{r}$$

In these equations, $\Phi^i_L(E, \boldsymbol{r})$ is the solution of a one-electron equation containing the single potential $v_i(\boldsymbol{r})$ that approaches the limit $\lim_{r\to 0} \Phi^i_L(E, \boldsymbol{r}) = j_l(\alpha r)\, Y_L(\boldsymbol{r})$. These equations are laborious to solve for nonspherical potentials because both $v_i(\boldsymbol{r})$ and $\Phi^i_L(E, \boldsymbol{r})$ have to be expanded in spherical harmonics. For the spherical potentials used in the MT approximation, they simplify to

$$c^i_{LL'} = -\alpha S_i^2 \delta_{LL'} \left[n_l(\alpha r) \frac{\mathrm{d}\Phi^i_l(E, r)}{\mathrm{d}r} - \frac{\mathrm{d}n_l(\alpha r)}{\mathrm{d}r} \Phi^i_l(E, r) \right]_{r=S_i}$$

$$c^i_{LL'} = \alpha S_i^2 \delta_{LL'} \left[j_l(\alpha r) \frac{\mathrm{d}\Phi^i_l(E, r)}{\mathrm{d}r} - \frac{\mathrm{d}j_l(\alpha r)}{\mathrm{d}r} \Phi^i_l(E, r) \right]_{r=S_i}$$

where S_i is the radius of the MT sphere.

The MT approximation works very well for electronic structure calculations on metals in close-packed structures. For nonperiodic structures, it is frequently desirable to calculate the forces on the atoms using the

Hellmann–Feynman theorem. Any shape approximation on the potential will cause significant errors in such calculations. The MT approximation is also not acceptable for loosely packed covalently bonded crystals. With some care, the multiple-scattering equations written in the preceding sections can be used for any nonoverlapping potential.

An atomic sphere approximation (ASA) has been proposed to simplify multiple-scattering calculations. The potential is forced into a form that is spherically symmetrical for r less than the radius of a sphere that has the same volume as the Wigner–Seitz cell for the atom. The ASA potentials overlap, and this violates the fundamental assumptions of the multiple-scattering theory.

Relativity

The multiple-scattering equations have been written in the nonrelativistic form because they are easier to visualize. The technical problems involved with a multiple-scattering theory based on the Dirac equation rather than the Schrödinger equation have been resolved, and all of the statements made above apply to the relativistic theory. Spin polarized versions of these equations have been used to discuss magnetism in metals, alloys, and surfaces.

Linearized Versions of the Multiple-Scattering Equations

The KKR equations are time-consuming to solve because all of the matrix elements depend on the energy. The eigenvalues and eigenvectors can be found much more easily for equations of the form that is obtained from a linear variational method in which the matrix $\boldsymbol{M}$ in eqn [21] is replaced by one with the elements:

$$M^{ij}_{L,L'}(E,\boldsymbol{k}) = E\delta_{ij}\delta_{LL'} - D^{ij}_{L,L'}(\boldsymbol{k})$$

because it is only necessary to diagonalize the matrix $\boldsymbol{D}$. The linear combination of MT orbitals (LMTO) approach achieves this by using trial functions suggested by the multiple-scattering theory in a Rayleigh–Ritz variational calculation.

When the potentials fill all space, the interstitial volume goes to zero. Thus, the value V_{int} of $V(\boldsymbol{r})$ when $\boldsymbol{r}$ is in the interstitial region, chosen to be zero in the preceding equations, becomes irrelevant. This fact can be used to derive a version of the multiple-scattering equations that has the eigenvalue form of the preceding equation.

The freedom to choose any value for V_{int} for space filling potentials can be used in another way to simplify the multiple-scattering equations. If V_{int} is chosen much larger than the average value of $v_i(\boldsymbol{r})$ in the region of the Wigner–Seitz cell farthest from the nucleus, the equations describe a barrier that the electron must tunnel through to propagate from one site to another. The sum that defines the structure constants in eqn [23] converges after a small number of nearest-neighbor shells. The resulting screened-structure-constant (SSC) approximation leads to multiple-scattering equations that are similar to tight-binding equations.

Electron–Phonon Interactions and the Response of Polarons

J T Devreese, Universiteit Antwerpen (UA), Antwerpen, Belgium

Developments in Polaron Physics

A conduction electron (or hole) together with its self-induced polarization in an ionic crystal or in a polar semiconductor forms a quasiparticle, which is called a polaron. The polaron concept is discussed in an article by E I Rashba in the present encyclopedia (for references about the standard polaron theory, see the "Further reading" section). A polaron is characterized by its binding (or self-) energy E_0, an effective mass m^* and by its characteristic response to external electric and magnetic fields (e.g., DC mobility and optical absorption coefficient).

If the spatial extension of a polaron is large compared to the lattice parameter of the solid, the latter can be treated as a polarizable continuum. This is the case of a "large polaron." An electron or a hole trapped by its self-induced atomic (ionic) displacement field in a region with linear dimension of the order of the lattice constant is called a "small polaron."

An all-coupling polaron theory was developed by Feynman using his path-integral formalism. He first studied the self-energy E_0 and the effective mass m^*, and later the mobility of polarons. Subsequently, the path-integral approach to the polaron problem was generalized and developed to become a tool to study optical absorption, magnetophonon resonance, and cyclotron resonance.

The present article, which is primarily devoted to the response properties of polarons, deals with the following aspects of polaron physics.

First, the polaron self-energy, the effective mass, the mobility, and the optical response are discussed. The optical absorption spectrum of a single large polaron at all electron–phonon coupling strengths has been analyzed using the path-integral method. The path-integral approach is also applied to investigate the properties of the interacting polaron gas including its optical absorption. Also Monte Carlo simulations have been used to examine the large-polaron model. Furthermore, the dynamics of the polaron formation has become a subject of investigation.

Second, polarons are studied in systems of reduced dimension and reduced dimensionality, for example, using cyclotron resonance. Magnetopolarons have been investigated in layered semiconductor compounds and quantum wells. The role of polaronic quasiparticles has been confirmed for the transport mechanism in quasi-1D conductors and for the optical properties of quantum dots. In semiconductor nanostructures, the mixing of the electron–hole or exciton states by the polaron interaction leads to the need for a nonadiabatic treatment.

Third, the polaron concept is used to study the properties of a variety of materials, for example, transition-metal oxides, conjugated polymers, perovskites, high-T_c superconductors, layered MgB_2 superconductors, and fullerenes. No consensus exists concerning the microscopic mechanism leading to the creation of Cooper pairs in high-T_c superconductors. Nevertheless, there is evidence for the existence of polarons and bipolarons in high-T_c superconductors (as manifested, for example, in their optical absorption spectra in the normal phase).

Recent Developments

Polaronic effects were observed in a 2D electron system on helium films covering a glass substrate. For thin films and for strong holding electric fields, the conditions were achieved under which the calculated binding energies are larger than k_BT, and the mobilities were shown to be in good agreement with the theoretically predicted values for the polaron mobility.

A theoretical analysis of the small-polaron and small-bipolaron formation in a cubic perovskite lattice showed that there exists a large window of electron–phonon coupling where the polaron is stable but the bipolaron decays into two polarons. An interesting development of the polaron concept was proposed in connection with recent studies in the theory of high-T_c superconductivity. The bipolaronic mechanism of superconductivity in terms of small bipolarons supposes that both electron–phonon and Coulomb interactions are short range (i.e., on-site). This model satisfactorily describes several properties of the insulating phase of the cuprates, but it cannot explain the high superconducting critical temperature. The effective mass of a bipolaron within the model with short-range interactions is very large, and the predicted critical temperature T_c is very low. Motivated by this fact, the so-called Fröhlich–Coulomb model of the high-T_c superconductivity was proposed, in which it is assumed that a long-range Fröhlich interaction, rather than a short-range Holstein interaction, should be the adequate model for the cuprates. Differently from the usual continuum Fröhlich polaron, a multipolaron Fröhlich-like lattice model is used with electrostatic forces taking into account the discreteness of the lattice, finite electron bandwidth and the quantum nature of phonons. Recently, this model was applied in order to explain various physical properties of superconducting cuprates (see the monograph by Alexandrov).

A path-integral Monte Carlo scheme was presented to solve the large-polaron model in three and two dimensions. The ground-state features of the Fröhlich polaron model were revisited numerically using a diagrammatic Quantum Monte Carlo method, and analytically using the variational Hamiltonian approach. Three aforementioned approaches demonstrate the remarkable accuracy of the Feynman path-integral approach to the polaron ground-state energy. A linear superposition of two variational wave functions, which describe the asymptotic regimes of weak and strong electron–phonon coupling, provides an estimate of the polaron ground-state energy, which is slightly lower than that obtained within the Feynman path-integral method, and compares well with the energies calculated within a diagrammatic Quantum Monte Carlo method. The α-dependence of the polaron effective mass and the other calculated ground-state properties suggest that the crossover between the two asymptotic regimes

characterizing a polaron occurs smoothly and does not suggest any sharp "self-trapping" transition. From the spectral analysis of the Green's function, it was concluded that, for all coupling strengths, in contrast to the small-polaron model, there is no stable excited state for the Fröhlich polaron in the energy gap between the ground-state energy and the incoherent continuum; however, several many-phonon unstable states are found.

The formation of a small polaron from a bare electron has been studied by Ku and Trugman. The polaron formation time is related to the dephasing time of the continuum of unbound phonon excited states in the spectral function, which depends on the phonon frequency and the electron–phonon coupling strength. As the electron–phonon coupling increases, qualitative changes in polaron formation occur when the one-phonon polaron bound states form. In the adiabatic regime, a potential barrier between the quasi-free and heavy polaron states exists in both two and three dimensions which is crucial for polaron formation dynamics.

The density-functional theory and its time-dependent extension is exploited by Bassani and co-workers to construct an appropriate effective potential for studying the properties of the interacting polaron gas beyond the mean-field theory. The main assumptions of the theory are to consider the coupled system of electrons and ions as a continuum, and to take the weak electron–phonon coupling limits into account.

The optical properties of quasi-one-dimensional metallic $LaTiO_{3.41}$ studied for the polarization along the *a* and *b* axes revealed that with decreasing temperature, modes appear along both directions suggestive of a phase transition. A pronounced midinfrared band was observed with a temperature dependence consistent with interacting polaron models. The polaronic picture was also corroborated by the presence of strong electron–phonon coupling and the temperature dependence of the DC conductivity. Band softening was interpreted in terms of large polaron models including polaron–polaron interactions. These findings suggest the general importance of polaronic quasiparticles for the transport mechanism in quasi-1D conductors.

The studies of thermal dissociation and photoionization for bound hole O^- polarons in oxide compounds MgO and corundum showed a surprising closeness of the results obtained on the basis of independent models: a continuum theory at arbitrary electron–phonon coupling and a quantum-chemical method. The bound-polaron model, applied to describe the optical properties of submonolayer CdSe insertions epitaxially grown between ZnSe layers, revealed excited-state energies equidistantly separated by the LO phonon energy as a typical signature of bound polarons.

Polaronic Response in Solids

Optical Absorption of Polarons at Arbitrary Coupling: Internal Structure of Polarons

The theoretical optical absorption spectrum of a single large polaron, at all electron–phonon coupling strengths, was obtained by Devreese and co-workers

$$\Gamma(\omega) = -\frac{1}{n\varepsilon_0 c}\,\frac{\mathrm{Im}\,\Sigma(\omega)}{[\omega - \mathrm{Re}\,\Sigma(\omega)]^2 + [\mathrm{Im}\,\Sigma(\omega)]^2} \quad [1]$$

with ω the frequency of the incident radiation expressed in units of the LO-phonon frequency in the medium ω_{LO}, ε_0 the dielectric permittivity of the vacuum, n the index of refraction of the medium, and c the velocity of light. The memory function $\Sigma(\omega)$ contains the dynamics of the polaron and depends on α and ω. This function is related to the impedance function $Z(\omega)$ of the polaron through $-iZ(\omega) = \omega - \Sigma(\omega)$. The starting point was the general eqn [1] together with the $[\mathrm{Im}\,\Sigma(\omega)]$ obtained by Feynman and co-workers for the Feynman polaron. A key ingredient is the calculation of $\mathrm{Re}\,\Sigma(\omega)$ (which is a Kramers–Kronig-type transform of $[\mathrm{Im}\,\Sigma(\omega)]$).

The resulting polaron optical absorption spectra are shown in **Figure 1** for values of α in the range from 1 to 6.

The absorption spectrum for relatively weak coupling (e.g., $\alpha = 1$) consists of a "one-phonon line," similar to the weak-coupling result obtained by Gurevich, Lang, and Firsov. The absorption peak for $\alpha = 3$ contains components with more than one free phonon in the final state. It was suggested that part of the oscillator strength in the polaron absorption for $\alpha = 3$ is due to incipient lattice relaxation in the final states, though to a much lesser extent than for $\alpha = 6$.

From [1], as applied to the Feynman model, the three different kinds of polaron excitations, which were found by Kartheuser, Evrard, and Devreese using the adiabatic strong-coupling approximation, appear in the calculated optical absorption spectra for polarons at $\alpha \geqslant 5$:

1. scattering states where, for example, one real phonon is excited (the structure starting at $\omega = \omega_{LO}$);
2. relaxed excited states (RES), the "resonance" polaron states, which result if the lattice polarization is allowed to adapt to the electronic distribution of the excited electron (which itself then adapts its wave function to the new potential etc., leading to a self-consistent final state);

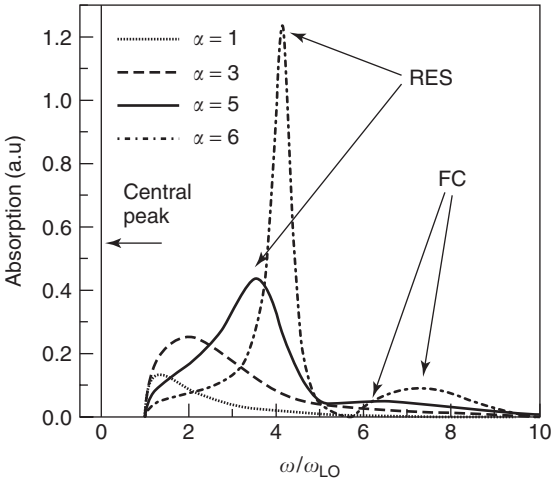

Figure 1 Polaron optical absorption spectra at zero temperature, calculated within the path-integral method according to J T Devreese and co-workers for different values of the electron–phonon coupling constant α. The peaks are labeled in the picture according to their physical origin ("RES" = relaxed excited state, "FC" = Franck–Condon state) as discussed in the text. A δ-like central peak (at $\omega = 0$) is schematically shown by a vertical line. (Reproduced with permission from Devreese JT (2003) Polarons. In: Avella A and Mancini F (eds.) *Lectures on the Physics of Highly Coordinated Electron Systems VII,* Proceedings of the 7th Training Course in the Physics of Correlated Electron Systems and High-T_c Superconductors, Vietri sul Mare, Italy, 14–16 October 2002, pp. 3–56 Melville: AIP; © American Institute of Physics.)

3. Franck–Condon (FC) states, the (unstable) polaron states, in which the lattice polarization corresponds to the electron ground state, while the electron is excited.

Furthermore, at zero temperature, the optical absorption spectrum for one polaron contains a "central peak" [$\sim\delta(\omega)$] at the origin. For nonzero temperature, this "central peak" smears out and the optical absorption spectrum consists of both a broad envelope and an "anomalous" Drude-type low-frequency component.

For example, in **Figure 1**, the main peak of the polaron optical absorption for $\alpha = 5$ at $\omega = 3.51\omega_{LO}$ is interpreted as due to transitions to an RES. A "shoulder" at the low-frequency side of the main peak is attributed to one-phonon transitions to "scattering states." The broad structure centered at about $\omega = 6.3\omega_{LO}$ is interpreted as an FC band. As seen from **Figure 1**, when increasing the electron–phonon coupling constant to $\alpha = 6$, the RES peak at $\omega = 4.3\omega_{LO}$ stabilizes and becomes very intense compared with the FC peak centered at $\omega = 7.5\omega_{LO}$.

Recent calculations of the optical conductivity for the Fröhlich polaron performed within the diagrammatic Quantum Monte Carlo method fully confirm the results of the path-integral variational approach at $\alpha \lesssim 3$. In the intermediate-coupling regime $3 < \alpha < 6$, the low-energy behavior and the position of the maximum of the optical conductivity spectrum as obtained by Mishchenko and co-workers follow well the prediction of the path-integral approach based on eqn [1]. There are the following qualitative differences between the two approaches in the intermediate and strong coupling regime: in the Quantum Monte Carlo method, the dominant peak broadens and the second peak does not develop, giving rise instead to a flat shoulder in the optical conductivity spectrum at $\alpha = 6$. This behavior can be attributed to the optical processes with the participation of two or more phonons. The nature of the excited states of a polaron needs further study.

Free-carrier polaron effects were revealed through measurements of the optical constants, of the cyclotron resonance, and of the carriers mobility in polar semiconductors and insulating photoconductors. Optical absorption experiments revealed spectra, consistent with the theoretical predictions in **Figure 1** up to $\alpha \sim 3$. The more dramatic structure of $\Gamma(\omega)$, eqn [1], characteristic of transitions to the RES for $\alpha \geqslant 5$ arises in cyclotron resonance experiments (see "Further reading" section).

Scaling relations for polarons in 2D and in 3D Several scaling relations connect the polaron self-energy, the effective mass, the impedance Z and the mobility μ in two dimensions to the same quantities in three dimensions. Those relations were obtained at the level of the Feynman model and are listed here:

$$E_{2D}(\alpha) = \frac{2}{3} E_{3D}\left(\frac{3\pi}{4}\alpha\right) \qquad [2]$$

$$\frac{m^*_{2D}(\alpha)}{m_{2D}} = \frac{m^*_{3D}(3\pi/4)\alpha}{m_{3D}} \qquad [3]$$

$$Z_{2D}(\alpha, v) = Z_{3D}\left(\frac{3\pi}{4}\alpha, v\right) \qquad [4]$$

where v is the frequency of the external electromagnetic field, and

$$\mu_{2D}(\alpha) = \mu_{3D}\left(\frac{3\pi}{4}\alpha\right) \qquad [5]$$

Expressions [2] to [5] provide a straightforward link between polaron characteristics in three dimensions with those in two dimensions.

Many-Polaron Systems

Interacting polarons In most polar semiconductors, the weak-coupling regime is realized. The perturbation theory is then adequate to describe the polaron gas in such semiconductors. In early approaches to

the problem of a high-density polaron gas, the interaction between polarons was supposed to be completely screened. The ground-state energy of a gas of interacting polarons was first derived by L F Lemmens, J T Devreese, and F Brosens using a canonical transformation extended to the case of a many-polaron system. It was shown that the minimum of the total ground-state energy per particle for a polaron gas in ZnS and in ZnO lies at a density lower than that for the electron gas.

A Wigner lattice of polarons is assumed to be the ground state of the many-polaron system in the low-density limit. The nondegenerate system of interacting polarons in polar-doped insulators is analyzed by Quimerais and Fratini using a Feynman model for the polaron, while the effect of other polarons forming a Wigner lattice is approximately described by a parabolic confinement potential. With increasing density, there is a competition between the melting of the polaron Wigner lattice and the dissociation of the polarons themselves. As a result, for sufficiently large values of the electron–phonon coupling constant α, the formation of a polaron liquid appears to be impossible.

Optical absorption coefficient of a many-polaron gas The possibility that polarons play a role in high-T_c superconductors has increased interest in the physical properties of many-polaron systems and, in particular, in their optical properties. Theoretical treatments were extended from one-polaron to many-polaron systems, and 2D as well as 3D structures were examined.

The optical absorption spectrum of a many-polaron gas has been derived starting from a many-polaron canonical transformation and from the variational many-polaron wave function. This approach to the many-polaron optical absorption allows one to include the many-body effects in terms of the dynamical structure factor of the electron (or hole) system. It is then possible, within the weak (and intermediate) coupling polaron theory, to select the level of approximation used in the treatment of the many-polaron gas by choosing an appropriate expression of the dynamical structure factor for the electron (or hole) gas.

The many-polaron optical conductivity is governed by the response of the current density to an applied electric field (here along the x-axis) with frequency ω. Introducing the standard expression for the dynamical structure factor of a system of charge carriers interacting through a Coulomb potential:

$$S(\boldsymbol{q}, v) = \int_{-\infty}^{+\infty} \left\langle \varphi_{\mathrm{el}} \left| \frac{1}{2} \sum_{j,\ell} \mathrm{e}^{\mathrm{i}\boldsymbol{q}\cdot(\boldsymbol{r}_j(t)-\boldsymbol{r}_\ell(0))} \right| \varphi_{\mathrm{el}} \right\rangle \mathrm{e}^{\mathrm{i}vt}\, \mathrm{d}t \qquad [6]$$

the real part of the many-polaron optical conductivity can be expressed in the form

$$\mathrm{Re}[\sigma(\omega)] = \frac{n}{\hbar\omega^3} \frac{e^2}{m_{\mathrm{b}}^2} \sum_{\boldsymbol{k}} k_x^2 |V_{\boldsymbol{k}}|^2 S(\boldsymbol{k}, \omega - \omega_{\mathrm{LO}}) \qquad [7]$$

where $n = N/V$ is the density of charge carriers, $V_{\boldsymbol{k}}$ is the electron–phonon interaction amplitude and k_x is the x-component of the wave vector. Formula [7] for the optical absorption of the many-polaron system has an intuitively appealing form. In the one-polaron limit, eqn [7] reduces to the result of Gurevich and co-authors for the nondegenerate case.

Equation [7] is reminiscent of the formula of Hopfield that describes the effect of impurities on the optical absorption of metals. The earlier discussion of many-body effects related to Fermi statistics was subsequently extended by Tempere and Devreese to study the influence of plasmons and the many-body effects in polaron systems.

The optical properties of the many-polaron gas were investigated by calculating the correction to the RPA dielectric function of the electron gas due to the electron–phonon interaction. Variational parameters of a single-polaron Feynman model were exploited for the treatment of the interacting many-polaron gas. In order to find the many-polaron optical conductivity, the memory-function approach for the optical absorption of noninteracting large polarons is used. As a result, a suppression of the optical absorption with increasing density is found, as seen from **Figure 2**.

Comparison of theoretical optical-absorption spectra to the observed infrared spectra of $Nd_{2-x}Ce_xCuO_{2-y}$ and $La_{2/3}Sr_{1/3}MnO_3$ The experimental optical absorption spectrum (up to $3000\,\mathrm{cm}^{-1}$) of $Nd_2CuO_{2-\delta}$ ($\delta < 0.004$), obtained by Calvani and coworkers is shown in **Figure 3** (shaded area) together with the theoretical curve for the interacting many-polaron gas and, for reference, the one-polaron optical absorption result. At lower frequencies (600–$1000\,\mathrm{cm}^{-1}$), a marked difference between the single polaron optical absorption and the many-polaron result is manifest. The experimental "d-band" can be clearly identified, rising in intensity at about $600\,\mathrm{cm}^{-1}$, peaking around $1000\,\mathrm{cm}^{-1}$, and then decreasing in intensity above that frequency. A good agreement between the theoretical predictions and the experimental results (for a density of $n = 1.5\times 10^{17}\,\mathrm{cm}^{-3}$) is found. A background contribution, taken to be constant over the frequency range of the "d-band," is subtracted in **Figure 3**.

The material parameters characterizing polarons ($\varepsilon_0, \varepsilon_\infty, m_{\mathrm{b}}$) are not known for $Nd_2CuO_{2-\delta}$ ($\delta < 0.004$). For ω_{LO}, a value of $7.005\times 10^{-2}\,\mathrm{eV}$

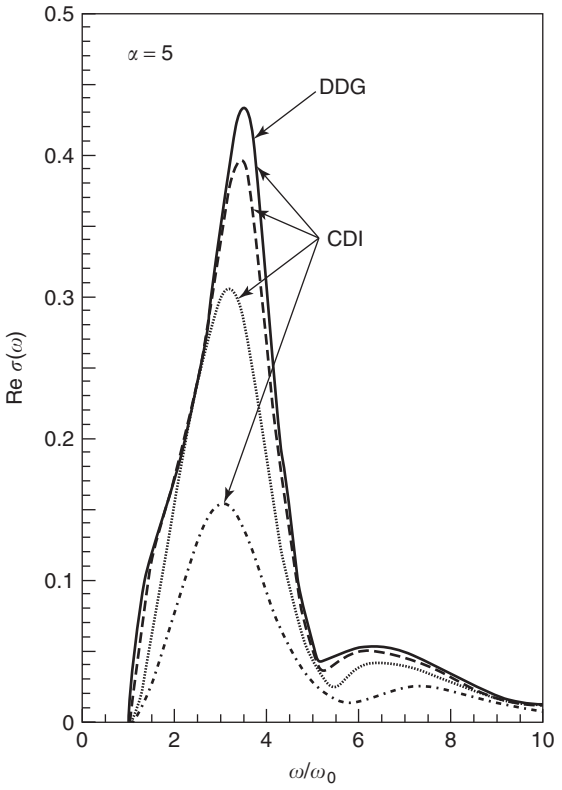

Figure 2 Optical conductivity of a polaron gas at $T = 0$ as a function of the frequency (CDI) for different values of the electron density: $n_0 = 1.4 \times 10^{-5}$ (solid curve), $n_0 = 1.4 \times 10^{-4}$ (dashed curve), $n_0 = 1.4 \times 10^{-3}$ (dotted curve), and $n_0 = 1.4 \times 10^{-2}$ (dotted–dashed curve). The value of $\varepsilon_0/\varepsilon_\infty$ is 3.4. The electron density is measured in units of R_p^{-3}, where R_p is the Fröhlich polaron radius. The solid curve practically coincides with the optical conductivity of a single polaron (DDG). (Reproduced with permission from Cataudella V, De Filippis G, and Iadonisi G (1999) *The European Physical Journal B* 12 : 17–22; © EDP Sciences, SIF, and Springer. Courtesy of G. Iadonisi.)

was derived from available experimental data. In the calculations, the values $\alpha = 2.1$ and $m_b = 0.5m_e$ were considered. However, these figures need further analysis in view of the limited available experimental data for $\varepsilon_0, \varepsilon_\infty, m_b$.

There exists also a fair agreement between the theoretical and the experimental values of the normalized first-frequency moment for the samples of $Nd_{2-x}Ce_xCuO_4$ with lowest density, which have a cerium doping content of $x < 0.12$. For $x > 0.12$, a discrepancy between the theoretically predicted first-frequency moment for unpaired polarons and the observed first-frequency moment appears. It has been observed experimentally that the weight of the low-frequency component in these samples (with $x > 0.12$) is significantly larger than the corresponding weight in samples with $x < 0.12$. This was interpreted as a consequence of an insulator-to-metal transition taking place around a cerium-doping level of $x = 0.12$. Therefore, it seems reasonable to assume that above this doping level a change in the nature of the charge carriers takes place. One could hypothesize that, as the formation of bipolarons is stabilized with increasing density of the polaron gas, bipolarons start playing a role in the optical absorption spectrum. In a variety of other cuprates and manganites, the presence of bipolarons has also been invoked to interpret a number of response-related properties.

The experimentally observed optical conductivity spectrum of $La_{2/3}Sr_{1/3}MnO_3$ is compared with different theoretical large-polaron models in **Figure 4**. The one-polaron approximations (the weak-coupling approach and the phenomenological model) lead to narrower polaron peaks than the peak with maximum at $\omega \sim 900\,\mathrm{cm}^{-1}$ given by the many-polaron approach. It is seen from **Figure 4** that the many-polaron approach describes the experimental optical conductivity better than the single-polaron methods.

Thermal conductivity of cuprates In cuprates, it is difficult to separate experimentally the electron and phonon contributions to the thermal conductivity, since they are of the same order of magnitude. Recently, a way to experimentally determine the Lorenz number has been realized by Zhang and co-authors, based on the thermal Hall conductivity. The thermal Hall effect allows for an efficient way to separate the phonon heat current from the electric heat current. The particular interest of the experiment lies in the conclusion of Alexandrov and coworkers that the Wiedemann–Franz law is violated in the cuprates in the temperature range below the temperature T^* of the BCS-Bose liquid crossover.

The Lorenz number of the electron–phonon system has been calculated by Lee, Alexandrov, and Liang in order to show that the Wiedemann–Franz law breaks down because of the interference of small-polaron and small-bipolaron contributions in the heat flow. When thermally excited polarons are included in the consideration, the bipolaron model explains the violation of the Wiedemann–Franz law in the cuprates and the behavior of the Hall–Lorenz number as seen in the experiment. As follows from **Figure 5**, the model is in good agreement with the experimental Hall–Lorenz number, which provides direct evidence for bipolarons in the cuprates. It also quantitatively reproduces the (quasi)linear in-plane resistivity and the inverse Hall ratio, as observed in the cuprates (upper inset of **Figure 5**). The lower inset of **Figure 5** shows a slightly lower Lorenz number compared to the calculated Hall–Lorenz number. Because the thermal Hall conductivity determines the Lorenz number in the framework of the model, it can be used to find the lattice contribution to the heat

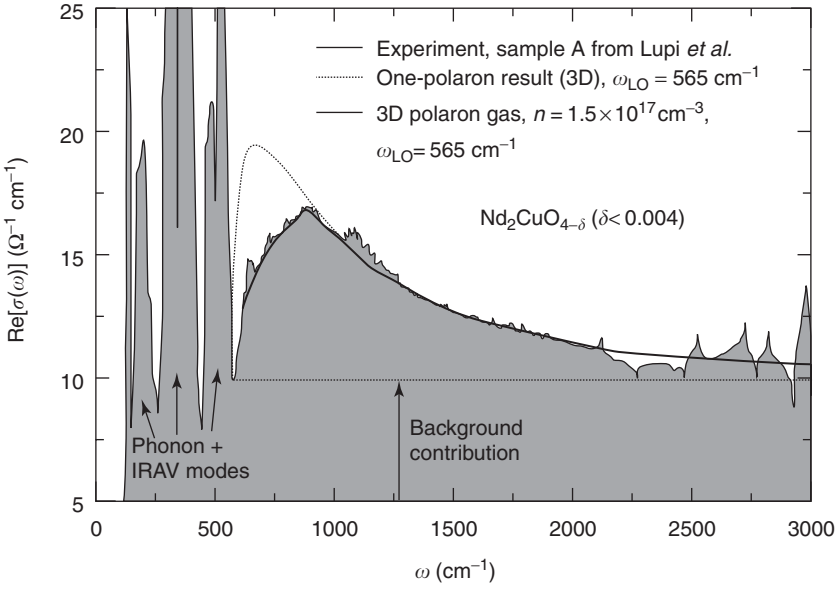

Figure 3 The infrared optical absorption of $Nd_2CuO_{2-\delta}$ ($\delta < 0.004$) as a function of frequency. The experimental results of P Calvani and co-workers are represented by the thin black curve and by the shaded area. The dotted curve shows the single polaron result. The full curve presents the theoretical results obtained for the interacting many-polaron gas with $n = 1.5 \times 10^{17}$ cm^{-3}, $\alpha = 2.1$, and $m_b = 0.5m_e$. (Recently, a numerical error was found in the fitting procedure, concerning strength of the plasmon branch, so that the parameter values given above may not be the optimal parameter values.) (Reprinted with permission from Tempere J and Devreese JT (2001) *Physical Review B* 64: 104504. 1–10; © American Physical Society.)

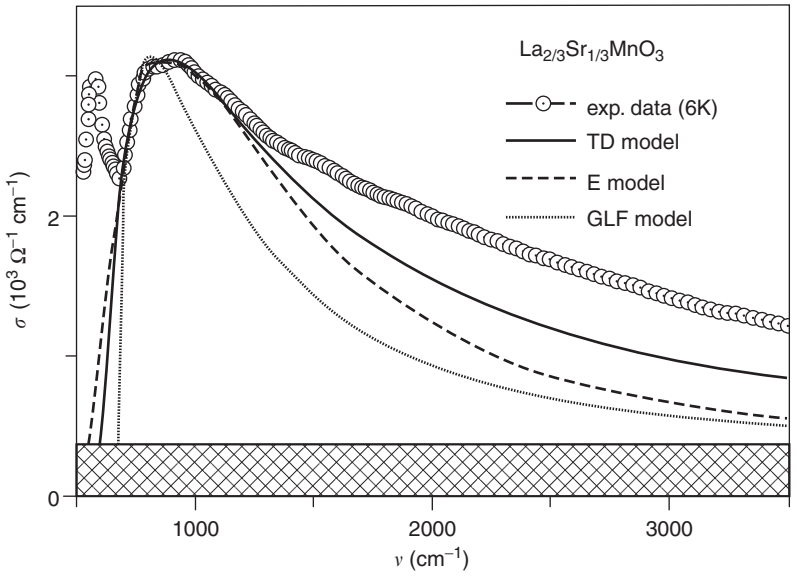

Figure 4 Comparison of the mid-infrared optical conductivity in $La_{2/3}Sr_{1/3}MnO_3$ measured by Ch Hartinger and co-authors at $T = 6$K to that given by several model calculations for $m_b = 3m_e$ and $n_0 = 6 \times 10^{21}$cm^{-3} . The solid curve refers to the many-polaron single-mode approach (TD model), the dashed curve is the result of the phenomenological approach for self-trapped polarons (E model by D Emin), the dotted curve is the weak-coupling one-polaron result (GLF model). (Reprinted with permission from Hartinger Ch, Mayr F, Deisenhofer J, Loidl A, and Kopp T (2004) *Physical Review B* 69: 100403(R). 1–4; © American Physical Society.)

flow as well. When the electronic contribution, determined by using the Lorenz number is subtracted, the lattice contribution to the diagonal heat flow appears to be much higher than is anticipated in the framework of any Fermi-liquid model.

Cyclotron Resonance of Polarons

Polaron effects in a magnetic field are sometimes referred to as "magnetopolaron" effects. These effects have been reviewed, for example, Larsen and Petrou and McCombe.

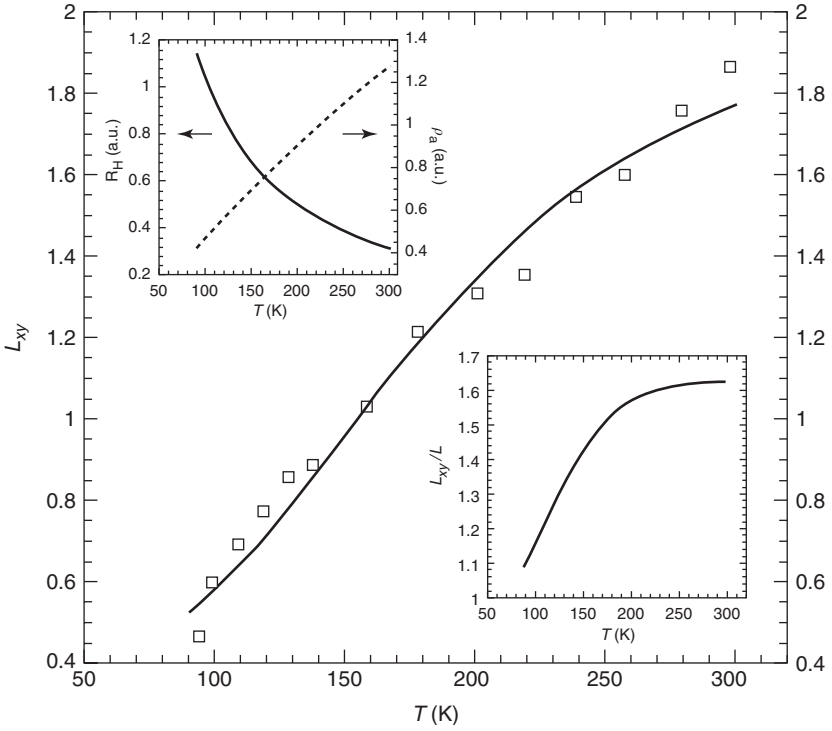

Figure 5 The experimental Hall–Lorenz number obtained by Y Zhang *et al.* in $YBa_2Cu_3O_{6.95}$ fitted by the small itinerant bipolaron theory. The upper inset shows the linear in-plane resistivity and the Hall ratio. The lower inset shows the ratio of the Hall–Lorenz number to the Lorenz number as a function of temperature. A powerful technique to study the electron–phonon coupling in semiconductors is cyclotron resonance. Changing the magnetic field B allows one to vary the cyclotron frequency $\omega_c = eB/m_b c$. When ω_c is brought closer to resonance with the phonon frequency ω_{LO}, a strongly renormalized "magnetopolaron" state is formed. This results in a splitting of the cyclotron resonance signal, which is a measure of the electron–phonon (polaron) coupling constant α.

The experimental observation by Johnson and Larsen of a discontinuity in the energy spectrum of a polaron in a magnetic field under the resonance condition $\omega_c = \omega_{LO}$ has stimulated numerous theoretical works aimed at the description of observed magnetoabsorption spectra. In the early works, the energy spectra of a polaron subjected to a magnetic field were studied in the weak-coupling limit, and the polaron cyclotron mass was determined from the energy differences between the polaron (Landau-) energy levels.

For an adequate description of experiment, the magnetoabsorption spectrum itself must be calculated. In the sixties and seventies, several weak-coupling approximations for the magnetoabsorption spectra of polarons were suggested.

The most direct approach to study the (magneto-) polaron mass is to calculate the magnetooptical absorption spectrum of the polaron (the quantity which is actually measured) and to define the polaron mass in the same way as the experimentalists do, from the peak positions in the spectrum. This approach was chosen by Peeters and Devreese on the grounds of the memory-function formalism and elaborated over many years as a basic theoretical tool to analyze experimental data on magnetopolaron spectra.

A direct evidence for the polaron character of charge carriers in AgBr and AgCl was obtained through CR experiments in external magnetic fields up to 16 T. The magnetoabsorption calculated within the all-coupling approach leads to the best quantitative agreement between theory and experiment for AgBr and AgCl.

Nicholas and co-workers demonstrated polaron coupling effects using cyclotron resonance measurements in a 2DEG, which naturally occurs in the polar semiconductor InSe. One clearly sees, over a wide range of magnetic fields ($B = 18-34$ T), two distinct magnetopolaron branches separated by as much as 11 meV ($\sim 0.4\omega_{LO}$) at resonance.

In quasi-2D semiconductor structures, the phonon modes are modified by the presence of the interfaces. Wang and co-authors studied the cyclotron resonance of polarons in $GaAs/Al_{0.3}Ga_{0.7}As$ multiple quantum well structures. It appeared possible to observe the anticrossing effects due to different phonon modes.

The analysis of the experimental data has shown that the observed anticrossing effects are caused by the resonant interaction of electrons with the confined GaAs slab phonon modes and the AlAs-like interface optical phonons.

The availability of very high magnetic fields allows one to achieve the resonant condition $\omega_c = \omega_{LO}$ as well as the condition $\omega_c > \omega_{LO}$ even for II–IV semiconductor compounds, where the effective mass of the conduction electrons can be considerably larger than in II–V semiconductors. Experiments on cyclotron resonance in bulk *n*-type CdS at ultrahigh magnetic fields (up to 450 T) revealed a pronounced maximum in the temperature dependence of the cyclotron mass. Polaron effects beyond the weak-coupling approximation significantly influence the magnetoabsorption even for a relatively small Fröhlich coupling constant like 0.527 in *n*-type CdS. Extending the memory-function approach to account for the elastic scattering of electrons by piezoacoustic phonons and lattice defects provides a quantitative interpretation for the experimental data of Imanaka, Mivra, and Nojiri.

Polaronic Response in Confined Structures

Electron–Phonon Interaction and Cyclotron Resonance in Quantum Wells

Numerous experiments on cyclotron resonance give clear evidence of this effect. The resonant magnetopolaron coupling manifests itself near the LO-phonon frequency for low electron densities and also for higher electron densities. Cyclotron resonance measurements performed on semiconductor quantum wells with high electron density reveal anticrossing near the TO-phonon frequency rather than near the LO-phonon frequency. This effect is interpreted by invoking mixing between magnetoplasmons and phonons and in terms of a resonant coupling of the electrons with the mixed magnetoplasmon–phonon modes.

The CR spectra for a polaron gas in a GaAs/AlAs quantum well are theoretically investigated, taking into account (1) the electron–electron interaction and the screening of the electron–phonon interaction, (2) the magnetoplasmon–phonon mixing, and (3) the electron–phonon interaction with all the phonon modes specific for the quantum well under investigation. As a result of this mixing, different magnetoplasmon–phonon modes appear in the quantum well which give contributions to the CR spectra.

It is clearly seen from **Figure 6** that, for the high-density polaron gas, anticrossing of the CR spectra occurs near the GaAs TO-phonon frequency ω_{T1} rather than near the GaAs LO-phonon frequency ω_{L1} for both the experimental and the calculated spectra. This effect is in contrast with the cyclotron resonance of a low-density polaron gas in a quantum well, where anticrossing occurs near the LO-phonon frequency. The occurrence of the anticrossing frequency close to ω_{T1} instead of ω_{L1} is due to the screening of the

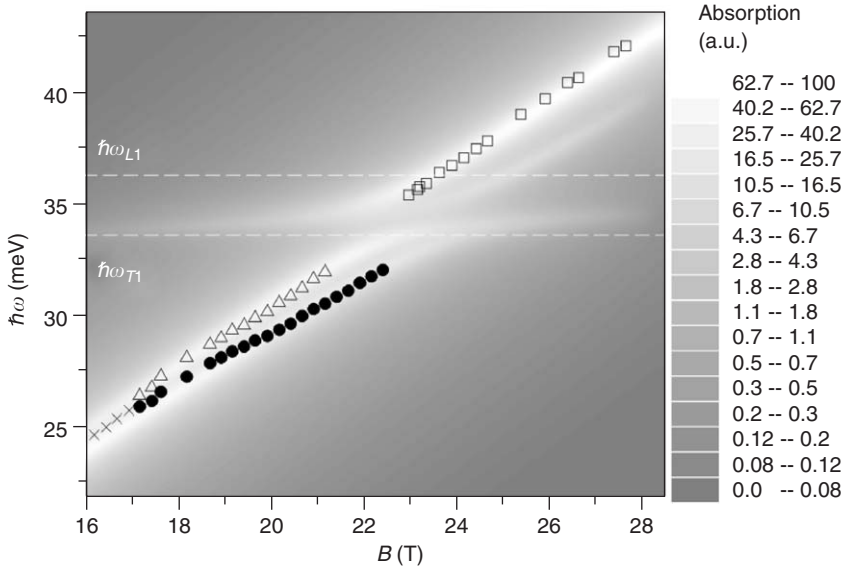

Figure 6 Density map of the calculated magnetoabsorption spectra for a 10-nm GaAs/AlAs quantum well. Symbols indicate peak positions of the experimental spectra (which are taken from figure 3 of Poulter AJL, Zeman J, Maude DK, Potemski M, Martinez G, *et al.* (2001) *Physical Review Letters* 86: 336–339.) Dashed lines show LO- and TO-phonon energies in GaAs. (Reprinted with permission from Klimin SN and Devreese JT (2003) *Physical Review B* 68: 245303. 1–8; © American Physical Society.)

longitudinal polarization by the plasma vibrations. A similar effect appears also for the magnetophonon resonance: as shown by Afonin and co-authors, the magnetoplasmon–phonon mixing leads to a shift of the resonant frequency of the magnetophonon resonance in quantum wells from $\omega \approx \omega_{L1}$ to $\omega \approx \omega_{T1}$.

Interacting Polarons in Quantum Dots

The ground-state energy and the optical conductivity spectra for a system with a finite number of interacting arbitrary-coupling large polarons in a spherical quantum dot are calculated using the path-integral formalism for identical particles. A parabolic confinement potential characterized by the confinement energy $\hbar\Omega_0$ and with a background charge is considered. Using a generalization of the Jensen–Feynman variational principle, the ground-state energy of a confined N-polaron system is analyzed as a function of N and of the electron–phonon coupling strength α.

The total spin S is analyzed as a function of the number of electrons in the quantum dot for different values of the confinement energy, of the coupling constant, and of the ratio η of the high-frequency and the static dielectric constants.

Confined few-electron systems, without electron–phonon interaction, can exist in one of the two phases: a spin-polarized state and a state obeying Hund's rule, depending on the confinement frequency. For interacting few-polaron systems with $\alpha \geqslant 3$, besides the above two phases, there may occur a third phase: the state with minimal spin.

To investigate the optical properties of a many-polaron system, the memory-function formalism is extended by Devreese and co-workers to the case of interacting polarons in a quantum dot. The shell structure for a system of interacting polarons in a quantum dot is clearly revealed when analyzing both the addition energy and the first-frequency moment of the optical conductivity. The envelope of the optical absorption spectrum for polarons in a quantum dot bears a similarity to the corresponding spectrum for an interacting polaron gas, especially at low densities.

Electron–Phonon Interaction and the Optical Response of Polaronic Excitons in Quantum Dots

The interest in the optical properties of quantum dots has been continuously growing, among others, because of the prospects of these structures for optoelectronic applications. Recent measurements of photoluminescence of self-assembled InAs/GaAs quantum dots reveal high probabilities of the phonon-assisted transitions. Attempts to interpret some of these experiments on the basis of the adiabatic theory meet with difficulties. For spherical CdSe quantum dots, for example, the Huang–Rhys factor S calculated within the adiabatic approximation takes values which are significantly (by one or two orders of magnitude) smaller than the so-called "experimental Huang–Rhys" factor, determined from the ratio of measured intensities of the phonon satellites. In the framework of the adiabatic approach, various mechanisms, which cause the separation of the electron and hole charges in space are commonly considered as a possible origin for the unexpectedly large Huang–Rhys factor.

It has been shown that nonadiabaticity of exciton–phonon systems in various quantum-dot structures drastically enhances the efficiency of the exciton–phonon interaction, especially when the exciton levels are separated with energies close to the phonon energies. Also "intrinsic" excitonic degeneracy can lead to enhanced efficiency of the exciton–phonon interaction. The effects of nonadiabaticity are important to interpret the surprisingly high intensities of the phonon "sidebands" observed in the optical absorption, the photoluminescence, and the Raman spectra of quantum dots. Considerable deviations of the oscillator strengths of the phonon-peak sidebands, observed in some experimental optical spectra from the Franck–Condon progression, which are prescribed by the commonly used adiabatic approximation, find a natural explanation within the nonadiabatic approach.

Fomin and co-authors proposed a method to calculate the optical absorption spectrum for a spherical quantum dot taking into account the nonadiabaticity of the excition–phonon system. This approach has been further refined by Gladilin and co-authors for the matrix elements of the evolution operator: a closed set of equations has been obtained using a diagrammatic technique. This set describes the effect of nonadiabaticity both on the intensities and positions of the absorption peaks.

From the comparison of the spectra obtained in the adiabatic approximation with those resulting from the nonadiabatic approach, the following effects of nonadiabaticity are revealed. First, the polaron shift of the zero-phonon lines with respect to the bare-exciton levels is larger in the nonadiabatic approach than in the adiabatic approximation. Second, there is a strong increase of the intensities of the phonon satellites as compared to those given by the adiabatic approximation. Third, in the optical absorption spectra found within the nonadiabatic approach, there appear phonon satellites related to nonactive bare-exciton states. Fourth, the optical absorption spectra demonstrate the crucial role of nonadiabatic mixing of different exciton and phonon states in quantum

dots. This results in a rich structure of the absorption spectrum of the exciton–phonon system. Similar conclusions about the pronounced influence of the exciton–phonon interaction on the optical spectra of quantum dots have been formulated by Verzelen and co-authors in terms of a strong coupling regime for excitons and LO phonons. Such a strong coupling regime is a particular case of the nonadiabatic mixing related to a (quasi-) resonance which arises when the spacing between exciton levels is close to the LO phonon energy. The large enhancement of the two-phonon sidebands in the luminescence spectra as compared to those predicted by the Huang–Rhys formula, which was explained by nonadiabaticity of the exciton–phonon system in certain quantum dots, has been reformulated in terms of the Fröhlich coupling between product states with different electron and/or hole states.

Due to nonadiabaticity, multiple absorption peaks appear in spectral ranges characteristic for phonon satellites. From the states, which correspond to these peaks, the system can rapidly relax to the lowest emitting state. Therefore, in the photoluminescence excitation (PLE) spectra of quantum dots, pronounced peaks can be expected in spectral ranges characteristic for phonon satellites. Experimental evidence of the enhanced phonon-assisted absorption due to effects of nonadiabaticity has been provided by PLE measurements on single self-assembled InAs/GaAs and InGaAs/GaAs quantum dots.

Electrons and Holes

G C La Rocca, Scuola Normale Superiore, Pisa, Italy

Introduction

The paramount role of semiconductors in technology ever since the invention of the transistor consists mainly in their use in electronic devices, particularly very large scale integrated circuitry, in which electric currents are due to mobile electrons and holes. The possibility of growing single crystals of very high purity and to control their transport properties through intentional *n*-type and *p*-type doping has been crucial to the development of the electronic industry. Silicon is presently the material of choice for electronic devices not only because of its outstanding processing properties, but also because its native oxide forms a high-quality semiconductor–insulator interface. Semiconductors have at the same time attracted a lot of attention from the viewpoint of basic science, and understanding their electronic structure, optical, and transport properties has been a great success of the modern theory of solids.

The resistivity of semiconductors is intermediate between that of metals and insulators, varying at room temperature between 10^{-4} and $10^{10}\,\Omega\,\mathrm{cm}$, and is extremely sensitive to the presence of impurities. The value of resistivity is not the best criterion defining a semiconductor, but rather the property that in pure enough samples the resistivity decreases with increasing temperature in a way that is exponential with the inverse temperature. Another property of semiconductors is that not only the electrons, but also the positive charge carriers (i.e., the holes) may be responsible for electrical conductivity, as shown by the sign of the Hall coefficient.

Semiconductors are characterized by an energy gap of the order of an electronvolt separating the highest occupied band (the valence band) from the lowest unoccupied one (the conduction band); the former may be populated by mobile holes (corresponding to missing electrons) and the latter by mobile electrons. In the following, the behavior of electrons and holes in homogeneous semiconductors will be described considering relevant electronic band structure properties, doping and equilibrium carrier concentration, mobility, and electrical conductivity.

Electron and Hole Pockets

The transport properties of semiconductors are dominated by carriers (electrons and holes introduced by doping or excited across the energy gap) which occupy the bottom of the conduction band or the top of the valence band. An accurate description of the electronic energy bands near these extrema is usually obtained employing the $\boldsymbol{k}\cdot\boldsymbol{p}$ perturbative method. Then, the response of the carriers to external perturbations, such as electric and magnetic fields, slowly varying on the scale of the lattice constant can be dealt with by using the effective mass approximation.

The $\boldsymbol{k}\cdot\boldsymbol{p}$ method consists of a perturbative calculation of the electronic states with a Bloch wave vector $\boldsymbol{k}$ close to a given $\boldsymbol{k}_0$ point (usually of high symmetry) in the Brillouin zone (BZ) corresponding to a maximum in the valence band (hole pocket) or a minimum in the conduction band (electron pocket). For a nondegenerate band, as typical for electrons, a single-band approximation is usually employed, the interaction with all other bands being treated in perturbation theory up to second order in $(\boldsymbol{k}-\boldsymbol{k}_0)$. In this case, one gets simply

$$E(\boldsymbol{k}) = E(\boldsymbol{k}_0) + \frac{\hbar^2}{2}\,(\boldsymbol{k}-\boldsymbol{k}_0)\cdot\mathbf{m}^{-1}\cdot(\boldsymbol{k}-\boldsymbol{k}_0) \quad [1]$$

where the inverse effective mass tensor $\mathbf{m}^{-1}$ for the extremum of interest has been introduced. Finally, measuring the energy from $E(\boldsymbol{k}_0)$ and the wave vector from $\boldsymbol{k}_0$, and choosing the $\hat{1}$, $\hat{2}$, and $\hat{3}$ directions along the principal axes of $\mathbf{m}^{-1}$, the standard expression for ellipsoidal pockets is obtained:

$$E(\boldsymbol{k}) = \frac{\hbar^2}{2}\left(\frac{k_1^2}{m_1}+\frac{k_2^2}{m_2}+\frac{k_3^2}{m_3}\right) \quad [2]$$

Then, in the presence of slowly varying external perturbations, the dynamics of the electrons in a conduction band minimum can be described as that of free carriers (i.e., without considering the rapidly varying crystal potential) with a positive (anisotropic) effective mass and a negative charge $-e$. In particular, they will give rise to a current in the same direction as the applied electric field while moving in the opposite direction. Likewise, a hole pocket is associated with a maximum in the valence band and is characterized by negative values of the effective mass parameters appearing in eqn [2]. Such states, which in a pure crystal at zero temperature are completely occupied, may become empty and, upon the action of an applied electric field, give rise to a current that can be thought of as due to positively charged particles with a positive (anisotropic) effective mass. This is so because instead of considering the motion of the very large number of electrons which fill almost the entire valence band, it is convenient to focus on the dynamics of the few empty

states whose electrons are missing (i.e., the hole states). As the energy of a hole state increases when the energy of the corresponding missing electron decreases, in the hole picture used in the following, the sign of the effective mass parameters of a hole pocket will be taken as positive and at the same time the charge of a hole as $+e>0$. A hole moves in the same direction as the applied electric field and contributes to a current in the same direction.

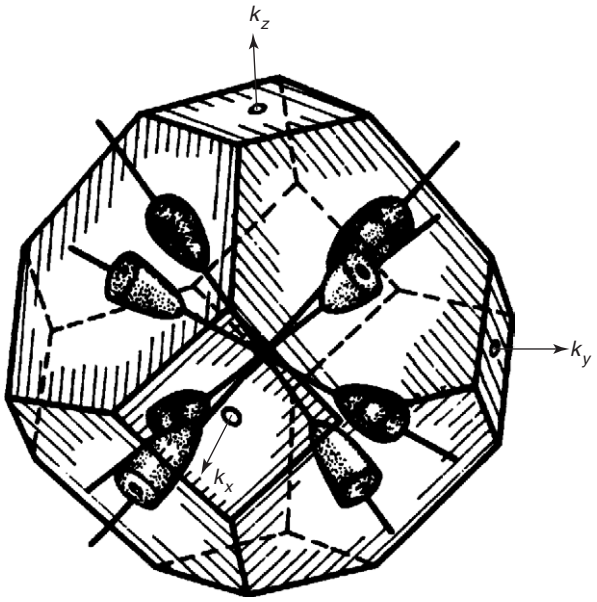

Figure 1 Electron pockets in Ge.

The symmetry of the dispersion relation of electron (or hole) pockets as well as the values of the corresponding effective mass parameters can be measured by cyclotron resonance, that is, the absorption of radio frequency radiation in the presence of an external magnetic field $\boldsymbol{B}$. The resonance frequency is $\omega_c = (eB/m^{\star}(\hat{B})c)$, with

$$m^{\star}(\hat{B}) = \sqrt{\frac{m_1 m_2 m_3}{m_1(\hat{B}\cdot\hat{1})^2 + m_2(\hat{B}\cdot\hat{1})^2 + m_3(\hat{B}\cdot\hat{3})^2}} \quad [3]$$

From the dependence of the observed absorption on the magnitude and direction of the magnetic field, the symmetry of the pockets of carriers as well as their effective mass parameters can be determined. Also magnetoresistance measurements are sensitive to the mass anisotropy and other band structure features, in particular from the strong dependence on the current and magnetic field directions with respect to the cubic axes the symmetry of the carrier pockets involved can be identified, similar to the case of cyclotron resonance measurements.

The conduction band of Ge has four electron pockets at the L point of the BZ (see **Figure 1**; the half pockets at $\boldsymbol{k}$ and $-\boldsymbol{k}$ are to be combined together); they are ellipsoids of revolution elongated along the $\langle 1\,1\,1\rangle$ directions. The values of the longitudinal mass $m_L = m_3 \simeq 1.6\,m$ and of the transverse mass $m_T = m_1 = m_2 \simeq 0.08\,m$ have been determined from cyclotron resonance measurements such as those shown in **Figure 2**: with $\boldsymbol{B}$ along

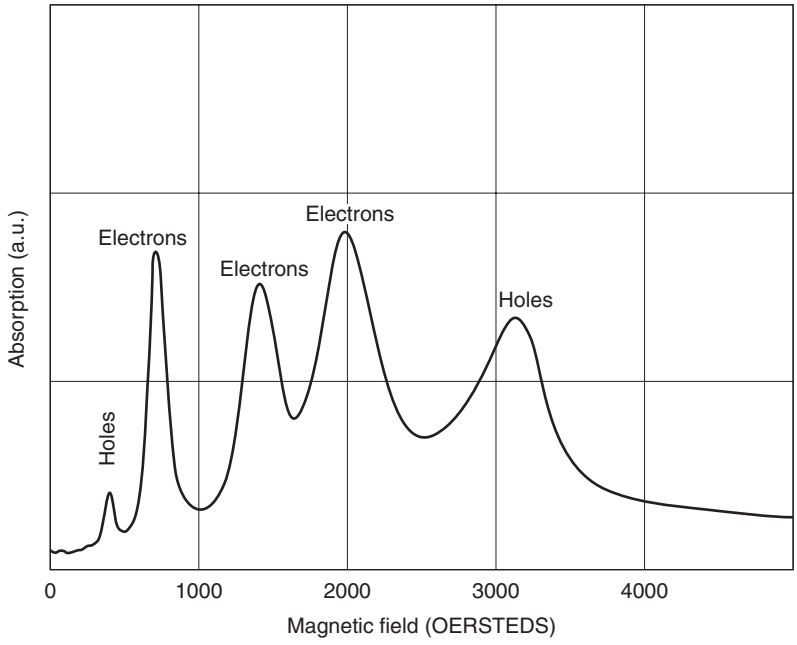

Figure 2 Cyclotron resonance in Ge (at a frequency of 24 GHz and a temperature of 4 K) with magnetic field in the (1 1 0) plane at 60° from the [0 0 1] axis. (From Dresselhaus G, Kip AF, and Kittel C (1955) *Physical Review* 98: 368.)

$[\sqrt{3}, \sqrt{3}, \sqrt{2}]/2$ the four $\langle 1\,1\,1 \rangle$ electron pockets split into three groups inequivalently oriented with respect to the magnetic field, each one of these giving rise to a distinct resonance according to eqn [3]. The conduction band of Si has six electron pockets along the $\langle 1\,0\,0 \rangle$ directions (see **Figure 3**); they are ellipsoids of revolution elongated along the same directions with a longitudinal mass $m_L = m_3 \simeq 1.0\ m$ and a transverse mass $m_T = m_1 = m_2 \simeq 0.2\ m$ (measured from cyclotron resonance; see **Figure 4**, where due to the choice of magnetic field orientation two distinct electronic resonances show up). Typical zinc blende semiconductors have a simple electron pocket at the center of the BZ (Γ point) with an isotropic effective mass; for instance, the electron effective mass of GaAs is $0.067\,m$.

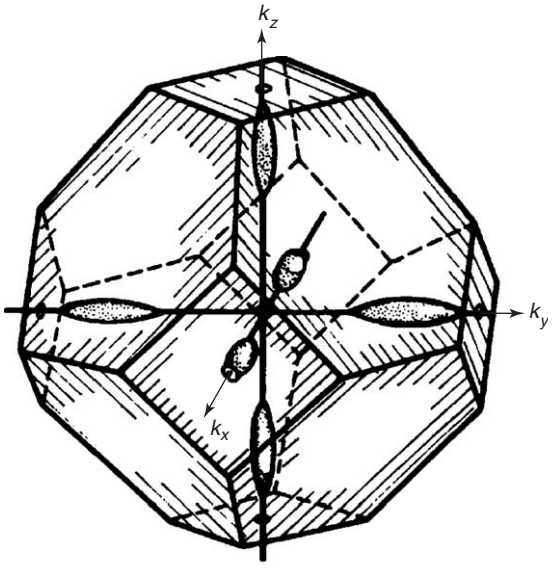

Figure 3 Electron pockets in Si.

The hole pockets in Si, Ge, and typical zinc blende semiconductors are at the center of the BZ and correspond to a threefold *p*-like degenerate band (without spin) that splits due to the spin–orbit interaction into an upper fourfold degenerate ($J = 3/2$) band and a lower twofold degenerate ($J = 1/2$) band (spin included). The former corresponds to the top of the valence band and the latter to the split-off valence band which, apart from spin, is nondegenerate. The split-off hole states can be described as a simple band with an isotropic effective mass $m_{so} \simeq 0.25\ m$ in Si, $m_{so} \simeq 0.08\ m$ in Ge, $m_{so} \simeq 0.2\ m$ in GaAs. In a rough approximation, the topmost hole states can be described as belonging to two distinct spherical pockets each characterized by an isotropic mass: the heavy hole pocket (with mass $m_{hh} \simeq 0.5\ m$ for Si, $m_{hh} \simeq 0.3\ m$ for Ge, $m_{hh} \simeq 0.5\ m$ for GaAs) and the light hole pocket (with mass $m_{lh} \simeq 0.16\ m$ for Si, $m_{lh} \simeq 0.044\ m$ for Ge, $m_{lh} \simeq 0.09\ m$ for GaAs). Also the hole masses have been determined from cyclotron resonance measurements such as those shown in **Figures 2** and **4**. A complete description of the hole states beyond this simple picture can only be given within a multiband $\boldsymbol{k} \cdot \boldsymbol{p}$ approach, in which the valence band degeneracy is fully accounted for.

Donors and Acceptors

The ability to control the content of impurities is a key issue in semiconductor technology: the concentration of undesired dopants in Si is typically kept below $10^{12}\,cm^{-3}$. A foreign atom may give rise to electronic states, more or less localized around the impurity site, with energies lying in the forbidden energy gap of the host material. The impurity levels may either be close to the conduction or valence band

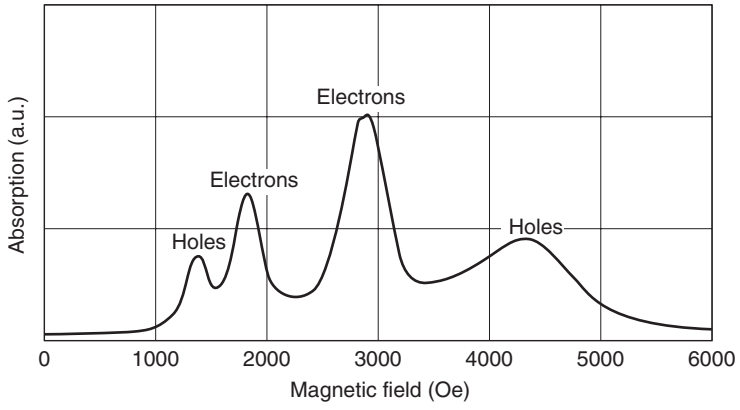

Figure 4 Cyclotron resonance in Si (at a frequency of 24 GHz and a temperature of 4 K) with magnetic field in the (1 1 0) plane at 30° from the [0 0 1] axis. (From Dresselhaus G, Kip AF, and Kittel C (1955) *Physical Review* 98: 368.)

edges (shallow donor or acceptor states) or to the middle of the gap (deep states). In the first case, they behave as dopants and dominate the transport properties providing extrinsic free carriers; in the second case, they mainly affect the recombination of free electron–hole pairs by trapping them at the same site.

Depending on their chemical valency, foreign atoms typically used as dopants may provide one extra electron or one extra hole (i.e., one missing electron) with respect to the host atoms they replace. For instance, a group V impurity, say P, substituting a group IV host atom, such as Si, provides an extra electron to the crystal (donor behavior), while a substitutional group III impurity, say B, at the same site would provide an extra hole (acceptor behavior). The extra hole or electron, with respect to the fully occupied valence band, is bound to the defect site by the long-range Coulomb potential due to the charge difference between the impurity and host nuclei. Because of the low effective masses ($m^\star \simeq 0.2\, m$) and the high dielectric constants ($\varepsilon \gtrsim 10$) typical of semiconductors, the corresponding localized states extend over many unit cells and may be described within the effective mass approximation as a solid-state analog of the hydrogen atom with scaled down Rydberg energy $R^\star = (m^\star e^4/2\hbar^2\varepsilon^2)$ and Bohr radius $a^\star = (\hbar^2\varepsilon/m^\star e^2)$ ($R^\star \simeq 20$ meV, $a^\star \simeq 50$ Å). As their binding energy is small, such impurity levels are shallow, that is, close to the bottom of the conduction band for the case of donors and close to the top of the valence band for the case of acceptors. Thus, they are easily thermally ionized providing free electrons to the conduction band (*n*-type doping) or free holes to the valence band (*p*-type doping), as discussed below.

Free Carrier Density

According to the Boltzmann distribution law (valid at typical carrier concentrations and temperatures, that is, excluding the case of quantum degeneracy), the density n of electrons in the conduction band and of holes p in the valence band can be expressed as

$$n(T,\mu) = N_c(T)\,\exp((\mu - E_c)/k_B T) \qquad [4]$$

$$p(T,\mu) = N_v(T)\,\exp((E_v - \mu)/k_B T) \qquad [5]$$

with a chemical potential μ well inside the energy gap between E_v and E_c (the top of the valence band and the bottom of the conduction band, respectively), being

$$N_c = \left(\frac{k_B T}{\pi\hbar^2}\right)^{3/2} \frac{(m_c^{(D)})^{3/2}}{\sqrt{2}}$$

$$N_v = \left(\frac{k_B T}{\pi\hbar^2}\right)^{3/2} \frac{(m_v^{(D)})^{3/2}}{\sqrt{2}}$$

where $m^{(D)}$ is the density of states effective mass given for a many-valley conduction band by an average over the equivalent valleys $m_c^{(D)} = g^{2/3}(m_T^2 m_L)^{1/3}$, g being the valley degeneracy (6 for Si, 4 for Ge), and for the valence band by an average over heavy and light holes $m_v^{(D)} = (m_{lh}^{3/2} + m_{hh}^{3/2})^{2/3}$. The densities of electrons and holes in thermal equilibrium at temperature T satisfy the law of mass action

$$np = N_c N_v e^{-E_g/k_B T} \qquad [6]$$

In a pure (intrinsic) semiconductor, the density of electrons n_i thermally excited into the conduction band equals the density of holes p_i left behind in the valence band and they are given by

$$n_i = p_i = \sqrt{N_c N_v}\,\exp(-E_g/2k_B T)$$

the intrinsic concentration of carriers is dominated by the exponential dependence on $E_g/(2k_B T)$. For instance, one obtains at room temperature, for Si, $E_g = 1.1$ eV, $N_c \simeq 3 \times 10^{19}$ cm^{-3}, $N_v \simeq 1 \times 10^{19}$ cm -3, $n_i = p_i \simeq 1.5 \times 10^{10}$ cm^{-3}; for Ge, $E_g = 0.66$ eV, $N_c \simeq 1 \times 10^{19}$ cm^{-3}, $N_v \simeq 6 \times 10^{18}$ cm^{-3}, $n_i = p_i \simeq 2.3\times 10^{13}$ cm^{-3}; for GaAs, $E_g = 1.43$ eV, $N_c \simeq 4.4\times 10^{17}$ cm^{-3}, $N_v \simeq 8 \times 10^{18}$ cm^{-3}, $n_i = p_i \simeq 2\times 10^{6}$ cm^{-3}. For the nondegenerate regime here considered, the intrinsic Fermi level (chemical potential) is given by $\mu_i = (E_c + E_v)/2 + (3/4)k_B T \ln(m_v^{(D)}/m_c^{(D)})$, and is close to the center of the gap (i.e., $(E_c + E_v)/2$).

In a doped semiconductor with a concentration of donors N_d and of acceptors N_a, if $N_d > N_a$ (*n*-type) the electron (majority carrier) density is approximately $n = N_d - N_a$ and the hole (minority carrier) density is correspondingly $p = (n_i p_i)/n$; if $N_d < N_a$ (*p*-type) similar formulas hold with the role of majority and minority carriers interchanged. In *n*-type semiconductors the chemical potential μ is shifted a bit closer to E_c with respect to μ_i, as given by

$$\frac{N_d - N_a}{2n_i} = \sinh\left(\frac{\mu - \mu_i}{k_B T}\right) \qquad [7]$$

the converse is true for *p*-type semiconductors. In the above, the temperature has been assumed to be high enough to ionize all the impurities, but not so high that the concentration of intrinsic carriers (i.e., those thermally excited across the energy gap) should be comparable to the majority carrier concentration. In this case, that is, the extrinsic regime, the carrier concentration is independent of temperature and determined by the doping level. At lower temperatures, the concentration of ionized impurities decreases because more and more electrons fall in the impurity bound states and the concentration of free carriers drops (freeze-out regime). The typical temperature dependence of the majority carrier concentration in a doped

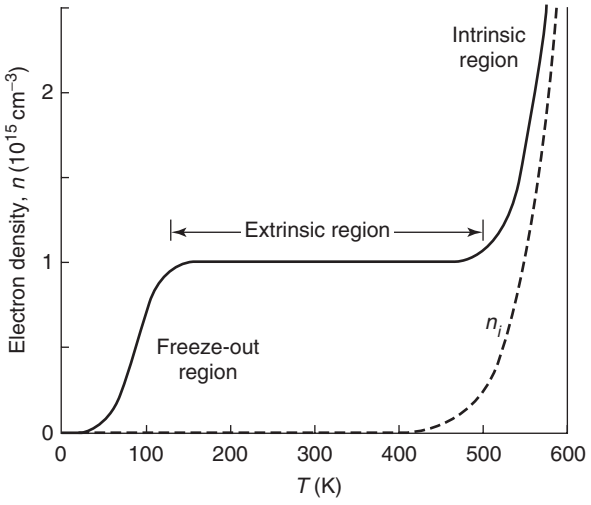

Figure 5 Temperature dependence of majority carrier concentration in *n*-doped Si ($N_d = 10^{15}$ cm^{-3}). The intrinsic carrier concentration is shown by the dashed line for comparison.

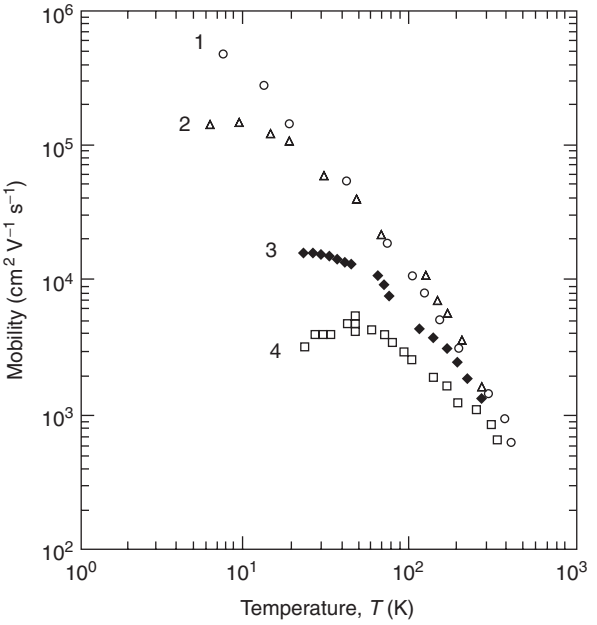

Figure 6 Temperature dependence of mobility in *n*-type Si at various doping levels: (1) $N_d < 10^{12}$ cm^{-3} (high purity), (2) $N_d < 10^{13}$ cm^{-3} (high purity), (3) $N_d = 1.6 \times 10^{16}$ cm^{-3}, (4) $N_d = 1.3 \times 10^{17}$ cm^{-3}. (From the database NSM maintained by the Ioffe Institute.)

semiconductor over a wide temperature range is depicted in **Figure 5**. The wide plateau (extrinsic regime) around room temperature shows how the carrier concentration can be suitably fixed by intentional doping, a characteristic semiconductor behavior of paramount importance for electronic applications.

Carrier Mobility and Electrical Conductivity

In a cubic semiconductor, the low-field conductivity tensor relating the current density $\boldsymbol{J}$ to the electric field $\boldsymbol{E}$ is a scalar $\boldsymbol{J} = \sigma \boldsymbol{E}$ given by

$$\sigma = e(n\mu_n + p\mu_p) \qquad [8]$$

where n and p are the densities of conduction band electrons and valence band holes, respectively, and μ_n and μ_p the corresponding mobilities, relating the average drift velocities of electrons or holes to the electric field, given by

$$\mu_{n,p} = (e/m_{n,p}^{(\sigma)})\tau_{n,p} \qquad [9]$$

where $m^{(\sigma)}$ is the appropriate effective mass and τ the appropriate momentum relaxation time as determined by the scattering mechanisms briefly discussed below. For a many-valley band extremum, such as for the electron pockets in Si and Ge, the conductivity effective mass to be used above is an average given by

$$1/m_n^{(\sigma)} = (2/m_T + 1/m_L)/3 \qquad [10]$$

and n is the total density of electrons equally distributed among the equivalent valleys. From the values of the electron transverse and longitudinal masses, one obtains, for Si, $m_n^{(\sigma)} \simeq 0.27\, m$ and, for Ge, $m_n^{(\sigma)} \simeq 0.12\, m$. When more than one electron or hole bands are populated (e.g., light and heavy hole bands) their contributions add up in the above expression for σ. The conductivity of a semiconductor, in contrast to that of a metal, varies strongly because of the dramatic dependence of the electron and hole densities on the temperature and the doping level; only a smoother variation is brought about by mobility changes. The carrier mobilities are related to the respective diffusion coefficients by the Einstein relation $eD_{n,p} = \mu_{n,p} k_B T$.

At room temperature, in pure or moderately doped elemental semiconductors, the mobility is limited mainly by phonon scattering, whereas, at lower temperatures or heavy doping levels, the ionized impurity scattering is dominant. In nonpolar semiconductors such as Si and Ge, the main electron–phonon scattering mechanism is due to longitudinal acoustic phonon deformation potential scattering with a scattering rate $1/\tau_{ac}$ depending on temperature like $T^{3/2}$. However, significant deviations from this behavior are observed, mostly due to the mixture of acoustic and optical phonon scattering. In zinc blende semiconductors such as GaAs, at room temperature the main scattering mechanism is due to polar longitudinal optical phonon scattering with a stronger dependence on temperature. The mobility values in pure materials at room temperature are, for Si,

$\mu_n \simeq 1500\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$, $\mu_p \simeq 500\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$; for Ge, $\mu_n \simeq 3900\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$, $\mu_p \simeq 1900\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$; for GaAs, $\mu_n \simeq 8500\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$, $\mu_p \simeq 400\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$. The impurity Coulomb scattering rate $1/\tau_{\text{im}}$, instead, is proportional to $T^{-3/2}N_{\text{im}}$, N_{im} being the density of ionized impurities. Experimentally, it is not easy to see the $T^{3/2}$ dependence of the impurity scattering limited mobility as the temperature range in which this mechanism is dominant is restricted at low temperatures by the carrier freeze-out and at high temperatures by the onset of phonon scattering. However, when more sources of scattering are competing the total resistivity is approximately given by the sum of the resistivities obtained from each single scattering mechanism at a time (Matthiessen's rule). As a result, the mobility of doped semiconductors may exhibit a maximum at the temperature corresponding to the crossover from impurity scattering to phonon scattering. Such a behavior is evident in **Figures 6** and **7** which show, respectively, the electron mobility in Si and GaAs versus temperature for various doping levels.

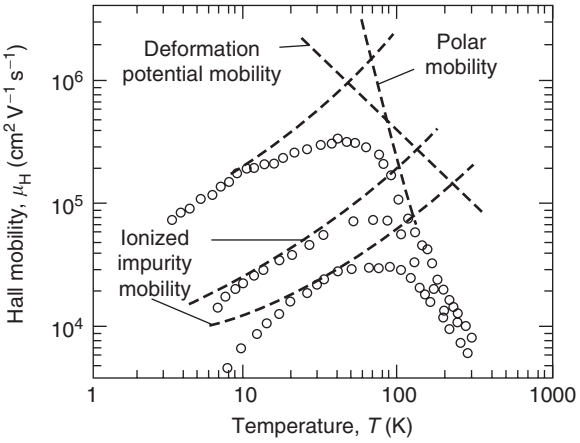

Figure 7 Temperature dependence of mobility in *n*-type GaAs at various doping levels: top curve $N_d = 5 \times 10^{14}\ \text{cm}^{-3}$, middle curve $N_d = 10^{15}\ \text{cm}^{-3}$, bottom curve $N_d = 5 \times 10^{15}\ \text{cm}^{-3}$. (From the database NSM maintained by the Ioffe Institute.)

The temperature dependence of the conductivity of Si at different doping levels is shown in **Figure 8**. The intrinsic regime is evident over most of the temperature range; the flattening of some of the curves at about room temperature corresponds to the extrinsic regime in which the conductivity is determined by

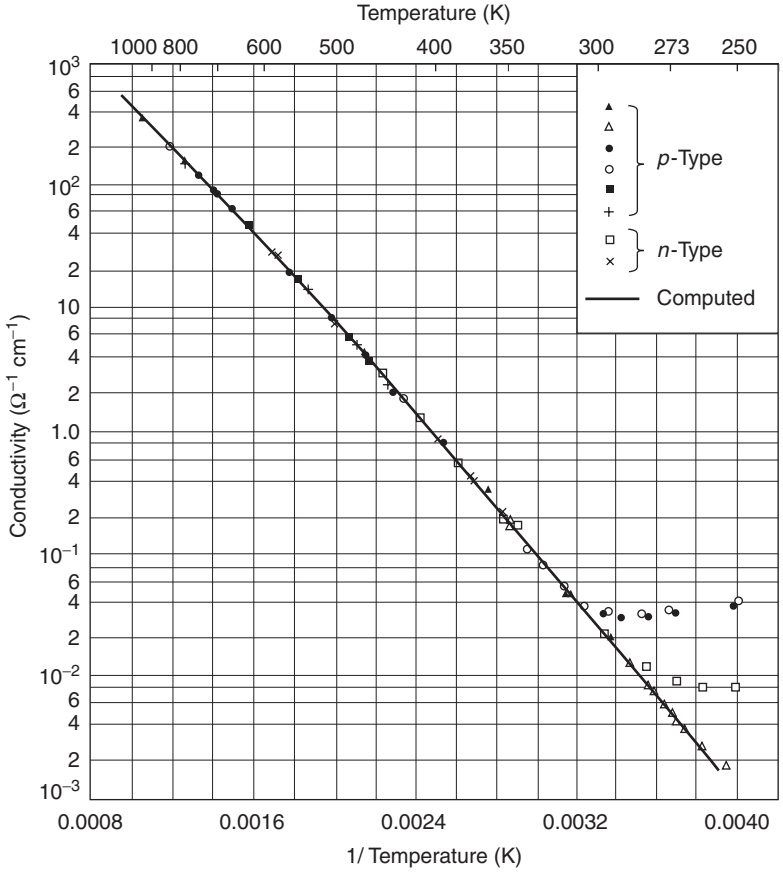

Figure 8 Temperature dependence of conductivity in Si at various doping levels. (From Morin EJ and Maita JP (1954) *Physical Review* 94: 1525.)

the doping level. The temperature dependence of σ is dominated by that of the carrier concentration in the intrinsic regime, whereas its weaker variation in the extrinsic regime is due to the temperature dependence of the mobility.

Measuring the Hall coefficient is a widely used method to characterize the concentration (and type) of free carriers; the Hall coefficient R_H is given by

$$R_H = \frac{p\mu_p^2 - n\mu_n^2}{ce(p\mu_p + n\mu_n)^2} \qquad [11]$$

In weak fields, the mobilities appearing in the numerator of the above expression are in general to be multiplied by corrective factors of order unity (i.e., the ratios of Hall mobilities to drift mobilities: μ_H/μ) which depend on the scattering mechanism and the band structure details. Notice that in *p*-type samples the sign of R_H is positive (i.e., opposite to that of *n*-type samples).

So far the low-field conductivity corresponding to the ohmic regime has been considered. With increasing field strength, the free carrier drift velocity approaches their thermal velocity and hot carrier effects become important. In particular, in Si and Ge, the high-field mobility (limited mainly by inelastic phonon scattering) eventually decreases linearly with the electric field and the drift velocity saturates to values close to $10^7\,\mathrm{cm\,s^{-1}}$ at electric fields $\sim 10\,\mathrm{kV\,cm^{-1}}$. In the presence of hot carriers, the equivalent valleys need not be equally populated and, as a consequence, even in a cubic material like *n*-type Ge, the current need not be parallel to the electric field. Moreover, also inequivalent, higher-energy valleys may become populated: for instance, dramatic changes in the Hall coefficient of *n*-type Ge at electric fields higher than $1\,\mathrm{kV\,cm^{-1}}$ are brought about by the transfer of electrons from the $\langle 1\,1\,1 \rangle$ lowest minima to the $\langle 1\,0\,0 \rangle$ higher minima, the Hall coefficient is dominated by the contribution of the $\langle 1\,1\,1 \rangle$ high-mobility valleys and starts to increase as their population starts to decrease. In several compound semiconductors such as GaAs, such a carrier transfer to inequivalent valleys is responsible for a decrease of drift velocity leading to negative differential resistance (at a field value of about $3\,\mathrm{kV\,cm^{-1}}$ in GaAs, as shown in **Figure 9**) and also to peculiar current oscillations (Gunn effect) at microwave frequencies. In the presence of hot holes, complex features of the degenerate valence band become important, such as the non-parabolicity of the hole dispersion (i.e., the variation with kinetic energy of the effective mass).

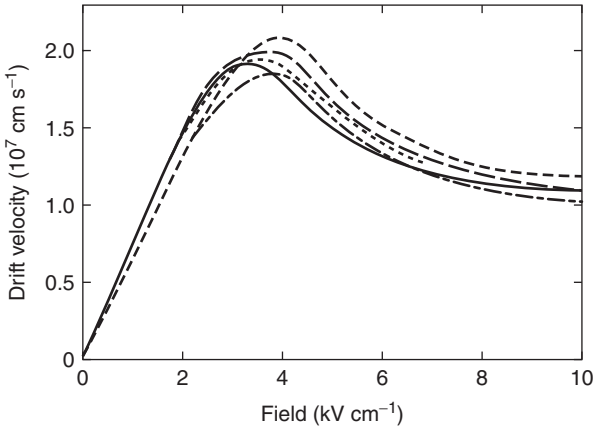

Figure 9 High-field electron drift velocity in GaAs at room temperature: the solid line is calculated, the other ones are experimental. (From the database NSM maintained by the Ioffe Institute.)

Finally, increasing the electric field strength beyond the saturation regime, a sudden "run-away" growth of the conductivity is eventually observed (breakdown). This is due to the avalanche multiplication of the number of free carriers: the field is so strong that a carrier can gain enough kinetic energy between two collisions to knock out an electron from the valence to the conduction band. Typical breakdown electric fields are $10^5\,\mathrm{V\,cm^{-1}}$ for Ge, $3 \times 10^5\,\mathrm{V\,cm^{-1}}$ for Si and $4 \times 10^5\,\mathrm{V\,cm^{-1}}$ for GaAs.

Electrons in Periodic Potentials with Magnetic Fields

J Bellissard, Georgia Institute of Technology, Atlanta, GA, USA

Introduction

A magnetic field applied to the electron gas of a solid breaks the time-reversal symmetry giving access to information at the atomic scale that is inaccessible otherwise. The de Haas–van Alphen oscillations of the magnetic susceptibility or the Shubnikov–de Haas oscillations of the conductivity are among the classical experimental tools used in high-magnetic-field facilities worldwide to investigate the structure of the Fermi surface. The Hall effect gives access to the type of charge carriers, electrons, or holes. The cyclotron resonance frequency can also be measured through radiowave oscillations, which give access to the electron effective mass or various relaxation times. Finally, NMR experiments give local information on the local density of states.

In most situations, the magnetic field can be considered as uniform at least on the scale of the electron mean free path. In much the same way, it is only at frequencies in the THz range and beyond, namely, of the order of the inverse of the inelastic collision time, that the magnetic field must be considered as non-constant in time. Hence, a magnetic field of up to 500 T applied during a microsecond (explosion) can still be considered as constant in time.

The determination of the energy spectrum of independent electrons in a periodic potential and submitted to a magnetic field was immediately recognized as a difficult task. This problem was investigated more systematically from the early 1950s onward. As a consequence of the Peierls approach, Harper designed, in 1955, a simplified model which is the paradigm of this problem (see eqn [6]). The calculation of the band spectrum of this model was investigated in several papers later on, until Hofstadter, in 1976, made a numerical computation and showed that it is a remarkable Cantor set (see **Figure 1**), at a time when even the word "fractal" had not been coined by Mandelbrot. Since then, this "Hofstadter butterfly" has never ceased to fascinate physicists and mathematicians, even though it is still controversial whether it can be fully observed in realistic experiments. This butterfly has zero Lebesgue measure, namely, it cannot fly!

Low Magnetic Fields

In the simplest approximation, the electron gas in a metal can be seen as a perfect Fermi gas of independent, free electrons (or holes) with mass m_* and charge $q = \mp e$. If $\boldsymbol{R} = (R_1, R_2, R_3)$ are the position operators and $\boldsymbol{P} = (P_1, P_2, P_3)$ the momentum operators, then $[R_i, P_j] = \mathrm{i}\hbar\delta_{ij}$. The free Hamiltonian is given by $H = \boldsymbol{P}^2/2m_*$. A uniform constant magnetic field $\boldsymbol{B} = (0, 0, B)$ can be added through the substitution

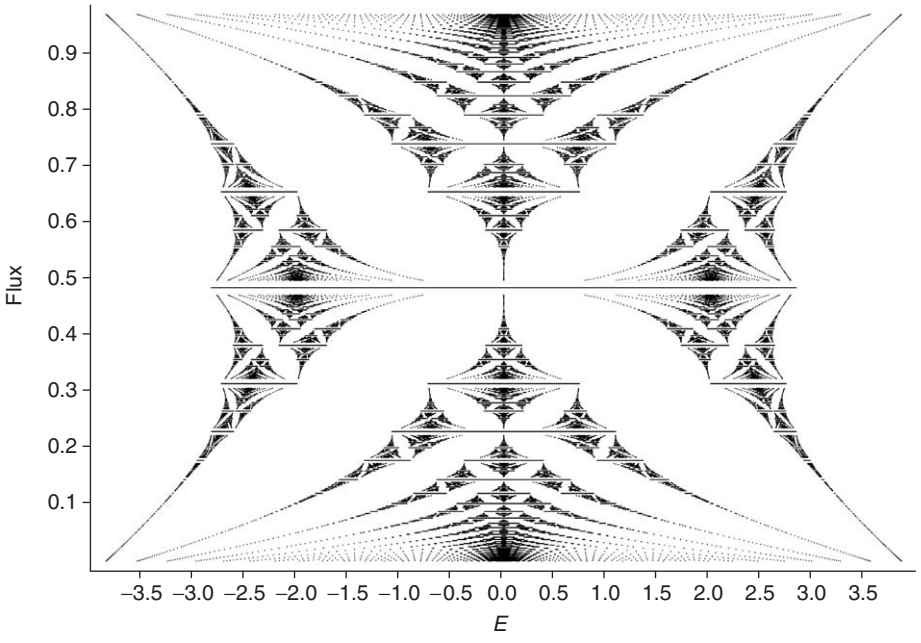

Figure 1 Band spectrum for the Harper model describing a 2D Bloch electron in a uniform magnetic field.

$\boldsymbol{P} \mapsto \boldsymbol{P} - q\boldsymbol{A}$ if $\boldsymbol{A} = (A_1, A_2, A_3)$ is the vector potential, depending upon the position and defined by

$$\partial_1 A_2 - \partial_2 A_1 = B$$
$$\partial_2 A_3 - \partial_3 A_2 = 0 = \partial_3 A_1 - \partial_1 A_3$$

The quasimomentum operator is defined by $\boldsymbol{K} = (\boldsymbol{P} - q\boldsymbol{A})/\hbar = (K_1, K_2, K_3)$ and satisfies the following commutation rules:

$$[K_1, K_2] = -\mathrm{i}\frac{qB}{\hbar}, \qquad [K_2, K_3] = [K_1, K_3] = 0 \quad [1]$$

The Hamiltonian for the free particle in a magnetic field becomes

$$\hat{H}_B = \frac{\hbar^2}{2m_*}(K_1^2 + K_2^2 + K_3^2) = H_B + \frac{\hbar^2}{2m_*}K_3^2$$

Since K_3 commutes with K_1 and K_2, it is sufficient to compute the spectrum of H_B. H_B is called the Landau Hamiltonian and represents the electronic motion in the plane perpendicular to $\boldsymbol{B}$. Thanks to the commutation rules [1], H_B can be seen as a harmonic oscillator with effective Planck's constant $\hbar_{\mathrm{eff}} = qB/\hbar$. In particular, its spectrum consists of isolated eigenvalues (called Landau levels)

$$E_n = \hbar\omega_{\mathrm{c}}(n + 1/2), \quad n = 0, 1, 2, \ldots, \quad \omega_{\mathrm{c}} = qB/m_*$$

ω_{c} is called the cyclotron frequency. Thanks to the translation invariance of the problem, each such eigenvalue has, however, an infinite multiplicity given by 2π times the number of flux quanta per unit area, namely, $eB/\hbar$.

If the electron gas is now placed in a periodic potential $V(\boldsymbol{R})$, such as what happens in a real metal, the one-particle Hamiltonian is $\hat{H}_B + V$. Then there are three vectors $\{\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3\}$ in $\mathbb{R}^3$ such that $V(\boldsymbol{R} + \boldsymbol{a}) = V(\boldsymbol{R})$ whenever $\boldsymbol{a} = m_1\boldsymbol{a}_1 + m_2\boldsymbol{a}_2 + m_3\boldsymbol{a}_3$ and $m_i \in \mathbb{Z}$. If $B = 0$, the Bloch theory shows that the energy spectrum is made of bands described by functions $E_j(\boldsymbol{k})$ depending upon the quasimomentum $\boldsymbol{k}$ and periodic with respect to the reciprocal lattice defined as the set of $\boldsymbol{b} \in \mathbb{R}^3$ such that $\boldsymbol{a}_i \cdot \boldsymbol{b} \in 2\pi\mathbb{Z}$ for $i = 1, 2, 3$. Here j is the band index and runs in a countable set. If $B \neq 0$ is small enough, the effective Hamiltonian describing electrons can be obtained from the band functions by substituting $\boldsymbol{K}$ to $\boldsymbol{k}$ (Peierls substitution). Using the periodicity, each band function can be expanded into a Fourier series

$$E_j(\boldsymbol{k}) = \sum_{m \in \mathbb{Z}^3} E_{j,m} \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot(m_1\boldsymbol{a}_1 + m_2\boldsymbol{a}_2 + m_3\boldsymbol{a}_3)}$$
$$\Rightarrow H_{\mathrm{Peierls}} = \sum_{m \in \mathbb{Z}^3} E_{j,m} \mathrm{e}^{\mathrm{i}\boldsymbol{K}\cdot(m_1\boldsymbol{a}_1 + m_2\boldsymbol{a}_2 + m_3\boldsymbol{a}_3)} \quad [2]$$

Actually this substitution is only the lowest order contribution to an expansion in powers of B, but the following theorem holds.

Theorem 1. *Let $\hat{H}_{B=0} + V$ have an interval $I \subset \mathbb{R}$ in its spectrum that is disconnected from the rest I^c of the spectrum and let I be generated by a finite family $E_1(\boldsymbol{k}), \ldots, E_N(\boldsymbol{k})$ of band functions. Then as $B \neq 0$ is small enough, the gaps separating I from I^c do not close. Moreover, the spectrum of $\hat{H}_B + V$ inside this region is described by an effective operator H_{Peierls} of the form given by eqn [2] where the Fourier coefficients are now $N \times N$ matrices depending continuously on the magnetic field.*

This theorem gives an effective Hamiltonian in terms of a noncommutative Fourier expansion using the three unitary operators

$$U_i = \mathrm{e}^{\mathrm{i}\boldsymbol{K}\cdot\boldsymbol{a}_1} = (U_i^{-1})^*$$
$$U_i U_j = \mathrm{e}^{\mathrm{i}\theta_{ij}} U_j U_i$$
$$\theta_{ij} = -\theta_{ji} = 2\pi\frac{e}{h}\,\boldsymbol{B}\cdot\boldsymbol{a}_i \times \boldsymbol{a}_j$$

The angle θ_{ij} represents 2π times the ratio of the magnetic flux through the parallelogram defined by vectors $\boldsymbol{a}_i$ and $\boldsymbol{a}_j$ by the flux quantum $\phi_0 = h/e$. To complete the analogy with Fourier series, $\mathscr{T}$ may be the linear map defined on the set of polynomials in the U_i's such that

$$\mathscr{T}(U_1^{m_1} U_2^{m_2} U_3^{m_3}) = 0 \quad \text{if } |m_1| + |m_2| + |m_3| \neq 0$$
$$\mathscr{T}(\mathbf{1}) = 1 \quad [3]$$

It can be checked that if A, B are two such polynomials, then $\mathscr{T}(AB) = \mathscr{T}(BA)$ (trace property). Moreover, it can be shown that $\mathscr{T}$ coincides with the trace per unit volume. Clearly, this map generalizes the integration over $\boldsymbol{k}$.

For most values (modulus and directions) of the magnetic field $\boldsymbol{B}$, the three angles θ_{ij} are incommensurate so that the algebra generated by the U_i's becomes simple, namely, it cannot be decomposed easily, making the explicit computation of the energy spectrum a very difficult problem. However, the $\theta_{ij}/2\pi$ can be seen as the dimensionless effective Planck's constant and for a realistic crystal with $|\boldsymbol{a}_i| = 1$ Å and a magnetic field $B = 1$ T, their value is $O(10^{-5})$, thus justifying the use of semiclassical methods.

Semiclassical Methods and Magnetic Oscillations

The semiclassical methods go back to the early days of the old theory of quanta, with the Bohr–Sommerfeld quantization formula. The use of

such methods for electrons in magnetic fields was the basis of the Onsager argument to explain the de Haas–van Alphen (dHvA) and Shubnikov–de Hass (SdH) oscillations.

As explained in the section "Low magnetic fields," the magnetic field B quantizes the quasimomentum space with an effective Planck constant proportional to B. Moreover, if a periodic potential is added, the relevant dimensionless Planck constant is so small as to make the problem semiclassical. In particular, the Heisenberg equations of motions for the effective Peierls Hamiltonian [2] give

$$\frac{\mathrm{d}\boldsymbol{K}}{\mathrm{d}t} = \frac{\mathrm{i}}{\hbar}[H_{\mathrm{Peierls}}, \boldsymbol{K}]$$

Since K_3 commutes with K_1, K_2, it follows that $\mathrm{d}K_3/\mathrm{d}t = 0$, so that the motion takes place in the plane perpendicular to $\boldsymbol{B}$. Moreover, the commutation rules [1] lead to the following approximate equation of motion:

$$\frac{\mathrm{d}k_1}{\mathrm{d}t} = -\frac{qB}{\hbar^2}\frac{\partial E_j}{\partial k_2}, \quad \frac{\mathrm{d}k_2}{\mathrm{d}t} = \frac{qB}{\hbar^2}\frac{\partial E_j}{\partial k_1}, \frac{\mathrm{d}k_3}{\mathrm{d}t} = 0$$

implying that $E_j(\boldsymbol{k})$ is conserved. Thus, the classical orbit associated with conduction electrons lies on the Fermi surface $E_j = E_{\mathrm{F}}$ in a plane perpendicular to the magnetic field corresponding to $k_3 = \boldsymbol{k}\cdot\boldsymbol{B} = \mathrm{const}$. Each such plane plays the role of a phase space for one degree of freedom, where k_2 is equivalent to the position and k_1 to the momentum, while the band function $E(k_1, k_2)$ plays the role of the Hamiltonian. Thanks to the Bohr–Sommerfeld quantization formula, only orbits with quantized action survive quantum interferences, leading to

$$\oint_{\mathrm{orb}} k_1\, \mathrm{d}k_2 = -2\pi e\frac{B}{\hbar}(n+v)$$
$$n\in\mathbb{Z}, \quad v = \text{Maslov index} \qquad [4]$$

where the contour integral is computed on the classical orbit. By the Stokes formula, the LHS is the area A enclosed by the classical orbit. The usual argument is now to compute the free energy F of such an electron gas. It should be noted that it takes into account these orbits with all possible values of k_3 provided $\boldsymbol{k}$ stays inside the Fermi surface. The Bohr–Sommerfeld condition [4] selects cylinders indexed by n with areas depending on the magnetic field (see **Figure 2**).

As the magnetic field increases, the radius of each such cylinder increases as well, until it gets out of the Fermi surface. Then the cylinder with index n has an area equal to the maximum area $A_{\max}$ of a section of the Fermi surface with a plane perpendicular to the magnetic field. As B increases again, the cylinder with index $n-1$ dominates, leading to oscillations of the free energy with periods given by the Onsager formula

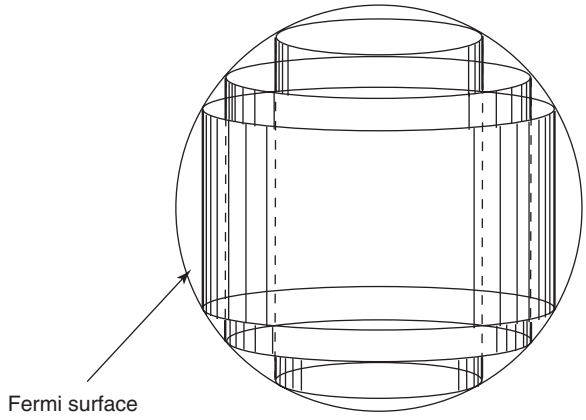

Figure 2 Landau cylinders inside the Fermi surface.

$$\Delta\left(\frac{1}{B}\right) = \frac{2\pi e}{\hbar A_{\max}}$$

Since the magnetization is given by the thermodynamical relation $M = \mu_0(\partial F/\partial B)\mu$, it also exhibits oscillations at the same period and this is what experiments measure, giving access to the size of the Fermi surface. Extensions of this theory (the Lifschitz and Kosevich formula, and the magnetic breakdown) have been discussed by Shoenberg.

Strong Magnetic Fields in 2D

If the magnetic field is oriented along one of the crystal axes, the operator U_3 commutes with the others, so the model can be reduced to the two-dimensional (2D) plane perpendicular to $\boldsymbol{B}$. On the other hand, modern devices which are effectively 2D are currently available in labs. Such is the case for interfaces between the semiconductor and the oxide of an MOSFET or between the two parts of a heterojunction used in mesoscale or nanoscale technology.

Then, if only one band contributes, two unitaries suffice to express the effective Hamiltonian as

$$H = \sum_{m_1,m_2} h_{m_1,m_2}\mathrm{e}^{\mathrm{i}\theta m_1 m_2/2}U_1^{m_1}U_2^{m_2}$$
$$U_1U_2 = \mathrm{e}^{\mathrm{i}\theta}U_2U_1 \qquad [5]$$

where $\bar{h}_{m_1,m_2} = h_{-m_1,-m_2}$ (self-adjointness of H) are called the Fourier coefficients of H. The simplest example is the almost-Mathieu model (if $t_1 \neq t_2$) or Harper model (if $t_1 = t_2$) given by

$$H_{\mathrm{Harper}} = t_1(U_1 + U_1^{-1}) + t_2(U_2 + U_2^{-1}) \qquad [6]$$

where t_1, $t_2 > 0$ are called the hopping parameters. A numerical calculation of the band spectrum is

possible if $\theta = 2\pi p/q$, where p/q is a fraction. Here is the recipe:

1. U_1 and U_2 are replaced by $U_i(k_1, k_2) = e^{ik_i}u_i$, where

$$u_1 = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ 1 & 0 & 0 & \cdots & 0 \end{bmatrix}$$

$$u_2 = \begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \\ 0 & e^{2i\pi p/q} & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 0 \\ 1 & 0 & 0 & \cdots & e^{2i\pi(p-1)p/q} \end{bmatrix}$$

   Then H becomes a $q \times q$ Hermitian matrix depending periodically on $k = (k_1, k_2)$ with period 2π. Then k is called the quasimomentum.
2. For each value of (k_1, k_2) the eigenvalues $e_1(k_1, k_2) \leqslant \cdots \leqslant e_q(k_1, k_2)$ of $H(k_1, k_2)$ are computed. The spectrum is obtained as the union of all these values. In practice, the e_j's are computed for only a finite number of values of (k_1, k_2). Then, as in the case of the band theory, the symmetries of the model to choose the relevant (k_1, k_2)'s are used. In the Harper or in the almost-Mathieu models, the values $(k_1, k_2) = (0, 0)$ or (π, π) give the band edges.

Figure 1 represents the energy spectrum of the Harper model (see eqn [6]) and was obtained for the first time in 1976 by D R Hofstadter in his PhD thesis as a numerical calculation following the previous algorithm. The vertical axis represents the values of $\theta/2\pi$ between 0 and 1, while the horizontal one represents the values of the energy in units of t (here $t_1 = t_2$), which then varies between -4 and $+4$. The picture obtained suggests that the gap edges are continuous with respect to θ even though a closer look shows that these functions have a discontinuous derivative at each rational point. This has been proved rigorously by J Bellissard in 1994.

Theorem 2. *Let H be given by eqn [5] with Fourier coefficients depending smoothly on θ and decreasing fast enough as (m_1, m_2) increase to infinity. Then the gap edges of the spectrum of H are continuous functions of θ. Moreover, these functions are differentiable almost everywhere. At each rational value of θ, the right and left derivatives of such functions exist but are not necessarily equal. The discontinuity of the derivative at a rational point p/q at the edge of the band j, represented by the band function $e_j(k_1, k_2)$, can be computed through the following formula:*

$$\Delta = |\det \partial_\mu \partial_\nu e_j(k^{(j)})|^{1/2}$$

where $k^{(j)} = (k_1^{(j)} k_2^{(j)})$ is the value of the quasimomentum corresponding to the gap edge of the band j.

In the specific case of the almost-Mathieu operator (see eqn [6]), additional properties have been proved over the years by several mathematicians, prominent among them being B Simon, Y Last, S Jitomirskaya, and J Puig.

Theorem 3. *Let H be given by eqn [6]. Then*

1. *for all irrational values of $\theta/2\pi$ and for $t_1 \neq t_2$, the Lebesgue measure of the spectrum of H is equal to $4|t_1 - t_2|$ (Aubry's conjecture);*
2. *for almost all irrational values of $\theta/2\pi$ and for $t_1 = t_2$, the spectrum of H has zero Lebesgue measure. For a large set of such θ's, the Hausdorff dimension of the spectrum is less than or equal to* 1/2; and
3. *if $\theta/2\pi$ satisfies a* diophantine condition, *then the spectrum of H is a Cantor set (i.e., its complement is a dense open set and it has no isolated points).*

Let $\mathcal{T}$ be the trace defined in eqn [3]. Then, the integrated density of states (IDoS) $\mathcal{N}(E)$ is defined as the number of eigenvalues of H per unit volume smaller than or equal to E. The Shubin formula asserts that

$$\mathcal{N}(E) = \mathcal{T}(\chi(H \leqslant E))$$

where $\chi(H \leqslant E)$ is the projection on the space spanned by the eigenstates of H with eigenvalues smaller than or equal to E. Then the following theorem holds.

Theorem 4. *Let H be given by eqn [5]. Then*

1. *Its IDoS is a nondecreasing function of E varying from 0 to 1. It is constant of spectral gaps and its values on spectral gaps are given by the fractional part of $n\theta/2\pi$ from some integer n* (gap labeling theorem).
2. *If H is the almost-Mathieu model and if $\theta/2\pi$ is irrational. then for any integer n there is a gap with IDoS equal to the fractional part of $n\theta/2\pi$.*

The previous class of models can be seen as a tight-binding representation for the effective Hamiltonian representing the charge carrier motion on a perfect

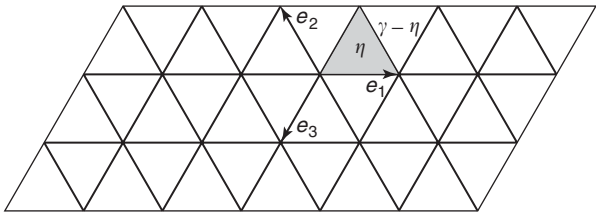

Figure 3 Triangular lattice, its basis, and two types of triangles.

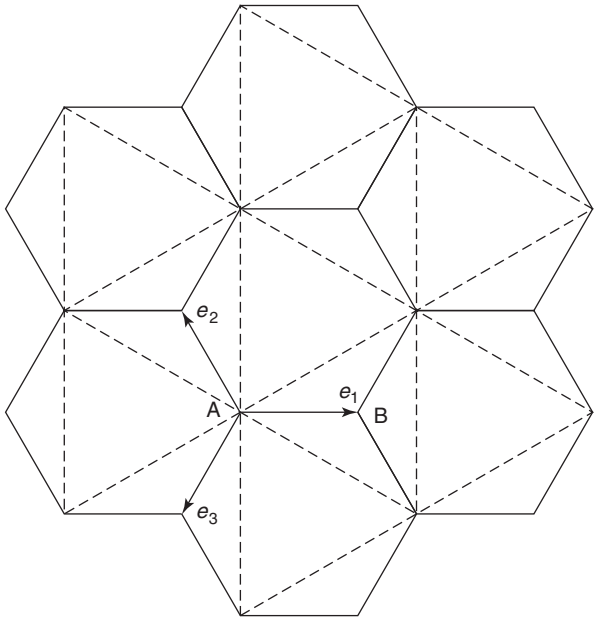

Figure 4 The honeycomb and its basis.

2D lattice. Other models can be constructed by considering that U_1 and U_2 represent translation along the basis vectors of a 2D crystal. Examples of models are given below.

1. The Harper model on a triangular lattice: there are three translations U_1, U_2, U_3 with $U_1U_2U_3 = e^{2i\pi\eta}$ and $U_1^{-1}U_2^{-1}\ U_3^{-1} = e^{2i\pi(\gamma-\eta)}$, if η and $\gamma-\eta$ are the dimensionless fluxes in the two types of triangles (see **Figure 3**). The Hamiltonian becomes

$$H_\Delta = t(U_1 + U_1^{-1} + U_2 + U_2^{-1} + U_3 + U_3^{-1})$$

2. The corresponding model for the honeycomb lattice takes into account the existence of two sublattices A and B (see **Figure 4**). Each site in A has its neighbors in B in directions $\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3$, where these three vectors add up to zero and make an angle of 120° and vice versa. Hence, a wave packet can be seen as a spinor with components $|\psi_A\rangle$ and $|\psi_B\rangle$ and the Hamiltonian becomes a 2×2 matrix with coefficients depending on the U_i's as follows:

$$H_{\text{hexa.}} = t\begin{bmatrix} 0 & U_1+U_2+U_3 \\ U_1^{-1}+U_2^{-1}+U_3^{-1} & 0 \end{bmatrix}$$

Here, γ represents the dimensionless flux through the cell generated by $\boldsymbol{e}_1, \boldsymbol{e}_2$ namely, it is the third of the flux through the unit cell given by a hexagon and $\eta = \gamma/2$.

Various compounds admit a honeycomb structure, such as graphite monolayers built on the surface of silicon carbide SiC. More generally for quasi-2D systems, the previous construction can be used to build the effective Hamiltonian. It has been applied, for instance, to the magnetic breakdown observed in organic conductors of type (BEDT–TTF) which are mainly a stack of weakly coupled 2D layers.

Semiclassical Methods at Strong Magnetic Field

It is remarkable then that semiclassical methods could be used at strong magnetic fields as well. For indeed, the stronger the magnetic field the bigger $\hbar_{\text{eff}}$. The work by Helffer & Sjöstrand in the eighties, and by Rammal & Bellissard in the 1990s on the Harper model and its extensions showed the method.

If θ is close to a rational multiple of 2π, say $\theta = 2\pi p/q + \delta$, with $\delta > 0$ small, then the two unitaries U_1 and U_2 can be taken as $U_i = e^{ik_i}u_i \otimes \hat{U}_i$ with $\hat{U}_1\hat{U}_2 = e^{i\delta}\hat{U}_2\hat{U}_1$ implying $U_1U_2 = e^{i\theta}U_2U_1$. These unitary operators are $q\times q$ matrices with operator coefficients. The phase factor e^{ik_i} can be chosen arbitrarily, without changing the spectrum. This substitution is the rigorous version of the Peierls one. The following representation is used

$$\hat{U}_i = e^{i\sqrt{\delta}K_i}, \quad K_i = K_i^*, \ [K_1, K_2] = -i\mathbf{1}$$

Then using the Feshback method (also called Schur complement or Green function method), the $q\times q$ Hamiltonian H is transformed into a 1×1 effective one given by

$$H_{\text{eff}}(z) = \langle j|H|j\rangle + \left\langle j\middle| HQ_j\frac{1}{z - Q_jHQ_j}Q_jH\middle|j\right\rangle,$$
$$Q_j = \mathbf{1}_q - |j\rangle\langle j|$$

For $\delta = 0$, the Hamiltonian becomes a $q\times q$-matrix valued function of k denoted by $\mathscr{H}$, while for $\delta \neq 0$ its matrix elements depend on $\hat{U}_1, \hat{U}_2$. It is possible to expand the Hamiltonian in powers of $\sqrt{\delta}$, leading to a generalization of the semiclassical expansion. However here, the Hamiltonian being a $q\times q$ matrix, some

complication occurs depending upon what point of the spectrum is considered. The simplest expansion corresponds to expanding near a band edge. Then $k=(k_1, k_2)$ is chosen to correspond to this band edge in the eigenvalue e_j of the Hamiltonian at $\delta=0$. Moreover, if $|j\rangle$ is the q-dimensional eigenvector of the Hamiltonian for eigenvalue e_j at k, the eigenvalue equation is then $E|\psi\rangle = H_{\text{eff}}(E)|\psi\rangle$, which is nonlinear in E. Expanding this operator in powers of $\sqrt{\delta}$ to the lowest order gives again a harmonic oscillator as the lowest-order contribution which can be interpreted as a Landau Hamiltonian.

Using the Landau spectrum, this gives eigenvalues in the following form (see **Figures 5** and **6**):

$$E_{n,j}(\delta) = e_j(k) + |\delta|(n+1/2)(\det D^2 e_j(k))^{1/2} + \delta \frac{\partial e_j(k)}{\partial \delta} + \delta\sigma + O(\delta^{3/2})$$

where

$$\sigma = \frac{\mathrm{i}}{2}\sum_{l:\neq j} \frac{(<_j|\partial_1 \mathscr{H}|l\rangle\langle l|\partial_2 \mathscr{H}|j\rangle - \langle j|\partial_2 \mathscr{H}|l\rangle\langle l|\partial_1 \mathscr{H}|j\rangle)}{e_j - e_l}$$

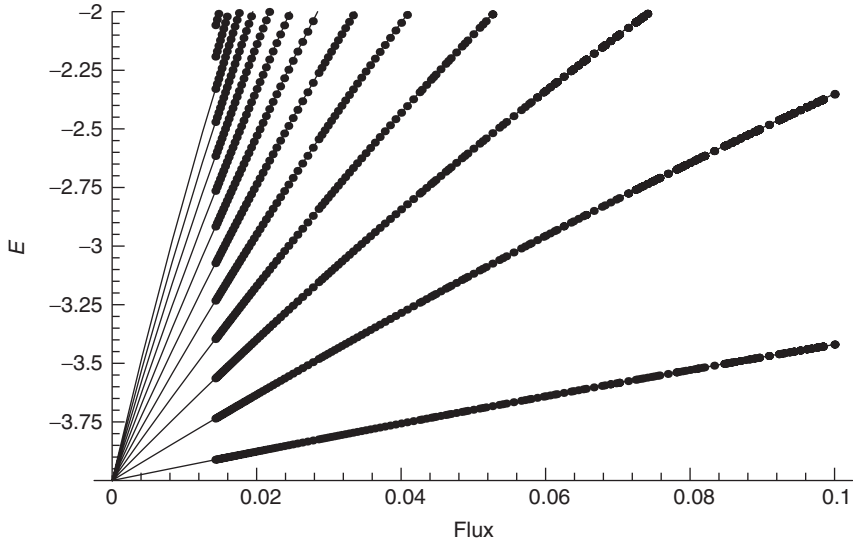

Figure 5 Comparison between semiclassical calculations (continuous lines) and exact numerical spectrum (points) for Landau levels in the Harper model [6] on the square lattice near the band edge at $\theta=0$.

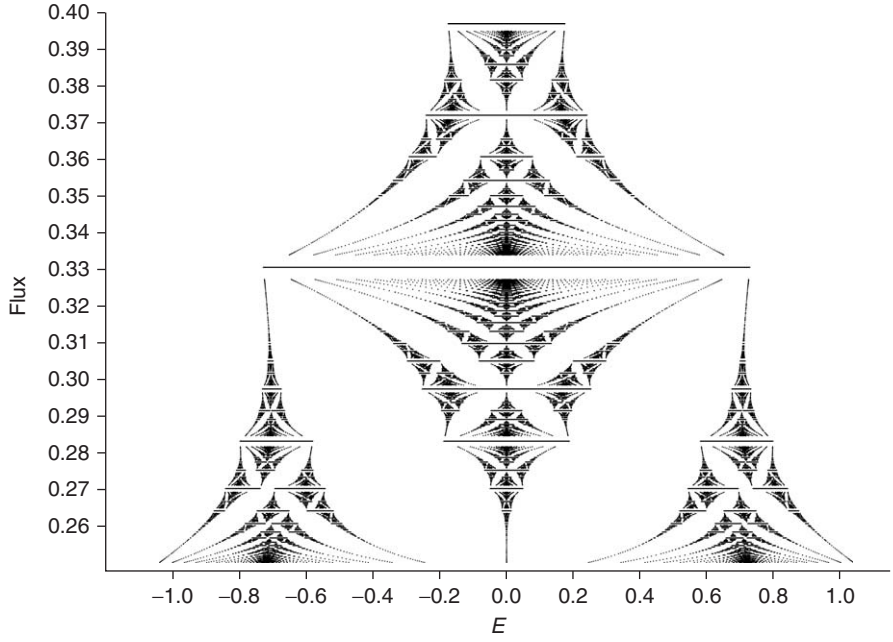

Figure 6 Discontinuity of derivatives of the band edge near the magnetic flux $\alpha=\theta/2\pi\approx 1/3$ for the Harper model on the square lattice.

The very same formula holds if $\delta < 0$ using a similar method. This formula gives rise to the discontinuity of the derivative of the band edges as stated in Theorem 2. It is remarkable that a systematic higher order expansion gives right corrections to the Landau levels, as long as the level width is ignored.

If two bands are touching (see **Figure 7**) for $\delta = 0$, the previous analysis fails. The degeneracy of the eigenvalues e_j and say, e_{j-1} at k for $\delta = 0$ requires using a degenerate perturbation theory. The lowest order in the $\sqrt{\delta}$ expansion is given by a 2D Dirac operator of the form

$$H_{\text{Dirac}} = C, \sqrt{\delta}\begin{bmatrix} 0 & K_1 + \mathrm{i}K_2 \\ K_1 - \mathrm{i}K_2 & 0 \end{bmatrix} + O(\delta)$$
$$\Rightarrow E_n^{\pm} = \pm C\sqrt{n\delta}(1 + O(\delta))$$

where C is a model-dependent constant, the $E_n^{\pm}$'s are the eigenvalues and $n = 0, 1, 2, \ldots$ is an integer (see **Figure 8**).

As can be seen in **Figures 1, 6,** and **8,** the Landau–Dirac level broadens into a band as δ gets too large. This is a general phenomenon due to tunneling in the phase space. A spectacular illustration of the tunneling effect is the braiding seen in **Figure 9** in the following model:

$$H_2 = t(U_1 + U_1^{-1} + U_2 + U_2^{-1} + \tau(U_1^2 + U_1^{-2} + U_2^2 + U_2^{-2})) \qquad [7]$$

As τ passes beyond the critical value 1/4, the minimum of energy at zero flux bifurcates to become a local maximum and gives four degenerate minima. If τ is close enough to 1/4, these four minima are so close that the tunneling effect between them becomes enormous. The semiclassical analysis for the tunneling effect consists in extending the classical motion into the complex values of (k_1, k_2). Then the classical (complex) action is given by

$$S = \oint_{\gamma} k_1 \, \mathrm{d}k_2$$

where γ is any path joining two such minima in the complex energy surface $E(k + \mathrm{i}k') = E_0$ (if E_0 is the minimum of the energy). Cohomology arguments

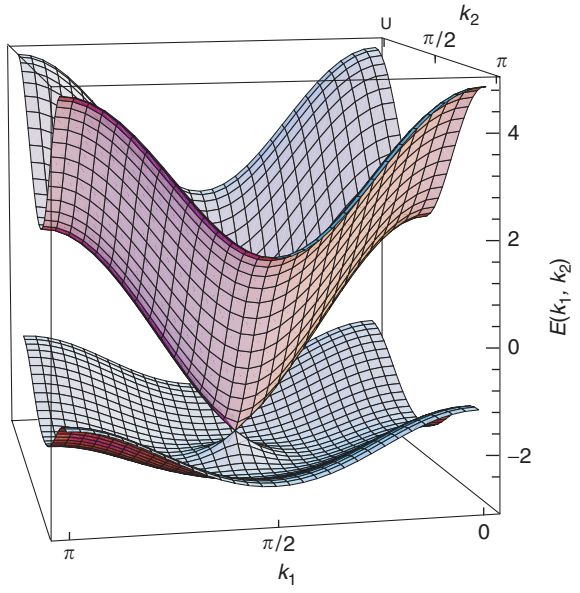

Figure 7 Bandtouching and bandoverlapping near half-flux in the model $H = U_1 + U_2 + 1/2(U_1^2 + U_2^2) + \text{h.c.}$

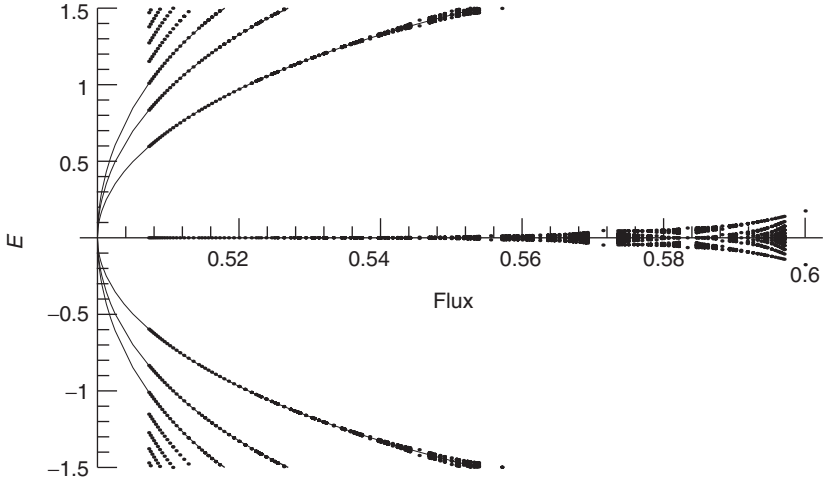

Figure 8 Comparison between semiclassical calculations (full curves) and exact numerical spectrum (points) for Dirac levels in the Harper model near half-flux.

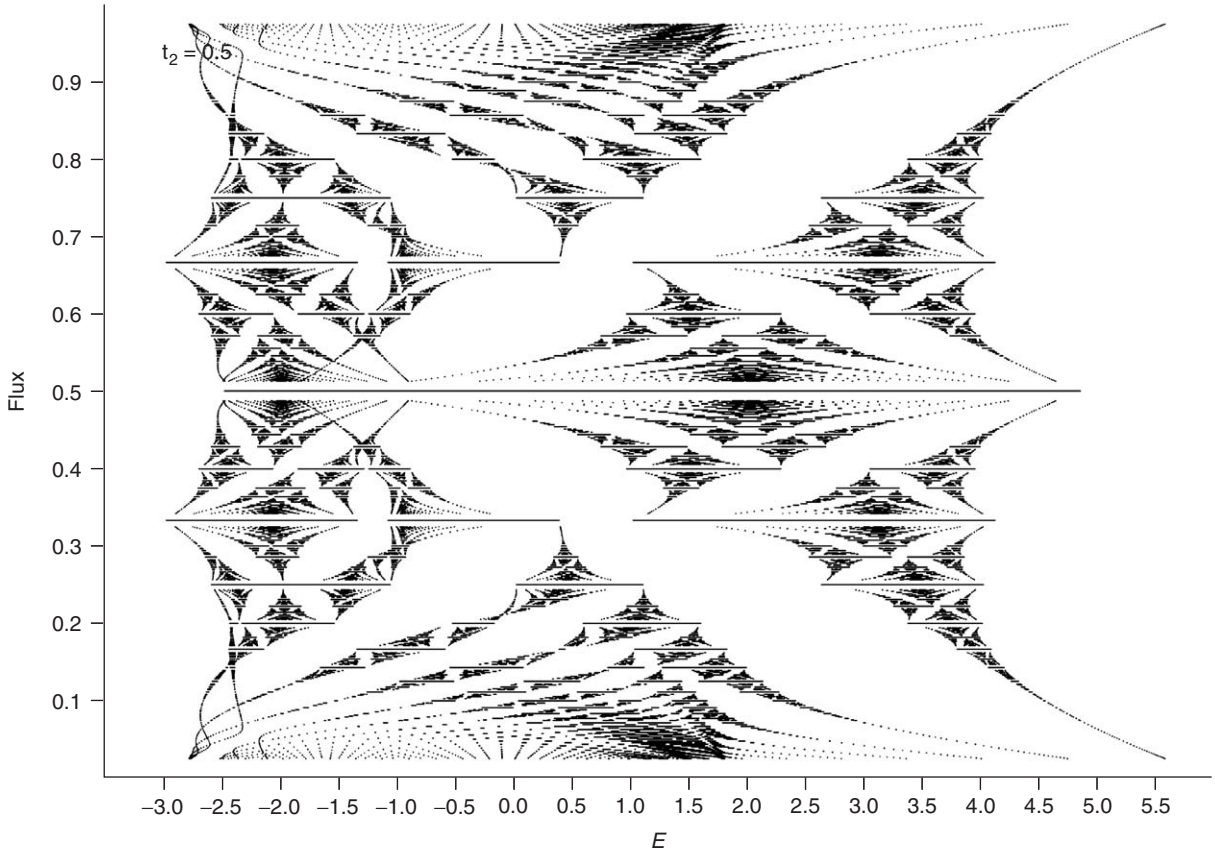

Figure 9 Spectrum of a Harper-like model [7] for $t_2 = 1/2$. In the left corners, braids are due to tunneling effect (magnetic breakdown).

(Stokes theorem) show that the value of S depends only upon the homotopy class of γ provided it stays in the energy surface. In the previous case, $S = S' + iS''$ with $S' \neq 0$ and $S'' > 0$. Then the splitting between the four levels, consecutive to tunneling between the classical minima is proportional to Re (exp $i(\phi + S/\delta)$), for some phase ϕ depending upon what splitting is considered, leading to (1) a damping of the amplitude as $\delta \downarrow 0$ given by $e^{-S''/\delta}$, and (2) an oscillation of the amplitude due to the term $e^{iS'/\delta}$. This is illustrated in **Figure 10**.

Tunneling also explains the broadening of the Landau subbands. Indeed, the classical effective Hamiltonian obtained for $\delta = 0$ (or for $\theta = 0$ when $p/q = 0$) is a periodic function of the quasi-momenta k_1, k_2. Thus, any band edge occurring at k also occurs at $k + 2\pi(m_1, m_2)$ for all $m_i \in \mathbb{Z}$. Hence, each classical orbit is infinitely degenerate in the phase space. Each such orbit represents an approximate eigenstate that can, in principle, be computed semiclassically and called a quasimode. Hence, the Hilbert space corresponding to these semiclassical eigenvalues is infinite dimensional and the tunneling effect between the quasimodes produces a broadening of the Landau or Landau–Dirac levels. As usual, with the tunneling effect, this broadening is exponentially small in the effective Planck constant (here given by δ). Such a calculation is difficult and many attempts were made in the 1960s. Eventually, Helffer and Sjöstrand carried it out for the special case of the Harper model based upon Wilkinson's analysis.

The main result of this analysis is that the Landau subbands are well described by an effective Hamiltonian of the form

$$H_{\text{subband}} \overset{\delta \downarrow 0}{=} E(\delta) + (e^{iS/\delta}(\tilde{U}_1 + \tilde{U}_2)e^{-i\bar{S}/\delta} \times (\tilde{U}_1^{-1} + \tilde{U}_2^{-1})) + O(e^{-S_1/\delta})$$

where $E(\delta)$ is the semiclassical value of the eigenvalue computed by the previous method, t is a model-dependent constant (computable by semiclassical methods), S is the classical action between the two nearest-neighbor repetitions of the corresponding band edge in the complex energy surface, $S_1 > |\text{Im } S|$ and

$$\tilde{U}_1 \tilde{U}_2 = e^{i4\pi^2/\delta} \tilde{U}_2 \tilde{U}_1$$

Hence the spectrum of the subband is itself approximately the same as the Harper spectrum, but for a renormalized value of the dimensionless flux namely

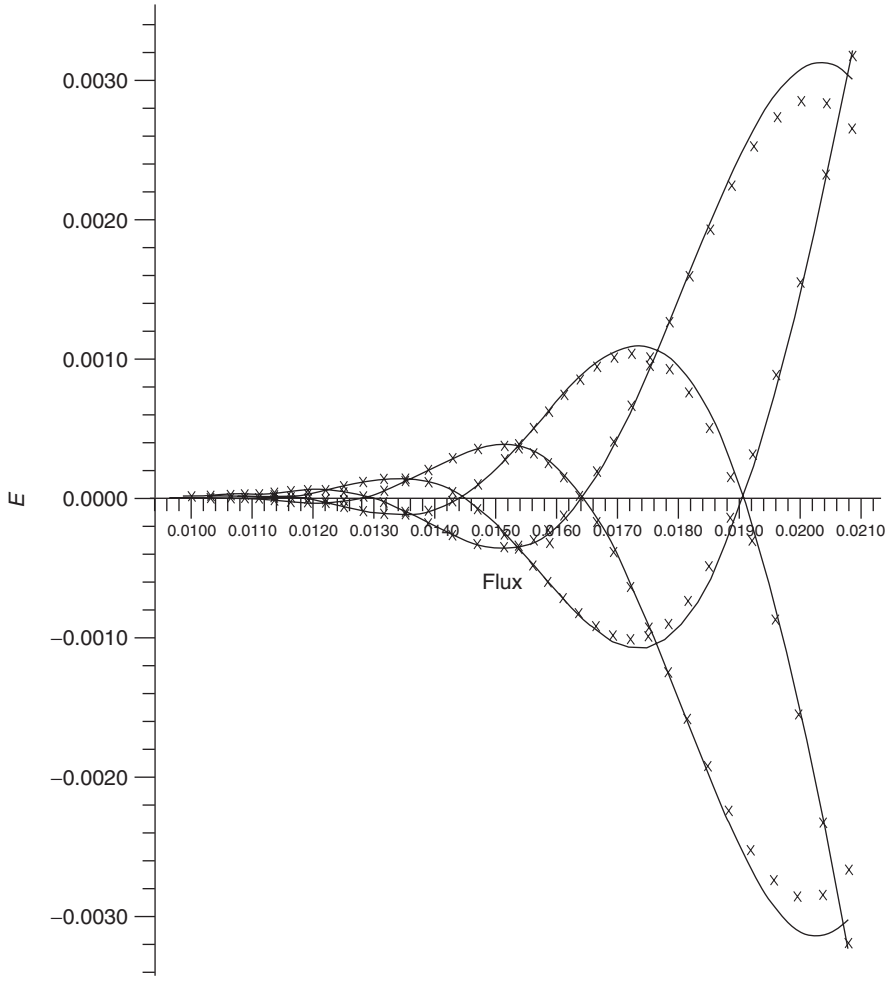

Figure 10 Comparison between semiclassical calculations (full curves) and exact numerical spectrum (crosses) for Landau braids of model [7] . (Barelli A and Kreft C (1991) Braid-structure in a Harper model as an example of phase space tunneling. *Journal of Physics I (France)* 1: 1229–1249.)

$\alpha = \delta/2\pi \mapsto 1/\alpha = 2\pi/\delta$. Since this new flux arises in a phase, adding or subtracting an integer to $1/\alpha$ does not change the phase, so that the map becomes $\alpha \in (0,1) \mapsto G(\alpha) = \{1/\alpha\} \in (0,1)$ where $\{x\}$ denotes the fractional part of x. G is called the Gauss map and is known to generate the continuous fraction expansion of the number α, namely, if $[x]$ denotes the integer part of x

$$\alpha = \cfrac{1}{a_1 + \cfrac{1}{a_2 + \cdots \cfrac{1}{a_n + \cdots}}}, \quad a_n = [G^{n-1}(\alpha)]$$

This rule does not work near a band center. Then the analysis is more complicated because the classical Hamiltonian associated with the Harper equation has a saddle point. Then tunneling between periodic equivalent quasimodes is enhanced by the proximity near a saddle point. Helffer and Sjöstrand showed that depending on the subband considered, there are three types of normal forms for the effective Hamiltonian describing them. Moreover, the rule for the new flux might not be given by the Gauss map as was shown by Hofstadter. They also showed that each of them can be analyzed in the same way as the Harper equation so that at each step of the renormalization procedure, the effective subband Hamiltonian takes on one of the four normal forms previously considered: Harper or the three ones occurring at saddle points. Such an analysis explains why the Hofstadter spectrum shown in **Figure 1** (see an enlargement in **Figure 6**) looks like a fractal set, namely it is self-reproducing at any scale.

Electrophysiology

S E Pagnotta, University of Rome "Roma Tre," Rome, Italy

Introduction

Physiology can be defined as the study of the functions of living organisms and their parts, together with the physical and chemical factors and processes involved. The branch of physiology dealing with the electric phenomena associated with living bodies and involved in their functional activity is called electrophysiology.

The major target of electrophysiological studies is the central nervous system, a structure composed of a particular cell type, the neuron. Indeed, neurons are cells specialized for the integration and propagation of electrical events, and through such electrical activity they communicate with each other as well as with muscles and other end organs. Even though some concepts and techniques that are discussed in this article are general and can be applied virtually to all cell types, some are specifically referred to neurons. In the first part of this article, basic theoretical concepts are introduced, and the ionic basis of cell membrane and action potential is discussed using an equivalent circuit treatment of the membrane. In the second part, the major experimental techniques applied to electrophysiological studies are described.

Basic Theories

Cell Resting Potential

All living cells are surrounded by a plasma membrane, which separates the internal cellular compartment from the environment. Across this plasma membrane, there is an unequal distribution of ions, both organic and inorganic. Potassium ions are predominant in the intracellular fluid, together with organic anions, such as amino acids, proteins, or nucleic acids. Conversely, in the extracellular fluid the predominant ionic species are sodium and chloride. Normally, electrical phenomena arise whenever charges of opposite sign are separated or can move independently. Indeed, one of the main electrical features of all cellular types is the existence, at resting conditions, of an electric potential difference between the inner and the outer sides of the cell membrane. This potential difference, called membrane resting potential, depends on the ionic concentration gradient across the membrane and on the relative permeability of the membrane to the ions present in the extracellular and intracellular medium. Moreover, as discussed later, transient changes in the membrane potential are used by nerve cells and muscle fibers to generate and propagate electrical signals. Such potential changes are in turn due primarily to changes in the permeability of the cell membrane to the different ionic species.

To better understand the nature of the established ionic gradients in the resting cell and how such gradients come to exist, some simple observations are described. Consider a water system (like the one depicted in **Figure 1a**) with two compartments separated by a membrane permeable only to small inorganic ions but not to large organic ones. Different concentrations of an organic potassium salt $[K^+A^-]$ are placed in each compartment, and the potential difference between them is measured with a voltmeter. Initially (at time $t = 0$), no voltage difference will be observed, because both sides of the system are electrically neutral. However, potassium (K^+) ions will immediately start diffusing from compartment 1 to compartment 2, down their concentration gradient following the Fick's law: $J_{diff} = -D\partial c/\partial x$ (J_{diff} is the ion flux, D is the diffusion coefficient, c the concentration of K^+ ions, and $\partial c/\partial x$ is the concentration gradient along the x axis). This diffusion process gives an excess of positive charge to compartment 1, building up across the membrane an electric field E directed against the movement of K^+ ions. Conversely to K^+ ions, the A^- inorganic ions cannot cross the membrane, so that the charge separation persists. Thus, at $t > 0$ there are two factors governing the movement of K^+ ions: the concentration gradient and the electric field. These factors push ions toward opposite directions, until a balance between electrical and diffusional fluxes of K^+ ions is reached, the total net flux is zero and the system no longer changes (**Figure 1b**). At this moment, the concentration of K^+ ions in both compartments changes, while the concentration of A^- ions does not change. There is no more electrical neutrality in each compartment and a potential difference ΔV_{1-2} between them is established. ΔV_{1-2} can be easily calculated with the well-known Nerst equation:

$$\Delta V_{1-2} = (RT/zF)\ \ln([K^+]_2/[K^+]_1) \qquad [1]$$

where R is the gas constant, T is the temperature, z is the charge of K^+ ion, F is the Faraday constant, and $[K^+]_1$ and $[K^+]_2$ are the K concentration in the compartments 1 and 2, respectively.

A real cell membrane is permeable to several inorganic ions (K^+, Na^+, Cl^-) present in the extracellular and intracellular medium in different concentrations. Assuming that: (1) the potential difference drops only across the membrane and occurs with a uniform gradient, (2) the membrane is a homogeneous phase, and (3) the fluxes of different ions are independent, it is possible to derive the so-called Goldman–Hodgkin–Katz (GHK) voltage equation, which gives the membrane potential (called the reversal potential V_{rev}) at which no net current flows:

$$V_{rev} = (RT/F)\ \ln[(P_K[K]_o + P_{Na}[Na]_o + P_{Cl}[Cl]_i)/(P_K[K]_i + P_{Na}[Na]_i + P_{Cl}[Cl]_o)] \qquad [2]$$

where indices i and o refer to inside and outside of the cell membrane, respectively, and P_K, P_{Na}, and P_{Cl} are the membrane permeability coefficients of the corresponding ions. When the cell is in resting condition, the GHK equation yields the membrane resting potential, which is now clearly established by ion concentration gradients and permeability. If the membrane is permeable only to one ionic species, the GHK equation reduces to the Nernst equation, which gives the reversal potential for that ion.

Measuring the membrane potential of real cells, one can observe that the intracellular compartment is always at a potential value more negative than the

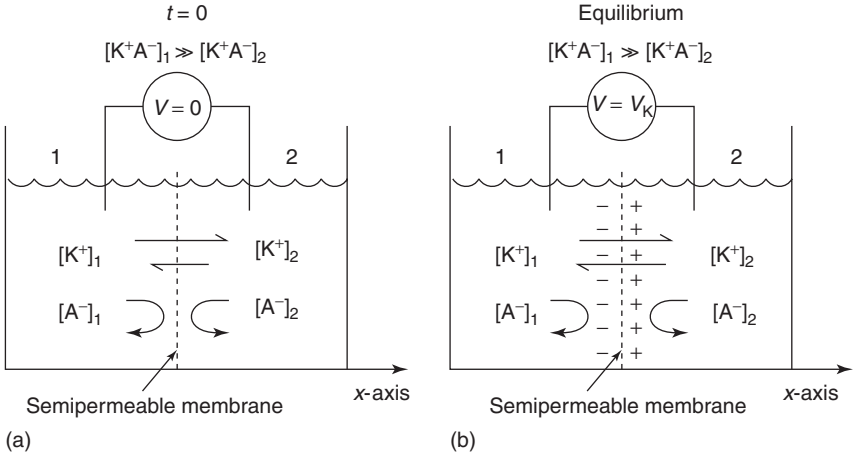

Figure 1 Ion diffusion across a semipermeable membrane.

Table 1 Ionic concentrations and reversal potentials for mammalian skeletal muscles and squid giant axon

Ion	*Extracellular concentraion* (mM)		*Intracellular concentration* (mM)		*Reversal potential* (mV)	
	Skeleton	*Squid*	*Skeleton*	*Squid*	*Skeleton*	*Squid*
Na^+	145	440	12	50	+67	+55
K^+	4	20	155	400	−98	−75
Cl^-	123	560	4.2	52	−90	−60

extracellular one. As just discussed, this is a consequence of the different concentration of ions in the two compartments. Typical values for such concentrations and for the corresponding reversal potentials are reported in **Table 1** for two kinds of cells. It is experimentally observed that membrane resting potential and potassium reversal potential values are quite similar if measured in the same cell, indicating that in resting conditions potassium gives the main contribution to membrane permeability. This is a general phenomenon observed in many cell types.

How do ions permeate the cell membrane? Particular membrane proteins, called ion channels, connect the intracellular and extracellular compartments of the cell forming a macromolecular pore in the membrane, which can be crossed by ions. A wide number of different ion channels, accounting for a variety of cellular functions, are expressed in all the cellular types. They can be selective for specific ions (sodium, potassium, etc.), and most of them are gated. This means that they fluctuate between closed and open states with characteristic open times. For a few channels, the open state predominates at resting conditions (e.g., some potassium channels responsible for the membrane resting potential), while the remainder are predominantly in the closed state, and the probability of an individual channel opening is low. An appropriate stimulus can activate or inactivate channels, sharply increasing or decreasing the frequency of openings. Some channels may respond to changes in the membrane potential, and thus are called voltage-gated ion channels, while others may respond to applied chemicals, and thus are called ligand-gated ion channels.

Electrical Properties of Cell Membranes

Depending on their electrical properties, biological membranes or cells can be subdivided into two main categories: excitable or nonexcitable. Both classes are characterized by passive electrical properties, while only excitable membranes or cells show active electrical properties and are, therefore, able to generate and propagate electrical signals.

Passive properties As far as it concerns passive properties, common to all cell types, the cell membrane can

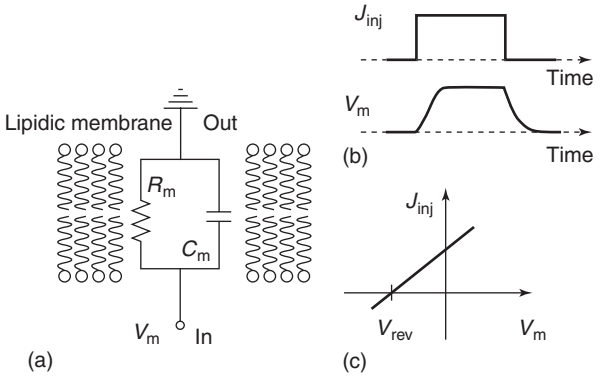

Figure 2 (a) Equivalent circuit of membrane passive properties. (b) Membrane voltage recorded in response to a current pulse injection. (c) Current–voltage relationship for a nonexcitable membrane.

be schematized with a simple RC circuit. C_m and R_m, the membrane capacitance and resistance, are independent of the membrane potential and represent the membrane dielectric or insulating properties and the ion permeability through the membrane, respectively (**Figure 2a**). If a pulse of electric current is passed through the cell membrane, its potential will rise to a maximal and sustained value and then will decay, following in both cases an exponential law:

$$V_m = V_0[1 - e^{-t/R_m C_m}] = V_0[1 - e^{-t/\tau_m}] \quad [3a]$$

for the rising phase and

$$V_m = V_0 e^{-t/R_m C_m} = V_0 e^{-t/\tau_m} \quad [3b]$$

for the decaying one (**Figure 2b**). τ_m is the membrane time constant. For the sake of the following discussion, a change in the membrane potential toward more positive values is referred to as a depolarization, while a change toward more negative values will be referred to as a hyperpolarization. The R_m values being voltage and time independent, the current–voltage relationship for the maximal sustained potential during current pulse application will be linear (**Figure 2c**), and if the membrane potential is kept at a particular voltage level V_m, the total current flow will be

$$J_m = J_c + J_i = C_m(dV_m/dt) + G_m(V_m - V_{rev}) \quad [4]$$

where $G_m = 1/R_m$ is the membrane conductance and V_{rev} is the previously defined reversal potential.

Actually, for excitable membranes C_m and R_m values are voltage-dependent (as voltage-gated ion channels are present on the membrane), and the previous schematic description holds only at resting condition or in a range of membrane potential below a particular threshold. Indeed, in these conditions the values of C_m and R_m become virtually constant, while in any other condition active properties arise.

Active properties: action potential and the Hodgkin–Huxley model Active electrical properties account for the generation of electrical signals and their propagation in excitable membranes. To this end, excitable membranes contain voltage-dependent ionic channels. Mainly, three different kinds of channels – selective for sodium, potassium, or chloride, respectively – are necessary. The electric equivalent circuit for the membrane now becomes a little bit more complicated, as depicted in **Figure 3a**. C_m is again the membrane capacitance, g_{Na}, g_K, and g_{Cl} are the voltage-dependent conductances, and V_{Na}, V_K, and V_{Cl} are the Nernst reversal potentials for sodium, potassium, and chloride, respectively. Holding the membrane potential at a value V_m, the current flowing is

$$\begin{aligned} J_m &= J_c + J_{Na} + J_K + J_{Cl} \\ &= C_m(dV_m/dt) + g_{Na}(V_m - V_{Na}) \\ &\quad + g_K(V_m - V_K) + g_{Cl}(V_m - V_{Cl}) \end{aligned} \quad [5]$$

and, in resting condition when $J_m = 0$ and $dV_m/dt = 0$, the membrane potential becomes

$$\begin{aligned} V_m &= V_{resting} \\ &= (g_{Na}V_{Na} + g_K V_K + g_{Cl}V_{Cl})/(g_{Na} + g_K + g_{Cl}) \end{aligned} \quad [6]$$

The current–voltage relationship of excitable membranes is obviously nonlinear, due to the voltage and time dependence of the ionic conductances present and, in particular, one can observe different nonlinear current–voltage relationships for the isolated potassium and sodium currents (**Figure 3b**).

But how do excitable cells, and in particular neurons, code electrical signals? As previously discussed, neurons are the basic units of the central nervous system – receiving, analyzing, and perceiving information, and communicating with one another through synapses. The single neuron codes and transmits signals using the so-called action potential (AP). The AP is a sudden and transient depolarization of the cell membrane, and it occurs as an all-or-nothing event. This means that, in the same cell, a stimulus intense enough to produce an AP will always produce APs with the same amplitude. The information about stimulus intensity will be coded in the frequency of APs. A qualitative scheme of an AP is depicted in **Figure 4a**. AP has three main phases: (1) depolarization; (2) repolarization (or hyperpolarization); and (3) after-hyperpolarization. It is mainly due to the activation of two kinds of voltage-dependent ionic channels, permeable to sodium and potassium, respectively, showing different and nonlinear current–voltage relationships. If the cell membrane is depolarized over a threshold level, sodium channels (inactive at resting conditions) are suddenly

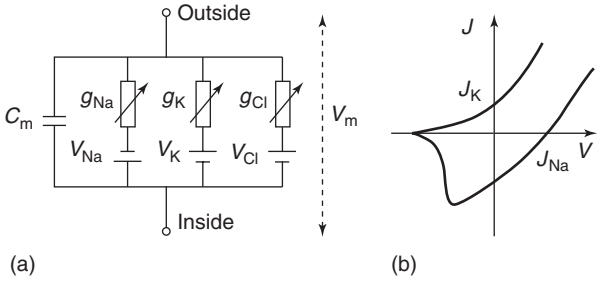

Figure 3 (a) Equivalent circuit of membrane active properties. (b) Current–voltage relationship for potassium and sodium channels.

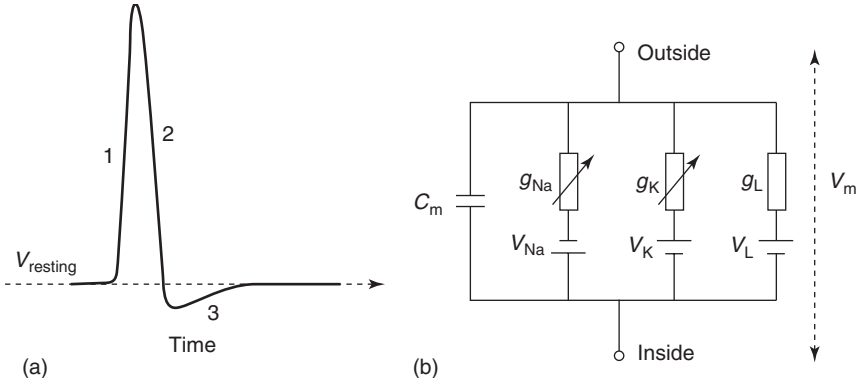

Figure 4 (a) Schematic representation of an action potential. (b) Equivalent circuit for cell membrane in the Hodgkin–Huxley model.

activated. Sodium enters into the cell and the membrane is further depolarized. When the membrane potential reaches the threshold for potassium channels activation, potassium starts to exit from the cell, repolarizing the membrane, even to values more negative that the resting one.

A fundamental step in understanding AP nature was done by A L Hodgkin and A F Huxley in the mid-twentieth century, proposing a semi-empirical model describing the AP generated in the squid giant axon. According to their model g_K and g_{Na}, potassium and sodium conductances, can be expressed as experimentally determined maximum conductances $\hat{g}_K$ and $\hat{g}_{Na}$ multiplied by coefficients, representing the fraction of the maximum conductances actually expressed. The kinetics of the conductances is considered to be driven by independent membrane-bound particles, each one with a certain probability to be in the right position to turn on the corresponding conductance. Thus,

$$\begin{aligned} g_K(V,t) &= n(V,t)^4 \hat{g}_K \\ g_{Na}(V,t) &= m(V,t)^3 h(V,t) \hat{g}_{Na} \end{aligned} \qquad [7]$$

where n, m, and h are the probabilities for the hypothetical particles to be in the permissive state. Consider the axon membrane patch represented by the equivalent circuit in **Figure 4b**, where g_L and V_L are the voltage-independent conductance and reversal potential of a leakage current J_L. Accordingly, the current flowing through this patch of the membrane will be

$$\begin{aligned} J_m = C_m(dV_m/dt) &+ n(V,t)^4 \hat{g}_K (V_m - V_K) \\ &+ m(V,t)^3 h(V,t) \hat{g}_{Na} (V_m - V_{Na}) \\ &+ g_L (V_m - V_L) \end{aligned} \qquad [8]$$

All the kinetic properties of J_m depend on the time and voltage dependences of n, m, and h. In the Hodgkin and Huxley model, these parameters can be calculated as

$$\begin{aligned} n(V,t) &= n_\infty - (n_\infty - n_0)\, e^{-t/\tau_n} \\ m(V,t) &= m_\infty - (m_\infty - m_0)\, e^{-t/\tau_m} \\ h(V,t) &= h_\infty - (h_\infty - h_0)\, e^{-t/\tau_h} \end{aligned} \qquad [9]$$

where n_∞, m_∞, h_∞, τ_n, τ_m, and τ_h are experimentally determined parameters related to the voltage-dependent rate of activation or inactivation of sodium and potassium conductances.

Equations [8] and [9] together are referred to as Hodgkin and Huxley equations. By solving them, it is possible to obtain remarkable fits between the recorded and calculated APs. Even though this model is to some extent oversimplified, it is yet sufficiently good to predict correctly the major feature of excitability, such as the AP shape and conduction velocity.

Electrical models of cells The equivalent electric circuit approach can be extended to the description of the electrical properties of the whole cell obviously with some simplifications. The simplest case is that of a spherical cell with a uniform membrane potential (isopotential cell). The current flowing across the membrane will be again due to capacitive and conductive terms: $J_m = J_i + J_c$. While considering particular cells like neurons, it should be borne in mind that these cells have extensive dendritic trees and axons, and that electrical signals, like APs, travel along them. When a neuron is active, or receives signals from other neurons, it is nonuniformly polarized and it cannot be considered isopotential. In this situation, the linear cable theory is applied. Axons or dendrites can be considered as cylindrical compartments schematized by the electrical equivalent circuit in **Figure 5**. For simplicity r_0, the extracellular space resistance, can be set equal to zero, because of the isopotentiality of such a compartment (this condition is not true only in some special cases). r_i, r_m, and c_m (the intracellular resistance, the membrane resistance, and the membrane capacitance,

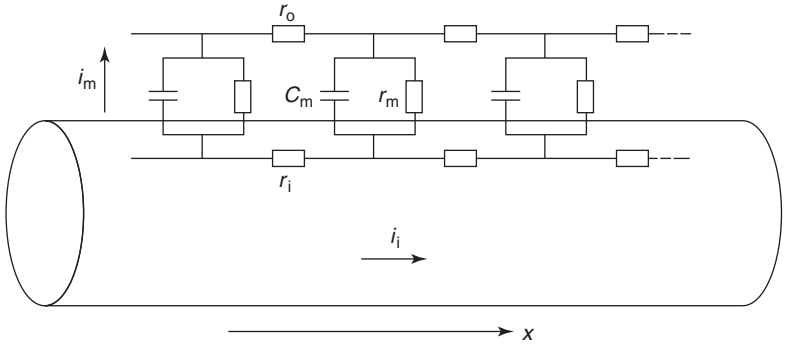

Figure 5 Equivalent circuit of an axon using the cable theory.

respectively) are considered to be uniform and constant along the entire cylinder, and to be independent of V_m. With some simple computations, it is possible to find the cable equation describing the membrane potential V_m produced in response to current injection at some point along the cylinder. This potential will be a function of time and of the distance from the point of injection:

$$\lambda^2 \partial^2 V_m(t,x)/\partial x^2 = \tau_m \partial V_m(t,x)/\partial t + V_m \qquad [10]$$

where $\lambda = \sqrt{(r_m/r_i)}$ is the space (length) constant and $\tau_m = r_m c_m$ is the membrane time constant. The solutions of the cable equation were derived for specific situations: infinite cable, finite cable, semifinite cable, and finite cable with soma. The potential V_x at a distance x for the infinite cable is given by $V_x = V_0 e^{-x/\lambda}$, with V_0 equal to the potential at the point of current injection. In this case, the conduction velocity, θ, of the potential is given by $\theta = 2\lambda/\tau_m$ and thus depends on cell membrane characteristics and on cell cytoplasm resistance.

Experimental Techniques

Several experimental techniques have been developed to understand the electrical functioning of cells, and in particular of neurons of the central nervous system. Depending on the level of analysis, different methods can be used. One can move from a subcellular approach, in which patch clamping and single-channel recording are the main techniques, to a behavioral approach where neuronal recordings in awake primates can be performed. Noninvasive electrophysiological techniques, such as electroencephalography (EEG) and event-related potential recordings, are also possible, together with methods of metabolic imaging to measure neuronal activity (e.g., the PET).

Channel Function

As discussed in previous paragraphs, electrical activity of biological systems at the cellular level consists of ion movement through highly specialized channels spanning the cell membrane. "Native" channels, normally expressed in a particular cell, can be studied. However, a deep understanding of the ion channels functioning is now greatly facilitated by the use of particular experimental systems, such as artificial and natural membranes in which specific ion channels can be selectively expressed. For natural membranes, ionic channels are newly synthesized by foreign DNA or RNA injected into a large living cell (such as the *Xenopus laevis* oocyte) via large pipettes.

Apart from the choice of the system expressing the ion channels under investigation, different techniques can be used to record their electrical activity. A fundamental method for electrophysiological studies, namely the single-cell patch clamp, was developed around 1978 by Sakmann and Neher. The starting point of this technique is the formation of a high-resistance (gigaohm) seal when the tip of a fire-polished glass micropipette is pressed against a cultured or acutely isolated cell membrane. The gigaohm seal essentially allows a high current gain, and low noise amplification, necessary for recording small, brief currents passing through single ionic channels. After this first step, the patch-clamp method can be applied in at least four configurations: cell-attached, inside-out, outside-out, and whole-cell (**Figure 6**). The first three configurations allow study of individual ion channels under different conditions.

The cell-attached configuration (**Figure 6a**) is essentially obtained with the formation of the gigaohm seal. In this mode, the electrical activity of single channels, present under the pipette tip, is recorded without disruption of the cell membrane. In the inside-out and outside-out configurations, the membrane patch is detached from the cell after the gigaohm seal is formed, and single-channel activity is recorded in isolation from the cell. In particular, in the inside-out configuration (**Figure 6c**), the patch of

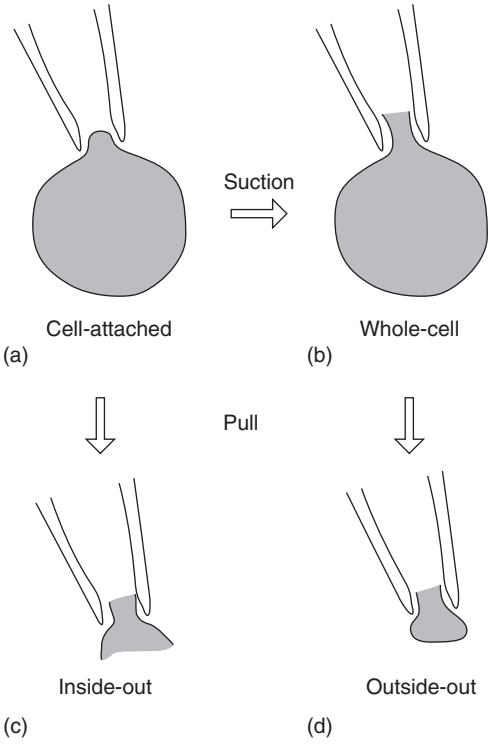

Figure 6 The four configuration of the patch-clamp technique.

membrane is gently pulled away from the cell, and the patch remains attached to the pipette with its cytoplasmic surface now exposed to the bathing solution. On the other hand, to reach the outside-out configuration (**Figure 6d**), the patch of membrane is gently pulled away from the cell only after an intermediate step (the whole-cell configuration that will be described below), in which the membrane patch under the pipette is ruptured by applying a strong suction to the recording pipette interior. Once detached, the membrane seals over the pipette tip, in favorable cases forming a membrane patch in which the extracellular membrane surface is exposed to the bathing solution.

The last configuration is the whole-cell clamp (**Figure 6b**). It is a form of the cell-attached configuration that uses the same pipette type and gigaohm seal method described above but that, by rupturing the membrane under the tip, allows recording of the "macroscopic" or summed currents flowing through all channels in the entire cellular membrane, rather than through a single channel, and for this reason is mainly used to study cellular electrical function (as it will be described in the next paragraph). In this configuration, the diffusible contents of the pipette exchange with those of the cell over time.

Cellular and Neural Circuit Function: *In Vitro* Studies

A neuron normally receives contacts from thousands of other neurons, and many of those inputs may be synchronized. To understand the way in which the cell integrates these numerous inputs and alters its own electrical activity, or how an action at one locus can lead to transmission of information to another locus, without interference from outside events, preparation of intact neurons in isolation or semi-isolation have been developed. An "acutely isolated neuron" model, prepared by mild enzymatic digestion and gentle agitation and trituration of brain slices, and chronically cultured neurons and cell lines (such as those also used for previously described single-channel studies) has been a major cellular source for electrophysiological studies, as have single neurons within brain slices. This last system can also be used in electrophysiological studies of synaptic transmission and local brain circuits. Another more recently developed model is the slice culture (or organotipic culture). In this case, cultures are prepared by long-term incubation of brain slices in a rotating drum, where the slices develop into a monolayer of neurons retaininig their local cytoarchitectonic organization.

To study the electrical activity of cellular systems, extracellular recording is probably the most straightforward electrophysiological recording situation. With this technique, the tip of a microelectrode is positioned immediately adjacent to, but outside of, a single neuron. In close proximity to the cell, current fields generated by APs in that cells are detected by the microelectrode as small voltage deflections. A multiple-cell recording configuration is also possible, with several microelectrodes inserted into one region of the system under study. By recording simultaneously from many neurons, their concerted activity can be investigated.

With intracellular recordings, membrane current or potential is measured via an electrode inserted into, or in contact with, the intracellular compartments. Two configurations are possible: the current clamp and the voltage clamp. In the current-clamp mode, the voltage difference across the cellular membrane is measured while injecting constant positive or negative current into the cell. Without current injection, the membrane resting potential can be measured. On the other hand, by injecting repetitive constant current pulses into the cell, a variety of information can be obtained, such as a relative measure of the resistance of the membrane, the current–voltage curves, and the voltage responses to activation of inhibitory or excitatory afferents. Conversely, during voltage-clamp recordings, the current required to hold the cell at a constant voltage is measured. A major advantage of this method over current-clamp recordings is that it is possible to measure ionic currents directly. In practice, voltage and current-clamp recordings involve the same sorts of micropipettes. In fact, one often penetrates a cell with the micropipette under the current-clamp mode. Then after the cell stabilizes, a series of adjustments of the recording characteristics can allow stable switching to the voltage clamp.

Neural Circuit Function and Behavioral Link

***In vivo* single-cell studies** The intact, functioning brain can be readily explored with microelectrodes in anesthetized animals. The microelectrode tip can be positioned in a desired position, so that any site within the brain can be found and cellular activity recorded. X-ray or magnetic resonance imaging methods may also be used for this purpose in human studies. In these experiments, the impulse activity of neurons is typically recorded extracellularly. There are many experimental applications of *in vivo* single-cell electrophysiology, such as iontophoresis (and other methods for local drug application), stimulation recordings (for discerning the functional effect of an afferent input to a neuron), and antidromic activation (used to confirm the projection to an area and to

determine the time required for conduction of an impulse along a projection pathway).

Behavioral electrophysiology A function at the behavioral level is a product of neuronal networks rather than simply the product of properties of individual neurons. To this end, neurons are typically associated in functionally related groups and circuits that can be specialized, for example, for sensory and motor functions or for associative activities. Many questions concerning cognition require experiments in the intact animal, because molecular and cellular experiments are unable to completely explain cognitive functions such as attention, perception, emotion, or memory. Hence, most studies in the electrophysiology of cognitive processes involve recording single neurons in behaving animals. Such studies often employ extracellular recordings from a metal microelectrode held in a miniature micropositioner on the animal's head. As with all extracellular recordings, it is important to know whether activity seen on an individual electrode is generated from one neuron only, or from several nearby neurons simultaneously recorded. Results of the latter, termed multiple-cell recording or multi-unit recording, are more difficult to interpret because neurons in the multiple-cell population may be physiologically heterogeneous. In addition, it is more difficult to ensure the stability of the recorded signal over time with multiple-cell activity.

Elemental Semiconductors, Electronic States of

G C La Rocca, Scuola Normale Superiore, Pisa, Italy

Introduction

Silicon, the paradigmatic elemental semiconductor, is by far the most relevant material in the electronic industry and possibly the best-known solid both from the point of view of basic science and technology. The present understanding of virtually all the properties of a crystalline solid such as Si is based on an accurate knowledge of its electronic states, that is, its electronic band structure. Quantum mechanics predicts the energies and wave functions available to the electrons in the periodic crystal potential. In contrast to the case of atoms or molecules, the translational symmetry of the crystal leads to extended states characterized by a Bloch wave vector $\boldsymbol{k}$. Just as in atoms and molecules, the Pauli exclusion principle dictates how distinct electronic states are occupied, each by a single electron starting from the lowest energy levels. From such information, mechanical, transport, and optical properties can be inferred.

Semiconductors are characterized by an energy gap (E_g) between the highest occupied states (top of the valence band) and the lowest unoccupied ones (bottom of the conduction band), which is comparable to 1 eV. Silicon ($E_g = 1.17$ eV) and germanium ($E_g = 0.774$ eV) are the most important elemental semiconductors, while diamond with an energy gap exceeding 5 eV is an insulator and grey tin a "zero-gap semiconductor." All these elements, belonging to group IV of the periodic table, are tetrahedrally coordinated and crystallize in the diamond structure with a cubic symmetry. The focus here is on Si and Ge, and to a lesser extent on α-Sn, while other elemental semiconductors, such as boron and selenium, having a more complex crystal structure and being less representative, are not considered.

The main features of electronic bands are determined by the symmetry of the crystal more than by the detailed shape of the crystal potential, and there are strong similarities in the band structures of C, Si, Ge, and α-Sn. In the following, the symmetry properties of

the diamond crystal and the main ingredients to calculate the energy bands are first described, and then the electronic band structures of Si, Ge, and α-Sn and their direct comparison with optical and photoemission experiments.

Crystal Structure and Symmetry

The group IV elemental semiconductors, such as carbon, are characterized by four electrons in the outer shell, with an electronic configuration s^2p^2 which, in the solid, gives rise to four tetrahedrally oriented sp^3 hybrid orbitals. The resulting network of covalently bonded atoms corresponds to a face-centered cubic (f.c.c) crystal in which each atom occupies an equivalent position. Such diamond crystals belong to the $Fd3m$ (O_h^7) crystallographic space group having the point group full cubic symmetry O_h.

Its translational symmetry is described by a Bravais f.c.c. lattice of primitive translations: $\boldsymbol{\tau}_1 = (a/2)\ (0,1,1)$, $\boldsymbol{\tau}_2 = (a/2)(1,0,1)$ and $\boldsymbol{\tau}_3 = (a/2)(1,1,0)$, where a is the side of the conventional unit cell, that is, the crystal is invariant for translations by any vector $\boldsymbol{R} = n_1\boldsymbol{\tau}_1 + n_2\boldsymbol{\tau}_2 + n_3\boldsymbol{\tau}_3$, with integral values of n_1, n_2, and n_3. The lattice constants of cubic elemental semiconductors are $a = 5.43$ Å for Si, $a = 5.65$ Å for Ge, $a = 6.46$ Å for α-Sn. The corresponding reciprocal lattice is body-centered cubic (b.c.c.) with primitive vectors: $\boldsymbol{K}_1 = (2\pi/a)(\bar{1},1,1)$, $\boldsymbol{K}_2 = (2\pi/a)(1,\bar{1},1)$ and $\boldsymbol{K}_3 = (2\pi/a)(1,1,\bar{1})$; the reciprocal lattice vectors, $\boldsymbol{G}$ ($\boldsymbol{G} = m_1\boldsymbol{K}_1 + m_2\boldsymbol{K}_2 + m_3\boldsymbol{K}_3$, with m_1, m_2, and m_3 integers), have the property: $e^{i\boldsymbol{R}\cdot\boldsymbol{G}} = 1$, for any lattice translation $\boldsymbol{R}$. The primitive (symmetric) cell of the reciprocal lattice, that is, the first Brillouin zone (BZ), of the diamond structure is shown in **Figure 1**. The physical significance of the reciprocal lattice and of the BZ is that, as a consequence of the periodic translational symmetry, the extended electronic states in a crystal are described by wave functions of the form $\Psi_{\boldsymbol{k}}(\boldsymbol{r}) = e^{i\boldsymbol{k}\cdot\boldsymbol{r}}u(\boldsymbol{r})$ (Bloch's theorem), where the wave vector $\boldsymbol{k}$ belongs to the BZ and the function u is invariant under lattice translations ($u(\boldsymbol{r}+\boldsymbol{R}) = u(\boldsymbol{r})$).

Beside the f.c.c. lattice translations, the rotations and reflections belonging to the full cubic group (O_h) leave the diamond structure invariant. At the microscopic level, though, half of the 48 symmetry operations of O_h are accompanied by a fractional translation such that the two interpenetrating f.c.c. lattices are exchanged (the space group of diamond being a nonsymmorphic space group with a basis of two atoms). This is the main difference with respect to the zinc-blende symmetry of compound semiconductors such as GaAs in which the two sublattices are not equivalent. In particular, an elemental semiconductor such as Si has an inversion symmetry with respect to the middle point of its homonuclear covalent bond, whereas in a compound semiconductor such as GaAs, this symmetry is lacking. The point-group symmetry determines the degeneracies of the electronic levels as a function of their wave vector $\boldsymbol{k}$ in the BZ. In particular, the electronic wave functions at points and lines of high symmetry in the BZ, those marked in **Figure 1**, are characterized by their transformation properties under point-group symmetry operations that leave their wave vector unchanged (i.e., they belong to the irreducible representations of the little group of their wave vector).

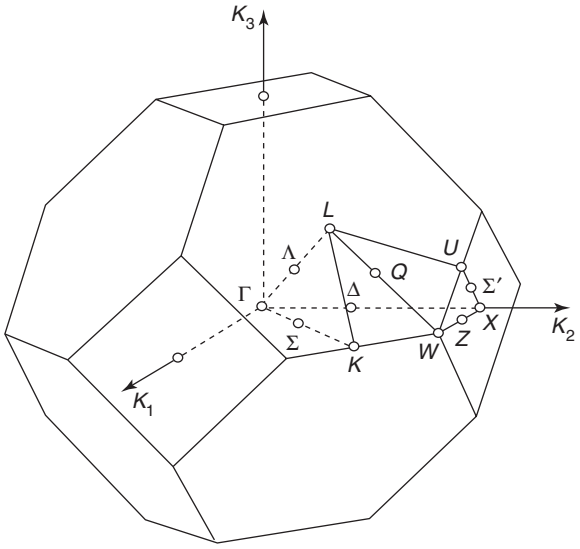

Figure 1 BZ of the diamond crystal; lines and points of high symmetry are indicated.

Besides space-group symmetry, time-reversal symmetry also affects the properties of a crystal, and it may bring about additional degeneracies of the electronic states. In particular, when the spin of the electrons is taken into account, in a crystal with inversion symmetry (such as Si) at each wave vector $\boldsymbol{k}$ the electronic states are (at least) doubly degenerate, because the state $|\boldsymbol{k}, \uparrow\rangle$ with spin up is degenerate with the state $|-\boldsymbol{k}, \uparrow\rangle$ by inversion symmetry, and the latter is degenerate with the state $|\boldsymbol{k}, \downarrow\rangle$ by time-reversal symmetry. The spin degeneracy between the states $|\boldsymbol{k}, \uparrow\rangle$ and $|\boldsymbol{k}, \downarrow\rangle$ is, in general, absent in materials lacking an inversion center (such as in GaAs). Standard group theoretical methods are employed to systematically obtain all the wealth of information that symmetry alone provides.

Energy Band Calculations

Even though translational symmetry enormously simplifies the computation of the electronic states

in a crystal, reducing the size of the problem to that of a unit cell, still a quantitative band structure calculation generally adopts a number of approximations. The electrons are considered to move in the presence of nuclei fixed at the equilibrium positions of the lattice (adiabatic approximation). The electron–electron interactions are treated at the mean field level neglecting many body correlations (one-particle approximation). Finally, the interactions with the nuclei, also including typically the core of inner electronic shells, and with all other electrons in average are lumped into a local potential $V(\boldsymbol{r})$ which has the full symmetry of the crystal (band approximation). The crystal potential $V(\boldsymbol{r})$ can be either chosen empirically or determined within a self-consistent *ab initio* scheme. The solution of the corresponding Schrödinger equation for the electronic states

$$\left[\frac{p^2}{2m} + V(\boldsymbol{r})\right]\Psi_{n,\boldsymbol{k}}(\boldsymbol{r}) = E_n(\boldsymbol{k})\Psi_{n,\boldsymbol{k}}(\boldsymbol{r})$$

gives the (possibly degenerate) Bloch eigenfunctions Ψ, with a wave vector $\boldsymbol{k}$ in the BZ and a band index n, which correspond to the electronic energy levels $E_n(\boldsymbol{k})$, that is, the energy bands which depend continuously on $\boldsymbol{k}$. Relativistic corrections can be included in the above equation and may be important for heavy elements as discussed later on.

There are numerous and diverse methods to calculate the energy bands. In particular, some consider a crystal as a collection of atoms (localized orbital methods), while others treat it as a perturbed uniform fluid (plane-wave methods). A very popular localized orbital approach is the tight-binding method in which the wave functions are expanded in a basis of linear combination of atomic orbitals (LCAO); usually, only a limited number of atomic orbitals are included and only the interactions among a limited number of neighbors are considered. This method, at least in its simpler semiempirical versions, is transparent and economical; it has been very successful in calculating both electronic and structural properties of semiconductors and establishing their chemical trends. The minimal tight-binding model to rationalize the electronic band structure of elemental semiconductors, at least concerning their valence band states, is sketched in **Figure 2**. For each one of the two atoms in the elementary unit cell, a basis of atomic states is chosen including only one *s* and one *p* level respectively (two and six times degenerate including spin). If one imagines bringing two atoms close together as in a diatomic molecule, each level would give rise to one bonding and one antibonding molecular orbital, the former having a lower energy.

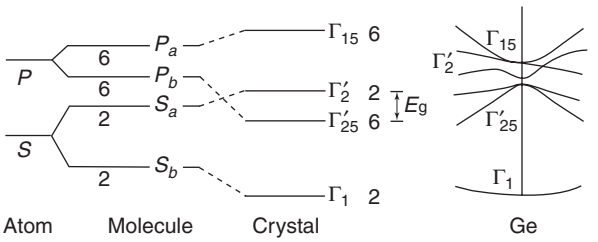

Figure 2 Scheme showing how lower-lying bonding (b) and higher-lying antibonding (a) molecular levels give rise to Bloch states of specific symmetry at the Γ point in Ge.

In the Ge crystal, for example, such states give rise at the center of the BZ at $\boldsymbol{k} = 0$ (the Γ point) to a sequence of levels having the full cubic symmetry and corresponding, in order of increasing energies, to an *s*-bonding-like Γ_1 level, a *p*-bonding-like $\Gamma_{25}^{'}$ level, an *s*-antibonding-like $\Gamma_2^{'}$ level and a *p*-antibonding-like Γ_{15} level. The eight outer shell electrons (four for each atom in the unit cell) fill the Γ_1 and $\Gamma_{25}^{'}$ levels completely, the latter being thus the top of the valence band, while the $\Gamma_2^{'}$ and Γ_{15} levels remain empty (conduction states). State-of-the-art tight-binding calculations, of course, are based on larger basis sets, possibly including also *d* states, and can also describe well the more delocalized conduction band states (see **Table 1**).

The plane-wave methods take an opposite point of view and start considering the electronic states in the presence of a very small crystal potential: in such an "empty lattice," the zeroth-order eigenfunctions of nearly free electrons are just plane waves folded back in the BZ according to the translational symmetry as sketched in **Figure 3**. For instance, looking again at

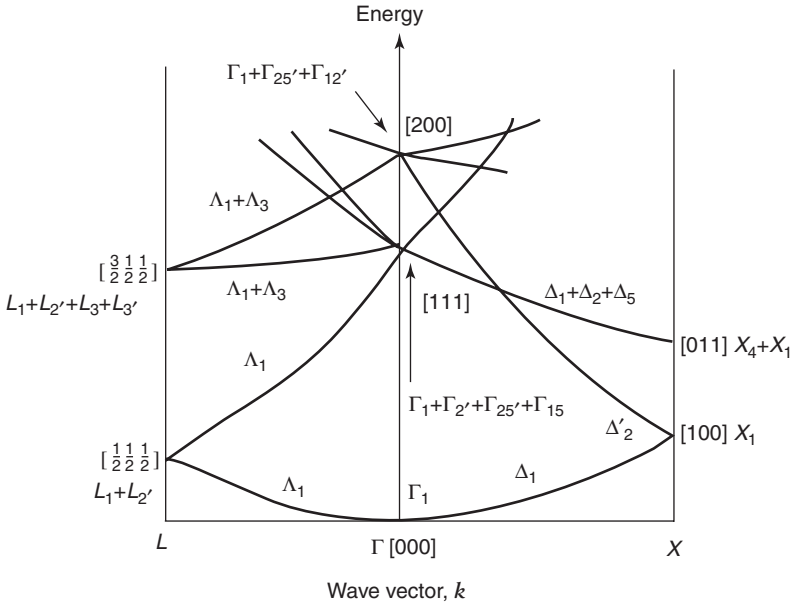

Figure 3 Empty lattice band structure for a diamond-like crystal.

the Γ point, the lowest energy level corresponds to a plane wave with a vanishing wave vector (Γ_1 state in the cubic crystal), while the next higher level includes the eight plane waves having a wave vector of the form $q=(2\pi/a)(\pm 1, \pm 1, \pm 1)$, which differ from zero by one of the shortest nonzero reciprocal lattice vectors. When the crystal potential is turned on, these eight states (sixteen including spin) split into several levels according to the cubic symmetry as indicated. However, the actual crystal potential is not small at all; the most important plane-wave method developed to circumvent this problem is the pseudopotential approach. In a crystal, the valence (or conduction) band wave functions are rapidly varying near each atomic site as they are orthogonal to those of the core states; therefore, their expansions in plane waves are very slowly convergent. It is possible, though, to substitute them with pseudo-wave-functions that are smooth (nodeless) near the atomic sites while replacing the ionic potential with a much smaller pseudopotential, in such a way that the energies $E_n(\boldsymbol{k})$ of the valence and conduction band states can be computed using a limited number of plane waves; furthermore, from the pseudo-wave-functions, the electronic charge density outside the cores can also be obtained. The pseudopotential (or rather its first few Fourier components) can be empirically chosen to reproduce a set of significant data (mostly optical transition energies and effective masses). For instance, empirical calculations using only three Fourier components of the pseudopotential can already give a reasonable description of the lowest energy bands of elemental semiconductors. A significant improvement is obtained using energy-dependent nonlocal pseudopotentials.

For state-of-the-art *ab initio* self-consistent calculations, made possible by the great increase of computational capabilities, the pseudopotential method has also been very successful in conjunction with the density-functional theory in the local-density approximation (LDA), that is, using an exchange-correlation potential dependent only on the local electronic charge density. Such an LDA is not quite satisfactory; in particular, the energy gaps of semiconductors are generally significantly underestimated (even though the shapes of both valence and conduction bands are well described). This shortcoming can be mended by going beyond the one-electron approximation and calculating the quasiparticle self-energies including (approximately) many-body effects, or adopting a time-dependent version of the density-functional theory.

Band Structures of Si, Ge, and α-Sn

The band structures of group IV elemental semiconductors show pronounced similarities and definite chemical trends. Strong analogies are expected in view of the identical configuration of the outermost electronic shell and of the identical crystalline symmetry. At the same time, going from Si to α-Sn, decreasing energy gaps accompany larger lattice constants due to the increasing size of the atomic cores.

The band structure of Si, qualitatively similar to that of diamond, is shown in **Figure 4** neglecting relativistic effects. The top of the valence band is at the

Γ point and corresponds to the $\Gamma_{25}^{'}$ level (three times degenerate, spin excluded). The bottom of the conduction band is along the Δ line from the Γ to the X point at $\boldsymbol{k} \simeq (2\pi/a)(0.85, 0, 0)$ and has a Δ_1 symmetry (nondegenerate, spin excluded). Thus, the conduction electrons have six pockets centered at the six equivalent conduction band minima (multivalley structure); they are ellipsoids of revolution elongated along the $\langle 1\,0\,0 \rangle$ directions with a longitudinal mass $m_{\mathrm{L}} = \simeq 1.0m$ and a transverse mass $m_{\mathrm{T}} \simeq 0.2m$, as measured from the cyclotron resonance. A peculiarity of the band structure of silicon, showing up in its optical spectrum around 3.4 eV as discussed below, is the fact that along the Λ line from the Γ to the L point the higher valence band (of symmetry Λ_3) and the lowest conduction band (of symmetry Λ_1) are very nearly parallel.

The band structure of Ge including the spin–orbit coupling interaction is shown in **Figure 5**. This is a relativistic effect which, similar to the atomic case, can reduce the degeneracy of the levels. For instance, without spin–orbit coupling, the top of the valence band would be, just as in Si, a p-bonding-like $\Gamma_{25}^{'}$. In the presence of spin–orbit coupling, the sixfold degenerate states obtained from the $\Gamma_{25}^{'}$ ones by the inclusion of spin are split into a fourfold degenerate Γ_8^+ level and a twofold degenerate Γ_7^+ level, which play the role, respectively, of $J = 3/2$ and $J = 1/2$ total angular momentum states. The corresponding spin–orbit gap is $\Delta = 0.3$ eV (the corresponding value for Si is only 0.04 eV). Besides spin–orbit splitting, other relativistic effects become more important in the heavier Ge than in Si; in particular, there are corrections affecting primarily s-derived states which lower their energy. These effects and the presence in the core of Ge of d electrons that, together with p electrons, contribute to pushing the Γ_{15} states to higher energies (corresponding to the Γ_8^- and Γ_6^- spin–orbit split states), through orthogonalization to the core states, explain why in Ge the s-derived $\Gamma_2^{'}$ level (i.e., the Γ_7^- state, spin included) is lower than the Γ_{15} states. The interchange of the conduction band energy level sequence at the Γ point with respect to Si is accompanied by the fact that the minimum of the conduction band in Ge occurs at the L point at the BZ border (the L_6^+ level). The conduction band of Ge, therefore, leads to a multivalley structure with four electron pockets (half pocket for each of the eight L points at the BZ border); they are ellipsoids of revolution elongated along the $\langle 111 \rangle$ directions. The values of the longitudinal mass $m_{\mathrm{L}} \simeq 1.6m$ and of the transverse mass $m_{\mathrm{T}} \simeq 0.08m$ have been determined from cyclotron resonance measurements.

The top of the valence band in both Si and Ge is at the center of the BZ: $\Gamma_{25}^{'}$ without spin, Γ_8^+ and Γ_7^+ including spin, as discussed above. The Γ_7^+ split-off hole states can be described as a simple band with an effective mass $m_{\mathrm{so}} \simeq 0.25m$ in Si and $m_{\mathrm{so}} \simeq 0.08m$ in Ge. In a rough approximation, the Γ_8^+ hole states can be described as belonging to two distinct spherical

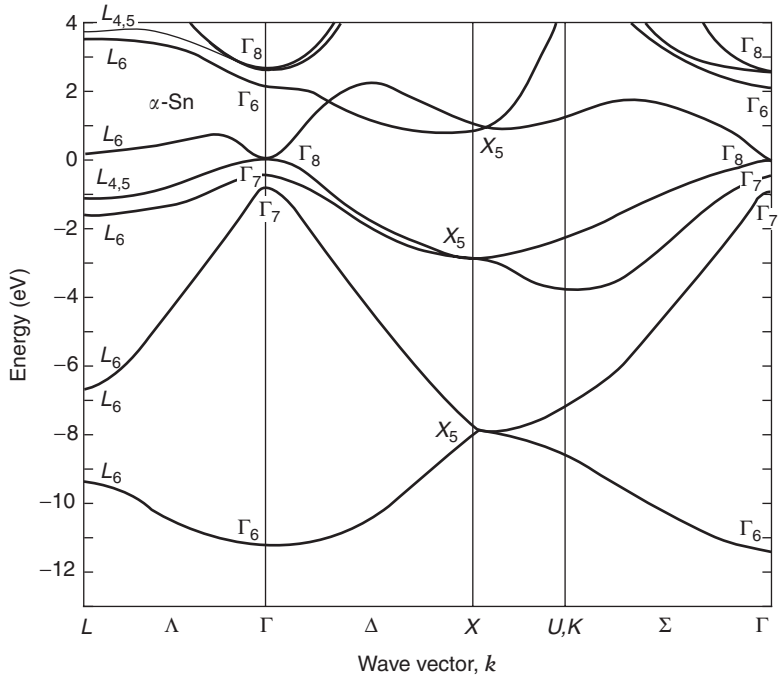

Figure 6 Band structure of α-Sn from an empirical nonlocal pseudopotential calculation. pockets each characterized by an isotropic mass: the heavy-hole pocket (with mass $m_{\mathrm{hh}} \simeq 0.5m$ for Si and $m_{\mathrm{hh}} \simeq 0.3m$ for Ge) and the light-hole pocket (with mass $m_{\mathrm{lh}} \simeq 0.16m$ for Si and $m_{\mathrm{lh}} \simeq 0.044m$ for Ge). Also, these hole effective masses have been determined from cyclotron resonance measurements in low magnetic fields (classical regime). However, this simple picture is not quite correct: because of the valence band degeneracy, the hole bands are not isotropic, but "warped" (particularly, the heavy-hole ones). A complete description of the hole states can be given using the multiband effective mass approach, in which the valence band degeneracy is fully accounted for.

The tendency to have a lower energy *s*-derived Γ_7^- level is even stronger in gray tin where this level is positioned between the spin–orbit split Γ_8^+ and Γ_7^+ levels ("inverted gap" configuration). As a consequence, the band structure of α-Sn, shown in **Figure 6**, is characterized by the fact that the fourfold degenerate (spin included) Γ_8^+ states correspond, at the same time, to the topmost filled valence band and to the lowest empty conduction band which touch each other at the Γ point. Gray tin is thus a "zero-gap semiconductor" rather than a semiconductor proper.

Comparison with Experimental Data

Just as for atoms and molecules, even for solids, the most direct and informative experimental techniques to study their electronic structure over a wide range of energies are optical spectroscopy and photoelectron spectroscopy.

In crystalline semiconductors such as Si and Ge, the absorption due to direct interband transitions is very strong and reflectivity measurements are more popular than transmission ones. From reflectivity spectra taken over a large frequency range, it is possible to obtain the real and imaginary parts of the complex dielectric function $\tilde{\varepsilon} = \varepsilon_1 + \mathrm{i}\varepsilon_2$ (via Kramers–Kronig analysis) and, thus, all the linear optical properties. From the theoretical point of view, the imaginary part $\varepsilon_2(\omega)$ can be calculated summing over all possible transitions between filled (valence) states and empty (conduction) states corresponding to the absorption of a photon of frequency ω. As the wavelength of light is much larger than the lattice constant, such optical transitions take place between electronic states having the same wave vector within the first BZ (direct or "vertical" transitions) and differing in energy by $\hbar\omega$, thus:

$$\varepsilon_2(\omega) = \frac{1}{\pi} \sum_{v,c} \int_{\mathrm{BZ}} \mathrm{d}^3k |d_{cv}|^2 \delta(E_c(\boldsymbol{k}) - E_v(\boldsymbol{k}) - \hbar\omega)$$

where d_{cv} is the transition electric dipole matrix element between the initial and final state. It is to be noticed that, because of the energy-conserving delta function in the equation above, specific singularities in the frequency dependence of ε_2 are obtained when $\nabla_k(E_c(\boldsymbol{k}) - E_v(\boldsymbol{k})) = 0$ (critical points). Such

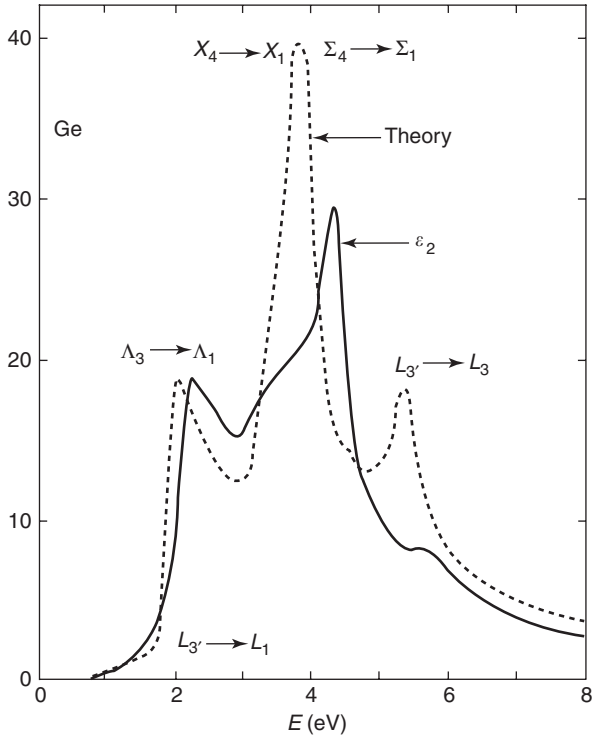

Figure 7 Imaginary part of the dielectric function of Ge: the solid line is experimental and the dashed one theoretical; optical transitions at critical points are identified. (Reprinted figure with permission from Brust D, Phillips JC, and Bassani F (1962) Critical points and ultraviolet reflectivity of semiconductors. *Physical Review Letters* 9: 94; © American Physical Society.)

structures (many of which are dictated by symmetry alone) have been found in all elemental semiconductors, and this has allowed the identification of the critical-point transition peaks and the verification of the band structure.

As a classical and pioneering example, **Figure 7** reports the optical excitation spectrum of Ge, measured as explained above, and computed from the equation above on the basis of an empirical pseudopotential band structure calculation. It is emphasized that not only have the critical points been identified, but also the full band structure has been put to test by the described analysis of the optical properties. A better resolution of the critical point behavior can be obtained by employing various kinds of modulation spectroscopy (e.g., piezoreflectance, electroreflectance) that amounts to measuring the first (or higher) derivatives of the dielectric function. As a further example, one considers a recent calculation of the optical absorption of Si shown in **Figure 8** in comparison with experimental data. The time-dependent density-functional theory includes electron–hole correlations (i.e., excitonic effects) which are crucial to reproduce the conspicuous peak at about 3.4 eV associated with interband transitions near the L point.

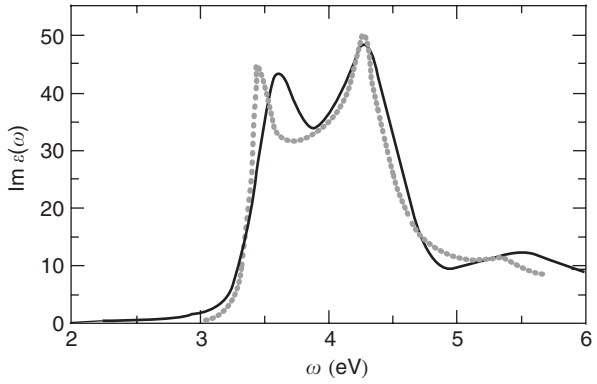

Figure 8 Imaginary part of the dielectric function of Si: the dots are experimental data and the solid line theory. The direct optical transitions discussed so far are usually dominant when allowed by energy conservation. It is however possible, through the absorption or emission of a phonon, to have indirect transitions in which the wave vector of the initial and final electronic states are different. These transitions are much weaker, but in the case of indirect gap semiconductors such as Si and Ge having the top of the valence band and the bottom of the conduction band at different points in the BZ, they give rise to absorption at energies below the onset of the much stronger direct transitions. The corresponding

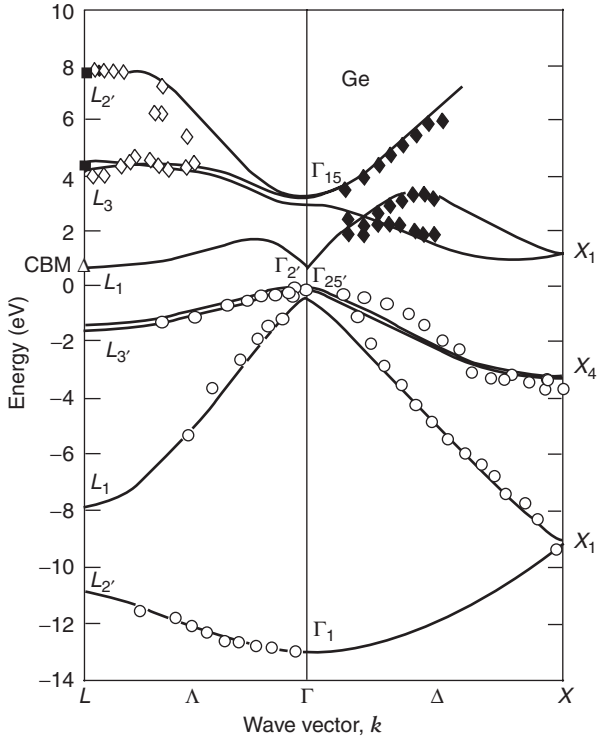

Figure 10 Conduction and valence band dispersions of Ge from angle-resolved photoemission and inverse photoemission. (Reprinted figure with permission from Ortega JE and Himpsel FJ (1993) Inverse-photoemission study of Ge(100), Si(100), and GaAs(100): bulk bands and surface states. *Physical Review B* 47: 2130; © American Physical Society.)

(temperature-dependent) characteristic features have also been observed and compared with theory providing additional evidence for the band structure determination.

Photoelectron spectroscopy has also proved to be a very useful experimental technique to measure the electronic structure of semiconductors. The photoemission process takes place through the following steps: first, upon absorption of an incoming photon, an electron is excited from a filled band to a higher empty band; then, the excited electron travels towards the surface and, finally, if energetic enough, it escapes into the vacuum to be detected. Thus, low-energy conduction states below the vacuum level are not involved in photoemission processes as they can be neither initial states (empty in the ground state) nor final states (unable to escape from the solid once excited). These levels can be investigated by inverse photoemission which is, in a sense, the time-reversed process of photoemission: an incoming electron falls in an electronic level available in the solid, emitting a photon which is then detected. In photoelectron spectroscopy, the energy, wave vector, and polarization (spin) of the photon (electron) can be selectively chosen or averaged over. The main advantage of photoemission and inverse photoemission with respect to optical spectroscopy is the capability of providing absolute energy levels rather than energy differences between levels. Besides a lower resolution and (especially for inverse photoemission) lower statistics, the main disadvantage for the study of bulk properties is that photoelectron spectroscopy is much more surface sensitive because of the short escape or penetration depths of electrons (~ 10 Å).

The detailed analysis of angle-resolved (inverse) photoemission data allows one to obtain the complete band structure of a semiconductor. In **Figures 9** and **10**, the energy bands of Si and Ge obtained by first-principle quasiparticle calculations are compared with photoemission and inverse photoemission data showing very good agreement.

In conclusion, all the main features of the band structures of elemental semiconductors are firmly established both from the theoretical and the experimental point of view. These results represent one of the most important achievements in solid state physics and provide a framework within which virtually all material properties can be understood.

Elementary Excitations in Biological Systems

H J M de Groot, J Matysik, and J Zaanen,
University of Leiden, Leiden, The Netherlands

Introduction

In condensed matter physics, it would be difficult to understand the fate of energy injected into a solid or a quantum liquid without invoking the notion of elementary excitation. An elementary excitation is an entity with a well-defined identity, interacting weakly with others of its kind, which is to a good approximation responsible for the dynamic evolution in the system when it is not driven too far from equilibrium. Quasiparticles are more often than not highly collective entities which have little, if anything, to do with the microscopic constituents of the system such as electrons or ions. Examples are the Landau quasiparticles in metals (electrons accompanied by an electronic screening cloud), the polarons (electrons dressed up with a phonon cloud), as well as topological excitations such as solitons, domain walls, and vortices involving a reshuffling of an infinity of microscopic degrees of freedom. In systems characterized by a degree of translational symmetry, elementary excitations are delocalized. However, when the symmetry is also broken by, for example, lattice defects, localized excitations are still considered essential to arrive at a proper theoretical description of the solid state.

While elementary excitations are nowadays central to the understanding of the physics of "hard" matter, the idea barely plays a role in the current descriptions of the biological solid state, in particular, the enzymes built up from soft condensed matter at the mesoscopic scale. While it lacks the regularity of crystalline matter, biological matter is quite orderly and it can be regarded as more similar to a solid than to a simple fluid, lacking structure. This problem is either approached in the language of chemistry with its emphasis on the microscopic scale (e.g., electrons covalently binding atoms) or from the perspective of molecular biology: protein function and the mechanisms of protein operation are linked to protein structure and the DNA sequence of a protein, according to the central dogma of molecular biology. Although still limited in scope, biophysicists have made some progress over the years in changing this situation and it appears that at least in some circumstances, the concept of elementary excitation is quite useful.

Since a biological system serves a purpose in the biological hierarchy, the energy entering the system is used in a coherent and orderly fashion through a time sequence of highly nonlinear self-organization events. For instance, enzymes involved in transport, energy transduction, or signal transduction processes operate unidirectionally, like molecular machines. Such devices rely on highly nonlinear self-organization mechanisms, a chain of elementary processes to channel thermal or external energy from one subprocess into the next. The resulting energetic pathway fulfills both the requirements set by the evolutionary constraints that apply to the system and the universal physical principle that physical changes and processes tend to take the easiest or least action path. This is possible since a protein is a biological construct; its folding is downward causal, and is controlled by the cellular hierarchy. Every protein is a small architecture, a compartment that is metastable. In this compartment, the energy pathways are part of the design properties.

Biology builds upon "stochastic machines" that are robust against noise. As illustrated with various examples, experimental evidence emerges that the notion of an elementary excitation is quite helpful in understanding the workings of these biological machines. This "mechanics" typically involves metastable states of the protein, with a well-defined identity, involving cooperative change of the equilibrium structure of the protein on a larger scale. As in the solid, this excitation is largely responsible for the dynamical evolution of the system when it is perturbed away from equilibrium. A difference with conventional solids is that the lack of symmetry renders these excitations to be quite a bit more diverse, "complex." Due to this complexity, mathematical theory is of much less use than in conventional condensed matter physics, while the standard methods of experimental physics are not quite suited to probe the time and length scales of relevance to protein dynamics. It is a blessing in disguise, however, that this complexity makes possible that these biological systems can resemble the machinery of the human world. The various examples discussed below might further illustrate the case. The discussion starts with the short-time dynamics in various photoactive systems where the analogies with condensed matter systems are quite obvious. The focus is then on the dynamics on larger lengths and timescales (ion channels, motor proteins, substrate channeling), where the situation is much less clear because of the aforementioned difficulties.

Light-Induced Electron Transfer in Photosynthetic Reaction Centers

In photosynthesis, the reaction center (RC) uses the sunlight to pump electrons to generate chemicals with a high redox potential. The O_2 synthesized by plants and trees drives the respiratory chain of many of the known life forms, and, therefore, the photosynthetic electron pumping complex reaction chain is among the most important chemical reactions for life on earth. The initial photochemical process in green plants occurs in RC protein complexes bound to the photosynthetic membrane of chloroplasts. Two RCs are working sequentially: photosystem II has a strong oxidation power, which allows the oxidation of water, and photosystem I has a strong reductive power.

In all types of RCs, light is absorbed by a (bacterio)chlorophyll aggregate, known as the primary electron donor P. In the RC of purple bacteria (**Figure 1**), P is a bacteriochlorophyll dimer, called the "special pair." In the photochemically excited state of the dimer, an electron (polaron) is emitted into one branch of cofactors (**Figure 2**). This functional asymmetry in the energy channel appears to be related to different mesoscopic Coulomb force fields in both branches. In RCs of purple bacteria, the primary electron acceptor is a bacteriopheophytin H cofactor. While the light-induced electron transfer from P to H occurs in 3 ps, the back-reaction to P in its electronic ground state occurs at the millisecond timescale. Originally, the slow-down has been explained by the high Gibbs energy, shifting the back-reaction into the inverted Marcus region. There are, however, several experimental observations, contrasting the view of a static cofactor arrangement, on which the Marcus concept is based. A change of mesoscopic dielectric properties as a consequence of the change of charge-state has been observed on bacterial RCs by optical spectroscopy and by photovoltage measurements and is described by theoretical methods. The temperature dependence of the electron transfer kinetics and photoacoustically detected volume contraction provide evidence for small structural (conformational) changes in the protein when the charge-separated state is established. Upon long illumination, radical-pairs with lifetimes of several minutes have been reported. The elementary excitation is here represented by the highly cooperative changes in the protein in response to the transfer of an electron, which leads to well-defined nonequilibrium states that are important for the function. A mesoscopic nonlinear dielectric screening phenomenon to stabilize the energy channel would help to prevent the back-reaction, and this is of interest for the construction of artificial RCs. In this sense, the operational mechanism of RCs could be described in terms of an electron pump. The piston P, shuttling between different electronic states is distinguished by its affinity to electrons. The valve avoiding electron back-transfer corresponds with the nonlinear dielectric response. Interestingly, a similar terminology was introduced in condensed matter physics by David Thouless already in 1983 for charge pumping and is now common in the field of solid-state photovoltaics.

Excitons in Photosynthetic Antenna Complexes

In photosynthesis, light energy is used to drive chemical processes. Under average conditions, the photon

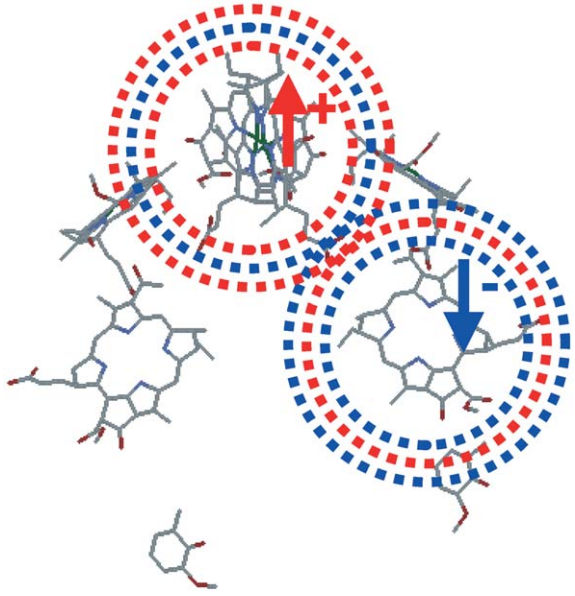

Figure 2 Charge separation in a photosynthetic reaction center. (Source: Leiden Institute of Chemistry, Leiden, NL.)

flux is limiting for photosynthesis. To improve the performance, all photosynthetic systems embed RCs in energy concentrators: arrays of light-harvesting antenna complexes that increase the photosynthetic efficiency. In most bacteria, the ratio is ~40 antennae to one RC; in plants, however, ratios of several hundreds antenna per RC are common. The structure of antenna complexes varies widely. The membrane-integrated antenna LH1 and LH2 of purple bacteria have ring-shaped structures (**Figure 1**). In LH2, 18 BChl *a* molecules (B850) are sandwiched between two polypeptides and form a continuous overlapping ring-shaped superstructure. Another ring of BChl *a* (B800) is positioned between the subunits of the outer cylinder with the bacteriochlorin rings perpendicular to the transmembrane helix axis. The entire LH2 complex has a ninefold rotational symmetry. Chlorosome antennae of green bacteria obtain a size of several micrometers and are bound to the surface of the photosynthetic membrane where they have contact with several dozens of RCs. The interior of chlorosomes is formed by self-aggregation of bacteriochlorophyll molecules, a process which can also be observed in an apolar solvent.

The elementary excitations in photosynthetic antenna systems are excitons. Despite differences in their structures, all antenna share similar functional properties: absorption of light over a broad spectral range, storage of this excitation in the form of an exciton, and excitation transfer into the RC. There is currently a discussion about the exact description of the exciton in LH2, whether it is localized on a single B850 cofactor and hopping around the superstructure, or delocalized over several B850 cofactors. Excitations in chlorosome-type aggregates have been shown to be delocalized over at least 10–15 BChl molecules and can migrate through the superstructure.

Double Bond Isomerization in Rhodopsin

The next example of an elementary excitation presented here is the polaronic-type structure that drives the isomerization process in the rhodopsin photoreceptor of vision, located in the disk membranes of the rod outer segment of the retina of higher organisms. Rhodopsin has a retinal chromophore in an 11-*cis* configuration that is bound to the protein by a covalent Schiff base bond to the nitrogen of a lysine residue L-296 (upper panel in **Figure 3**). The nitrogen is protonated and stabilized by a negative counterion. The proton positive charge is delocalized into the polyene chain of the retinal. The charge in the electronic ground state can be observed with NMR. This is illustrated in the lower panel of **Figure 3**. The color-coded spheres over the carbons represent an

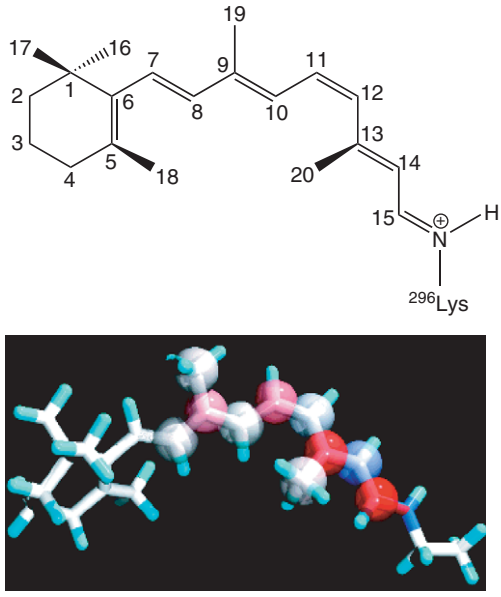

Figure 3 Retinal chromophore.

NMR "snapshot" of the chemical shifts relative to a neutral polyene. These shifts translate into charge, from excess negative charge (blue) to strong positive charge (red). The alternating charge pattern over several bonds in **Figure 3** corresponds with a trapped positively charged polaron at the odd-numbered lattice sites with a half-width of several bonds. This example shows how the self-organization by nature produces biological constructs that are physically in a metastable state, far out of equilibrium. The rhodopsin can adapt to environmental constraints. For instance, the electronic structure of the extended π-system and the polaron can be tuned by the properties of the protein pocket by variation of Coulomb fields, which cause stabilization or destabilization of the different electronic states (Opsin shift). In this way, variations in the protein can affect the HOMO–LUMO gap and the action spectrum of vision.

Upon excitation with light, the 11-*cis* double bond isomerizes to *trans* within 200 fs and this chemical reaction triggers the visual signal transduction cascade. The precise energy channel is difficult to assess experimentally, but *ab initio* molecular dynamics suggests that a light-induced flip of the *cis*-hydrogen bound to *C*-12 to the corresponding *trans*-position relative to *C*-11 yields a strained *trans*-chromophore in the 11-*cis* binding pocket. Upon excitation with light, the positive polaronic charge in **Figure 3** is transferred to the left side of the polyene, at the even lattice sites. This initiates the motion of the charge along the polyene backbone in the excited state, where it is attracted by the negative counterion charge at the Schiff base end. Since the electronic

charge is present in the form of a polaron, it increases its effective mass by two orders of magnitude, by autodressing with phonons on a very short timescale, $\sim$20 fs. Hence, the electronic charge is a very heavy particle on the 200 fs timescale of the isomerization. This leads to a classically coherent channel in the excited state that keeps the energy focused. The potential energy stored in the excitation is partly transferred into kinetic energy of the atoms and for another part into molecular strain by the isomerization. The polaron carries a node in the electronic wave function into the isomerization region that is eliminated in a quantum nuclear tunneling event, and leads to a spring-loaded molecule that activates the receptor protein in a series of first-order dark reactions: the visual cascade. Every subsequent step in this cascade takes more time, from picoseconds to nanoseconds, microseconds, milliseconds, and seconds. At every intermediate, the system partially relaxes and prepares itself for the next step, on a longer time and length scale. Hence, a least action path is effectuated by a compartmentalization in space and time, where every self-organizing process in a chain of events helps to stabilize the energy in the corresponding subsystem.

Proton Transport in Bacteriorhodopsin

Another retinal protein, bacteriorhodopsin, is a light-driven proton pump found in halophilic archaebacteria. During the photocycle, a proton is pumped through this protein. The difference in pH and electric potential associated with the proton gradient is used for the synthesis of the cellular "fuel" adenosine triphosphate (ATP). Similar to the rhodopsin, the retinal Schiff base in bacteriorhodopsin is protonated and stabilized by a complex counterion that is part of the proton conduction pathway. A schematic representation of the proton pathway is presented in **Figure 4**. A complex counterion in a biological solid is an ice-like structure and can support elementary excitations in the form of ionic defects and Bjerrum defects that participate in a Grotthus proton transfer mechanism. The figure shows the proton background potential for the idealized case of a one-dimensional channel of hydrogen-bonded atoms. The potential energy is highest at the position of the heavy atoms, and the two minima between each pair of atoms are separated by a barrier u and correspond with symmetric hydrogen bonds. An excess proton in the chain forms an ionic defect extending over $d \sim 3$ atoms. Such defects are thermodynamically stable if the proton chemical potential in the protein μ_p exceeds the defect creation energy μ_c. To first order, the $\mu_c \sim j/d + u \times d$, that is, the energy cost associated with improper charge balance between adjacent atoms due to the Coulombic interactions between the protons (measured by j), and the energy cost from the energy barriers u between the minima in each hydrogen bond. Stability requires that $\partial\mu_c/\partial d = 0$ and $\mu_c \sim 2\sqrt{j \times u}$ with $d \sim \sqrt{j/u}$. This illustrates how a simple self-organization process can give rise to an elementary excitation in a protein water channel. It has been experimentally verified that such excitations can migrate. The H-bonding network, required for such Grotthus/Bjerrum proton transfer mechanism, has been found by X-ray structure analysis in many cases, for instance in bacteriorhodopsin and in photosynthetic RC electron-pumping proteins. In cytochrome *c*-oxidase, it was proposed that a H-bonded unit may operate as a temporary storage device for multiple elementary excitations, to accumulate energy for its electron pump mechanism. Mechanistic details about structural changes of the protein during the proton pumping in the bacteriorhodopsin protein are currently under discussion.

Conformational Changes during Molecular Transport

The broad definition of an elementary excitation as a well-defined entity that is responsible for the dynamic evolution of a system encompasses a wide variety of biological machines that operate with mechanical changes. In this context, the elementary excitations are the few unique conformations of the protein that it cycles through during its function. For instance, ion channels are membrane-spanning proteins forming a

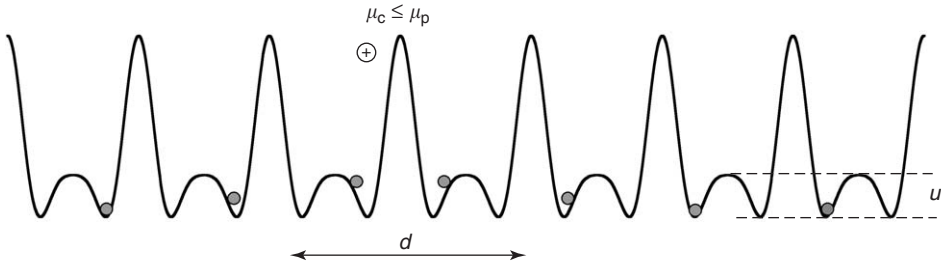

Figure 4 A one-dimensional proton wire.

pathway for the flow of inorganic ions across cell membranes. Like enzymes, ion channels have their specific substrates as potassium, sodium, calcium, and chlorine ions. Potassium channels exhibit a remarkable ability to discriminate between potassium and sodium by a factor of $\sim 10\,000$, even though these ions are similar in size. Without such selectivity, electrical signal production, which is related to many fundamental biological processes as electrical signaling in the nervous system, would be impossible. The flow of ions occurs down their electrochemical gradient. Although the high selectivity suggests strong energetic interaction between ion and protein, the transport rate approaches the diffusion limit. The flow of ions can be gated by external triggers as ligand binding or membrane polarization. Potassium channels are tetramers of identical subunits forming a pore in the center. Selectivity and gating are the main features of this molecular machine. Cation selectivity is an intrinsic property of the pore architecture originating from a special arrangement of cation-attractive α-helices. This specific sequence of amino acids forming the selectivity filter is conserved in all potassium channels. In potassium channels opening in response to intracellular calcium, the receptor binding leads to structural changes opening the gating ring at the intracellular membrane surface. Voltage-dependent potassium channels are switched by "voltage-sensor paddles" on the outer perimeter of the channel surface. These paddles positioned inside the membrane contain positively charged arginine residues. The angle of the paddles relative to the axis of the pore changes with the polarization of the membrane. This movement controls the gate of the pore.

Molecular motors or "mechanochemical proteins" convert chemical energy, usually in the form of ATP, or the potential energy of an ion gradient into mechanical forces and motion. The motion can be translational or rotational. Molecular motor proteins that carry cargo directly along a cytoskeletal track are myosins (along actin) and kinesins and dyneins (along microtubules). Rotary motors are bacterial flagelar motors and F_1F_0 ATP synthase (**Figure 5**). The molecular structures of these motors show a large variation. In the past, it was generally assumed that motor proteins generate forces by rectifying thermal fluctuations. According to such fluctuation ratchets models, motion is not produced directly by the chemical reaction or diffusive process. Feynman had shown that Brownian ratchets cannot produce a net-transport at equilibrium conditions but require a gradient. Under nonequilibrium conditions, transport can occur due to fluctuations correlated to the surroundings. Driving by such colored noise is called stochastic resonance. This means, that random walk moves the

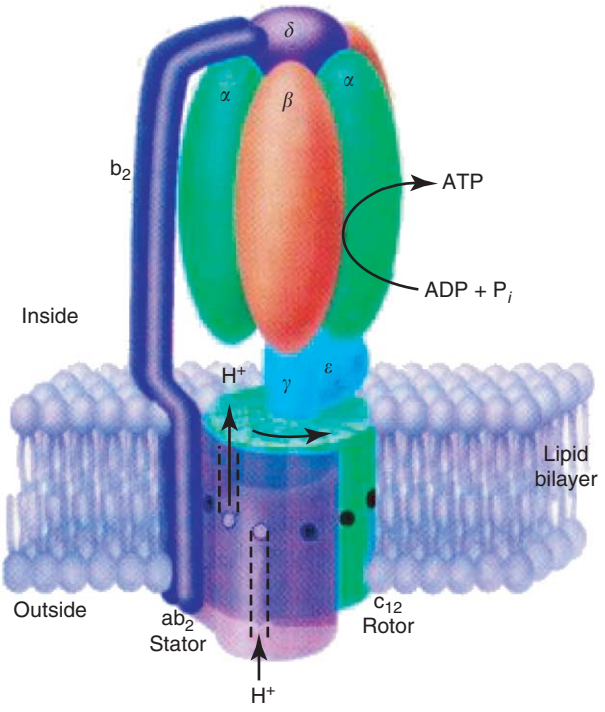

Figure 5 ATP synthase.

motor, and a linked chemical or diffusional process biases the walk such that forward steps become more likely than back steps. However, recent experiments have shown that motor proteins "walk" over a biological rail by a series of conformational changes. Dyneins, for example, are ATP-driven microtubule motors assembled from three parts: stalk, head, and stem. The stalk is linked to the track, and the stalk and stem are connected to the head similar as the two hands of a clock. During the chemomechanical cycle, the positions of the hand change. Here, the elementary excitation is the coherent dynamics in the form of a stepping motion involving conformational changes when it burns ATP.

Finally, direct transfer of metabolites from one protein to another or from one active site to another in the same protein is called substrate channeling. Such direct link decreases transport time of metabolites, prevents loss by diffusion, protects reactive intermediates from solvent interaction, and avoids interference with competing metabolic pathways. The longest channeling pathway discussed currently is that connecting the three active sites of carbamoyl phosphate synthase (CBS) separated by a linear distance of ~ 100 Å. One of the best-studied examples is the intramolecular hydrophobic tunnel in tryptophan synthase connecting two active sites of ~ 25 Å distance. As a channeling mechanism, tunneling by Brownian dynamics as well as electrostatic attraction

of the metabolite are considered. Although conformational changes are not included in the traditional definition of elementary excitations in condensed matter physics, they do generally fit into the broader definition. It is a challenge for condensed matter biophysicists to deal with these elementary excitations experimentally, and to understand the dynamic evolution theoretically. One can only speculate at present how far this can go, from the molecular level upwards, to the cellular level, and beyond.

Environmental Science, Physical Principles and Applications

A Speranza and V Lucarini, University of Camerino, Camerino, Italy

Introduction

Environmental science almost invariably proposes problems of extreme complexity, typically characterized by strongly nonlinear evolution dynamics. The systems under investigation have many degrees of freedom – which makes them complicated – and feature nonlinear interactions of several different components taking place on a vast range of time–space scales – which makes them complex. Such systems evolve under the action of macroscopic driving (typically the solar heating) and modulating (e.g., the Earth's rotation and gravitation) agents. The most comprehensive example is the entire climatic system. In its most rigorous definition, the climatic system is constituted by four intimately interconnected subsystems: atmosphere, hydrosphere, cryosphere, and biosphere (**Figure 1**), and is powered by the electromagnetic radiation emitted by the Sun (**Figure 2**). These subsystems are by themselves complicated and complex and interact nonlinearly with each other on various time–space scales.

Moreover, environmental sciences are not usually provided with real laboratories where theories can be tested against experiments, since phenomena often take place only once and cannot be reproduced. Theories can often be tested only against observational data from the past, which may feature problems of various degrees of criticality, essentially because of the physical extension of the systems under analysis. In many cases, the available observations feature a relatively low degree of reciprocal synchronic coherence and individually present problems of diachronic coherence, due to changes in the strategies of data

gathering with time. The presence of strong variability of both the outputs of theoretical models and of the real systems contributes to blur the line between a failed and a passed test, in terms of model reliability.

It is important to emphasize that the theoretical models unavoidably suffer from two distinct kinds of uncertainties. The uncertainties in the initial conditions of the systems, termed "uncertainties of the first kind," are problematic because of the effects of chaos. These uncertainties may be partially dealt with using well-suited Monte Carlo approaches on the initial conditions.

The "uncertainties of the second kind" are structural uncertainties, due to the simplifications adopted in the models for the description of the processes and of the feedbacks characterizing the system under

investigation. These latter uncertainties seem to be somehow more fundamental – the dynamic framework is uncertain – and harder to deal with.

Therefore, it is conceptually incorrect to expect that the essentially phenomenological theories which have been developed for the environmental sciences could provide answers having comparable precision and similar structure to those provided by theories relevant for the study of systems having lower degree of complexity.

In view of the above difficulties, it is not surprising that the historical development of "environmental science" took place essentially along two different main paths: on the one side the descriptive, basically qualitative, approach of naturalistic tradition, and on the other the, quantitative formulation of physical–mathematical tradition. Linneo's classification of living beings and Laplace tidal equations are classical examples. The synthesis between the two approaches took place in the nineteenth and twentieth centuries mostly through applications of fluid dynamics and/or thermodynamics to specific systems. However, a certain separation (sometimes even contradiction) between the two approaches occasionally still emerges today. Meteorological maps, interpreted on the basis of the analogies of the so-called "synoptic" meteorology, are examples of the modern evolution in the descriptive tradition, while numerical weather forecasting exemplifies the quantitative one.

The description of the macroscopic dynamics of environmental systems is based on the systematic use of dominant "balances" derived on a phenomenological basis in order to specialize the dynamical equations. Such balances are suitable classes of approximate solutions of the evolution equations which represent a reasonably good approximation to the actual observed fields when sufficiently large spatial or temporal averages are considered. Actually, different balances have to be considered depending on the time and space scales that are being focused on. Such an approach reflects the fundamentally heuristic-inductive nature of the scientific research in environmental sciences, where the traditional reductionistic scientific attitude is not always effective. In order to exemplify this procedure, the very relevant case of the motion of the fluids that permit the existence of life on Earth, air and water: the so-called geophysical fluids is considered.

Geophysical Fluids and Phenomenological Balances

Geophysical fluid systems are very complex in microphysical structure and composition and evolve under the action of macroscopic driving (solar heating) and modulating (Earth's rotation and gravitation) agents. The complexity essentially depends on the presence of nonlinear interactions and feedbacks between the various parts of the system, which couple very different time and space scales. In many cases, the dynamics of such systems is chaotic (the self-correlation of the fields vanishes within a finite time domain) and is characterized by a large natural variability on different timescales.

The dynamics of a geophysical fluid for an observer in a uniformly rotating frame of reference is described by the Navier–Stokes equation:

$$\rho\frac{\mathrm{d}u}{\mathrm{d}t} + 2\rho\Omega \times \boldsymbol{u} = -\boldsymbol{\nabla}p - \rho\nabla\Phi + F \qquad [1]$$

where ρ is the density of the fluid, $\boldsymbol{u} = (u, v, w)$ is the velocity vector, Ω is the Earth's rotation vector, p is the pressure, Φ is the geopotential (essentially coincident with the gravitational potential), F is the frictional force per unit mass, and the total derivative is expressed as

$$\frac{\mathrm{d}}{\mathrm{d}t} \equiv \frac{\partial}{\partial t} + \boldsymbol{u} \cdot \boldsymbol{\nabla} \qquad [2]$$

thus including the nonlinear advection term.

Through the use of suitable approximations, the equations of motion can be focused upon the desired components of the flow. The filtering process is the introduction of a set of mathematical approximations into the Navier–Stokes equation having the scope of filtering out (excluding) solutions corresponding to the physical processes that are heuristically assumed to contribute only negligibly to the dynamics of the system at the time and space scale under examination. The magnitudes of various terms in the governing equations for a particular type of motion are estimated using the so-called scale analysis technique.

Hydrostatic Balance

As a relevant example of these procedures, the "hydrostatic approximation" is considered here. In a local Cartesian coordinate system where z is perpendicular to the surface, an obvious fixed point (stationary solution) of the Navier–Stokes equation can be derived from the time-independent classical "hydrostatic equilibrium" equations:

$$\begin{aligned} \boldsymbol{u} &= (0, 0, 0) \\ -\rho_{\mathrm{h}} g - \frac{\partial p_{\mathrm{h}}}{\partial z} &= 0 \end{aligned} \qquad [3]$$

where the functions $\rho_{\mathrm{h}}(x, y, z, t)$ and $p_{\mathrm{h}}(x, y, z, t)$ satisfying the above balance (the subscript h stands for "hydrostatic") depend only on the spatial variable z.

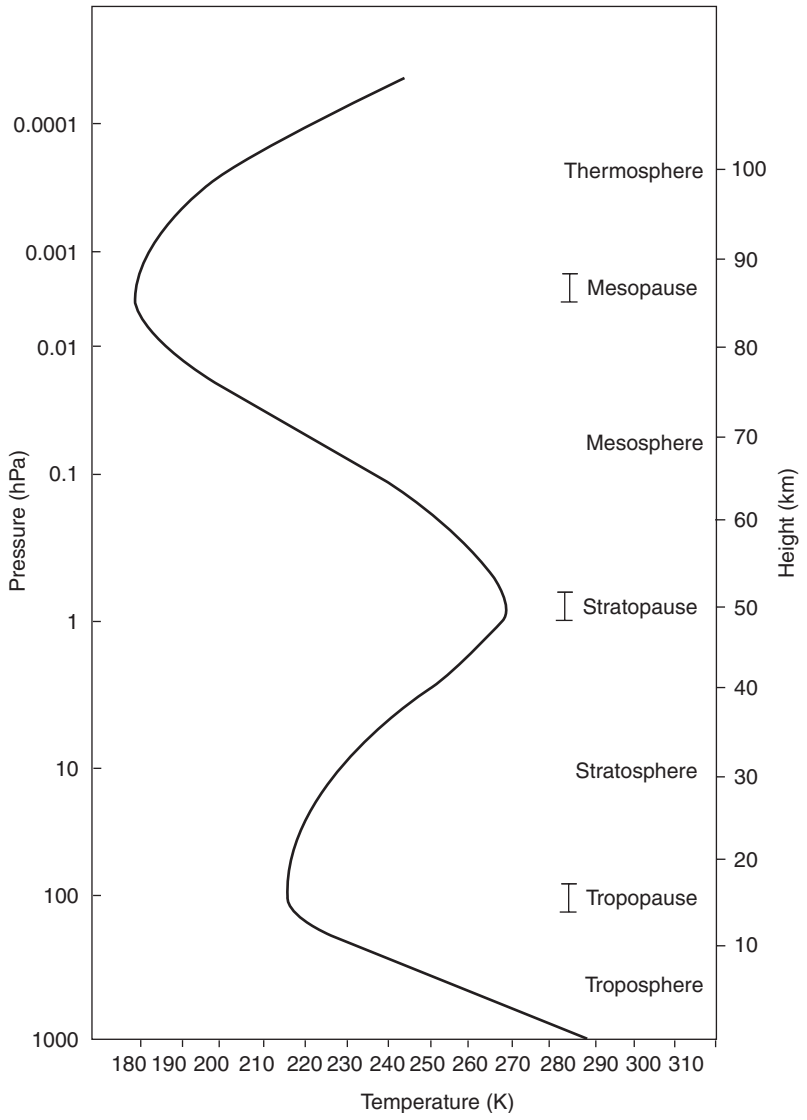

Figure 3 Typical temperature vertical profile of the atmosphere. The main sections of the atmosphere are indicated and the small extent of the quasi-constant temperature sections is emphasized.

Three points related to the above-described balance are worth mentioning explicitly:

1. the fluid velocity is assumed negligible everywhere in the system;
2. the condition of hydrostatic equilibrium does not determine univocally the thermodynamic fields $\rho_h(z)$ and $p_h(z)$ but only their relationship; other information are requested in order to determine univocally the profiles of density, pressure, and temperature; and
3. the balance is observable (and practically useful!) only if it is stable.

Now, the interesting point is that quite different geophysical flows (atmosphere, ocean, surface, and ground water) can be represented as being in near hydrostatic equilibrium when suitable spatial and temporal averaging process is considered (**Figure 3**).

In general terms, hydrostatic equilibrium is realized when the portions of a fluid with lower specific entropy are positioned below those with higher specific entropy, where directions are defined by the local gravity force vector. When this condition is broken because of an external forcing, the stratification is not stable and the fluid rearranges so that hydrostatic condition is re-established. Therefore, violations of hydrostatic equilibrium exist only on short time and space scales and often are not easily observable. Typical models are formulated in such a way that local nonhydrostatic conditions are quickly eliminated and the equilibrium condition that is

recovered is parametrized in terms of variables explicitly represented on the numerical grids. In a later section, the general scope of the parametrization procedures is briefly described.

As a matter of fact, nonhydrostatic models are nowadays available and are currently used. However, for any practical purpose, sufficiently detailed initial and boundary conditions are not available and the above-expressed methodological problems reappear in connection with their definition.

Geostrophic Balance

Another instructive example is that of time-independent purely horizontal balanced flows where the horizontal components of the pressure gradient force and the Coriolis force cancel out in the Navier–Stokes equation. Such flows are termed geostrophic, which, etymologically, means Earth-turning. The structure parameter determining qualitatively the goodness of such approximation is the Rossby number $Ro = U/f_0L$, where U is a characteristic horizontal velocity of the fluid, L is a characteristic horizontal extension of the fluid, and f_0 is twice the value of the projection of Earth angular velocity vector on the plane tangent to the surface of the Earth at the considered latitude. This approximation holds for relatively large-scale extratropical flows in the regions where friction is not important – that is, away from the boundaries of the fluid. Geostrophic equations are obtained as a zeroth-order Ro expansion of the Navier–Stokes equation. The fluid motion is introduced by considering small perturbations breaking the translation symmetry of the baseline purely hydrostatic density and pressure fields. This is achieved by assuming that the actual density and pressure fields are given by $\rho(x,y,z) = \rho_g(x,y,z) + \rho_h(z)$ and $p(x,y,z) = p_g(x,y,z) + p_h(z)$, respectively. Geostrophic equations thus result to be the following:

$$\begin{aligned} \rho_h u f_0 &= -\frac{\partial p_g}{\partial y} \\ \rho_h v f_0 &= -\frac{\partial p_g}{\partial y} \\ g\rho_g &= -\frac{\partial p_g}{\partial z} \end{aligned} \qquad [4]$$

Geostrophic and hydrostatic balance constrain atmospheric motions so that the fluid flows are uniquely determined by the pressure field, since the currents are parallel (rather than perpendicular as in nonrotating fluids) to the isobars at a given geopotential height (**Figure 4**). The time-independent nature of these equations implies that the nongeostrophic terms, although relatively small, are important for the time evolution of the flow.

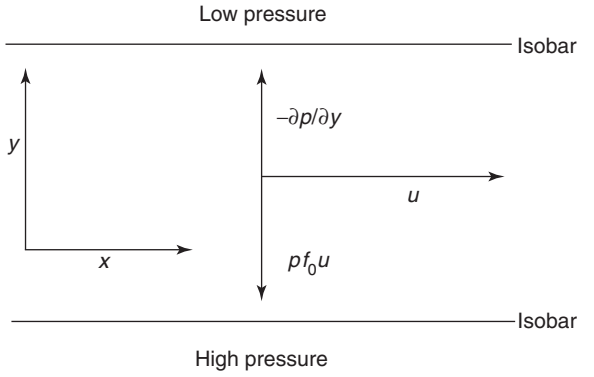

Figure 4 Geostrophic balanced flow; pressure gradient force (upper arrow), and Coriolis force (lower arrow) cancel out and the flow (horizontal arrow) is parallel to the isobars.

A system or flow that evolves slowly in time compared to $1/f_0$ can be described using the so-called "quasi-geostrophic" theory. This is a perturbative theory obtained as a first-order Ro filtering of the Navier–Stokes equation and analyzes departures from geostrophic balance. The quasi-geostrophic approximation is used in the analysis of extratropical systems, in which currents can be closely approximated by their geostrophic values. The use of the quasi-geostrophic approximation effectively filters out solutions corresponding to high-speed atmospheric gravity waves. This approximation is not accurate in situations in which non-geostrophic currents play an important advective role, for example, around the frontal discontinuities. Although modern computers allow a fully nongeostrophic description of most geophysical fluids, quasi-geostrophic approximation remains a fundamental tool of theoretical research and is used for practical applications in everyday life: every time we read an atmospheric isobaric map in terms of wind flowing along the isobars we are, in fact, using the notion of geostrophic balance.

Applications of Geophysical Fluid Dynamics: Weather and Climate

Given the nature and the impact on human society of their research, environmental scientists have had access to powerful computers since the early days of numerical computing. Actually, in the late 1940s, the first large-scale application of automatic computing consisted in the first numerical weather forecast, based on greatly simplified equations, which was proposed by Von Neumann and mainly devised by Charney. Since the late 1950s, the US technical services have been using computer-assisted numerical integration of relatively accurate equations descriptive of the physics of the atmosphere to routinely produce publicly available weather forecasts.

Numerical models of geophysical fluids are usually divided into limited area and global models, the fundamental difference being that the former require lateral boundary conditions (at the boundaries of the integration domain) that have to be continuously provided by either observations or, more typically, larger-scale models, while the latter essentially perform quasi-autonomous integrations – obviously, still there is external forcing. In geophysical fluids model, the three-dimensional fields are discretized on a lattice, and the temporal evolution is discretized through the adoption of a time-step. The adoption of a finite spatial and temporal resolution implies that the physical processes occurring on a space and/or timescale smaller than the actual resolution of the model can be taken care of only with approximate parametrizations relating such processes to coarser grain information. The parametrization of the so-called subgrid processes is usually heuristic and devised *ad hoc* by statistical interpretation of observed or model-generated data.

Numerical modeling options strongly rely on the available computer power, so that the continuous improvements in both software and hardware have permitted a large increase in the performances of the models and at the same time an impressive widening of their horizons. On one side, the adoption of finer and finer resolutions has allowed a more detailed description of the large-scale features of the dynamics, and, more critically, a more direct physical description of a larger set of processes, thus limiting the need for parametrization procedures, which, where needed, have become more accurate. On the other side, it has been possible to implement and then refine the coupling between models pertaining to different systems having a common boundary, such as the atmosphere and the ocean. The main purpose of such procedure is to study in detail the time–space scales of the interactions between the different systems and reframe such interactions in the more intrinsic terms of internal feedbacks of the compounded system.

Today, computer simulations probably constitute the best laboratory instruments for environmental scientists, since on one side permit the testing of theories, at least in the previously exposed weak sense, and on the other side provide stimulations for formulating new hypotheses. It is notable that the present most powerful computer has been engineered in order to simulate geophysical fluid dynamics with the particular scope of providing the most detailed simulation of the present and past climate.

When considering complex systems like those investigated by the environmental sciences, there is a clear distinction between providing efficient descriptions of the local and of the global properties in the phase space of the system. The local properties of the phase space are addressed by considering dynamic equations able to represent the short-time deterministic evolution of the system. The study of the global properties of the phase space entails considering dynamic equations whose goal is to represent the statistical properties of the system. The efficient description of such properties requires very long integrations of the equations. In order to clarify these very distinct – albeit intersecting – perspectives, the problems of weather forecast and of climate simulation are specifically discussed.

Weather Forecast

The task of weather forecast is to provide the best description of the short-time evolution of the relevant fields descriptive of the state of the atmosphere – wind, temperature, pressure, humidity, and precipitation – as represented on a 3D lattice. Weather forecast is addressed to describing and predicting the instantaneous values of the main atmospheric variables. Weather forecast models use in the equations quite a number of *ad hoc* assumptions and parametrizations that have empirically proved their reliability for that purpose. Since the aim of these models is to be as precise as possible in the local sense, they do not necessarily need to obey global constraints, for example, energy conservation, which are obviously fundamental in terms of physics, but not necessarily relevant when a small neighborhood of the phase space is considered.

The time range of such forecasts extends up to the deterministic predictability horizon of the atmosphere, which can be estimated in $\sim$7–10 days. It is important to emphasize that the actual spread of the model predictions can be estimated by using Monte Carlo techniques on the initial state of the system. Such an approach is termed "ensemble forecasting" and relies on sampling the phase space of a system by integrating forward in time a set of initial conditions. The initial conditions are suitably selected in order to represent the unavoidable uncertainty on the initial state of the system (**Figure 5**).

Climate Simulation

The climate consists of a set of statistical properties – in the time and/or space domains – of quantities that describe the structure and behavior of the various parts of the climatic system. The goal of climate modeling is to represent such statistical properties, thus aiming at a precise picture of the main properties of the phase space attractor of the system (**Figure 6**). In the case of past or present climate change studies, models try to assess how such statistical properties change with time. In the case of climate

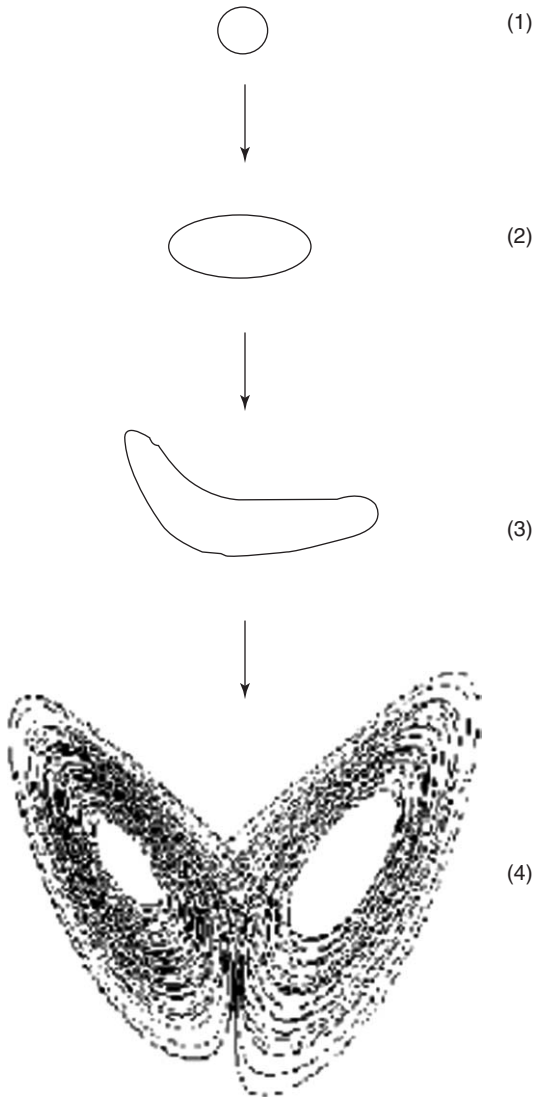

Figure 5 Scheme of the loss of predictability for ensemble forecasting. The initial Gaussian distribution of the ensemble (1) is distorted (2), and then loses its Gaussian shape (3), eventually the ensemble points populate the attractor of the system (4).

modeling, the relevant uncertainties are not related to the initial conditions of the system but rather to the very structure of the model. Since *ab initio* formulations based on first principles are not possible and since anyway the relatively coarse-grain discretization is being used (the best available models have average resolutions of 100 km in the horizontal and 200 m in the vertical directions), the presence of structural uncertainties, which are equivalent to uncertainties in the attractor's shape, is unavoidable.

A critical point in climate modeling is that, depending on the timescale of interest and on the problem under investigation, the relevant active degrees of freedom, which need the most careful modelization, change dramatically. For relatively short timescales (1–100 years) the atmospheric degrees of freedom are active while the other subsystems can be considered essentially frozen. For longer timescales (100–1000 years) the ocean dominates the dynamics of climate, while for even longer timescales (1000–10 000 years) the ice sheet changes are the most relevant factors of variability. Therefore, the very structure of climate models is gauged with respect to the purpose of the specific study and, depending on this, the models may be formulated in totally different ways.

Lately, a relevant strategy, which may be termed "statistical ensemble forecasting," has been proposed for dealing with the delicate issue of structural uncertainties, especially in the context of the study of the future projections of climate change, even if in principle this is not its only application. The main idea is to consider a climate model and apply Monte Carlo techniques not only on the initial conditions, but also on the value of some key uncertain parameters characterizing the climate machine. The resulting statistics (and change of the statistics) is expressed as a set of probability distributions rather than as a set of values.

Statistical Inference

Another prominent approach to the problem of providing an efficient description of the main properties of the environmental systems consists in trying to infer information directly from observations. Such an approach constitutes a natural and necessary complement to the theoretical and model-based analyses, which unavoidably suffer from the above-discussed uncertainties. A classical way of gathering information on the investigated system from the actual measurements consists in applying techniques that fall into the wide chapter of statistical inference. Environmental science is rich in such applications, some of which are quite well known to a wide public. In the last two decades, the outstanding example is that of global warming. In statistical terms, the problem consists in trying to detect signs of anthropogenic changes (expressed in terms of trends) of local as well as global measures of relevant climatic variables. In particular, the average global surface temperature is – somewhat anthropocentrically – usually considered as the variable descriptive of such change. The general problem is quite abundantly documented in the reports of the International Panel on Climate Change (IPCC).

What is the concrete appearance of surface temperature time-series? The presence of variability on a vast range of timescales, or, in other terms, of a rather composite spectrum, implies that suitable filtering

Figure 6 Evolution of the complexity of climate models in terms of representation of the main processes; the red lines indicate the integration of specific models into climate models. (Reproduced with permission from IPCC (2001) *Climate Change 2001: The Scientific Basis*, Contribution of Working Group I to the 3rd Assessment Report of the IPCC. Cambridge: Cambridge University Press.)

procedures are needed in order to detect changes with time of the signal. An example of how statistical inference can be applied to characterize the climatology of a system is discussed below.

Figure 7 shows the 1951–2000 daily maximum temperature records for two synthetic stations representative of northern and southern Italy. These data have been obtained after a suitable homogenization process of few dozens of real meteorological stations in each of the two parts of Italy. Apart from the signature of the seasonal cycle, the signal features an evident noisy structure. When the higher-frequency components are removed and the inter-annual components only are retained, one may observe an increasing trend for both records, which is consistent with the large-scale picture for the last 50 years. The observed warming trend can be proved to be statistically significant. But, instead of focusing on the long-term changes in the value of the signal, we are often interested in detecting changes in the properties of the seasonal cycle, defined in terms of phase and amplitude of the $(1\,\text{year})^{-1}$ component of the spectrum. Such a problem may be approached by providing a time-dependent estimate of the spectrum, obtained with a "shifting window" Fourier analysis, and then performing a statistical analysis of the various estimates of the locally defined (in time) seasonal signal.

In the case of the records shown in **Figure 7**, the amplitude and the phase of the signal, albeit characterized by a relatively large variability, do not have statistically significant trends. In **Figure 8**, the results for the amplitude of the signal are provided: the linear trend does not have a statistically well-defined sign for both records. Similar situation occurs for the phase of the signals. From these results, one can infer that the seasonal cycle has not undergone relevant long-term changes. Apart from the analysis of the variability of the signals under examination, one can infer from the average properties some basic climatic differences between the two systems, which in this case are defined in terms of geography only. First, quite trivially, northern Italy is colder, since its average temperature is notably lower (**Figure 7**). This is mostly due to latitudinal effects. Second, northern Italy has a more continental climate, since its seasonal

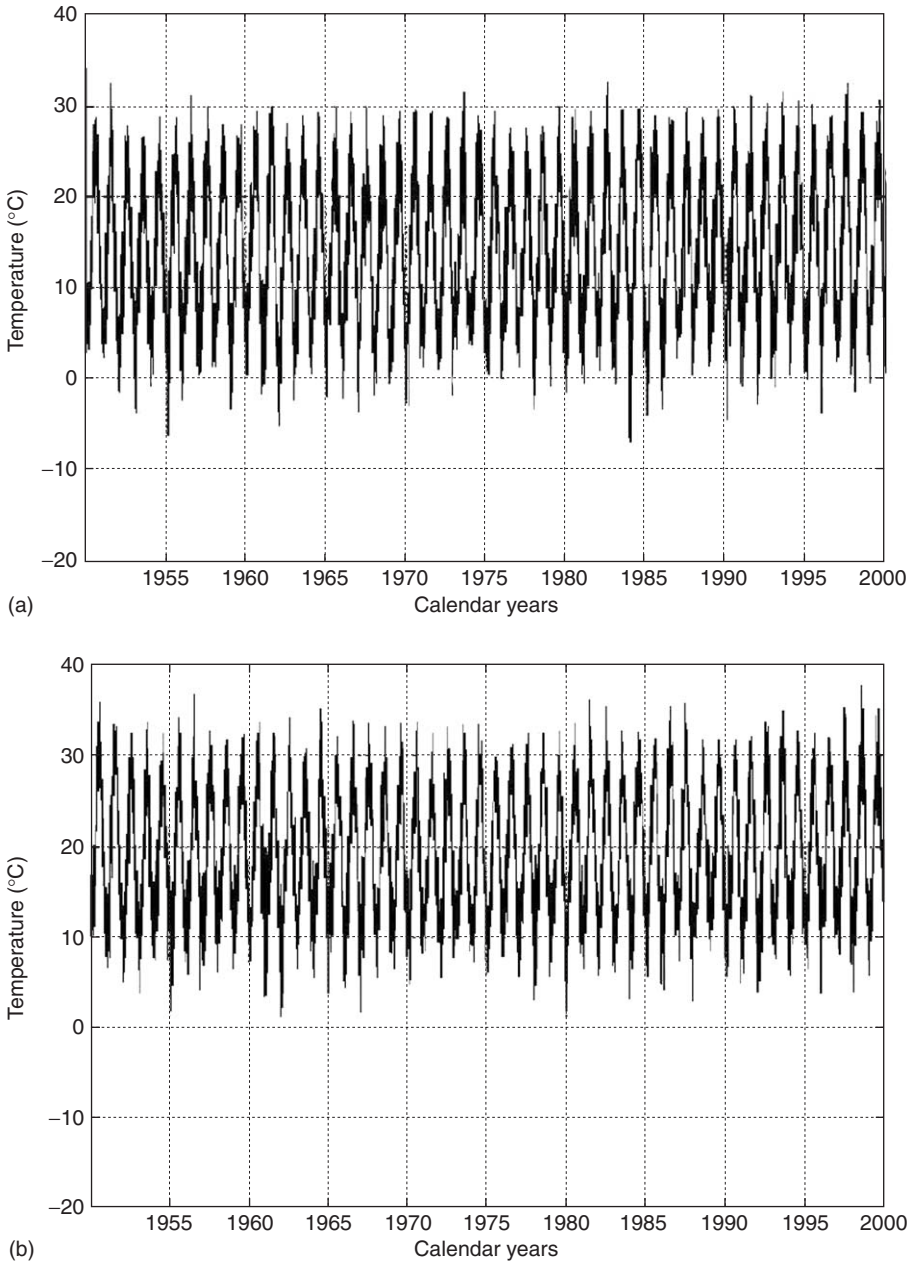

Figure 7 Daily records (1951–2000) of maximum temperature for northern (a) and southern (b) Italy. The signature of the seasonal cycle is evident.

cycle has larger average amplitude (**Figure 8**). As a first approximation, one can interpret this property as an effect of the smaller effectiveness of the air–sea thermal exchanges in smoothing out the effect of the annual changes in the intensity of the incoming solar radiation.

Diagnostics

Another relevant area of matching between quantitative and qualitative approaches to the study of environmental systems is that of diagnostics of the complex space–time structure of fields based on indicators derived from measure theory. It is well known that, for example, the definition of the structure of precipitation, land cover, etc., can be given in terms of estimators of the fractal measure derived from observations. In fact, the very concept of "fractal dimension" has been elaborated also in the effort of measuring territorial systems, with the classical example given by Mandelbrot for the evaluation of the length of the southern coast of England.

Consider standard precipitation, which is defined as the quantity of atmospheric water reaching the

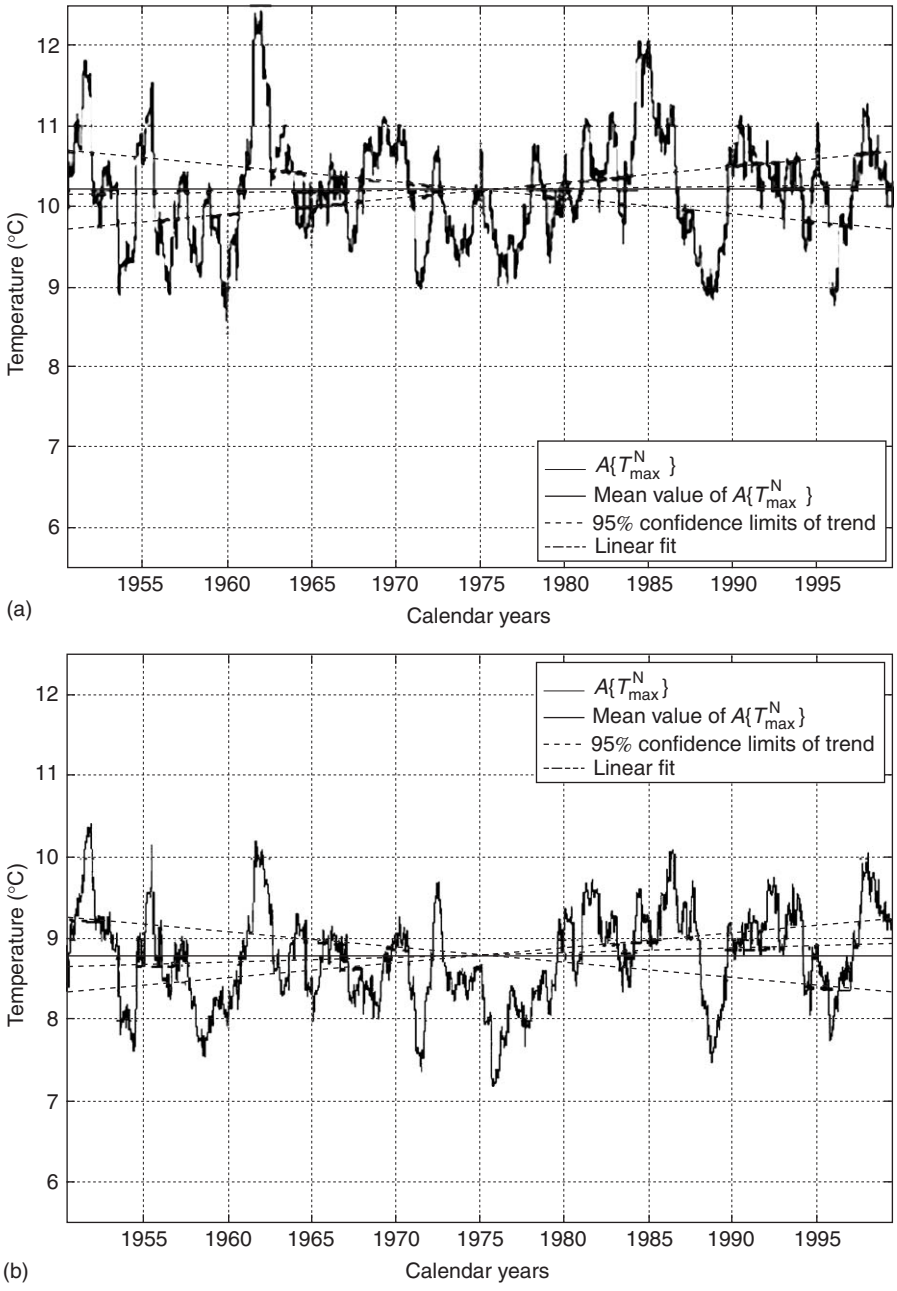

Figure 8 Amplitude of the seasonal signal $A\{T^{N/S}_{max}\}$ for the maximum temperature of northern (a) and southern (b) Italy. No statistically significant trend can be detected in either case.

Earth's surface in unit time. Such a quantity is the final result of an extremely long and complex chain of events, virtually covering all the space scales, from molecular water to the global scale of cyclonic areas, and the timescales from the fractions of second of enucleation to the lifetime of weather perturbations (days). Of course, other modulations exist at longer timescales (like the seasonal oscillation), but these are to be considered variation of external forcing rather than part of the precipitation process in itself. Therefore, any series of precipitation observations shows structure virtually at all scales. One way of measuring such structure is to make use of the so-called "box counting," which is very instructive since it makes reference to a basic definition of dimension in terms of the statistics of occupation of the considered parameter space. When investigating the statistical properties of homogeneous, stationary, and isotropic rainfall, a more appropriate definition of structure functions can be given through the moments of the integral measures of precipitation. Consider a positive random field $P(x)$, $P(x) > 0$, defined in

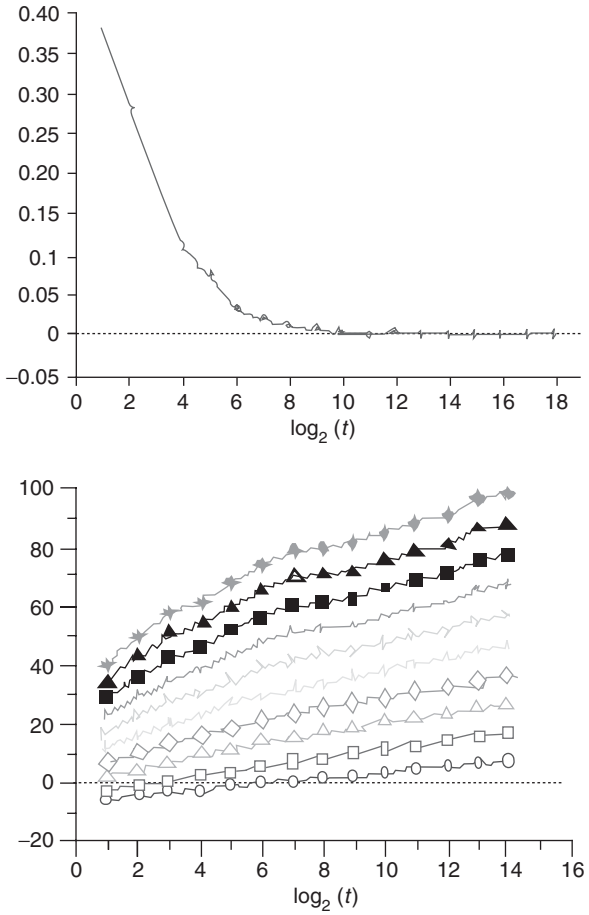

Figure 9 Time-structure of the precipitation at a rain gauge in the area of Rome (1 min interval of sampling from 1992 to 1998). Autocorrelation (top); and sequence of moments in increasing order from bottom up (bottom). The timescale in abscissa is in powers of 2 min. Ordinates are expressed in nondimensional units.

the set $x \in [0, L]$. Without loss of generality, $P(x)$ is normalized to 1, that is,

$$\int_0^L P(y)\, \mathrm{d}y = 1 \qquad [5]$$

for any realization. Our primary interest is to discuss the scaling properties of the structure function:

$$\int_x^{x+r} P(y)\, \mathrm{d}y \equiv \mu_x(r) \qquad [6]$$

$P(x)$ is said to display anomalous scaling properties if

$$\langle [\mu_x(r)]^q \rangle \sim r^{\xi(q)} \qquad [7]$$

where $\xi(q)$ is a nonlinear function of q. The scaling exponents $\xi(q)$ are also referred to as multifractal exponents of $P(x)$. The random field is assumed to be ergodic, so that in the previous equation $\langle\ \rangle$ stands both for x-average (x being either a space or time coordinate) and ensemble average. It follows that one must require also stationarity and homogeneity. Furthermore, if the field is embedded in a space of dimension $d > 1$, the field is also assumed to be isotropic, that is, the scaling properties depend only on the modulus of r.

In **Figure 9**, some statistical results for the precipitation in Rome are presented. It is learnt from correlation (the station of Rome is quite typical in this respect) that precipitation is characterized by a limited (with respect to other atmospheric variables like, for example, the surface temperature considered above) autocorrelation. The scale of decay of correlation is of the order of hours. A simple fractal structure would be represented in the logarithmic diagram of moments by a straight line. Apart from modulations due to sampling, it is seen that the higher moments show exponent dependence on scale and, therefore, indicate a multifractal distribution. The meaning of the inflection $\sim 2^8$ min (~ 4 h) is that organized dynamical processes (like the formation of rain bands) are operating at larger timescales, while the incoherent, micrometeorological processes dominate at smaller scales. This kind of analysis can be performed also in space (although this requires an extensive observational coverage that is rarely available) and produces similar results. Other statistical approaches are possible, in particular for what concerns the parametric distributions that are used in order to represent the above shown type of behavior. As seen earlier, such an analysis can identify statistical features revealing aspects of the structure and the dynamics of the systems in question. Another use is for operations of upscaling and downscaling the observed fields.

Epitaxy

L Miglio and A Sassella, Università degli Studi di Milano – Bicocca, Milan, Italy

Introduction

Epitaxy is the growth of a crystalline film suitably oriented onto a substrate: the first advantage in pursuing such a condition is to force the crystal in exposing free surfaces, which are not naturally obtained by cleavage or by conventional bulk growth. Moreover, the structural and compositional quality obtained by recent epitaxial growth techniques is better than the one obtained in the bulk: this quality can be controlled by very sensitive and precise methods, which are particularly suited for thin films. Easy and spatially resolved doping, along with monolithic integration on silicon wafers, have fostered this technique for microelectronic applications. Moreover, the stacking of different semiconductors in quantum wells and superlattices with sharp interfaces is a building block of modern optoelectronics. Finally, the strain control obtained by governing the lattice mismatch between the substrate and the film allows for intriguing modifications of the relevant physical properties in the latter, which in turn can be used to tailor device performances. Due to these exciting and recent applications, the focus here is on epitaxial semiconductors, both inorganic and organic, the latter ones being a rapidly growing field, which contains interesting basic issues and promising device developments. Epitaxial structures by metallic materials have been historically and conceptually important, particularly relevant for microstructural applications, for example, the elastic stiffening in superlattices produced by the long debated supermodulus effect, and for magnetic applications, more recently, in the field of spintronics. Still, for the sake of synthesis, a satisfactory review of this domain cannot be included, and the interested reader is referred to the "Further reading" section.

What is an Epitaxial Structure?

The concept of epitaxy was introduced by the mineralogist L Royer in 1928 to describe the growth of crystalline nuclei on various solid substrates. Since then, it has been widely extended to any case when some crystallographic relationship holds between a film and its substrate. A general definition of epitaxy comes from the Greek origin of the term itself, composed of the prefix 'επί (= on, over, above) and the word τάξις (= ordered arrangement), so that one can propose: EPITAXY – ordered growth of a crystalline or, at least, highly oriented material over another one, acting as substrate.

Epitaxy is therefore a fairly general concept, indicating rather different relationships between the substrate and the film, depending on their structural features and on the strength of their interactions, as is seen in the organic case. In particular, the surface unit vectors of the substrate, $a_{1\mathrm{sub}}$ and $a_{2\mathrm{sub}}$, are to be compared to the ones of the film, $a_{1\mathrm{film}}$ and $a_{2\mathrm{film}}$. When the lattice constants match, that is, $a_{\mathrm{sub}} = a_{\mathrm{film}}$, the interface is coherent; when a relation such as $ma_{\mathrm{sub}} = na_{\mathrm{film}}$ exists, with m and n integers (and the lengths ma_{sub} and na_{film} not too long on the lattice length scale), the interface is commensurate; otherwise it is incommensurate, although some weaker relationship, typically an orientational one, may hold, especially when the intralayer or molecular interactions are stronger than substrate-layer interactions. In the case of incommensurability, real epitaxial growth and perfect matching can still be obtained upon deformation of the film structure. Indeed, for sufficiently thin layers and for moderate deformations, well within the linear elastic regime (i.e., some percentage of the lattice parameter), the incommensurate film can be fully accommodated on the substrate. To this end, an important parameter is the geometric misfit f, expressing (usually in percentage) the amount of mismatch between the two structures, along one surface vector or the other one:

$$f = |a_{\mathrm{film}} - a_{\mathrm{sub}}|/a_{\mathrm{sub}} \qquad [1]$$

When a film is epitaxially grown on a substrate, crystallographic information on the former is usually expressed in terms of the ones of the latter following the notation introduced by E A Wood. An example can be α-Fe on GaAs (1 1 0), $1 \times 1/2$, where the indication of the substrate plane, (1 1 0), is followed by the expression $j \times k$, representing the number of unit vectors of the substrate plane, j along one direction and k along the other one, needed for matching the ones of the overlayer. In case the unit vectors of the film are not aligned with respect to the ones of the substrate, the rotation by XX° necessary to obtain alignment is indicated at the end by R XX°. Simple examples of (2×1) and $(\sqrt{2} \times 2\sqrt{2})$ R45° interfaces between substrate and epitaxial film are illustrated in **Figure 1**.

Homoepitaxy, Heteroepitaxy, van der Waals Epitaxy, and Quasi-Epitaxy

The increase of a solid by addition of new atoms or molecules of the same material on top of its surface is

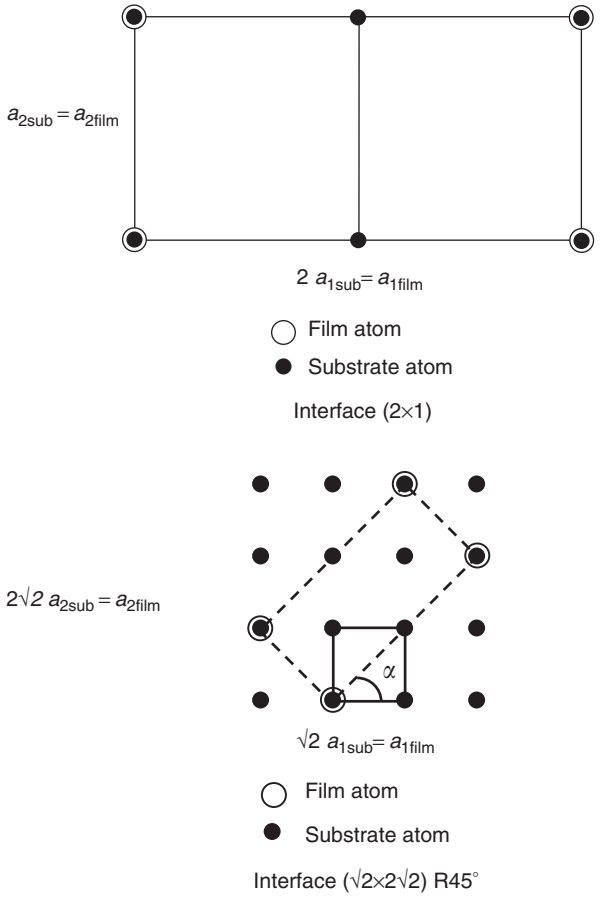

Figure 1 Examples of epitaxial relations between the film and the substrate: (2×1) and $(\sqrt{2} \times 2\sqrt{2})$ R45°.

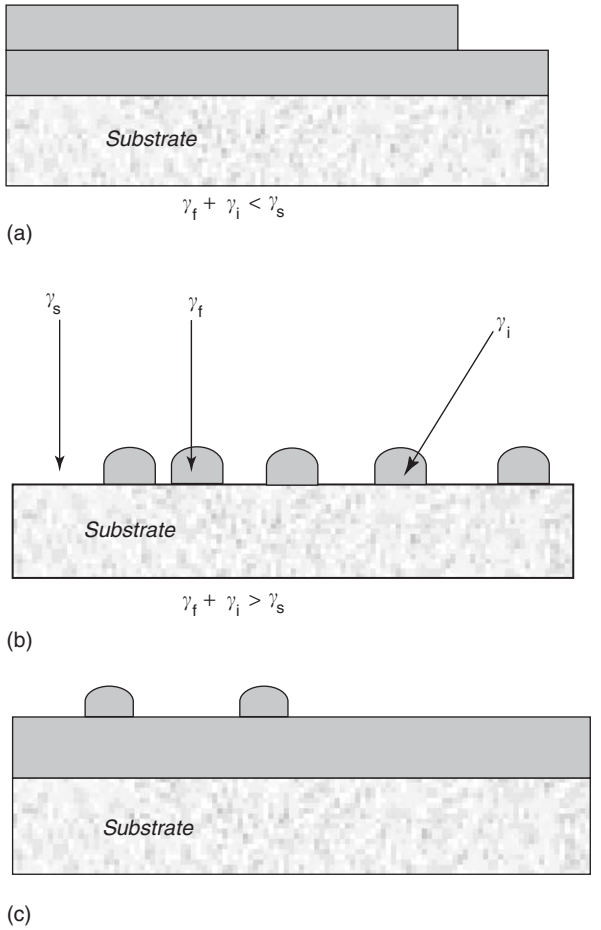

Figure 2 Different growth modes: (a) Frank–van der Merwe, (b) Volmer–Weber, and (c) Stranski–Krastanov; γ_f, γ_s, and γ_i are the free energies of the film surface, the substrate surface, and the film/substrate interface, respectively.

called "homoepitaxy" or "isoepitaxy" ('όμοιος = same, 'ι΄σος = equal). Although the process does not seem to need a particular attention, being in principle close to the usual growth of a bulk crystal, homoepitaxy is very important, since it is a fully controlled process, leading to structurally perfect and chemically clean surface layers. The most important example of homoepitaxy comes from silicon technology, where the (0 0 1)-oriented wafers are usually refined by an epitaxial Si deposition, whose quality is superior to that of the original substrate surface. In addition, such homoepitaxial layers can be properly doped for particular applications, independently of the substrate doping.

When the oriented or single-crystalline growth of a layer occurs on a substrate of a different material, "heteroepitaxy" is considered ('έτερος = different); in the case of a liquid substrate, one has rheotaxy. Heteroepitaxy is widely employed in semiconductor technology, where, through the choice of proper materials and alloys, artificial structures, such as quantum wells and superlattices, can be grown with precisely tuned properties. The first criterion proposed for a prediction of heteroepitaxial growth was the structural one, requiring a small misfit value. In the general case, however, this is not essential, since heteroepitaxial interfaces between materials with large misfit, even exceeding 15%, can also be grown and have actually been reported. In this respect, more complete theories identify the nucleation of crystalline islands, two- or three-dimensional (2D or 3D), as the essential process driving epitaxy, so that the balance between the surface and the volume contributions is critical, as usual. Heteroepitaxial films can indeed grow in the following three modes, schematically illustrated in **Figure 2**. The Frank–van der Merwe (FM), or layer-by-layer mode, which leads to smooth surfaces, is rather rare (classical examples are rare gases on graphite, incommensurate, and GaAs on Ge, forming a coherent interface). It is characterized by the fact that each monolayer starts growing by 2D islands, after the previous one is completed. FM growth is favored when the misfit is very low and when the surface free energy of the film is lower than

the sum of the one of the substrate and of the interface free energy (full wettability), $\gamma_s > \gamma_f + \gamma_i$. The Volmer–Weber (VW), or island mode is the opposite one, which leads to the formation of 3D islands nucleating over the substrate surface. In terms of surface free energy, VW mode occurs when $\gamma_s < \gamma_f + \gamma_i$, that is, when the surface energy of the film is larger than the ones of the substrate and interface, as it is frequently the case when the elastic energy produced by a sizeable misfit is included in γ_f. An intermediate situation is called Stranski–Krastanov (SK), or layer-plus-island mode, and it is characterized by the layer-by-layer growth of a few monolayers (the so-called wetting layer), followed by the nucleation of 3D crystalline islands on top of them. This process is the most frequent one: it is produced by an increasing unbalance with thickness between the tendency to wet the substrate surface and the accumulation of elastic energy by misfit in the film.

Another type of heteroepitaxy, named van der Waals (vdW) epitaxy, was recently suggested by the successful growth of organic thin films on inorganic substrates, occurring when the film and substrate interact only through van der Waals forces. The organic molecules are just physisorbed on the substrate surface, without forming strong chemical bonds, as in the case of inorganic films: the prototypical example is the growth of phtalocyanines on alkali halides. This type of epitaxy holds also when, strictly speaking, a huge misfit (above 100%) exists, since the lattice parameters for common organic crystals are easily larger than 10–20 Å. In this case, the lattice parameters of the organic material may be perfectly matched with a (very large) multiple of the ones of the inorganic substrate, so that commensurability and proper epitaxy is recovered. When the growth of an organic material on an organic substrate is concerned, a small misfit may be expected and heteroepitaxy occurs similarly as for the inorganic case, still at larger lattice parameters.

Finally, in the case of the weakest interaction, a sort of vdW epitaxy may hold between incommensurate structures, and the term quasi-epitaxy (or orientational epitaxy) is used. In such a situation, azimuthal order has to be attained at least, originating from a well-defined orientational relationship between the crystalline structure of the organic film and the substrate. Since the organic structures are usually fairly deformable, quasi-epitaxy may also lead to the growth of a strained organic film, which closely resembles a vdW epitaxial layer (indeed, quasi-epitaxy is also called strained vdW-epitaxy).

Organic films usually grow as crystalline 3D islands, whose size strongly depends on the substrate and growth conditions. Some cases of FM growth mode have also been reported, for example, pentacene on silicon. Among organic materials, polymers can also grow epitaxially, but this is often limited by the difficulty in setting proper crystallographic interactions between the substrate, either inorganic or organic, and the polymer film: quasi-epitaxy occurs in most of these cases. It is, nonetheless, a very interesting phenomenon, since it provides a tailored change of the physical properties: for example, it improves the adhesion of the two materials.

Analysis of the Epitaxial Film

The epitaxial growth process can be monitored *in situ* by reflection high energy electron diffraction (RHEED), which is sensitive to the roughness of the surface and, in turn, to the crystallographic completion of the surface layer. Another *in situ* technique which is able to identify the growth mode in heteroepitaxy is the Auger electron spectroscopy (AES) by a progressive monitoring of the peak intensity for the substrate and the film. For organic films, electron diffraction techniques can be destructive, so that they can be used in test samples, which permit the process tuning for further depositions. Optical monitoring, for example, by ellipsometry or by reflectance anisotropy spectroscopy (RAS) is usually to be preferred in such cases, even if the interpretation of the results is not straightforward and needs some modeling.

Assessing the quality of an epitaxial film, mostly *ex situ*, is an important branch of applied physics: as it happens for bulk materials, the analysis can be divided into structural (i.e., crystallographic) issues, microstructural (i.e., defect-related) features, and morphologic aspects of the surface, which are particularly relevant in a thin film. The first one deals with the crystal phase obtained during the growth, which may not be the one corresponding to the bulk phase (see next section). Moreover, the determination of the surface orientation and of the surface reconstruction, along with possible domain patterns, is a routine characterization of the film structure. This is performed by RHEED, together with other diffraction techniques, such as low-energy electron diffraction (LEED), transmission electron diffraction (TED), and X-ray diffraction (XRD), including recent developments, for example, Bragg rod scattering and coherent Bragg rod analysis, which are also suitable for checking the crystallographic relationships between the film and substrate, eventually determining whether the film is epitaxial or not. Finally, when high-resolution transmission electron microscopy (HR-TEM) is used, a complete characterization of the interface in cross section is obtained.

The microstructural analysis mostly considers the interior of the film and the interface with the substrate, which is likely to be a source of defects propagating in the film. They can be extrinsic point defects, including the intermixing at the interface in heteroepitaxy; intrinsic point defects, such as interstitials, vacancies, and clusters of them, which are quite frequent in the case of low-temperature growth; grain boundaries, as a final consequence of island ripening and coalescence; dislocations induced by the process of strain release in sufficiently thick layers (see next section), which are usually composed by misfit segments at the interface with the substrate and threading arms crossing the film up to the surface; twins, staking faults, and related "oval defects," which are particularly observed during the growth of compound semiconductors by molecular beam epitaxy (MBE). Classical TEM micrographs, along with indirect analysis of photo luminescence spectra, and other optical spectroscopies (recently, also micro-probe mapping techniques, such as micro-Raman) can be used to get a quantitative estimate of defect position and concentration. In **Figure 3** a schematic representation of crystal defects is reported, while the reader is referred to the "Further reading" section for a more detailed discussion. Here, it may be mentioned that controlling the density of such defects, in particular the threading dislocations and the stacking faults, is a major goal of present semiconductor epitaxy, since they critically degrade the performances of microelectronic devices by altering the carrier concentration and mobility. Acting as nonradiative recombination centers, they also reduce the minority carrier lifetime and the quantum efficiency of photonic devices.

The surface morphology is the last important feature to be considered: large-scale modulations on the micrometer scale or 3D islanding, from tens to hundreds of nanometers in width, generate a surface roughness, which is the by-product of the elastic strain release in competition/collaboration with the plastic process involved by dislocations in large misfit heteroepitaxy. Therefore, a morphologically flat surface is the first indication that strain relaxation has been obtained, and for a few decades this has been the primary goal of epitaxial growers. Nowadays, quantum dot formation by strain is a key issue of novel nanoelectronic and photonic devices, and strained layer governance is also required in present microelectronics, for example, in Si–Ge field effect transistors. Therefore, the full and quantitative characterization of the surface morphology by microscopy techniques (such as TEM, scanning tunnel microscopy (STM), and atomic force microscopy (AFM) (also used for evaluating the areal density of emerging threading dislocations after etching)) is presently an unavoidable feedback in epitaxial growth experiments. Some examples of epitaxial growth for inorganic and organic films are reported in **Figure 4**.

Heteroepitaxy and Strain Control in Semiconductors

Small Misfit Systems: Plastic Relaxation by Misfit Dislocations

This section considers systems of small misfits, typically of a few percent. In the following, the possibility of SK or VW growth is neglected and the

surface of the epitaxial films is simply assumed to be flat. These are the conditions for which a sufficiently thin film has the same in-plane lattice parameter as the substrate (**Figure 5a**). Since the stress imposed by the substrate, $\sigma_{||}$, is 2D and the component perpendicular to the surface, $\sigma_{\perp}$, is zero, the epitaxial film is free to rearrange its lattice parameter perpendicular to the surface, in such a way that its internal energy is

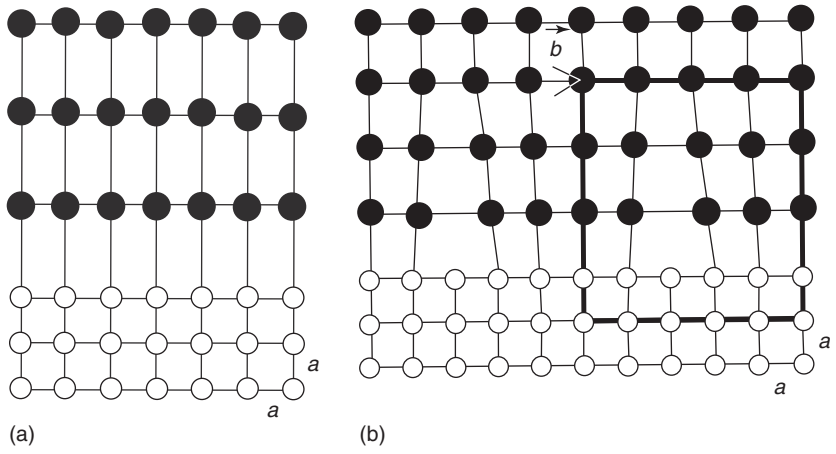

Figure 5 Sketch of (a) coherent and (b) incoherent interface; the film lattice parameters are indicated in relation to the one of the substrates; in (b) in the Burgers vector ***b*** is also defined. minimized. The resulting strain components are $\varepsilon_{||}$ and $\varepsilon_{\perp}$, parallel and perpendicular to the surface, respectively. They are opposite in sign, since the natural tendency of the strained structure is to preserve the volume of the unit cell. In fact, they can be expressed in terms of stress components, via the elastic equations involving the Poisson ratio v and the Shear modulus μ, which are in turn related to the bulk modulus B, that is, the stiffness of the material:

$$\begin{pmatrix} \varepsilon_{||} \\ \varepsilon_{\perp} \end{pmatrix} = \frac{1}{2\mu(1+v)} \begin{pmatrix} 1-v & -v \\ -2v & 1 \end{pmatrix} \begin{pmatrix} \sigma_{||} \\ \sigma_{\perp} \end{pmatrix} \quad [2]$$

Since $\sigma_{\perp} = 0$, $\varepsilon_{\perp}$ and $\sigma_{||}$ can be expressed in terms of $\varepsilon_{||}$:

$$\sigma_{||} = 2\mu\left(\frac{1+v}{1-v}\right)\varepsilon_{||} \quad [3]$$

$$\varepsilon_{\perp} = -\left(\frac{2v}{1-v}\right)\varepsilon_{||} \quad [4]$$

The elastic energy per unit area stored in a homogeneously strained film of thickness h is therefore given by

$$\begin{aligned} u_{\text{el}} &= \tfrac{1}{2}\, h(2\sigma_{||}\varepsilon_{||} + \sigma_{\perp}\varepsilon_{\perp}) \\ &= 2\mu\left(\frac{1+v}{1-v}\right)h\varepsilon_{||}^2 = 3B\left(\frac{1-2v}{1-v}\right)h\varepsilon_{||}^2 \end{aligned} \quad [5]$$

It may be noted that the elastic energy is a quadratic form of the strain $\varepsilon_{||}$, as in the case of a hydrostatic deformation, where $\varepsilon_{||} = \varepsilon_{\perp}$:

$$u_{\text{hyd}} = \frac{9}{2}\, Bh\varepsilon_{||}^2 \quad [6]$$

The energy in eqn [5] is obviously smaller, since relaxation in the perpendicular direction occurs, and it correctly vanishes in the limit case of volume preservation, when $v = 0.5$. Actually, the latter ranges, for most materials, between 0.25 and 0.35.

As long as the film is strained in such a way that its in-plane lattice constants match those of the substrate, the modulus of the parallel strain equals the misfit, that is, $|\varepsilon_{||}| = f$. As the thickness h increases, the elastic energy increases correspondingly, up to a limit h_c above which the uniformly strained state is no longer energetically favorable. The system can lower its total free energy instead, by generating so-called misfit dislocations (**Figure 5b**), in order to relieve part of the strain.

Actually, the calculation of the critical thickness h_c is not an easy task, since several contributions enter the energy balance. In the simplest approach, one assumes thermodynamic equilibrium and takes into account just two elastic energy contributions:

1. the energy due to the residual homogeneous strain $|\varepsilon_{||}| < f$, and
2. the energy stored in the inhomogeneous strain field of a square grid formed by two independent sets of parallel dislocation lines.

In order to evaluate the first contribution, one has to consider the misfit f_d taken up by an array of dislocations with linear density p_d, and with the component $b_{||}$ of the Burgers vector lying in the interface plane and perpendicular to the dislocation line. This somewhat complicated definition stems from the fact that in many relevant cases the Burgers vector is neither perpendicular to the dislocation line nor lying in

the interface plane, as in fact it is defined in **Figure 5b** for simplicity.

In the general case, the misfit taken up by a set of parallel dislocations spaced at a distance of $1/p_d$ is given by

$$f_d = p_d b_{||} \equiv p_d b \cos \lambda \qquad [7]$$

where λ is the angle between the Burgers vector and the direction in the interface plane, which is orthogonal to the dislocation line. The magnitude of the reduced strain is proportional to the modulus of the reduced misfit:

$$|\varepsilon_{||}| = |f - f_d| = |f - p_b b_{||}| \qquad [8]$$

and finally, eqn [5] provides the reduced elastic energy as a function of dislocation density:

$$u_{el}(p_d) = 2\mu\left(\frac{1+\nu}{1-\nu}\right)h(f - p_d b_{||})^2 \qquad [9]$$

The second contribution to elastic energy stems from the energy per unit length required for the bond breaking (at the core) and from the long-range strain field surrounding a misfit dislocation. The region of interest is a semicylindrical crust, extending from the dislocation core (conventional radius $= b/4$) at the interface to the free surface of the film. By a classical integration procedure, one finds

$$u_{dis} = \frac{\mu b^2}{4\pi}\left(\frac{1 - \nu \cos^2 \beta}{1 - \nu}\right)\ln\left(\frac{4h}{b}\right) \qquad [10]$$

where β is the angle between the Burgers vector and the dislocation line. This dislocation energy correctly displays a quadratic dependence on b, to which the related strains are proportional.

The energy per unit area of a square grid of independent dislocations is simply twice the linear density times the dislocation energy. The total elastic energy is therefore a sum of two contributions, that is, one quadratic (eqn [9]) and one linear in the dislocation density. Up to a critical thickness h_c, the minimum total energy is found at $p_d = 0$, that is, the film is homogeneously strained, and there are no dislocations. Beyond that limit p_d is finite, so that partial strain relief is obtained. An implicit expression for h_c at a given misfit f is obtained by setting to zero the first derivative of the total elastic energy, at zero dislocation density:

$$h_c = \frac{b}{8\pi f \cos \lambda}\left(\frac{1 - \nu \cos^2 \beta}{1 + \nu}\right)\ln\left(\frac{4h_c}{b}\right) \qquad [11]$$

Figure 6 shows the dependence of the critical thickness with the misfit, as predicted by eqn [11] for SiGe/Si(0 0 1).

Intermediate Misfit Systems: Elastic Relaxation by Surface Corrugation and 3D Dots

If the misfit is some percents, consider the prototypical case of Ge on Si(0 0 1) with $f = 4.2\%$, elastic relaxation takes place before the critical thickness for dislocation nucleation is reached. In this case, $\varepsilon_{||}$ is lowered via surface roughening, which allows for local lateral expansion of the lattice parameter at the edges of 2D islands, or at the facets of 3D aggregates, including the case of surface modulations (see **Figures 4a** and **4b**). In particular, coherent clusters as large as tens or hundreds of nanometers appear in the SK or VW growth modes, with different shapes from rectangular-based pyramids (huts) to square-based pyramids, to larger domes with increasing aspect ratio (vertical size/lateral size). Indeed, as the aspect ratio increases the strain relaxation increases, especially close to the top, as reported in **Figure 7**, which is obtained by numerical simulations at the atomic scale. But for kinetic effects, which are important at growth temperatures below some 450°C, the different shapes are essentially produced by a balance between the elastic energy release in volume, depending on the aspect ratio, and the surface energy, which is related to the orientation of the facets and on their reconstruction. In Ge/Si(0 0 1), the (1 0 5) facets are particularly low in energy, and they appear both in the pyramids and in the surface modulations. As the size of the larger domes increases

with deposition, and the amount of residual strain with it, plastic relaxation by dislocations within the dots may take place, leading to very interesting structures where plastic and elastic relaxation phenomena coexist in a nanometric region.

Large Misfit Systems and Symmetry Mismatch: Growth of Epitaxially Stabilized Metastable Phases

As the misfit gets larger, say 8–10%, it becomes increasingly likely that, apart from the effects associated with the growth mode and with strain relaxation, other phenomena come into play. Actually, with a misfit in this range existing, it is no longer possible to strain even a single monolayer into coherency with the substrate. On the other hand, the symmetry of the film structure could be lower than the one of the substrate, with large differences in misfit depending on the orientations, so that a patchwork of domains is the best epitaxial result one can obtain. Still, it may exist in another phase, with a cohesion energy not much larger than that of the bulk phase and a symmetry closer to that of the substrate. By a suitable orientation, it may display equilibrium lattice parameters close to one of the substrates. In this case, the growth of a coherent film with such metastable (in the bulk) structure may be energetically favored, and it becomes an epitaxially stabilized phase. An appropriate term for such a phase would really be pseudomorphic, although this expression is misused in place of coherent in much of the literature.

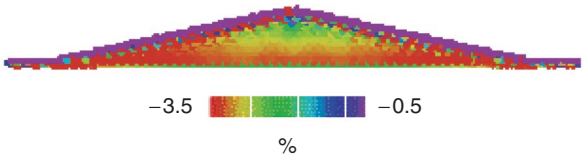

Figure 7 Compressive strain release inside a Ge pyramid on Si(0 0 1), as large as 27 nm; in a color scale (red = compression), the simulated strain component parallel to the surface is mapped, showing an expansion close to the top of the pyramid. (Courtesy of R Marchetti, University of Milano – Bicocca, Milano.)

The situation leading to the epitaxial stabilization of an unstable bulk phase is indicated schematically in **Figure 8**. The left panel shows the total energy curves of the two phases in question, under hydrostatic conditions and with the tetragonal relaxation included (see eqns [5] and [6]), as a function of the substrate lattice parameter, with the misfit of the bulk stable phase assumed to be larger. The important parameter, as far as phase stability is concerned, is the value of the energy at the substrate lattice constant a_{sub}. Evidently, the energy of the bulk stable phase strained into coherency with the substrate exceeds the energy of the coherent bulk unstable phase. This shows that the term epitaxial stabilization is actually a misnomer since it is rather the bulk stable phase that is destabilized under epitaxial conditions. It is clear that the pseudomorphic phase cannot remain stable to arbitrary film thicknesses. The energy of the stable bulk phase will start to decrease at the

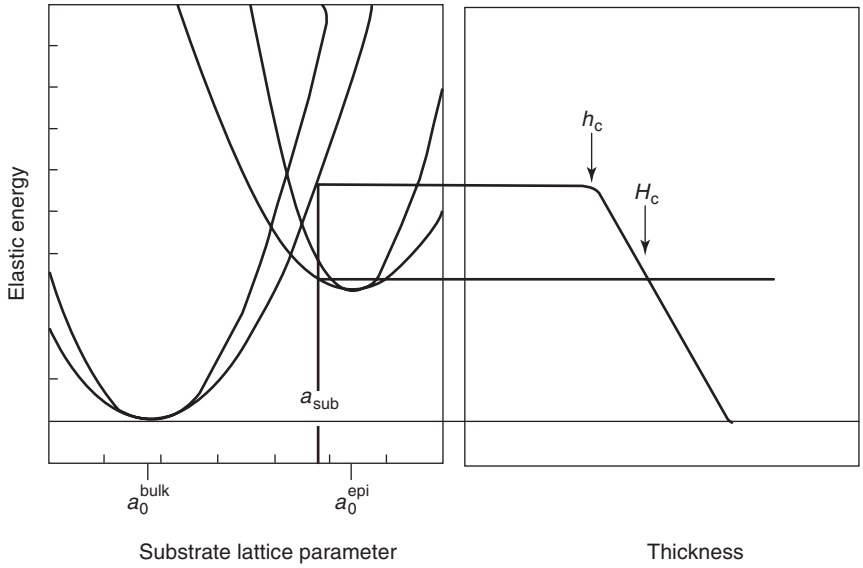

Figure 8 Left side: elastic energy of the two competing phases under hydrostatic stress (light curves) and after tetragonal relaxation (bold curves), as a function of the substrate lattice parameter. Right side: energy variation with film thickness; here, h_c is the critical thickness value at which strain relaxation sets in and the energy of the bulk phase decreases; H_c is the critical thickness value at which the bulk phase becomes favorite. (Reproduced with permission from von Känel H, Onda N, and Miglio L (1995) *Science and Technology of Thin Films*, p. 37. Singapore: World Scientific.)

film thickness h_c where plastic relaxation sets in, as is indicated schematically in the right panel of **Figure 8**. As the film thickness grows further, the two total energy curves eventually cross, giving rise to a new critical thickness H_c, at which the bulk stable phase becomes energetically favorable again. The epitaxial stabilization process is very interesting, since it virtually allows for the growth of new material phases with different properties with respect to the bulk ones. Still, it occurs just in case several polymorphic phases are possible, such as the case of metals or transition metal silicides, which have been studied very intensively in the last 20 years in relation to metallization and interconnects of integrated circuits.

Kinetic Issues

At small misfits, especially in semiconductor epitaxy, eqn [11] predicts a lower value for h_c than is often found experimentally. Films with thickness $h > h_c$ are thus frequently found in a metastable, strained state: in Si–Ge heterostructures, for instance, h can be 10 times h_c. However, by increasing the growth temperature (see **Figure 9**), or by subsequent annealing, h is reduced to h_c. Such a thermally activated behavior is usually governed by kinetics rather than by equilibrium thermodynamics. Indeed, the activation energies associated with the nucleation of new misfit dislocations at the interface and with the displacement or bending of the existing ones, in order to position the Burgers vector for the maximum strain relief, are not considered in the current thermodynamic model outlined above. Early attempts to include the kinetics of strain relief are due to Matthews (see "Further reading" section), but most of the work is still to be done. In the case of large misfits, where metastable phases may be stabilized by the substrate, the kinetics of the evolution with thickness is complicated by the fact that, in addition to the activation energies required to nucleate and move misfit dislocations, the activation energy for the structural transition from one phase into the other has to be taken into account. In particular, it has to be considered which kind of atomic motion is involved in the particular transition (martensitic, displacitive, massive, etc.), where the new phase nucleates, and how it grows. This is a formidable task, both from the experimental and the theoretical points of view. Finally, kinetic aspects are also very important when 3D islands provide an elastic release of the misfit strain. In fact, the growth in size and the morphological evolution to higher aspect ratios with deposition are surely directed toward an elastic energy lowering, but the way this is accomplished fully relies on the surface diffusion of the deposited atoms. Activation energies related to the diffusion of single atoms (or molecules) onto the wetting layer, along the dot facets, and across the multiple steps shaping the dot morphologies are key issues in understanding why rather different results are experimentally obtained for different deposition rates and temperatures. Probably, this is the most affordable, still complex, path in addressing the kinetic issues of the epitaxial growth, a subject still relying more on speculations than on predictions.

Nomenclature

a_{film}	lattice parameter of the film (m)
a_{sub}	lattice parameter of the substrate (m)
b	Burgers vector (m)
$b_{\|\|}$	component of Burgers vector lying in the interface plane (m)
$b_{\perp}$	component of Burgers vector perpendicular to the dislocation line (m)
B	bulk modulus ($N\,m^{-2}$)
f	misfit
f_d	misfit taken up by an array of dislocations
h	film thickness (m)
h_c, H_c	critical film thickness (m)
p_d	linear density of dislocations (m^{-1})
u_{el}	elastic energy per unit area stored in a strained film ($J\,m^{-2}$)
ν	Poisson's ratio
β	angle between the Burgers vector and the dislocation line
γ_f	surface free energy of the film ($J\,m^{-2}$)
γ_i	surface free energy of the interface ($J\,m^{-2}$)
γ_s	surface free energy of the substrate ($J\,m^{-2}$)
ε	film strain
$\varepsilon_{\|\|}$	component of strain parallel to the substrate
$\varepsilon_{\perp}$	component of strain perpendicular to the substrate
λ	angle between the Burgers vector and its component in the interface plane
μ	shear modulus ($N\,m^{-2}$)
σ	stress of the film ($N\,m^{-2}$)
$\sigma_{\|\|}$	component of stress parallel to the substrate ($N\,m^{-2}$)
$\sigma_{\perp}$	component of stress perpendicular to the substrate ($N\,m^{-2}$)

Exciton Complexes

B P Zakharchenya[†] **and S A Permogorov**, Ioffe Institute, St. Petersburg, Russia

Introduction

Exciton complexes are the electronic excitations of the crystal, the existence of which is caused by the presence of impurities or defects or by the interaction of more than two free carriers of different signs. In most cases, the exciton complex can be considered as an electron–hole pair bound to the impurity or defect. It does not move in the crystal and does not transfer the energy. As a result, the alternative description of exciton complexes as excited states of defects is possible. However, since the energies of such electronic excitations are normally close to that of free excitons, in most cases such complexes are designated as "bound" or "localized" excitons, as they are referred to further.

Exciton complexes were first detected in alkali–halide crystals, where the so-called α and β absorption bands downshifted in energy by some tenths of eV below the main exciton peaks were observed. In 1957, using the method of adiabatic cycles, F Bassani and N Inchauspe showed that the observed shifts are compatible with the model, assuming the exciton localization to be at the anion (α) or at the F-center (β). Later, the exciton complexes were observed and studied in many ionic, molecular, and semiconductor crystals.

The interest in the study of exciton complexes is based on its large role in photoluminescence. An optical excitation creates free excitons which migrate along the crystal and localize on defects forming the exciton complexes, which are very stable at low temperatures. As a result, most of the emission comes from the bound exciton states. The better the crystal quality, the longer is the exciton diffusion length, and higher is the intensity of bound exciton emission in relation to the free exciton emission. The particular lines of bound excitons can serve as fingerprints for the presence of certain defects and impurities.

Besides the localized exciton complexes, the mobile exciton complexes can be formed. An example of such complexes is the biexciton, which represents a bound pair of two Frenkel excitons in molecular crystals, or two holes bound with two electrons in semiconductors. Another kind of mobile complexes (trion) has been observed in recent times in semiconductor quantum wells (QWs). A trion consists of two electrons or holes bound with one carrier of the opposite sign (hole or electron).

[†]Deceased.

Exciton Complexes in Semiconductor Crystals

In good quality crystals, the absorption and emission lines of immobile exciton complexes are extremely sharp (halfwidth ~ 0.1 meV), and the strict resonance of absorption and emission exists at the energy, corresponding to the total energy of the exciton complex, even in semiconductors with indirect bandgaps. The momentum conservation for complexes is relaxed due to the presence of heavy impurities accommodating any excessive momentum. The high intensity of the bound exciton absorption is caused by the giant oscillator strength of the corresponding transitions. The oscillator strength of the bound exciton transition per one impurity f_b exceeds, by far (up to 10^4 times), that for the free exciton f_{exc} per unit cell. The reason is that a large crystal volume (of the order of, or exceeding a free exciton volume) is involved in this transition. As it was predicted by E Rashba in 1957, the ratio of oscillator strengths is $f_b/f_{exc} \approx (E_b/\Delta E_{exc})^{3/2}$, where E_b is the binding energy of the exciton complex, representing the energy difference between the free and bound exciton states, and ΔE_{exc} is the energy width of the free exciton band. This relation has been proved experimentally in the study of luminescence decay times in the range 10^{-9}–10^{-10} s for bound excitons with different binding energies in CdS crystals. The sharpness and a high oscillator strength of bound exciton transitions make them very suitable for studies of magnetooptic effects allowing one to determine the nature, symmetry, and the values of the carrier *g*-factors in exciton complexes.

Complexes of Excitons with Shallow Donor or Acceptor Impurities: Quantum Chemistry of Bound Excitons

The analogy of a free exciton in semiconductor crystals with a hydrogen atom has proved to be very instructive. In 1958, M A Lampert generalized this analogy to exciton complexes with shallow donors and acceptors comparing their electronic structure and binding energy with hydrogen molecules, molecular ions, or positronium aggregates. In such an approach, the binding energy of a bound exciton E_b can be expressed as $E_b \approx R_{ex} E_{mol}/R_H$, where R_{ex} is the exciton Rydberg in the crystal, E_{mol} is the binding energy of the corresponding molecular analog, and R_H is the Rydberg energy of the hydrogen atom (13.6 eV). The binding energies of hydrogen-like molecular analogs are well known from the molecular spectroscopy of gases.

Donors and acceptors in semiconductors, due to the central cell corrections, are not exactly hydrogen-like. To account for this fact, the exciton Rydberg R_{ex} in the above relation should be substituted by $E_{A,D}$, the ionization energy of the particular acceptor or donor, so that $E_b \approx E_{A,D} E_{mol}/R_H$. It appears that the type of molecular analog and the magnitude of E_b strongly depend on the ratio of electron and hole effective masses m_e^*/m_h^*. The theoretical estimations of binding energies for some exciton complexes are presented in **Table 1**.

In the limit $m_h^*/m_e^* \gg 1$, the complex of an exciton with a neutral donor is analogous to the hydrogen molecule H_2. Two light electrons with antiparallel spins move on the orbit enveloping the positively charged core of the donor and the hole with the maximum of the electron density situated between two positive centers. The binding energy of the H_2 molecule is 4.6 eV and the Rydberg energy of the H atom is 13.6 eV, which leads to the value of 0.33 E_D for the binding energy of the complex. In the opposite case of $m_h^*/m_e^* \ll 1$, the character of the carrier orbital motion is quite different. Two relatively heavy electrons move around the positively charged donor core forming the center analogs to the negatively charged H^- ion with a net charge (-1). The motion of the hole around this center has a hydrogen-like character. Using the method of adiabatic cycles, W Kohn in 1960, showed that the energy necessary to remove the free exciton from such a complex approximately corresponds to the dissociation energy of H^- ion and can be represented as 0.055 E_D. The exciton bound to the charged donor in the limit $m_h^*/m_e^* \gg 1$ has an analogy with the molecular ion of hydrogen H_2^- (dissociation energy 2.6 eV), and its binding energy can be estimated as 0.19 E_D. The complex becomes unstable at $m_h^*/m_e^* < 1.4$. The above considerations can be applied also to the acceptor-based exciton complexes taking into account the reversal of the sign for all charges.

The realistic values of m_h^*/m_e^* ratio are 4–5 in II–VI and ~ 10 in III–V semiconductors. So, the real binding energies of exciton complexes should have intermediate values within the limits indicated in the table. The complexes both with the donors and acceptors can be expected for neutral centers, whereas for ionized centers only the donor-based complex is stable.

The emission spectra of excitons bound to neutral donors and acceptors were first observed by J R Haynes in 1960 in a study of low-temperature luminescence of high-quality Si intentionally doped by Sb, P, As, and Bi group-V donors, and by B, Al, Ga, and In group-III acceptors. Very sharp and intensive lines were observed and attributed to the emission of excitons bound to neutral impurities. The binding energies of complexes E_B were measured as energy shifts of emission lines from the exciton band bottom.

Table 1 Binding energies E_b of some types of exciton complexes in the units of donor or acceptor ionization energies E_D and E_A in dependence on the carrier effective mass ratio

Type of complex	*Effective mass ratio* (m_h^*/m_e^*)	*Model*[a]	*Molecular analog*	*Binding energy* (E_b)
Exciton bound to neutral donor	$\gg 1$		H_2	0.33 E_D
	$\ll 1$		$H^- + e^+$ See text	0.055 E_D[b]
Exciton bound to charged donor	$\gg 1$		H_2^+	0.19 E_D
	< 1.4			Unstable
Exciton bound to neutral acceptor	$\gg 1$		$H^- + e^+$ See text	0.055 E_A[b]
	$\ll 1$		H_2	0.33 E_A

In column 4, the molecular analogs of the complexes are indicated.

[a] In model drawings, the symbol " $-$ " represents the electron in conduction band with effective mass m_e^* and the symbol " $+$ " the hole in valence band with effective mass m_h^*. Symbols $\oplus$ and $\ominus$ represent the charged (ionized) donors and acceptors, respectively. e^+ stands for positron. Thin dotted lines show the character of carrier orbital motion in the complexes.

[b] Estimated by W Kohn in private communication to: Haynes JR (1960) *Physical Review Letters* 4(7): 361–363.

In agreement with theoretical predictions, it has been found that both for donor- and acceptor-bound complexes $E_B \approx 0.1\, E_i$, where E_i is the ionization energy of impurity. However, a slight but distinct difference between the two cases can be detected (**Figure 1**).

Similar regularity has been established for II–VI semiconductors also. However, for these compounds, in distinction to the case of Si, it has been found that $E_B \approx 0.2\, E_D$ and $E_B \approx 0.1\, E_A$ for complexes with neutral donors and acceptors, respectively. Besides that, complexes with charged donors were observed. In uniaxial II–VI compounds with a wurtzite structure, where the valence band is split by a crystal field into three components A, B, and C, the complexes of the $n = 1$ excitons of the two uppermost valence subbands A and B were detected. In CdSe crystals, the complexes of the excited state $n = 2$ of the A-exciton with the neutral donor were observed. The molecular analogs of such complexes are the excited states of the hydrogen molecule H_2^*. The fine structure of the spectrum and the binding energies (normalized on the binding energy of the complex with the ground exciton state $n = 1$) were in reasonable agreement with those for the three lowest stable states of H_2^* ($2s\sigma$, $2p\sigma$, and $2p\pi$). The identification of the types of exciton complexes in II–VI compounds was carried out mostly on the basis of magnetooptical measurements. The energies of bound excitons in different II–VI compounds are ranging from 3 to 7 meV for donor complexes, and from 6 to 60 meV for acceptor complexes.

Biexcitons in Semiconductors

A biexciton in semiconductors is a bound state of two electron–hole pairs. The hydrogen-like analog of a biexciton is a hydrogen molecule H_2. However, this analogy cannot be used for the estimation of the biexciton binding energy since the effective masses of the electron and hole are usually comparable in magnitude. More elaborate variational calculations predict that the binding energy of biexciton complexes should increase from $\approx 0.03\, R_{ex}$ to $\approx 0.15\, R_{ex}$ (R_{ex} is the exciton Rydberg), when the mass ratio m_h^*/m_e^* increases from 1 to 10. So, the expected values of the biexciton binding energy are rather small.

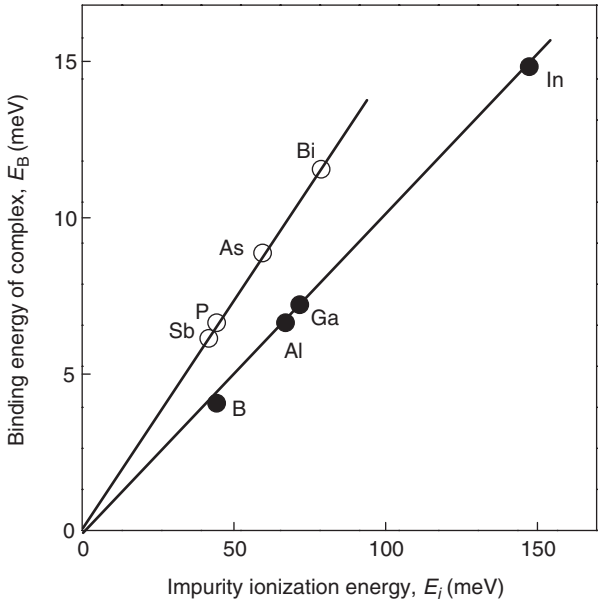

Figure 1 Dependence of the binding energy E_B on the ionization energy of impurity E_i for exciton complexes bound to Sb, P, As, and Bi neutral donors (open circles) and B, Al, Ga, and In neutral acceptors (filled circles) in high-quality Si crystals at $T = 2$ K. (Modified from Haynes J R (1960) *Physical Review Letters* 4(7): 361–363.)

Experimental observation of biexciton optical transitions in conventional one-photon spectroscopy is very difficult. The absorption process, corresponding to creation of the biexciton in a bound state has an energy approximately twice the transitions into the exciton states, and falls in the region of strong interband absorption. So, only the emission processes, when one of the excitons annihilates radiatively leaving the other in the ground or excited state, can be observed. The biexciton population is proportional to the square of the exciton concentration, and observation of biexcitons needs high-excitation density. In such conditions, the biexciton transitions are overlapped with some other emission processes, corresponding to elastic and inelastic exciton collisions which makes their identification difficult. Moreover, the increase of the excitation density leads to the formation of the electron–hole plasma, which screens both the biexcitons and free excitons. As a result, the biexciton emission can be observed only in a certain range of excitation intensities. Nevertheless, the observation of biexciton luminescence has been claimed for several direct-gap semiconductors (Cu_2O, CuCl, CuBr, ZnSe, HgI_2, etc.). In most cases, the difference between the measured and expected binding energies of biexcitons has been observed.

A reliable observation of biexciton luminescence has been made in Si crystals uniaxially stressed in different crystallographic directions. The effect of stress is to lift the degeneracy of both the valence and conduction bands, which increases the effective mass ratio m_h^*/m_e^* for the lowest exciton state. In conditions of maximum lifting of degeneracy (stress along $\langle 1\,0\,0 \rangle$ direction) at the increase of the excitation intensity, a new band appears in the luminescence spectrum. On the basis of the line position, its quadratic dependence on the excitation intensity, the temperature dependence of line intensity, and the theoretical analysis of the lineshape, a new band was assigned to the luminescence of biexcitons with a binding energy ≈ 2 meV.

The large progress in the detection of the biexciton states in direct-gap semiconductors has been achieved by means of two-photon nonlinear spectroscopy. Basically, three different experimental methods can be used.

1. Two-photon absorption (TPA), corresponding to direct excitation of biexciton states at simultaneous absorption of two photons. For observation of TPA, a narrow-band intensive laser pulse and a time-synchronized light source with a broad spectrum are normally used. The process of TPA is observed as an appearance of a new absorption line in a broadband spectrum when the sample is excited by both pulses simultaneously. The position of this line changes with the tuning of the narrow-band laser frequency so that the sum of the energy positions of the laser and the new absorption line is constant. This summary energy corresponds to the energy of the biexciton state.
2. If the exciton lifetime in the sample is sufficiently long, the stationary exciton population is formed at excitation with a properly tuned narrow-band laser. In such a case another new line can appear, corresponding to the optical transitions from the exciton into biexciton states. In comparison to the case of TPA, the position of this line does not change on tuning the laser frequency. This two-step process is called the induced biexciton absorption.
3. Resonant hyper-Raman (HR) scattering through the biexciton states. This process represents a version of the four-wave mixing (FWM) of polariton states in the crystal. Two photons of a narrow-band tunable laser with energies $\hbar\omega_l$ and the wave vector $\boldsymbol{q}_l$ and $\boldsymbol{q}_2$ (with some angle between them) excite a real or virtual biexciton state with energy $2\hbar\omega_l$ and wave vector $\boldsymbol{K} = \boldsymbol{q}_l + \boldsymbol{q}_2$. This state decays with the creation of two polaritons. One of them $E_1(q)$ is photon-like and the other $E_2(k)$ is the exciton-like polariton or the longitudinal exciton. The energy and momentum conservation laws require that $\boldsymbol{q} + \boldsymbol{k} = \boldsymbol{K}$ and $E_1 + E_2 = 2\hbar\omega_l$. As a result, the produced photon-like polaritons can

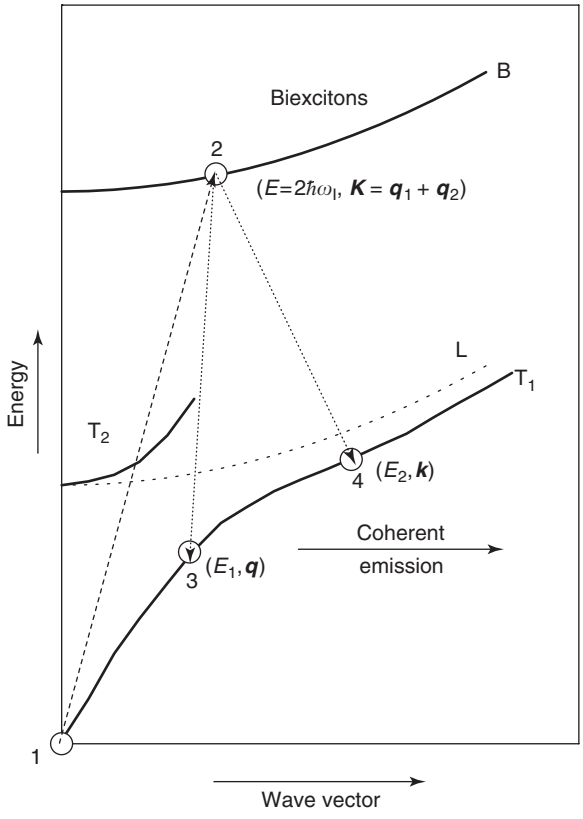

Figure 2 Schematic representation of hyper-Raman scattering in the region of biexciton resonance. Laser light produces a two-photon transition from crystal ground state 1 into biexciton state 2, which decays into photon-like polariton 3 and exciton-like polariton 4. Energy and wave vector for states 2, 3, and 4 are indicated in brackets. T_1 and T_2 are lower and upper polariton branches, L and B are the bands of longitudinal excitons and biexcitons. Only one of the possible processes is shown.

propagate only along some selected directions. These allowed directions and the energy of photon-like polaritons $E_1(q)$ depend on the detailed character of the polariton dispersion curves. At the crystal surface, the photon-like polaritons are converted into spatially resolved coherent light beams representing the output of HR scattering. The cross section of the HR scattering shows a giant enhancement at the exact resonance of the energy of two exciting photons with the real biexciton state. The process of HR scattering is presented schematically in **Figure 2**.

The biexciton states were studied in detail by means of two-photon spectroscopy in CuCl, CuBr, and CdS semiconductors.

Multiexciton Complexes in Indirect-Gap Semiconductors

A study of the low-temperature ($T = 2\,\mathrm{K}$) luminescence of Si crystals intentionally doped with shallow donor or acceptor impurities has shown that on increasing the excitation intensity, in addition to the lines of bound excitons (BE) reported by J R Haynes in 1970 (see above), a series of new narrow emission lines appears at lower energies. The series includes $\sim$10 lines and the distances between the lines have an order of 2–3 meV. The intensities of all lines grow with the increase of the excitation density: the larger is the line red-shift, the stronger is the intensity dependence. A similar emission has also been observed in doped Ge crystals.

The new type of emission has been attributed to complexes formed by the neutral donor or acceptor and several excitons. The possibility of formation of such complexes is connected with the complicated band structure of Si and Ge, and is caused by high degeneracy of both the valence and conduction bands in these semiconductors. With the account for the spin, the valence band is fourfold degenerate. The conduction band in Si has six valleys at Δ-points of the Brillouin zone. In Ge, there are four electron valleys at the L-points. Correspondingly, the degeneracy of conduction bands is 12 and 8 for Si and Ge, respectively, whereas in direct-gap semiconductors the conduction band degeneracy is only 2. As a result, in multivalley semiconductors several electrons can occupy the lowest 1*s* state.

A complete understanding of the electronic structure of multiexciton complexes has been achieved with the help of the "shell" model proposed in 1977 by G Kirczenow. An explicit consideration of the donor electronic spectrum, taking into account the local symmetry and valley-orbit splitting, has shown that it can be represented as a system of "shells" (3 for Si – Γ_1, Γ_3, and Γ_5; 2 for Ge – Γ_1 and Γ_5), which are gradually filled by electrons in accordance with the Pauli principle when the number of excitons in the complex is increased. This model has allowed one to get a full understanding of line positions, optical selection rules, and the number and polarization of split components in an external magnetic field and under uniaxial stress.

The impurity-bound multiexciton complexes were also observed in other indirect-gap materials (GaP, SiC, AlAs, AlSb). Presently, the possibility of observation of free multiexciton complexes (triexcitons, tetraexcitons, or even complexes of higher order) is discussed theoretically.

Trions in Semiconductor Heterostructures with Quantum Wells

Trions are complexes of an electron–hole pair (e–h) with one more electron (2e–h, X^-) or hole (e–2h, X^+). The stability of trions in semiconductors was discussed first by M Lampert in 1958. For realistic

effective mass ratio, very small binding energies were expected, much less than the 0.1 of exciton Rydberg. Experimentally, trions were not observed in bulk semiconductors.

The situation has changed drastically with the development of exciton spectroscopy of low-dimensional semiconductor heterostructures. The reduction of the dimensionality from 3D to 2D leads to an increase of the exciton binding energy up to four times, so that the excitons in some QW systems remain stable up to room temperatures. A similar effect of dimensionality is also expected in the case of trions. The first observation of stable trions was performed for CdTe/CdZnTe in 1993.

Afterwards, both negatively (X^-) and positively (X^+) charged trions were observed in many other systems with QWs (GaAs/GaAlAs, CdTe/CdMgTe, ZnSe/ZnMgSSe, ZnSe/ZnBeSe, and others).

Due to giant oscillator strength, the optical transitions to and from trion states were observed both in reflection and luminescence. The control of the charge sign of trion states is usually performed by providing excess carriers in the QW by δ-doping of the adjacent regions of the barrier layers either by donors or acceptors. It has been found that the binding energy of a trion has an order of several meV and strongly depends on the parameters of the QW, first of all on its width. The decrease of the width of the QW can increase the binding energy of the trion up to five times.

A trion is a charged particle, in which the spins of two carriers are compensated by one another. Such an electronic structure opens wide possibilities for electrooptical and magnetooptical studies of trion states. Also, the present state of QW engineering allows one to design many new experiments with trion states. As a result, the study of trion properties in different types of structures with QWs forms an interesting and a fast developing domain of semiconductor physics.

Excitons in Crystals

B P Zakharchenya[†] **and S A Permogorov**, Ioffe Institute, St. Petersburg, Russia

Introduction

Excitons represent a wide class of intrinsic electronic excitations in crystals of semiconductors and dielectrics. A characteristic feature of excitons is that their formation (e.g., at optical excitation) does not lead to the separation of carriers, so that the excitons are electrically neutral excitations. Originally, the concept of excitons was introduced by Ya I Frenkel in 1931 to explain the light absorption in crystals which does not lead to photoconductivity. In the Frenkel model, the exciton is considered as an electronic excitation of one crystal site with the energy close to, but a bit smaller than that necessary for the excitation of a free electron. Due to the translation symmetry of the crystal, the exciton can move along the lattice sites transferring the energy to the electrically

[†]Deceased.

active or luminescence centers. So, the excitons play a significant role in most of the photoconductivity and light emission processes.

The character of exciton motion depends on the strength of the exciton interaction with phonons. In the limits of a weak interaction, the exciton can be considered as a free particle with a well-defined wave vector and kinetic energy. In the opposite case, the exciton strongly polarizes the crystal lattice, and self-trapping of the exciton occurs. There is a variety of intermediate cases, when the exciton motion can be described either as a hopping process or by a strong scattering regime.

The Frenkel model is a good approximation for molecular crystals with van der Waals bonding, where the exciton is well localized within one molecule. For semiconductor crystals with covalent or slightly ionic bonding, a better description of excitons is given by another model proposed by G Wannier and N Mott. In this model, the exciton is considered as an electron–hole pair bound by a Coulomb interaction. In the case of weak electron–phonon interaction, both the electron and the hole can be considered as free particles which results in the hydrogen-like spectrum of exciton energies with a large number of excited states. However, in strongly ionic crystals, such as alkali halides, a self-trapping of holes at exciton formation takes place which leads to an essential deviation from the hydrogen-like model.

Excitons in Semiconductor Crystals

Energy Spectra of Excitons

In semiconductor crystals, the exciton can be considered as a hydrogen-like quasi-atom in which the electron and the hole are bound by Coulomb attraction. Since the distance between the electron and the hole in the exciton in most of the semiconductors is much larger than the lattice constant, the joint influence of all the crystal atoms on the exciton can be accounted for by using the band values of effective masses m_e and m_h, and the macroscopic value of the static dielectric constant ε_0. The exciton states, as in the case of hydrogen, can be characterized by quantum numbers n, l, and m. The binding energy of the exciton with the principal quantum number n is given by

$$R_n = \mu e^4/2\hbar^2\varepsilon_0^2 n^2$$

where e is the electron charge, μ is the exciton reduced mass $\mu = m_e m_h/(m_e + m_h)$, and ε_0 is the static dielectric constant. Since the exciton reduced mass is usually much smaller than a free electron mass ($\mu \cong 0.1 m_0$) and the typical value of the static dielectric constant ε_0, is ~ 10, the exciton binding energy is

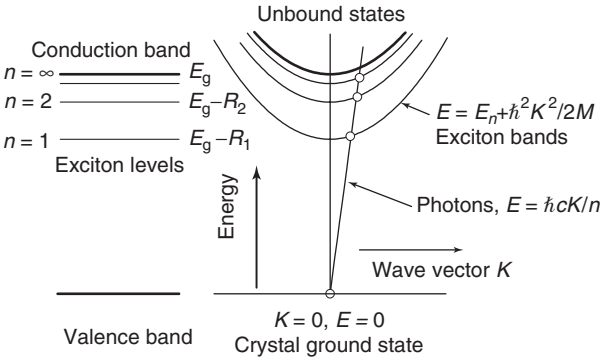

Figure 1 Exciton levels in the band scheme of semiconductor (left). Right part shows the exciton bands taking into account the exciton kinetic energy. Open circles indicate the crystal ground state and the states in the exciton bands to which the optical transitions occur.

$\sim 10^3$ times smaller than that of a hydrogen atom and ranges from 0.1–5 meV in III–V semiconductors to 10–30 meV in partly ionic II–VI semiconductors. Due to the possibility of a free motion, every exciton state can be characterized by a wave vector K and the kinetic energy $E_{kin} = \hbar^2K^2/2M$, where M is the exciton translation mass $M = m_e + m_h$. The full energy of the exciton state is given by $E_n = E_g - R_n + E_{kin}$ and the exciton energy spectrum represents a series of bands, the bottoms of which are downshifted below the fundamental gap E_g by the corresponding binding energies R_n, as it is shown in **Figure 1**.

Optical Transitions to Exciton States

At optical excitation below the fundamental gap E_g, the excitons can be directly created by light. The first experimental observation of an exciton optical absorption spectrum was performed by E F Gross in 1951 for Cu_2O crystals, where the hydrogen-like series with up to 6 lines was observed at $T = 77$ K. Further measurements at helium temperatures allowed one to resolve up to 11 members of this series. The important difference between the optical spectra of excitons and atoms is that in the case of the hydrogen atom, the photons induce the transitions from the ground state $n = 1$ to higher excited states $n = 2, 3, \ldots$, whereas for excitons the optical transitions take place from the "crystal ground state" ($E = 0$, $K = 0$) to the exciton states $n = 1, 2, 3, \ldots$. In pure crystals, in accordance with the energy and momentum conservation laws, the energy and momentum of the exciting photon has to be completely transferred to the newly produced exciton quasi-atom, so that $K_{ex} = K_{\hbar\omega}$ and $E_{ex} = \hbar c K_{ex}/n$. In the range of typical exciton energies (1–5 eV), the wave vectors of photons are much smaller than the limiting values at the edge of the Brillouin zone. As it can be seen from **Figure 1**, the conservation laws allow only

the creation of excitons with very small wave vectors $K_{ex} = K_{\hbar\omega} \approx 0$. The kinetic energies of such states are negligibly small $E_n(K_{\hbar\omega}) = E_n + \hbar^2 K_{\hbar\omega}^2/2M \approx E_n$. As a result, in the absorption spectrum of direct-gap materials appears a series of narrow (~ 1 meV) lines, with the positions corresponding to E_n ($K \approx 0$) energies. An example of such a spectrum for Cu_2O crystals is given in **Figure 2**. The oscillator strength for the transitions into the excited states decreases proportionally to $1/n^3$.

The exciton states can be formed also by conduction and valence bands with the extrema situated at different points of the Brillouin zone, like it is the case in GaP, Ge, or Si. The direct optical transitions into the exciton states in this case are forbidden. However, the optical transition into the exciton states is possible with simultaneous absorption or emission of the lattice phonon, which compensates the difference in K – positions of the band extrema. In the framework of the perturbation theory, such a process can be considered as a direct optical transition from the crystal ground state into the virtual state at $K \approx 0$ with subsequent scattering by phonons into the final state (**Figure 3**). Phonon-assisted transitions can excite the exciton states with any value of a wave vector (or kinetic energy). As a result, the indirect absorption leads to the appearance of the continuous "steps," the low-energy edges of which are shifted in position from the exciton band bottom by $\pm\hbar\omega_{MC}$, the energy of the momentum conserving phonon. The intensity of transitions with phonon absorption is proportional to phonon occupation number N and strongly depends on temperature, whereas the processes with phonon emission depend on temperature only as $(N+1)$. The indirect or phonon-assisted optical transitions also take place in the direct-gap semiconductors. However, the oscillator strength of such transitions is much smaller than that for direct transitions.

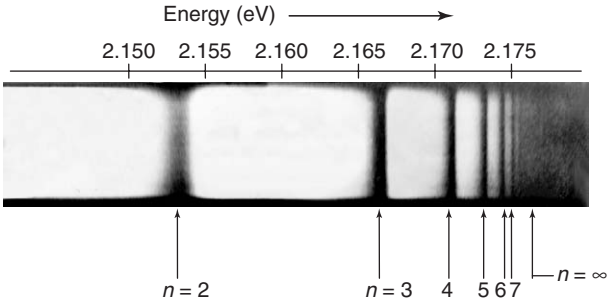

Figure 2 Part of the absorption spectrum of high-quality Cu_2O crystal at $T = 2$ K. The arrows with numbers indicate the optical transitions to the states with the corresponding principal numbers n. (BP Zakharchenya, unpublished data.)

Exciton Optical Spectra and Band Structure

Exciton optical spectra are closely related to the band structure of the crystal. Exciton transitions usually

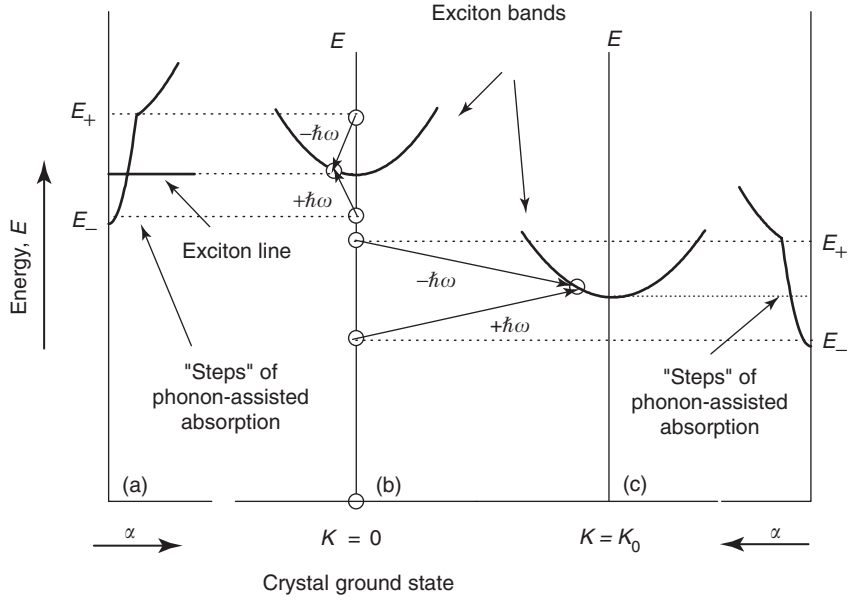

Figure 3 Schematic illustration of phonon-assisted exciton absorption in direct-gap and indirect-gap semiconductors (central part b). Open circles indicate crystal ground state, virtual intermediate states, and the final states in which the excitons are created. Arrows $-\hbar\omega$ and $+\hbar\omega$ show the scattering processes with the emission and absorption of the momentum conserving phonons, respectively. Left and right parts (a and c) depict schematically the spectra of phonon-assisted absorption. The absorption, corresponding to the processes shown in central part, starts at the energies E_- and E_+.

have high oscillator strength, narrow bandwidth, and strict polarization selection rules. This provides a unique tool for the study of the crystal band structure and determination of its parameters, such as the bandgap energies, the symmetry properties of the bands, and the carrier parameters. Each pair of valence/conduction bands produces a separate exciton series. In cubic semiconductors with zinc blende structure (GaAs, InP, ZnSe, ZnTe, CdTe, etc.), the valence band is split by a spin–orbital interaction into two components. The upper band, in turn, consists of two degenerated at $K = 0$ bands of light and heavy holes. As a result, two exciton series are expected in the exciton spectra. However, the series originating from the spin–orbit split valence band falls into the energy region of strong continuous interband absorption from the upper valence band and is strongly damped. In some zinc blende semiconductors (GaP, AlAs) and crystals of elemental semiconductors with a diamond-like structure (Ge, Si), the bandgap corresponds to transitions from the $K = 0$ states of the valence band to the conduction band minima situated at the edge of the Brillouin zone. In these cases, the transitions into the exciton states are possible only with the phonon participation, and have a form of continuous "steps."

The brightest example is given by the cubic Cu_2O crystals (cuprite structure), where the two hydrogen-like series (yellow and green) arising from the valence band splitting were observed. In the case of the yellow series, the wave functions of the carriers in the valence and conduction bands had the same parity. As a result, the optical transitions to the s states ($l = 0$) are forbidden in the dipole approximation, and the $n = 1s$ line is observed only as a weak quadrupole transition. The allowed (dipole) transitions starts $n = 2p$. The exciton lines up to $n = 11p$ were observed for the absorption spectrum of the "yellow" exciton series at $T = 4.2$ K. The transitions into the s and d states in Cu_2O were studied in detail using the two-photon absorption and excitation spectra of Raman scattering. In very thin Cu_2O platelets, two additional exciton series ("blue" and "violet") were observed. These series correspond to transitions from two upper valence subbands to the next conduction band with higher energy.

In uniaxial semiconductors with the wurtzite structure (CdS, CdSe, ZnS, ZnO, GaN), the valence band is split into three components, which give rise to three exciton series (A, B, and C) with different degrees of polarization of the dipole optical transitions with respect to the direction of the crystal axis c.

The precise determination of the bandgap energy is possible when at least two lines of the exciton series are detected. However, if even only one exciton line is observed, the analysis of the exciton spectra complimented by the independent information on the effective masses of carriers and the value of the dielectric constant allows a good estimate of the bandgap.

Fine Structure of Exciton Levels

The analogy of the exciton energy spectrum with that of the hydrogen atom is valid only in a first approximation. The important distinctions, leading to the essential and specific features of the exciton spectra, should be noted.

1. The screening of the Coulomb interaction between the electron and the hole cannot be described by the unique value of the dielectric constant. This screening arises due to the displacement of many atoms or ions in the crystal lattice, and depends on the character of internal motion of the electron and the hole, in particular, exciton state. As a result, the position of the $n = 1s$ exciton state, which is characterized by the fastest relative motion, is usually up-shifted with respect to the position predicted by the series convergence. Also, for the excited states, in distinction to the hydrogen atom, the degeneracy of s, p, and d levels in the exciton is usually lifted. In addition to the different character of the carrier motion, the splitting of s and p excited states arises also from the anisotropy of the hole effective masses, resulting from the complex character of the $E(K)$ dispersion in the valence bands.
2. The band states of electrons in the conduction band are characterized by the spin value $s = \pm 1/2$, and the states of the holes in the doubly degenerated valence band by the values of the angular momentum $J = \pm 1/2;\ \pm 3/2$. As a result, the exciton states with the magnetic quantum numbers $m = 0,\ \pm 1,\ \pm 2$ can be formed. As it follows from the conservation of the angular momentum, the one-photon (dipole) transitions are allowed only into the $m = \pm 1$ states ("bright" excitons). The energy levels of the exciton states with different m are split by exchange interaction. The magnitude of this splitting is usually small (0.1–1 meV for $n = 1s$), and decreases for the excited states in proportion to the oscillator strength. The exciton states with $m = 0,\ \pm 2$ ("dark" excitons), for which the dipole transitions are forbidden, nevertheless play a significant role in exciton relaxation and are very important for an understanding of the polarization properties and recombination kinetics of exciton emission.
3. For excitons, as for other intrinsic dipole excitations, one should distinguish the transverse states (T, with the exciton dipole momentum directed

perpendicular to the exciton wave vector K) and the longitudinal states (L, with the dipole momentum along the exciton propagation direction). The macroscopic electric field associated with the exciton oscillating polarization splits the L and T states by an energy proportional to the oscillator strength of the corresponding exciton transition. The magnitude of L–T splitting for $n = 1$ states in direct-gap semiconductors is ~ 0.5–2 meV. Due to the transversal character of the electromagnetic field of light, only the transverse excitons can be excited at the normal incidence of light on the crystal surface.

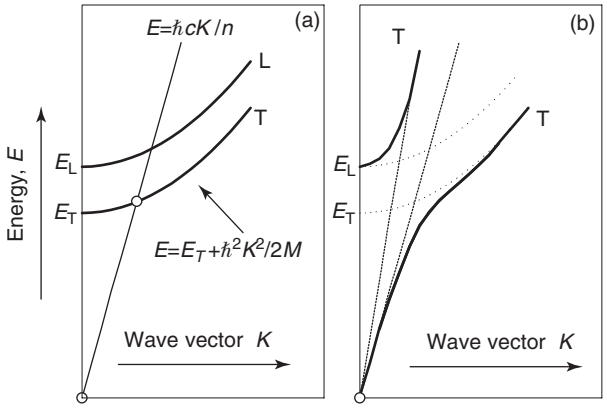

Figure 4 (a) Splitting of transversal T and longitudinal L excitons bands in mechanical approximation. Open circles indicate the unique exciton state which can be excited by light. (b) Dispersion curves of transverse polariton branches T_1 and T_2 arising due to the exciton–photon coupling.

The transversal waves of exciton polarization in the region of the exciton resonance are strongly mixed with the transversal waves of photon polarization, like it is a case for transversal optical phonons. As a result, in the resonance region, corresponding to the transition energy into the exciton state, the intrinsic excitations of the crystal can be no more considered as excitons or photons but represent a mixed excitation with a specific dispersion curve called the polaritons (**Figure 4**). The relative part of the exciton and photon properties smoothly changes along this dispersion curve, and the rather extended energy region (of the order of L–T splitting) is involved in the processes of resonant light absorption. In the region of the exciton resonance at the same energy, two waves transfer the energy inside the crystal. This situation was first designated by S I Pekar as an appearance of the additional waves. The oscillating structure, arising due to the interference of these two waves, was clearly detected in the transmission and reflection spectra of CdSe and CdS thin films (**Figure 5**). The dielectric constant in this region is a function not only of the energy, but also of the wave vector which represents a clear manifestation of the spatial dispersion. The account for the polariton nature of the exciton resonance is very important in the analysis of the

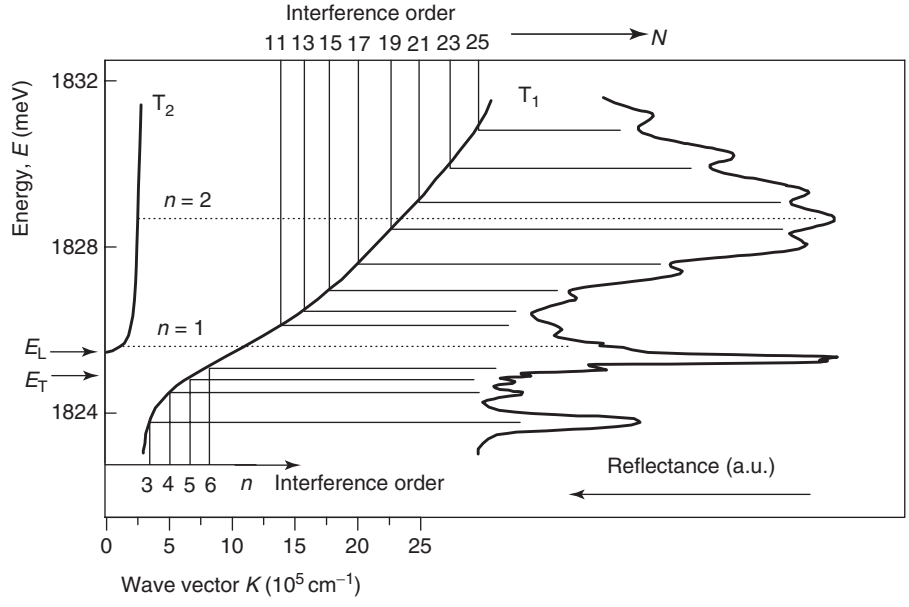

Figure 5 Interference pattern in the reflection spectrum in the region of $n=1s$ exciton resonance for thin CdSe platelet (thickness 0.24 μm, $T=4.2$ K) (right part). Left part shows the branches of polariton dispersion T_1 and T_2. The reflection minima with orders $n=3$–6 correspond to Fabri–Peroit interference of branch T_1 below the resonance. Dotted lines $n=1$ and $n=2$ indicate the minima of Fabri–Peroit interference for branch T_2 above the resonance. Reflection maxima with orders $N=11$–25 correspond to the interference between the branches T_1 and T_2. optical reflection spectra in the region of the exciton transitions.

Exciton Luminescence

At optical excitation below the fundamental gap E_g, the excitons can be created by light through the direct transitions to the E_n states. At optical excitation above E_g, the excitons can be formed through the Coulomb attraction of free electrons and holes generated in the process of interband absorption. The binding of free carriers into the excitons takes place after the carrier cooling on phonons and takes less than 10^{-9} s. However, in the process of cooling, an essential part of the free carriers can be trapped by donor or acceptor impurities.

The study of the excitation spectra of the exciton luminescence in partly ionic semiconductors has shown that a very efficient mechanism of exciton formation at the optical excitation above E_g is the creation of excitons in the process of phonon-assisted absorption with the simultaneous emission of LO phonons. This process takes part in resonance with the continuum exciton spectrum with many intermediate states available. As a result, the process of exciton formation through this mechanism is very fast ($\sim 10^{-12}$ s) and can involve emission of several LO phonons (up to 5–6), so that the spectral region for which it is important has an extent of ~ 0.2 meV.

The character of exciton luminescence in semiconductor crystals essentially depends on the purity of the crystal and the exciton lifetime. The translation motion of excitons in the crystal lattice provides an efficient transport of the energy of optical excitation to the impurities or defects where the excitons can be trapped or ionized. As a result, the luminescence spectra of semiconductors are usually dominated by the impurity-related emission, and the detectable luminescence of free excitons can be observed only in the most pure samples. For such crystals, the stationary population of excitons in the exciton bands can be formed. If the exciton lifetime is sufficiently long, the distribution of excitons on the kinetic energy will be in thermal equilibrium with the lattice. The excitons are quasiparticles with an integer spin and should obey the Bose statistics. However, for not very large exciton concentrations and not very low temperatures, the distribution of exciton kinetic energies can be described by the Boltzmann statistics. The resulting distribution can be written as

$$\frac{dN}{dE} \propto E_{kin}^{1/2} \exp\left(-\frac{E_{kin}}{kT}\right)$$

where E_{kin} is the exciton kinetic energy and T is the temperature. This distribution can be visualized through the process of phonon-assisted exciton annihilation which is a reciprocal one to the phonon-assisted exciton absorption. The exciton wave vector is transferred to the emitted phonons. As an example, **Figure 6** shows the luminescence spectrum of free excitons in thick ZnSe/GaAs epitaxial films, where the bands with the threshold energies down-shifted from the exciton resonance E_1 by the energy of 1LO and 2LO phonons are observed. At elevated temperature ($T = 30$ K), the shape of these bands demonstrates the Maxwell–Boltzmann distribution of excitons on the kinetic energy. The bands of phonon-assisted exciton annihilation were observed in many semiconductors, and they provide an excellent instrument for the monitoring of exciton stationary populations and the temperature of electronic subsystems.

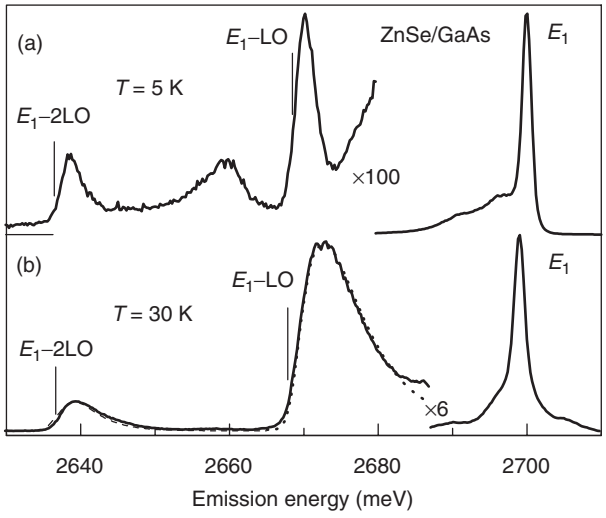

Figure 6 Exciton luminescence spectra of thick (4 μm) epitaxial ZnSe layer on GaAs at (a) $T = 5$ K and (b) $T = 30$ K. E_1 is the line of resonance luminescence of $n = 1s$ exciton state, bands $E_1 - \text{LO}$ and $E_1 - 2\text{LO}$ represent phonon-assisted exciton annihilation with simultaneous emission of one or two LO phonons. Dotted lines are theoretical fits of band shapes. (SA Permogorov, unpublished data.)

The theoretical description of the band shape and intensity of the zero-phonon line of exciton annihilation is more complicated due to the effects of resonant reabsorption. In this case, the model, simultaneously taking into account the exciton diffusion inside the crystal and the polariton structure of dispersion curves in the region of exciton resonance, should be used.

Exciton Spectra in External Fields

The apparent analogy between the exciton and atomic states has stimulated extensive studies of the influence of the external fields on the exciton spectra. The application of the uniaxial stress to the crystal

causes the splitting of exciton lines into several polarized components. The number and polarization of these components depends on the orientation of stress direction and the exciton wave vector with respect to the crystallographic axes, and allows one to obtain information on the symmetry of the exciton states, and hence, the bands responsible for exciton formation.

The study of the influence of an electric field on the exciton states is very difficult, both experimentally and theoretically. The experimental difficulties are connected with a strong heating of the sample by photocurrent arising at the sample illumination. Another difficulty is connected with the strong inhomogeneity of the electric field inside the sample caused by the formation of depletion regions. However, several experiments have been performed on low-conductivity Cu_2O samples and in compensated Ge.

The electric field causes a strong mixing of exciton states with different orbital numbers within one exciton series as well as between the states of different series. The main effect is the appearance of new lines forbidden without the electric field. A strong interaction of exciton states produces a complicated pattern of splitting and a nonlinear shift of exciton lines. In a strong electric field, the progressive broadening and disappearance of the exciton lines (starting from the higher members of the series) occur due to the exciton ionization (Franz–Keldysh effect).

The influence of a magnetic field on exciton spectra has been studied extensively. At low fields, a linear splitting of lines, very similar to the Zeeman effect in atoms, is observed. Additionally, a shift to the higher energies, quadratic in the magnetic field, (diamagnetic shift) takes place for all exciton lines. This purely relativistic effect is caused by the cyclotron acceleration of internal motion of the carriers in the exciton. In atoms, such a shift has been observed only for highly excited states in very strong fields. However, due to the large radii of exciton orbits, the diamagnetic shift in exciton spectra can be observed even at a few tesla.

A strong magnetic field modifies the internal structure of excitons. Due to the cyclotron acceleration of carrier motion, the exciton dimensions in the plane perpendicular to the magnetic field shrink and the binding energies of the exciton states increase. These modified states strongly elongated in the direction of the magnetic fields are called diamagnetic excitons. Further increase of magnetic fields leads to the formation of Landau subbands, both in the conduction and valence bands. The optical transitions between the Landau subbands lead to the appearance of oscillations in the spectrum of interband absorption above the fundamental edge. It has been found that these oscillations have a fine structure corresponding to the optical transitions in the states of diamagnetic excitons associated with every pair of the Landau subbands. In high magnetic fields, the shift of the lines of diamagnetic excitons follows that of the Landau subbands and is linear in the magnetic field.

Another analogy between the excitons and atoms is demonstrated by the possibility of exciton optical orientation at resonant pumping by circularly polarized light, or of the optical alignment of exciton dipole momenta at linearly polarized excitation. At resonant excitation, the resonant exciton emission demonstrates a very high degree of polarization of corresponding sense (up to 100%). A study of the dependence of this polarization on the strength and direction of the external magnetic field provides detailed information on the processes of energy and spin relaxation of excitons.

Excitons in Low-Dimensional Structures

In recent time, research efforts are concentrated mostly on the study of exciton states in heterostructures involving ultrathin "quantum wells" (QWs) formed by materials with bandgaps smaller than that of surrounding barriers. The confinement of carriers in QWs strongly influences both the internal motion of electrons and holes in the exciton and the translation motion of the exciton as a whole. The shrinkage of the exciton dimensions in the direction perpendicular to the plane of the QWs (z) increases the exciton binding energy up to four times, which is a theoretical limit for the ideal two-dimensional QWs. As a result, the exciton states can be stable and observable in the spectra up to room temperatures. This makes such heterostructures very attractive for practical applications in optoelectronics.

The exciton wave vector K_z is quantized in the z-direction, and the free translation exciton motion is possible only along the xy-plane, which essentially modifies the energy distribution of the density of states in the exciton bands.

The study of exciton spectra in QWs provides vast information on the properties of QWs, such as geometrical parameters, composition of forming material, the band offsets relative to the barrier, and the strain conditions of the QWs.

Excitons in Molecular Crystals

Energy Spectra and Band Properties of Excitons

In molecular crystals, the excitons can be very well described by the Frenkel model. Since the interaction between the atoms in the molecule is much stronger

than that between the atoms in different molecules, most of the crystal excitations are well localized within the single molecule and are closely connected with the molecular excitations in the gas phase. However, even relatively weak intermolecular interaction produces two very important features of the exciton. First, due to translation symmetry of the crystal lattice, the excitons can propagate in the crystal with a definite wave vector. The width of exciton bands is relatively small and ranges from 0.01 to 0.1 eV for dipole states. As a result, the exciton bands are strongly nonparabolic and the exciton velocities are rather small. Another consequence of intermolecular interaction is the splitting of nondegenerate levels into several components, the number of which is equal to or less than the number of molecules in the elementary cell of the crystal (so-called Davydov splitting). Optical transitions into the exciton states in molecular crystals, as in semiconductors, due to the momentum conservation are allowed only into the states with $K \approx 0$. The components of Davydov splitting are strictly polarized along the crystallographic axes.

Classical objects for the study of molecular excitons are crystals of benzene, naphthalene, anthracene, and other aromatic molecules, the lowest electronic excitations of which are situated in the visible or near-UV region of the spectrum. The crystals of aromatic molecules have a low symmetry (rhombic D_{2h}^{15} for benzene with four molecules in the unit cell, and monoclinic C_{2h}^{5} for naphthalene and anthracene with two molecules in the unit cell).

Three different kinds of excitons – electronic, vibrational, and vibronic – can exist in molecular crystals. Electronic excitons correspond to internal molecular electronic transitions into singlet and triplet excited states. The transitions into singlet states are allowed and produce strong absorption lines. The radiative times for such transitions have an order of several nanoseconds, whereas for triplet states the radiative times can reach tens of milliseconds.

Vibrational excitons originate from the high-frequency intramolecular vibrations and in many aspects are similar to the electronic excitons. They are characterized by narrow bands with a well-defined wave vector and are split on strictly polarized Davydov components. The intermolecular vibrations have much smaller frequencies and form a usual phonon spectrum of a crystal.

Since the electronic transition inside the molecule decreases the frequencies of intramolecular vibrations, the bound state of electronic and vibration excitations can be formed. Such new excitations can propagate in a crystal with a common wave vector, and are called vibronic excitons. However, in most cases the dissociated pairs of electronic and vibronic excitons are produced by optical excitation. This process is completely analogous to the phonon-assisted absorption in semiconductors and leads to the appearance of broad bands. Since the widths of some exciton bands (electronic or vibronic) are very small, the shape analysis of such bands allows one to restore the distribution of density of states in the exciton bands.

Exciton Luminescence in Molecular Crystals

As in semiconductor crystals, the luminescence spectra of molecular crystals strongly depend on the crystal purity and exciton lifetime. In crystals of moderate quality, most of the luminescence is associated with defects or impurities, since the excitons provide a good transport of energy to these centers. The luminescence of free excitons can be observed only in extremely pure and perfect crystals.

A very interesting phenomenon has been observed in the decay kinetics of free exciton luminescence in molecular crystals. The allowed singlet transitions have radiative lifetimes of several nanoseconds and demonstrate very fast decay at pulsed excitation. However, it has been found that the corresponding emission can last for tens of milliseconds. Such a phenomenon has been called a delayed fluorescence. It occurs if the long-living states of triplet excitons have lower energy than the singlet states. A fast relaxation of optical excitation to the triplet states creates a pool of stored energy. The radiative annihilation takes place at the collision of two triplet excitons with the formation of a singlet state. The delayed fluorescence in molecular crystals represents one of the most clear examples of cooperative radiation processes in solids.

Excitons: Theory

P B Littlewood, University of Cambridge, Cambridge, UK

Introduction and Basic Ideas

The electronic band structure in a solid gives a formal accounting of the excitation energy $E_n(\boldsymbol{k})$ for adding to the ground state of the system a single carrier in the state of momentum $\boldsymbol{k}$. If the energy is greater than the chemical potential – that is, an empty state – this refers to an electron; if the energy is below the chemical potential – a filled state, the excitation is a hole. In a semiconductor or insulator there is a gap between the creation of electrons and holes. Of course, adding one electron and one hole in different bands or with different momenta creates an excited state of the system – and if the electrons and holes did not interact, one could of course enumerate the energies of the excited states just from the one-particle bands. However, the electron and hole are oppositely charged and therefore attract – the minimum energy required to create an electron–hole pair is therefore always less than to create either particle separately. The attraction between these two oppositely charged single-particle excitations creates a bound state called an exciton – just as the Coulomb attraction between a proton and an electron creates the bound states of the hydrogen atom (**Figure 1**).

Excitons recapitulate within a solid much of the physics of solids themselves, but with the added richness provided by the complexity of the bandstructure on which they are based. There are varieties of excitons, just as there are varieties of excited atomic states. Excitons themselves interact: there exist

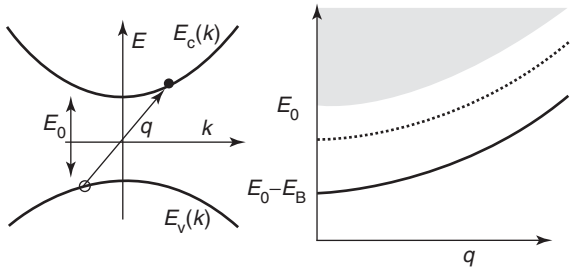

Figure 1 On the left is a sketch of the lowest conduction $E_c(k)$ and highest valence $E_v(k)$ bands for a simple direct gap semiconductor with a quadratic dispersion and masses for electron and hole of m_e, m_h. If these bands described noninteracting particles, the lowest excitation energy of total wave vector q is then $E_o + \hbar^2 q^2/2M$, where $M = m_e + m_h$, which marks the edge of a continuum of excitations of free electrons and free holes, shown by the grey hatched region on the right. Allowing for the binding of the electron and hole, the lowest excitations are now excitons – a series of discrete states that disperse approximately parallel to the bottom of the continuum, but shifted downward by the binding energy E_B.

excitonic molecules, excitonic liquids, and possibly even coherent condensed states akin to the Bose–Einstein condensation of cold atoms – though these have not yet been unequivocally observed. In some materials, excitons are heavy and easily localized, whereas in others they are very light and readily propagate throughout the solid. Excitons are composite bosons (formed from two fermions) and have spin degrees of freedom. They may trap on defects and disorder, and may also have strong interactions with the lattice leading to the formation of excitonic polarons. And most importantly, excitons often interact strongly with light, so that they are often the dominant feature in optical spectra of solids. Excitons may be observed in such a case by their absorption profile, but more frequently by their luminescence – the recombination emission of light

which is therefore, at the total energy of the electron–hole pair. Even if they do not decay radiatively, excitons are a transient phenomena – they have a finite lifetime, which can however be very long in some materials at low temperature.

Binding of Excitons

Frenkel Excitons

Conceptually, the simplest picture of an exciton emerges for crystals made of tightly bound electron states, such as rare gases or highly ionic solids. In these materials the electronic bands are narrow, and excitations within the solid are thus nearly localized. An atomic excited state, embedded within a lattice of unexcited atoms, is a cartoon for a Frenkel exciton – but of course since all the atoms in the solid are identical, this excitation hops from atom to atom throughout the solid to form a weakly dispersing band with a large mass. While the original concept of a Frenkel exciton was based on a transition occurring in a lattice of neutral atoms, highly localized excitons may also involve charge transfer between orbitals on nearby atoms or groups of atoms. The latter is often the dominant situation in polymers, and organic materials. Often the correct description is a mixture of Frenkel and charge transfer exciton, as one can see in **Figure 2** by the shift of absorption and the development of new structure between an isolated molecule and a crystal.

Generally, these highly localized excitons require detailed microscopic theory to analyze their spectral structure. Being localized, they couple strongly to vibrational degrees of freedom of the molecule, often producing extra "vibronic" structure.

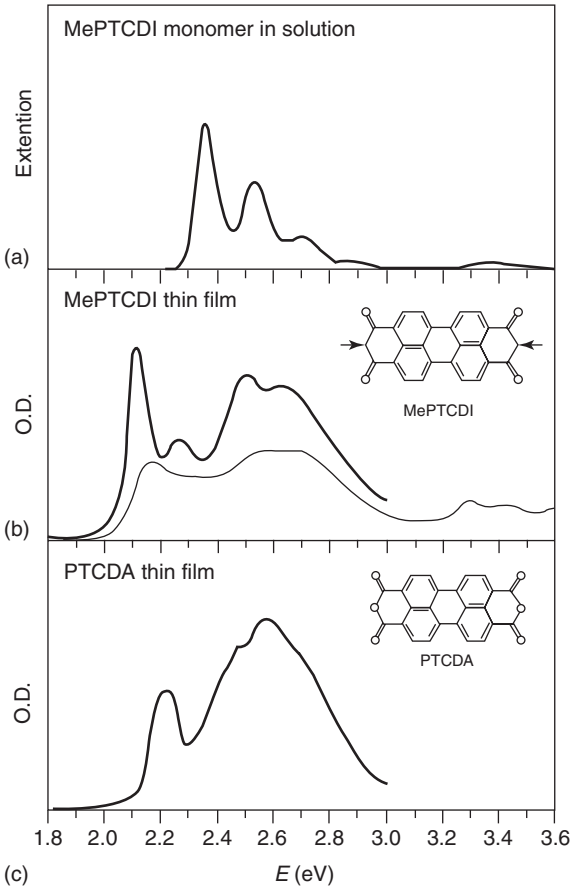

Figure 2 A comparison of absorption spectra of monomers with crystals where the excitons are highly localized. (a) The absorption of isolated molecules in solution, (b) The optical density of a polycrystalline film of the same material. The thick curve is at 5 K in *p*-polarization and the thin curve at 293 K in *s*-polarization. (c) A crystalline film of a similar compound at 5 K. (From Hoffmann M, Schmidt K, Fritz T, Hasche T, Agranovich VM, and Leo K (2000) *Chemical Physics* 258: 73.)

Hydrogenic Excitons

The opposing limit of weakly bound excitons is much more straightforward to analyze, and this produces the excitons familiar in direct gap semiconductors such as GaAs. Here the band dispersion is large, so that the energy cost of occupying states of large momentum $k \approx \pi/a$ (where a is the lattice constant) is large. Hence, the excitonic bound state is a wave packet made up from electron and hole states near $k \approx 0$. The valence and conduction band states are Bloch states, of the form

$$\psi_{nk}(\boldsymbol{r}) = u_{nk}(\boldsymbol{r})\mathrm{e}^{\mathrm{i}k\cdot r} \qquad [1]$$

where u is a periodic function on the crystal lattice, and $n = c, v$ will refer to the conduction and valence bands respectively. If the momentum dependence of u_{nk} is neglected, the wave function for an exciton becomes separable,

$$\Psi(\boldsymbol{r}_\mathrm{e}, \boldsymbol{r}_\mathrm{h}) = u_{c\boldsymbol{k}=0}(\boldsymbol{r}_\mathrm{e}) \times u_{v\boldsymbol{k}=0}(\boldsymbol{r}_\mathrm{h}) \times f(\boldsymbol{r}_\mathrm{e} - \boldsymbol{r}_\mathrm{h}) \times \mathrm{e}^{\mathrm{i}q\cdot R} \qquad [2]$$

Here R is the center of mass coordinate, and q the corresponding momentum (see **Figure 1**). $f(\boldsymbol{r})$ is the exciton wave function in relative coordinates, and satisfies the Schrödinger equation

$$\left[\frac{-\hbar^2}{2\mu}\nabla^2 - \frac{e^2}{4\pi\varepsilon\varepsilon_\mathrm{o} r}\right] f(\boldsymbol{r}) = (E - E_0) f(\boldsymbol{r}) \qquad [3]$$

where $\mu = m_\mathrm{e} m_\mathrm{h}/(m_\mathrm{e} + m_\mathrm{h})$ is the reduced mass, ε the relative dielectric constant, and E_0 the single-particle gap.

This Wannier exciton then has the spectrum of a hydrogen atom, with the difference being that, in

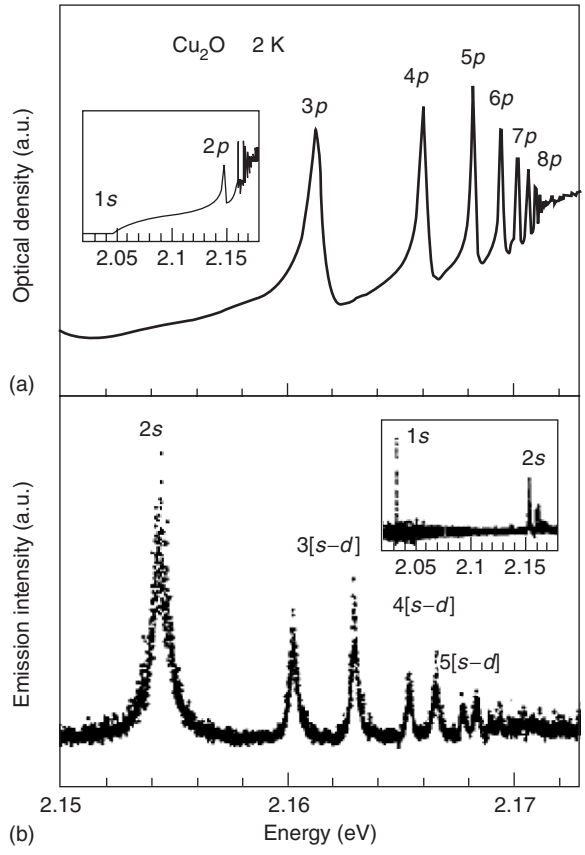

Figure 3 Exciton spectrum in Cu_2O. The upper panel is derived from one-photon absorption (and thus begins with the 2*p* state) and the lower panel shows the two-photon absorption, showing thus *s*- and *d*-series. The insets show the full spectrum. (From Matsumoto H, Saito K, Hasuo M, Kono S, and Nagasawa N (1996) *Solid State Communications* 97: 125.)

direct gap semiconductors such as GaAs, the effective mass is small ($\mu/m \approx 0.1$) and the dielectric constant is large ($\varepsilon \approx 10$). This means that the binding energy

$$E_B = \frac{\mu e^4}{8\varepsilon^2 \varepsilon_o^2 h^2} = \frac{\mu}{m}\frac{1}{\varepsilon^2}\,\text{Ryd} \qquad [4]$$

may be a small fraction of the Rydberg (Ryd = 13.6 eV). The size of the exciton is given by an effective Bohr radius

$$a^* = \frac{\varepsilon \varepsilon_o h^2}{\pi \mu e^2} = \varepsilon \frac{m}{\mu} a_o \qquad [5]$$

much larger than the hydrogen Bohr radius $a_o =$ 0.05 nm. Thus, the wave function extends over several unit cells, which justifies the approximate expression made for the wave function in eqn [2] (**Figure 3**).

Indirect Excitons

It is not necessary for exciton states to correspond to vertical band transitions (i.e., $q = 0$ in **Figure 1**) because a wave packet can be constructed about any band extremum. So, for example, in Ge the lowest excited state is made from wave packets of holes at $k = 0$ and electrons at the equivalent conduction band minima along the [1 1 1] direction at the Brillouin zone boundary. A similar situation pertains for Si, except that the electrons are confined to six pockets in the [1 0 0] directions (inside the Brillouin zone). These excitons are called "indirect" because they require a nonzero momentum to connect the electron and hole. Momentum conservation then does not allow the exciton to directly decay into a photon, and one requires either a process involving recombination also with emission of a phonon, or scattering from an impurity, a surface, or other confinements. This is typically very inefficient, which is why Si is not used for optical devices.

Confined Excitons: Quantum Wells, Wires, and Dots

The engineering of quantum wells in semiconductors can also be used to manipulate excitonic states. In $GaAs/Ga_{1-x}Al_xAs$ quantum wells (the canonical system, though many of the III–V and II–VI series are used), one may confine both electron and hole to a narrow sheet, comparable or smaller in size than the effective Bohr radius a^*. It is also possible to create more complicated structures including quantum wires and quantum dots. There are two principal effects. First, the extra confinement brings the electron and hole closer together and increases (sometimes substantially) the binding energy producing a shift in the energy of absorption and luminescence in comparison to bulk material. The second effect arises because of the structure of the top of the valence band which in a bulk system has a degeneracy between the light and heavy hole bands at $k = 0$ (the states are *p*-like, which therefore have a threefold orbital degeneracy under cubic symmetry; with spin–orbit coupling the pair of bands are the fourfold-degenerate $J = 3/2$). This degeneracy is broken by the quantum well, which fixes a local axis, and splits the light and heavy hole bands, leading to a further separation of the two types of excitons.

Since an applied field will pull the electron and hole apart from each other the exciton energy and its binding are affected by applied electric fields. In a bulk system quite small fields can ionize the exciton, but if the exciton is confined either to a well or a quantum dot (see **Figure 4**) the electron and hole will be trapped and very large shifts of the exciton luminescence with electric fields can be produced. This is the "quantum-confined Stark effect," a principle used in semiconductor laser modulators.

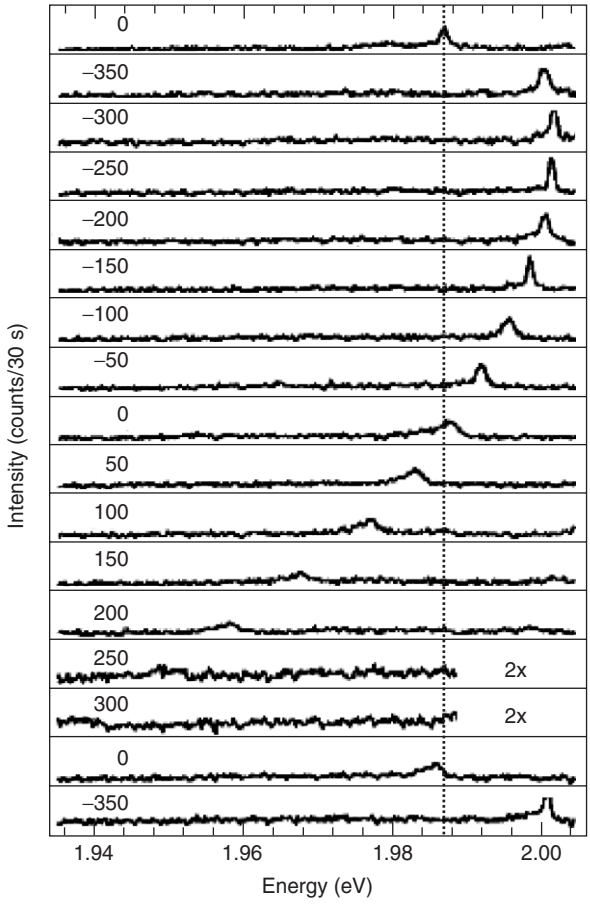

Figure 4 Luminescence of a 7.5 nm CdSe nanocrystal shows the quantum-confined Stark effect. The position of the exciton line shifts under a range of electric fields – values in kV cm^{-1} are shown for each trace. (From Empedocles SA and Bawendi MG (1997) *Science* 278: 2114.)

Interactions between Excitons

Excitonic Molecules and Complexes

Like atoms, excitons interact and may bind to form molecules and other complexes. Atomic H binds to form H_2 in an exothermic reaction that generates about 1/3 Ryd per molecule. The analog of H_2 is the biexciton (sometimes labeled as X_2) – which is however typically less bound than H_2 because of the finite hole mass. In a bulk semiconductor with equal mass electrons and holes, the binding energy of a (hydrogenic) biexciton is about 0.03 E_B, proportionately one order of magnitude smaller than for H_2; but in GaAs, where the hole is proportionately heavy, the binding energy can be substantial (see **Figure 5**).

Stable species can also be made when excitons bind to electrons and holes (trions) – a situation which can arise upon optical excitation of a low-density electron or hole gas in a semiconductor. In general, many exciton complexes have been discovered.

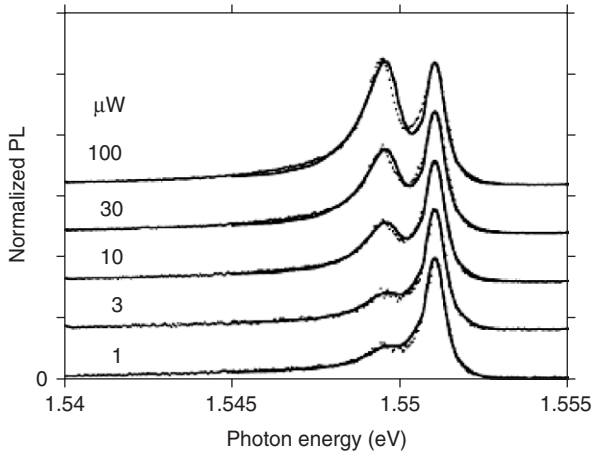

Figure 5 Optical emission from excitons and biexcitons in GaAs, normalized to the intensity of the excitonic peak and resulting from optical pumping at an energy well above the exciton emission. At increasing intensities of illumination, the biexciton emission grows because two excitons must collide and bind within the timescale for recombination. The solid line is a fit to the data. (From Phillips RT, Lovering DJ, and Denton GJ (1992) *Physical Review B* 45: 4308.)

Electron–Hole Liquid

If the density of excitons is increased so that they overlap, they lose their individual character as atoms, as the electrons and holes become unbound. The high-density two-component plasma so formed is then an electrical conductor – with one fermi surface each for electrons and holes – similar to an equilibrium semimetal. The transition between the excitonic insulator and the plasma state occurs at the density $n(a^*)^d \approx 1$ for the Mott metal–insulator transition. This has for many years been a focus of study in semiconductors because the large effective Bohr radius means that this regime can be reached at moderate excitation levels. A typical semiconductor laser is in this density range, though also usually at a temperature well exceeding the exciton binding energy.

In Si and Ge, it turns out that the dense plasma phase is lower in energy than to distribute the electron–hole pairs as a dilute gas of excitons or biexcitons. The origin of this phenomenon is the multivalley nature of the conduction band in these materials – in the plasma phase the kinetic energy cost of the excitons is distributed over many valleys so its stability is correspondingly enhanced. In consequence, high-density electron–hole droplets (**Figure 6**) form spontaneously and can also be manipulated by applied elastic strain.

Coherence and Bose–Einstein Condensation

Because excitons are light-mass bosons (albeit composite), there has been a long-standing interest to

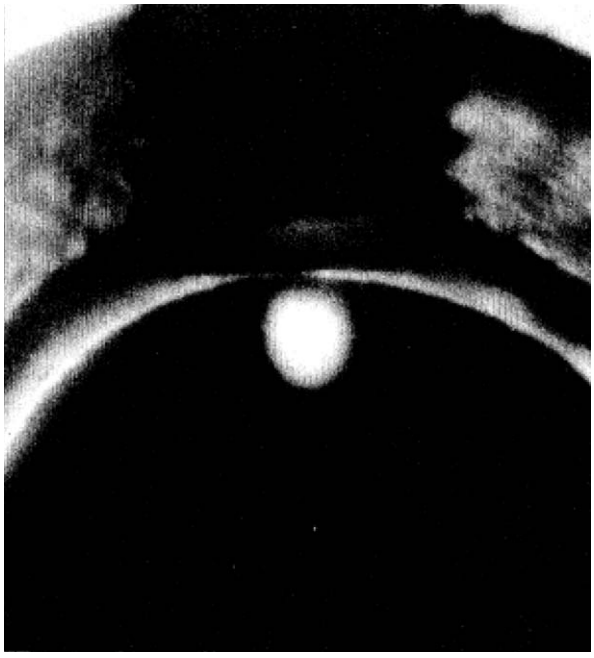

Figure 6 Electron–hole liquid in Ge. A photograph of a droplet of electron–hole liquid at 2 K in a 4 nm diameter Ge disk, stressed by a nylon screw (top) along (110) and viewed through an (001) face. The central bright region is the *e–h* recombination luminescence from the liquid confined in a potential well of maximum shear stress. The bright ring around the sample is recombination luminescence scattered from the surface of the crystal. (From Markiewicz RS, Wolfe JP, and Jeffries CD (1977) *Physical Review B* 15: 1988.)

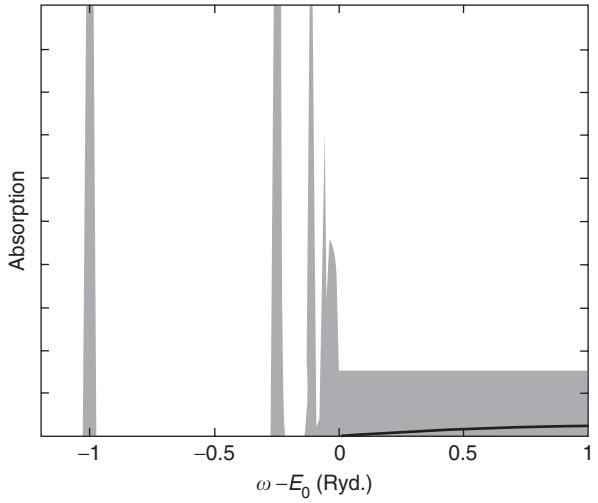

Figure 7 Absorption predicted by the Elliott formula of eqn [7]. Notice that even above the continuum edge at E_0 the absorption (gray) is enhanced over that predicted in the absence of Coulomb interactions (solid line).

observe Bose–Einstein condensation of excitons. In order to explore such physics, one needs to lower the temperature below the point where the thermal de Broglie wavelength exceeds the interparticle spacing, that is, a temperature $k_B T_o = \hbar^2 n^{2/3}/M$. Amongst the systems studied are Cu_2O (which has long-lived excitons that are dipole forbidden), CuCl (which has very stable biexcitons), and two-dimensional quantum wells (in which the electrons and holes can be physically separated). Such a state would be interesting not just for its statistical physics, but also because of the presence of spontaneous phase coherence, as in superfluid He, or cold atomic condensates.

While it has proved possible to enforce or encourage coherence through optical means, evidence for Bose–Einstein condensation of excitons in thermal equilibrium is still meagre.

Optical Properties

As discussed above, one of the principal reasons that excitons are so evident is because of their strong effects on the optical properties of solids. For very localized Frenkel excitons, it is largely correct to think of excitons as being atomic or molecular species, localized on specific sites in the solid. In general, it is not simple to calculate optical properties of excitons, except for the specific (and fortunately rather common) case of the hydrogenic Wannier exciton.

Dipole Coupling

Here, only the common case where the conduction and valence bands are of relative odd parity is considered (as in zinc blende II–VI and III–V semiconductors) so that the dipole matrix element

$$p_{cv} = \langle \psi_{ck} | \boldsymbol{e} \cdot \hat{\boldsymbol{p}} | \psi_{vk} \rangle_{k=0} \qquad [6]$$

is nonzero and in a cubic system independent of the polarization direction $\boldsymbol{e}$. The probability P per unit time and per unit volume that an electromagnetic wave with a vector potential $A\boldsymbol{e}\, e^{i\omega t - \boldsymbol{q}\cdot\boldsymbol{r}}$ will be absorbed to create an exciton is given by the Elliott formula

$$P = \frac{4\pi}{\hbar}\left(\frac{eA}{m}\right)^2 |p_{cv}|^2 f(0)^2 \delta(E_{ex} - E_0 - \hbar\omega) \qquad [7]$$

where the wavelength of light is assumed to be long enough so that $\boldsymbol{q} = 0$.

The answer is a sequence of lines at the energies $\hbar\omega_n = E_0 - \mathrm{Ryd}^*/n^2$ corresponding to the principal quantum numbers $n = 1, 2, 3, \ldots$, their intensities depending on the relative wave function $f(r)$ evaluated at the origin (when the electron and hole are coincident). Thus, the absorption is largest if the

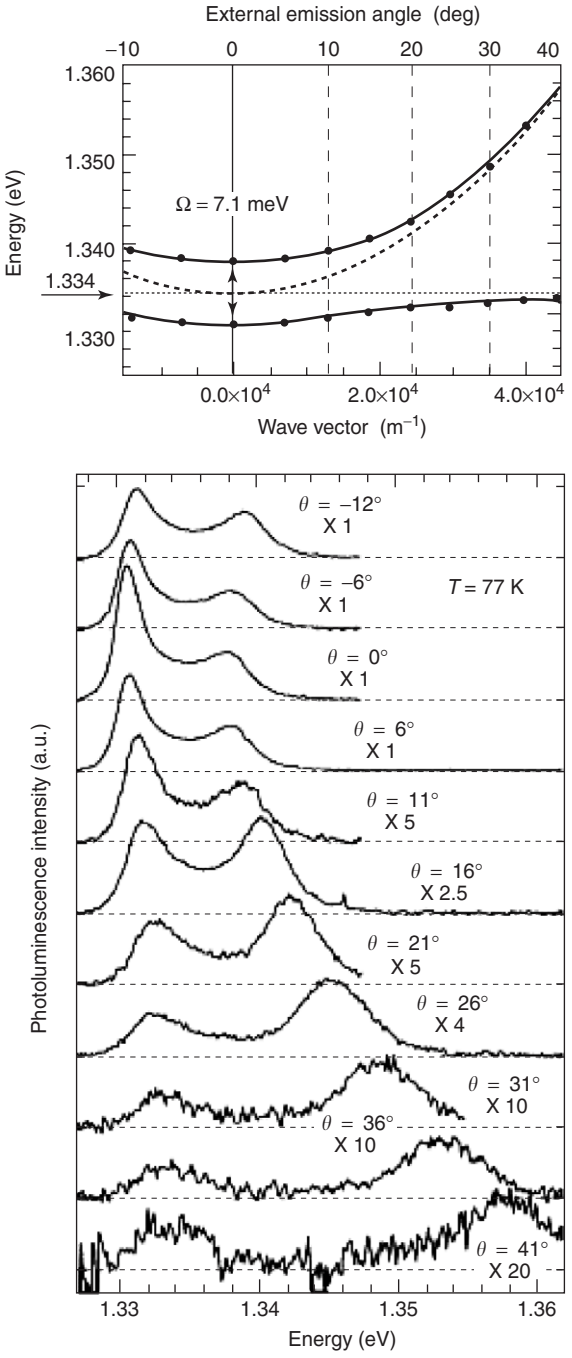

Figure 8 Dispersion of two-dimensional microcavity polaritons. Light is confined between two planar mirrors so as to fix the perpendicular momentum and to give a dispersion $\omega = \sqrt{\omega_0^2 + c^2k^2}$, where k is the momentum parallel to the plane, $\omega_0 \approx c\pi/L$, where L is the separation between the mirrors, and this can be chosen to be resonant with the exciton energy as in the figure (a). On the scale of the wavelength of light, the exciton dispersion is negligible. The mixing of the two modes gives rise to level repulsion, and the dispersion marked by the solid points. This dispersion is derived from the lower figure, which shows the luminescence from the microcavity as a function of angle, which can be directly converted into the parallel momentum k. (From Houdre R, Weisbuch C, Stanley RP, Oesterle U, Pellandini P, and Ilegems M (1994) *Physics Review Letters* 73: 2043.)

exciton is tightly bound (since $f(0)^2 = 1/\pi(a^*n)^3$) and also if the basis states supporting the Bloch states are strongly dipole active. Equation [7] gives only the Rydberg series below the continuum, but above and close to the edge of the continuum absorption, the excitonic effects enhance the absorption above that to be expected in free electron theory, as shown in **Figure 7**.

Exciton Polaritons

A peak in the absorption such as shown in **Figure 7** corresponds to a pole in the real part of the dielectric function, so below the gap,

$$\varepsilon(\omega) \approx \varepsilon_\infty + \frac{A_n}{\omega_n - \omega} \qquad [8]$$

where the amplitudes A_n are proportional to the coefficients in eqn [7]. A pole in the dielectric response is a free mode of oscillation of the polarization; when light travels in a polarizable medium such as this, the coupled modes are called "polaritons." These modes can be made visible beautifully by confining the light between mirrors to form a planar microcavity (**Figure 8**).

For excitons that are strongly localized and thus subject to disorder and incoherent fluctuations, one rarely observes fully coherent modes. But nevertheless the resonant process that transfers an exciton from one localized state to a resonant one nearby can be important, in a process called Förster transfer.

Fermi Surface Measurements

C Bergemann, University of Cambridge, Cambridge, UK

Introduction

The Fermi surface is the envelope of the filled electronic states of a metal in momentum space. In the simplest and radically approximate view of a metal as free electrons in a box, for example, the electronic states are plane waves with an energy depending quadratically on the momentum. The Pauli exclusion principle prevents the electrons from all simultaneously occupying the lowest energy, zero momentum state, and instead the overall ground state is formed by the electrons occupying distinct states such that the total energy is minimized: they are bunched around the origin of momentum space in a sphere. In this case, the Fermi surface is simply the surface of that sphere.

Surprisingly, the basic notions of this picture survive even when the free-electron approximation is not applicable, for example, in the presence of substantial crystal lattice potentials or strong electron–electron correlations. The deep insight gained by Fermi-liquid theory is that the elementary excitations in most metals still possess a well-defined wave vector, and that there is still a Fermi surface separating filled from empty states. The main differences to the free-electron case are (1) that surface is, in general, no longer spherical, and (2) the effective electron mass can deviate from its bare value.

The physical properties of any system at low temperatures are determined by the low-energy excitations, and for a metal these are the states near the Fermi surface. This means that knowledge of the shape of the Fermi surface, and of the energy dispersion in its immediate vicinity, are of paramount importance in order to understand the properties of a metal.

Correspondingly, there are many direct as well as indirect ways of determining Fermi surface properties from experiment. On the most basic level, the DC conductivity is proportional to the overall Fermi surface area, for example, while the Hall effect can indicate whether the surface is mostly electron-like (enclosing filled states) or hole-like (enclosing empty states). However, a small number of experimental methods have proved to be extraordinarily sensitive and suitable to give a full account of the Fermi surface geometry, and this article attempts to give a brief introduction into these methods, with a particular focus on the de Haas–van Alphen (dHvA) effect and angle-resolved photoemission spectroscopy (ARPES).

New Materials and New Questions

Fermi surface measurements date back to the seminal discovery of the dHvA effect in bismuth in 1930. From that time until the 1970s, both measurement techniques and theoretical insight were gradually refined until the physics of most ordinary metals, in particular the elements, was very precisely and satisfactorily understood. This "golden age of fermiology" was superseded in the 1980s by a new era where novel materials broadly denoted as correlated electron systems have posed new challenges, both theoretical and experimental, to our understanding of metals. Examples of such new materials are the heavy fermion compounds, organic molecular crystals, high-T_c and other unconventional superconductors, and quantum critical systems.

These challenges have been met both with further refinements of existing techniques, like dHvA, and the arrival of new ones such as ARPES. At the same time, the experimental scope has shifted slightly, in that Fermi surface probes are increasingly used to study not merely the Fermi surface geometry itself, but also the influence of correlations on the electronic structure. Such experimental information is very valuable since a realistic and reliable quantitative prediction of the effect of correlations, and especially of the electron mass enhancement, is

presently well beyond the capabilities of theoretical band structure calculations.

One further development, less obvious at first sight, is that many correlated materials of contemporary interest possess a reduced effective dimensionality. In particular, the layered transition metal oxides and a number of organic molecular metals can be very anisotropic: quasi-2D or even quasi-1D. This has led to the development of new techniques specifically tailored for such materials of reduced dimensionality.

Quantum Oscillations – Physical Principles

The dHvA effect is the traditional workhorse of Fermi surface measurements. Broadly speaking, it relies on the interplay between the Fermi surface and orbital quantization in a magnetic field. This interplay is only visible under conditions that require significant experimental efforts: very low temperatures ($\sim$1 K or less), very large magnetic fields ($\sim$10 T or more), and for very pure materials, typically with mean free paths $\sim$1000 Å or longer, corresponding to low-temperature residual resistivities $\sim 1\,\mu\Omega$ cm or less. These efforts are rewarded with precise information about both the Fermi surface geometry and the thermodynamic effective masses.

To understand the origin of the effect, we need to consider the behavior of electrons in a magnetic field B. Classically, a freely moving electron in this case undergoes helical motion in real space; in momentum space, the electron traverses a circular orbit. In quantum mechanics, the solutions ψ_n of the Schrödinger equation in the presence of a magnetic field reflect this cyclotron motion, with a radial part peaked at a distance $r_n^2 = (2n+1)\hbar/eB$ from the center of the motion. The orbital radius and area in momentum space are $k_n = eBr_n$ and $A_{k,n} = (n+1/2)2\pi eB/\hbar$, respectively. Thus, the cyclotron orbits in k-space are confined to so-called Landau tubes with an area that is quantized in units proportional to B.

Consider a 2D gas of free, noninteracting electrons, at low temperature and in zero magnetic field. The filled plane wave eigenstates are inside the Fermi contour with radius k_F around the origin in momentum space. If a magnetic field is switched on, the electrons redistribute into the orbital eigenstates, and instead of having all k-states up to $k < k_F$ filled, one now has all the orbital states up to $k_n < k_F$ occupied. (Taking k_F, and with it the chemical potential, to be constant – this is valid in most 3D metals, but in materials of reduced electronic dimensionality this assumption can break down, necessitating a more intricate treatment than set out here.)

As the magnetic field is increased, the orbital areas $A_{k,n}$ grow proportional to B, and one by one the orbital states will pass through the Fermi contour. As a state does so, it abruptly becomes vacant. Since the degeneracy of the orbital states is extremely high, this means that the system is abruptly shedding a macroscopic fraction of its electrons. This occurs every time an orbit crosses the Fermi contour: $A_{k,n} = A_F$, where A_F is the Fermi contour area, or $\hbar A_F/eB = 2\pi(n+1/2)$. This implies that the electron number has an oscillatory component proportional to $\sin(2\pi F/B)$ as a function of inverse magnetic field, where F is the so-called dHvA frequency: $F = \hbar A_F/2\pi e$ (which has the units of magnetic field).

In real metals, which are non-2D, the basic concept remains the same: in the presence of a magnetic field, the quasiparticle eigenstates of a Fermi liquid redistribute analogously into orbital states in k-space along an equal energy contour of the electronic band dispersion perpendicular to the applied field. The geometrical shape of these orbits can vary, but provided one deals with closed orbits, their area is still quantized in units of $2\pi eB/\hbar$ (this is a consequence of the Bohr–Sommerfeld quantization rule). Orbital states still become vacant as they cross the Fermi level, but the major difference to the idealized 2D case is that now the area A_F of the equal energy contour at the Fermi level is not constant any more. The respective local dHvA frequency $F = \hbar A_F/2\pi e$ therefore varies in k-space, so that there is a continuous band of oscillations $\sin(2\pi F/B)$ which has to be integrated.

This integration can usually be simplified in the saddle-point approximation. The integrand $\sin(2\pi F/B)$ is rapidly varying, and only the extremal cyclotron orbits areas lead to a macroscopic magnetization. Therefore, the observed oscillation frequencies give information about the "maximum" and "minimum" cross-sections of the Fermi surface perpendicular to the magnetic field direction (**Figure 1**).

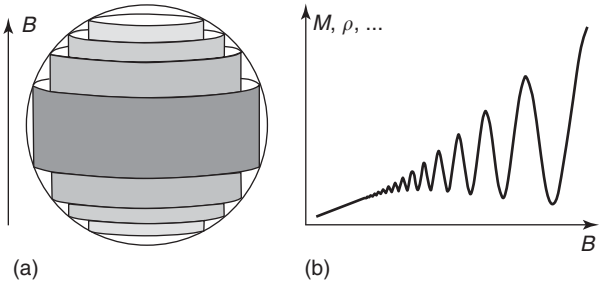

Figure 1 (a) Landau tubes and the Fermi surface in momentum space. As the magnetic field increases, the tubes expand and move through the Fermi surface, leading to (b) quantum oscillations. They are sketched here with typical impurity damping, leading to rapid loss of signal at low fields.

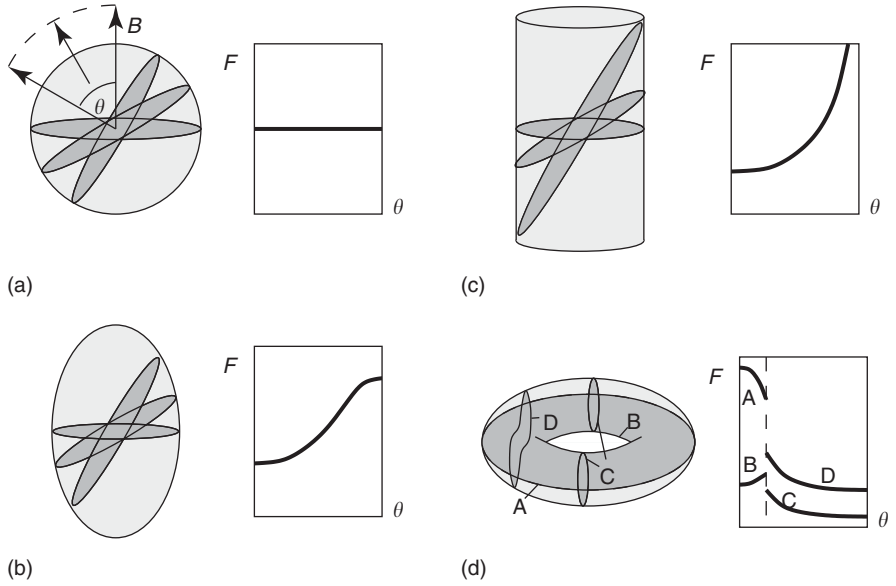

Figure 2 Fermi surface tracing using dHvA frequency information. (a) A spherical Fermi surface has direction-independent dHvA frequencies. (b) The cross-sectional areas, and dHvA frequency, of prolate ellipsoids increase for off-axis field directions, and (c) even diverge in the extreme case of a cylindrical Fermi surface. (d) More complicated features are possible, in particular for multiply connected surfaces with hole orbits.

In order to establish the overall shape of the Fermi surface one has to solve the inverse problem: given the observed dHvA frequencies along several field directions, what is the likely shape of the surface? This is usually done with the guidance of band structure calculations, but **Figure 2** gives a flavor of the relation between Fermi surface shape and the angular frequency behavior.

Quantum Oscillations – Experimental Approach

These quantum oscillations can, under favorable conditions, be observed in most thermodynamic and transport material properties. Experimentally, the best signal-to-noise level is usually achieved by probing quantum oscillations in the susceptibility (dHvA effect) or in the resistivity (Shubnikov–de Haas, SdH effect), the latter being the method of choice in restricted geometries without sufficient space for susceptibility coils, such as pressure cells.

The material in question needs to be of sufficient purity that, broadly speaking, the scattering time is longer than the cyclotron orbital period. This requirement translates, for typical Fermi velocities and Fermi surface geometries, into an impurity-limited low-temperature resistivity of $1\,\mu\Omega\,\mathrm{cm}$, or a mean free path of 1000 Å. These values constitute serious challenges to metallurgists and materials scientists, in particular for the binary and ternary compounds of contemporary interest. The purity requirement becomes less stringent in larger fields; so many dHvA experiments are carried out at dedicated DC or pulsed high magnetic field facilities.

Temperature Damping and Effective Masses

Finally, observation of the dHvA effect necessitates very low sample temperatures – but this temperature sensitivity turns out to be not just a vice, but also a virtue of the technique. The energy difference between two adjacent Landau tubes is $\hbar\omega_c^* = \hbar eB/m^*$, and if the thermal energy $k_B T$ exceeds this value, the quantum oscillations will be rapidly attenuated. The characteristic frequency ω_c^* and mass m^* are the fully renormalized thermodynamic values which – in most cases studied so far – add up to the α-coefficient in the low-temperature specific heat. ω_c^* and m^* usually differ from the values probed in a cyclotron resonance experiment.

An exact quantitative treatment shows that the oscillations will be damped by a factor $X/\sinh X$, known as the Lifshitz–Kosevich formula, where $X = 2\pi^2 k_B T m^*/\hbar eB$ is related to the ratio of the two energy scales above. The characteristic temperature scale is $\sim 1\,\mathrm{K}$ for carriers with bare electron mass m, but only 10 mK for carriers in a heavy fermion system with masses of order $m^* = 100m$. Conversely, the experimental determination of the temperature dependence of the dHvA amplitude can identify the electron masses with high accuracy.

Angle-Resolved Photoemission Spectroscopy

Photoemission spectroscopy provides, in principle, a direct way to measure the electronic density of states of a material. It uses the photoelectric effect: an incoming photon, typically in the ultraviolet, transfers its energy onto an electron and expels it from the material (**Figure 3a**). The energy difference between the photon and the electron corresponds to the binding energy of the electron relative to the vacuum level, and the energy distribution of the outgoing electrons hence mimics the electronic density of states and their occupancy inside the material (**Figure 3b**).

Photoemission experiments are conducted either at synchrotron sources, tapping into their vast supply of intense UV rays with variable energy, or in a more standard laboratory setup, typically using a He gas discharge lamp at a fixed photon energy of 21.2 eV. With modern detectors and at low temperatures (down to $\sim 10\,\mathrm{K}$), electron energy resolutions on $\sim 1\,\mathrm{meV}$ can be achieved. One problematic aspect of photoemission spectroscopy is the short escape depth of the photoelectrons, typically only a few Å for UV energies. Therefore, the technique is sensitive to a thin surface layer only, which necessitates careful sample preparation and treatment under UHV conditions. Even then, subtraction techniques using different photon energies often have to be employed to separate the surface from the "bulk" signal.

Importantly, for correlated materials the "density of states" probed by photoemission is really the spectral function $A(\omega)$ which can exhibit many-body features like Hubbard bands or superconducting, pseudo-, and Mott gaps. Photoemission spectroscopy has therefore become one of the most powerful modern probes of electronic structure.

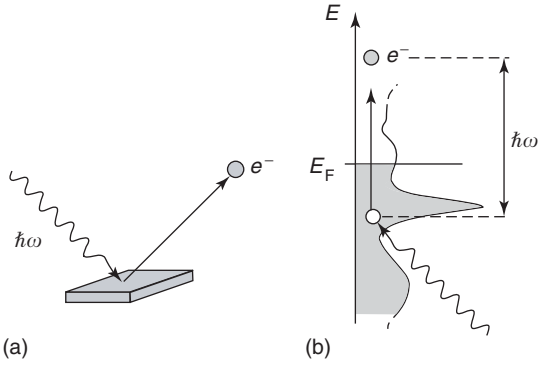

Figure 3 (a) Schematics of a photoemission experiment. (b) The energy distribution of the emitted electrons mimics the occupied density of states (i.e., $A(\omega)f(\hbar\omega - E_F)$; gray shaded area) inside the material.

The real power of photoemission is unleashed in angle-resolved spectroscopy (ARPES) on single-crystalline samples, where the momentum of the photoelectron is measured along with its energy. Within limits – discussed below – this photoelectron momentum can be related to the crystal momentum k of the initial electronic state. Within common approximations, the energy distribution curve measured at the detector for a particular angle, or momentum, is proportional to $A(k, \omega)f(\hbar\omega - E_F)$, the momentum-resolved spectral function times the Fermi function. This product in turn encodes the complete band structure and Fermi surface of the material since the spectral function $A(k, \omega)$ peaks whenever $\hbar\omega = E(k)$, while $f(\hbar\omega - E_F)$ demarcates the filled states in k space (**Figure 4**). For noninteracting electrons, the peak in $A(k, \omega)$ is δ-like, while for interacting systems the peak broadens out and is supplemented by an incoherent background contribution to $A(k, \omega)$.

Much of the quantitative analysis relies on what happens to the crystal momentum k when the electron is excited by the photon, refracted at the surface, and expelled from the material, to arrive at the detector with a momentum K. The momentum component parallel to the surface is usually taken to be conserved, apart from a reciprocal lattice vector, $k_{=} = K_{=} + G_{=}$. In contrast, the perpendicular component $k_{\perp}$ is usually not conserved during the refraction process. The analysis then either requires

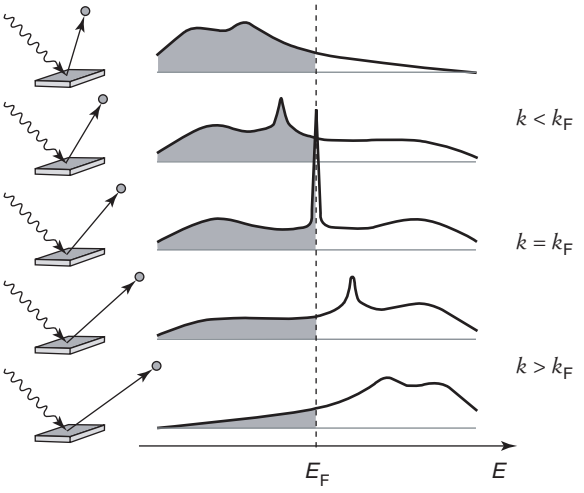

Figure 4 Angle-resolved photoemission spectroscopy (ARPES). For a particular emission direction, the momentum-resolved occupied spectral function $A(k, \omega)f(\hbar\omega - E_F)$ is probed (gray shaded). For Fermi liquids, $A(k, \omega)$ possesses a quasiparticle peak which indicates the band dispersion. The peak narrows when k approaches the Fermi surface from the inside and gets depopulated outside it. In this way, ARPES can probe band structure, Fermi surface, and many-body effects.

some assumptions about the (nearly free electron) nature of the excited state inside the crystal, or comparison of extensive data sets from different crystal faces, to determine $k_\perp$.

In the special case of materials with a quasi-2D electronic structure, the spectral function only depends weakly on $k_\perp$ anyway, and it is in these materials that ARPES is at its most powerful. Quasi-2D materials offer a few more experimental simplifications – for example, they often cleave easily, exposing flat crystalline faces with little surface reconstruction. This is true for the high-T_c superconductors, especially the Bi-based compounds, where ARPES has made major contributions to the understanding of the electronic structure of both the normal and superconducting states.

Angle-Dependent Magnetoresistance Oscillations

In metals with reduced effective dimensionality of the electronic structure (quasi-1D and quasi-2D), the magnetoresistivity for currents along the low conductivity axes shows a strong dependence on the direction of the applied magnetic field. This angle-dependent magnetoresistance oscillation (AMRO) effect was first observed in the late 1980s in a number of organic metals and subsequently explained as being due to "magic angles" in the Fermi surface geometry. In this way, the exact form of the AMROs constitutes a subtle probe of the shape of the Fermi surface.

One can understand AMROs from the viewpoint of semiclassical transport theory. If an electric field is applied to drive a current in a metal, this field acts as a force on the electrons and changes their momentum and hence their k value. Depending on the relative orientation of the electric field and the Fermi velocity, this amounts to an acceleration or deceleration of the electron, and hence to a positive or negative change in electron energy, respectively. This energy change induces an occupancy redistribution that deviates from the ground state, which in turn leads to a net current.

In the presence of a magnetic field one technically has to deal with orbital states again, but it is sufficient to view the problem in the semiclassical approximation in which the wave vector k is taken to be an almost good quantum number which slowly evolves along the cyclotron trajectory: along the Fermi surface and perpendicular to the applied magnetic field.

For some directions of the applied magnetic field, known as magic angles and to be determined below, the Fermi velocity component along some crystallographic direction can average to zero over every cyclotron trajectory. In this situation the time-averaged energy shift induced by a c-axis electric field is very small: over the course of each cyclotron trajectory, the electric field sometimes accelerates the electron, sometimes decelerates it, with little net effect. This means that the occupancy redistribution, and the resulting current, are both small – the magnetoresistance is large.

The two best-known magic angle situations are so-called "Yamaji oscillations" for quasi-2D metals, and "Danner–Chaikin oscillations" for the quasi-1D case. Both cases are illustrated schematically in **Figure 5**. Yamaji oscillations are visible in the interlayer resistivity as a function of the polar angle of the magnetic field, while Danner–Chaikin oscillations can be observed in the resistivity along the lowest conductivity axis as the magnetic field is rotated from that axis onto the highest conductivity direction.

The exact positions of the Yamaji magic angles depend on the details of the geometry of the Fermi surface. From **Figure 5a**, it is evident that, if the Brillouin zone height remains the same, larger Fermi surfaces will have smaller Yamaji angles. In fact, it can be shown that in the simplest case and in the clean limit the magnetoresistance behaves like $\rho_c = \rho_0 / J_0^2(ck_F \tan\theta)$ where c is the interlayer spacing, θ is the polar angle of the applied magnetic field, and J_0 is the Bessel function. In this way, the oscillation period (in $\tan\theta$) yields the Fermi wave vector, so that Yamaji oscillations constitute a "caliper" measurement of the Fermi surface. This periodicity also applies in more general cases although the exact shape of the AMROs can be different, corresponding to more unusual interlayer transport behavior.

For Danner–Chaikin oscillations, the magnetoresistance behaves like $\rho_c = \rho_0 / J_0^2(2t_b c \tan\theta / \hbar v_F)$ and gives information about the relative strength of the corrugation of the Fermi surface, and in particular the tight-binding transfer integral t_b along the intermediate conductivity direction.

In practice, the analysis of AMROs works best if the Fermi surface possesses one sheet only, and if a reasonable first guess at its geometry is available from theory or from other techniques. This is because quite often only the first few oscillations are visible, so that fitting procedures are required, and it is correspondingly difficult to disentangle the contributions from several bands.

Sufficient Fermi velocity averaging over the whole cyclotron orbit is only possible if the scattering rate is small and the magnetic field is large ($\omega_c \tau \geqslant 1$). AMROs are therefore subject to similar impurity damping as dHvA oscillations, but to much weaker

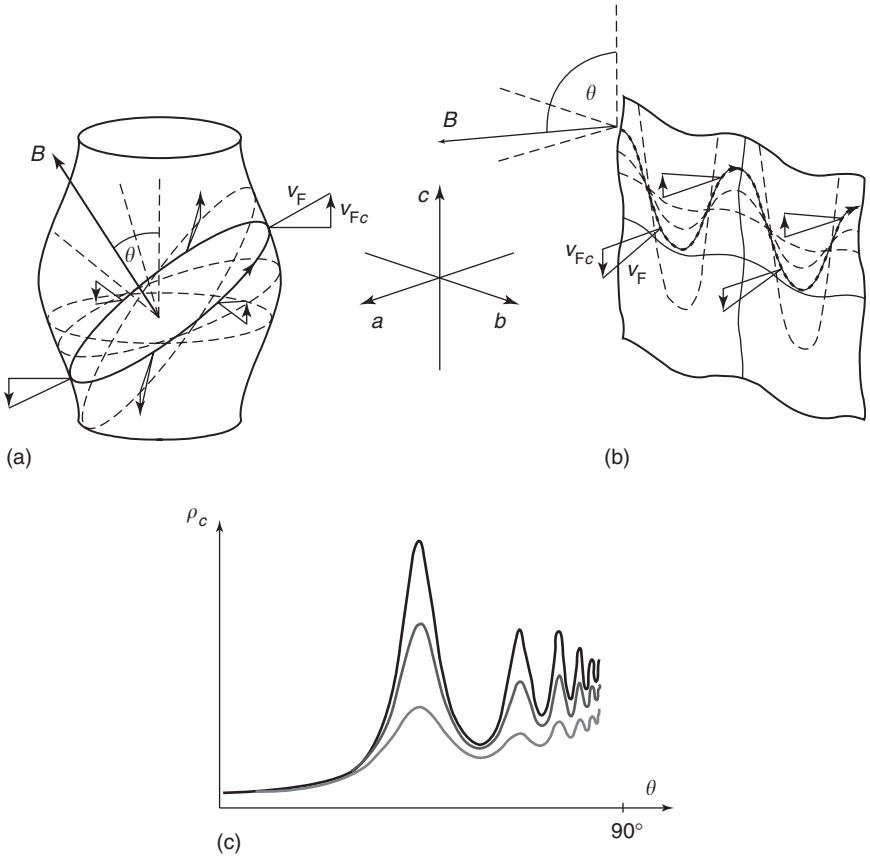

Figure 5 Geometry for (a) Yamaji and (b) Danner–Chaikin oscillations. The bold solid trajectory is at the magic angle where the *c*-component v_{Fc} of the Fermi velocity always averages to zero. (c) The magnetoresistance is similar in both cases and shows peaks at the magic angles – quasi-periodic in $\tan\theta$ – that grow stronger with increasing field.

thermal damping since AMROs are a semiclassical effect independent of orbital quantization.

Advantages and Disadvantages

Depending on the material and the situation, the three experimental methods discussed above each have their own relative merits and disadvantages – in this section some of the key aspects are covered for guidance.

Sensitivity to Correlations

DHvA probes the effects of correlations on the low-energy scale (<0.1 meV), through the effective electron masses. In contrast, electron correlations are manifest in photoemission and ARPES on a higher energy scale (typically 1 eV), in Hubbard bands and in the incoherent part of $A(k, \omega)$. In this sense, dHvA and photoemission provide very complementary information. Unfortunately, AMROs are largely independent of many-body renormalization effects and do not therefore constitute a suitable experimental probe for electronic correlations.

Purity Requirements

DHvA and AMROs have similar crystal purity and homogeneity requirements ($\omega_c\tau \geqslant 1$); ARPES is much less stringent as long as the surface preparation is adequate. This is one of the key reasons why ARPES has been so useful for investigating the high-T_c cuprates.

Temperature Requirements

DHvA is most demanding ($k_BT < \hbar\omega_c^*$); AMROs remain visible until the temperature-induced extra scattering invalidates the condition $\omega_c\tau \geqslant 1$; the ARPES signal remains observable at much higher temperatures (with an energy resolution slightly broadened by k_BT). This means that typically AMRO and dHvA studies are restricted to the low-temperature ground state of a material, while ARPES can often probe electronic phase transitions at elevated temperatures.

Dimensionality

AMROs are only visible in quasi-1D and quasi-2D materials. A reduced dimensionality is also helpful for the interpretation of ARPES and boosts the signal size in dHvA, but both techniques still retain much of their power for 3D materials – dHvA perhaps even more so than ARPES.

k-Space Resolution

In favorable situations, dHvA can resolve k-space features ~ 10 ppm of the Brillouin zone; more typically, it can achieve $\sim 0.1\%$ resolution with accurate magnetic field calibration. While significant improvements have been made in ARPES, state-of-the-art detectors discriminate by $\sim 0.2^\circ$ in angle, and Fermi surface determination down to within perhaps 1% of the Brillouin zone is often possible. The resolution offered by AMROs depends strongly on the number of oscillations visible in the magnetoresistance – $\sim 1\%$ precision in k_F is realistic for Yamaji oscillations in good crystals.

Bulk Sensitivity

DHvA and AMROs probe the bulk of the material, while ARPES is restricted to a thin surface layer. The vicinity and influence of the surface can on occasion distort the electronic structure, especially when the exposed surface undergoes a structural and/or electronic reconstruction. Photons with variable energies and escape depths can be used to separate surface from bulk contributions, but this separation is often not reliable, and cases where a variation of photon energy itself drastically modifies the observed apparent electronic structure have also been reported.

Other Fermi Surface Probes

The three experimental methods discussed above are probably the most common Fermi surface measurement techniques today. There are a number of other probes, some of them occupying specialist niche roles, others mostly of historical interest. These are briefly presented here for completeness.

Positron Annihilation

If positrons from a radioactive source are injected into a solid, they thermalize in a very short time, losing most of their momentum in the process. After about a few hundred picoseconds, the positron and one of the electrons in the material annihilate in a flash of two γ-rays. The γ-ray trajectories are almost back-to-back, but angular corrections can be observed and attributed to the initial crystal momentum of the electron. This maps out the filled states of the material in k-space. The advantage of the technique is that it is a rare bulk probe that also works at elevated temperatures, or for inhomogeneous materials. On the downside, it only offers filling information that is integrated along lines in k-space; its resolution is less than spectacular (typically 5% of the Brillouin zone); and the effects of positron trapping in lattice vacancies can distort the observed bulk electronic structure.

Cyclotron Resonance

The cyclotron motion of the electrons of a metal in a magnetic field causes resonant absorption of an incident microwave field if its frequency coincides with the cyclotron frequency $\omega_c = eB/m_c$, or – in the so-called Azbel'–Kaner geometry – integer multiples thereof. Primarily, the technique does not measure the Fermi surface geometry itself but the dynamical cyclotron mass m_c. Importantly, m_c can differ from both the bare band mass and from the effective mass m^* measured in dHvA, and those differences give clues about the electronic interactions in the material. In addition, recent measurements on quasi-1D and -2D systems have uncovered geometrical resonances (known as Fermi surface traversal and periodic orbit resonances, respectively) which can be more closely related to the Fermi surface geometry itself.

Magnetoacoustic Effect

Rarely used today, this method relies on resonant attenuation effects between cyclotron motion in real space and propagating sound waves in a metal every time the cyclotron orbit diameter $2r_c$ and the sound wavelength λ form a half-integer ratio, $2r_c/\lambda = n + 1/2$.

Anomalous Skin Effect

Famous for its role in the experimental determination of the Fermi surface of copper, this technique is also very rarely used today. It exploits a subtle relation, valid only if the mean free path is much longer than the skin depth, between the magnitude of the microwave surface impedance and the Fermi surface curvature near those points where v_F is parallel to the sample surface.

Ferroelectricity

A P Levanyuk, Madrid Autonomous University, Madrid, Spain
B A Strukov, Moscow State University, Moscow, Russia

Introduction

Ferroelectricity refers to many related phenomena specific to ferroelectrics. Properties of these materials have made them important for various applications, some of which are mentioned in this article. Most ferroelectrics have small conductivity and are considered to be a special class of insulators (dielectrics). Some ferroelectrics are semiconductors. However, considering them as dielectrics is an adequate starting point. Ferroelectrics exhibit unconventional pyroelectricity and piezoelectricity. The article begins with a classification of electrical properties of dielectrics with a view to identify the position of ferroelectrics among related classes of materials. A plethora of specific features of ferroelectrics is connected to their "structural softness," which is an indication of the closeness of a second-order phase transition. The meaning of this "closeness" is explained below; considering this transition is the key to understanding ferroelectricity. The transition is included in the formulation in a way that is model-independent and general, but somewhat formal. In order to illustrate this approach and also give general ideas on the microscopic mechanisms of the transition, this article employs a simple model that nonetheless offers a physically transparent treatment.

Ferroelectrics, Pyroelectrics, and Piezoelectrics

Properties of a dielectric can be derived from its equation of state, which describes the dependence of the polarization P, on parameters that define the state of the material. The most important among these are voltage, elastic strains, and temperature. In fact, it is not the polarization that is probed experimentally, but either the charge of the capacitor containing the dielectric (**Figure 1**) or the current in the circuit containing the capacitor (**Figure 2**). According to electrostatics, the density of charge at the capacitor plate is equal to the electric displacement $D = \varepsilon_0 E + P$, where $E = V/L$ is the electric field, (L being the distance between the electrodes and V the voltage), and ε_0 is the permittivity of vacuum. (It should be noted that in normal experimental conditions, $\boldsymbol{D}$ is along the perpendicular to the plate. The use of vectors is thus avoided in this article by assuming that all vectors are directed along the same line.)

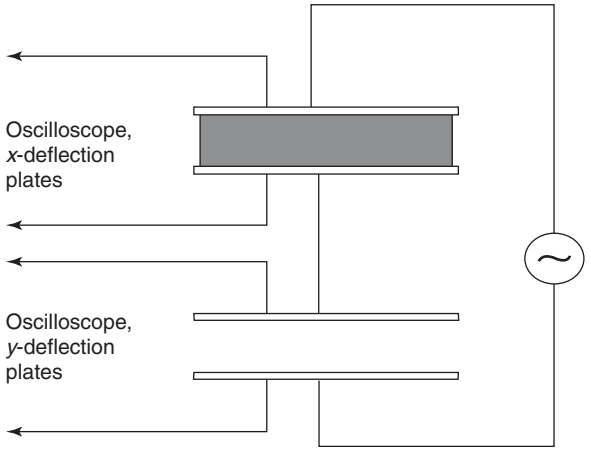

Figure 1 Probing the dependence of polarization on the electric field by measurements with alternating voltage. The y-deflection is proportional to the charge Q of the reference (empty) capacitor, which is the same as the charge of the capacitor filled by dielectric. The x-deflection is proportional to the voltage on the dielectric plate. Since $D = Q/S$, where S is the area of the plate, the experiment provides $D(E)$ and the dependence $P(E)$ can be then calculated. In ferroelectrics $\varepsilon_0 E \ll P$, so that $D \sim P$.

By controlling the voltage on the dielectric plate and the charge of the reference capacitor (**Figure 1**), one can obtain the dependence $P(E)$. For most dielectrics, P depends linearly on E, up to dieletric breakdown fields (**Figure 3a**). In ferroelectrics, however, $P(E)$ has a different form (**Figure 3b**). The measurement frequency is so low (see caption for **Figure 3**) that the dependence $P(E)$ in **Figure 3b** is considered as "static." Remarkably, in ferroelectrics $P(E)$ is nonlinear and even multivalued. There are two values of P for $E = 0$. After switching the voltage off, the ferroelectric finds itself in one of the two states that correspond to the remanent ("spontaneous") polarization of opposite signs. By applying an electric field in the direction opposite to the spontaneous polarization and exceeding the "coercive field" (see **Figure 3b**), the spontaneous polarization can be inverted (switched). This property makes ferroelectrics useful in memory and logic devices. This was proposed before the 1950s but has become commercially significant only recently. Another application of ferroelectrics is connected with the fact that their dielectric response is large: note the difference in scales of the P-axis in **Figures 3a** and **3b**. If the amplitude of the change in the field is much less than the coercive field, the ferroelectric behaves as an ordinary dielectric, but with a very high dielectric constant $\varepsilon = 1 + dP/dE$. This explains why ferroelectrics are used in $\sim 50\%$ of the total number of the commercially available capacitors: high capacitance can be achieved in a small volume. The name "ferroelectrics" is due to the similarity of the hysteresis curves of the ferroelectrics (**Figure 3b**) and the ferromagnetics.

Another type of experiment is presented in **Figure 2**, where there is no voltage source and one probes only the current. In most dielectrics, no current appears but in some of them a transient current is observed to flow. If it flows because of a change in the temperature of the dielectric, one observes the pyroelectric effect. If it does because of a deformation, one observes the piezoelectric effect. The dielectrics in these two cases are, respectively, pyroelectrics and piezoelectrics. These effects are not completely independent. Indeed, there are two types of deformations: those lowering the symmetry of the crystal (e.g., unilateral stretching of a cubic crystal), and those leaving it unchanged (e.g., deformation due to hydrostatic pressure). Since the deformations due to thermal expansion are symmetry-conserving, the piezoelectric effect is a contribution to the pyroelectric effect, that is, the two effects take place simultaneously. Conversely, if the symmetry-conserving strains do not provoke the piezoelectric effect, the crystal is not a pyroelectric. Symmetry-lowering strains may not necessarily lead to the piezoelectric effect. Symmetry arguments of this type are very effective in predicting the crystal properties. It is the crystal symmetry that "allows" or "forbids" these properties. Later this point is illustrated for the case of a simple model, but here it suffices to mention that the pyroelectric effect is possible in structures

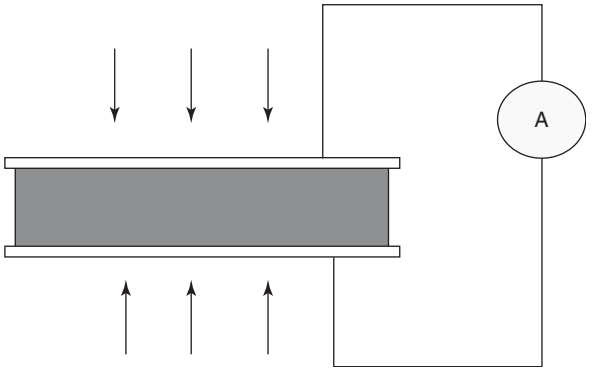

Figure 2 Probing the polarization change by measurement of transient current provoked by change of temperature (pyroelectric effect) or by deformation (piezoelectric effect). The current $I = S\ dP/dt$ in a circuit without resistance. The arrows indicate either heat flow or mechanical stress.

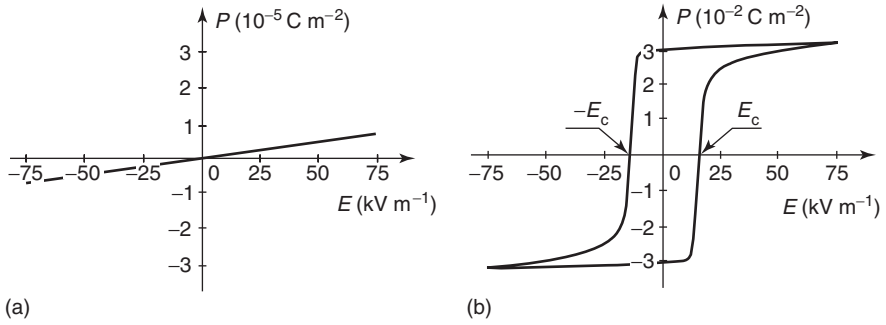

Figure 3 Dependence $P(E)$ (a) for a linear dielectric with $\varepsilon = 10$ and (b) obtained experimentally for ferroelectric triglycine sulfate (TGS) (see **Table 1**) at ambient temperature and frequency 0.1 Hz. The coercive field $E_c = 15\,\mathrm{kV\,m^{-1}}$, the spontaneous polarization is $3.1 \times 10^{-2}\,\mathrm{C\,m^{-2}}$.

whose point group does not contain transformations that change a vector. Such structures are generally called polar.

Ferroelectrics have (at least) two polar structures: the pyroelectric current has opposite directions in the two states with opposite spontaneous polarization, that is, the temperature influences the modulus of the spontaneous polarization but not its direction. The same is valid for the piezoelectric effect, because of the symmetry-conserving strains. This is not the only specific feature of a ferroelectric as a special case of pyro- and piezoelectric. As noted below, the magnitude of the two effects can be much higher in these materials than in ordinary pyro- and piezoelectrics. There are large scale practical applications of ferroelectrics as pyroelectric thermal detectors and, especially, as piezoelectric transducers.

Ferroelectric Phase Transition

An important property of ferroelectrics is that they change their structure to become nonpolar at relatively moderate changes of their external conditions, for example, by heating to temperatures that are much less than the melting temperature or by applying a low enough pressure that does not change the density significantly. This is another aspect of the polar state "softness," which is a characteristic of the dielectric response of ferroelectrics. The reason of this softness is that the polar structure of a ferroelectric is a result of small structural changes of a nonpolar structure; here, "small" means, in particular, that the average positions of the ions are shifted by values much less than the typical interatomic distances.

The observation that some structural changes though arbitrarily small lead to a change in the crystal symmetry, that is, to a phase transition is the basis of the Landau theory of second-order (continuous) phase transitions. This theory allows one to predict specific properties ("anomalies") of a crystal close to a second-order transition. The term "close" has the same meaning as the above "small." In this sense, most ferroelectrics are almost always "close" to the transition. This is not surprising if one takes into account that the temperatures of ferroelectric (nonpolar–polar) phase transitions are typically several hundred kelvin, whereas the characteristic scale of the temperature dependence of crystal constants is the so-called "atomic temperature" (T_{at}) estimated as 10^4–10^5 K. The estimation is made by comparing the kinetic energy of thermal motion of an ion and the binding energy, that is, the work necessary to remove it from the crystal. Therefore, the Landau theory is useful in understanding the properties of a ferroelectric, say, at ambient pressure and temperature. This was demonstrated by Ginzburg and Devonshire, and thus the Landau theory applied to ferroelectrics is usually called Landau–Ginzburg–Devonshire (LGD) theory.

Ferroelectric phase transitions *per se* are also of great interest. In the vicinity of a transition, the crystal has unusual properties, which are discussed below. It is significant to note that the Landau theory is not applicable in some neighborhood of a second-order phase transition. This theory is applicable "close" but not "too close" to the transition. For a long time, it was difficult to develop a theory valid in the immediate neighborhood of the transition. This development is frequently characterized as the main achievement of statistical physics of the twentieth century, which has had an important impact on other branches of physics. However, it seems very difficult to apply this theory to interpret experimental data regarding ferroelectrics. First, this immediate neighborhood ("scaling region") proves to be fairly narrow in ferroelectrics. Second, and even more important, various and poorly controllable crystalline defects become important in this region where the phase-transition anomalies are changed and often the transition is "smeared." Beyond the scaling region, the observed deviations from the Landau theory are small and should be interpreted within another theory, which is more simple and more informative, than the strict theory, but, is inapplicable in the immediate neighborhood of the transition. Beyond this immediate vicinity, the LGD theory can well account for the main properties of ferroelectrics.

An important advantage of this theory is its generality: it only uses symmetry considerations and some other macroscopic arguments, that is, it is model-independent. This theory provides the shortest way to understand the physical background of ferroelectricity; it establishes relations between different experimental data, but it cannot provide numerical values of the relevant physical quantities without the use of other experimental data. It cannot predict, in particular, the composition of crystals that could have, especially, advantageous ferroelectric properties. This is why theories that start from a basic quantum mechanical approach are now being intensively developed. At the intermediate level, various types of microscopic model theories are considered that help in understanding the underlying physical mechanisms specific for a given class of crystals.

One-Ion Model

For pedagogic convenience, the basic ideas of the LGD approach are presented. It has been mentioned

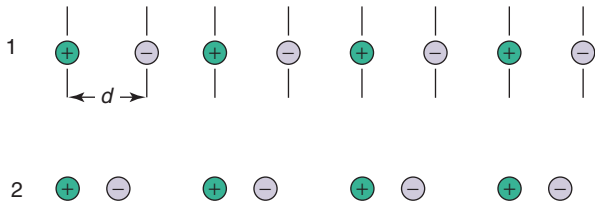

Figure 4 Two periodic ionic chains ("one-dimensional crystals"). Chain 1 has symmetry planes perpendicular to the page and crossing the ions. Chain 2 is a result of displacement of anions of chain 1 by the same distance. The symmetry planes are lost because of the displacement ("breaking of symmetry").

already that the structures of polar and nonpolar phases of a ferroelectric are very similar. An example of two structurally similar one-dimensional "crystals" is presented in **Figure 4**. The structures have different symmetries: the symmetry planes in structure 1 are perpendicular to the plane of the page and pass through the ions. In structure 2, they are absent.

Pyroelectric Effect and Spontaneous Polarization

Imagine a crystal consisting of parallel chains with electrodes on the surfaces perpendicular to the chains and short-circuited (**Figure 2**). The pyroelectric effect means that a change in temperature leads to a transfer of charge from one electrode to the other. Since $E = 0$, the density of charge at the electrodes is proportional to P. It will now be checked whether the polarization changes with temperature.

Structures 1 and 2 both have a dipolar moment. Still, the more symmetric structure does not exhibit the pyroelectric effect. Indeed, the dipole moment of a pair of neighboring negative (anion) and positive (cation) ions is qd, where q is the ion charge and d is the distance between the ions. The dipole moment of the whole crystal is qdN_1N_2, where N_1 is the number of anions (cations) in a chain and N_2 is the number of chains. The volume of the crystal is $v_f = S \times L = S \times (2N_1 - 1)d$, where S is the area of the capacitor electrode and L the distance between electrodes of a capacitor, and the polarization (dipole moment per unit volume) is $qN_2/2S$. The charge at the electrode is $qN_2/2$. This charge is independent of temperature. For structure 2 (**Figure 4**), there is a contribution to the polarization which is associated with a difference in distances between, say, an anion and two neighboring cations and not with the unit cell length $2d$. This contribution is dependent on temperature.

Frequently, pyroelectricity is ascribed to materials having "spontaneous polarization," normally understood as the dipole moment of the sample divided by its volume. However, this can be confusing.

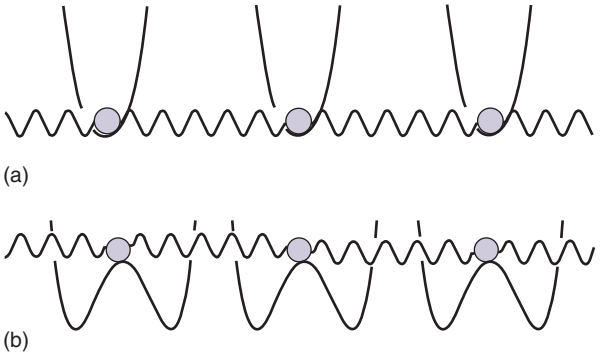

Figure 5 Diagrams illustrating the model: (a) $p > p_c$, stable symmetric configuration and (b) $p < p_c$, unstable symmetric configuration, the anions will shift to the right or to the left.

Symmetry does not prohibit the existence of the so-defined spontaneous polarization in a finite crystal, although it prohibits the pyroelectric effect. But if the term spontaneous polarization is understood as the difference between the polarization of a given structure and that of the "reference" (more symmetric) structure, just as in **Figure 4**, the term becomes meaningful. It does not contradict the above empirical definition, and one can associate the pyroelectric effect with the spontaneous polarization defined in this manner.

Symmetry Breaking

To illustrate a nonpolar–polar phase transition, consider a model in which the cations are immobile and their role is to create potential energy for the anions ("one-ion model"). This energy does not originate because of the Coulomb interaction between the ions which is neglected for now. A short-range interaction of an ion with only its nearest neighbors is considered. The interaction between anions in different cells is also short-ranged and is modeled with springs (**Figure 5**). The ions are heavy enough to be considered as classical and not quantum particles ("quantum fluctuations" are neglected). The phase transition occurs because of a change in the pressure p. Suppose that at $p > p_c$ the potential energy has only one minimum (**Figure 5a**). The anions are, of course, in this minimum. If, for $p < p_c$, the potential energy is a two-well one (**Figure 5b**), the anions shift either to the right or to the left, forming a less symmetric structure with the loss of structural equivalence of two neighboring ions. The springs do not deform: all the anions shift by the same distance. Only one variable is needed to describe different configurations of the systems: the shift of any anion. The role of the springs is to force them to shift collectively.

LGD Theory for the Model

For models with classical ions at $T=0$, the Landau theory is exact. What this theory means for the above model is discussed below.

The Landau theory describes lowering of the symmetry as a result of some internal deformation, which nowadays is called the "order parameter." In this case, the order parameter can be identified with the shift of anions or with a difference in polarizations of structures with shifted and nonshifted anions. Here it is termed "polarization" and designated as P. It has been seen earlier that it is the only variable needed. Choosing the simplest function to describe the evolution of potential energy of an anion, the potential energy per unit volume U is obtained in the form

$$U = N\left(a\frac{P^2}{2} + b\frac{P^4}{4}\right) \qquad [1]$$

where N is the number of anions (cations) in a unit volume, $a = a'(p - p_c)$ and $b = \text{const}$.

Even if the Coulomb interaction can be neglected when considering the interaction between the ions ("at microscopic level"), the shift of the anions leads to a macroscopic effect. Let a capacitor with the ferroelectric (FC) (**Figure 6**) be connected to a voltage source capacitor (SC) with $C \to \infty$ (C is the capacitance and voltage V). For $P=0$, one has $U=0$ and the total energy is due to the electric field:

$$\int_{v_f} \frac{\varepsilon_0 E^2}{2}\,dV + \int_{v_s} \frac{\varepsilon_0 E^2}{2}\,dV$$

where v_f, v_s are the volumes of FC and SC, respectively. The second integral is $Q^2/2C$, where Q is the charge of SC. For $P \neq 0$, the electric field energy within FC remains the same but the energy of SC changes: a part of the charge passes to FC. If P and E have the same sign, the charge of the source diminishes. The surface density of the additional charge is P and the energy of SC changes by

$$\frac{(Q-PS)^2}{2C} - \frac{Q^2}{2C} = \frac{PSQ}{C} + \frac{(PS)^2}{2C}$$

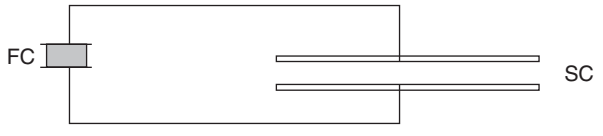

Figure 6 For the calculation of energy of the system consisting of a ferroelectric capacitor (FC) and the voltage source ("large capacitor," SC).

Since $Q \gg PS$, the second term can be neglected and the difference in energies is equal to $-PSV$ or $-PEv_f$. The total energy per unit volume is

$$U(P) = \frac{\alpha P^2}{2} + \frac{\beta P^4}{4} - PE \qquad [2]$$

where $\alpha = aN$, $\beta = bN$. The next step is to minimize $U(P)$ with respect to P to obtain the equation of state: $P = P(E, p)$. However, consider first the generalization of the treatment to the case $T \neq 0$.

Generalization

Experimentally, ferroelectric phase transitions are mainly due to change in temperature, not in pressure. Recall that the equilibrium state at $T \neq 0$ is that of maximum probability. Instead of the probability of states with different values of P ($w(P)$), one can consider a "nonequilibrium thermodynamic potential" $F(P) = kT \ln w(P)$, where k is the Boltzmann constant. The minimum of $F(P)$ corresponds to the equilibrium just as the minimum of $U(P)$ does at $T=0$. Naturally, F is a different function of P at different T and p. Therefore, in eqn [2], U can be replaced by F, and α (and, in principle, β) can be considered as functions of T, p. At $p = \text{const.}$, the phase-transition temperature (T_c) is given by the condition $\alpha(T_c) = 0$. Landau assumed that $\alpha = \alpha'(T - T_c)$ close to T_c. Nontrivially, this natural assumption proved to be incorrect very close to T_c. But as already mentioned, this is of no practical importance for ferroelectrics.

The form of $F(P; E=0, T, p)$ can be obtained without referring to any model but from symmetry arguments. Considering the nonpolar phase, F can be expanded in the Maclaurin series in P taking into account that some symmetry elements (in this model: reflection in the plane) of this phase change the sign of P. The form of the function has to remain unchanged under symmetry transformations, so the series can contain the powers of P^2 only. Incorporating then the voltage source in the same way as above, one obtains

$$F(P; E, T, p) = F_0 + \frac{\alpha(T,p)P^2}{2} + \frac{\beta(T,p)P^4}{4} - PE + \cdots \qquad [3]$$

where the higher-order terms are omitted. For a nonpolar phase, $\alpha > 0$ and changes its sign at phase transition into a polar phase.

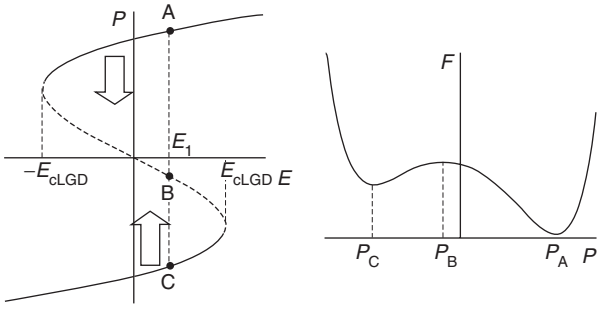

Figure 7 (a) Dependence $P(E)$ according to eqn [4]. The points of the broken line correspond to maxima, not to minima, of the free energy as shown in (b). They present unstable, not realizable states. The thin lines present metastable states, the bold lines present equilibrium ones. This is illustrated in (b), where $F(P, E=E_1)$; E_1 is shown in (a). Points A, B, C correspond to equilibrium, nonstable, and metastable states. Vertical arrows indicate transitions between metastable and equilibrium states.

Equation of State and Switching

Minimizing F given by eqn [3] with respect to the order parameter P, one obtains $P(E)$ as

$$\alpha P + \beta P^3 = E \qquad [4]$$

For $T<T_c$ ($\alpha<0$), $P(E)$ is shown in **Figure 7a**. Transitions from metastable to equilibrium states shown in the figure prevent the system from reaching the "coercive field," E_{cLGD} calculated with the help of eqn [4]. The barrier for these transitions disappears at $E=E_{cLGD}$ but, at any finite temperature, the transitions become possible before disappearance of the barrier. It is not surprising, therefore, that the experimental coercive fields are less than E_{cLGD}. But it is surprising that this difference is very high: two or three orders of magnitude. Escapes from metastable states normally occur locally, similar to the liquefaction of under-cooled vapor. It proceeds because of nucleation, that is, formation of very small drops of water, and subsequent growth of the nuclei. The nuclei arise either because of thermal fluctuations or due to the assistance of some "nucleation centers" as those provided by a jet liner, leading to the formation of the trace visible from the surface. It is natural to expect that a change of direction ("switching") of the polarization occurs in a similar manner: first, small regions (small "domains") of opposite polarization arise and then these regions grow and merge to complete the switching. Some small domains in partially switched crystals were repeatedly observed, but it remains unclear how they do arise. However, what is clear is that only large enough nuclei can grow and not collapse, both in the under cooled vapor and the ferroelectric. The estimations of the "critical dimensions" provide very high values both for the dimensions and the energy of "critical nuclei" in ferroelectrics. It is unimaginable that they arise because of thermal fluctuations at electric fields much lower than E_{cLGD}. A natural assumption is that the nucleation is because of some centers, just as in the case of the jet liner. Unfortunately, one has no idea what these centers are as no model of such a "nucleation-assisting" center has yet been developed. Although the "nucleation and growth model" helps in understanding many experimental data, it has no solid base yet.

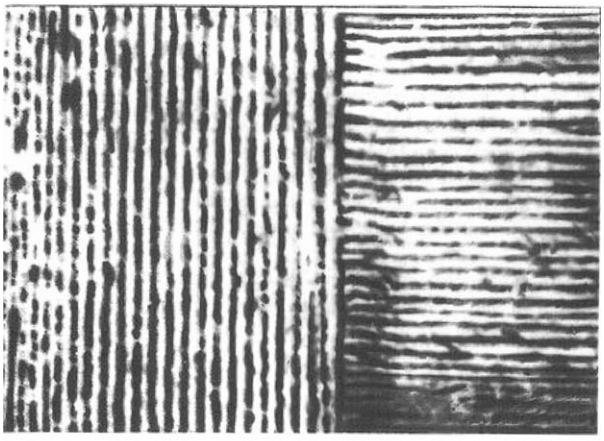
Domains

Domains or regions with different directions of the spontaneous polarization do not arise only in the process of switching. Ferroelectrics normally appear to consist of domains when cooled through the transition temperature (**Figure 8**). Despite the domain structures being diverse, even for the same crystal, there are some regularities, especially in the orientations of the boundaries between the domains – domain walls. Their energy strongly depends on their orientations. In particular, this prevents the walls from being "charged": the spontaneous polarizations in the adjacent domains tend to have equal components perpendicular to the wall. A domain wall normally has positive energy, that is, the formation of domain walls is energetically unprofitable for the crystal. The domain structures present either metastable states, or there are energetic gains associated with their formation. The most evident gain is diminishing of the energy of the electric field associated with any inhomogeneity of the polarization along a direction that is not perpendicular to the polarization. It might, in particular, be due to the boundary of the sample. In a short-circuited plate whose plane is perpendicular to the spontaneous polarization, the domains are not expected to appear if the electrodes are ideal and the sample is completely homogeneous. Experimentally, this is hardly possible, and it is not surprising that the domain structures are almost always observed.

Phase-Transition Anomalies

Phase-transition anomalies or peculiarities of crystal properties near a second-order phase transition have already been mentioned. However, only anomalies obtainable from eqn [3] are touched upon here. For

(a)



(b)

Figure 8 Domain structures of (a) TGS and (b) KH_2PO_4 as observed in a microscope. In both cases, the cross section is perpendicular to the direction of P_s. In the case (a), the crystal surface is covered by a liquid crystal to make the visualization possible. In case (b), the water steam was used as a contrast reagent. ((a) Courtesy of Natalia A Tikhomirova, Universidad Autonoma de Madrid, Madrid.)

$E = 0$, one finds that

$$P_s = 0 \quad \text{for } T > T_c$$

and

$$P_s = \pm(-\alpha/\beta)^{1/2} \quad \text{for } T < T_c$$

This means that $P_s \propto (T_c - T)^{1/2}$.

For small values of E, one can linearize the equation in both the phases. For $T > T_c$, one finds $P = E/\alpha$, that is, for dielectric permeability in a small electric field, $\varepsilon = 1 + dP/\varepsilon_0 dE$, one obtains the Curie–Weiss law, $\varepsilon = C/(T - T_c)$, where $C = 1/\alpha'\varepsilon_0$ is the Curie–Weiss constant. The value of C is an important parameter of a ferroelectric material. Similar temperature dependence, $\varepsilon \propto 1/|T - T_c|$ with another Curie–Weiss constant, takes place for $T < T_c$. One also finds that the pyroelectric coefficient $\gamma = dP_s/dT \propto (T_c - T)^{-1/2}$, so it also tends to infinity as $T \to T_c$ but with a different power behavior. The same is valid for the piezoelectric coefficient $r = dP_s/d\sigma$, where σ is a symmetry-conserving strain.

Dynamic Properties

Consider again the model for $T = 0$. Since P is proportional to the collective shift of ions B, the equation of motion for P in the case of small oscillations in the nonpolar phase reads:

$$\frac{Md^2P}{dt^2} + \alpha P = E(t) \qquad [5]$$

where $M = mN$, and m is the mass of an anion. This is the equation of a harmonic oscillator whose natural frequency is $(\alpha/M)^{1/2}$. The oscillator presents one of the modes of the optic branch corresponding to the vibrations of the anion sublattice with respect to the cation one. The frequency of the mode becomes zero at the phase transition. This is why it is called the "soft mode." Vibrations corresponding to other modes of the branch involve deformations of the springs, and their frequencies remain positive at the transition.

Generalization of eqn [5] to the case $T \neq 0$ is a difficult problem, which has not been solved satisfactorily. A natural and minimalist assumption is to take into account the damping of the oscillator:

$$\frac{Md^2P}{dt^2} + \frac{\xi dP}{dt} + \alpha P = E(t) \qquad [6]$$

where ξ is the viscosity coefficient. If the damping constant ($\Gamma = \xi/2M$) is much larger than the natural frequency, the oscillator converts into a "relaxator," that is, the equation of motion takes the approximate form

$$\frac{\xi dP}{dt} + \alpha P = E(t) \qquad [7]$$

Instead of the frequency, it is the reciprocal relaxation time α/ξ, that goes to zero at the transition. The dynamics described by eqn [6] is considered as typical for the displacive systems, while that described by eqn [7] is typical for the order–disorder ones. The motivation for these terms is explained in the following. Since the two equations represent two extreme cases, it is quite natural that there are many cases where none of the equations is applicable.

This is especially valid for eqn [5]. In fact, a soft mode whose frequency goes to zero at the transition has never been observed. Equation [5] is relevant for high enough frequencies but not close to the transition, if at all. The dynamics of "displacive"

systems close to the transition is still poorly understood.

Displacive and Order–Disorder Systems

These systems can be illustrated as limiting cases of the simple model. At $T=0$, the only possibility for the transition is due to the change of the potential exerted by the cations on the anions. The transition consists in the displacement of the anion sublattice and is of the displacive type. At $T\neq 0$, the phase transition can take place even if the potential does not change at all and remains two-well one. Indeed, at high T, the atoms have high kinetic energy, which allows them to jump between the wells if the springs are relatively soft. For high enough T, the anions find themselves in the left or the right well with the same probability, that is, they become disordered. The average position of an anion is symmetric, that is, the system is in the nonpolar phase. This "order–disorder" transition occurs when the kinetic energy of the ion (kT) becomes comparable with the typical change of the potential energy of the spring when an ion changes the well. The depth of the well is still much larger than kT. A nonequilibrium population of wells in such a system approaches equilibrium in a relaxation process similar to that described by eqn [7]. The phase-transition temperature T_c is the only temperature scale for α, that is, $\alpha' \sim \alpha_{at}/T_c$, where α_{at} is the "atomic" value of α, that is, its typical value far from the phase transition or in an "ordinary" nonferroelectric material. Since the dielectric constants of such materials are of the order of magnitude of unity, one finds that $\alpha_{at} \sim \varepsilon_0^{-1}$ and $C \sim T_c$.

For very rigid springs, such a phase transition is impossible. But if the one-ion potential changes with temperature and becomes a single-well one, the transition will take place once again, as at $T=0$, due to displacement of the anion sublattice. This again is a displacive transition. Of course, the springs should be infinitely rigid to have only displacement and no disorder. Therefore, any real displacive system has an admixture of "order–disorder component," and there exists no boundary between the two types of systems.

The above example of displacive phase transition is good to illustrate the dynamics, but it does not correspond to any real case. A characteristic temperature scale for changes of atomic potentials is T_{at}, and this temperature is much higher than the melting temperatures. It may seem that a displacive transition cannot result by a change in T. However, recall that the Coulomb interaction between the ions has been neglected. The difference between the Coulomb interaction energies in polar and nonpolar structures, called the dipole–dipole interaction energy, is now of much interest. Calculation of this part is fairly involved. What is important here is that the dipole–dipole interaction can be destabilizing for a nonpolar state.

In the model at $T=0$, it can well happen that, because of the dipole–dipole interaction, the polar state is realized even for single-well one-ion potential. In other words, the coefficient α in eqns [2] and [3] now has two contributions: the short-range interactions and the dipole–dipole interactions, $\alpha=\alpha_s+\alpha_d$; $\alpha_s>0$, $\alpha_d<0$. The two contributions are, in principle, temperature-dependent and the scale of this dependence is, of course, T_{at}. If $\alpha(T=0)<0$ but $|\alpha(T=0)| \ll |\alpha_s|, |\alpha_d|$, that is, the effects of the dipole–dipole and short-range interactions are nearly compensated, it can well happen that, at some $T \ll T_{at}$, the balance changes its sign, and the nonpolar state becomes the equilibrium one. Otherwise, the polar state conserves up to the melting temperature, and the crystal is a pyroelectric but not a ferroelectric. Therefore, a system with "rigid springs" can also exhibit polar–nonpolar phase transition because of a change in T. Although the temperature of such a transition is much less than T_{at}, the latter conserves its role as the scale for the temperature changes, that is, in this case $C \sim T_{at}$. This is very different from the order–disorder systems. Note that no dynamics was referred to in the discussion of reasons for the phase transition. It is not surprising, therefore, that ferroelectrics can be fairly well divided into two classes with different orders of magnitude of the Curie–Weiss constant (see **Table 1**), while their division into the order–disorder and displacive systems with respect to their dynamics is far less definitive.

First-Order Phase Transitions: Perovskites

In most ferroelectrics, the phase transition is discontinuous, that is, it is of the first order. In particular, this is the case of ferroelectrics with the perovskite structure (perovskite is a mineral, $CaTiO_3$). Another specific feature of this group of ferroelectrics, which is very important for applications, is that they are cubic in the nonpolar phase. This means that the order parameter of the ferroelectric transition is a three-component one. This can be treated within the Landau theory (as well as the discontinuity of the transition) as long as the structural changes are relatively small. The generalization is straightforward but it is beyond the scope of this article.

Table 1 Some parameters of some ferroelectrics

Substance	*Chemical formula*	*Transition temperature*	*Curie–Weiss constant C* (K)
Potassium niobate	$KNbO_3$	435°C	2.9×10^5
Barium titanate	$BaTiO_3$	130°C	1.5×10^5
Lead titanate	$PbTiO_3$	490°C	1.1×10^5
Antimony sulphide iodide	SbSI	20°C	0.5×10^5
Sodium nitrite	$NaNO_2$	163°C	5.0×10^3
Potassium dihydrogen phosphate	KH_2PO_4	123 K	3.3×10^3
Triglycine sulfate	$(CH_2NH_2COOH)_3 \cdot H_2SO_4$	49°C	3.2×10^3
Rochelle salt	$NaKC_4H_4O_6 \cdot 4H_2O$	−18, 24°C	2.2×10^3

In most perovskite ferroelectrics, the spontaneous polarization arising at transition between nonpolar and polar phases is directed along one of the cubic axes. The crystal symmetry changes from cubic to tetragonal. As a result, the unit cell expands (or shrinks) along the polarization direction losing its cubic form. This symmetry-breaking strain is another aspect of the structural changes at the transition. Without polarization, it would lead to a lowering of the cubic symmetry but less radical than the polarization: a prism with a quadratic base has, as a symmetry element, a mirror plane parallel to the base at half the height of the prism. This symmetry element is absent if there is a polarization perpendicular to the base. This means that the symmetry-breaking strain is a secondary effect of a more profound change of symmetry.

Improper, Liquid Crystalline, and Incommensurate Ferroelectrics

Spontaneous polarization can also be a result of another, more profound change of symmetry. Such ferroelectrics are called improper. They exhibit quite different phase-transition anomalies than the usual ("proper") ferroelectrics, for example, their dielectric constant changes little near the transition and has low values, similar to those of ordinary dielectrics.

In some liquid crystals, the so-called chiral smectics, there exists spontaneous polarization that changes its direction ("winds") if one translates along a special direction in these systems. The winding is periodic with a macroscopic pitch: 5–10 μm. The polarization can be made homogeneous by applying a relatively small electric field.

Another type of spatially inhomogeneous polarization, with changing magnitude rather than direction, is observed in some ordinary (solid) crystals. The period of the inhomogeneity is larger only by one to two orders of magnitude than typical interatomic distances. It changes with temperature independently of the period of structural features that do not contribute to the polarization ("basic lattice"). The crystal has two independent ("incommensurate") periodicities. At some temperature, the polarization becomes homogeneous (within macroscopic domains, as usual), that is, there is a phase transition between the incommensurate and the ordinary ("commensurate") ferroelectric phase. This phase transition belongs to a special class of transitions ("lock-in transition"), which take place not only in ferroelectric but in many other systems, for example, in systems with charge density waves. In ferroelectrics, this transition is usually accompanied by a strong increase of the dielectric constant.

Nomenclature

a'	coefficient in the dependence of a on pressure
a, b	coefficients of expansion of the potential energy U in a series of powers of P^2
C	capacitance

$2d$	unit cell length
D	electric displacement
E	electric field
E_c	coercive field
E_{cLGD}	coercive field within the LGD theory without accounting for domains
F	free energy
I	current
k	Boltzmann constant
L	distance between electrodes of a capacitor
m	anion mass (within the model)
M	anion mass density (within the model)
N	number of anions (cations) in a unit volume
N_1	number of anions (cations) in the atomic chain
N_2	number of the atomic chains in a crystal
p	pressure
p_c	pressure of change of the form of the short-range potential energy of anions within the model
P	polarization
P_s	spontaneous polarization
q	anion (cation) charge (within the model)
Q	charge of a capacitor
S	area of the capacitor electrode
T_{at}	atomic temperature
T_c	phase-transition temperature
U	potential energy of an anion due to its short-range interaction with the cations (within the model)
V	voltage
w	polarization probability density distribution
α'	coefficient in the dependence of α on the temperature
α, β	coefficients of expansion of the potential energy U and the free energy F in series of powers of P^2
α_{at}	atomic value of α
α_d	contribution to α due to dipole–dipole interactions
α_s	contribution to α due to short-range interactions
ε_0	permittivity of vacuum
v_f	volume of ferroelectric
v_s	volume of the voltage source considered as a large capacitor
ξ	viscosity coefficient

Ferromagnetism

N Magnani, Università di Parma, Parma, Italy

Introduction

As far as isolated atoms are concerned, only two different magnetic behaviors exist: diamagnetism and paramagnetism. The latter property is only present if the considered atoms possess a nonzero permanent magnetic dipole, and is responsible for the weak attractive force experienced by a paramagnetic substance in an applied magnetic field. However, the most interesting magnetic properties of condensed matter arise when the interaction between the individual elementary moments of each atom is considered. In particular, ferromagnetism concerns the situation where the moments have the tendency to align, one parallel to another, even in the absence of any external magnetic field, thus leading to the possibility of obtaining very large values of the magnetization with very little values of the applied magnetic field (spontaneous magnetization). Only a few elements in the periodic table (Fe, Co, Ni, Gd, Dy, and Tb) order ferromagnetically, but an extremely large number of compounds and alloys do. From the practical point of view, apart from their high values of the magnetic susceptibility and relative permeability, one of the most interesting properties of ferromagnetic compounds is the possibility of retaining a large amount of the induced magnetization when the external field is completely removed. This makes it possible to develop devices such as permanent magnets (i.e., magnetized bodies which produce a constant magnetic field in a given volume of space without the need to continuously supply electrical or chemical energy), memory storage devices, magnetic circuits, etc.

The Molecular Field Approach to Ferromagnetism

At the beginning of the twentieth century, Pierre Weiss interpreted the tendency of ferromagnets to spontaneous magnetization by introducing a "molecular field" responsible for the ordering of the elementary magnetic moments, and he assumed that this field is linearly proportional to the bulk

magnetization (total magnetic moment per volume unit). It may be recalled that the magnetization of a set of identical noninteracting ions, each having total angular momentum J, in a magnetic field H can be expressed as

$$M = ng\mu_B J B_J\left(\frac{g\mu_B JH}{k_B T}\right) \qquad [1]$$

where g is the Landé factor and

$$B_J(x) = \frac{2J+1}{2J}\coth\left(\frac{2J+1}{2J}x\right) - \frac{1}{2J}\coth\left(\frac{x}{2J}\right) \qquad [2]$$

is the Brillouin function; the magnetization of a ferromagnet can then be obtained by substituting in eqn [1] the applied magnetic field H with $H + \lambda M$, leading to the implicit equation

$$\frac{M}{ng\mu_B J} = B_J\left(\frac{g\mu_B J}{k_B T}H + \frac{g\mu_B J}{k_B T}\lambda M\right) \qquad [3]$$

In order to investigate the possibility of spontaneous magnetization, the $H = 0$ case is considered; eqn [3] can be rewritten as

$$m = tx = B_J(x) \qquad [4]$$

with

$$x = \frac{g\mu_B J\lambda M}{k_B T}; \quad t = \frac{k_B T}{n\lambda(g\mu_B J)^2} \qquad [5]$$

A graphical solution of eqn [4] is given in **Figure 1**; if $t \geqslant t_C = (J+1)/3J$, only the trivial solution $x = 0$ is present, while otherwise there is also a possible solution with $x \neq 0$. This means that there exists a critical temperature T_C (Curie temperature), below which a ferromagnetic compound can have a nonzero magnetization in the absence of an applied magnetic field. The Curie temperature and saturation magnetization for several ferromagnetic elements are listed in **Table 1**. It is worth noting that eqn [4] can be expressed in terms of J, $m = M(T)/M(0)$ and $t = (J+1)/(3J)\ T/T_C$ only. In the classical limit ($J \to \infty$), $B_J(x)$ is substituted by the Langevin function $\coth x - 1/x$, and the function $m(t)$ is the same for all ferromagnetic materials; the latter statement is often referred to as the law of corresponding states.

Figure 2 shows the temperature dependence of the magnetization measured for nickel (Ni), together with the curve derived from eqn [4] considering a pure-spin moment $J = S = 1/2$. The overall agreement is fairly good, and can be further improved

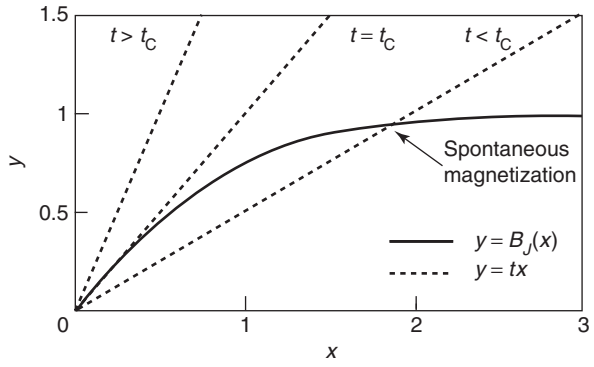

Figure 1 Graphical solution of eqn [4] (see text for details).

Table 1 Curie temperature, saturation magnetization at room-temperature, and magnetic moment per formula unit (at 0 K) of ferromagnetic elements

Element	T_C (K)	M_S (10^6 A m^{-1})	μ_B/*formula unit*
Cobalt	1388	1.42	1.72
Iron	1043	1.71	2.22
Nickel	627	0.48	0.61

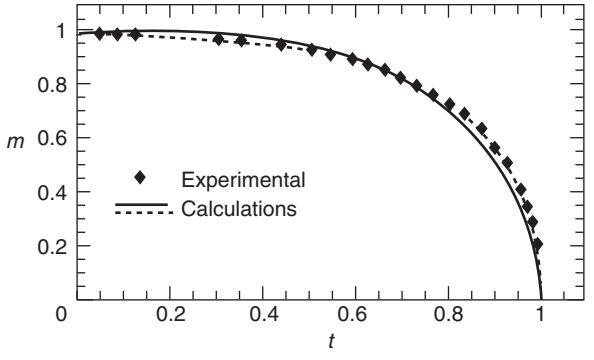

Figure 2 Experimental (diamonds) and calculated (lines) value of $m = M(T)/M(0)$ vs. $t = T/T_C$ for nickel ($J = S = 1/2$). Experimental data are taken from Weiss P and Forrer R (1926) Aimantation et phenomene magnetocalorique du nickel. *Ann. Phys.* 5: 153. The full black line is calculated by means of eqn [4]; dashed lines take into account the spin-wave excitations at low T and the critical behavior near the Curie point.

by the use of more accurate models (the low-temperature decrease due to spin waves and the critical behavior near T_C are shown as dashed lines for comparison).

Above T_C, the sample is in a paramagnetic phase (disordered moments), and its magnetic susceptibility can be calculated by noting that $B_J(x) \simeq (J+1)\,x/(3J)$ for small values of x, leading to

$$\chi \equiv \frac{M}{H} = \frac{C}{T - \lambda C} \qquad [6]$$

where C can be identified with the paramagnetic Curie constant ($\chi = C/T$ if no ferromagnetic order exists, i.e., $\lambda = 0$) and $T_C = \lambda C$. This very simple model gives a fairly accurate description of the experimental magnetic susceptibilities of ferromagnetic compounds at high temperatures.

It must be noted that λM can be as large as several times the maximum magnetic field which can be produced in a standard laboratory, and is about four orders of magnitude larger than the dipolar interaction due to the other magnetic ions in the crystal. The physical origin of this huge molecular field was not clear until the development of quantum mechanics made it possible to point out the role of the exchange interaction (a purely quantum effect and a direct consequence of Pauli's principle) in determining the magnetic spin alignment. The exchange interactions between a collection of N spins can be described by the Heisenberg–Dirac Hamiltonian, which has the form

$$H_{\text{H–D}} = -\sum_{i,j} J_{ij} \boldsymbol{S}_i \cdot \boldsymbol{S}_j \qquad [7]$$

where the sign of the exchange constants J_{ij} depends on whether the two spins labeled i and j are coupled ferromagnetically (positive) or antiferromagnetically (negative), and the sum usually involves only the z nearest neighbors since the interaction strength drops very rapidly as the distance increases. In the presence of an applied magnetic field $\boldsymbol{H}$, the Zeeman term

$$H_Z = -2\mu_B \sum_i \boldsymbol{H} \cdot \boldsymbol{S}_i \qquad [8]$$

must also be considered (a gyromagnetic factor of 2 was taken, in the hypothesis that pure spin moments are being dealt with). The molecular field approximation consists in reducing the N-body Hamiltonian $H_{\text{H–D}} + H_Z$ to N one-body Hamiltonians H_i, by replacing all the spin operators except $\boldsymbol{S}_i$ with their average values:

$$H_i = -\boldsymbol{S}_i \cdot \left[\sum_j J_{ij} \langle \boldsymbol{S}_j \rangle + 2\mu_B \boldsymbol{H} \right] \qquad [9]$$

The case now considered is that of a ferromagnetic body, with all the relevant exchange constants $J_{ij} = J > 0$ for simplicity. Since

$$\boldsymbol{M} = 2\mu_B \sum_l \langle \boldsymbol{S}_l \rangle \qquad [10]$$

is the total magnetization of the sample, eqn [9] can be rewritten as

$$H_i = -2\mu_B \boldsymbol{S}_i \cdot [\boldsymbol{H} + \lambda \boldsymbol{M}] \qquad [11]$$

with

$$\lambda = \frac{zJ}{4\mu_B^2 N} \qquad [12]$$

Equation [11] immediately shows that the mean-field analysis based on the Heisenberg–Dirac exchange Hamiltonian provides an *a posteriori* justification to Weiss' molecular-field hypothesis; as one might expect, the accuracy of this approximation is higher when z and J are larger, since in this case the role of the fluctuations $\boldsymbol{S}_i - \langle \boldsymbol{S}_i \rangle$ is practically negligible and the substitutions made in eqns [7] and [8] are well-grounded.

One word of caution is required before the end of this section. The existing theories of magnetism may roughly be divided into two groups, dealing respectively with localized and itinerant magnetic moments. The Heisenberg approach which was mentioned before belongs to the former; to give a meaning to eqn [7], it must be explicitly assumed that each ion in the crystal carries on it a well-defined magnetic moment $\boldsymbol{S}_i$ due to the electrons which are bound to it. Although this approach is very useful when dealing with certain substances and alloys and for studying critical magnetic behaviors, its validity for metals is questionable due to the presence of conduction electrons, not tied to a specific ion but belonging to the whole crystal. On the other hand, band models considering the role of itinerant electrons have managed to solve several flaws of localized theories, such as the noninteger values of the magnetic moment per atom experimentally measured in most ferromagnets (**Table 1**), which could not be explained within a localized-moment framework.

Magnetostatic Energy and Demagnetizing Field

One may consider a sample of a magnetic substance, composed of n magnetic atoms per unit volume, each carrying an elementary moment $\boldsymbol{\mu}$, and imagine applying a magnetic field which is strong enough to align all these dipoles along the same directions. As a result of this process, the sample will display a saturation magnetization

$$M_S = n|\boldsymbol{\mu}| \qquad [13]$$

(it may be recalled that the magnetization is defined as the total magnetic moment per volume unit).

The energy required to obtain this configuration is

$$E = -\mu_0 \int \boldsymbol{H} \cdot \mathrm{d}\boldsymbol{M} \qquad [14]$$

where $\boldsymbol{H}$ indicates the magnetic field and $\boldsymbol{M}$ is the magnetization vector. In the absence of dissipative processes, an equivalent amount of magnetic potential energy is stored within the sample.

In turn, any magnetized body produces a magnetic field in its surrounding space, as one can immediately witness by means of a compass needle. In close analogy with the charge polarization of a dielectric material, one can describe this field as being generated by "free" magnetic poles (i.e., positive poles not neutralized by the presence of a negative pole in their immediate neighborhood and vice versa) on the surface; in addition to this, the presence of a magnetic field generated by an external source is usually considered. Outside the sample, the magnetic induction $\boldsymbol{B}$ and the magnetic field $\boldsymbol{H}$ are always proportional (as $\boldsymbol{B} = \mu_0[\boldsymbol{H} + \boldsymbol{M}]$ and $\boldsymbol{M} = 0$) and their flux lines are oriented from the north (N) to the south (S) poles. On the other hand, the total magnetic field $\boldsymbol{H}_{\mathrm{int}}$ inside the sample is found by summing the external field, which is parallel to the magnetization, and the contribution from the free poles, which is antiparallel to it (in fact, the flux lines of $\boldsymbol{H}$ always begin on N poles and end on S poles except when the magnetic field is due to electric currents, in which case they are closed and continuous). The free-poles contribution is also called demagnetizing field, and can be represented as

$$\boldsymbol{H}_{\mathrm{d}} = -\underline{N}_{\mathrm{d}} \cdot \boldsymbol{M} \qquad [15]$$

where $\underline{N}_{\mathrm{d}}$ is, in general, a second-order tensor whose components depend on the geometry of the studied system; in some particular cases and/or for special directions of the magnetic field, $\boldsymbol{M}$ and $\boldsymbol{H}$ are collinear, and one can write a simpler relation where N_{d} is a dimensionless number called demagnetizing factor. For example, a homogeneous spherical sample (**Figure 3**) has $N_{\mathrm{d}} = 4\pi/3$, hence

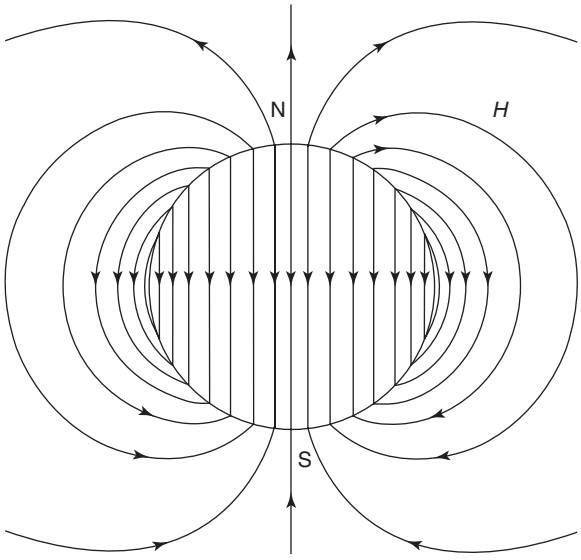

Figure 3 Magnetic field generated inside and outside a uniformly magnetized sphere. The magnetization vector $\boldsymbol{M}$ is directed from the S to the N pole; the resulting demagnetizing field (inside the sphere) is antiparallel to $\boldsymbol{M}$.

$$\boldsymbol{H}_{\mathrm{d}} = -\frac{4\pi}{3}\boldsymbol{M} \qquad [16]$$

Demagnetizing factors for samples of various geometries and for different field directions can be found in specialized textbooks.

Magnetic Anisotropy

Another contribution to the energy balance, that is, magnetic anisotropy, will be dealt with now. While the meaning of such a locution is quite simple (the magnetic behavior of a material depends on the direction), it is not easy to understand the physical reasons behind its very existence. In fact, magnetic anisotropy may be produced by several different mechanisms, which include (but are not limited to) magnetocrystalline (or crystal-field) anisotropy, shape anisotropy, stress anisotropy, annealing in a magnetic field, etc. For the sake of simplicity, the considerations made in the following will be referred to a uniformly magnetized single-crystal sample.

From a phenomenological point of view, the effect of magnetic anisotropy may be taken into account by adding to the energy balance an extra term E_{A} (anisotropy energy), which depends on the relative orientation of the magnetization vector with respect to the crystallographic axes. As shown by the Russian

physicist Akulov, the free anisotropy energy per unit volume can always be expressed by an infinite series

$$\begin{aligned} E_A &= \sum_{n=1}^{+\infty}\left(\sum_{i_1=1}^{3}\sum_{i_2=1}^{3}\cdots\sum_{i_n=1}^{3} c_{i_1,i_2,\ldots,i_n}\alpha_{i_1}\alpha_{i_2}\ldots\alpha_{i_n}\right) \\ &= \sum_{i=1}^{3} c_i\alpha_i + \sum_{i=1}^{3}\sum_{j=1}^{3} c_{i,j}\alpha_i\alpha_j \\ &\quad + \sum_{i=1}^{3}\sum_{j=1}^{3}\sum_{k=1}^{3} c_{i,j,k}\alpha_i\alpha_j\alpha_k \\ &\quad + \sum_{i=1}^{3}\sum_{j=1}^{3}\sum_{k=1}^{3}\sum_{l=1}^{3} c_{i,j,k,l}\alpha_i\alpha_j\alpha_k\alpha_l + \cdots \end{aligned} \quad [17]$$

where α_1, α_2, and α_3 are the direction cosines of the magnetization vector with respect to the Cartesian axes x, y, and z, and several coefficients may equal zero for symmetry reasons; for example, all the terms of the sum with odd n vanish if eqn [17] is invariant under inversion of the magnetization. In most relevant cases, eqn [17] can be rewritten as

$$E_A = \sum_{n=1}^{+\infty} K_n A_n(\alpha_1, \alpha_2, \alpha_3) \quad [18]$$

for example, a ferromagnetic crystal with cubic lattice symmetry has $A_0(\alpha_1, \alpha_2, \alpha_3) = 1$; $A_1(\alpha_1, \alpha_2, \alpha_3) = \alpha_1^2\alpha_2^2 + \alpha_1^2\alpha_3^2 + \alpha_2^2\alpha_3^2$; $A_2(\alpha_1, \alpha_2, \alpha_3) = \alpha_1^2\alpha_2^2\alpha_3^2$; etc. The coefficients K_n, named anisotropy constants, can be determined by magnetization measurements; a knowledge of a reliable set of anisotropy constants for a given sample can lead to a direct phenomenological interpretation of the magnetic processes and is useful to make comparisons between different systems.

For lattices with uniaxial symmetry (e.g., cylindrical, hexagonal, and tetragonal), compact expressions for the anisotropy energy can be derived as a function of the polar and azimuthal angles θ and φ, which define, respectively, the angle between the magnetization vector $\boldsymbol{M}$ and the z-axis (coincident with the symmetry axis), and the angle between the projection of $\boldsymbol{M}$ on the xy-plane and the x-axis. In this case,

$$E_A = \sum_{n=0}^{+\infty} \sin^{2n}\theta \sum_{0 \leqslant l < n/m} K_n^{(l)} \cos(lm\varphi) \quad [19]$$

As for the cubic phase, the K_0 term is an isotropic energy shift, and will therefore be dropped in the following. The value of m depends on the particular symmetry, leading to

$$\begin{aligned} E_A &= K_1 \sin^2\theta + K_2 \sin^4\theta + K_3 \sin^6\theta \\ &\quad + K_3' \sin^6\theta \cos 6\varphi + \cdots \end{aligned} \quad [20]$$

($m = 6$) for a hexagonal lattice and

$$\begin{aligned} E_A &= K_1 \sin^2\theta + K_2 \sin^4\theta + K_2' \sin^4\theta \cos 4\varphi \\ &\quad + K_3 \sin^6\theta + K_3' \sin^6\theta \cos 4\varphi + \cdots \end{aligned} \quad [21]$$

($m = 4$) for a tetragonal system. For a perfectly cylindrical system ($m \to \infty$), the anisotropy on the xy-plane vanishes and one is left with

$$E_A = \sum_{n=0}^{+\infty} K_n \sin^{2n}\theta \quad [22]$$

If no applied field is present, the sample magnetization will have the tendency to stay along a direction where the anisotropy energy is lowest; this is called in brief "easy magnetization direction" (EMD). This feature will be discussed in detail later, but it may be immediately inferred that the larger the anisotropy, the larger the magnetic field required to rotate the magnetization direction. Therefore, anisotropy is a key property to take into account when designing or choosing suitable magnetic compounds for particular applications.

In the following section, the most important physical mechanisms giving rise to magnetic anisotropy are discussed in brief.

Magnetocrystalline Anisotropy

Exchange interaction in a ferromagnet can be seen as a spin–spin coupling which aligns the spin moments along the same direction. On the other hand, the orbital moments of any magnetic ion in the lattice preferably align along given crystallographic directions due to the crystal-field potential, which reflects the local crystal symmetry. Magnetocrystalline anisotropy is generated by the spin–orbit interaction, which favors mutual alignment between the spin and orbital moments; if this coupling is relatively strong, as for rare-earths and actinides, moment directions which are farther from the crystallographic easy-axis will have a higher cost in energy. Although several types of anisotropy exist, only magnetocrystalline anisotropy is intrinsic to the material.

In terms of anisotropy constants, subsequent terms of eqn [18] will contain increasing powers of the ratio of the spin–orbit energy to that of the crystal field. As the spin–orbit interaction is weak for $3d$ metals, the series is generally truncated after the second or fourth order, and only terms in K_1 and K_2 are included. In principle, this is not possible for $4f$ elements; however, in the case of intermetallic rare-earth–transition-metal alloys, approximate expressions can be found as linear combinations of generalized Brillouin functions, with appropriate

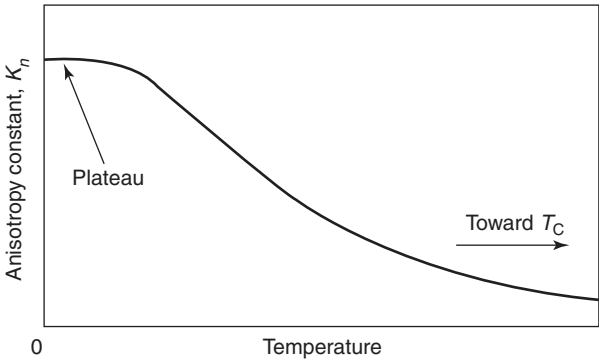

Figure 4 Typical temperature behavior of anisotropy constants (arbitrary units are used).

coefficients related to the decomposition in terms of spherical harmonics of the crystal-field potential at the rare-earth site. On these grounds, it is usually possible to consider $K_n = 0$ for $n \geqslant 4$. The typical temperature dependence of anisotropy constants is shown in **Figure 4**. On changing the temperature, the anisotropy constants of different order can have different relative variations; as a result of this, the EMD of a sample may spontaneously change, giving rise to a spin reorientation transition (SRT) induced by temperature even in the absence of a magnetic field.

Shape Anisotropy

The free poles on the surface of a perfectly spherical and homogeneous sample give rise to a demagnetizing field which is collinear and linearly proportional to the magnetization vector, as described by eqn [16]. In more general terms, however, one must refer to eqn [15] to find the correct value and direction of the demagnetizing field corresponding to a given magnetization vector. The relatively simple case of an elongated rotation ellipsoid with two axes of equal length is considered; for symmetry reasons, one has

$$\underline{N}_{\mathrm{d}} = \begin{pmatrix} N_\perp & 0 & 0 \\ 0 & N_\perp & 0 \\ 0 & 0 & N_\parallel \end{pmatrix} = \begin{pmatrix} N_\perp & 0 & 0 \\ 0 & N_\perp & 0 \\ 0 & 0 & N_\perp + \Delta N \end{pmatrix} \qquad [23]$$

where $\Delta N = N_\parallel - N_\perp$ According to eqn [15] and knowing that all homogeneous bodies delimited by second-order surfaces magnetize uniformly, one can write

$$\boldsymbol{H}_{\mathrm{d}} = -\underline{N}_{\mathrm{d}}\boldsymbol{M} = -N_\perp \boldsymbol{M} - \Delta N(\boldsymbol{M}\cdot\hat{\boldsymbol{z}})\hat{\boldsymbol{z}} \qquad [24]$$

where $\hat{\boldsymbol{z}}$ is the unit vector along the direction of the elongated axis of the ellipsoid. The associated energy can be calculated as

$$E = -\mu_0 \int \boldsymbol{H}_{\mathrm{d}} \cdot \mathrm{d}\boldsymbol{M} = \mu_0 M^2 \left(\frac{N_\perp}{2} + \frac{\Delta N}{2}\cos^2\theta\right) = \mu_0 M^2 \left(\frac{N_\parallel}{2} - \frac{\Delta N}{2}\sin^2\theta\right) \qquad [25]$$

which corresponds to eqn [22], the only nonzero anisotropy constants being $K_0 = \mu_0 M^2 N_\parallel/2$ and $K_1 = -\mu_0 M^2 \Delta N/2$. The extrinsic character of shape anisotropy can be immediately noticed, as the calculated K_1 strongly depends on the shape and bulk magnetization of the sample. While shape anisotropy is usually smaller than crystal-field anisotropy for ferromagnetic rare-earth elements and alloys, they may be of the same order of magnitude for transition metals such as iron and cobalt.

Stress Anisotropy

Applying mechanical stress treatments such as lamination, rolling, or extrusion to a magnetic sample can lead to significant crystal deformations. Stress anisotropy may then be generated due to the magnetoelastic coupling between the lattice and the magnetic moments present in the system (magnetostriction).

Anisotropy Induced by Magnetic Annealing

Heat treatments performed under the Curie temperature of the sample in the presence of an applied magnetic field ("magnetic annealing") may result in the generation of uniaxial anisotropy with respect to the field direction. The induced anisotropy is, in general, rather small, although larger effects may be obtained when a structural transition takes place during the annealing.

Magnetic Domains

As has been mentioned in the introduction, the situation of complete alignment of the elementary magnetic dipoles present in a ferromagnetic substance is energetically favorable due to the exchange interaction. However, it is easy to verify that a piece of iron, taken off the shelves and kept below its Curie temperature, is basically unmagnetized and does not produce any magnetic field. Thermal disorder should obviously not be expected to affect the net magnetization significantly, since the exchange interaction responsible for the alignment of the moments is several orders of magnitude larger than the dipole–dipole interaction in a paramagnet. On the other

hand, if one sticks to the molecular-field approach, one must be aware that the solution $M = 0$, $H = 0$ satisfies eqn [3] both above and below T_C.

In order to gain some physical insight on this point, the energy of a magnetized body, under the effect of an external magnetic field $\boldsymbol{H}$, is considered:

$$E = -\mu_0 \int (\boldsymbol{H} + \boldsymbol{H}_d) \cdot d\boldsymbol{M} \qquad [26]$$

In the simple case that the magnetization is uniform all over the sample and that the demagnetizing field can be expressed as $\boldsymbol{H}_d = -N_d\boldsymbol{M}$, eqn [26] becomes

$$\begin{aligned} E &= -\mu_0 \boldsymbol{H} \cdot \int d\boldsymbol{M} + \mu_0 N_d \int \boldsymbol{M} \cdot d\boldsymbol{M} \\ &= -\mu_0 \boldsymbol{H} \cdot \boldsymbol{M} + \mu_0 N_d \frac{M^2}{2} \end{aligned} \qquad [27]$$

The first term on the right-hand side is the familiar expression for the Zeeman energy, and can be minimized by aligning the magnetization vector with the external field and maximizing its modulus. The second term is the self-energy of the magnetized body due to the free poles, and can be minimized by minimizing the net magnetization. On the other hand, this term also represents the amount of energy which is stored in the external magnetic field generated by the sample; therefore, if the applied field $\boldsymbol{H}$ equals zero, it can be inferred that in the lowest energy state, the magnetic field generated by the sample must be as small as possible. From the microscopic point of view, the energy balance results from a competition between exchange coupling (which lowers the total energy if two spins are parallel) and the dipole–dipole interaction (which raises the total energy if two spins are parallel). As a result, the sample is divided in several macroscopic regions, each one having uniform magnetization, called domains. Within a single domain, the spins are parallel to one another; in turn, spins belonging to two different domains can have very different directions (**Figure 5**) in order to minimize the bulk magnetization.

One may naively expect that the subdivision in domains occurs as in **Figure 6a** (i.e., all the spins belonging to domains A and B are arranged along the easy-axis direction), and that spins belonging to different neighboring domains are antiparallel to one another. This configuration certainly minimizes the anisotropy energy, but at a large cost of exchange energy for the two antiparallel spins situated at the interface. In general, it is less expensive to have the spins arranged as in **Figure 6b**; the 180° spin rotation is performed in several different steps within a region between domains A and B, known as "Bloch wall."

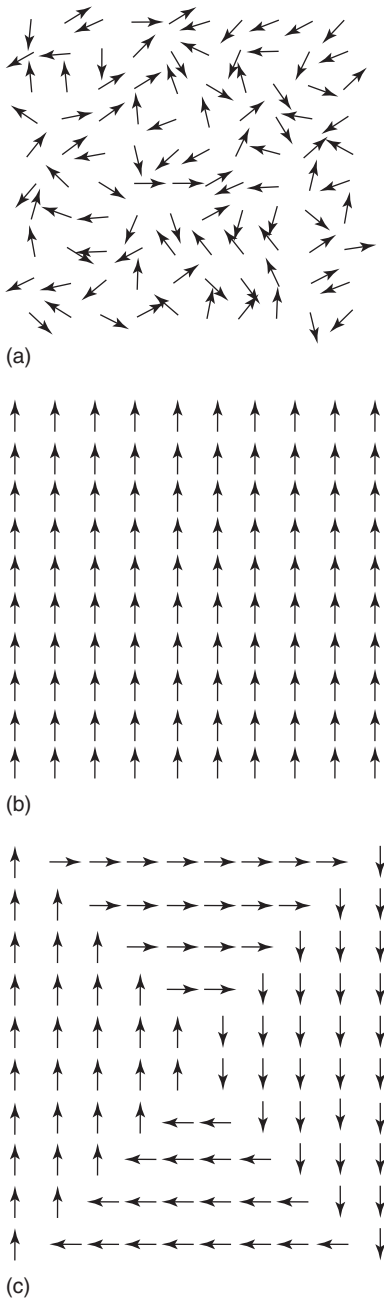

Figure 5 Schematic view of the dipole arrangements in (a) a paramagnet (or ferromagnet above T_C), (b) a magnetized (saturated) ferromagnet, and (c) an unmagnetized ferromagnet (divided into domains). While the moments in the paramagnetic phase are disordered at the atomic level, the domain size is macroscopic (even several hundred micrometers).

For the sake of clarity, consider the case of a simple cubic crystal with lattice constant a, with a nearest-neighbor exchange constant J and EMD along [1 0 0]. The energy balance may be estimated by assuming that the rotation is performed within the xz-plane in N equal steps, each of an angle π/N; then the total exchange energy per unit area of the Bloch

wall is

$$E_{ex} = -J \sum_{l=0}^{N} \boldsymbol{S}_l \cdot \boldsymbol{S}_{l+1} = -J \sum_{l=0}^{N} S^2 \cos\frac{\pi}{N}$$
$$= -JS^2 \frac{(N+1)}{a^2} \cos\frac{\pi}{N} \qquad [28]$$

while, according to eqn [18] with $\alpha_y = 1$, $\alpha_z = \cos\theta$, and $\alpha_x = \cos(\pi/2 - \theta) = \sin\theta$, the anisotropy energy per area unit is

$$E_A = a \sum_{l=0}^{N} K_1 \sin^2\frac{l\pi}{N} \cos^2\frac{l\pi}{N} = \frac{aK_1}{8} N \qquad [29]$$

(strictly valid for $N > k$). E_{ex} and E_A are opposite in sign, and the absolute value of both grows with N; the actual size of the Bloch wall then results from a competition of the two, being smaller when the anisotropy dominates and larger when the exchange interaction dominates. In the large-N limit $E_{ex} \simeq JS^2\pi^2/(Na^2)$, and minimizing the total energy gives an approximate domain wall width of

$$\ell = Na \simeq 2\pi S \sqrt{\frac{2J}{aK_1}} \qquad [30]$$

typically a few hundred lattice constants for iron.

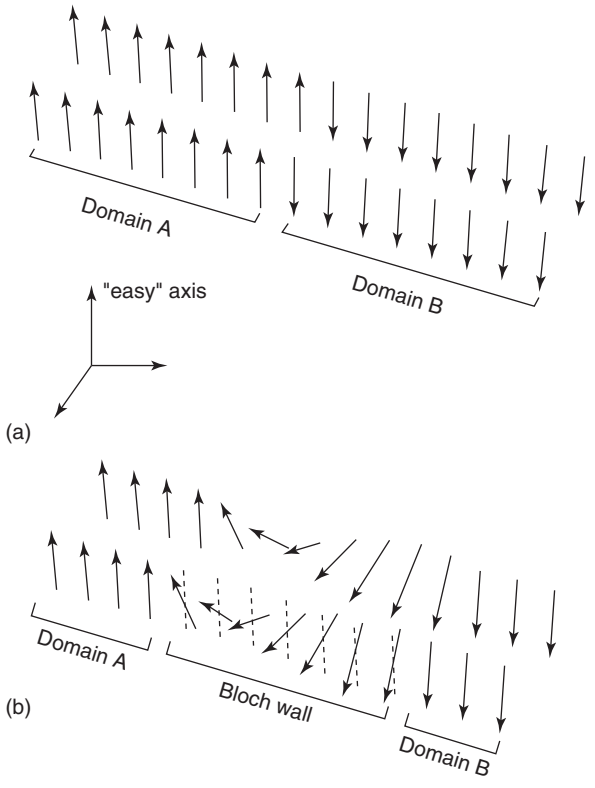

Figure 6 Schematic view of the dipole arrangements at the boundary between two domains (Bloch wall).

The Magnetization Curve

From the macroscopic point of view, ferromagnets may be considered at a first glance as magnetic materials with extremely large susceptibility and permeability. In practice, as both of them are strongly dependent not only on the temperature, but also on the applied field and on the past history of the sample, they are not very useful parameters and it is quite simple to describe the physical properties of a ferromagnet by means of $\boldsymbol{M}$ versus $\boldsymbol{H}$ (or $\boldsymbol{B}$ versus $\boldsymbol{H}$, being $\boldsymbol{B} = \mu_0(\boldsymbol{H} + \boldsymbol{M})$) plots, whose main characteristics will be discussed in the following sections.

The Hysteresis Cycle

When an external magnetic field is applied to a ferromagnetic sample in a demagnetized state in order to bring its resulting magnetization to saturation, one obtains the magnetization curve shown in **Figure 7**. Two distinct and coexistent processes must be considered in order to understand this (**Figure 8**): boundary motion and domain rotation. In the former case, those domains which are favorably oriented with respect to the applied field grow in size at the expense of the others, without changing their overall magnetization direction; this process is dominant at low fields. At intermediate fields, the process of sudden rotation of the magnetization of unfavorably oriented domains to the easy-axis direction(s) nearest to that of the applied field also becomes significant. At a given value of the magnetic field (labeled H_S), saturation is finally achieved ($M = M_S$, defined in eqn [13]), mainly by coherent rotation of the domain magnetization toward the applied field direction. For $H > H_S$, the $M(H)$ curve is flat since the applied field is already strong enough

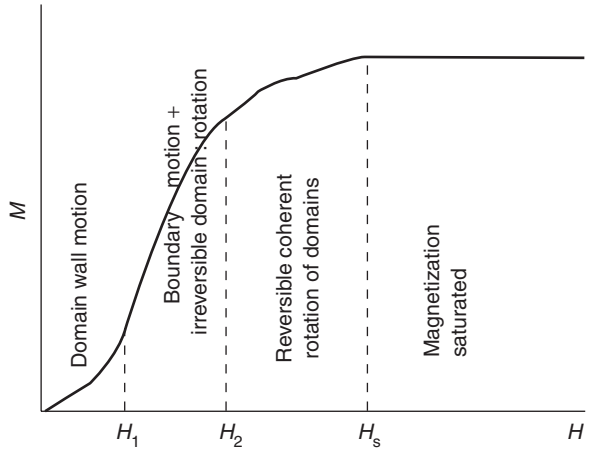

Figure 7 "Virgin" magnetization curve of a ferromagnet. The main mechanisms by which the magnetization process advances for several applied field values are indicated.

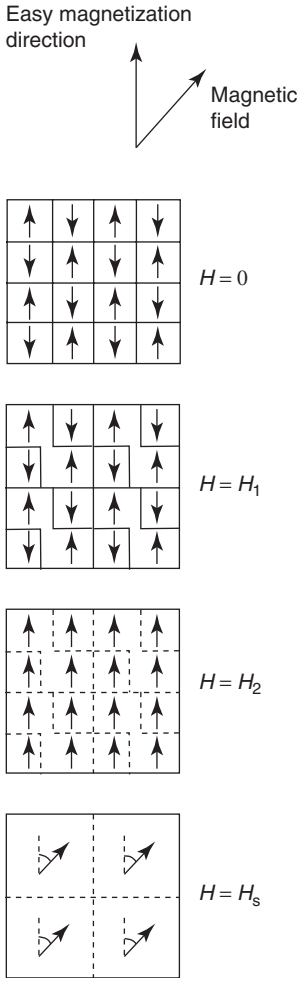

Figure 8 Schematic view of the main mechanisms by which the magnetization process advances for several applied field values.

to align all the elementary dipoles in the sample along its direction.

If the value of the applied field is now reduced to zero, it is noticed that the obtained $M(H)$ curve does not coincide with the previous one apart from a small region near H_S. In particular, the magnetization at zero applied field does not go back to zero (retentivity), and its value M_R is called remanence or remanent magnetization. In order to force the magnetization to zero, it is necessary to apply a magnetic field H_C in the opposite direction; this value is called coercivity or coercive field. (Some authors make use of a distinction between remanence/coercivity (indicating the sample behavior after it has reached saturation) and remanent magnetization/coercive field (relative to a magnetization curve reaching an arbitrary value $M<M_S$).) Raising the reverse field strength to H_S leads to the saturation of the magnetization in the opposite direction as before. Reversing the field once again, one obtains the so-called hysteresis loop (**Figure 9**).

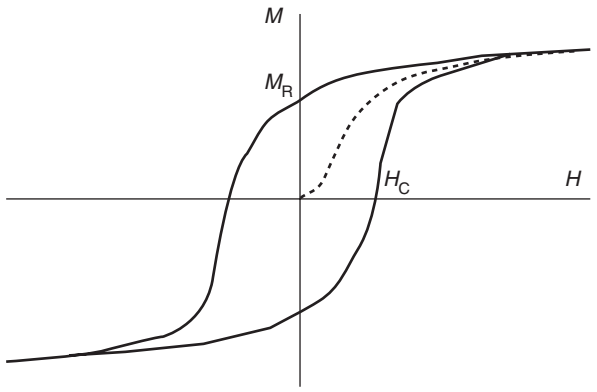

Figure 9 Hysteresis cycle of a ferromagnet. Remanence (M_R) and coercivity (H_C) are indicated on the graph axes.

While "hard" magnetic materials (i.e., those displaying a large coercivity) are generally useful as permanent magnets or for memory-storage purposes (in order to avoid demagnetization due to stray magnetic fields), "soft" ones may be good candidates for the realization of power transformers or electromagnets. In the former case, apart from retentivity, coercivity, and Curie temperature, another figure of merit which is often used in practice is the maximum energy product BH_{max}, which is the maximum value of the product $\boldsymbol{B}\cdot\boldsymbol{H}$ in the demagnetizing quadrant ($M>0$, $H<0$) of the hysteresis curve. This corresponds to the energy stored in the considered material within a magnetic circuit operating at an optimized workpoint, and should not be confused with the energy lost due to the irreversible processes during one hysteresis loop, that is,

$$\oint \boldsymbol{B}\cdot \mathrm{d}\boldsymbol{H} \qquad [31]$$

Magnetization Rotation and Anisotropy

Most of the energy loss during the hysteresis cycle occurs at low fields as a result of irreversible domain boundary motion, due to inhomogeneous microstrains (dislocations) which obstructs the rotation of the magnetic moments. On the other hand, processes involving domain rotation are governed by a competition between the anisotropy and the Zeeman energy $E_Z = -\mu_0 \boldsymbol{H}\cdot\boldsymbol{M}$. To study the role of anisotropy in determining the shape of the magnetization curve, assume that the boundary motion of domain walls can be achieved with a negligibly small magnetic field. In the case of a uniaxial sample, $M(H)$ can be found by minimizing

$$E_A + E_Z = \sum_n K_n \sin^{2n}\theta - \mu_0 \boldsymbol{H}\cdot\boldsymbol{M} \qquad [32]$$

Let θ be the angle between the magnetization vector and the c-axis, which will be considered also as the EMD, for simplicity. If $\boldsymbol{H}$ is applied along the c-axis, both E_A and E_Z are minimized with $\boldsymbol{M} \| \boldsymbol{H}$ and saturation is reached immediately when the external applied field is equal to the demagnetizing field. If $\boldsymbol{H}$ is applied perpendicularly to the easy-axis, differentiating eqn [32] and knowing that $M = M_S \sin\theta$ leads to

$$HM_S = \sum_n 2nK_n \left(\frac{M}{M_S}\right)^{2n-1} \quad [33]$$

an implicit expression for the magnetization curve. By putting $M = M_S$, one can immediately find

$$H_S = \frac{2}{M_S} \sum_n nK_n \quad [34]$$

and

$$\left.\frac{dM}{dH}\right|_{H=0} = \frac{M_S^2}{2K_1} \quad [35]$$

Similar calculations can be made for any other orientations of the field and of the EMD, leading to the remarkable result that, in principle, complete saturation cannot be achieved if $\boldsymbol{H}$ is not parallel to an "extremal" direction (i.e., one which minimizes or maximizes the anisotropy energy).

Film Growth and Epitaxy: Methods

F Lévy, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Introduction

The growth of thin films is achieved through many methods resulting from the combination of various steps and devices as:

- source material and its handling,
- transport from the source to the substrate,
- growth substrate and its conditioning, and
- suitable environment in a reactor chamber.

The methods of deposition and growth can be classified according to the source and transport. In the most frequent cases where the material is transported through the vapor phase, two main groups are distinguished: physical vapor deposition (PVD) and chemical vapor deposition (CVD). Besides vapor transport, films can grow from liquid or solid phases.

The key process parameters determine the source, transport, and growth steps as well as the properties of the deposited films. The substrate temperature is the most important parameter. Depending on the method, the pressure, the energy delivered to the growing film (applied power density, electrical bias, bombardment, etc.), the chemistry and the environment considerably influence the growth and properties of the films. The functionality of the film meets the requirements of surface engineering or of sophisticated physical and chemical exigencies in microelectronics and photonics, for example. It leads to the distinction between normal polycrystalline thin films and epitaxial single crystalline films.

The growth of epitaxial thin films by PVD and CVD needs special techniques and equipment. These methods are therefore described in separate sections. The thicknesses of the functional thin films and coatings grown by thin-film techniques, range from a few

nanometers to a few micrometers. Thicker films are generally called thick films, as obtained, for example, by serigraphy or powder technology.

Several characterization and analysis techniques are used to control the film during the growth process such as thickness measurement, growth velocity, structural analysis, chemical composition, etc. The impressive variety and number of deposition methods express the absolute necessity of tailoring the surface properties of a material to meet the requirements of functionality.

Film Growth by Physical Vapor Deposition

The common feature of the PVD methods is the vapor-phase transport of the source material which constitutes the film material. Reactive processes can induce chemical reactions during the transport or at the surface of the growing film.

Evaporation

Thermal evaporation methods include the simple case of emission at the heated source of the material which condenses on the cold substrate. The source can be a refractive wire or a crucible electrically heated and containing the material to be evaporated (**Figure 1**). The evaporation rate is determined by the vapor pressure of the source material at the evaporation temperature. The Joule heating of typical tungsten or molybdenum crucible allows reaching 2800 K, which provides appreciable vapor pressures for most metals. A deposition chamber under high vacuum ($<10^{-2}$ Pa) is necessary in order to avoid oxidation of the source. To prevent the harmful reaction between source and the crucible, the heating can be done rapidly and the process is known as flash evaporation. The properties of the deposited films are usually different if thermally or flash evaporated. Inductive heating of the crucible is also possible.

The thermal evaporation of highly sensitive materials, in particular in ultrahigh vacuum (UHV) ($<10^{-6}$ Pa), is achieved by electron-beam (e-beam) heating (**Figure 1c**). The main advantages of e-gun heating is to prevent contamination by the crucible and the high evaporation temperature reachable. Electron-beam sources are generated either by thermoionic emission or by field effect cathodes.

Every evaporation process can be assisted by plasma, microwave, or electron resonance, in order to influence the deposition rate or the properties of the species condensing on the substrate.

Sputtering

The sputter deposition method includes a large number of particular techniques, from classical cathode sputtering to more sophisticated reactive magnetron sputtering, for example. The material is extracted from the source (cathode) by bombardment with accelerated positive ions of inert gas such as argon, transmitting energy and momentum to the target atoms. In the reactor, the ions are created in a DC or RF plasma sustained at pressures between 0.1 and 10 Pa. For the diode-sputtering reactor, the target and the substrate face each other (**Figure 2**). Other configurations are possible, such as confocal multitargets, ion beam sputtering or triode sputtering, each with specific advantages. Reactive sputtering takes place when a chemically active gas is mixed in the plasma, such as nitrogen or oxygen.

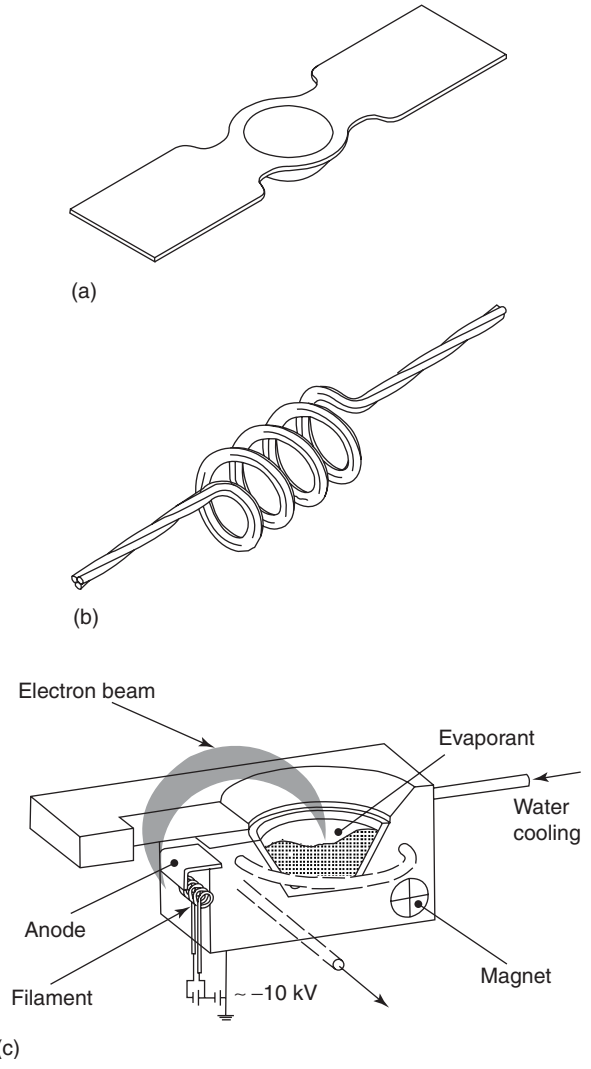

Figure 1 Thermal evaporation: basic design of evaporation sources; (a) boat crucible, (b) twisted wire, and (c) electron beam evaporator.

Magnetron sputtering One of the most powerful sputtering techniques includes permanent magnets or

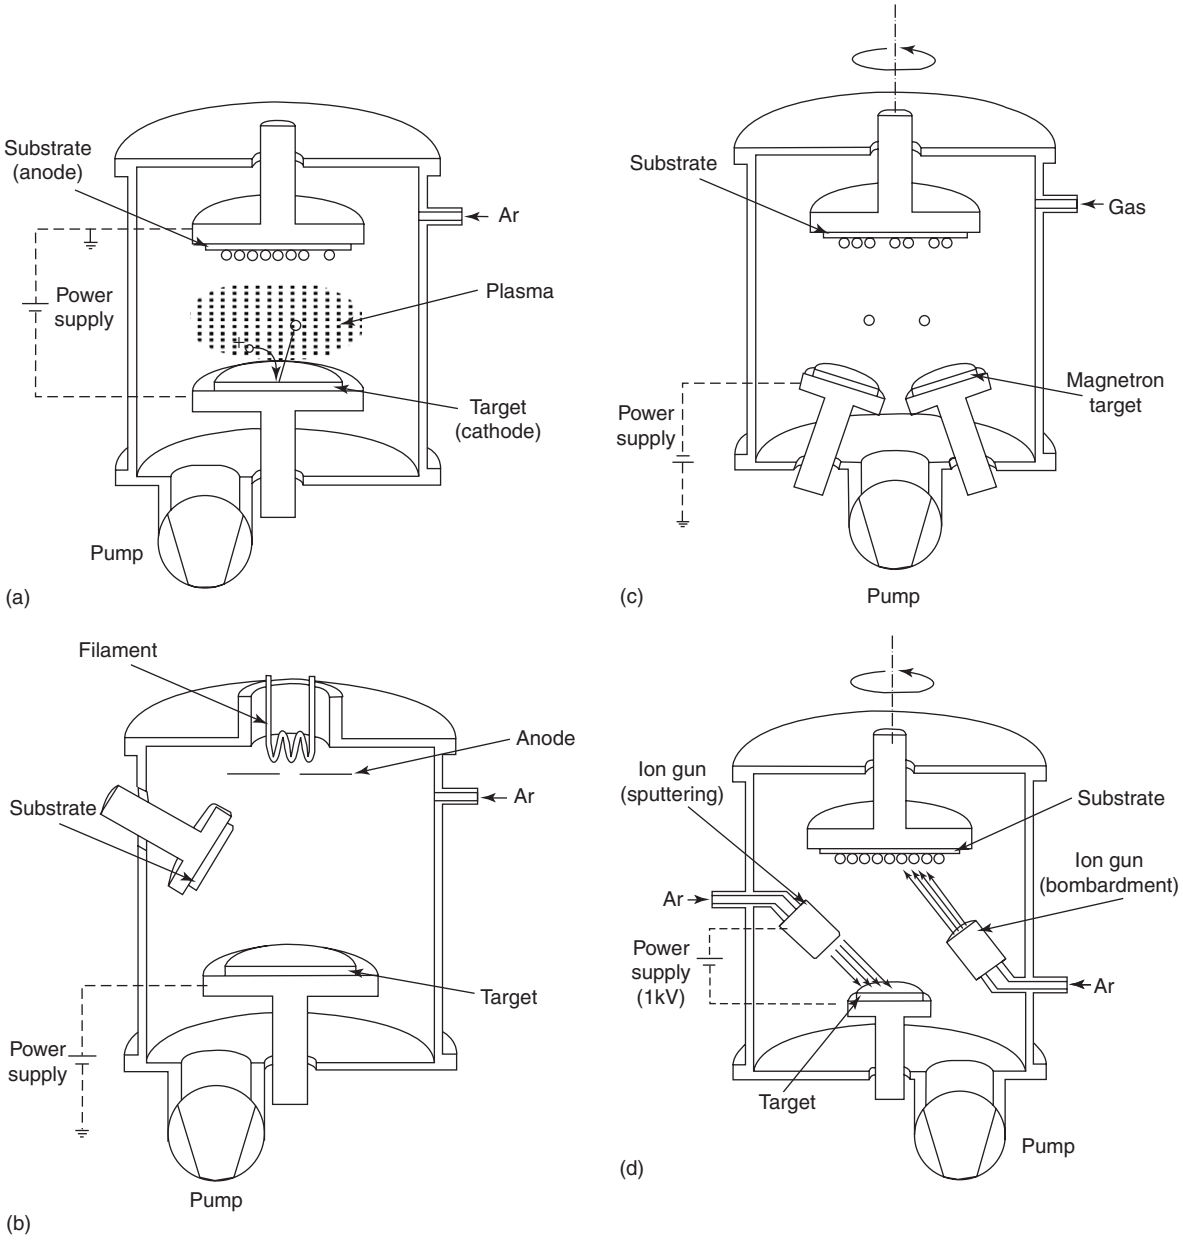

Figure 2 Reactors for PVD; (a) planar diode sputtering, (b) triode sputtering, (c) Two-source confocal magnetron sputtering, and (d) ion beam sputtering or IBAD.

coils in the target holder. The resulting magnetic field bends the secondary electron paths and concentrates the ion sputtering on specific domains on the target. The increased ionization rate results in high-deposition rates, large-deposition areas. The low substrate heating impressively extends the application ranges of magnetron sputtering to substrates with low melting temperature. Shaped cathodes allow coating the surface of the most irregular substrate, in particular, hollow vessels and tubes.

In the normal planar diode magnetron configuration, the magnetic confinement encloses the discharge near to the cathode. There is no current on the substrates. The discharge potential remains lower ($\sim 500\,\mathrm{V}$) and the work pressure of $\sim 0.1\,\mathrm{Pa}$ increases the discharge current and the deposition velocity. Several high-performance magnetron sources have been developed.

It can be profitable to keep the magnetic field open, including the substrate. This process of unbalanced magnetron sputtering allows increasing the plasma density near the substrate. Resulting currents on the substrate are then significantly higher than the normal current density $\sim 1\,\mathrm{mA\,cm^{-2}}$ produced by a

substrate bias of -30 to -100 V. The process becomes ion assisted similar to ion plating.

Cathodic-Arc Deposition

The cathodic arc deposition takes place between two metallic electrodes in vacuum (≈ 1 Pa). A cathodic arc is a low-voltage, high-current plasma discharge. The process can be made reactive by introducing a reactive gas, for example, nitrogen, in the argon plasma. The arc current is concentrated at the cathode at discrete sites called cathode spots ~ 1–$10\,\mu$m in size. The current carried by a cathode spot reaches 1–10 A. A typical arc discharge current of a few 100 A gives rise to a dense plasma of cathode material. The equipment extends from a few millimeter cathodes to typically large plants of a meter size with suitable power supplies (**Figure 3**).

The extracted material can be in the form of atoms or molecules, or metallic droplets rapidly solidified, 0.1–10 μm in diameter. This process is one of the most industrially used techniques and is suitable, for example, to TiN coatings.

Ion Plating

The definition of ion plating does not specify the source. It refers to the substrate and the growing film originally negatively polarized. The process applies in evaporation or sputtering to improve the film adhesion or influence the morphology. It provides a high energy flux to the surface, increasing the surface temperature which enhances the surface diffusion and the possible chemical reactions. It can also increase the defect concentration, at the interface and on the surface.

A variation of the technique is the "ion beam assisted deposition" where the bombardment originates from an independent ion source (ion or plasma gun) in the reactor (**Figure 2d**).

Laser Beam Ablation

Laser beam ablation or pulse laser deposition (PLD) results from the interaction of laser light with a solid. The energy of the absorbed light turns into heat and melts the solid at the surface, which evaporates (**Figure 4**). The beam light through the vapor is absorbed producing a plasma. The plasma ions can reach energies up to 1000 eV. Filters between the substrate and the source are necessary to avoid the splashing effect of liquid droplets reaching the substrate. Compounds of complicated composition such as superconducting or ferroelectric oxides, and incongruently melting solids can be deposited by laser ablation with the correct original chemical composition.

Thermal-Spraying Processes

Thermal spraying consists in melting and projecting particles (droplets of diameter $\sim 10\,\mu$m) onto a substrate, where they spread out and form a thick coating (several 10 μm thick) by progressive stacking. The material in the form of wire or powder has to melt congruently. The necessary source of energy must be powerful enough to melt, or, at least, soften the material (heat transfer) and accelerate the droplets (momentum transfer). Depending on the spraying energy source, several processes exist (**Table 1**).

- In the flame-spraying process, the powdered metal is melted in a combustion flame which expands and sprays the droplets (**Figure 5a**)

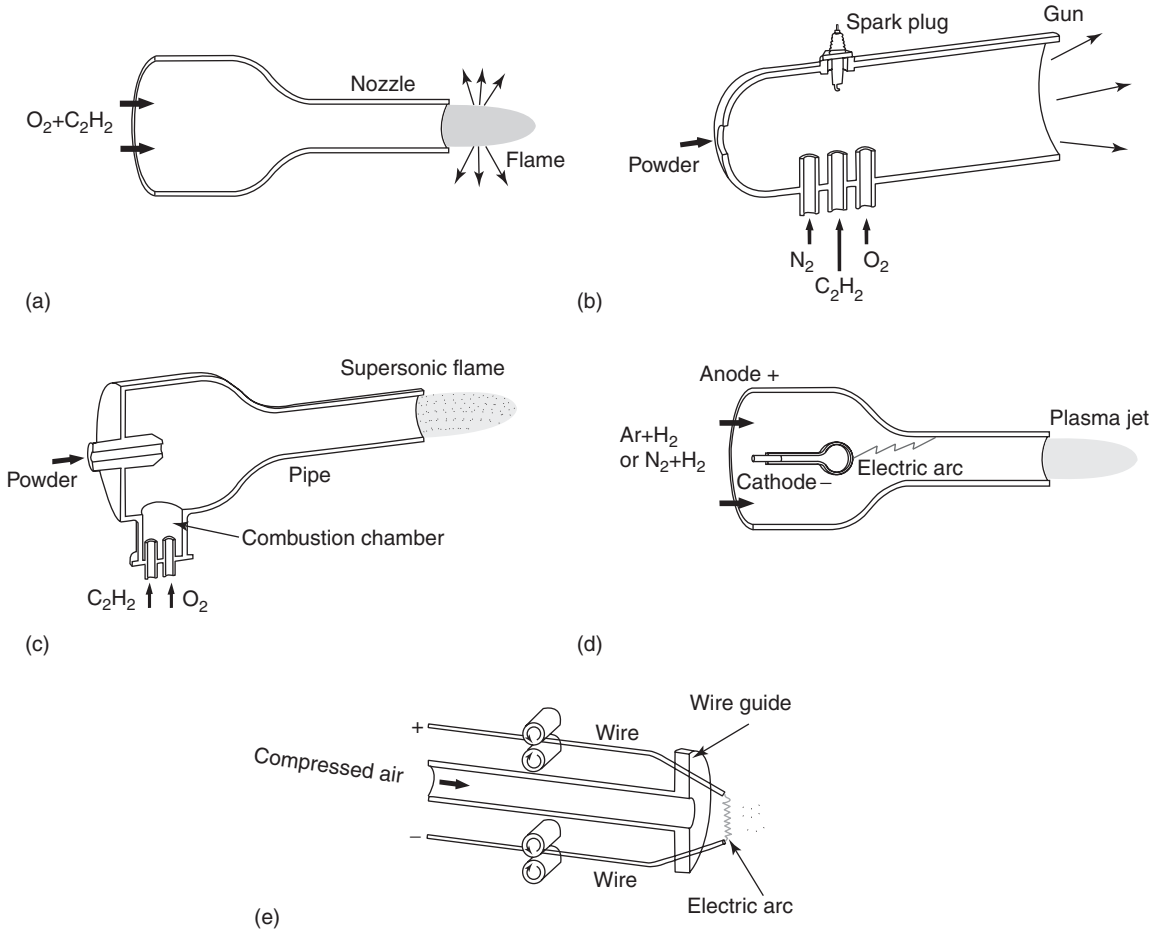

Figure 5 Thermal-spraying processes: (a) flame spraying, (b) detonation gun spraying, (c) HVOF spraying, (d) arc plasma spraying, and (e) wire arc or electric-arc spraying.

- In the gas-detonation process, the powder is injected into a gun with a gas mixture (oxygen and acetylene), which is ignited by a sparkle at a frequency of $\sim$10 Hz (**Figure 5b**). This process can maintain the substrate below 150°C.
- The high-velocity oxy-fuel (HVOF) process is a continuous combustion flame spraying under pressure. The gas temperature and, especially, the jet velocity are increased (**Figure 5c**).
- In arc plasma spraying, the powder is introduced in a low-voltage, high-current plasma. High temperature is reachable so that refractory materials can be deposited (**Figure 5d**).
- The electric-arc spraying applies to metallic wire electrodes, which are molten by the arc with the help of a compressed-air jet and projected on the substrate. The wires are continuously fed near to their intersection point (**Figure 5e**).

Thick coatings deposited by thermal-spraying processes are usually dense (up to 99.5% of theoretical density), hard, with low porosity and high adhesion.

Film Growth by Chemical Vapor Deposition

In CVD processes, the source materials generally in the form of vapors or gases are projected onto the heated substrate and react chemically to produce the expected deposit. In principle, the chemical reaction is irreversible. In order to avoid too high a deposition temperature, complementary activation processes are applied such as plasma, light, and microwave. The properties of the films depend on the precursor and the activation process.

Pyrolysis

Polycrystalline silicon (polysilicon) is deposited by pyrolyzing silane (SiH_4), for example, at 600–650°C. The deposition temperature depends on the precursor. Originally, the use of trichlorosilane ($SiHCl_3 + H_2 \rightarrow Si + 3HCl$) needed 1000–1200°C. Such a temperature is compatible with the silicon growth on hot silicon slim rods. It is less suitable to epitaxial growth or microelectronics technology. Pyrolysis also applies to the deposition of refractory metals such as tungsten and tantalum.

Chemical Vapor Deposition

The process applies to the deposition and the growth of compounds such as SiO_2, Si_3N_4, TiN, and TiCl:

$$\text{Oxides:} \quad SiCl_2H_2 + 2N_2O \rightarrow SiO_2 + 2N_2 + 2HCl$$
$$\text{or} \quad SiH_4 + O_2 \rightarrow SiO_2 + 2H_2$$

$$\text{Nitrides:} \quad 3SiH_4 + 4NH_3 \rightarrow Si_3N_4 + 12H_2$$
$$\text{or} \quad TiCl_4 + N_2 + 4H_2 + Ar \rightarrow 2TiN + 8HCl + Ar$$

$$\text{Carbides:} \quad TiCl_4 + CCl_4 + 4H_2 + Ar \rightarrow TiC + 8HCl + Ar$$

The processes evolve at atmospheric pressure or low pressure in various reactors (**Figure 6**). One of the most impressive applications of CVD is the

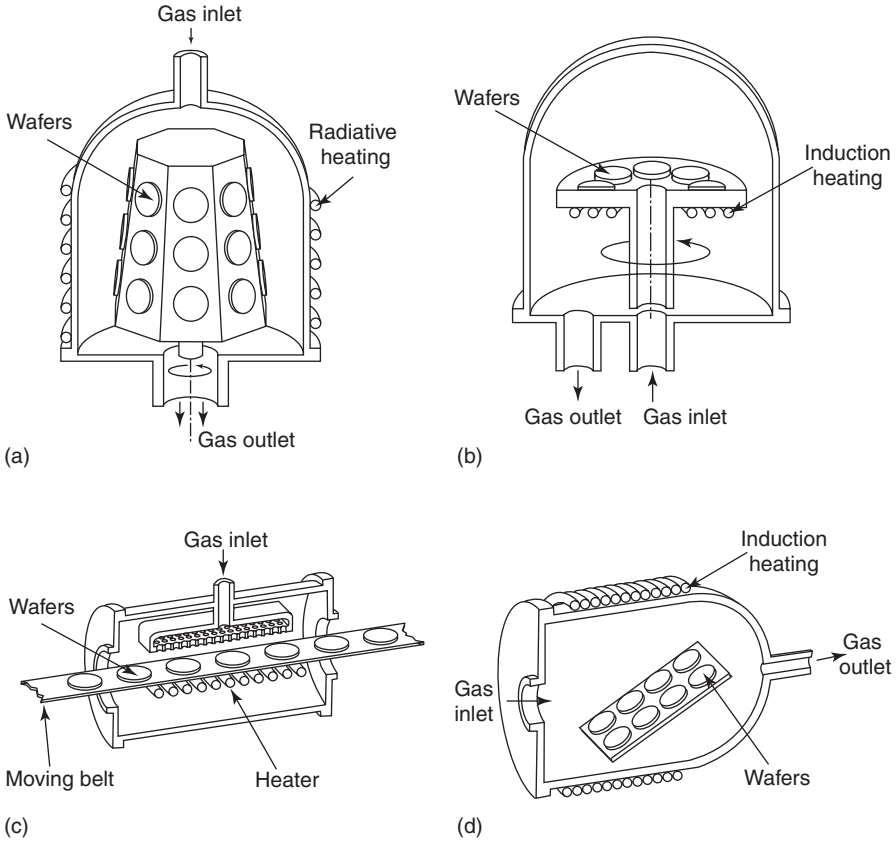

Figure 6 Reactors for vapor-phase epitaxy; (a) barrel reactor, (b) bell jar reactor radial flow, (c) continuous CVD reactor, and (d) horizontal lateral flow reactor.

vapor-phase epitaxy from $SiCl_4$, of silicon layers on Si wafers for microelectronics.

The thermal activation of the chemical reactions up to 1400°C imposes limitation to the heated substrate. Because of the temperature homogeneity in the reactor, the deposited films are also homogeneous and conformal. Geometries with the gas flow perpendicular to the surface of the substrate generally provide faster growth velocities (**Figure 6b**).

Organometallic Chemical Vapor Deposition

The thermal instability of organometallic compounds is advantageous for low-temperature decomposition and reaction. Used as precursors, these organometallics extend the chemical deposition process to many substrates. Care has to be taken regarding the toxicity of most of them. Besides, some properties (e.g., adhesion and stability) of the deposited coating can change. For example, the deposition of gallium arsenide from trimethylgallium and arsine precursors involves the reaction

$$(CH_3)_3Ga + AsH_3 \underset{H_2}{\rightarrow} GaAs + 3CH_3$$

The method is principally used for epitaxial growth, as described later.

Laser Chemical Deposition

The thermal activation of the chemical reaction can be achieved locally by irradiation with a laser beam (continuous wave or pulsed). The light beam can also excite the precursor molecules and increase the reactivity of the gas species.

Plasma-Enhanced Chemical Vapor Deposition

Low-temperature deposition ($\sim$25–400°C) is possible with a plasma process induced by microwaves or RF fields. Active species are produced in the gas phases either in the reactor or at the surface of the substrate. Besides the extension to nearly every kind of substrates, the deposition velocity increases.

Microwave-Assisted Deposition

Microwave energy (at industrial frequency of 2.45 GHz) can be beamed into a deposition reactor through a dielectric window. With a magnetic field ***B*** parallel to the direction of the microwave beam, the electrons describe spiral trajectories and gain energy due to the phenomenon of electron cyclotron resonance (ECR) (**Figure 7**). This ECR-activation contributes to sustaining any plasma by increasing the local plasma density by typically two orders of magnitude. Increased, directed, and focused deposition also results with suitable geometries and ***B*** values.

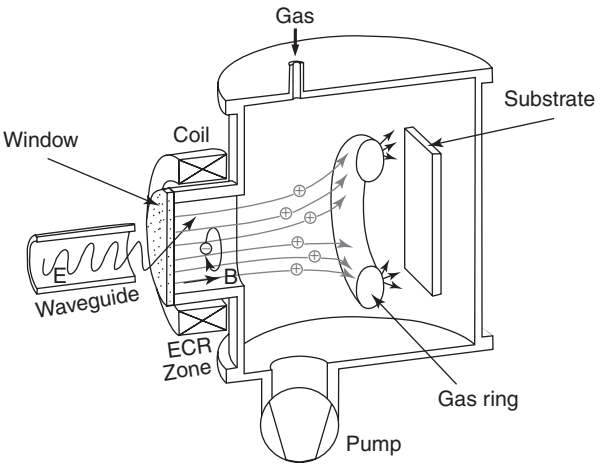

Figure 7 Microwave-enhanced plasma deposition with an ECR zone.

Microwave assistance also applies to every physical evaporation source (PVD) instead of gas supplies.

Hot Wire Chemical Vapor Deposition – Catalytic Chemical Vapor Deposition

The technique of catalytic chemical vapor deposition (Cat-CVD) is based on the decomposition of precursor process gases by a catalytic reaction at the surface of a hot catalyser wire. It applies to large-area substrates (1 m size) and high-deposition rates (2–30 nm s^{-1}). Silicon-based thin films have been deposited such as Si:H, poly-Si, SiN_x from silane or Teflon-like films from hexafluoropropylene oxide (HFPO), for example. The process gas is introduced in a showerhead equipped with catalyzer wires heated at 1300–1800°C (**Figure 8**). The wires or ribbons arrays can be tungsten or nichrome filaments. The deposition generally occurs in the pressure range 1–10 Pa.

Thermoionic Arc Ion Plating

Anodic arc deposition techniques (**Figure 9**) are considered among CVD methods since they are often operated reactively. They allow evaporating refractory metals with high melting points and low vapor pressure such as titanium. An arc current of a few 100 A (50 V) melts the metal in the crucible (anodic source). The ionized metallic vapor, in the reactor, progressively substitutes for the argon in the anodic arc and serves as a deposition source. Reactive gases introduced in the reactor involve chemical reactions, plasma or thermally (heated substrates) activated. The process is known as activated reactive ion plating. The anodic arc deposition becomes a true CVD technique, if the source is just the high-current DC plasma constituted by precursor reactive gases

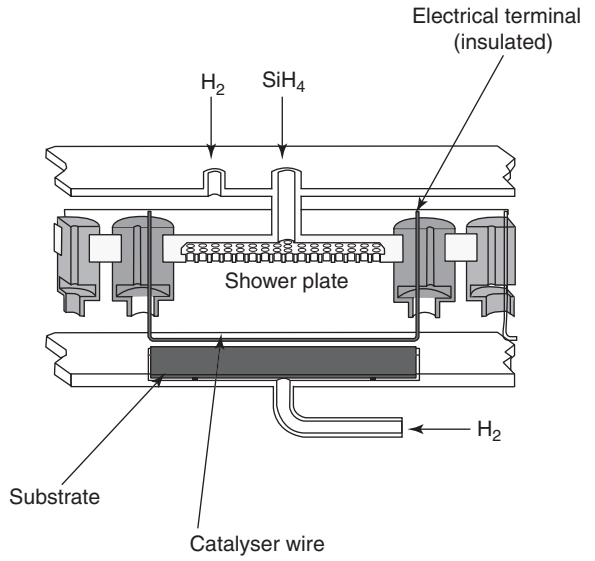

Figure 8 Cat-CVD.

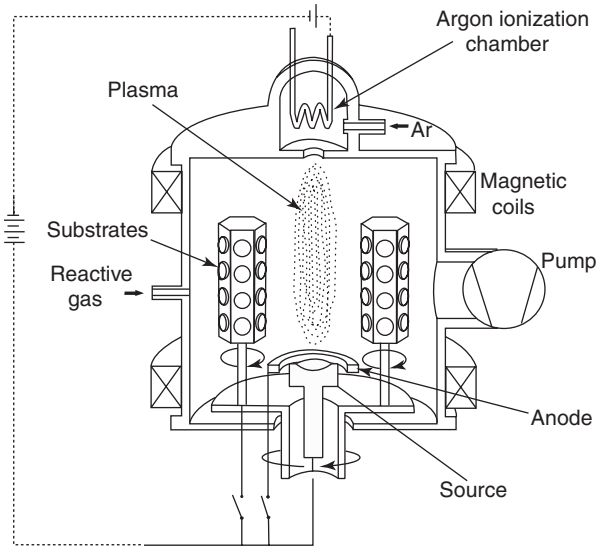

Figure 9 Thermoionic arc ion plating.

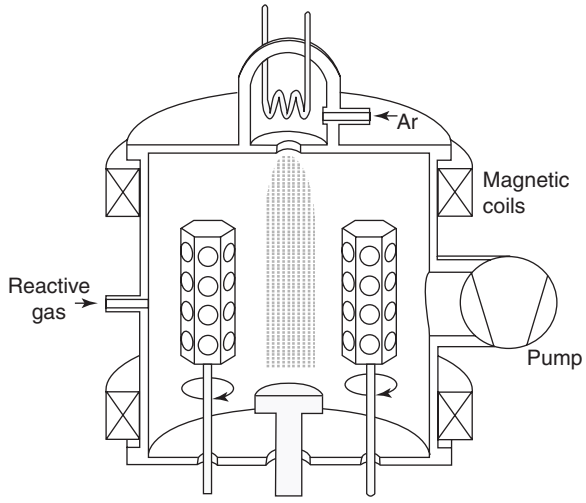

Figure 10 Reactor with a high-current DC plasma source.

(**Figure 10**). Using argon, hydrogen, and methane, this low-pressure process appears particularly efficient for the deposition of diamond coatings. Ammonia offers the possibility of nitriding, in particular with diborane and silane, to produce boron or silicon nitride, respectively.

Film Growth by Condensed-Phase Reaction

Sol–Gel Deposition

The sol–gel deposition process includes synthesis techniques to produce a large quantity of nanosized material with modeled and controlled particle size, morphology, orientation, and crystal structure as well as optimized physical and chemical properties. It applies to the fabrication of metal oxide thin-films including chemical reaction, nucleation, growth, and aging, as an aqueous thin-film processing method (aqueous chemical growth). Tuning the thermodynamics and kinetics of nucleation, growth, and aging, and the precipitation conditions provides a simple and efficient control of the particle size and its distribution. The requirement of minimum surface energy drives nanoparticles to develop spherical morphology. However, in suitable synthesis (precursors) and dispersion conditions, the shape can be driven by the crystal symmetry and the chemical environment. Most process parameters influence the interfacial tensions which appear to play a prominent role. The control of the crystal structure is related with the nucleation kinetics. The more stable phase appears to be more sensitive to secondary growth after heteronucleation, such as the anatase–rutile transition.

The low-cost technique consists of heating the aqueous solution of metal salt or complex at given pH and temperature ($<100^{\circ}C$) in a closed bottle including substrates. Organic solvents or surfactants can also be used with the disadvantages of safety hazards, toxicity, and purity of the deposited film. For example, coatings of crystalline nanoparticulate of various textures have been grown with magnetite (Fe_3O_4), hematite (Fe_2O_3), CrO_3, Cr_2O_3, ZnO, Mn_2O_4, or RuO_2.

Langmuir–Blodgett Films

The film-deposition method known as Langmuir–Blodgett (LB) consists in transferring a floating

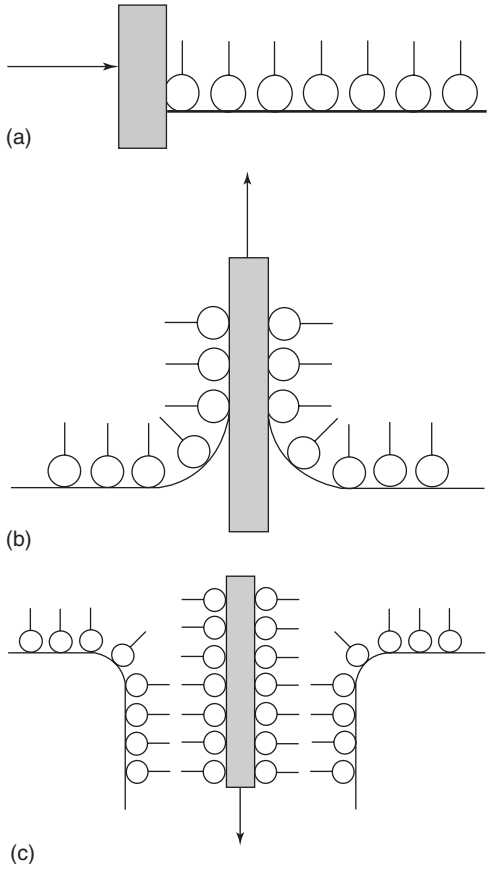

Figure 11 Schematic LB film deposition: pulling and dipping; (a) compression of the monolayer, (b) raising (hydrophilic substrate), and (c) dipping (second layer).

monolayer on water, to a solid plate (substrate). It applies to molecular structures characterized by a hydrophilic head group in contrast with a hydrophobic tail. Stearic acid ($C_{17}H_{35}$ CO_2H) is a classical monolayer forming molecule with (–CO_2H) which is easily soluble in water and a long alkyl chain ($C_{17}H_{35}$–) which is hydrophobic or oleophilic. Various molecular structures (fatty acids, polymerizable materials, aromatic compounds) have been developed with incorporation of metal ions sometimes. The principle of the transfer is illustrated by the extraction or dipping of the substrate through the surface monolayer on the water (**Figure 11**). Simple and sophisticated troughs have been developed to achieve every inventive deposition (**Figure 12**), including surface pressure measurements and displacements control.

Chemical-Bath Deposition

The chemical-bath deposition process uses a controlled chemical reaction to lead the deposition of a thin film by precipitation. In practice, the substrates are

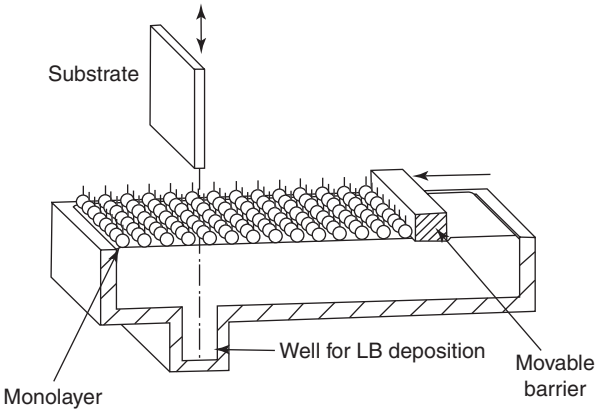

Figure 12 Example of LB trough.

immersed in an alkaline solution containing, for example, the chalcogen source, the metal ion added base, and a complexing agent. In the chemical-bath deposition of ZnS thin films, ammonia and hydrazine have been used as the complexing agents, for example.

Electrodeposition

The essential characteristic of the electroplating technique consists in the passage of an electric current between an anode (positive electrode) and a cathode (negative electrode) immersed in an electrolytic bath. The cathode is the part to be plated. At the anode, the metal is dissolved and then transported to the cathode. If the metal is insoluble in the plating solution, a soluble compound in solution constitutes the electrolyte, such as copper sulphate. Dissolved in an aqueous medium, $CuSO_4 \cdot 5H_2O$ ionizes. The copper cations are attracted to the cathode, whereas the negatively charged sulphate radicals reach the anode. The presence of sulfuric acid increases the conductivity of the electrolyte and permits the decrease of the electrode voltage of the order of a few 10 V. The growth velocity of the deposited film depends on the current density, the plating time, the cathode efficiency, the distance between anode and cathode. The important metals electrodeposited from aqueous baths are chromium, copper, gold, silver, nickel, tin, and zinc, including alloys. Besides metals, ceramics, epoxy resins, composite functional coatings are deposited on conductive substrates. The application fields include printed circuit boards, automobile bodies, rotating shafts, jewelry or electrical contacts.

The equipment include DC power supplies, eventually pulsed generators, and plating tanks either in polyvinyl chloride or lined steel. Automatic continuous processes are common for strip and large-objects plating. Small pieces are electroplated in perforated tumbling barrels.

The related "anodizing" process refers to the deposition of an oxide film on a metal polarized as an anode in an electrolytic aqueous solution. It is mainly used for aluminum. The oxide results from the reaction at the anode of dissolved aluminum, with oxygen: $2Al + 3O^{2-} \rightarrow 6e^- + Al_2O_3$, whereas hydrogen is produced at the cathode. The film consists in a thin barrier below a porous film which supports the electric current by the electrolyte in the pores.

Electroless plating or chemical deposition does not need the passage of an electric current. It is based on a chemical exchange reaction, for example, in immersion tin flashing of aluminum. The oxidation reaction of aluminum, dipped in a $NaS_2SnO_3 . 3H_2O$ aqueous solution, provides three electrons which reduce tin in $HSnO_3^-$. This reduction consumes three electrons as at a cathode. The global reaction leading to a tin deposit is

$$3Na_2SnO_3 + 3H_2O + 6Al \rightarrow 6NaAlO_2 + 3H_2 + 3Sn$$

It is improved by heating (at $\sim 100^\circ C$).

Another example is electroless nickel (Ni–P films) for which wide variations in the properties are reported, related with chemical composition and structure. The properties of the deposited films depend on the operating conditions of solutions. Increasing the metal-ion concentration, the temperature, and the agitation result in an increase of the grain size. In contrast, additive agents and increase in current density or polarization decrease the grain size. The use of additives in aqueous electroplating includes various benefits such as morphology (porosity, texture, grain size, etc.), surface (roughness, optical, and so on), stress reduction, wider range of current density, etc.

Interdiffusion and Solid-State Reaction

The reaction at the interface of two solid phases can lead to the growth of a functional film. Transition metal silicides are grown on silicon single crystals by interdiffusion at the metal–silicon interface which progressively moves as Si is consumed to form, for example, $TiSi_2$ with epitaxial relationships on the Si lattice. The first step consists in the deposition of the material on the substrate in clean conditions (PVD or CVD). The diffusion between the film and the substrate, as well as the chemical reaction is thermally activated. Optimized conditions allow building interfaces as perfect as possible, chemically and structurally. Since rather high temperatures are necessary, the method is less suitable to device production in microelectronic than in interface research.

Epitaxial Growth

The basic property of epitaxial growth is the single-crystalline structure of the deposited film with close orientation relationships with the substrate which generally is a single crystal also. Usually, the substrate and the growing film have the same composition, such as silicon epitaxial layers deposited on silicon wafers (homoepitaxy). Nevertheless, often the film is deposited with changes in the chemical composition like in $GaAs - Al_xGa_{1-x}As$ superstructures, or in lead zirconate titanate (PZT) films grown on $SrTiO_3$ (heteroepitaxy). In this case, the structural relationships require a lattice matching. The lattice constants that mismatch $\Delta a/a$ should be within a few 10^{-3}. Moreover, since the thermal expansion coefficients of the substrate (e.g., InP) and of the epitaxial layer (e.g., GaInAsP) are different, the layer can be lattice-matched at the temperature of growth and not at room temperature. Depending on the thickness, the epi-layer can nevertheless admit some degree of stress. By using complementary controlled sources, all the techniques described below are well adapted for doping.

The simplest methods are known as atomic layer deposition (ALD) or atomic layer epitaxy (ALE) and can use rather simple equipment even with stringent vacuum requirements. The choice of the precursors is crucial for the chemical reactions and the process temperatures. The halogen-based metal precursors react with atomic hydrogen near room temperature to form volatile HCl, whereas the CVD process with H_2 takes place above 800°C (**Figure 13**).

Liquid-Phase Epitaxy

The first technique developed to grow epitaxial layers of compound semiconductors was liquid-phase epitaxy of GaAs, AlGaAs, and then GaInAsP. Single-layer and heterostructure devices have been prepared by this method. The simplest technique is to fix the substrate at the extremity of a tube containing the melt or the solution, in a tube furnace that can be tipped. The source material is melted and after tipping, the substrate is dipped in the melt or in the sursaturated solution. If suitable temperature and pressure conditions are reached, epitaxial growth occurs. In more sophisticated equipment, the compounds are melted in a graphite boat, whose bottom includes a slider containing the single-crystalline substrates (**Figure 14**) which are pushed in contact with the liquid phase. A barrel slider has been developed to grow GaP-epitaxial layers. The growth boat is protected in a growth apparatus with rigorous temperature and atmosphere control.

Vapor-Phase Epitaxy

A primitive technique of vapor-phase epitaxy is based on the chemical transport reactions realized in a closed evacuated crucible in a tube furnace (**Figure 15a**). The source material, in the hot zone, reacts with a transport agent (generally I_2). In a suitable temperature gradient, it is transported to the growth zone where a reverse reaction occurs, and the growth takes place on a seed at lower temperature. The technique has been applied to the growth of III-V semiconductors but has been rapidly replaced by a continuous-flow reactor (**Figure 15b**) with several process parameters to control the growth: source materials (volatile or nonvolatile), temperature profile, and gas flow rates. For As or P, the trichloride XCl_3 or better the hydride XH_3 is transported by the carrier gas H_2. It reacts with the heated metal source Ga or In. If HCl is used as a carrier gas, the metal chloride forms and mixes with the hydride. The reacted compound is then epitaxially deposited if correct thermodynamic conditions are secured.

Actually, the CVD processes described above, can be run under such conditions that epitaxial growth occurs on the appropriate single-crystalline substrate.

Metal Organic Chemical Vapor Deposition

The complexity of new compound semiconductors and heterojunction devices as well as the sophisticated engineering requirements in ultrathin layers, graded layers, or abrupt interfaces has stimulated the development of metal organic chemical vapor deposition (MOCVD), which utilizes volatile organometallic compounds as the source of metallic atoms. These organometallics are mixed with transport agents of the other elements, most often hydrides, and give rise to chemical reactions of the types, for example,

$$(CH_3)_3Ga + (CH_3)_3Sb \rightarrow GaSb + 6CH_4$$

$$(C_2H_5)_2Zn + H_2Se \rightarrow ZnSe + 2C_2H_6$$

The organometallics are transported to the heated substrate by a carrier gas (nitrogen or hydrogen) charged by passing through a bubbler vessel. All the temperatures, gas flows, and pressures can be controlled. The method is particularly efficient for the deposition and growth of mixed compounds. The growth temperatures are within the range 700–900°C. Depending on the process parameters, the typical growth rate are a few tens of nanometers per minute.

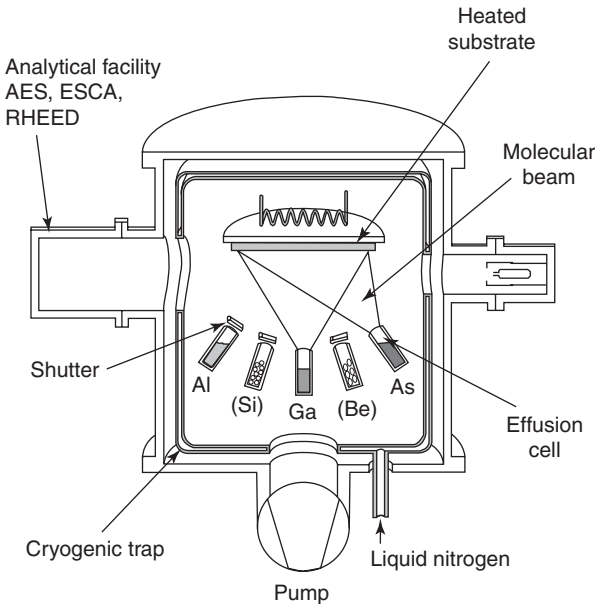

Figure 16 Schematic reactor for MBE.

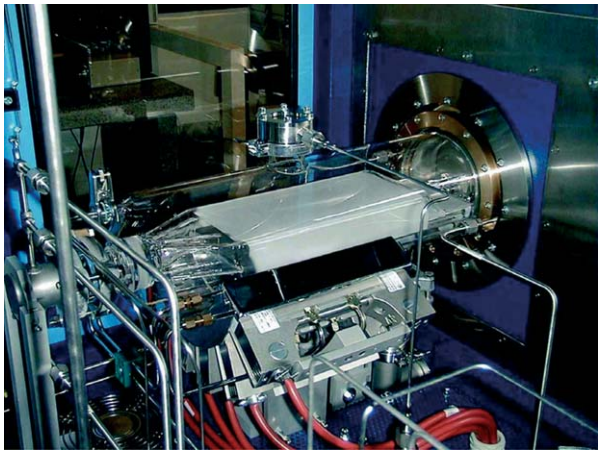

Figure 17 Double reactor for MOVCD epitaxial growth of GaAs-InP semiconductors; in the quartz reactor, the graphite substrate susceptor is radiatively heated; gas inlets from the left hand side. (Courtesy from IPEQ-SB-EPFL.)

The reactors are similar to those developed in the CVD technology (**Figure 16**). The equipment to deliver and mix the gaseous sources is important. The carrier gases, hydrides, and other gases are obtained in high-pressure cylinders. Stainless steel or quartz bubblers are used for the organometallic compounds and other liquid sources. Filtering, purification, drying, mixing are essential steps, avoiding dead spaces and leak. Automated control systems are necessary for the switching of the valves and the control of the flow rates, temperatures, and growth.

Molecular Beam Epitaxy

The method of molecular beam epitaxy (MBE) is the most improved deposition technique to control the chemical composition and doping, the thickness and smoothness of the grown epitaxial layers. The growth actually occurs layer by layer and the growth rate is determined by the flux of the high-temperature melting element (Al, Ga, and In), independent of the substrate temperature. The UHV condition of the reactor avoids external contamination. The materials sources are the elements heated and evaporated in effusion cells controlled by automated shutters (**Figure 16**).

The UHV in the reactor is compatible with surface analytical tool-like reflection high-energy electron diffraction (RHEED), electron spectroscopy for chemical analysis (ESCA), and Auger spectroscopy used *in situ*. The growth of high-purity materials necessitates unbroken UHV in the deposition chamber (10^{-8}–10^{-9} Pa), which is accessible through a sample exchange chamber.

A molecular beam is generated by heating (resistive or electron-beam heating) the source material in a cylindrical crucible (Knudsen cell). The effusion beam is directed through an orifice oriented toward the substrate. The vapor pressure of the heated materials strongly depends on the temperature. It requires a precise control of the effusion cell temperature. For the group-III elements (Al, Ga, and In), organometallic gases are also well adapted for supplying the metal (**Figure 17**). Transported to the heated substrate, the pyrolytic reaction takes place and generates the metal by removing the alkyls. For the group-V elements, the standard method is to feed arsine (AsH_3) or phosphine (PH_3) into a high-temperature "cracker" cell, where it decomposes and supplies As_2 and P_2 beams for the reaction and growth of the deposited film. The reproducible, uniform, and controlled heating of the substrate is a peremptory requirement for the growth of epitaxial films.

The study of the fluorescence emission of biological molecules provides information on quite a number of their intrinsic properties as well as a variety of structural and functional features of macromolecules or subcellular/multicellular systems which they are associated with.

The first section of this chapter briefly discusses the main aspects of the fluorescence phenomenon in polyatomic organic molecules (in condensed phase, at room temperature), the second section concisely describes some of the principal and most advanced experimental techniques, the third section reports the key fluorescence properties of some of the main natural biological fluorophores, and the final section shows, through a few examples, how the study of fluorescence can provide crucial data to (1) elucidate structural properties of proteins and other macromolecules, (2) investigate biological membrane properties and functions, and (3) clarify the basic mechanisms responsible for biophysical/biological processes.

Fluorescence Basics

Fluorescence is the emission of light that occurs, after the absorption of a photon, from an electronically excited state which has the same spin multiplicity of the ground state. The different processes taking place between the absorption and the emission of light in organic molecules are schematized in the Perrin–Jablonski diagram, shown as **Figure 1**.

The ground state of a polyatomic molecule is generally a singlet state (S_0) with zero total spin (an exception to this rule is molecular oxygen, $^3O_2$, which is in a triplet state (T_0) in the ground state, with a total spin value equal to 1).

At room temperature, thermal energy ($kT \sim 200\,\mathrm{cm}^{-1}$) is too low to significantly populate the excited states of bond stretching or bending vibrational modes. The absorption typically occurs from molecules in the lowest vibrational level of the ground electronic state (S_{00}). After the absorption of a photon, the molecule is promoted to an excited singlet state (S_{ij}, where i refers to the electronic level and j to the vibrational level), with a probability (molecular cross section or molar extinction coefficient) that depends on the nature of the electronic charge distributions of both states (i.e., nature of the involved orbitals) and the molecular structure (in particular symmetry). The probability to directly excite the molecule into a triplet state (with a spin change) is extremely low and generally not observed. The absorption transition has an "instantaneous" nature: in solution, it occurs in times of the order of femtoseconds ($1\,\mathrm{fs} = 10^{-15}\,\mathrm{s}$, about one period of a UV–visible light cycle) and too short a time for significant displacements of the nuclei to occur (Franck–Condon principle). The $S_{00} \rightarrow S_{ij}$ vibronic transition probability (shape of the absorption spectrum) is dictated by the overlap of the initial and final vibrational wave functions in the ground-state configuration of the nuclei (Franck–Condon factors). The probability for the subsequent fluorescence, emitted from the lowest vibrational level of S_1 to any vibrational level of the ground state, is directly

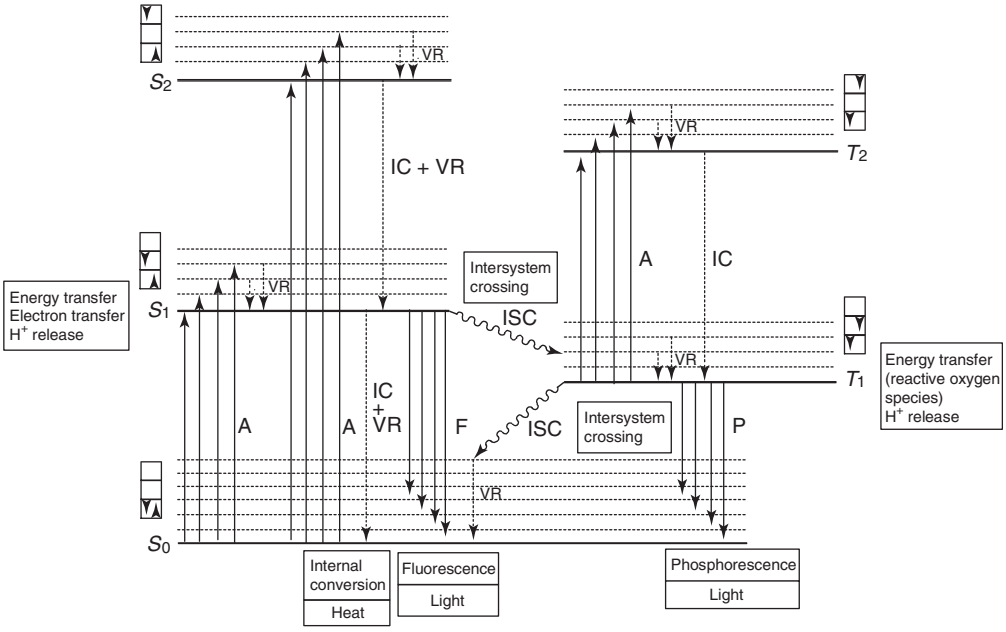

Figure 1 Perrin–Jablonski diagram of electronic states (*S* for singlet and *T* for triplet states) and of intramolecular transitions of polyatomic molecules. A: absorption; VR: vibrational relaxation; IC: internal conversion; ISC: intersystem crossing; F: fluorescence; P: phosphorescence (see A Krasnovsky's comment, in C Lambert and L Jones "Basic Photophysics" Digital Photobiology Compendium, D. Valenzeno Editor). Aleksander Jablonski did not propose a triplet manifold of states to explain phosphorescence (delayed fluorescence). Perrin was the first to claim the existence of a metastable state between the ground and fluorescent states of dyes (Perrin F (1929) *Annals of Physics* (Paris) 12: 169). A few years later Jablonski proposed that radiative transition from the metastable to the ground state is a reason for the low-temperature phosphorescence of dyes (Jablonski A (1933) *Nature* 131: 839 and (1935) *Zeitschrift für Physik*. 94: 38). The idea that the metastable state is a triplet state was first proposed by Terenin AN ((1943) *Acta Physico-Chimica USSR* 18: 210–241) and by Lewis GN and Kasha M ((1944) *Journal of American Chemical Society* 66: 2100–2116). The diagram referred to as a Jablonski diagram, is really a Perrin–Jablonski diagram modified by Terenin and Lewis–Kasha.

related to that of the corresponding $S_0 - S_1$ absorption transition.

A fluorophore excited to some high-lying vibrational level of S_1 or to higher singlet excited states rapidly relaxes (10^{-12} s or less), in condensed phase, to the lowest vibrational level of S_1 (Kasha's rule), by internal conversion and vibrational relaxation with energy transfer to the solvent. Several processes, both radiative and nonradiative, are known to depopulate the first excited singlet state, all of them influencing the characteristics of the fluorescence emission. Nonradiative de-excitations are given as follows:

1. internal conversion between same-spin electronic states (the lowest vibrational level of the highest electronic state overlaps the vibrational levels of the lowest electronic state that have the same energy);
2. intersystem crossing between states with different spin multiplicity (typically from S_1 to T_1); this transition is forbidden by the spin selection rule, but occurs because the real molecular electronic states are a superposition of singlet and triplet states due to the spin–orbit interaction; the molecule in the lowest triplet state can then return to the ground state by phosphorescence emission, but the probability of this transition is very low and phosphorescence is generally not observed at room temperature; and
3. any de-excitation process resulting from collisions with solute molecules or any reaction such as charge or energy transfer and functional reactions.

Fluorescence Spectral Distribution

As mentioned above, Kasha's rule states that the fluorescence emission of a molecule in condensed phase generally occurs from the lowest vibrational level of the first excited singlet state, S_{10}. Consequently:

1. As clearly appears from the Perrin–Jablonski diagram, the energy of emission is typically less than that of absorption (Stokes' shift), that is, the fluorescence emission spectrum is almost completely localized at longer wavelengths with respect to the absorption spectrum. In addition, fluorophores can exhibit an increased Stokes' shift due to solvent reorganization, excited-state reactions (such as photocomplexation) or energy transfer.
2. The emission spectral distribution (measured upon excitation at a single constant wavelength) is

usually independent of the selected excitation wavelength. This is intuitively understood: upon excitation to higher electronic and vibrational levels, the excess energy is quickly dissipated into the solvent, leaving the fluorophore in the lowest S_{10}, from which fluorescence occurs. In this way, the fluorescence spectrum is always the same set of the allowed $S_{10} \rightarrow S_{0n}$ transitions, irrespective of the excitation wavelength.

3. The emission spectrum is normally the mirror image of the $S_0 \rightarrow S_1$ absorption band, not of the whole absorption spectrum. In fact, the probability of a particular vibronic absorption transition ($S_{00} \rightarrow S_{1n}$) – between the zeroth vibrational level of S_0 and the nth vibrational level of S_1 – is close to one of the "corresponding" emission transition ($S_{10} \rightarrow S_{0n}$, with nearly identical overlap of the initial and final vibrational wave functions).

Fluorescence Lifetime and Quantum Yields

Fluorescence lifetimes and quantum yields, together with the spectral distribution, are the most important characteristics of a fluorophore. The fluorescence quantum yield (Φ_F) is the ratio of number of emitted photons (per time and volume unit) relative to the number of absorbed ones ($\Phi_F \leqslant 1$). Hence, Φ_F is the ratio of the intrinsic radiative rate constant (k_{rad}) to the sum of the rate constants of all the processes that contribute to depopulate the first excited singlet state:

$$\Phi_F = \frac{k_{rad}}{k_{rad} + k_{IC} + k_{ISC} + k_{react}} = \frac{k_{rad}}{k_{rad} + k_{nr}} \quad [1]$$

Such processes are: internal conversion (k_{IC}), intersystem crossing (k_{ISC}), and quenching or photophysical/photochemical reactions of various types (k_{react}). Thus, the fluorescence quantum yield is close to unity, only if the sum of the radiationless decay rates is much smaller than the rate of radiative decay, that is, $k_{nr} \ll k_{rad}$.

It is worthwhile emphasizing that, due to the many nonradiative processes, the first singlet excited state lifetime (in other words, the observed fluorescence lifetime τ_F) is, in general, shorter than the radiative lifetime (the reciprocal of the radiative rate). On the other hand, the time-dependent fluorescence intensity is proportional to the excited-state population. The kinetic equation, describing the decay of the singlet excited-state population $[S_1]$, after the excitation has been switched off, is constructed by adding up all parallel de-excitation pathways:

$$\frac{d[S_1]}{dt} = (k_{rad} + k_{nr})[S_1] \quad [2]$$

The solution of this equation reads

$$[S_1](t) = [S_1](0)e^{-t/\tau_F} \quad [3]$$

where $[S_1](0)$ is the excited-state population at time zero (defined any moment after the end of the excitation), and τ_F is the observed fluorescence lifetime:

$$\tau_F = (k_{rad} + k_{IC} + k_{ISC} + k_{react})^{-1} = (k_{rad} + k_{nr})^{-1} \quad [4]$$

In practice, when employing eqn [3] for describing the observed decay of the fluorescence intensity, one chooses the origin of time at the end of the excitation, that is, at the maximum of the measured fluorescence signal.

Combining eqns [1] and [4], one obtains

$$\Phi_F = \tau_F k_{rad} = \tau_F / \tau_{rad} \quad [5]$$

Fluorescence quantum yields and lifetimes, likewise fluorescence emission spectra, generally do not depend on the excitation wavelength. For an ideal instrument, the fluorescence excitation spectrum of a molecule (defined as the fluorescence intensity measured at a fixed wavelength as a function of the excitation wavelength), therefore, entirely overlaps the absorption spectrum. Discrepancy between absorption and excitation spectra is a clear indication of excitation-wavelength-dependent photoinduced reactions.

Time-Resolved Fluorescence

As absorption occurs in $\sim 10^{-15}$ s, steady-state absorption spectra are not sensitive to molecular dynamics and only provide information on the ground state itself and on the ground-state environment of the chromophore. Steady-state fluorescence is more informative on excited-state processes, but some information is unavoidably lost during the time-averaging process. For example, macromolecules can exist in more than one conformation without much change of the emission spectrum. The decay time, on the other hand, may strongly depend on the conformation because it reflects the interactions of the fluorophore with the solvent or with other molecules and macromolecules of its close environment. Time-resolved fluorescence then appears as a valuable tool to discriminate these conformations and, in general, to understand the dynamical photoinduced processes in molecules and macromolecules. In practice, a fluorescence decay profile can exhibit several lifetimes that one has the possibility to assign to specific reactions or species.

Fluorescence Quenching

In photoinduced biological phenomena originating from the first excited singlet state, the very primary events (electron, proton, or energy transfer, photoisomerization, and, in general, any kind of photophysical or photochemical reaction) are alternative nonradiative pathways for the excited-state decay. They yield a decreased fluorescence intensity, called "quenching," and reduced fluorescence quantum yield and lifetime (see **Figure 2**).

Quite a number of very different processes can be responsible for fluorescence quenching. In the following, some aspects of collisional quenching and of energy transfer are concisely discussed.

Collisional quenching takes place when the excited-state fluorophore is deactivated upon contact with some other molecules in solution (quencher). The mechanism of quenching varies with the fluorophore–quencher pair. For instance, it can be due to an electron transfer from the fluorophore to the quencher, which does not occur in the ground state. Alternatively, in the case of oxygen, halogens, and heavy atoms, it can be due to spin–orbit coupling and intersystem crossing (triplet-state formation). For collisional quenching, the decrease in fluorescence yield and lifetime is described by the Stern–Volmer equation (the fluorescence yield can be probed by the fluorescence intensity F, as long as the experimental conditions are kept identical):

$$\frac{F_0}{F} = \frac{\tau_{F_0}}{\tau_F} = 1 + K[Q] = 1 + k_q \tau_{F_0}[Q] \qquad [6]$$

where K is the Stern–Volmer quenching constant, k_q is the bimolecular quenching constant, τ_F and τ_{F_0} are the quenched and the unquenched fluorescence lifetimes respectively, F and F_0 are the quenched and the unquenched fluorescence intensities respectively, measured under the same experimental conditions, and $[Q]$ is the quencher concentration. The value of k_q, which can be obtained simply by plotting F_0/F or τ_{F_0}/τ_F versus $[Q]$, for a free fluorophore in solution is, at most, $\sim 10^{10}\,M^{-1}s^{-1}$, that is, the rate at which the fluorophore and the quencher molecules diffuse through the solvent and encounter. However, k_q can be smaller than the diffusion rate, if the reaction occurring in the encounter complex has a low probability. When chromophores are bound to or incorporated into macromolecules, k_q sometimes is substantially smaller, because of the shielding effects of the macromolecules structure.

Another important quenching process is the fluorescence resonance energy transfer (FRET). This process occurs whenever the emission spectrum of the fluorophore, called the donor, overlaps the absorption spectrum of another molecule, called acceptor. It is very important to note that FRET does not involve emission of light by the donor and consequent absorption by the acceptor. The donor, in its excited state, and the acceptor, in the ground state, are coupled by dipole–dipole interaction, resulting in the deactivation of the donor excited state and the excitation of the acceptor. This process is also called long-range coulombic or Förster-type energy transfer. Another type of nonradiative excitation energy transfer is the Dexter-type energy transfer, by electron exchange in an encounter complex, which is not discussed here. The rate constant of the Förster resonance energy transfer $k_T(r)$ strongly depends on the distance r between the donor and the acceptor:

$$k_T(r) = \frac{1}{\tau_D}\left(\frac{R_0}{r}\right)^6 \qquad [7]$$

where τ_D is the donor fluorescence lifetime in the absence of energy transfer and R_0 the Förster radius or critical distance which depends on the donor fluorescence quantum yield, the acceptor absorption transition probability, the spectral overlap mentioned above, and the relative orientation of the two interacting dipoles. On the basis of eqn [7], when the donor–acceptor distance is equal to the Förster distance ($r = R_0$), the rate of transfer is equal to the decay rate of the donor in the absence of the acceptor

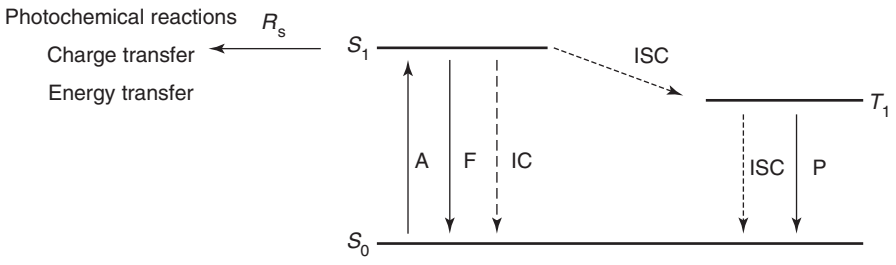

Figure 2 Nonradiative deactivation pathways originating from the first excited singlet state resulting in "functional" processes (e.g., photosynthesis (energy transfer) and photoperception (photoisomerization, photoinduced charge transfer)).

and, consequently, the transfer efficiency is 50%. The transfer quantum efficiency (Φ_{FRET}), defined as the r-dependent fraction of photons absorbed by the donor that are transferred to the acceptor, can be obtained directly by eqn [7]:

$$\Phi_{FRET} = \frac{k_T}{k_T + (1/\tau_D)} = \frac{R_0^6}{R_0^6 + r^6} = 1 - \frac{\tau_{DA}}{\tau_D} = 1 - \frac{F_{DA}}{F_D} \quad [8]$$

The transfer efficiency is typically measured using the relative fluorescence yield (or intensity under the same experimental conditions) or lifetime in the absence (F_D and τ_D) and presence (F_{DA} and τ_{DA}) of the acceptor, provided that the donor–acceptor pairs are separated by a fixed distance during the lifetime of the donor. On the basis of eqn [8], fluorescence resonance energy transfer provides an opportunity to measure the distance between sites on macromolecules, provided r is not too different from the Förster distance R_0: typically, in the range of 15–60 Å, which is comparable to the diameter of many proteins and the thickness of a membrane.

A completely different cause of fluorescence intensity decrease is photobleaching, due to a photoinduced degradation or damage of the fluorophore, normally caused by focused laser beams or very high intensity excitation light.

Fluorescence Anisotropy

Fluorescence anisotropy measurements, commonly used in a variety of biochemical applications, provide information on the size and shape of macromolecules or the rigidity of various molecular environments. Anisotropy measurements are based on the principle that linearly polarized excitation light selectively excites the fluorophores, the absorption transition dipole of which is parallel to the electric vector of the excitation. In an isotropic solution, the fluorophores are randomly oriented, so that this selective excitation results in a partially oriented population of excited fluorophores, provided the excitation pulse duration is shorter or of the same order of magnitude as the fluorophore reorientation time (e.g., with femtosecond pulses). The fluorescence emission, in turn, is polarized along the direction of the emission transition dipole of the fluorescent molecule. The anisotropy (r) of the emission is defined as follows:

$$r = \frac{I_\parallel - I_\perp}{I_\parallel + 2I_\perp} \quad [9]$$

where $I_\parallel$ and $I_\perp$ are the fluorescence intensities, respectively, measured parallel and perpendicular to the polarization direction of the excitation light. The maximum attainable anisotropy (r_0) depends on the relative angle (β) between the absorption and emission transition moments. For an initially randomly oriented sample, it reads

$$r_0 = \frac{2}{5}\left(\frac{3\cos^2\beta - 1}{2}\right) \quad [10a]$$

so that the "maximum maximorum" value of (r_0) is 0.4, with $\beta = 0$. Several phenomena can decrease the measured anisotropy to values lower than this maximum. The most obvious cause is rotational diffusion that, during the lifetime of the excited state, induces a randomization of the orientation of the fluorophore, namely its emission dipole moment. In fluid solution, most molecules rotate in 50–100 ps (10^{-12} s). Hence, fluorescent molecules can rotate many times during their 1–10 ns excited-state lifetime and, consequently, the emission is completely depolarized (the steady-state anisotropy is close to zero). Nevertheless, provided that the experiments are done with a sufficiently short time resolution, the molecular reorientation can be followed by measuring the time-resolved anisotropy $r(t)$:

$$r(t) = \frac{I_\parallel(t) - I_\perp(t)}{I_\parallel(t) + 2I_\perp(t)} = r_0 e^{-6D_r t} \quad [10b]$$

where D_r is the rotational diffusion coefficient and $(6D_r)^{-1}$ the rotational correlation time (θ).

For macromolecules and proteins, the rotational correlation time is much longer ($\sim$1–100 ns) and it is possible to use fluorescence anisotropy for probing the mobility of any fluorophore and determine how rigidly it is bound to some macromolecule. Assuming no other processes result in fluorescence depolarization, the expected steady-state anisotropy (r) is given by the Perrin equation:

$$r = \frac{r_0}{1 + (\tau_F/\theta)} \quad [11]$$

where r_0 is maximum anisotropy (given by eqn [10a]), τ_F is the fluorescence lifetime, and θ is the rotational correlation time for the diffusion process, which is given by the Debye–Stokes–Einstein relation

$$\theta = \frac{\eta V}{kT} \quad [12]$$

where η is the medium viscosity (in poise, P), V the molecular volume, k is the Boltzmann constant, and T is the temperature in kelvins.

Main Instrumentation

Steady-State Fluorimetry

Figure 3 shows a simplified scheme of a typical multipurpose fluorimeter. The excitation light from a xenon (high pressure) lamp is used to excite the sample at a wavelength selected by a motorized monochromator (UV–visible). The fluorescence is collected at right angle with respect to the excitation beam direction and sent onto a photomultiplier through a second motorized monochromator. Computer-controlled scanning of the latter at a fixed excitation wavelength allows measurements of the fluorescence spectra, whereas scanning of the excitation monochromator at a fixed emission wavelength allows measurements of the excitation spectra. A small part of the excitation beam is sent to a reference detector, the signal of which is used for compensation of the excitation intensity fluctuations and correction of the excitation spectral distribution when recording excitation spectra. Fluorescence emission spectra are also corrected for instrumental distortions. For anisotropy measurements, polarizers are added on the excitation and emission beams as shown in the scheme.

Time-Resolved Fluorescence Techniques

Different techniques can be used for measuring fluorescence decays. The most straightforward is to excite the sample by a short light pulse $E(t)$ (lamp or laser flash) and to record the fluorescence signal $F(t)$ as a function of time. The time resolution is then limited by the excitation pulse width and the temporal response of the detection device. The measured signal $F(t)$ is the convolution product (eqn [13]) of the apparatus response function $R(t)$ (equal to $E(t)$, if detection is not a limit) and the purely molecular fluorescence function $I_F(t)$, expected for an infinitely short excitation pulse, that is, the relevant decay function that describes the excited-state dynamics.

$$F(t) = R(t) \otimes I_F(t) = \int_{-\infty}^{t} R(t')I_{\mathrm{F}}(t - t')\, \mathrm{d}t' \quad [13]$$

Provided a short enough excitation source is available, nanosecond (10^{-9} s) and subnanosecond decay times can be easily measured by collecting the sample emission onto a photodiode or a photomultiplier coupled to an oscilloscope. To date, equipments even allow to readily achieve the picosecond regime. For this time range, streak cameras are, however, more suitable, although they have an intrinsic limitation due to their low dynamic range (low saturation level).

Alternatively, the time-correlated single-photon counting technique is a powerful method quite often used for reliable measurements in time ranges that extend from a few tens of picoseconds to a few nanoseconds. For longer lifetimes, care must be taken when choosing the excitation-pulse repetition rate, since the fluorescence signal must have decayed when the next excitation pulse comes in. On the other hand, decay components of $I_{\mathrm{F}}(t)$ shorter than the width of the response function $R(t)$ can be determined by deconvolution of the fluorescence signal $F(t)$, according to eqn [13].

A typical single-photon counting setup is shown in **Figure 4**. The principle consists in measuring a

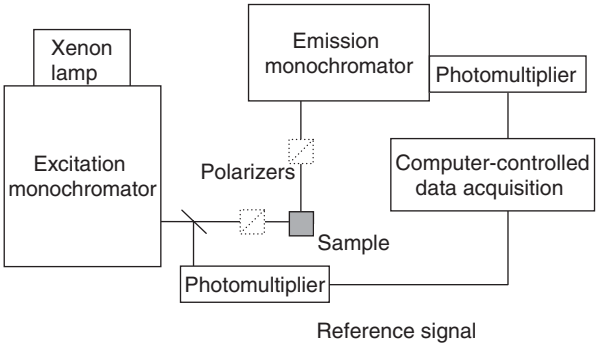

Figure 3 Scheme of a fluorimeter. The sample is excited with a xenon lamp at a wavelength selected by the excitation monochromator. Its fluorescence is collected at right angle and sent onto a photomultiplier through the emission monochromator. Scanning of the latter allows measurements of fluorescence spectra. A small part of the excitation beam is used to produce a reference signal which is used for compensation of the excitation-intensity fluctuations. Excitation spectra can be measured with the same setup by fixing the emission wavelength and scanning the excitation monochromator. Polarizers can be inserted in the beams for anisotropy measurements.

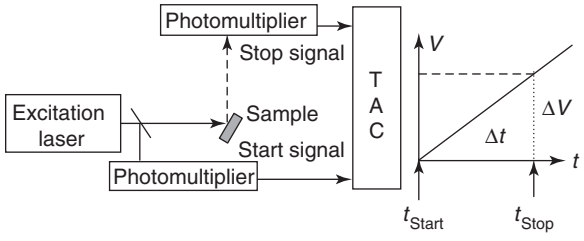

Figure 4 Simplified scheme of a single-photon counting setup. The sample is excited with a low fluence, high repetition rate, and excitation pulse. An electrical pulse associated to the optical pulse starts the deflection ramp of a time-to-amplitude converter (TAC) while the sample is excited. The fluorescence is collected onto a photomultiplier operating in a single-photon counting mode providing a signal that stops the deflection ramp when a single photon is detected. The voltage at which the deflection ramp is stopped is proportional to the delay between the start and stop signals. Measurements are repeated until the histogram of delays builds up. The histogram, recorded with a multichannel analyzer, reproduces the rise and decay $F(t)$ of the sample fluorescence.

histogram of the time delays at which a single photon of fluorescence is emitted after excitation. Without going into details, the excitation pulse is split into two pulses, one of which is used to excite the sample. The second pulse is used to generate an electrical pulse that triggers (start signal) the deflection ramp of a time-to-amplitude converter (TAC) while the sample is excited. The excitation fluence is fixed at such a low level that less than one photon of fluorescence is recorded per excitation pulse. The emitted fluorescence is collected onto a photomultiplier operating in a single-photon counting mode so that, when a single photon is detected, the photomultiplier provides a signal that stops the deflection ramp of the TAC. The voltage at which the deflection ramp is stopped is proportional to the delay between the start and stop signals. Measurements are repeated until the histogram of delays builds up. This histogram, recorded with a multichannel analyzer, reproduces the rise and decay $F(t)$ of the sample fluorescence.

Several other time-resolved fluorescence techniques, such as phase-modulation fluorimetry, Kerr-shutter fluorimetry, and fluorescence up-conversion, exist. The up-conversion technique is the only technique that allows direct measurements of femtosecond fluorescence decays, that is, the fluorescence from quasi nonfluorescent molecules, but is out of the scope of this review. In the Kerr-shutter fluorimetry, the electric field of an intense laser pulse is used to induce a temporary anisotropy (Kerr effect) in a Kerr sample placed between two crossed polarizers so that light can be temporarily transmitted by this arrangement. By adjusting the delay between the time at which a fluorescent sample is excited and the time at which the Kerr-shutter is opened, one can record the transmitted fluorescence intensity, or spectrum, as a function of time. In phase-modulation fluorimetry, the sample is excited with a sinusoidally modulated light, at high frequency. The fluorescence response is sinusoidally modulated at the same frequency, but delayed in phase and partially demodulated. These effects depend on the modulation frequency of the excitation light and on the fluorescence decay time. The experiments allow measurements of the Fourier transform of the fluorescence kinetics. Kerr-shutter and phase-modulation fluorimetry are suitable techniques for lifetime measurements in the nanosecond and picosecond regimes.

Fluorescence Correlation Spectroscopy

In fluorescence correlation spectroscopy (FCS), one measures the fluorescence intensity of a very small sample volume ($\sim 10^{-15}$), for example, under a confocal microscope, and records its fluctuations in time, $\delta F(t)$, around an equilibrium value, $\langle F \rangle$. The result is quantified in terms of the normalized autocorrelation function $G(\tau)$:

$$G(\tau) = \frac{\langle F(t+\tau)F(t) \rangle}{\langle F \rangle^2} = \frac{\langle \delta F(t+\tau)\delta F(t) \rangle}{\langle F \rangle^2} + 1 \quad [14]$$

where $\delta F(t) = F(t) - \langle F \rangle$. The main source of fluctuation comes from the molecules diffusing in and out of the examined volume. The mean diffusion time and thus the size of the molecule can be calculated on the basis of an analysis of the G function. The photophysics (intersystem conversion) and photochemistry (photobleaching, excited-state reactivity) of the fluorophores may also come into play. The high sensitivity of the detectors even allows the measurement of the fluorescence fluctuations of a single molecule. Fluctuation analysis has proved to be a very versatile and powerful tool for the detection and dynamics study of biomolecules at ultralow concentrations on surfaces, in solutions, and in living cells.

In practice, a parallel laser beam is concentrated through a high aperture microscope lens on a focal point of $< 0.5\,\mu m$ in diameter. This focal point forms the open measuring volume in a highly diluted solution in which the fluorescing molecules diffuse. The focal point is confocally imaged on a pinhole behind which a single photon detector is placed. In this way, only fluorescent biomolecules stimulated by the laser in the focal point are detected. Although the route of the molecule through the focal point is random, the mean diffusion time and thus the size of the molecule can be calculated on the basis of a temporal correlation of the signal of many single molecules.

Main Natural Biological Fluorophores

In **Figure 5**, the formulas and the optical absorption and emission spectra of the three aromatic amino acids are reported. Tyrosine and phenylalanine have lower molar extinction coefficients ε ($\varepsilon = A$ (absorbance)/(C (molar concentration in M) $\times$ l (optical path in cm))) with respect to tryptophan, the molar extinction coefficient of which, however, is rather low when compared to that of other absorbing molecules (e.g., for tryptophan, ε is $\sim 5600\,M^{-1}\,cm^{-1}$, whereas for chlorophyll, ε is $\sim 120\,000\,M^{-1}\,cm^{-1}$). As a matter of fact, tryptophan is the most commonly and easily studied amino acid as an intrinsic probe for protein microenvironment and bulk properties. Usually, tryptophan is selectively excited at 295 nm because, exciting at 280 nm, a significant contribution to fluorescence by tyrosine can also be observed.

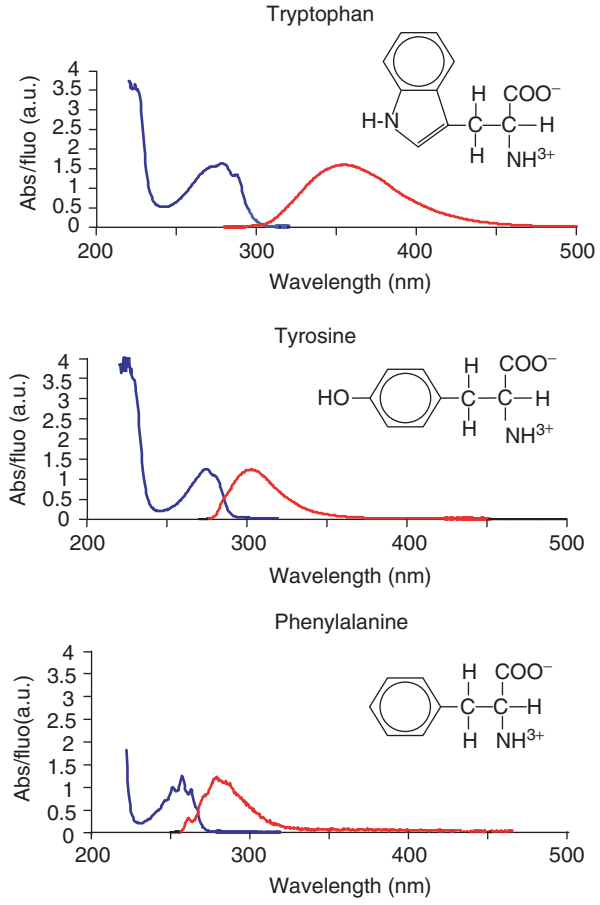

Figure 5 Formulas and absorption and fluorescence spectra of aromatic amino acids.

Figures 6–9 show the formulas and the spectra of some of the most widely distributed biological fluorophores: chlorophyll (see **Figure 6**), which play a key role in photosynthesis, flavins (riboflavin, flavin mono- and dinucleotide) (see **Figure 7**), which play a key role in quite a number of biological processes (see the next section), phytochrome (see **Figure 8**), a most important photosensing system for plant photomorphogenesis, and hypericin (see **Figure 9**), a typical natural pigment with photodynamic properties.

Fluorescent Biomolecules for Structural and Functional Studies

When a fluorescent biomolecule is used for structural or functional studies, one usually measures the main fluorescence parameters described in the first section which explains the fluorescence excitation and emission spectra, the fluorescence quantum yield, lifetime, and anisotropy.

If the biological system under investigation does not contain any intrinsic fluorophore or if its intrinsic fluorophores are of limited use, smart synthetic fluorescing molecules can be used as probes and labels in areas such as membrane biophysics, cell sorting, ion transport, and immunoassay, to mention only a few. In this article, the case of these numerous extrinsic fluorescent probes are not discussed: their different, specific, and dedicated applications can be easily found in a number of commercial catalogs. The focus is rather on "intrinsic" probes, such as tryptophan, flavins, and the other fluorophores described in the previous section.

In the following, the comparison of the fluorescent properties of these fluorophores in different molecular environments highlights how and why fluorescence is a valuable tool to probe and monitor molecular or supramolecular structures and chromophore–protein interactions.

Fluorescence for Probing Molecular Environments

The chemical and physical properties of the solvent, such as pH and polarity, can strongly affect the fluorescence emission spectrum as well as the fluorescence quantum yield and lifetime of a free fluorophore. These changes may alter its fluorescence anisotropy, if the nature of the optical transitions is changed (see eqns [9] and [10]), by a different excited-state pathway for example, or through a change of lifetime (eqn [11]). If it is assumed that this is not the case (same transitions and fluorescence lifetime), then the fluorescence anisotropy depends solely on the solvent viscosity as eqns [11] and [12] express.

In flavin adenine dinucleotide (FAD), for example, the strength of the ground-state stacking interactions between the flavin and the adenine moieties, which are responsible for the flavin moiety fluorescence quenching with respect to riboflavin or flavin mononucleotide (FMN), depends on pH. The unfolding of the complex at pH 3 is reflected by an increase in the flavin fluorescence quantum yield.

In isolated fluorophores, solvent polarity can influence the fluorescence spectra (solvatochromic shift) and high viscosity can enhance the fluorescence anisotropy. The vibronic structure of the electronic transitions can also be affected by the solvent nature, depending on the type and strength of fluorophore–solvent interaction. Quite similar effects can be observed, when the fluorophore binds to (or associates with) a protein or a macromolecular structure.

As mentioned before, selective excitation of the tryptophan fluorescence has been extensively used as an endogenous probe of the amino acid location. Because of their particular interactions with their molecular microenvironments, the insertion of

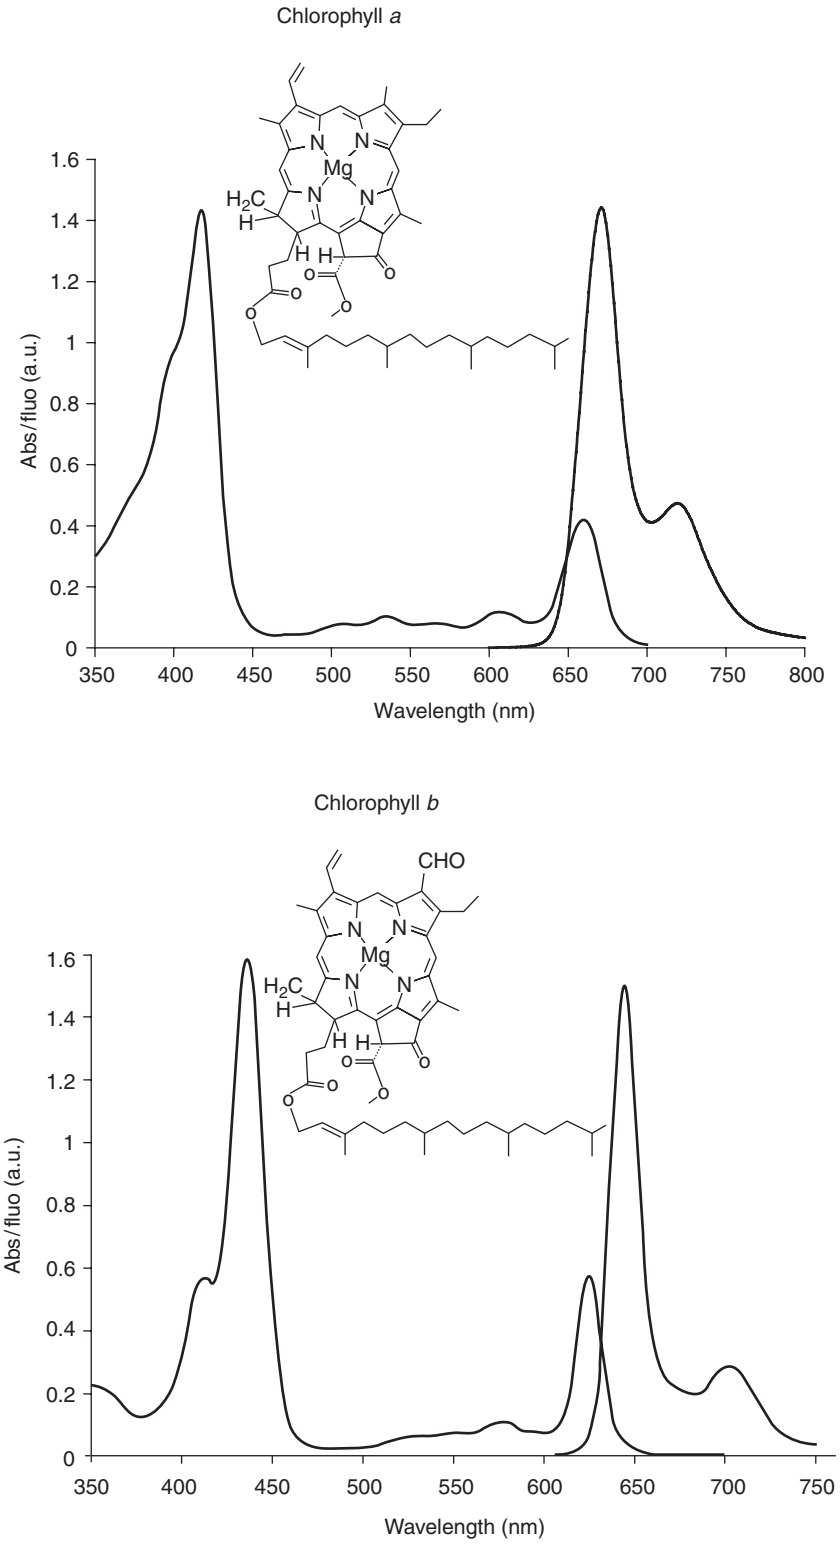

Figure 6 Formulas and absorption and fluorescence spectra of chlorophyll *a* and *b*.

tryptophan molecules into a proteic framework causes marked changes in its spectroscopic properties. Among these characteristic effects of the surrounding environment is hypochromism, a phenomenon that affects both absorption and emission and has several causes. For example, the presence of ordered layers of chromophores favors the screening of light, thus effectively reducing the molar extinction coefficient

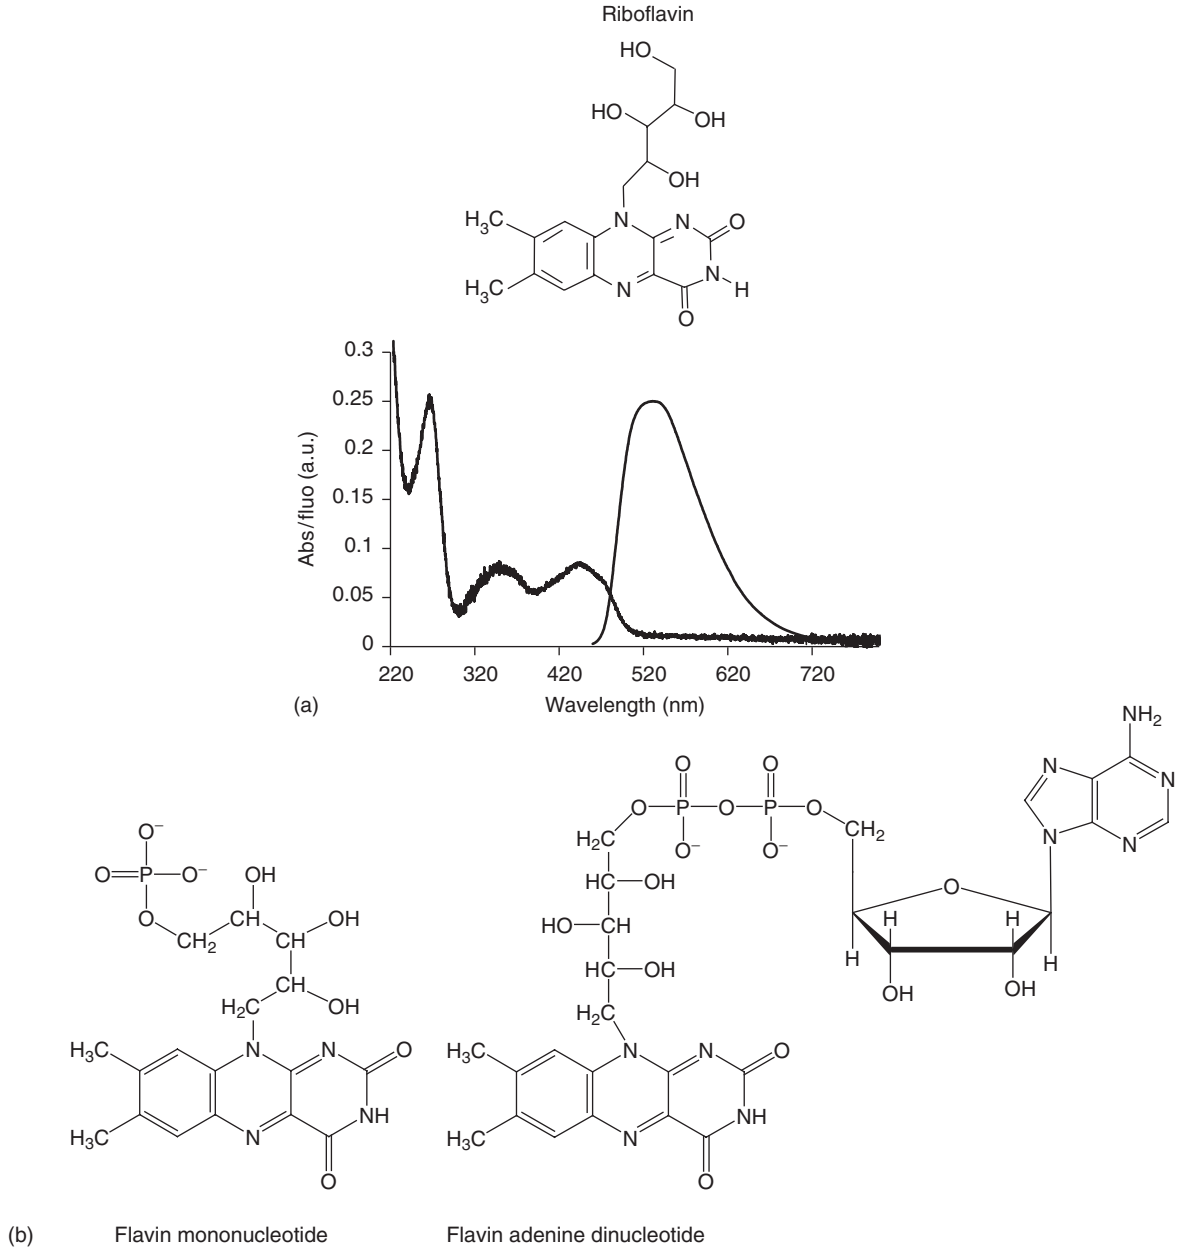

Figure 7 (a) Formulas, and absorption and fluorescence spectra of riboflavin. (b) Formulas of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). Their absorption and fluorescence spectra are not reported because substantially indistinguishable from those of riboflavin.

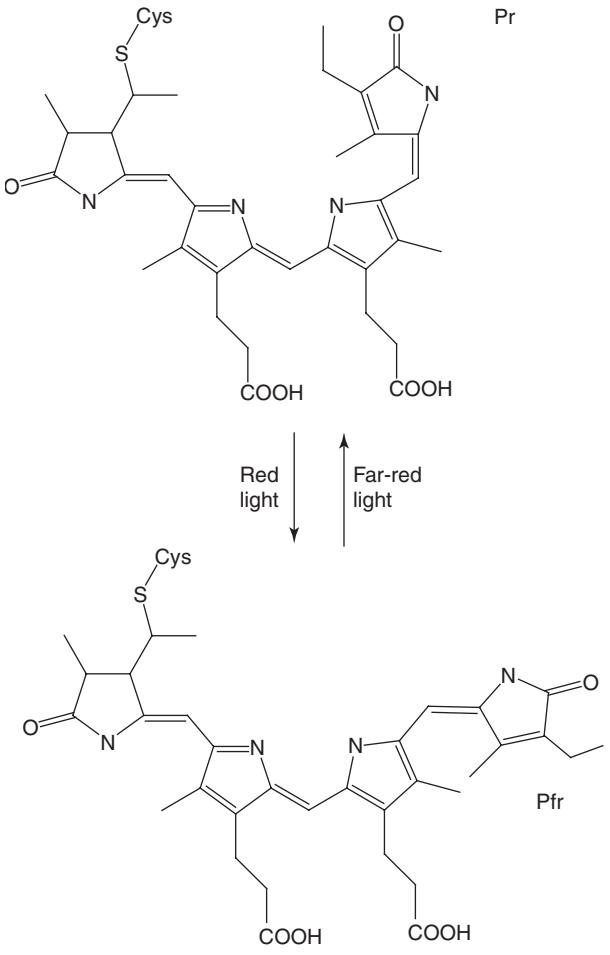
of the amino acid (self- or hetero-screening hypochromism); the screening can decrease the molar extinction coefficient to half, depending on the parallelism of the chromophores dipoles (the higher the parallelism, the lower the coefficient). Also non-absorbing groups can affect the emission properties of this amino acid. In fact, in a protein, several groups can quench the fluorescence because their presence favors a photoinduced intramolecular charge transfer process. For example, a proton transfer is at the basis of tryptophan fluorescence quenching caused by carboxyl and thiolate groups, whereas amide, peptide, ammonium, ammine, histidine, and other sulfur-containing groups quench tryptophan fluorescence by means of an electron transfer. Changes in the structure of the fluorescence emission spectrum have also been observed. In tryptophan up to five different emission maxima can be identified, depending on how buried is the amino acid in the protein. When the amino acid is close to a hydrophilic environment (i.e., near the external surface of the protein), the fluorescence maximum is similar to that shown by the amino acid in aqueous solution (peak at 353 nm), while the maximum shifts



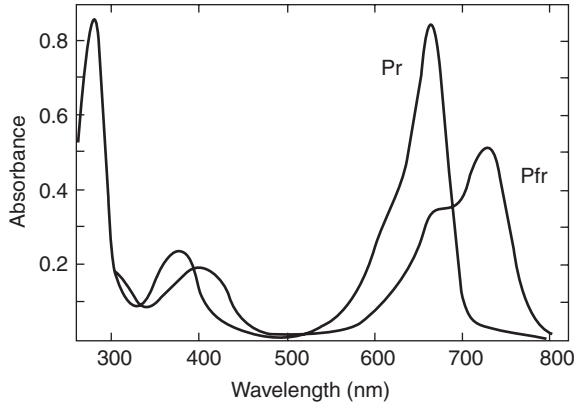


Figure 8 Formulas and absorption spectra of red (Pr) and far-red (Pfr) forms of phytochrome.

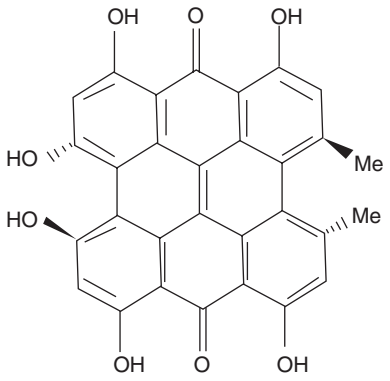

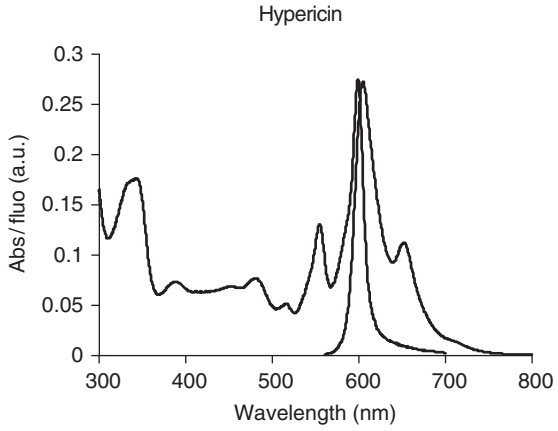

Figure 9 Formula, and absorption and fluorescence spectra of hypericin in ethanol.

toward the blue (peak at 307 nm) when tryptophan is buried in the inner hydrophobic parts of the protein. Also fluorescence polarization measurements (eqns [9] and [11]) can provide information on the degree of rigidity of the tryptophan specific molecular environment, both in physiological and denaturating conditions. Shielding effects by the macromolecular structure which tryptophan is associated with can cause a decrease of the fluorescence collisional quenching constant k_q (see Stern–Volmer equation, eqn [6]). Measurements of Φ_F and τ_F can, therefore, contribute to evaluate the accessibility of the residue to the solvent and dissolved quenchers, such as iodide or acrylamide.

Fluorescence as a Tool for Probing Biological Photoprocesses

Among important enzymes, flavoproteins constitute an important class of redox systems. The study of flavin fluorescence has provided key contributions to the study of their dynamic behavior as well as detailed information on both their catalytic mechanisms and atomic structure.

As light irradiation can elicit transient variations, and subsequent dark-regeneration, of flavin fluorescence emission, light-induced fluorescence changes (LIFCs) can be used as a spectrophotometric assay for photochemical primary reactions in light-modulated flavoproteins. Fluorescence quenching of flavin by photoinduced electron transfer can be used as a probe for angstrom-scale structural changes in the

proteic framework. Probing the fluorescence lifetime of flavins also allows observing the variation of the flavin–amino acid residue distance over time. Correlation analysis can finally reveal conformational fluctuations at multiple timescales due to the existence of multiple interconverting conformers related to the fluctuating catalytic reactivity.

The case of chlorophyll fluorescence as a "spy" of an efficiency loss in the photosynthetic process is dealt with elsewhere in this encyclopedia. Here it is to be recalled that a damage to the photosynthetic apparatus, due to any kind of environmental stress, can lower the yield of Förster energy transfer to the reaction centre (see **Figure 2**) and can impair the electron transport chain between PhotosystemII and PhotosystemI (Z scheme), thus giving rise to a more efficient radiative transition. Chlorophyll fluorescence can, therefore, be used, also by means of space-based remote-sensing systems, to monitor the healthiness of vegetation in terrestrial and aquatic ecosystems.

Plants and even microorganisms have evolved a range of sophisticated photosensing and phototransducing devices to adapt and respond to their natural habitat. A number of light-absorbing molecules enable organisms to respond to changes in the natural light environment. The responses range from the regulation of the organism motile behavior to changes in structure and form, such as seed germination, leaf expansion, stem elongation, flower initiation, and pigment synthesis. Several families of photoreceptors are known to mediate the effects of light on plant development. These include the phytochromes (phy), which monitor the red (600–700 nm) and far-red (700–750 nm) regions of the solar spectrum and two classes of blue light receptors: the cryptochromes and the phototropins.

The phytochromes, a family of soluble homodimeric biliproteins responsible for photomorphogenic responses, have a number of spectroscopic properties which make them potentially good candidates for fluorescent probe development. Particularly interesting are their long wavelength absorption maxima, high molar extinction coefficients and the ability of phytochrome apoproteins to, spontaneously and covalently, assemble with the linear tetrapyrrole chromophore precursors, phytochromobilin (PFB) and phycocyanobilin (PCB). Owing to photoisomerization, native phytochrome can adopt two photo-interconvertible configurations, termed the Pr (red light absorbing) and Pfr (far red light absorbing) forms. A direct consequence of the high yield of photo-interconversion is the very low fluorescence quantum yield for both Pr and Pfr forms ($<10^{-3}$ at room temperature). When the natural bilin prosthetic group of phytochrome is substituted with phycoerythrobilin (PEB), the phytochrome is converted into a highly fluorescent biliprotein, termed "phytofluore" (Φ_F of the order of 0.7), photostable, stable over a wide pH range, which can be reconstituted in living cells. Phytofluores represent a resourceful new family of fluorescent protein probes which can give important contributions to understand how plants perceive and transduce environmental light signals to control their growth and development.

In phototropins (phot1 and phot2), the light-activated molecular switches that regulate important plant responses to blue light (such as phototropism, blue light-induced chloroplast relocation, and blue light-induced stomatal opening), the light-absorbing chromophore, noncovalently bound, is FMN. Phototropins undergo a self-contained photocycle (see **Figure 10**), characterized by fluorescence and absorption changes induced by blue light. The generation of the signalling state, a covalent protein–FMN photo-adduct, can be monitored by fluorescence spectroscopy. A decrease in fluorescence intensity, in fact, is measured upon formation of the FMN-cysteinyl adduct, whereas during subsequent dark incubation, the fluorescence recovers completely.

DNA Photolyase (involved in the repair of DNA damaged by pyrimidine dimers formation), photoactivated adenylyl cyclase (PAC, the photoreceptor for some photomotile responses of the flagellated microalga *Euglena gracilis)* and Cryptochromes (cry1 and cry2, the photoreceptors for circadian rhythms in plants and mammals) use FAD as

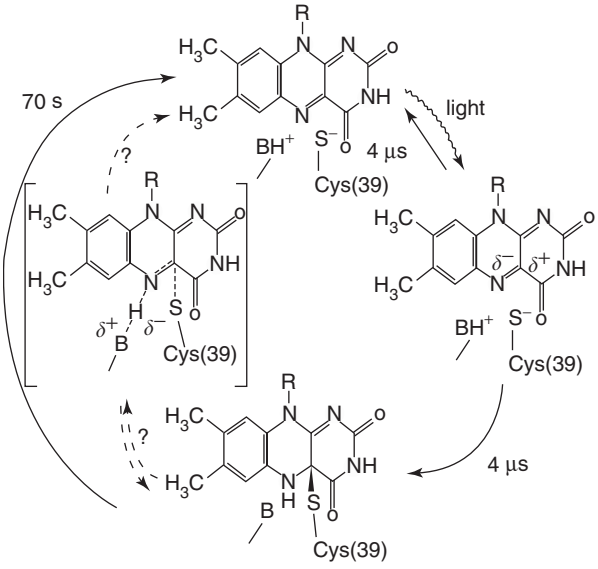

Figure 10 Scheme of FMN photoadduction reaction in phototropins.

chromophoric group. Also in these cases, FAD fluorescence dependence on pH and denaturation (in native PAC, for instance, the FAD fluorescence is strongly reduced) can valuably be used to test the photoreception process.

The fluorescence of the single tryptophan residue of the photoactive yellow protein (PYP), the photoreceptor pigment of the photomotile bacterium *Ectothiorhodospira* (*Halorhodospira*) *halophila,* efficiently monitors the structural changes of PYP which are responsible for the signalling state formation. The fluorescence spectral distribution and quantum yield of this tryptophan, in fact, depend on the local polarity, which changes during the PYP photocycle and accompanies the formation of the signalling state.

FRET is of distinctive efficiency for studying membrane model systems, such as liposomes and bilayers, biological membrane structure and processes, and protein–protein and protein-membrane interactions. FRET has been extensively used to study interactions between soluble proteins or membrane proteins and soluble protein binding partners and, also, more recently successfully employed to investigate the interaction of membrane proteins in their native environment.

Molecular interactions between natural pigments and proteins and other cellular components can be studied by means of fluorescence spectroscopy, thus clarifying if and how the pigment binds to the proteins. These data can be of great importance, if the pigments under investigation are photosensitizers generating radicals and reactive oxygen species following illumination. Wide varieties of natural and selectively artificially modified dyes are, in fact, currently utilized in the photodynamic therapy of tumors and bacterial and viral infections. A detailed study of the different fluorescence parameters (fluorescence excitation and emission spectra, fluorescence quantum yield, fluorescence lifetime, and fluorescence anisotropy) can reveal the occurrence and elucidate the characteristics of the chromophore binding to the target biological macromolecule and its localization in the target tissue/cellular compartment, thus providing key information for assessing its therapeutic efficacy or undesired phototoxicity. Hydrophobic and amphiphilic chromophores, like hypericin, for example, which give rise to non fluorescent polydispersed aggregates in aqueous solutions, monomerize and fluoresce when inserted in suitable molecular pockets.

Concluding Remarks

This article briefly: (1) presents the fundamental aspects of the fluorescence phenomenon in polyatomic organic molecules in condensed phase, (2) schematically describes the basic instrumentation for measuring fluorescence parameters (spectral distribution of the intensity, polarization, yield, and lifetime), and (3) concisely discusses a few typical examples of the use of fluorescence spectroscopy as a tool for probing structural and functional properties of biomolecules involving fluorophores such as tryptophan, flavins, chlorophyll, phytochrome, phototropins, and hypericin. The "Further reading" section will help the interested reader to find further information on the fluorescence spectroscopy and deeper and more detailed presentations of the different specialized topics.

Fluorescent Proteins

R Nifosí, V Tozzini, and F Beltram, Scuola Normale Superiore, Pisa, Italy

Introduction

Among the 20 natural amino acids, three (tryptophan, tyrosine, and phenylalanine) contribute to the intrinsic fluorescence of a protein. This UV intrinsic fluorescence is commonly used to monitor the dynamics of protein folding, since the excitation/emission wavelength of fluorescent amino acids (mainly that of tryptophan, the one with strongest fluorescence) is sensitive to the local molecular environment. Fluorescent proteins can be engineered by covalently linking various fluorophores or by insertion of synthetic fluorescent amino acids. Extrinsic fluorescence is also achieved upon binding of fluorescent molecules, such as specific cofactors.

The focus here is on a special case of protein fluorescence, the green fluorescent protein (GFP). The intrinsic fluorescence of GFP, brighter than common protein fluorescence and red-shifted to the visible spectrum, stems from the presence of a chromophore fragment, spontaneously formed starting from an internal three-amino-acid sequence. Such a reaction is completely autocatalytic, so that the protein scaffold acts as the enzyme for chromophore formation and also provides the original fragment from which chromophore formation proceeds. Thanks to this unique feature, GFP can be functionally expressed in host cells and used to create fluorescent chimeras by fusion technology allowing noninvasive fluorescent labeling of proteins in living cells. The application of GFP in molecular biology experiments has had and is still having a tremendous impact. Such a relevance stimulated an intense effort in understanding GFP properties and tuning them by molecular engineering. It also stimulated the search for new fluorescent proteins and the subsequent discovery of several GFP homologs emitting in other regions of the spectrum. Together with the artificial GFP mutants, they constitute a broad class of intrinsic fluorescent proteins (FPs) virtually covering the entire visible spectrum.

Investigation of FPs requires a highly interdisciplinary approach, which involves biology, chemistry, and physics tools and concepts. From the perspective of condensed matter physics, on one side, visualization of fluorescent proteins down to the single molecule level stimulates progress in optical spectroscopy techniques; on the other side, the complex and intriguing photophysics of GFP is a challenge to understand the details of protein internal dynamics. These studies hold the promise of enabling novel applications that exploit these naturally evolved structures for nanoscale biomolecular photonic devices.

Natural Sources of Fluorescent Proteins

GFP was discovered in the luminescent jellyfish *Aequorea Victoria*. *Aequorea* glowing originates from Aequorin, a protein that in the presence of calcium ions catalyzes the oxidation and subsequent blue-light emission of the cofactor coelenterazine. The luminescence of *Aequorea* is however green, pointing to the existence of an energy-shifting mechanism, identified in radiationless energy transfer from Aequorin to GFP.

GFPs exist in other luminescent coelenterates, among which are hydroid *Obelia* and sea pansy *Renilla*. There, as in *Aequorea*, they convert the blue chemiluminescence of coelenterazine into green light. As recently discovered, GFP-homologous proteins are present in a variety of nonluminescent animals of the Anthozoa class, such as reef corals and sea anemones. At present, $\sim$30 members of this family have been cloned and found to share a sequence homology $\sim$20–30% with GFP. Not all members of this family are fluorescent: some are chromoproteins (CPs). Whereas they are not functionally linked to bioluminescence, these homologs are responsible for the blue-purple colorations and act as photoprotectors. Photoprotection might indeed have been the function of GFP ancestors, fluorescence being only an accessory function of the protein. Unless otherwise stated, in this article GFP refers to the original

Aequorea protein and GFPs indicate wild-type GFP (wtGFP) and its mutants.

GFP Structure

GFP contains 238 amino acids (**Figure 1a**) and weighs ~27 kDa. As discovered by X-ray studies of GFP crystals, GFP sequence folds in a compact cylindrical form, which measures 42 Å in height and 24 Å in diameter and contains several secondary structure motifs (**Figures 1b** and **1c**). This rather unique fold is called β-can or β-barrel, since its lateral wall is an 11-stranded β-sheet.

The β-can is capped on both ends by short α-helical sections and run through by an α-helix, which contains the three-amino-acid sequence from which chromophore formation originates. As a result, the chromophore is positioned right in the middle of the protein, rigidly held within the barrel and screened from the outer solvent and fluorescence quenchers such as molecular oxygen and halides. All structurally solved FPs and CPs share the same fold as GFP.

Whereas *Aequorea* GFP can exist as a monomer at diluted concentrations, *Renilla* GFP exists only in the dimeric form; DsRed is an obligate tetramer and all other homologs appear to be oligomeric. This has somehow hindered their applications in biology experiments and great effort is currently being devoted to obtain bright monomeric mutants.

Chromophores of Fluorescent Proteins

Figure 2 shows the chromophores of some proteins within the GFP family. Besides GFP and the already cited DsRed, the figure shows the chromophore of EqFP611 (a far-red FP from the sea anemone *Enctamea quadricolor*), AsCP (a red-light absorbing CP

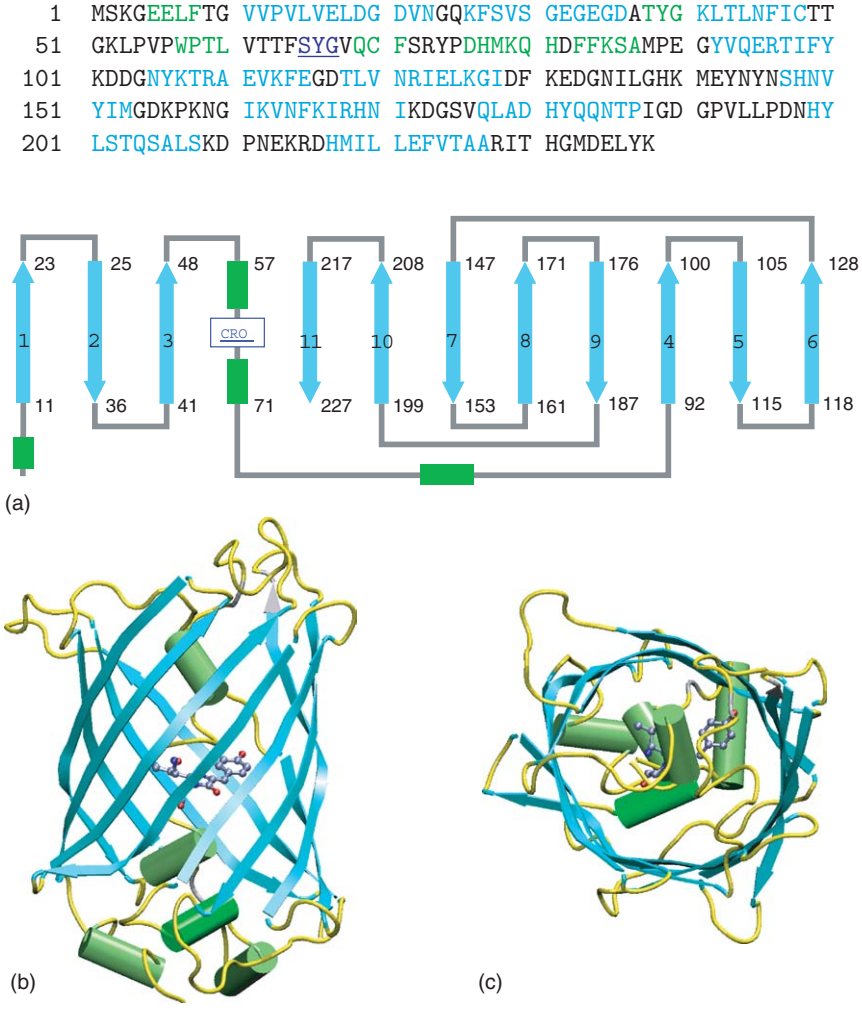

Figure 1 (a) Primary, (b) secondary, and (c) tertiary structure of GFP. In (c) the usual cartoon representation is employed, where α-helices are cylinders and β-sheets arrows. The chromophore is shown in a ball-and-sticks representation with the standard coloration for atom elements (i.e., gray for carbon, blue for nitrogen, and red for oxygen).

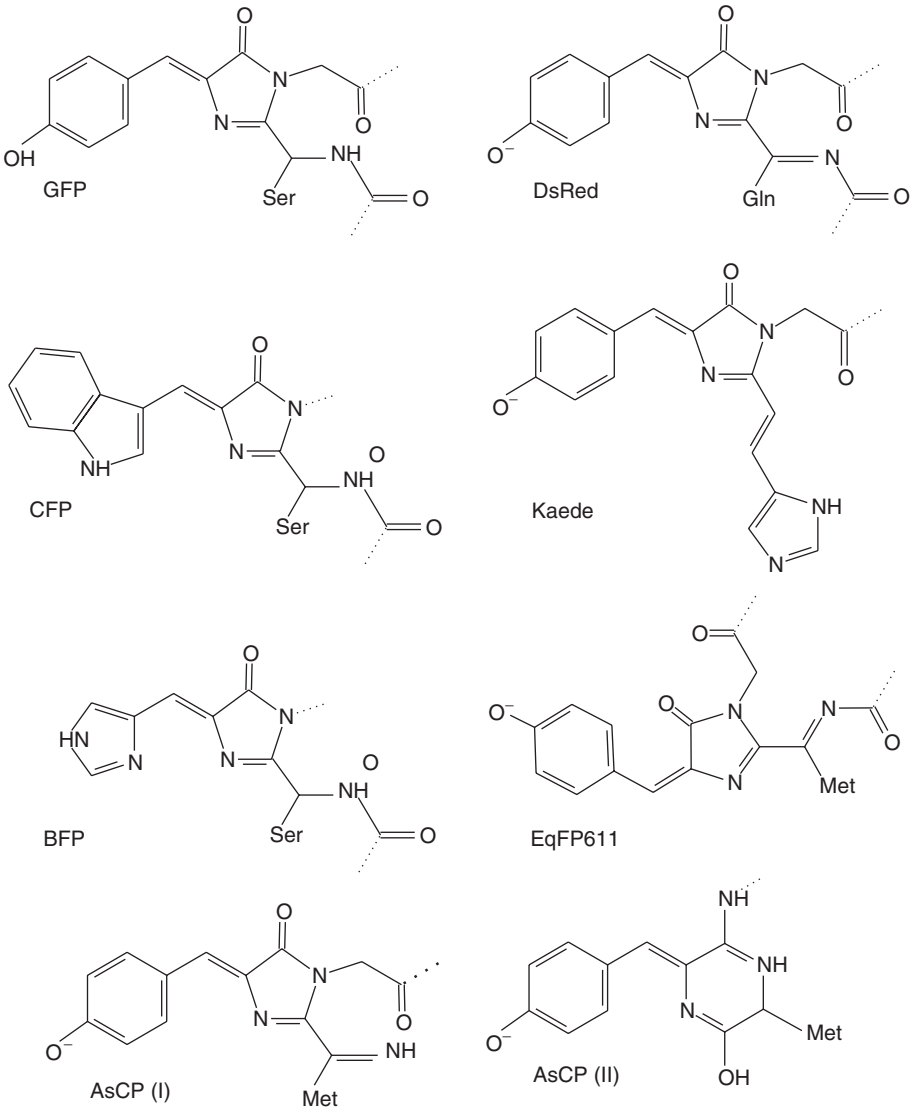

Figure 2 Structure of chromophores of fluorescent proteins. Each chromophore is labeled with the name of the corresponding FP.

from another sea anemone, *Anemonia sulcata*), Kaede (a red FP from stony coral *Trachyphyllia Geoffroyi*), and blue and cyan fluorescent proteins (BFP and CFP). The last ones are obtained by mutations of amino acid at position 66 of wtGFP, from the original tyrosine into histidine and tryptophan, respectively. EqFP611 chromophore is similar to that of DsRed but in trans-conformation. In the protein, it yields a far-red emission peaking at 611 nm, to date the most red-shifted fluorescence among the natural GFP homologs. Since no X-ray structures of AsCP and Kaede are available as yet, the structures of their chromophore are deduced only from indirect observations (in the case of ASCP, **Figure 2** reports the two hypotheses).

The different excitation/emission energies (see **Table 1**) can be explained in terms of the extension of the π-conjugated system and of the presence of electron–donor groups that compensate the electron-withdrawing carbonyl of the imidazolidinone (where present). Histidine has a moderately electron-donating NH, so excited-state transfer of electron density over the carbonyl requires higher energy with respect to tryptophan, which is rather electron rich. The phenolate anion of tyrosine in wtGFP is the most electron-donating group. The chromophore of DsRed gives even larger excitation wavelength, because the increased alternation of single and double bonds supports a more extended π-conjugated system.

The currently accepted mechanism of GFP and DsRed chromophore formation is shown in **Figure 3**. An alternative cyclization mechanism was proposed for AsCP, which leads to a cleavage of the protein in

two chains that remain bound together. As demonstrated by the fact that expression of FP genes in other organisms leads to fluorescence, chromophore synthesis does not require any organism-specific enzyme. It requires, however, exogenous oxygen, in the absence of which FPs do not develop fluorescence.

The dynamics of GFP maturation and subsequent onset of fluorescence is rather slow, taking 90 min to 4 h after protein synthesis. The bottleneck of the process is chromophore dehydrogenation by molecular oxygen, which requires up to 2 h. DsRed maturation occurs in two steps: in the initial fluorescent stage, the proteins emit green light. Because of the additional dehydrogenation, formation of the mature red chromophore takes several hours and is incomplete.

As shown in **Figure 4**, inside GFP the chromophore participates to a structured network of hydrogen bonds, being surrounded by four entrapped water molecules and a surprising number of charged and polar residues, among which are Gln69, Gln94, Arg96, His148, Thr203, Ser205, and Glu222. Analogous hydrogen-bond (H-bond) interactions are found in other FP structures. These networks crucially determine the excited-state dynamics of the chromophore. Indeed, isolated model chromophores in solution are nonfluorescent at room temperature but become fluorescent when the temperature is decreased to 77 K. Accordingly, even after the chromophore is formed, denaturation of the protein results in loss of fluorescence, whereas renaturation restores the fluorescent state, indicating that in order to emit light the chromophore must be embedded in the folded β-can. Because of this property, GFP is also a useful system for the study of folding dynamics in proteins with extended β-motives.

Spectral Properties of GFP

The excitation energy of the chromophore depends on its protonation state, so that proton (H^+) equilibrium between the chromophore and the surrounding protein matrix strongly influences GFP spectral properties. In addition, H-bonds to and from the chromophore finely tune the excitation energy because they drive the electronic structure toward one or the other of the possible resonant structures.

Figure 5 shows the room-temperature absorption and emission spectra of wtGFP. In addition to the 278 nm band, which stems from aromatic amino acids (one tryptophan and ten tyrosine residues), wtGFP exhibits a broad absorption band at 398 nm that is roughly three times higher than a minor band at 475 nm. These two lower-energy bands uniquely attribute to absorption of the chromophore. Their

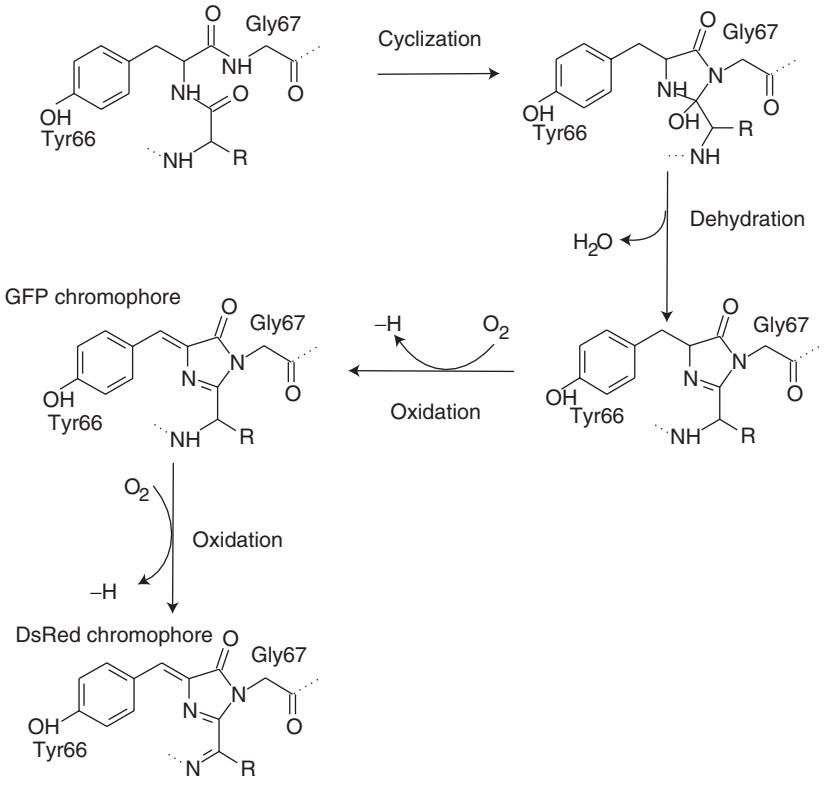

Figure 3 Accepted mechanism of formation of the GFP chromophore. Once GFP folds in a nearly native conformation, the imidazolidinone (the five-membered heterocyclic ring) is formed by cyclization, through nucleophilic attack of Gly67 on the carbonyl of residue 65, and subsequent dehydration. Then, molecular oxygen dehydrogenates the β-carbon of Tyr66, and leads to formation of the conjugated π-electronic system responsible for near-UV/visible light absorption and fluorescence. The final structure consists of two rings: the phenol, coming from the side chain of Tyr66, and the imidazolidinone, coming from the cyclization of the backbone. In the case of the DsRed chromophore, a second dehydrogenation occurs at the α-carbon of Gln66 resulting in additional extension of the π-conjugated system.

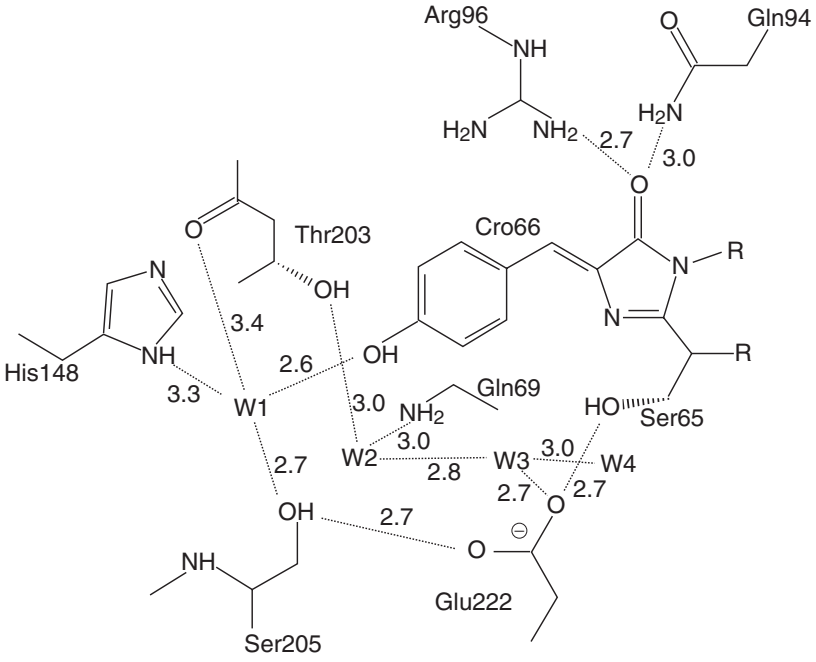

Figure 4 Two-dimensional scheme of amino acid side chains and water molecules in the immediate vicinity of the chromophore in wtGFP. The relevant distances (given in Å) are taken from the X-ray structure. (Yang F *et al.* (1996) The molecular structure of green fluorescent protein. *Nature Biotechnology* 14: 1246.)

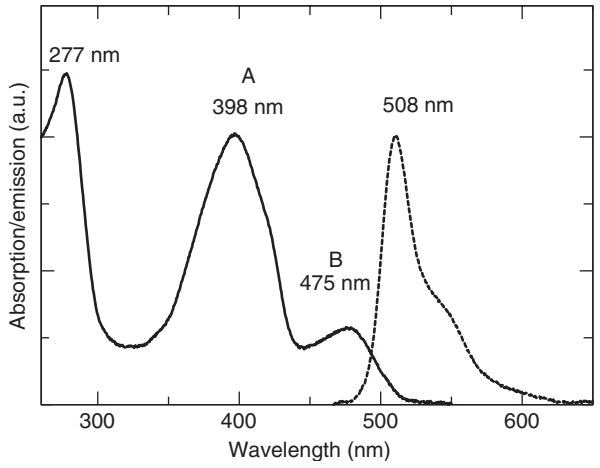

Figure 5 Absorption (solid line) and emission (dashed line) spectrum of wtGFP at room temperature and pH = 7.

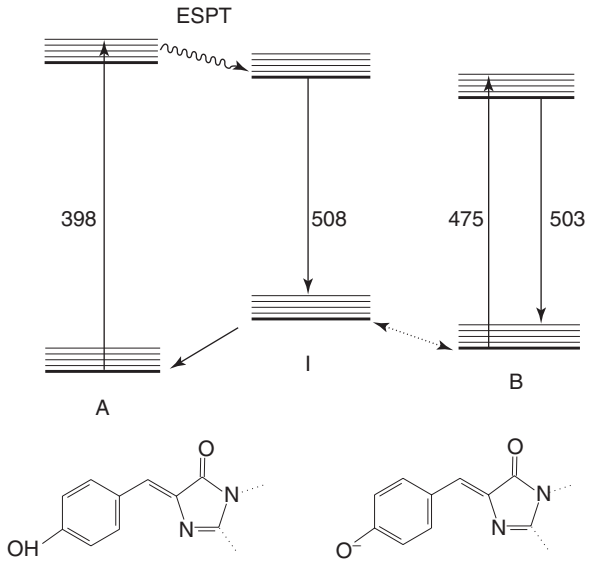

Figure 6 Fluorescence mechanism of wtGFP. The spectroscopic states are reported together with the corresponding excitation and emission wavelengths. Upon excitation of A, corresponding to the neutral chromophore, ESPT efficiently occurs to the excited I state (with anionic chromophore), which after photon emission reconverts to A. Excitation of state B (with anionic chromophore) leads instead to direct fluorescence. The equilibrium between B and I is believed to be relatively slow, because it involves the conformational rearrangement of Thr203.

relative height depends on proton concentration: at increasing pH, the minor lower-energy band increases at the expense of the higher-energy band.

This behavior arises from the ground-state equilibrium between two states of the chromophore, differing in protonation of the phenolic group from Tyr66. The phenolic oxygen of the chromophore is protonated in the state absorbing at 398 nm (state A) and deprotonated in the state absorbing at 475 nm (state B). It is largely accepted that the two other possible protonation sites (i.e., the nitrogen and the carbonyl oxygen of the imidazolidinone) in the chromophore are deprotonated in both the absorbing states, thereby giving an overall neutral chromophore in state A and anionic in state B.

Excitation of state A by irradiation at 398 nm leads to the fluorescence spectrum of **Figure 5**, peaking at 508 nm and with a rather high quantum yield of 0.79. State B (475 nm) yields a similar fluorescence spectrum, slightly blue-shifted and peaking at 503 nm. In both cases, fluorescence comes from emission of the singlet excited state of the anionic chromophore. This is suggested by a well-known tendency of phenols to become acidic in their excited state. Thus, while excitation of the anionic chromophore yields direct fluorescence, excitation of the neutral chromophore results in ultrafast (4 ps) excited-state proton transfer (ESPT) and subsequent emission of the anionic form (see **Figure 6**). ESPT is thus the origin of the large Stokes shift observed when exciting at 398 nm.

Though the anionic chromophore is the emitting species in both states, the configuration of the surrounding residues is different and the decay time of the excited state (few nanoseconds) is too short to allow equilibration, resulting in the observed slight shift of emission peak (508–503 nm). The intermediate state resulting from ESPT, called I, thus contains the anionic chromophore in an unrelaxed environment, where the hydroxyl of Thr203 points away from the chromophore phenolate, as in the state A.

Effects of Mutations on the Optical Properties

About 60 mutants of GFP have been characterized so far. Several mutation sites were selected that yield to improved maturation of GFP or to changes in the optical properties, either by shifting the absorption/emission wavelengths or by affecting brightness (extinction coefficient and/or quantum yield) or photostability. The interested reader is referred to the reviews cited in the "Further reading" section for a detailed analysis of the various mutants. Here, some significant examples of the effect of mutations on the spectral properties are given. The optical properties of selected GFP mutants are reported in **Table 1**, together with those of other FPs.

Mutations that modify the chromophore Altering the covalent structure of the chromophore results in sizable changes of the excitation/emission spectrum. In addition to mutations Tyr66His and Tyr66Trp,

which lead to the already mentioned BFPs and CFPs, synthetic amino acids such as amino-, methoxy-, iodo-, and bromo-phenylalanine were recently tried at position 66. The resulting fluorescence is blue-shifted and the quantum yield is lower than that of wtGFP ($\sim$0.4 for amino- and methoxy-phenylalanine and less than 0.02 for iodo- and bromo-phenylalanine). Red-shifted mutants were instead obtained by changing the substituent group on the CFP chromophore. Inclusion of a 4-amino-tryptophan at position 66 leads to an excitation peak at $\sim$460 nm and an emission peak at 560 nm, the most red-shifted spectra among the GFP mutants existing to date.

CFPs and BFPs are suitable partners for fluorescent resonant energy transfer (FRET) experiments with complementary GFPs. In both cases, however, additional mutations than those at position 66 are required in order to increase folding efficiency and brightness, such as in the enhanced blue and cyan variants (EBFP and ECFP). Even with those improvements, CFPs and BFPs suffer from a low quantum yield (0.24–0.42) and are prone to fast photobleaching.

Mutations that red-shift the fluorescence On the other side of the spectrum, longer emission wavelengths are obtained by replacing threonine at 203 with aromatic residues. Indeed, thanks to their delocalized π-electron system, aromatic groups are more polarizable than the aliphatic side chain of threonine and provide a more responsive medium to dipole-moment changes due to electron excitation. As a result, the emission wavelengths of mutants with Thr203Tyr are red-shifted to 525–527 nm. The crystal structures of Thr203Tyr mutants show that Tyr203 phenolic ring is stacked right below the phenolic ring of the chromophore, supporting the increased polarizability as the main mechanism for red shifting. Though the fluorescence peak is still in the green region, mutants containing Tyr203 are known as yellow because the emission appears yellowish to the eye, thanks to the long tail of the fluorescence spectrum. Yellow fluorescent proteins (YFPs) are generally brighter and more resistant to photobleaching than BFPs and CFPs.

Mutations that change the relative population of A and B: acid–base equilibrium The ground-state equilibrium between states A and B can be affected by modifying the environment of the chromophore phenolic ring (Tyr66) or of Glu222. Glu222 is commonly believed to be the other titrable group that influences GFP fluorescence (the first one being Tyr66). The titration curve of fluorescence by excitation in the 475 nm band (the one of the anionic chromophore) exhibits two abrupt increases, one at pH $\sim$ 5 and the other at pH $\sim$ 13. At pH $<$ 4 both sites are protonated, at pH between 6 and 11 only one is protonated, and at pH $>$ 13 both are deprotonated (at pH $>$ 12 the protein is denaturated and fluorescence is lost). In the intermediate region, an equilibrium is established between the two protonation states Glu222$^-$/Tyr66 (corresponding to state A) and Glu222/Tyr66$^-$ (state B). Such an equilibrium can be affected by mutations of and around the two sites.

For example, substitution of Glu222 with glycine promotes complete deprotonation of the chromophore, because glycine is necessarily neutral. The same effect is achieved when nonpolar residues are inserted at position 65, because Ser65 H-bond to anionic Glu222 is subtracted. Also mutation of Ser65 into threonine results in destabilization of state A, though threonine still possesses a H-bond donor. Presumably, because of the extra methyl, threonine side chain solvates Glu222 less efficiently than serine.

Mutations of Thr203 into nonpolar residues suppress state B, because they cannot form any H-bond with the anionic phenolate of the chromophore, which is instead H-bonded with a hydroxyl group when Thr203 is present. By contrast, state B can be favored by addition of H-bond donors close to Tyr66, such as in the Ile167Thr mutation.

Mutants with a predominant state B are preferred for applications because their red-shifted excitation wavelengths lead to a decreased background from cell autofluorescence. They are also more photostable, since the A–B photoconversion observed in wtGFP is absent, the B state being already the stable form in these mutants. A popular mutant of this class is the enhanced GFP (EGFP) with mutations Ser65Thr and Phe64Leu. The latter is a folding mutation that improves protein maturation at higher temperatures (i.e., 37°).

Spectral Properties of GFP Homologs

Less is known about the spectral properties and fluorescence mechanisms of the GFP homologs. The absorption spectrum of DsRed reveals only one band, corresponding to the anionic form of the chromophore. FRET between the chromophores in the tetramer was invoked to explain the high extinction coefficient and quantum yield. Tetramerization might also be responsible for the reduced photobleaching.

Whereas the X-ray structure of eqFP611 shows interactions between the chromophore and the protein matrix that are similar to those of GFP, the trans-conformation of the chromophore drastically

changes its environment, inserting it in a π-stacking "sandwich" between a histidine and a phenylalanine. This might be the source of the large red shift (~ 30 nm) in the absorption wavelength.

The color transitions and activation phenomena occurring in several GFP homologs are also mentioned here. Apart from the already-mentioned green-to-red transition of DsRed upon maturation, several other homologs – such as Kaede, mcavFP, and rfloRFP – were reported to undergo green-to-red transition upon UV illumination. AsCP and some of its mutants can be "kindled," that is, they become fluorescent in the red in response to intense green-light illumination, and are quenched back in the chromo form by blue-light illumination. The activation is accompanied by a 10–15 nm red shift in absorption. Stable fluorescent forms were obtained by site-directed mutagenesis. Chromophore cis–trans isomerization was proposed as the mechanism of kindling.

Fluorescence Dynamics and Dark States

Because of the interplay between the chromophore and the surrounding residues, several configurational substrates couple to the possible protonation forms of the chromophore, giving rise to many intriguing photophysical and photochemical processes. ESPT, already mentioned above, is an example (actually, the first) of the several effects discovered by studying the fluorescence dynamics of FPs. A new class of phenomena was found by applying fluorescent correlation spectroscopy (FCS) to FPs in solution and single-molecule microscopy to individual proteins immobilized in aqueous polymer gels. These studies revealed intensity fluctuations, blinking, and fluorescence switching, which were completely hidden in ensemble measurements, thus providing further insight into GFP photophysics.

Fluorescence Correlation Spectroscopy of GFP and DsRed

FCS is based on the analysis of fluctuations in fluorescence emission. In the case of free fluorophores in solution, fluctuations arise either from the change in the number of emitting molecules as they randomly diffuse in and out of the focal volume (order of 10^{-15} l $= 1\,\mu m^3$) or from intramolecular transitions between different states. From FCS experiments, it is possible to extract the decay times associated with diffusion and with the transitions from fluorescent to nonfluorescent (dark) states. The diffusional relaxation limits the timescale of detectable processes to submillisecond scale. In this range, wtGFP and other investigated mutants display "fast" fluctuations named flickering. Flickering at the 100 μs timescale probably stems from transitions between the anionic and the neutral state of the chromophore. Such transitions can occur either by protonation from the external solvent (pH-dependent component of flickering) or from the internal residues (light-driven component). In addition, intersystem crossing to the triplet state might play a role for the fastest fluctuation $\sim 50\,\mu s$. Also DsRed does exhibit several flickering components, though none seems to be dependent on pH, supporting the view that DsRed chromophore is always in the deprotonated form. Understanding the molecular mechanisms of DsRed flickering is challenging since energy transfer among the units of the tetramer is involved in the process.

Single-molecule Behavior

GFP fluorescence is bright enough to be observed at the single-molecule level. Observation of single GFP molecules dated to 1997 and was achieved independently by Moerner and co-workers and by Vale and co-workers. Sudden bursts of fluorescence were observed separated by dark intervals of the order of some seconds. Unlike the dark times, the bright times depend upon irradiation intensity (they become shorter at increasing laser power), so that fluorescence termination is light driven, while conversion back to the bright state is spontaneous. DsRed

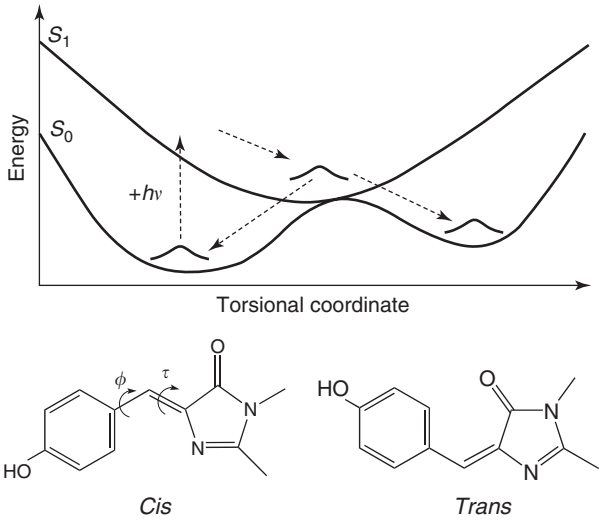

Figure 7 Scheme of a photoisomerization process. The absorption of a photon of energy $h\nu$ brings the (nuclear) wave packet to the S_1 state PES. Upon dynamics on S_1 PES, it encounters a conical intersection from which it relaxes to the ground-state energy surface, either in the same configuration as the starting one or in a different isomer. Energy curves are plotted qualitatively against a hypothetical reaction coordinate with main contribution from the torsion around the exocyclic bond. Cis- and trans-configurations of the chromophore are shown in the bottom part of the figure with the two possible torsion angles τ and ϕ.

single-molecule behavior also includes blinking events. Each single molecule is a tetramer, and within each tetramer all combinations of mature red and immature green monomers are possible. Energy effectively transfers between the various units, and emission proceeds from any of the four fluorophores.

After few cycles of blinking, all GFP molecules undergo photobleaching, that is, irreversible transition to a dark state. The relatively short lifetime of these fluorophores limits single-molecule applications in biology experiments that require detection limits longer than few tens of seconds. A very promising property of some YFP mutants is their ability to be photoconverted back to the bright state after seemingly irreversible photobleaching. The E^2GFP mutant (see **Table 1**) can be "switched on" with 350 nm light irradiation, once the reversible dark state is reached upon intense 476 nm irradiation.

It is challenging to determine the nature of the dark states associated with blinking and "on/off" switching, and the molecular pathways for bright-to-dark transition and vice versa. Switching seems to occur only in mutants with Thr203Tyr and Thr203Phe. Variants that embody Thr203Tyr mutation have a poor quantum yield of fluorescence upon excitation of the state A, so that both intrinsic fluorescence and ESPT are suppressed by some competing nonradiative decay mechanism. One such mechanism for the GFP chromophore is cis–trans photoisomerization, an ultrafast excited-state process that involves torsion around the bonds connecting the two rings of the chromophore. This dynamics (see **Figure 7**) involves crossing from the excited state to the ground-state potential energy surface (PES) through a conical intersection, resulting in complete quenching of photon emission. Cis–trans photoisomerization is known to play an important role in the retinal of rhodopsin and is probably the origin of the extremely poor quantum yield of the free GFP chromophore in solution. In this line of thought, it is tempting to consider cis–trans photoisomerization as the molecular mechanism of E^2GFP switching, where the reversible dark state of the protein is attributed to the trans-configuration of the chromophore.

Applications of FPs

High-resolution optical-spectroscopy techniques applied to the imaging of proteins labeled with fluorescent tags offer new tools for investigating protein trafficking and interactions inside the living cell. In this context, GFP fusion technology offers an

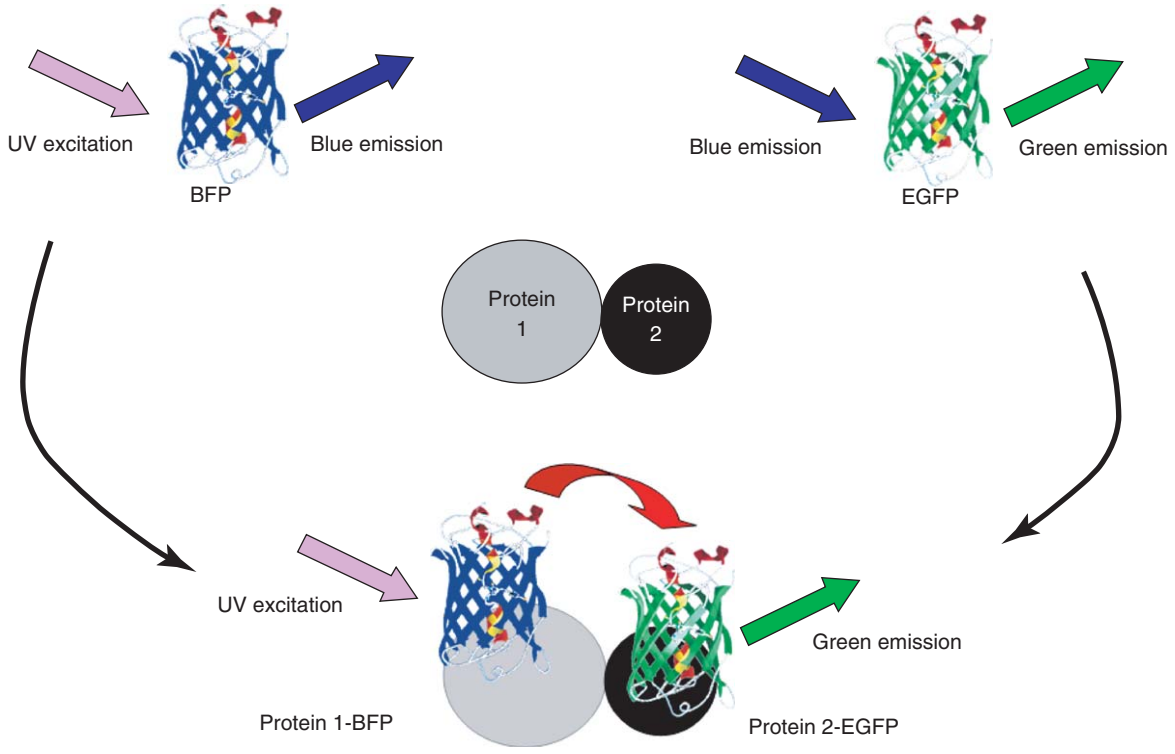

Figure 8 A typical FRET experiment with FPs would employ, for example, EGFP and EBFP as FRET partners (EYFP and ECFP is also a common pair), fusing them with the proteins of interest. Interaction between the two proteins is then detected by comparing the EGFP emission at 520 nm excited at (direct EGFP fluorescence) with emission by excitation of EBFP at 360 nm (EGFP fluorescence via FRET). Comparable levels of fluorescence in the two cases prove that the pair is interacting.

inexpensive way to mark one protein with one-to-one protein-tag correspondence, avoiding toxicity associated with exogenous fluorescent dyes. In addition, the availability of a large set of GFP mutants is precious in that it offers several pairs of fluorophores with suitable overlap between absorption and emission spectra, ideal for FRET experiments. Detection of FRET between donor and acceptor fluorophores previously fused to a pair of proteins indicates that the pair is actually interacting at distances of the order of the nanometer (see **Figure 8**). Indeed, thanks to FRET sensitivity to the pair distance, this technique discriminates between interaction and simple colocalization in cellular compartments.

FRET between a GFP pair interposed by a peptide is also exploited to monitor conformational rearrangements, either in protein folding studies or for sensing calcium concentration. GFP-based calcium reporters, the so-called Cameleons, are composed of a GFP pair linked by a peptide that changes conformation in the presence of calcium. Other sensing applications exploit the fact that GFP fluorescence is (or can be made by mutagenesis) sensitive to pH and is quenched upon binding of halides or metal ions.

Photobleaching can be used to investigate protein dynamics. The mobility of GFP chimeras is determined by high-intensity illumination of a defined cellular area and subsequent monitoring of the fluorescence recovery after photobleaching (FRAP) within the same area. Fluorescence loss in photobleaching (FLIP) works in the opposite way, that is, by monitoring the loss of fluorescence outside the repeatedly bleached area.

There exist also potential applications of GFPs outside the cell. As mentioned above, it is possible to toggle the molecular states of certain GFP mutants by purely optical means (on/off switching). Such photoinduced bistability can be the basis for information storage down to the single molecule level. Thanks to molecular recognition, FPs are easily targeted to specific sites of a patterned substrate for building ultradense optical memory devices.

Applications of the other FPs are still at the embryo stage. Tuning the optical properties of these new proteins by mutagenesis will extend the spectral range of biological fluorophores available for applications. New building blocks for photonic devices might emerge from the investigation of their largely unexplored photophysics and the increasing ability to manipulate protein structure by mutagenesis and insertion of synthetic amino acids.

Folding and Sequence Analysis

A Tramontano, University of Rome "La Sapienza," Rome, Italy

Introduction

A genome is a string made of four different characters, the nucleotides. The human genome consists of a collection of three billion of these nucleotides, and it is believed to code for at least one hundred thousand different functions. Since *Homo sapiens* is only one of the many species whose genomic sequence is known, it is clear that the amount of available data is impressive. However, handling such a large amount of data is not a problem; many other sciences need to cope with equivalently large data sets, and powerful techniques and computers are available to handle them. The problem rather arises from the peculiarities of biological data, which are of different types,

ranging from sequences, that is, linear arrays of monomers, to three-dimensional structures to their interactions to functional assignments. The real hurdle is indeed to try and extract functional information by correlating the many diverse sets of information. This is not only an intellectual challenge, but is also of enormous practical importance, since it is the basic requirement to try and interfere rationally with these functions for medical and biotechnological applications.

A function is the result of the action of interacting atoms positioned in a specific relative position, so that they can, for example, bind a ligand, catalyze a biochemical reaction, recognize foreign substances, regulate the transcription or translation of other proteins, and build scaffolds to achieve cellular organization and compartmentalization. These mechanisms can achieve an exquisite specificity and sensitivity in response to internal and external stimuli, allowing a living organism to survive and evolve.

The large majority of these functions is performed by proteins, linear polymers of 20 different amino acids whose sequence is specified by the genetic material. Proteins fold to a unique three-dimensional structure, which determines the relative position of their atoms and, therefore, their function. For example, the biological function of an enzyme is to catalyze a biochemical reaction by lowering the free energy of the activation barrier. This is achieved through the stabilization of the reaction intermediately brought about by a few specific amino acids located in a very precisely defined relative position in the protein (**Figure 1**).

The structure of a protein is by and large only dictated by the specific linear sequence of its building blocks as first demonstrated by Anfinsen in a historical experiment.

He showed that a protein (in this particular case, ribonuclease S) once denatured, that is, unfolded, *in vitro*, recovers its native conformation when the

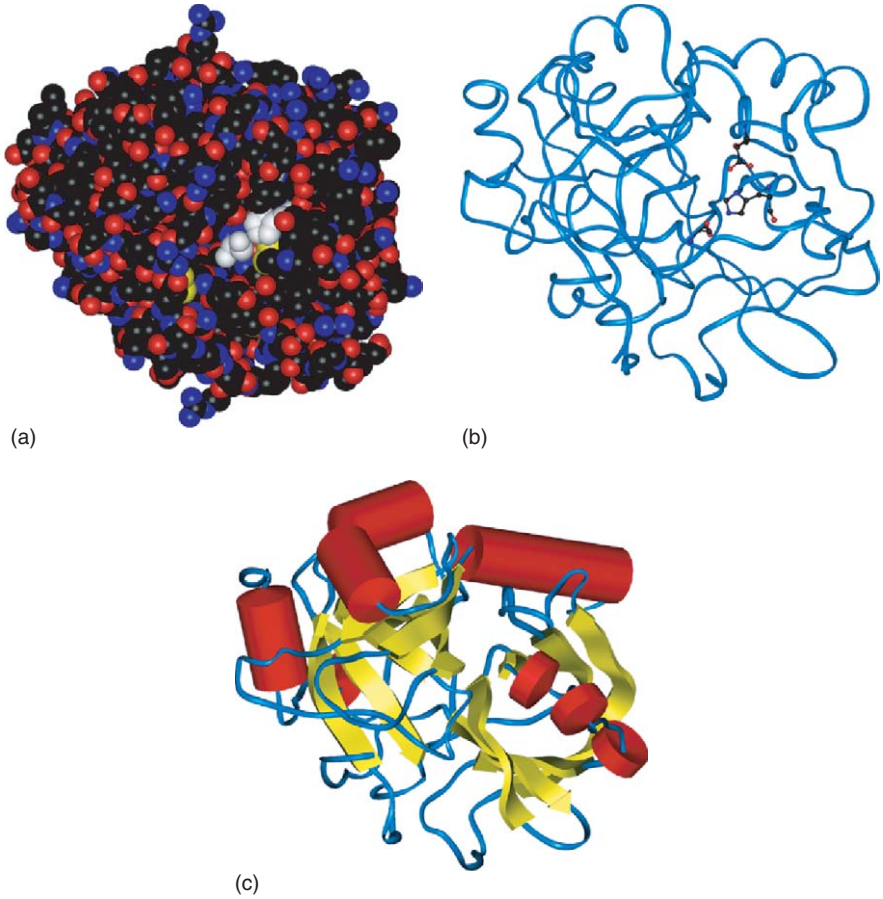

Figure 1 Different representations of the three-dimensional structure of the enzyme thrombin. (a) All atoms of the enzyme are shown as spheres. The white spheres indicate the atoms involved in the catalysis. (b) The enzyme is shown as a ribbon connecting its amino acids and the three amino acids involved in the catalytic mechanism are shown in ball and stick representation. They are distant in the amino acid sequence, but come close together upon folding of the protein, (c) Regular elements of secondary structures are shown as cylinders (α-helices) or arrows (β-strands).

denaturing agents are removed from the test tube. This implies that the information about the three-dimensional structure of a protein is contained in its amino acid sequence.

The subsequent discovery of cellular mechanisms that catalyze folding of some proteins has left this view unchallenged, since these systems accelerate the folding process, but do not affect the structure of the final native state.

Therefore, a function is directly linked to the genetic material via the encoded proteins and their three-dimensional structure.

One needs to understand how a given genomic sequence codes for a protein, how the protein folds into its defined three-dimensional structure, and how this structure is able to carry on a function either alone or through its interactions with other partners.

In higher organisms, the detection of the segments of a genome that code for a given protein (genes) is not straightforward. In humans, only three percent of the genome codes for proteins and the portions of the genes coding for the corresponding protein sequences are not contiguous in the DNA sequence. The gene-finding problem is not discussed here; it suffices to say that methods to identify the coding regions are still being developed and that the problem is not yet satisfactorily solved.

The Protein Folding Problem

Once the amino acid sequence of a protein is known, one faces the problem of determining its three-dimensional structure, a problem that can be addressed with experimental techniques, such as X-ray crystallography or nuclear magnetic resonance. However, it is unthinkable that it is possible to determine experimentally the structure of all the proteins of the universe. Therefore, one of the most important problems of modern biology, often referred to as "the holy grail" of computational biology, is to be able to infer (or predict, as we erroneously say) the three-dimensional structure of a protein from its amino acid sequence.

A protein folds if the difference in free energy between its disordered, unfolded state and its structured native state is negative. Upon folding, a protein loses the entropy associated with the many alternative conformations that it can assume when disordered, and gains internal interactions and entropy. Interactions in a protein structure are weak, mainly van der Waals and electrostatic interactions (the latter are usually few and quite weak, since most proteins are embedded in a polar solvent). Entropy gain is due to the burial of the hydrophobic side chains of amino acids. The main problem is that the difference between the free energy of the unfolded state and that of the structured state derives from the difference of large terms, but is a very small number, of the order of a few kcal/mol. In other words, proteins are only marginally stable and one would need to calculate the energetic contribution of each interaction with a precision that is not achievable today. Therefore, the search for the free-energy minimum conformation of a protein, that is, the *ab initio* solution of the folding problem, is beyond one's present capabilities.

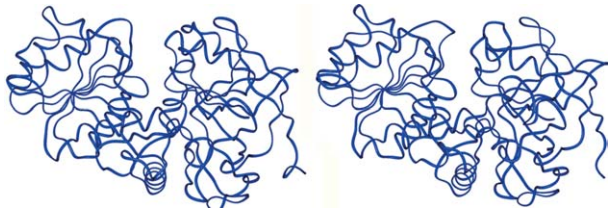

Figure 2 Structure of two evolutionary related proteins (human and cod alcohol dehydrogenase). Their sequences share 60% identity but their main-chain structure is virtually identical.

Computational biology is, therefore, trying to find a heuristic solution that, although not satisfactory from the point of view of an intellectual understanding of the problem, is able to provide practically useful solutions.

One of the most interesting approaches widely used today is to address the problem in its differential form. In other words, rather than asking the question of which is the structure and function of a protein, the following question can be asked: given a protein of known structure and function, how do changes in its sequence affect its structure and its function(s)?

Evolution provides one with many examples of proteins that descend from a common ancestral protein and whose structure and function have been modified via a process of sequence changes and selection. One can, therefore, use these solved examples to try and infer the rules relating the relationship among sequence, structure, and function changes (**Figure 2**).

The Protein Sequence Space

Two protein sequences are linear arrays of basic building blocks, the amino acids, and their distance can be measured by counting the number of evolutionary events (amino acid substitutions, for example) that can transform one into the other.

It is reasonable to use a maximum parsimony approach by calculating the correspondence between the two linear arrays of amino acids that minimizes the number of differences between them, a problem

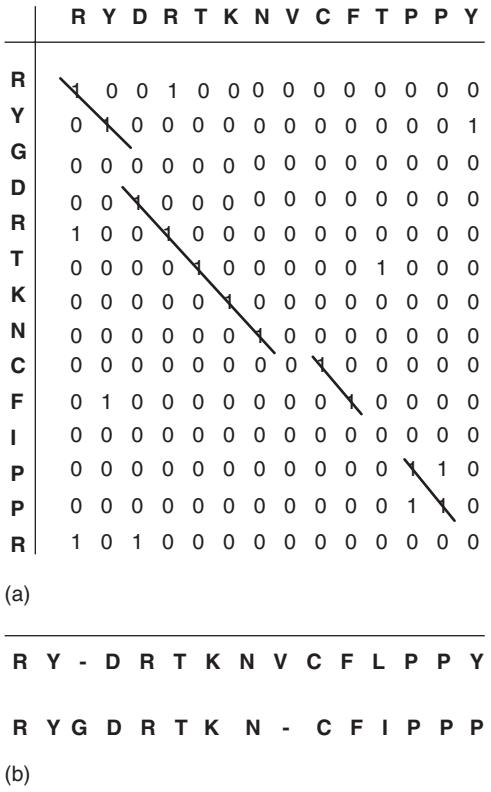

Figure 3 (a) Example of a matrix indicating the identity between two protein sequences. The maximum likelihood aligned regions between the two protein sequences are represented by the segments and the corresponding optimal overall alignment is shown in (b).

that can be solved exactly, for example, with dynamic programing.

Figure 3 illustrates the method. A matrix is used, where each column represents one amino acid of the first sequence, and each row an amino acid of the second. One element of the matrix is set to 1 if the amino acid in the column and that in the row are the same, and to zero, otherwise. The problem of finding the correspondence between the amino acids of the proteins is equivalent to finding the path that goes from the upper left corner to the lower right corner, such that the sum of the content of the cells it connects is maximal.

In order to obtain a biologically sensible alignment of two protein sequences, one more level of sophistication is required. Two amino acids are not simply the same or different, they can be more or less similar according to their physicochemical properties. The probability that a charged amino acid is replaced by another charged amino acid is expected, and found to be higher than the probability that it is replaced by a small hydrophobic amino acid. These probabilities can be estimated by analyzing families of evolutionary related proteins, and counting how frequently a given amino acid substitution is observed with respect to a background distribution. These numbers are derived from closely related proteins or well-conserved regions of proteins, where changes can be detected without ambiguity and subsequently, one would need to extrapolate their values for distantly related proteins. This can be done in different ways but in all cases, one then faces the problem of having to assign probabilities also to some phenomena, which are rarely observed in closely related proteins or in well-conserved regions, such as insertions or deletions of residues. This is usually done using empirical methods.

Improvement in the quality of sequence alignments, that is, in their ability to reproduce the course of evolution, can be achieved by taking advantage of the availability of more sequences from the same evolutionary family. It can be said that, with some limitations, one knows how to measure the distance between two evolutionary related protein sequences.

Given what has been said before, the accuracy is higher for closely related proteins and it can become very low when the distance between the two proteins is very large.

The Protein Structure Space

Given two protein structures and a correspondence table between their atoms, the definition of their distance in structural space is trivial; one needs to find the rigid body translation and rotation that minimize the distance (usually the root mean square distance (RMSD)) between corresponding atoms.

The problem becomes far more complex when the correspondence between the atoms is unknown and/or incomplete (that is, when some regions of one protein might not correspond to any region in the other), and several methods have been developed for this purpose.

First of all, it should be clear that the solution to the problem is not unique, since different superpositions can include different numbers of atoms and result in different values of RMSD (**Figure 4**).

The most commonly used methods rely on either substructure superpositions or on distance matrix analysis. The latter is an interesting, and often very useful, representation of a protein structure where the protein sequence is written both in the first column and first row of the matrix, and a cell of the matrix is filled if the two corresponding amino acids are within a certain threshold distance. Distances can be calculated between Cα atoms, Cβ atoms, between the center of mass of the side chains, or even between the midpoints of secondary structure elements. The matrices corresponding to two protein structures can

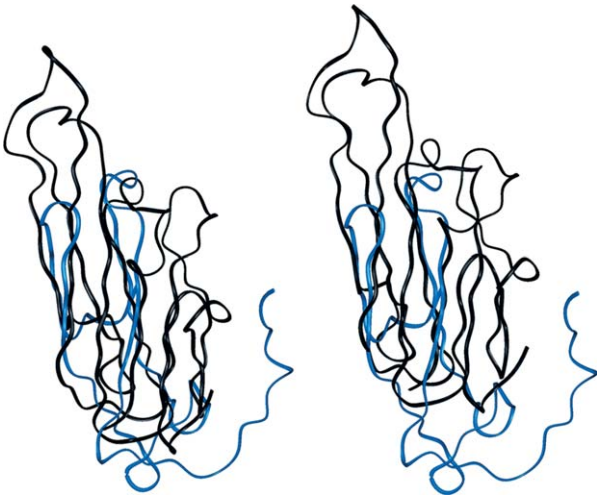

Figure 4 Two alternative structural superpositions of comparable quality of tumor necrosis factor-α (in black) and of the middle component of the bean pod mottle virus (in blue).

be compared to find the optimal superposition between their structures, for example, with a "divide and conquer" algorithm.

The problem of the nonuniqueness of the computation of the superposition, and consequently, the uncertainty in the measure of the distance between two protein structures, becomes clearly more relevant as the more different the two protein structures the more distantly related the two proteins are.

The Protein Function Space

In the previous paragraphs, the problem of defining distances between well-defined entities, sequences, and structures was faced. In function space the problem becomes much more complex, because it is very difficult to univocally define function.

Not only can the coding of a function be ambiguous, but the protein function is, by nature, multidimensional. A molecule has a molecular, a biological, and a cellular function, and each of them can be defined at different levels of detail.

For example the protein "thrombin" can be functionally defined as:

- an enzyme, that is, a biological catalyzer;
- a hydrolase, that is, an enzyme catalyzing the hydrolysis of a chemical bond;
- a protease, that is, a hydrolase that hydrolyzes the peptide bond of proteins;
- a serine protease, that is, a protease where the catalytic reactive group is the side chain of the amino acid serine;
- a trypsin-like serine protease, that is, with a specific topology that allows the clustering of the catalytic site residues; and
- thrombin, that is, a specific trypsin-like serine protease.

At the same time, it has the biological function of being part of the blood coagulation cascade and the cellular function of being an extracellular protein.

How does one then define the distance between the thrombin function and, say, the function of polymerase, the enzyme that catalyzes the replication of a nucleic acid molecule?

Finding an exact solution to the problem is probably unfeasible, but at least there are now attempts to systematically classify the functions through the production of controlled vocabularies that can be used to describe gene product attributes, such as the system under development by the gene ontology (GO) consortium.

The Relationship between Sequence Space and Structure Space

As mentioned, a native protein structure is stabilized by a large number of weak interactions; therefore, the probability that small accepted changes, such as those happening during evolution, can change the overall structure substantially is very low. This implies that evolutionarily related proteins, that is, proteins that derive from a common ancestral protein via the stepwise accumulation of small changes will have similar structure. The buildup of the effects of these small changes might change the details of the structure quite substantially, but it is not expected to modify the overall topology of the protein chain.

On the other hand, if two proteins derive from a common ancestor via small changes, their sequences might preserve a similarity sufficiently high to highlight their evolutionary relationship.

One can derive that proteins with similar sequences have similar structures. This observation, that has been quantitatively analyzed by several authors, forms the basis of one method for protein-structure prediction, called "modeling by homology" or "comparative modeling." Blind tests of the method, evaluating the predictions of a protein structure before its experimental determination, demonstrate that the accuracy of the method can be rather high for evolutionarily closely related proteins.

It should be mentioned that the relationship between sequence and structure in proteins is more complex; often proteins with seemingly unrelated sequences have similar topologies. This might be due to the fact that some topologies are favored and, therefore, many protein sequences have structurally converged toward them, or to the fact that they are indeed evolutionarily related, but the number of

accumulated changes is too high for the relationship to be detectable.

This observation has led to a method for protein-structure prediction, called "fold recognition" whereby a fitness value is calculated for the compatibility of a given protein sequence with each of the previously known topologies.

The accuracy of the predictions is somewhat lower for this method than for comparative modeling, but in both cases the question is, which level of accuracy does one need to be able to use the prediction to define the function.

The Relationship between Sequence Space and Function Space

The most common assumption in relating sequence to function is that proteins evolving from a common ancestor preserve their function, implying that functional information can be transferred from one protein to evolutionarily related ones. However, complications arise since two homologous proteins can be diverged after a speciation event and, therefore, preserve the same function (orthologous), or after a duplication event (paralogous) could have developed new functions. The problem, therefore, is to understand how their distance in sequence space can be used to discriminate between the two cases or, in other words, which minimum level of sequence identity between two sequences is required to safely conclude that the function is preserved. Several studies have addressed this problem concluding that, in general, a sequence identity of 50% or higher is strongly correlated with function conservation.

The Relationship between Structure Space and Function Space

Until a few years ago, the determination of the structure of a protein was carried out by groups interested in the specific protein and, therefore, on proteins that had been extensively biochemically characterized.

More recently, there are several worldwide projects, the so-called structural genomics projects, devoted at solving experimentally the structure of as many proteins as needed to "cover" the structure space, that is, at solving preferentially the structure of proteins unrelated to any protein of known structure. Furthermore, the genomic projects have made available a large number of putative protein sequences.

This implies that more and more often, structural information on proteins of unknown function is available and the question arises as to whether the latter can be deduced from the former.

The problem is very complex, partly because a measure of "distance" between functions cannot be defined and partly because proteins develop novel functions not only through the evolution of an existing function (which is often achieved after the genetic material encoding for the original function is duplicated, and can therefore evolve without the constraints of preserving it), but also via recruitment of structural modules and mixing of pre-existing protein domains (structurally compact segments of proteins).

There are several examples that illustrate the difficulty of the problem. For example, the same identical protein is used in the duck as the eye lens protein and as an enzyme that hydrolyzes lactose in the same organism, but in a different cellular environment. Clearly, the knowledge of the sequence and structure of the protein, identical in the two cases, would be of no help to deduce the function.

Furthermore, it is as yet unclear how unique a protein function is; in other words, how often the same protein can perform different functions in different cellular compartments or in the presence of different ligands.

Present approaches to structure-based function prediction rely on methods to detect common substructures in proteins that can be associated with specific activities, in the hypothesis that important functional features are structurally conserved during evolution. On the experimental side, the development of whole-organism investigations permits other approaches to function prediction. Novel high-throughput experiments, namely transcriptomics and proteomics experiments, allow the detection of proteins that are coregulated in response to an external stimulus or that interact with one another.

These data, combined with the recognition of conserved sequence and/or structural features in coregulated proteins and of correlations between occurrences of related proteins in different organisms, can give strong indications about functional properties and are, therefore, slowly but steadily enlarging our catalogue of sequence, structure, and function relationships.

Genetic Algorithms for Biological Systems

Introduction

Cells are controlled by the action of molecules upon molecules. Receptor proteins in the outer cell membrane sense the environment and may subsequently induce changes in the states of specific proteins inside the cell. These proteins then interact again and convey the signal further to other proteins and so forth, until some appropriate action is taken. The final results of such signaling may be a transcription regulation, thereby making more of some kinds of proteins.

The reader is reminded that proteins are produced from DNA through a two-step process, where first the DNA code is transcribed into mRNA by an RNA polymerase, and subsequently, the mRNA is translated into a protein by a ribosome. This is illustrated in **Figure 1**. The simplest way that one protein regulates the production rate of another protein is illustrated in **Figure 2**. The regulated protein may in turn regulate other proteins, and thereby be part of the transcription regulatory network. Regulatory genetic networks are essential for epigenetics and thus multicellular life, but are not essential for life. In fact, there exist prokaryotes with nearly no genetic regulation.

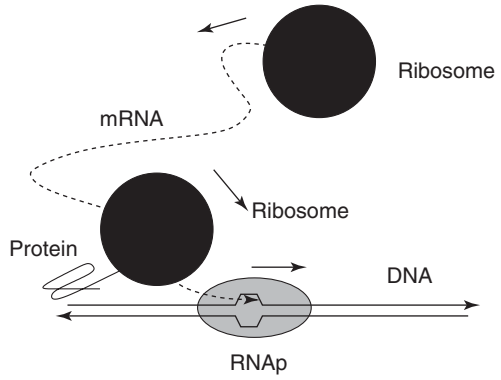

Figure 1 RNA polymerase (RNAp) moves along the DNA while transcribing it into an mRNA string. This mRNA is subsequently translated into a protein by a ribosome, here shown in black. The same mRNA may easily be translated into several proteins.

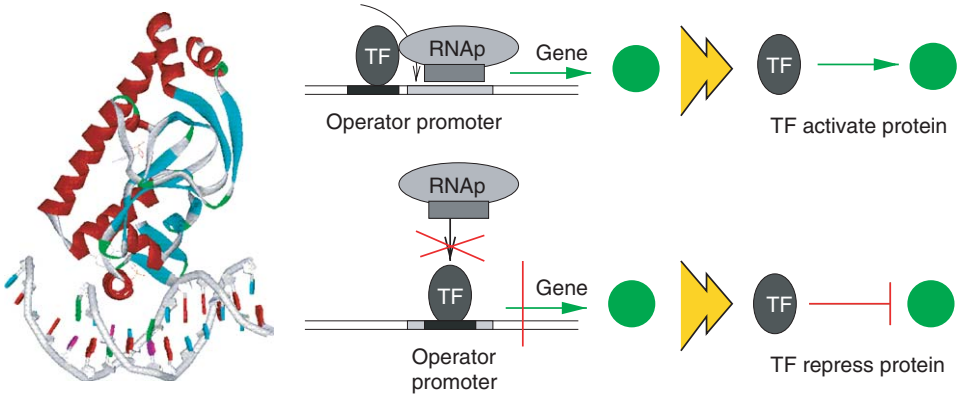

Figure 2 On left panel an example of a transcription factor is shown, the protein CAP that binds to a piece of DNA. On right panel is illustrated respective positive and negative regulation by a transcription factor (TF) on a protein shown as a green filled circle. The TF is a protein that binds to a region on the DNA called an operator (dark region on the DNA). The positive regulation is through a binding between the TF and the RNAp, that increases the chance that RNAp binds to the promoter that is shown as a medium dark region on the DNA strand. Negative regulation occurs when the operator is placed such that the bound TF prevents the RNAp from binding to the promoter. On the rightmost panels is shown how one typically draws the elementary regulation as an arrow in a regulatory network.

An interesting overall observation dealing with the architecture of genetic regulatory networks is that the fraction of proteins that regulate other proteins N_{reg}/N increases with total number of proteins N. In other words, the relative size of the bureaucracy increases with system size. In fact for prokaryotes, the fraction of regulators increases linearly with the system size, reaching $\sim$10% for the prokaryote *Pseudomonas auriginosa* with its $\sim$6000 genes. If a living cell could be understood as an essential core plus a number of modules (genes regulated together), each, for example, associated to respond to a corresponding external situation, then the fraction of regulators would be independent of the number of genes N. The fact that N_{reg}/N grows linearly with N indicates that each added gene or module should be regulated with respect to all other gene modules. Thus, already prokaryotic organisms show features of a highly integrated computational machine. Networks are indeed important, from the smallest hubs with feedback to the whole integrated circuitry.

Topology of Genetic Regulatory Networks

In **Figure 3**, the known regulatory network for the single-celled eukaryote, the yeast *Saccromyces cerevisia* is shown. One feature of regulatory networks is the wide distribution of directed arrows from individual proteins. There are many proteins which control only few other proteins, but there also

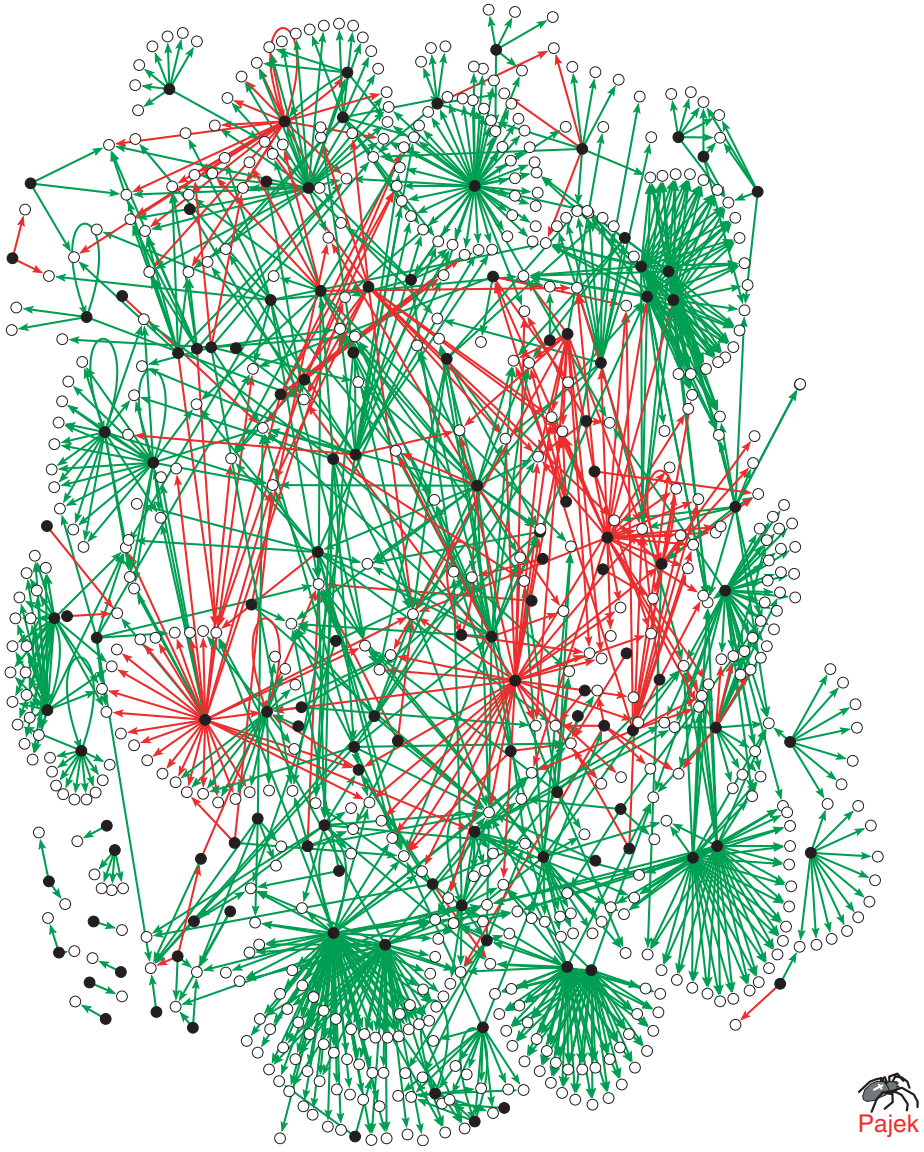

Figure 3 Presently known transcription regulations in yeast (*Saccromyces cerevisia*), with green arrows indicating positive regulation (activation) and red arrows indicating repression.

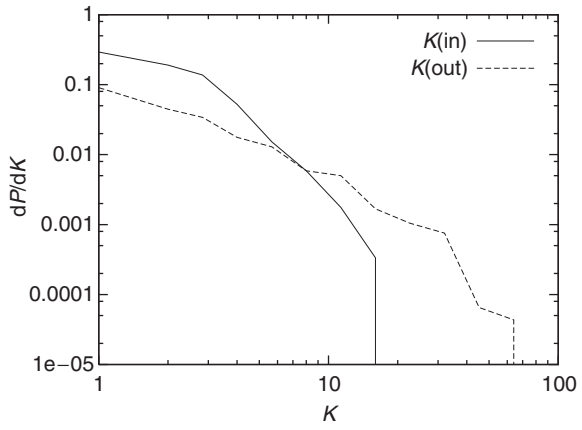

Figure 4 Statistics of regulation in the yeast *Saccromyces cerevisia*. (Data from Proteome.)

exist some proteins which control the expression level of many other proteins. In fact, the distribution of proteins with a given number of neighbors (connectivity) K may (very crudely) be approximated by a power law

$$N(K) \propto 1/K^{\gamma} \qquad [1]$$

with exponent $\gamma \sim 1.5 \pm 0.5$ for the "out-degree" distribution of transcription regulators (see **Figure 4**). It is also to be noticed that the distribution of the number of proteins in which a given protein regulates, the "out-degree" differs from the narrower distribution of "in-degrees." Overall however, both of these distributions are broad, and one would like to develop an intuition to find possible reasons why life organizes its regulation in this way.

One aspect of a wide distribution of connectivity in signaling networks is the possible amplification of signals in the network. Thus on an average, a signal entering a node could be transmitted to a number of other nodes given by the amplification factor:

$$\mathscr{A} = \frac{\langle K_{\text{in}} K_{\text{out}}(\text{given } K_{\text{in}}) \rangle}{\langle K_{\text{in}} \rangle} = \frac{\langle K_{\text{in}} K_{\text{out}} \rangle}{\langle K_{\text{in}} \rangle} \qquad [2]$$

the last equality implies that the output connectivity is independent of the input connectivity. The above formula follows from following a signal that enters a node with probability proportional to K_{in}, and leaves along any of the K_{out} links. The equation is thus the average amplification factor in a randomly wired directed network. When $\mathscr{A} > 1$, signals tend to be exponentially amplified and thus, most signals will influence signaling over the entire network. For networks with degree distribution which is a power law, $\mathscr{A}$ typically depends on the most highly connected node. Thus, highly connected nodes will be effective in transmitting a signal very fast to a substantial part of the whole system. This has obvious advantages, and may be one of the reasons why one also observes very highly connected nodes in both genetic and other signaling networks in living cells.

Power-law networks have also been proposed to be due to statistical processes, with little regard to functionality. One very widespread suggestion is the preferential attachment idea, that uses the fact that, if a network is growing by a mechanism where each new node is attached to nodes selected as being in the ends of already existing links in the network, then one obtains a steadily growing scale-free network. Another suggestion is the observation that even a nongrowing network can develop into a steady-state attractor with a scale-free degree distribution, if one assumes that a major element in the network rewiring dynamics is merging of old vertices and creation of new vertices. In the perspective of signaling networks, the latter model represents an on-going attempt to minimize the length of signaling pathways, competing with an on-going pressure to increase the protein diversity. In any case, traces of the actual evolution of networks can be quantified using the rather frequent gene duplication and associated protein homologs that one finds in any presently living organism. The overall lesson of such studies is that the genome of any organism is dynamic, and that reorganizations indeed are possible if they are functionally desirable.

The real reason for the observed broad distribution of edge degrees in biological networks should probably be seen in the perspective of where especially the highly-connected nodes sit in the network. To analyze this, a discussion on how to analyze network topologies beyond the degree distribution is taken up now. The key idea is to generate a random network, and then to compare this with the real network.

As was pointed out in the general context of complex scale-free networks, a broad distribution of degrees indicates that the degree itself is an important individual characteristic of a node and as such, it should be preserved in the randomized null-model network. In addition to degrees, one may choose to preserve some other low-level topological properties of the network in question. Any measurable topological quantity, such as, the total number of edges connecting pairs of nodes with given degrees, the number of loops of a certain type, the number and sizes of components, the diameter of the network, can then be measured in the real complex network and separately in its randomized version. One then

concentrates only on those topological properties of the real network that significantly deviate from their null-model counterpart.

An algorithm giving rise to a random network with the same set of individual node degrees, as in a given complex network, was proposed by Maslov S and Sneppen K in 2002. It consists of multiple repetitions of the following simple switch move (elementary rewiring step) illustrated in **Figure 5**: "Randomly select a pair of edges A→B and C→D and rewire them in such a way that A becomes connected to D, while C to B."

To prevent the appearance of multiple edges connecting the same pair of nodes, the rewiring step is aborted and a new pair of edges is selected if one or two of the new edges already exist in the network.

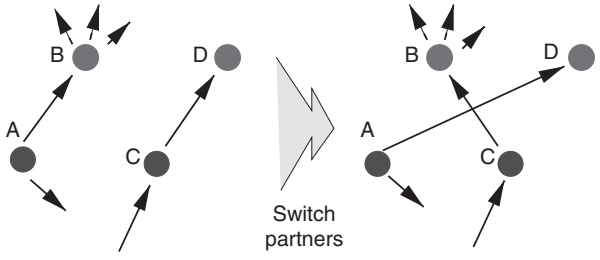

Figure 5 One step of the local rewiring algorithm. A pair of directed edges A→B and C→D. The two edges then switch connections in such a way that A becomes linked to D, while C to B, provided that none of these edges already exist in the network, in which case the move is aborted and a new pair of edges is selected. An independent random network is obtained when this is repeated a large number of times, exceeding the total number of edges in the system. This algorithm conserves both the in- and out-connectivity of each individual node. (Reproduced from Maslov S and Sneppen K (2002) Specificity and stability in topology of protein networks. *Science* 296: 910–913; American Association for the Advancement of Science.)

A repeated application of the above rewiring step leads to a randomized version of the original network. The set of MATLAB programs generating such a randomized version of any complex network can be downloaded from the internet.

Sometimes it is desirable that the null-model random network in addition to degrees of nodes, conserves some other topological quantity of the real network. In this case, one could supplement the random rewiring algorithm described above with the Metropolis acceptance/rejection criterion.

The "correlation profile" of any large complex network quantifies correlations between degrees of its neighboring nodes. The topological property of the network giving rise to its correlation profile is the number of edges $N(K_0, K_1)$ connecting pairs of nodes with degrees K_0 and K_1. To find out if in a given complex network the degrees of interacting nodes are correlated, $N(K_0, K_1)$ should be compared to its value $N_r(K_0, K_1) \pm \Delta N_r(K_0, K_1)$ in a randomized network, generated by the edge rewiring algorithm. When normalized by the total number of edges E, $N(K_0, K_1)$ defines the joint probability distribution $P(K_0, K_1) = N(K_0, K_1)/E$ of degrees of interacting nodes. Any correlations would manifest themselves as systematic deviations of the ratio

$$R(K_0, K_1) = P(K_0, K_1)/P_r(K_0, K_1) \qquad [3]$$

away from 1. The correlation profile for the yeast regulatory network is shown in **Figure 6**. The statistical significance of such deviations can, in principle, be quantified by their Z-score

$$Z(K_0, K_1) = (P(K_0, K_1) - P_r(K_0, K_1))/\sigma_r(K_0, K_1) \qquad [4]$$

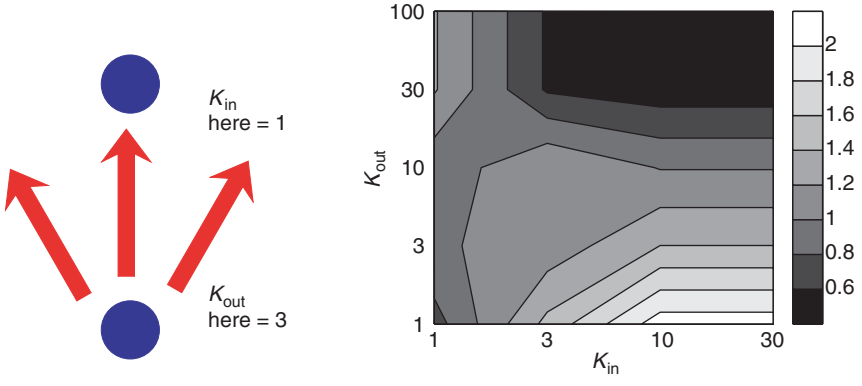

Figure 6 Correlation profile showing correlation between connected proteins in the regulatory network of yeast, quantified in terms of Z scores. The single output module is reflected in the abundance of high K_{out} controlling single K_{in} proteins. The dense overlapping regulons correspond to the abundance of connections between $K_{out} \sim 10$ and $K_{in} \sim 3$ proteins. Finally, the suppression of connections between highly connected proteins show that these tend to be on the periphery of the network. (Maslov S and Sneppen K (2002) Specificity and stability in topology of protein networks. *Science* 296: 910–913.)

where $\sigma_r(K_0, K_1) = \Delta N_r(K_0, K_1)/N$ is the standard deviation of $P_r(K_0, K_1)$ in an ensemble of randomized networks.

The result of the above analysis is that there is a significant suppression of links between hubs, both for regulatory networks analyzed in **Figure 6** and also for the protein networks measured in large-scale two-hybrid experiments on yeast. Similarly, by defining higher-order occurrences of various local patterns of control, Shen-Orr and co-workers suggested some frequent motifs of gene control in 2002, as illustrated in **Figure 7**.

Finally, it may be mentioned that the tendency of highly connected proteins to be at the periphery of regulatory networks in itself teaches one something about the origin of broad connectivity distributions. To see this, one could consider the fact that a protein is a fairly simple unit, that presumably gives essentially the same information to each of its downstream targets. Thus, the feature that a hub protein sits on the periphery of the network and does not link to other hub proteins, presumably reflects a one-hub-one-function structure. As a corollary of this, one may suspect that the broad distribution of molecular networks is not an intrinsic property of the network, but rather reflects the broad distribution of external requirements that the surroundings of an organism puts on it. Some functions simply require many proteins, whereas many functions require only a few proteins. This scenario is also supported by the observation that there is essentially no correlation between connectivity of a regulatory protein and its importance measured by its chance to be essential in knock-out experiments. If highly connected proteins were involved in many functions, their likelihood of being essential would grow linearly with their connectivity. This is not the case, for the yeast transcription network: the chance that a transcription factor is lethal is independent of how many proteins it regulates!

To summarize the topological properties of regulatory and signaling networks, the broad connectivity distributions may very well reflect the widely different needs associated to widely different functions that a living cell needs to cope with as it changes its environment.

Combinatorics in Genetic Networks, and an Evolution Model

In addition to the topological properties, the regulation of genes also have a combinatorical part. This means that the regulation of a given gene may depend on the combination of the concentration of its regulators. An inspiring way to model such a combinatorical regulation was proposed already in 1969 by S Kauffman. In this very simplified approach, each gene was assigned a binary number, 0 or 1, that counts whether the gene was off or on. Each gene i was assumed to be on or off depending on some logical function of the state of the gene that regulated it. A very simple version of this Boolean rule would be the threshold network where the state of the gene i at time t is given by

$$\sigma(i,t) = \Theta\left(\sum A_{ij}\sigma(j,t-1)\right) \qquad [5]$$

where $\Theta(x)$ is zero for $x<0$ and $=1$ otherwise. The A_{ij} is nonzero for genes j that regulate gene i. A_{ij} is positive for activation, and negative for repression. For a large regulatory network, the above update defines a cellular automata in a geometry defined by the connectivity matrix. Starting in an arbitrary initial condition, the system will move through a sequence of states that at some point is bound to repeat itself. This is because the state space is finite and the update deterministic. Thus, much effort has been used to characterize the behavior of these attractors as a function of the connectivity pattern of the system.

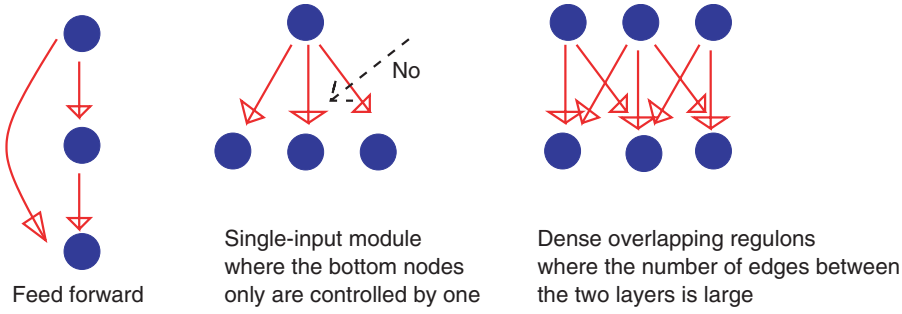

Figure 7 Genetic control motifs which are found to be over represented in regulatory networks of both *E. coli* and yeast. (Milo R, Shenn-Orr S, Itzkovitz S, Kashtan N, and Chklovskii D (2002) Network motifs: simple building blocks of complex networks. *Science* 298: 824–827.)

One simple result is that the system undergoes a percolation phase transition when the average connectivity is increased beyond a critical out-connectivity $\langle K_{\text{out}} \rangle \sim 2$. Above this transition, the attractors become very long (exponentially growing with system size) and the behavior is called chaotic.

The Boolean paradigm allows for modeling large-scale expression patterns of idealized regulatory networks. Thus, it also allows one to address how long-time evolution of rewiring and changes of combinatorical rules may constrain the evolution of such networks. In this regard, it is especially interesting to consider robustness as an evolutionary principle. One way to implement this is to "Evolve a new network from an old network by accepting rewiring mutations with a probability determined by the expression overlap."

This minimal-constraint scenario has no outside fitness imposed. Also, it ignores competition between networks, as it only compares a network with its predecessor. However, the model naturally selects networks which have a high overlap with neighbor mutant networks. This feature is associated to robustness, defined as the requirement that not only should the present network work, but also mutations of the networks should work. In terms of network topology, this means a change in the wiring $\{A_{ij}\} \rightarrow \{A'_{ij}\}$ that takes place on a much slower timescale than the $\{\sigma_i\}$ updating using the Boolean dynamics itself.

The system that is evolved is the set of couplings A_{ij} in a single network. One evolutionary time-step of the network is:

1. Create a daughter network by (a) adding, (b) removing, or (c) adding and removing a weight in the coupling matrix A_{ij} at random, each option occurring with probability $p = 1/3$. This means turning an $A_{ij} = 0$ to a randomly chosen ± 1 or vice versa.
2. Select a random input state $\{\sigma_i\}$. Iterate simultaneously both the mother and the daughter system from this state until they either have reached and completed the same attractor cycle, or until a time where $\{\sigma_i\}$ differs between the two networks. In case their dynamics is identical, then replace the mother with the daughter network. In case their dynamics differs, keep the mother network.

The result of this type of modeling is an intermittent evolutionary pattern: occasionally the evolved network is trapped in states with few evolution paths away from it; sometimes it is, instead, in highly active regions of "network space," thus allowing fast readjustments of genome architecture. More important, the obtained network exhibits a less chaotic behavior than random ones. The computational structure thus emerging has a simplicity of form consistent with that obtained with real molecular networks by placing highly connected nodes on the periphery of the network. In the Boolean model networks explored here, the attractors for the networks are shorter, and there are more frozen regulators in a random network at the same average connectivity.

Geometrical Optics

G Molesini, Istituto Nazionale di Ottica Applicata, Florence, Italy

Introduction

Geometrical optics is a branch of optics where light is described by rays. Light rays are conceived as geometrical lines originating from sources, extending through media, and being revealed by detectors; their directions account for paths along which light flows.

Although it was originated and developed as a discipline on its own, geometrical optics can be traced to Maxwell's equations within the general theory of electromagnetism. The derivation evidences the approximations that are made, and defines the realm of validity for geometrical optics.

Light paths are intrinsically related to the refractive index n of the media, where light propagates (n is the ratio between the speed of light in vacuum and in the medium). Ray equations can be written in general form, assuming n is a smooth continuous function of the position. In particular, if n is constant, rays are straight lines. Discontinuities in the refractive index due to interfaces between different media result in abrupt deviation of rays, named "refraction" and accounted for by simple equations.

Based on such equations, and a proper selection of the nature, shape, and location of the interfaces, rays can be guided to flow in an orderly manner through selected media ("lenses"), and eventually reproduce the source features ("image"). The basic properties of optical imaging systems are described by the first-order approximation of the ray equations. The resulting scheme is classically the core of geometrical optics.

Derivation from Maxwell's Equations

The major steps from electromagnetism to geometrical optics are summarized in **Figure 1**.

In a dielectric medium free of charges and currents, Maxwell's equations result in the wave equation

$$\nabla^2 \boldsymbol{E} = \varepsilon\mu \frac{\partial^2}{\partial t^2} \boldsymbol{E} \qquad [1]$$

where $\boldsymbol{E}$ is the electric field, t is time, and ε, μ are the electric permittivity and the permeability of the particular medium, respectively; in vacuum, $\varepsilon_0 = 8.8542 \times 10^{-12}\,\mathrm{F\,m^{-1}}$ and $\mu_0 = 4\pi \times 10^{-7}\,\mathrm{H\,m^{-1}}$.

The velocity of light in vacuum is $c = 1/\sqrt{\varepsilon_0\mu_0}$, and $v = 1/\sqrt{\varepsilon\mu}$ in general. The equation for the magnetic induction $\boldsymbol{B}$ is identical to that for $\boldsymbol{E}$.

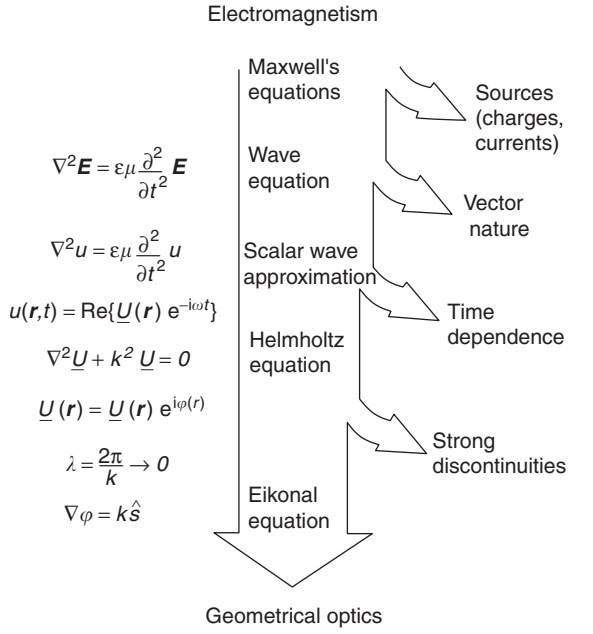

Figure 1 Schematic derivation of geometrical optics from Maxwell's equation.

Several classes of optic phenomena are satisfactorily described by separate components of the electromagnetic field. The resulting approach is the scalar approximation, where the vector nature of $\boldsymbol{E}$, $\boldsymbol{B}$ is dropped; eqn [1] is then written for a single (scalar) component u, it being a function of position $\boldsymbol{r}$ and time t. Monochromatic fields, that is, single harmonics at angular frequency ω, are sought as solutions. The complex notation $\underline{U}$ is also adopted, intending that the physical quantity u is the real part of $\underline{U}$:

$$u(\boldsymbol{r}, t) = \mathrm{Re}\{\underline{U}(\boldsymbol{r})\mathrm{e}^{-\mathrm{i}\omega t}\} \qquad [2]$$

Substitution in the wave equation leads to the Helmholtz equation

$$\nabla^2 \underline{U} + k^2 \underline{U} = 0 \qquad [3]$$

which is independent of time; the quantity k is termed the wave number and is given by

$$k = \frac{\omega}{c} \qquad [4]$$

The wavelength λ is also introduced:

$$\lambda = \frac{2\pi}{k} \qquad [5]$$

The generic solution to the Helmholtz equation is written as

$$\underline{U}(\boldsymbol{r}) = U(\boldsymbol{r})\mathrm{e}^{\mathrm{i}\varphi(\boldsymbol{r})} \qquad [6]$$

with $U(\boldsymbol{r})$ and $\varphi(\boldsymbol{r})$ the amplitude and phase of the field, respectively. Substitution into eqn [3] provides

$$\nabla^2 U - U\boldsymbol{\nabla}\varphi \cdot \boldsymbol{\nabla}\varphi + k^2 U = 0 \qquad [7]$$

Now, the basic assumption is made that U does not vary significantly over distances of the order of λ, and particularly

$$\frac{\nabla^2 U}{U} \ll k^2 \qquad [8]$$

differently stated, the limiting case of $\lambda \to 0$ is studied. Under the above assumption, eqn [7] leads to the so-called eikonal equation:

$$\boldsymbol{\nabla}\varphi = k\,\hat{s} \qquad [9]$$

where $\hat{s}$ is the unit vector in the direction of $\boldsymbol{\nabla}\varphi$. Surfaces $\varphi = \text{const.}$ are geometrical wave fronts; $\hat{s}$ is, at every point, orthogonal to such surfaces. Since in isotropic media, the Poynting vector has that same direction, energy flows along lines singled out by $\hat{s}$ above. Such lines are the rays of geometrical optics.

The Ray Equation

Equation [9] can be written as

$$\boldsymbol{\nabla}\varphi = nk_0 \frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}s} \qquad [10]$$

where

$$n = \frac{k}{k_0} = \frac{\lambda_0}{\lambda} = \frac{c}{v}$$

is the refractive index. Deriving eqn [10] with respect to s, and noting $\mathrm{d}\varphi/\mathrm{d}s = nk_0$ yields

$$\boldsymbol{\nabla}n = \frac{\mathrm{d}}{\mathrm{d}s}\left(n\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}s}\right) \qquad [11]$$

which is the differential form for the ray equation. The above equation is also the analytical expression for the Fermat's principle, according to which the light, going from point P_1 to point P_2, traverses a trajectory such that the quantity optical path length (OPL) defined by

$$\mathrm{OPL} = \int_{P_1}^{P_2} n(s)\,\mathrm{d}s \qquad [12]$$

is stationary with respect to neighboring trajectories. As a physical property, the optical path is reversible.

The curvature vector $\mathrm{d}\hat{s}/\mathrm{d}s$ of a ray is defined as

$$\frac{\mathrm{d}\hat{s}}{\mathrm{d}s} = \frac{1}{\rho}\,\hat{\sigma} \qquad [13]$$

where ρ is the radius of curvature, and $\hat{\sigma}$ is the unit principal normal, so that

$$\frac{1}{\rho} = \hat{\sigma} \cdot \boldsymbol{\nabla}(\log n) \qquad [14]$$

Equation [14] shows that a ray bends toward the region where n is higher. Overall, the ray equation provides the light path through continuous media assuming that $n(\boldsymbol{r})$ is known (e.g., bending of the rays in the Earth's atmosphere). As a particular case, in a homogeneous medium it is $n = \text{const.}$, and the ray path is a straight line ($\rho = \infty$).

Laws of Reflection and Refraction

Resting on homogeneous media, interfaces are defined as surfaces of separation between contiguous media with different n. A plane interface separating media with refractive indices n, n', and a single ray impinging on the surface at an angle i to the surface normal is considered first. The ray and the surface normal at the point of incidence define the plane of incidence. In most conditions, the incident ray is split into two secondary rays, one reflected and the other refracted (**Figure 2**), such that:

- both the reflected and the refracted rays belong to the plane of incidence,
- the reflected ray remains in the medium where the incident ray is from, at an angle i' symmetrical with respect to the surface normal, that is,

$$i' = -i \qquad [15]$$

- the refracted ray enters the facing medium, forming an angle i' to the surface normal so that

$$n \sin i = n' \sin i' \quad \text{(Snell's law)} \qquad [16]$$

(by widespread convention, primed symbols refer to quantities after refraction or reflection).

If i is fixed and light is analyzed in terms of single harmonics (i.e., pure colors, or wavelengths), the angle of reflection, $-i$, is the same for all colors, while the angle of refraction i' from eqn [16] depends on the color (**Figure 3**). This phenomenon is called dispersion and is described in terms of physical optics as a dependence of the refractive index of each medium on the wavelength.

Although formulas of geometrical optics are quite general, it is customary to refer to the various wavelength intervals as follows: 400–700 nm, where the eye is sensitive – visible spectrum; and the close

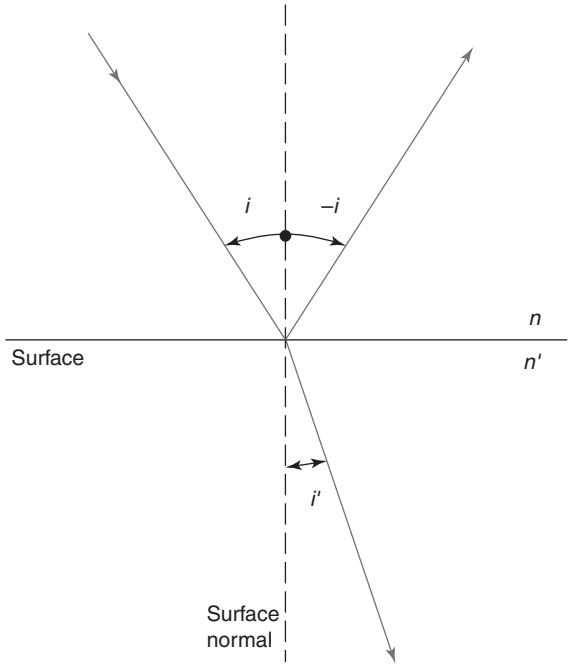

Figure 2 Ray reflection and refraction at a plane interface.

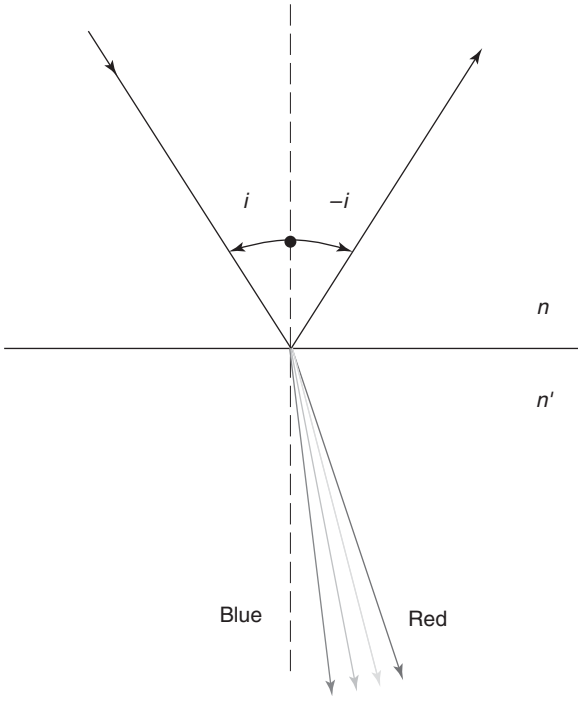

Figure 3 Fan spreading of refracted rays due to dispersion.

neighboring ranges, shorter wavelengths (<400 nm) – UV (ultraviolet), and longer wavelengths (>700 nm) – IR (infrared). For most optical materials, such as glasses, the dispersion equation for $n(\lambda)$ commonly referred to is

$$n^2(\lambda) - 1 = \frac{B_1\lambda^2}{\lambda^2 - C_1} + \frac{B_2\lambda^2}{\lambda^2 - C_2} + \frac{B_3\lambda^2}{\lambda^2 - C_3} \quad [17]$$

(Sellmeier equation). A particular glass is specified by a set of B_1, B_2, B_3, C_1, C_2, C_3 coefficients. For easy reference, the refractive index at spectral lines listed in **Table 1** is usually quoted.

An example of the curve $n(\lambda)$ for a typical glass is given in **Figure 4**. By convention, optical materials are characterized by two parameters, indicating the central height of the curve and its slope: the refractive index n_d at the line d, and the so-called V-number V_d defined as

$$V_d = \frac{n_d - 1}{n_F - n_C} \quad [18]$$

According to eqn [18], more dispersive materials exhibit smaller V-number. For optical glasses, n_d and V_d range from 1.45 to 1.90, and from 85 to 20, respectively. Due to historical reasons, glasses with $n_d > 1.60$, $V_d > 50$, and $n_d < 1.60$, $V_d > 55$, are named crowns; the others are flints.

Ray Tracing and Image Formation

Sources are luminous objects emitting rays in directions around. In a simple case, a single point on an extended object can be modeled as a point-like source. An image is obtained by making the emitted rays to reconverge, or to focus, to a further ray concentration, where detection can take place or a new propagation process can begin. The image may be real, in the sense that it can be cast on a true screen, or a virtual one, if it only appears to diverge from a nonexistent ray concentration by virtue of reflection or refraction effects. The focusing action can be provided by a single surface, either refracting or reflecting, or by a sequence thereof. For reasons of fabrication, such surfaces are generally spherical. In particular, in refraction the ray-bending mechanism is produced by the application of Snell's law to each incident ray (**Figure 5**), with reference to the interface given by the osculating plane at the point of incidence. An extended object is considered to be made of many point sources, all processed in parallel, so that the final image results in many elementary images of the object points.

Modeling the refraction mechanism, as depicted in **Figure 6**, requires a consistent set of conventions to be established. Although it is not unique, the set here adopted is as follows:

- light travels from left to right, surfaces are numbered in a sequence, according to the order they are encountered by light;

Table 1 Reference spectral lines commonly used in geometrical optics

Line	*H*	*g*	*F'*	*F*	*e*	*d*	*C'*	*C*	*r*
Element	Hg	Hg	Cd	H	Hg	He	Cd	H	He
λ (nm)	404.7	435.8	480.0	486.1	546.1	587.6	643.8	656.3	706.5

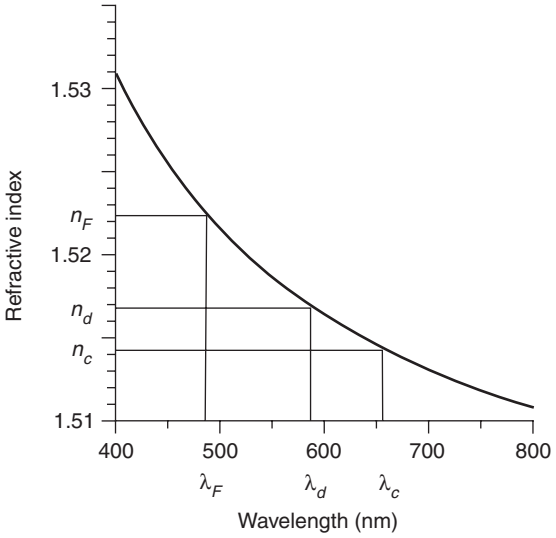

Figure 4 Curve of the refractive index as a function of the wavelength for a typical glass.

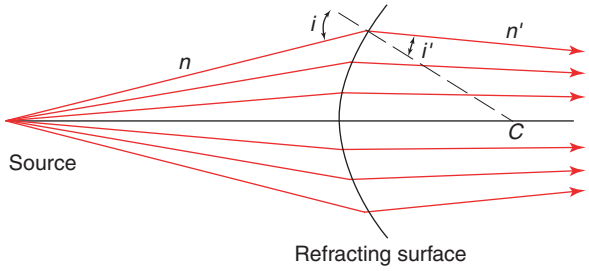

Figure 5 Bending of rays emitted by a point-like source at a spherical interface.

- the point source and the surface center define the optical axis, the origin is located at the surface vertex *V*, distances to the right and above the origin are positive, and those to the left and below are negative;
- the surface radius of curvature *r* is positive if the center of curvature *C* lies to the right of the vertex *V*, and negative otherwise;
- the angle *u* (and *u'* as well) formed between a ray and the optical axis is positive if an anticlockwise rotation smaller than 180° leads the oriented axis to the oriented ray, and negative otherwise;
- the angles of incidence and of refraction *i*, *i'* follow the same rule as *u*, *u'*, considering the surface normal in place of the axis.

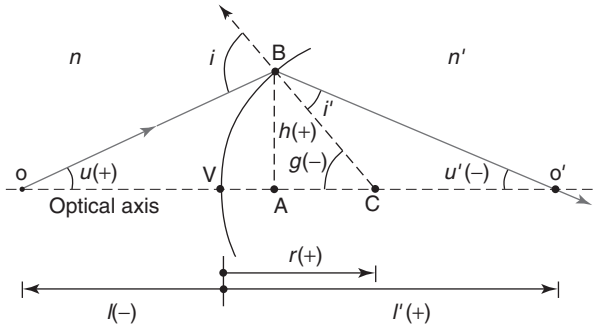

Figure 6 Refraction at a single spherical interface.

Table 2 Ray tracing through a refracting surface

Quantity	*Formula*
Incidence angle	$i = \arcsin\left[(r-l)\dfrac{\sin u}{r}\right]$
Refraction angle	$i' = \arcsin\left(\dfrac{n}{n'}\sin i\right)$
Angle at the center	$g = u - i$
Image side angle	$u' = i' + g$
Image distance	$l' = r\left(1 - \dfrac{\sin i'}{\sin u'}\right)$
Height at the surface	$h = -r \sin g$

Where the incident ray intercepts the axis is the object point O; the distance $\overline{VO}$ in **Figure 6** is $l<0$. Similarly, after refraction in B, the ray intercepts anew the axis at the image point O'; the distance $\overline{VO'}$ is $l'>0$.

The values for *n*, *n'*, *r*, *l*, and *u* are assigned; the mathematical expression for the quantities *i*, *i'* *g*, *u'*, *l'*, *h* is given in **Table 2**.

The ray so traced lies entirely on a plane containing the axis, and is thereupon named axial (or meridional). The plane itself is called meridional (or tangential). Rays which do not intercept the axis are called skew rays. Tracing skew rays requires more elaborate computations, and is not treated here.

Optical systems are made of a sequence of optical surfaces, encountered by the ray while it progresses from left to right. Here it is assumed, for simplicity, that all the surface centers are aligned along the same axis. A generic surface of an ordering number *j* is specified by a set of three data: the radius of curvature r_j, the axial distance d_j to the next surface, and

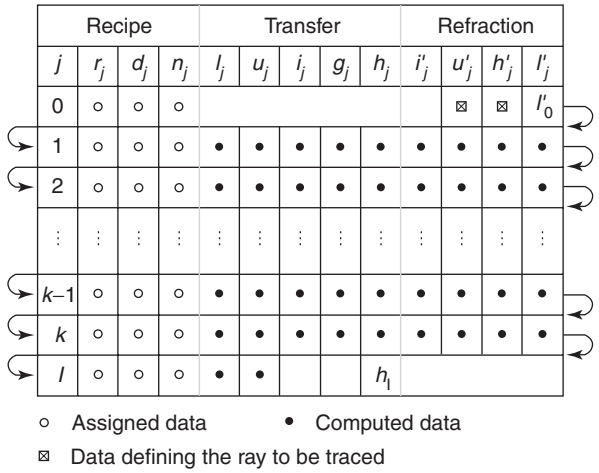

Figure 7 Scheme for recursive ray tracing through an optical system.

Table 3 Recursive ray tracing

Transfer equations	*Refraction equations*
$l_j = l'_{j-1} - d_{j-1}$	$i' = \arcsin\left(\frac{n_{j-1}}{n_j} \sin i_j\right)$
$u_j = u'_{j-1}$	$u'_j = i'_j + g_j$
$i_j = \arcsin\left[(r_j - l_j)\frac{\sin u_j}{r_j}\right]$	$h'_j = h_j$
$g_j = u_j - i_j$	$l'_j = r_j\left(1 - \frac{\sin i'_j}{\sin u'_j}\right)$
$h_j = -r_j \sin g_j$	

the refractive index n_j of the medium in between. The overall sequence of r_j, d_j, n_j sets makes up the optical prescription (or recipe) of the system. Starting from an object at an assigned distance from the first surface, a ray to be traced is identified by its slope angle u and height h above the axis. Tracing the ray implies transferring from each surface to the next, applying refraction there and so forth, proceeding from left to right until the last surface, say of ordering number k, and finally closing with the image surface. Computations can then be carried out by recursive methods according to the flow scheme of **Figure 7** and **Table 3**, to end up with the slope and height of the output ray on the image plane assigned by the recipe.

The use of electronic computers and specific software has speeded up the ray tracing task enormously. Ideally, neglecting diffraction, the image of a point-like source is a point-like image; tracing a high number of evenly spaced rays gives an idea of the departure of the actual system from the ideal case. The ray intercept so produced on the image plane is the spot diagram. Programs are available that evaluate the extent of the spot diagram, and can vary the recipe data with optimization cycles so as to minimize the spot size.

Paraxial Optics

Ray tracing is made easier in the case of rays approaching the optical axis. In that case, the argument α of sine and tangent functions is $\alpha \ll 1$ rad; expanding in power series and retaining only the first significant term, it is written as

$$\sin\alpha \approx \tan\alpha \approx \alpha \qquad [19]$$

The domain of such approximation, to be adopted from now on, is paraxial (or first-order, or Gaussian) optics. Ray tracing is accounted by simple algebraic equations, where a key parameter is the optical power ϕ. For a single refracting surface, the optical power is

$$\phi = \frac{n' - n}{r} \qquad [20]$$

Tracing a ray from O to O′ is described by

$$\frac{n'}{l'} - \frac{n}{l} = \phi \qquad [21]$$

showing that l' is independent of the particular ray that has been traced. The distances l, l' are said to be conjugate.

Paraxial formulas are also written approximating those given in **Tables 2** and **3**. As a special approach, two-element column vectors are used to represent rays, and 2×2 matrices to implement transfer and refraction. The usual algebra of matrix operators is found to apply. The main properties of optical systems are then derived from the resulting matrix elements.

Lenses and Lens Systems

When it comes to fabricating interfaces, optical surfaces can only be made in pairs, enclosing some transmissive material. The result is a lens. Lenses can be given different shapes, as indicated in **Figure 8**. The behavior of a lens with respect to image formation is first studied in cases when its thickness can be neglected as compared to l, l' (thin lens approximation). Equation [21] still holds, provided that the optical power ϕ assumes the form

$$\phi = \phi_1 + \phi_2 \qquad [22]$$

with

$$\phi_1 = \frac{n_L - n}{r_1}, \qquad \phi_2 = \frac{n' - n_L}{r_2} \qquad [23]$$

n_L, n, n' are the refractive indices of the lens material and the media on the source and image side,

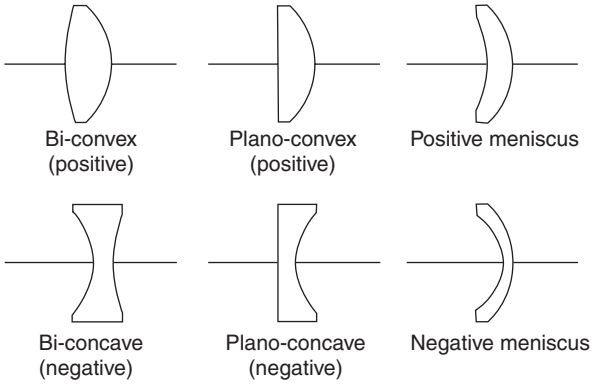

Figure 8 Basic layout of simple lenses.

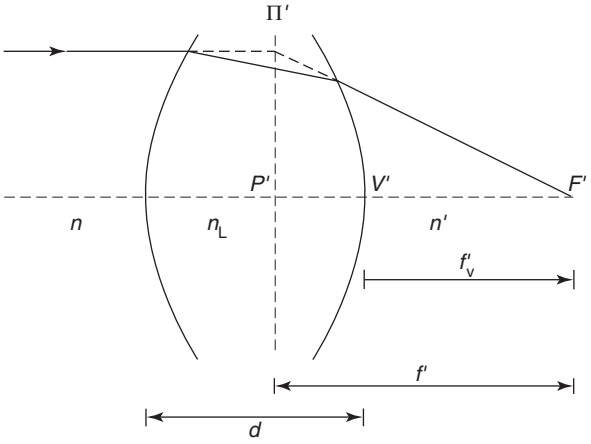

Figure 10 Definition of principal plane Π' and principal point P'.

respectively, and r_1, r_2 are the radii of curvature of the two surfaces; the domain of validity of eqn [21] is also bound to the truth table detailed in **Table 4**. Lenses with $\phi>0$ are said to be positive, or convergent, and are graphically represented with a segment with a pair of outward pointing arrows; otherwise, lenses are negative, or divergent, and are drawn with inward pointing arrows. It is customary to introduce the focal lengths f, f' according to

$$f = -\frac{n}{\phi}, \qquad f' = \frac{n'}{\phi} \qquad [24]$$

As it appears, f' locates the point F' where rays intersect the axis when the object goes to infinity ($l \to -\infty$), while f locates the point F where the object should be placed to produce an image at infinity ($l' \to \infty$). F, F' are the focal points. To a graphical representation of the general eqn [21], l' is normalized to f', and l to f. The resulting plot is presented in **Figure 9**. The plot is valid both for positive and negative lenses, paying due attention to the sign of the quantities involved.

Next is taking into account the actual thickness of the lens (thick lens approximation). Considering the scheme of **Figure 10**, a ray from infinity on the left is drawn. The ray undergoes two refractions, and crosses the axis at the focal point F'. Extending the in and out rays within the lens (dashed lines) shows that the overall deflection can be thought of as produced by a thin lens located at the intersection of the ray extensions. The location of such a thin lens is the principal plane Π'; its axial intercept is the principal point P'. In a similar manner, but with a ray going to infinity on the right, the principal plane Π and the principal point P are defined. The resulting scheme for the thick lens is presented in **Figure 11**. Again, the conjugation law is provided by eqn [21], but the optical power ϕ is now

$$\phi = \phi_1 + \phi_2 - \frac{d}{n_L}\phi_1\phi_2 \qquad [25]$$

d being the axial thickness of the lens; in addition, distances l, l' have to be measured from P, P', respectively. Also the focal lengths, still defined by eqn [24], are taken from P, P', that is, $f = \overline{PF}$, $f' = \overline{P'F'}$. Further quantities of interest are the front focal length

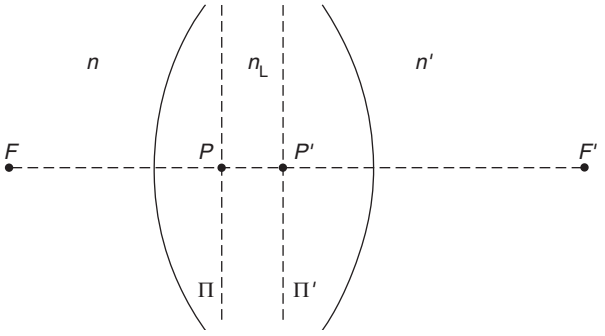

Figure 11 Paraxial scheme for a thick lens.

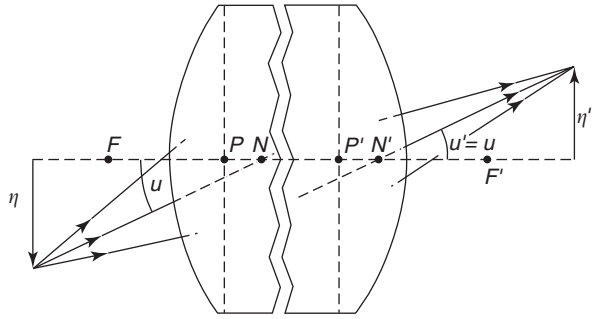

Figure 12 Nodal point construction for a thick lens.

Table 5 Thick lens parameters

	Unprimed quantity	*Primed quantity*
Front and back focal lengths	$f_v = \frac{n((d/n_L)\phi_2 - 1)}{\phi}$	$f'_v = \frac{n'(1-(d/n_L)\phi_1)}{\phi}$
Front and back vertex power	$\Omega = \frac{\phi}{1-(d/n_L)\phi_2}$	$\Omega' = \frac{\phi}{1-(d/n_L)\phi_1}$
Location of principal points	$\overline{VP} = \frac{nd\phi_2}{n_L\phi}$	$\overline{V'P'} = -\frac{n'd\phi_1}{n_L\phi}$
Location of nodal points	$\overline{PN} = \frac{n'-n}{\phi}$	$\overline{P'N'} = \frac{n'-n}{\phi}$

$f_v = \overline{VF}$, the back focal length $f'_v = \overline{V'F'}$, the front vertex power $\Omega = -n/f_v$, and the back vertex power (or ophthalmic power) $\Omega' = n'/f'_v$. Expressions for the above quantities are given in **Table 5**, along with formulas locating P, P' with respect to V, V'.

The case of a system of two thin lenses with powers ϕ_1, ϕ_2 separated by a distance d can be analyzed as if it were made of a single thick lens, with surface powers ϕ_1, ϕ_2, thickness d, and refractive index n_L equal to that of the medium in between. Formulas are available also for the case of three thin lenses. In general, however, the relevant quantities are computed by ray tracing.

So far, only on-axis point sources have been considered. Tracing rays from an off-axis source, it is noticed that just one ray exits the optical system without any angular deviation. Extending the in and out portions of that ray to cross the axis, the nodal points N, N' are singled out (**Figure 12**). Their positions, also given in **Table 5**, are shifted by the same amount with respect to the principal points, and coincide with P, P' for $n' = n$. The six points F, F', P, P', N, N' are named cardinal points, and thoroughly define the optical system within the paraxial approximation.

In the case of an off-axis source, the image is off-axis as well. Indicating with η the height of the source above the axis, and with η' that of the image, the lateral (or transverse) magnification m_L is defined as

$$m_L = \frac{\eta'}{\eta} \qquad [26]$$

In paraxial conditions, it is found to be

$$m_L = \frac{nl'}{n'l} \qquad [27]$$

A negative value of m_L indicates that the image is reversed upside down with respect to the object; $|m_L| < 1$ means that the image size is smaller than that of the object.

Considering infinitesimal increments of l, l', the axial (or longitudinal) magnification m_A is defined as

$$m_A = \frac{\delta l'}{\delta l} \qquad [28]$$

Differentiating eqn [21] yields

$$m_A = \frac{n'}{n} m_L^2 \qquad [29]$$

Being positive, m_A shows that increments δl and $\delta l'$ are pointing in the same direction.

As stated, conjugate distances l, l' are measured from the principal points P, P', which are difficult to locate. Measuring instead axial distances from the foci F, F', which are more easily identified, and posing $z = \overline{FO}$, $z' = \overline{F'O'}$ for the conjugate distances, it is found that

$$zz' = -\frac{nn'}{\phi^2} \quad \text{(Newton's equation)} \qquad [30]$$

Alternative expressions for the lateral and axial magnification can be written as well.

Mirrors

Formally, reflective optical surfaces may be treated with the same equations as refracting surfaces by posing

$$n' = -n \qquad [31]$$

After reflection, light travels backwards, so that in optical recipes the axial distance d that follows should be taken as negative. If a second reflection occurs, the refractive index returns positive, light proceeds forward, and d is positive again.

The power ϕ of a mirror is

$$\phi = -\frac{2n}{r} \qquad [32]$$

with r the radius of curvature of the reflecting surface; the sign convention for r is the same as that of refractive surfaces. The focal points F, F' are coincident; the focal lengths f, f' become

$$f = f' = \frac{r}{2} \qquad [33]$$

It follows that concave mirrors have positive power and negative focal length; such mirrors behave as convergent lenses. The opposite occurs with convex mirrors. The principal points P, P' are also coincident; their location is at the surface vertex. The nodal points N, N' coincide as well, and are located at the center of curvature of the reflecting surface. The cardinal points are indicated in **Figure 13**, both for a concave and a convex mirror.

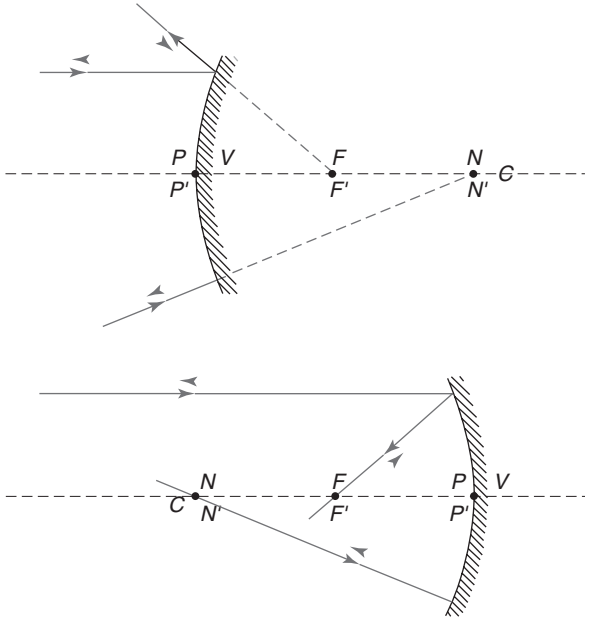

Figure 13 Cardinal points of concave and convex mirrors.

The conjugation law reads

$$\frac{1}{l'} + \frac{1}{l} = \frac{2}{r} \qquad [34]$$

The truth table for eqn [34] to hold is given in **Table 6**. The lateral magnification m_L becomes

$$m_L = -\frac{l'}{l} \qquad [35]$$

and the axial magnification m_A is

$$m_A = -m_L^2 \qquad [36]$$

Simple equations can be written also for the case of two mirrors, separated by a given distance. Ray tracing mechanisms do apply as well, provided that the appropriate conventions are observed.

Stops and Pupils

In a strict sense, the paraxial approximation is only valid at infinitesimal height from the axis. However, to convey an effective amount of light, the actual opening of optical components should be increased to finite values. Any element, be it the edge of a lens or a suitable diaphragm, that sets a maximum limit to the amount of light emitted by an axial source which is accepted by the optical system, is the aperture stop, or simply the stop. The ray that touches the edge of the stop is the axial marginal ray.

The stop physically divides the optical system into two parts. The part in front forms an image of the stop that is seen from the source side; such an image is the entrance pupil of the system. In a similar manner, the part following the stop forms an image of it that is seen from the image side and constitutes the exit pupil. Rays traced from the object toward the entrance pupil pass through the stop and are relayed to the exit pupil. Considering an off-axis point source, the ray that passes through the center of the stop (and the center of the pupils as well) is called the principal ray.

The extent of the object, either angular or linear, whose image is to be formed constitutes the field. The aperture that defines the actual size of the field accepted by the system is the field stop. Such an aperture is usually located at or near an intermediate image, or at the final image plane. As a general constraint, to

Table 6 Truth table for eqn [34] to hold

$l<0$	Real source
$l>0$	Virtual source
$l'>0$	Virtual image
$l'<0$	Real image

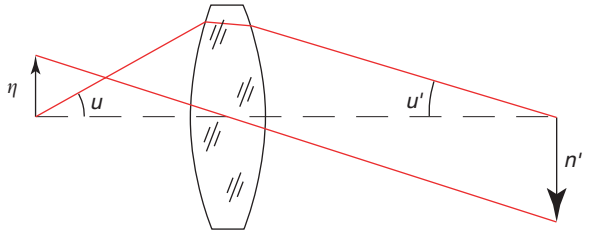

Figure 14 Paraxial quantities related to the definition of the optical invariant.

avoid having a system with infinite aperture, the axial position of the aperture stop is not allowed to coincide with the axial position of field planes, neither the field itself nor its images.

In order to obtain the relevant paraxial properties of an optical system, only two rays need to be traced. A very useful choice for such rays is the pair made of the axial-marginal ray and the principal ray. Referring to **Figure 14**, quantities related to the axial-marginal ray are the angle u and the height h. Similarly, the same quantities belonging to the principal ray are noted as $\bar{u}$, $\bar{h}$. The quantity H defined as

$$H = n(\bar{u}h - u\bar{h}) \qquad [37]$$

is named the optical (or Lagrange) invariant; the value of H does not change throughout the optical system. In particular, considering the object plane, where $h = 0$, $\bar{h} = \eta$, and the image plane, where $h = 0$, $\bar{h} = \eta'$, it is written as

$$H = -nu\eta = -n'u'\eta' \qquad [38]$$

In other words, u and η are inversely proportional. This is a basic relationship that has its counterpart in radiometry ("conservation of the radiance") and in optical information processing ("conservation of the space-bandwidth product").

The data about the maximum u-value $u_{\max}$ accepted by an optical system are conventionally expressed by the numerical aperture NA, defined as

$$\mathrm{NA} = n \sin u_{\max} \qquad [39]$$

Such a parameter expresses the ability of the system to resolve the object details and is typically given for optics that work with an object conjugate shorter than the image conjugate, as it happens with microscope lenses. In the opposite case, the f-number, $f_{\#}$, is preferably given and defined as

$$f_{\#} = \frac{\text{Focal length } f'}{\text{Entrance pupil diameter}} \qquad [40]$$

Typically, this is the parameter referred to in photographic lenses. The $f_{\#}$ also relates to luminosity and resolution of the optics. In principle, small f-numbers denote bright images and fine resolution.

Optical instruments are generally given a first description in terms of paraxial optics. These include visual instruments such as the eye itself, the magnifier, the eyepiece, the telescope, and the microscope. Other basic devices are the camera, the projector, relay systems, and more.

Aberrations

With a few exceptions, even if the lenses were perfect in terms of the spherical shape of the surfaces and centering on the optical axis, the image is affected by basic defects known as aberrations. Aberrations are intrinsic to the mechanism of image formation by refraction or reflection, and become significant as the aperture and the field depart more and more from infinitesimal values. After the name of the scientist who first investigated this subject, the primary image defects are usually referred to as the Seidel aberrations. In addition, due to the fact that the refractive index is a function of the wavelength, chromatic aberrations are produced. Here, only the noticeable effects of these aberrations are mentioned. Although an effective mathematical account can be given in terms of geometrical wave fronts, rays and spot diagrams are used.

There are five Seidel aberrations. Three of them – spherical aberration, coma, and astigmatism – cause basic deterioration of the image quality, making it blurred. The remaining two – Petzval field curvature and distortion – alter the image geometry.

- For a point-like source, the effect of spherical aberration is a symmetrical blurring of the image (**Figure 15**). Under ideal conditions, this is the only defect that can affect the image near the center of the field. Spherical aberration occurs because of a variation of the focal length along the diameter of the lens: in a single positive lens, the outer rays intersect closer to the lens than the inner rays (**Figure 16**).
- Coma can be defined as the variation of magnification with the aperture. When a bundle of rays is incident on a lens with coma, the rays passing through the peripheral part are imaged at heights different from those passing through the central part. A typical spot diagram is shown in **Figure 17**. The name of this aberration derives from the comet-shaped flare of the image.
- Astigmatism is produced because the incident cone of rays from an off-axis point-like source encounters different curvatures of the optical surfaces in their principal sections. In the presence of

astigmatism, the image of a point is not a point but takes the form of two axially separated lines. Between these lines, the spot evolves to an elliptical and circular blur (**Figure 18**).

- Every optical system has, associated with it, a basic field curvature, called Petzval curvature, which is a function of the index of refraction of the lens elements and their surface curvatures. As a consequence, the sharpest image is formed on a curved focal surface rather than a flat focal plane. If the detector geometry does not conform to this focal surface, image blurring will result locally.
- Distortion is a variation of the magnification with the field angle. In the case of a square object, distortion may produce a "pincushion" image or a "barrel" image.

Chromatic defects are longitudinal chromatic aberration and lateral color. Longitudinal chromatic aberration is caused by dispersion: in polychromatic light, the focal region of a lens is actually an axial

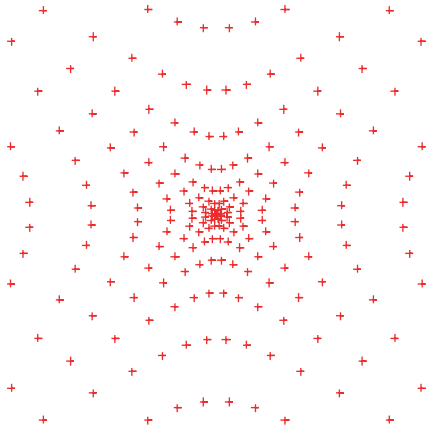

Figure 15 Typical spot diagram in the presence of spherical aberration.

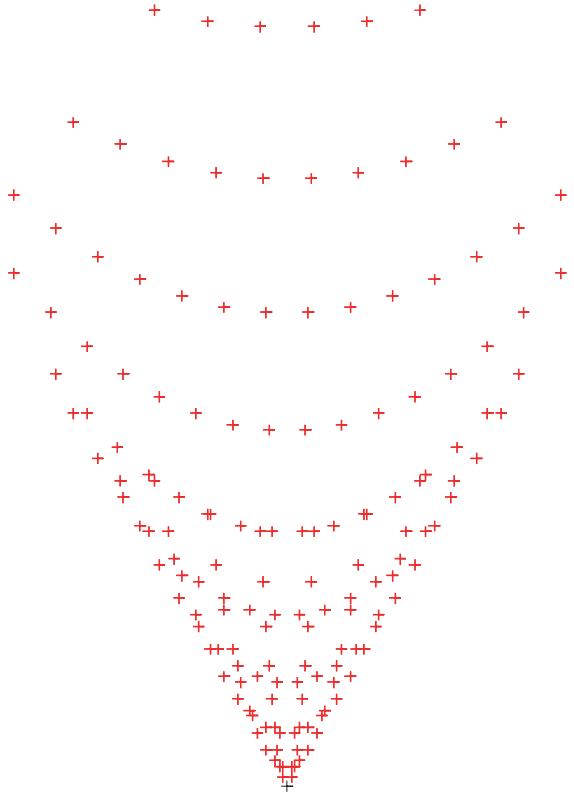

Figure 17 Typical spot diagram in the presence of coma.

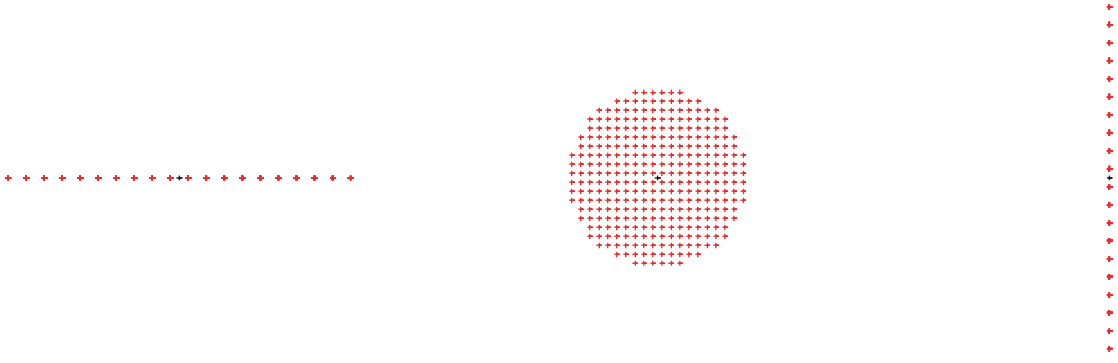

Figure 18 Typical through-focus spot diagrams in the presence of astigmatism.

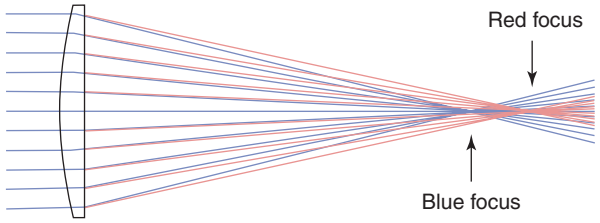

Figure 19 Longitudinal chromatic aberration of a simple positive lens.

sequence of foci of the different colors of the rainbow (**Figure 19**). As a result, the image of a point is a bright dot surrounded by a variously colored halo. Lateral color occurs in off-axis images because of the varying magnification with wavelength. The result is a lateral spread of rainbow colors and manifests itself as edge color fringes.

Although discussed separately, in general, the aberrations are simultaneously present in differing degrees. Combined, they tend to degrade the image quality; efforts are then made to develop optical recipes such that aberrations are minimized. This usually leads to optical systems of increased complexity.

Geometrical Phase and Polarization in Solids

R Resta, University of Trieste, Trieste, Italy

Introduction

The macroscopic polarization $\boldsymbol{P}$ is the most essential concept in any phenomenological description of dielectric media: it is an intensive vector quantity that intuitively carries the meaning of electric dipole moment per unit volume. It is thus tempting to try to define $\boldsymbol{P}$ as the dipole of the macroscopic sample divided by its volume, that is,

$$\boldsymbol{P} = \frac{1}{\Omega_{\text{sample}}} \int_{\Omega_{\text{sample}}} \mathrm{d}\boldsymbol{r}\, \boldsymbol{r}\rho(\boldsymbol{r}) \qquad [1]$$

where ρ is the charge density. Notice, however, that the integral has contributions from both the surface and the bulk regions, which are not easily disentangled: in fact, the value of [1] can be modified by just varying the surface charge of the sample, without varying its bulk charge density while instead, bulk polarization must be unambiguously defined by something "happening" in the bulk. For a crystalline solid, where the bulk charge density is lattice-periodical, a second tempting definition would be

$$\boldsymbol{P} = \frac{1}{\Omega_{\text{cell}}} \int_{\Omega_{\text{cell}}} \mathrm{d}\boldsymbol{r}\, \boldsymbol{r}\rho(\boldsymbol{r}) \qquad [2]$$

with Ω_{cell}, a crystal cell. However, this definition – appearing in many textbooks – is also flawed, because the result of [2] depends on the shape and location of the unit cell.

The clue to understanding polarization comes from a closer look at the experiments. Most measurements of bulk macroscopic polarization $\boldsymbol{P}$ do not address its absolute value, but only its derivatives, which are expressed as Cartesian tensors. By definition, permittivity is the derivative of $\boldsymbol{P}$ with respect to an electric field, pyroelectricity with respect to temperature, piezoelectricity with respect to macroscopic strain, and Born charges (also known as "dynamical" or

"infrared" charges) with respect to zone-center phonon amplitudes. Even when the "spontaneous" polarization of a ferroelectric material is measured, the genuine observable bulk property is the finite difference of polarization between two states of the same solid (polarization reversal, discussed below). The modern theory concerns polarization differences $\Delta \boldsymbol{P}$ as well, and avoids defining absolute polarization at all.

At this point, it is convenient to clearly distinguish between two cases, which prove to be very different from a theoretical standpoint. Case one concerns polarization in an electric field, and is, of course, needed for defining the dielectric constant (or tensor). Case two concerns, instead, polarization in a zero field, under which circumstances are most normally defined by the piezoelectric tensor, the Born effective charge tensor, and the spontaneous polarization in ferroelectric materials. In both cases, the polarization difference $\Delta \boldsymbol{P}$ induced by a given perturbation coincides with the transient current flowing through the bulk of the sample while the perturbation is switched on:

$$\Delta \boldsymbol{P} = \boldsymbol{P}(\Delta t) - \boldsymbol{P}(0) = \int_0^{\Delta t} \mathrm{d}t\, \boldsymbol{j}(t) \qquad [3]$$

where $\boldsymbol{j}$ is the macroscopic (i.e., cell-averaged) current density. The theory addresses precisely this same current, but the typical methods for dealing with the two cases are very different.

The problem of evaluating the dielectric constant of a solid has been solved in 1962. This solution relies on the linear-response theory; first-principle implementations date from the mid-1980s. A modern formulation of linear-response theory in crystalline solids, also known as density-functional perturbation theory is outlined. Next, an outline of the so-called "modern theory of polarization," developed in the 1990s is given, which allows one to evaluate a polarization difference $\Delta \boldsymbol{P}$ between two states of a given solid in a zero field. This theory is based on a Berry phase, also called geometric phase. Preliminarily, a brief treatment of the Berry phases in a general setting beyond the polarization problem is provided.

Throughout, a density-functional framework is adopted: the single-particle orbitals ψ and potential V, unless otherwise noted, are the Kohn–Sham ones.

Macroscopic Fields and Dielectric Constants

The discussion starts by observing that the problem of an extended solid in a macroscopic field is a very difficult one, given the fact that the electrons are in a nonperiodic potential, and therefore, the orbitals no longer have the Bloch form. Even worse, the Hamiltonian is no longer bounded from below. Despite such major problems for finite fields, it is possible to perform electronic-structure calculations which are correct to the first-order in the field magnitude, without trading away the major simplification of dealing with pure Bloch states.

Consider a finite macroscopic sample, having discrete single-particle orbitals ψ_i, which vanish at infinity: the thermodynamic limit will be taken only at the end. The electronic density is written as

$$n(\boldsymbol{r}) = \sum_i f_i |\psi_i(\boldsymbol{r})|^2 \qquad [4]$$

where f_i is an occupancy factor (either 2 or 0) selecting the doubly occupied orbitals. The crystalline observable of interest is the macroscopic dielectric tensor ε_∞, defined as

$$\varepsilon_\infty = 1 + 4\pi \frac{\partial \boldsymbol{P}_{\mathrm{el}}}{\partial \boldsymbol{E}} \qquad [5]$$

where $\boldsymbol{P}_{\mathrm{el}}$ is the macroscopic electronic polarization linearly induced by the (screened) field $\boldsymbol{E}$; in a cubic material, such a tensor obviously reduces to a constant. Using [4], one may evaluate

$$\frac{\partial \boldsymbol{P}_{\mathrm{el}}}{\partial \boldsymbol{E}} = \frac{q_{\mathrm{e}}}{\Omega_{\mathrm{sample}}} \sum_i f_i \left\langle \psi_i | \boldsymbol{r} | \frac{\partial \psi_i}{\partial \boldsymbol{E}} \right\rangle + \mathrm{cc} \qquad [6]$$

where q_{e} indicates the electron charge and cc stays for complex conjugate. The dipole matrix elements are then transformed using the identity:

$$\langle \psi_i | \boldsymbol{r} | \psi_j \rangle = -\mathrm{i}\hbar \frac{\langle \psi_i | \boldsymbol{v} | \psi_j \rangle}{\varepsilon_i - \varepsilon_j}, \quad i \neq j \qquad [7]$$

where ε_i are the single-particle eigenvalues, and the velocity operator $\boldsymbol{v}$ coincides with $\boldsymbol{p}/m_e$ in the simple case where all potentials are local.

It may be emphasized that the current appears in the formulation precisely at this point. If one is actually dealing with a finite system, both members of [7] can be equivalently used. But eventually, the thermodynamic limit is to be performed, in which case the left-hand member of [7] becomes ill-defined: for an extended system in the thermodynamic limit, it is then mandatory to use the velocity formula, hence the current.

Straightforward manipulations transform [6] into a Kubo formula:

$$\frac{\partial \boldsymbol{P}_{\mathrm{el}}}{\partial \boldsymbol{E}} = -\frac{\mathrm{i}q_{\mathrm{e}}}{\Omega_{\mathrm{sample}}} \sum_{i,j} \frac{f_j - f_i}{\varepsilon_j - \varepsilon_i} \langle \psi_i | \boldsymbol{v} | \psi_j \rangle \left\langle \psi_j \middle| \frac{\partial \psi_i}{\partial \boldsymbol{E}} \right\rangle \qquad [8]$$

where the fact that $|\partial \psi_i / \partial \boldsymbol{E}\rangle$ has been exploited may be chosen as orthogonal to $|\psi_i\rangle$.

In order to proceed further, a self-consistent scheme providing the derivatives of the orbitals and of the potential with respect to the perturbation is needed. The first step consists in writing the first-order corrections to the orbitals as

$$|\Delta\psi_i\rangle = \sum_{j\neq i} |\psi_j\rangle \frac{\langle\psi_j|\Delta V|\psi_i\rangle}{\varepsilon_i - \varepsilon_j} \qquad [9]$$

As a second step, one looks for an independent relationship providing, instead, ΔV in terms of the orbital variations $|\Delta\psi_i\rangle$: iterating over these two steps, the self-consistency goal is reached.

The self-consistent perturbation potential ΔV is written as

$$\Delta V = \Delta V_{\text{ext}} + \Delta V_{\text{H}} + \Delta V_{\text{xc}} \qquad [10]$$

where ΔV_{ext} is the bare perturbation (in the present case the potential of the unscreened field), and the remaining two terms are the Hartree and exchange-correlation contributions, respectively. The Hartree term is linear in the induced charge density:

$$\Delta V_{\text{H}}(\boldsymbol{r}) = q_{\text{e}}^2 \int \mathrm{d}\boldsymbol{r}' \Delta n(\boldsymbol{r})/|\boldsymbol{r} - \boldsymbol{r}'| \qquad [11]$$

or in shorthand

$$\Delta V_{\text{H}} = v_{\text{c}} \Delta n \qquad [12]$$

while the exchange–correlation contribution is linearized as

$$\Delta V_{\text{xc}} \simeq f_{\text{xc}} \Delta n \qquad [13]$$

The functional derivative defining this linear term is

$$f_{\text{xc}}(\boldsymbol{r}, \boldsymbol{r}') = \frac{\delta V_{\text{xc}}(\boldsymbol{r})}{\delta n(\boldsymbol{r}')} = \frac{\delta^2 E_{\text{xc}}[n]}{\delta n(\boldsymbol{r}) \delta n(\boldsymbol{r}')} \qquad [14]$$

where E_{xc} is the exchange–correlation energy functional.

When a macroscopic field $\boldsymbol{E}$ acts on the solid, it proves useful to write the self-consistent perturbation potential ΔV in a slightly different form from [10], separating the macroscopic field from the microscopic one (also called local field). The potential of the screened macroscopic field – due to both the bare and the Hartree terms in [10] – is written as $-q_{\text{e}}\boldsymbol{E}\cdot\boldsymbol{r}$, while the remaining microscopic term is lattice-periodical in the thermodynamic limit. Therefore [10] is replaced with

$$\Delta V = -q_{\text{e}}\boldsymbol{E}\cdot\boldsymbol{r} + v_{\text{c}}\Delta n + f_{\text{xc}}\Delta n \qquad [15]$$

where the term $v_{\text{c}}\Delta n$ amounts to solving Poisson's equation.

The self-consistent loop is performed cycling over [15] and [9], while the value of the screened field $\boldsymbol{E}$ is kept constant during the iteration. Whenever [15] is inserted in [9], the matrix elements of $\boldsymbol{r}$ are transformed to the velocity form again using [7]. Once self-consistency is reached, one gets the orbital variations $|\Delta\psi_i\rangle$ induced by a given macroscopic field $\boldsymbol{E}$, which are exact to linear order in the field magnitude: whence the field derivative to be used in [8] and in ε_∞, eqn [5].

All of the above equations have a simple and well-defined expression for the infinite periodic crystal in the thermodynamic limit, where the index i is identified with the band index and the Bloch vector altogether. Essentially, this is the formulation of the linear-response theory, which is nowadays implemented in first-principle calculations (see the "Further reading" section for a complete account).

Piezoelectricity and Ferroelectricity

Next to be addressed are the phenomena where the macroscopic polarization is induced by a source other than an electric field. Even in this case, the polarization may (or may not) be accompanied by a field, depending on the boundary conditions chosen for the macroscopic sample.

Two possible realizations of the piezoelectric effect are schematically shown in **Figure 1**. In (a) the crystal is uniaxially strained (along a piezoelectric axis) while kept in a shorted capacitor; in (b) the sample is strained while kept isolated. Focusing on (a), one may notice that the phenomenon manifests itself as a bulk current traversing the sample, while nothing peculiar happens at the surfaces. Indeed, the current flowing across the shorting wire is the quantity which is actually measured in experiments, and the modern theory addresses precisely this same current. Since it is the phase of the wave function which carries

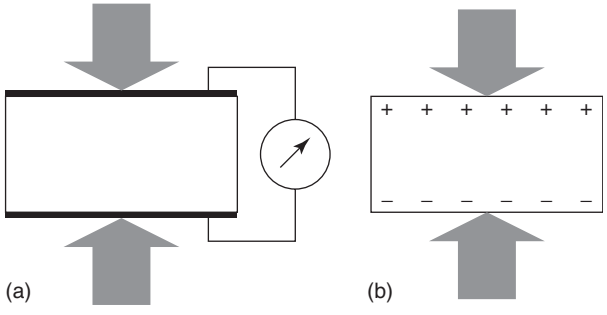

Figure 1 Two possible realizations of the piezoelectric effect: (a) The sample is in a shorted capacitor, and the current is measured. (b) The sample is isolated.

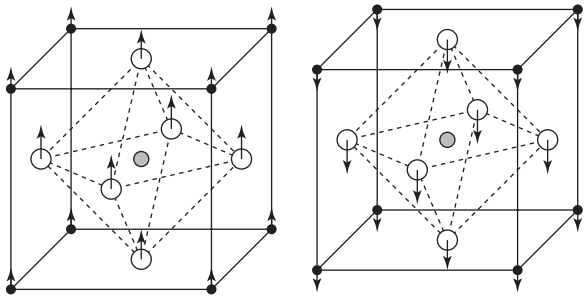

Figure 2 Tetragonal structure of $KNbO_3$. Solid, shaded, and empty circles represent K, Nb, and O atoms, respectively. The internal displacements (magnified by a factor 4) are indicated by arrows for two ($\bar{A}$ and $\bar{B}$) enantiomorphous ferroelectric structures.

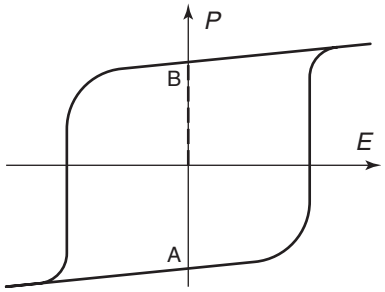

Figure 3 A typical hysteresis loop; the magnitude of the spontaneous polarization P_{spont} is also shown (vertical dashed segment). Notice that P_{spont} is defined as a zero-field property.

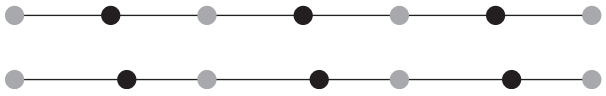

Figure 4 A one-dimensional chain in the centrosymmetric structure (upper sketch) and in the broken symmetry ferroelectric structure (lower sketch). Black and gray circles schematize anions and cations.

information about the current, it is not surprising that a phase (Berry phase) occurs in the theoretical description of electronic polarization.

Now a discussion on the phenomenon of spontaneous polarization in ferroelectrics is taken up. The most studied ferroelectric materials are in the class of perovskite oxides: they have a cubic prototype phase above the Curie temperature, and display a series of structural transitions to low-symmetry ferroelectric phases when the temperature is lowered. Typically, the first transition is to a tetragonal phase, which is characterized by microscopic displacements of the ions out of their high-symmetry sites. These determine a preferred polarity of the tetragonal axis, and are responsible for the occurrence of spontaneous polarization. This is illustrated in **Figure 2** for the tetragonal structure of $KNbO_3$, which was the very first case study for the modern theory of polarization in 1993.

A typical measurement of the spontaneous polarization, performed through polarization reversal, is schematically shown in **Figure 3**. The two enantiomorphous ferroelectric structures A and B are characterized by opposite values of the displacements, and the transition between them is driven by an applied electric field: the experimental setup typically measures the integrated macroscopic current flowing through the sample during the hysteresis cycle, shown in **Figure 3**. One half of the difference $P_B - P_A$ defines the magnitude P_{spont} of the spontaneous polarization; from **Figure 3**, it is also clear that P_{spont} can also be defined as the polarization difference ΔP between the ferroelectric B structure and the centrosymmetric structure (where the displacements are set to zero). Notice that ΔP can be evaluated along the vertical axis, where the macroscopic field is identically zero.

The phenomenon is schematized with a toy model in one dimension, **Figure 4**, meant to represent the central vertical line of Nb and O atoms in **Figure 2**. By definition, the spontaneous polarization of the ferroelectric structure is the integrated current, which flows through the linear chain while the ions are continuously displaced from the centrosymmetric (top sketch) to the ferroelectric (bottom sketch) structures, keeping the electric field vanishing.

Berry Phases

A digression about the Berry phase on most general grounds is provided; its relevance in the polarization phenomena is discussed in the next section.

One may start with a quantum Hamiltonian having a parametric dependence

$$H(\xi)|\psi(\xi)\rangle = E(\xi)|\psi(\xi)\rangle \qquad [16]$$

where ξ is defined in a suitable domain: a two-dimensional real ξ has been chosen for display in **Figure 5**. For the time being, there is no need to specify which quantum system is described by this Hamiltonian, or which is the physical meaning of the parameter; the special case of polarization is addressed below. It is also assumed that $|\psi(\xi)\rangle$ is the ground state, nondegenerate for any ξ. The phase difference between the ground eigenstates at two different ξ points is defined in the most natural

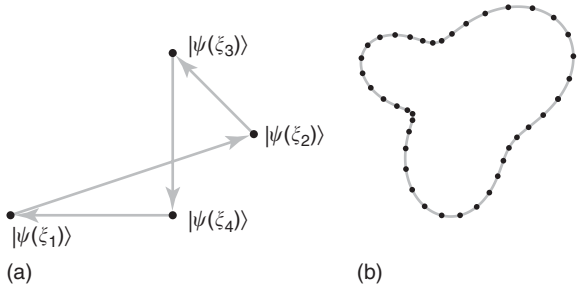

Figure 5 (a) Four state vectors in parameter space, and a closed path connecting them. (b) A smooth closed curve C in parameter space, and its discretization.

way:

$$e^{-i\Delta\varphi_{12}} = \frac{\langle\psi(\xi_1)|\psi(\xi_2)\rangle}{|\langle\psi(\xi_1)|\psi(\xi_2)\rangle|} \quad [17]$$

$$\Delta\varphi_{12} = -\mathrm{Im}\log\langle\psi(\xi_1)|\psi(\xi_2)\rangle \quad [18]$$

This phase, defined modulo 2π, cannot have any physical meaning. In fact, any quantum-mechanical state vector is arbitrary by a constant phase factor: one may refer to choosing this phase as to the choice of the gauge. A simple change of gauge at ξ_1 and/or at ξ_2 will give to $\Delta\varphi_{12}$, the most arbitrary value. Despite this fact, when one considers the total phase difference along the closed path in **Figure 5a**:

$$\begin{aligned}\gamma &= \Delta\varphi_{12} + \Delta\varphi_{23} + \Delta\varphi_{34} + \Delta\varphi_{41} \\ &= -\mathrm{Im}\log\langle\psi(\xi_1)|\psi(\xi_2)\rangle\langle\psi(\xi_2)|\psi(\xi_3)\rangle \\ &\quad\times\langle\psi(\xi_3)|\psi(\xi_4)\rangle\langle\psi(\xi_4)|\psi(\xi_1)\rangle \end{aligned} \quad [19]$$

one easily realizes that γ is gauge invariant, since all the gauge-arbitrary phases cancel in pairs.

The Berry phase is generally defined in the continuum limit. Suppose a smooth closed curve C in the parameter domain, such as in **Figure 5b**, is discretized with a set of points on it: it is assumed that the gauge is so chosen that the phase is single-valued and varies in a differentiable way along the path. The phase difference between two contiguous points is

$$e^{-i\Delta\varphi} = \frac{\langle\psi(\xi)|\psi(\xi+\Delta\xi)\rangle}{|\langle\psi(\xi)|\psi(\xi+\Delta\xi)\rangle|} \quad [20]$$

$$-i\Delta\varphi \simeq \langle\psi(\xi)|\nabla_\xi\psi(\xi)\rangle\Delta\xi \quad [21]$$

The total phase difference γ converges to the circuit integral of a real linear differential form, called the Berry connection:

$$\gamma = \sum_{s=1}^{M}\Delta\varphi_{s,s+1} \to i\oint_C\langle\psi(\xi)|\nabla_\xi\psi(\xi)\rangle d\xi \quad [22]$$

The above simple-minded algebra leads to a result of overwhelming physical importance: in fact, a gauge-invariant quantity is potentially a physical observable. Traditionally, one is accustomed to regard any observable effect in quantum mechanics as the eigenvalue of some operator. But in 1984, in a milestone paper, M V Berry pointed out that there may be observable effects of a completely different nature: γ cannot be expressed in terms of the eigenvalues of any Hermitian operator, whereas it is, by definition, a gauge-invariant phase of the state vector. Having understood this, one must reexamine the initial assumption of a parametric Hamiltonian, and discuss its most fundamental meaning. In general, a quantum system having a parametric dependence in its Hamiltonian is not isolated: the parameter schematizes a kind of coupling with other variables not included in the Hilbert space, or more generally with "the rest of the Universe," to use Berry's words. The parametric Hamiltonian allows one to deal with a part of a larger system as if it were isolated: as a trade-off, some observable effects may occur as gauge-invariant phases. As far as polarization is concerned, the coupling to the rest of the universe is perspicuous in **Figures 1a** and **3**, which refer to ideal measurements closely related to the theoretical approach outlined below.

How the Modern Theory of Polarization Works

One may show how the polarization problem fits into the general Berry-phase setting: what the parameter ξ is; what the Berry connection of the problem is; which is the closed path C allowing one to evaluate ΔP as a Berry phase. The article is limited to giving a flavor of how the theory works, using the specific example of the toy model of **Figure 4** and without providing any proof (see the "Further reading" section for more details).

A scalar parameter λ is first introduced, which measures the amplitude of the ferroelectric distortion in dimensionless units: $\lambda = 0$ for the paraelectric structure (**Figure 4**, top), and $\lambda = 1$ for the ferroelectric one (**Figure 4**, bottom). Since the electric field is zero (see also **Figure 3**), for any value of λ the electrons move in a lattice-periodical potential $V^{(\lambda)}(x)$, having period a. In the simplest model insulator, there are only two electrons per cell, hence one doubly occupied band, whose orbitals have the form:

$$\psi^{(\lambda)}(k,x) = e^{ikx}u_k^{(\lambda)}(x) \quad [23]$$

where k is the Bloch vector in the one-dimensional Brillouin zone $[-\pi/a, \pi/a]$, and $u_k^{(\lambda)}(x)$ is a periodic function of x with period a. The Schrödinger

equation written in terms of u reads

$$\left[\frac{\hbar^2}{2m_e}\left(-i\frac{d}{dx}+k\right)^2+V^{(\lambda)}(x)\right]u_k^{(\lambda)}(x) = \varepsilon_k^{(\lambda)}u_k^{(\lambda)}(x) \quad [24]$$

In order to apply the above general Berry-phase formulation to this Hamiltonian, it is enough to define a two-dimensional parameter $\boldsymbol{\xi}$ whose two components are k and λ:

$$H(\boldsymbol{\xi}) \equiv \frac{1}{2m_e}(p+\hbar k)^2 + V^{(\lambda)}; \quad |\psi(\boldsymbol{\xi})\rangle \equiv |u_k^{(\lambda)}\rangle \quad [25]$$

The Berry connection of the problem is

$$i\langle\psi(\boldsymbol{\xi})|\nabla_{\boldsymbol{\xi}}\psi(\boldsymbol{\xi})\rangle\cdot d\boldsymbol{\xi} = i\left\langle u_k^{(\lambda)}\middle|\frac{\partial}{\partial k}u_k^{(\lambda)}\right\rangle dk + i\left\langle u_k^{(\lambda)}\middle|\frac{\partial}{\partial\lambda}u_k^{(\lambda)}\right\rangle d\lambda \quad [26]$$

The Berry phase [22] is evaluated, where the curve C is chosen as the contour of the rectangle shown in **Figure 6**. According to the modern theory, the polarization difference ΔP between the ferroelectric and paraelectric structures is

$$\Delta P = \frac{q_e}{\pi}\gamma + \Delta P_{ion} \quad [27]$$

where ΔP_{ion} is the trivial contribution of the classical ions.

The three-dimensional, multiband analog of eqn [27] is nowadays implemented – at the first-principle level and using various technical ingredients – in most publicly available electronic-structure codes. Applications have concerned piezoelectricity, lattice dynamics, and ferroelectricity in real materials. In the case of ferroelectric polarization, where no quantum-mechanical theory was available prior to 1993, the numerical results are in spectacular agreement with the experimental data and provide an insight into the physics of ferroelectricity.

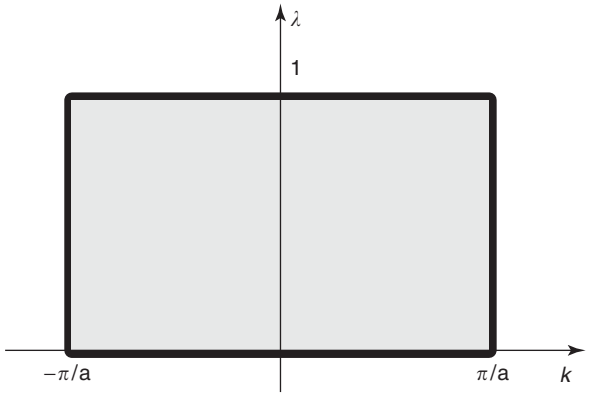

Figure 6 The Berry phase γ, which defines the electronic contribution to ΔP is evaluated along the contour of the rectangular domain in the (k, λ) plane.

Conclusions

The modern theory of polarization provides an unambiguous definition of what the physical observable really is: an integrated current, whose electronic contribution can be evaluated either from the linear-response theory, or as a gauge-invariant phase of the occupied crystalline orbitals. Macroscopic polarization bears no relationship to the periodic charge density of the polarized crystal: the latter, in fact, only depends on the square modulus of the occupied orbitals, where any phase information is deleted. Besides providing profound insight into the polarization phenomenon, the modern theory is also an extremely powerful tool for calculations in real materials.

Nomenclature

$\boldsymbol{E}$	macroscopic electric field (inside the material)
m_e	electron mass
$\boldsymbol{p}$	canonical momentum (equal to $-i\hbar\nabla$ within the Schrödinger representation)
$\boldsymbol{P}$	macroscopic dielectric polarization
$\boldsymbol{P}_{el}$	electronic contribution to the macroscopic dielectric polarization
$\boldsymbol{P}_{spont}$	spontaneous polarization in ferroelectrics
q_e	electron charge ($= -\|e\|$)
ε_∞	"static high-frequency" dielectric constant (or tensor)

Glasses

J M Parker, Sheffield University, Sheffield, UK

Introduction

Glasses feature widely in everyday life and also in science. Their transparency and chemical durability, combined with ease of fabrication, ensure a role in windows, containers, tables, and laboratory ware; they are key components in optical instrumentation, for example, microscopes, cameras, and optical fibers. Some devices utilize specific interactions between light and glass, for example, lasers. Other applications use their electrical and magnetic behavior, strength, and thermal characteristics, including crystallization and phase separation. The range and flexibility of known glass compositions allow their properties to be independently tailored. Combining glasses with other materials or modifying their behavior by coating has further extended their use. Understanding glass structure and its consequences is also challenging the boundaries of condensed matter physics.

What Is a Glass?

Glasses have been defined as inorganic products of fusion cooled to a solid without crystallizing. This encapsulates key properties: glasses have a liquid-like structure, but cooling has caused a transition from liquid to solid behavior. It also implies features that are now disputed: organic glasses exist, and melting is not the only route for glass making. A characteristic implicit in the definition is that crystallization rates are low; this is often associated with high melt viscosities below the liquidus (T_L). Glasses differ from amorphous solids, in that they can be reheated to the liquid state; the latter crystallize on heating before melting.

How Are Glasses Made?

Often glasses are made from solids by heating until fully melted, bubbles have dissipated and the melt is homogeneous. Commercially, temperatures may reach 1600°C and melting may take days. Laboratory melts need a few hours. Density separation of batch components, differential melting rates, contamination by the container, and volatilization losses can limit the glass quality. High melt viscosities limit diffusion and militate against homogeneity; mechanical or convection-driven stirring may be necessary. The oxidation state of any multivalent ions depends on the atmosphere around the batch during initial melting; subsequently, equilibrium with the furnace atmosphere is achieved only slowly. Rapid quenching may be needed, for example, roller quenching, splat cooling onto a rotating copper wheel, or fiber pulling.

Alternative production routes include: condensation of vapor phase reaction products on cold substrates; hydrolysis of organic derivatives of silicon (e.g., $Si(OC_2H_5)_4$) or other components to give a gel that is dried and sintered to a fully dense product; and extended grinding or applying pressure to crystals.

Glass Structure

Short-Range Order

Glass structures have been studied by X-ray or neutron diffraction, various spectroscopic techniques, and computer modeling. Their short-range structure often mirrors that of corresponding crystalline compounds, particularly higher temperature phases. Zachariasen postulated that single-component glass-forming systems have cations with low coordination numbers (3 or 4) surrounded by bridging anions, each linking two coordination polyhedra at corners

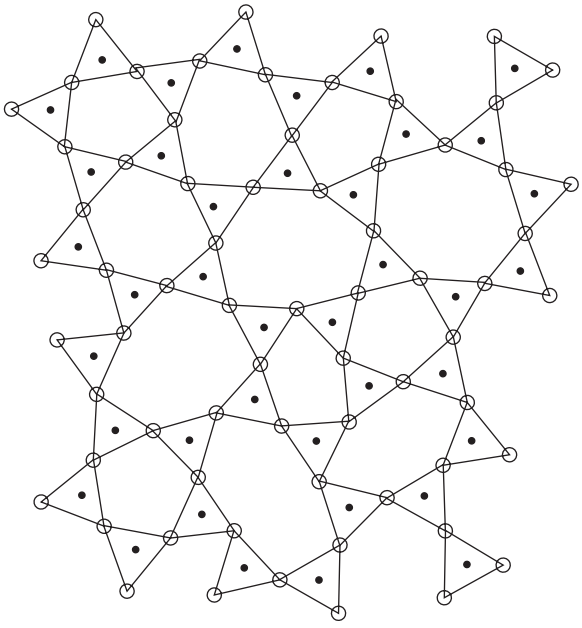

Figure 1 A schematic representation of the structure of vitreous silica. The tetrahedral SiO_4 units in silica are represented by triangular units.

rather than edges. SiO_2 consists of a matrix of SiO_4 tetrahedra (**Figure 1**) that defines its low thermal expansion coefficient (TEC), high viscosity at T_L, and high melting point. Other single-component glass-forming systems include GeO_2, BeF_2, B_2O_3, and As_2O_3.

A second component can extend glass formation, for example, to 58 mol.% Na_2O in the Na_2O–SiO_2 system. Each oxygen added breaks one corner linkage in the network, creating two nonbridging oxygens (**Figure 2**). Silicons are called "network formers" and sodiums, which enter interstices surrounded by bridging and nonbridging oxygens, are termed "network modifiers." A silicon linked to three bridging and one nonbridging oxygen is denoted by Q_3; the spread of Q_n species is generally narrow. Adding soda (Na_2O) increases the TEC and reduces viscosity by depolymerizing the network, while increasing density by filling interstices. Various cations adopt a network-forming role (e.g., Ge, P, Pb). The melt structure, being flexible, can accommodate many modifier ions in spite of different radii and preferred coordination, for example, Li, K, Rb, Mg, Ca, Fe^{2+}. Intermediate ions (Al^{3+}, Fe^{3+}) can take either role in the structure. Some oxide combinations form glasses even though the components do not – the network-forming ion is called a "conditional" glass former, for example, Al in CaO–Al_2O_3 glasses. The oxygens can also be (partially) replaced by other anions, for example, F, S, N.

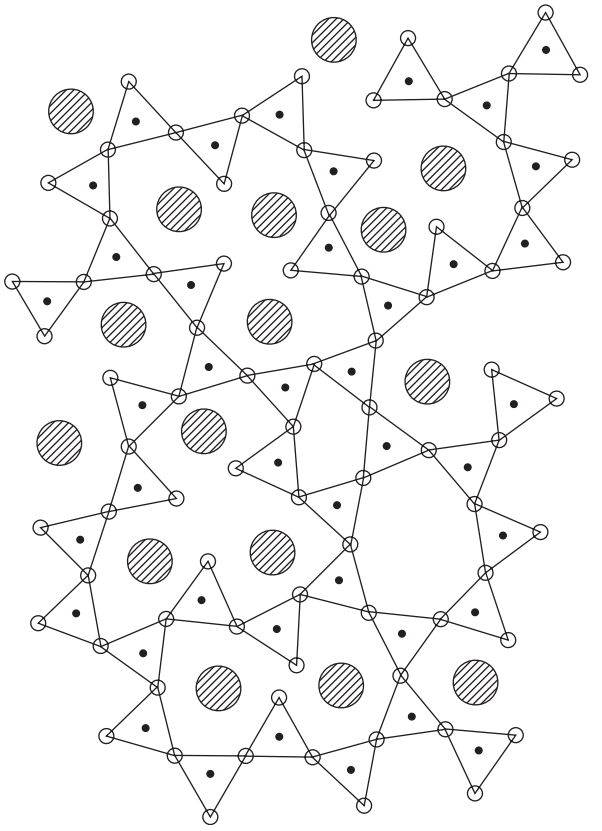

Figure 2 A schematic representation of the structure of an Na_2O–SiO_2 glass illustrating the break-up of the network by the introduction of nonbridging oxygens (linked to only one Si), and the sites taken by the sodium ions.

Properties can often be modeled using expressions that are linear functions of composition and the viscosity of industrial glasses is usually calculated rather than measured. Difficulties occur if a cation changes role with composition (e.g., B coordination depends on alkali content); the TECs of M_2O–B_2O_3 glasses display a minimum with composition (the "boric oxide anomaly"), requiring a $[B_2O_3]^2$ term in composition models. Liquidus temperatures, which are discontinuous across phase boundaries, are best modeled using the underlying free energy functions. Components can also interact: Na_2O decreases network connectivity, while Al_2O_3 is a network former at low concentrations and, being oxygen deficient, removes nonbridging oxygens. If $Na_2O{:}Al_2O_3 = 1$, a highly connected, viscous system results; excess Na_2O or Al_2O_3 decreases viscosity, in the latter case because Al coordination changes from [4] (former) to [6] (modifier).

Medium-Range Order

Diffraction experiments give structural data in the form of radial distribution functions, representing the

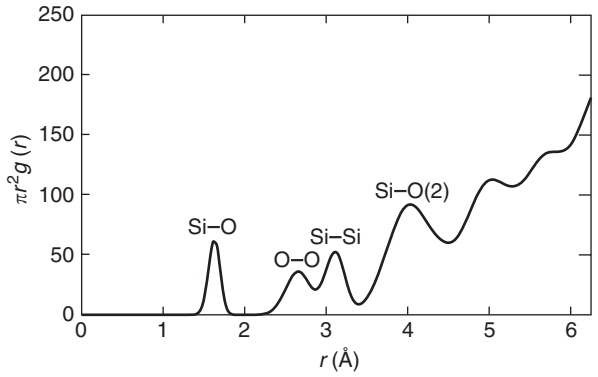

Figure 3 An idealized radial distribution function for SiO_2. The first four peaks give the distribution of nearest neighbor Os around Si, the Si–Si distribution, the O–O distribution, and the distribution of second nearest neighbor oxygens around Si. The peak areas give coordination numbers and the breadths indicate thermal and structural disorder. A random distribution would give a parabolic curve. Experimental curves show some ripple at low r caused by data termination errors. Many authors now plot correlation functions ($\pi r\, g(r)$) rather than r.d.f.s.

summed distribution of atoms with distance around all species present (**Figure 3**); network-forming ions sit in remarkably regular sites but longer distance correlations are harder to resolve because of peak overlap. Extended X-ray absorption fine structure (EXAFS) experiments allow study of the environment of individual species and suggest that network modifiers also sit within polyhedra of notable regularity, that is, all cations optimize their local structure.

Such distribution functions show that the network-forming polyhedra can also form extended structures, for example, vitreous B_2O_3 consists of BO_3 triangles, that form planar groupings, termed boroxol rings (B_3O_6), not found in B_2O_3 crystals. The modified random network model for alkali silicate glasses is based on segregation of network-modifying atoms into layers surrounding SiO_2-rich regions (**Figure 4**). The diffraction patterns for many glasses have a sharp low-angle first diffraction peak, consistent with extended ordering, as confirmed by modeling and electron microscopy.

IR spectroscopy supports such structural models by accounting for the network vibrational modes. In Raman and Brillouin scattering experiments, glasses have, as a common feature, a boson peak at $\sim 100\,\mathrm{cm}^{-1}$ that provides additional insight into nanometer-scale inhomogeneities. Models incorporating medium-range order are distinct from older microcrystallite theories of glass, discounted by the lack of small angle X-ray or neutron scattering beyond that predicted from incipient random fluctuations in density.

These conclusions underpin the thermodynamic modeling of glass properties based on contributions

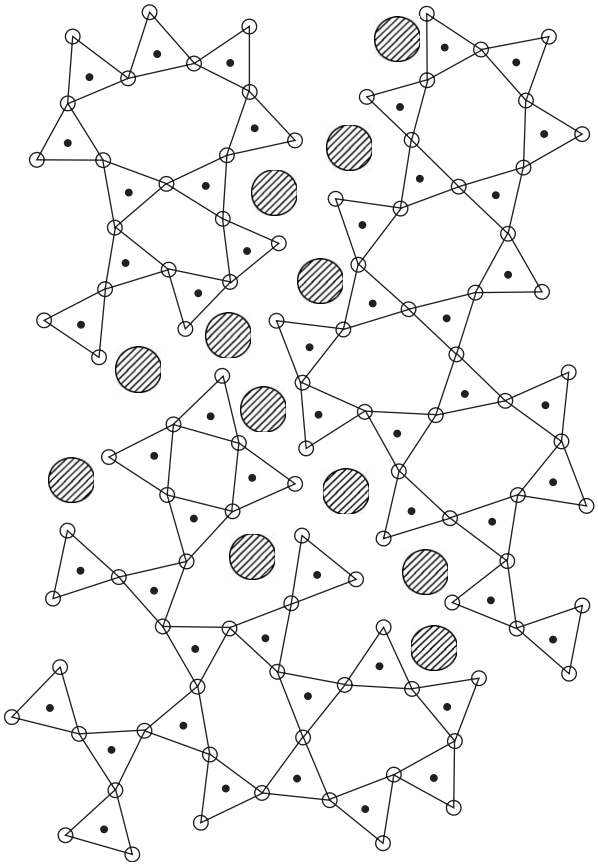

Figure 4 A schematic representation of the modified random network model for an Na_2O–SiO_2 glass showing the tendency for modifier ions to segregate.

from components with appropriate compositions in defined proportions.

Defects

Glasses can contain bonding and electronic defects induced by radiation or high temperatures. Their concentrations are low but they influence optical properties by introducing visible or ultraviolet (UV) absorptions and causing refractive index (r.i.) changes. Defects may involve unpaired electrons (*) and include: the nonbridging oxygen hole center, $\equiv Si-O^*$; E′ center, $\equiv Si^*$; peroxy radical, $\equiv Si-O-O^*$; or species such as Zr^{3+}, F_2^-. Some defects can be eliminated by optical or thermal bleaching, while others survive for years under normal conditions.

Nonsilicate Glass-Forming Systems

Silicate glasses have three-dimensional (3D) network structures with intermediate ionic/covalent bonds. Alkali phosphate glasses have similar bonding but are often better described as chains. Chalcogenide glasses are largely covalent and based on networks,

sheets, chains, and rings. Hydrogen-bonded molecular glasses are common in organic systems (e.g., sugars), while some highly ionic or metallic systems adopt almost random close-packed structures. Various salts (nitrates, sulfates, acetates) also form glasses. Even crystals can show glassy behavior. Spin glasses may form in magnetic systems, based on disordered arrangements of unpaired electron spins, or molecules may have random orientations on a regular lattice as in KBr–KCN. Polymers usually consist of covalently bonded chains, which may have irregular monomer unit sequences or cross-link randomly along their lengths, giving glassy materials at low temperatures that cannot untangle into crystalline forms. In extreme cases, oxide glass melts have been described with two or more configurations that transform only slowly from one to the other, or may coexist in equilibrium.

Crystal Growth and Phase Separation

Once a melt is cooled below T_L, crystal growth is possible. The driving force (difference in free energy between crystalline and liquid state) increases with undercooling and initially growth rates rise as temperature falls (**Figure 5**). Subsequently kinetic factors, for example, diffusion through the melt to the growing crystal and atomic rearrangement at the interface, limit growth. In stable glass-forming systems, growth rates may be only $\mu m\,h^{-1}$ but may reach $m\,s^{-1}$ in glassy metals. For large undercoolings the fastest growing phase is not necessarily the primary phase defined by the phase diagram; metastable phases also often form.

Crystallization requires a nucleation step. Homogeneous nucleation is an intrinsic property. The free energy gain on producing a crystalline nucleus must balance the energy penalty of generating its surface. Surface effects dominate for small particles and so nuclei must exceed a critical size before they are viable. Small undercoolings require a large critical nucleus whose spontaneous formation is improbable, so melts can exist metastably for long periods just below T_L. At lower temperatures, the critical nucleus size decreases and nucleation rates rise rapidly to a maximum just above T_g, subsequently falling as kinetic factors dominate.

Homogeneous nucleation is, however, rare. Nucleation starts more easily from pre-existing discontinuities, for example, "dirty" surfaces or container walls. Nucleation can be engineered by dissolving at high temperatures a component that becomes insoluble on cooling and precipitates (by homogeneous nucleation or phase separation). Examples include halides (NaF, CaF_2, CuCl), oxides (TiO_2, ZrO_2, P_2O_5), or metals (Ag, Au).

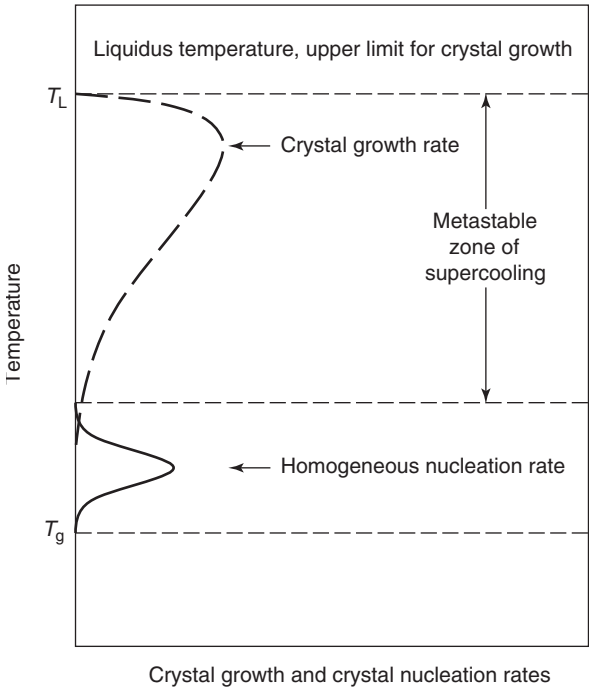

Figure 5 A schematic representation of the crystal growth and nucleation curves for a single phase precipitating from a glass-forming melt. In reality other phases may also appear at different temperatures with their own growth rate curves.

If homogeneous nucleation rates are high, two-step heat treatment in the nucleation and growth regions can give a finely crystalline structure. The resulting "glass ceramics" are made by standard melting and forming technology but, once crystallized, can have enhanced properties, while lacking the porosity intrinsic to conventional ceramics. Glass ceramics can remain transparent if the crystals are smaller than the wavelength of light and r.i. differences are minimized.

Phase Separation

Phase separation is the chemical segregation of a melt into two liquids, driven by an associated reduction in free energy, for example, Na_2O–SiO_2 melts, with $Na_2O < 20$ mol.%, separate into SiO_2 and sodium silicate; the SiO_2 structure is relatively intolerant to impurities. The minor phase may occur as droplets or a continuously connected phase, whose scale depends on heat treatment time and whose microstructure can be preserved by quenching. The initial step may involve homogeneous nucleation or spinodal decomposition (no energy barrier). Borosilicate glasses also phase separate; the connected phase can be removed by solution, allowing manufacture of finely porous SiO_2.

Glass Formation

First, the flexibility of linkages in network systems results in only small energy differences between glassy and crystalline states (cf. the many SiO_2 polymorphs). This is a key thermodynamic factor in glass formation. Second, the network connectivity and bond strength cause the high melt viscosity and slow crystallization rates. Finally, the high melting temperatures destroy, by reaction or solution, foreign particles that might otherwise catalyze crystallization.

Mathematical models, based on crystal growth and nucleation behavior, and their degree of overlap with temperature, can predict critical cooling rates for glass formation. They suggest that many systems, including some metal alloys, can form glasses. Cooling rates of $10^{6\circ}C\,s^{-1}$ may be needed, so heat transfer limits their production to thin artifacts, for example, ribbons or wires. New glass-forming systems have been identified, based on TeO_2, Al_2O_3, Ga_2O_3, ZrF_4, InF_3, by using faster quenching, smaller samples, and purer materials melted under clean conditions to eliminate nucleating agents.

Glasses are often associated with eutectics where liquidus temperatures are low and the melts differ most in composition (and structure) from crystalline compounds. Adding more components can also improve glass-forming ability – the so-called "confusion" or "garbage-can" principle.

Viscosity

Melt viscosities (η) typically follow the Vogel–Tammann–Fulcher equation (VTF) with temperature: $\log \eta = A + B/(T - T_0)$ with A, B, and T_0 as fitted constants. At the temperature where $\eta = 10^{12}\,Pa\,s^{-1}$, deformation rates are slow, the material is effectively solid over short times ($\sim 10^2$ s), and this provides one definition of the "glass transition temperature, T_g." By the strain point ($\eta = 10^{13.6}\,Pa\,s^{-1}$), stress release takes hours. First-order thermodynamic properties such as volume are continuous through the glass transition, in contrast to phase changes such as crystallization, but second-order thermodynamic properties (specific heat (C_p) or TEC) are stepped (**Figure 6**). T_g can therefore also be measured from C_p or length changes using a differential scanning calorimeter or a dilatometer, but the values depend on the heating rate used, since the transition is kinetically defined, and are not necessarily equal for different properties.

Some have concluded that glass flows at room temperature, it being a liquid, and have perpetuated a myth that old windows are thicker at their base. Neither measurements nor calculations substantiate such conclusions, flow having become immeasurably slow. Where old panes are thicker at one edge, it is a manufacturing defect.

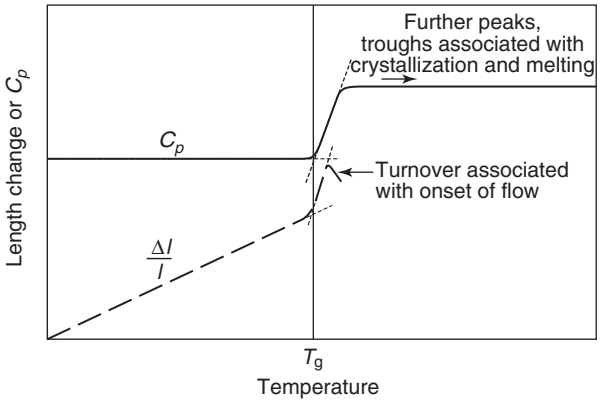

Figure 6 An idealized graph of the specific heat of a glass as a function of temperature during a constant heating rate experiment and the length of a glass specimen as a function of temperature under similar heating conditions. There is a step in C_p at T_g and a change of slope (corresponding to a step in the TEC) in the specimen length.

A glass artifact, cooled quickly, will solidify with large temperature gradients present; the differential contraction on reaching room temperature can induce significant stresses. These stresses depend on cooling rate, TEC, elastic properties, and thickness; bulk articles are therefore annealed, by equilibration above T_g, followed by slow cooling to the strain point.

Angell has compared glass-forming systems using normalized plots of $\log \eta$ against T_g/T; those displaying Arrhenius behavior most closely he termed "strong" glasses while those with large deviations he termed "fragile." Fragility implies cooperative breakdown of the melt structure into increasingly small units above T_g. The VFT formalism predicts $\eta = \infty$ at $T \to T_0$. Many studies have attached physical significance to T_0, relating it to the temperature where extrapolation of experimental data predicts that the entropy of a glass becomes equal to that of the corresponding crystal, that is, the configurational entropy falls to zero, a concept underpinning the "Kauzmann paradox."

Processing

High melt viscosities, along with gravity and surface tension, aid shaping as the melt cools. Sheet glass achieves optical flatness by gravity-driven flow, while floating on a molten tin bath with a 7 mm equilibrium thickness defined by surface tension and density. Optical fibers maintain their r.i. profiles during drawing. Containers and laboratory ware are blown and pressed by complex machinery to give the desired glass distribution. Strain rates may be high.

Some glasses display non-Newtonian flow by structural alignment during forming.

Transformation Range Effects

Glass structure does not depend only on composition but also on thermal history; densities may vary by 1%. Fast quenching freezes in a structural state corresponding to equilibrium at a higher temperature than slow cooling. The effective quenched-in equilibrium temperature is called the "fictive temperature." Control of cooling through the transformation range allows fine tuning of an optical glass r.i., and low cooling rates ensure the whole sample has the same thermal history (and minimum stress). Optical glass manufacturers recommend that their products should not be heated above $T_g - 150°C$ because of potential property changes. Similar considerations apply to the processing of glass sheets for LCD displays. The electronic circuitry used to address individual pixels is printed at high temperatures in several layers; precise registry demands dimensional stability.

A glass heated in the transformation range may, after an initial instantaneous change, relax exponentially to a new equilibrium state (Maxwell spring and dashpot model). Stress release rates can be measured and accurate data as $f(t, T)$ are needed for high-precision fabrication. Detailed analysis suggests a stretched exponential formulation: $S_t = S_0 \exp(-[t/\tau]^n)$ where S_t is the stress at time t, S_0 the initial stress, and τ is proportional to viscosity, n ranges typically from 0.5 near T_g to 1. Many other properties behave similarly although not necessarily with the same constants for a given glass. Study of relaxation behavior and structural dynamics has given fruitful insights into the nature of the glass transition.

At lower temperatures, bulk flow ceases but atoms can slide into new relative positions corresponding to different local energy minima, associated with the disordered structure. Such effects are manifest in internal friction experiments, for example, measurement of the damping of a pendulum suspended from a glass fiber under torsion. Damping involves transfer of mechanical energy to thermal energy and is observed down to room temperature in silicate glasses. Different mechanisms, termed α and β relaxations, dominate as temperature rises. These are attributed to mechanisms from modifier ion motion and relative movement of nonbridging oxygens, to motion of whole structural units.

A related phenomenon is semipermanent densification of v-SiO_2 at high pressures (GPa). Deformations of several percent do not fully relax on return to normal atmospheric conditions. Kinetic studies of relaxation suggest a low activation energy process, which is therefore not bond breakage; Raman spectroscopy confirms this.

Early mercury-in-glass thermometers also displayed delayed elasticity. After calibration at 100°C, the mercury failed to return immediately to its 0°C calibration point on cooling. This relaxation behavior was minimized in mixed alkali glasses. Similar effects have been observed in rare-earth doped glasses; optical pumping into particular excited states, and the consequent energy transfer to the lattice, has excited structural changes that only recover at raised temperatures. The associated r.i. changes allow holographic image storage.

Thermal Properties

Specific heats are consistent with Dulong and Petit's law near T_g but show a positive step at T_g, the size of which indicates the level of structural breakdown occurring.

Thermal conductivities are lower than for equivalent crystalline phases and decrease with falling temperature, consistent with the short phonon mean free paths associated with structural disorder. At high temperatures, heat transport by photons becomes significant – glass is semitransparent in the near infrared allowing absorption and re-emission as a heat transport mechanism, termed radiation conductivity. Radiation conductivity varies as T^3 and is significant in commercial glass melting.

Mechanical Behavior

Glasses are brittle, with strengths dominated by their surface state. In microhardness tests, they exhibit limited flow under compression, attributed to densification and faulting. No flow occurs under tensile stress however; surface flaws remain atomically sharp at high loads and are effective stress raisers (stress at crack tip is enhanced by $(r/\rho)^{1/2}$ where r is crack length and ρ tip radius).

Flaws are induced by impact, friction, adhering particles of different TEC, and devitrification. Strengths of several GPa in undamaged fibers can fall to < 50 MPa. Water attack at flaw tips under stress causes static and dynamic fatigue, which is maximized in glasses of poor chemical durability; conversely, v-SiO_2 is unusually strong because of its excellent durability. The stress intensity factor, K_{1c}, allows isolation of compositional factors by eliminating the effects of flaw size. Variations between glasses are small and related to bond strengths or atomic packing densities.

Strengths are improved by protective coating or surface compressive stresses induced by rapid cooling or ion exchange, where large cations replace smaller

cations. Many glass ceramics have enhanced strengths, the crystals impeding crack growth.

Optical Properties

Glasses are intrinsically transparent because they lack internal structure (e.g., grain boundaries) where r.i. changes would scatter light. Transparency also requires the absence of absorption mechanisms. UV photons can excite bonding electrons into empty molecular orbitals, limiting transparency. v-SiO_2 and phosphate glasses have strongly bound electrons and are transparent to <200 nm, but nonbridging oxygens, with their more weakly bound electrons, reduce transmission. IR photons can excite atomic vibrations and SiO_2 is opaque beyond 4.5 μm. OH absorptions usually limit transmission beyond 3 μm. Transmission can be extended by reducing the natural vibrational frequencies using heavier ions and weaker bonding. Fluoride glasses based on singly charged anions and heavy cations (Zr, La, In, Hf) will transmit to 7.5 μm and chalcogenide glasses (based on S, Se, Te) can transmit to 20 μm.

The UV and IR absorptions in glass are responsible for its r.i., n, and wavelength dispersion, v, as implicit in the semi-empirical fitting formula of Helmholtz–Ketteler: $n^2 - 1 = A + \sum_i c_i \lambda^2/(\lambda_{0i}^2 - \lambda^2)$ with $\lambda_{0i} =$ wavelength of absorption bands and c_i a weighting factor related to band strength. SiO_2 has a low n because its strong bonding gives short λ_{0i} values, whereas PbO-rich glasses have longer λ_{0i}, and correspondingly higher n and v values. The UV absorption is associated with the $6s \rightarrow 6p$ transition of the lone pair electrons in Pb^{2+}. These weakly bonded, highly polarizable electrons also increase the second-order coefficient of optical nonlinearity (n_2). $d^2n/d\lambda^2 = 0$ near 1.5 μm for SiO_2 because of the competing effects of UV and IR absorptions, minimizing materials-based signal dispersion in fibers.

Transition metal and rare-earth ions introduce weak absorptions, which are broader than in crystals because of the inherent structural disorder. Such species color glass. The matrix composition can strongly influence excited state lifetimes, and affects absorption and emission peak shapes. Halide and chalcogenide glasses are often preferred hosts because their low phonon energy lattices increase excited state lifetimes. Crystallization, where dopant ions segregate into the crystal phase, can offer similar advantages but with more tightly defined dopant ion environments. Both glassy and transparent glass–ceramic materials make efficient lasers (in fiber form for telecommunications).

Color can result from precipitated particles, for example, Au, Cu, and Ag color glass red or yellow and Cu(Cl,Br), Cd(S,Se), or PbTe give sharp absorption edges in the UV, visible, or IR, depending on their bandgap. If particles exceed 20 nm, light scattering can become excessive. The electronic energy levels of these precipitates are influenced by particle size via quantum confinement effects, giving rise to enhanced optical nonlinearities.

Such materials require dissolution of an appropriate compound at high temperatures that will precipitate on cooling. Metals are dissolved as ions, reduced to atoms on cooling by a redox process (e.g., $Au^+ + Ce^{3+} \rightarrow Au^0 + Ce^{4+}$), and subsequently agglomerate. Electron transfer can be catalyzed by UV photons. Thus regions of high metallic particle concentrations, capable of nucleating bulk crystallization, can be engineered. The crystallized regions can display differential HF etching rates, and finely structured products for fluidics or replacement bones for the ear can be made.

Glasses are rarely birefringent being intrinsically isotropic, but anisotropy can be induced temporarily by stress, or permanently by shearing melts with chain-like structures or showing phase separation, while cooling through T_g.

The Faraday effect involves rotation of the plane of polarization of a light beam by a magnetic field. Applications include optical devices requiring rapid switching or protection against back-reflected light. The plane of polarization is rotated in one sense by diamagnetic materials and in the reverse by paramagnetic materials. Large diamagnetic effects occur in $PbO–Bi_2O_3–Ga_2O_3$ glasses because of the polarizable Pb and Bi ions, while typical paramagnetic materials contain rare-earth ions with unpaired $4f$ electrons, for example, Tb^{3+}, Pr^{3+}, and Dy^{3+}. The equivalent effect for electrical fields is named after Kerr.

Energetic photons can form point defects or rearrange bonds, causing density and r.i. changes that may be used for laser writing; Bragg reflecting gratings, for telecoms signal demultiplexing or stress sensors, are written in Ge-doped SiO_2 optical fibers by two interfering beams from an excimer laser. Light-induced differential etching rates in chalcogenide glasses allow manufacture of photodiffractive elements.

Diffusion and Electrical Behavior

SiO_2 has an open structure allowing solution of small molecules (e.g., He, H_2) and significant diffusion rates, even at 20°C. Modifier ions block the diffusion paths but, being weakly bonded, may themselves diffuse below T_g. Some surface modification technologies, for example, chemical toughening or planar

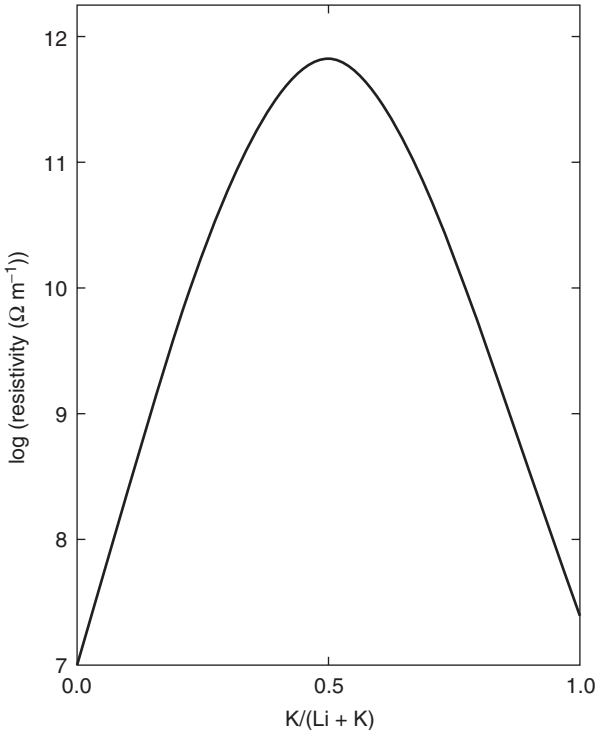

Figure 7 An idealized graph of resistivity against the concentration of K as a fraction of total alkali content [K/(Li + K)] for an M_2O–$2SiO_2$ glass. The peak in resistivity is a result of the mixed alkali effect.

waveguide manufacture, use this. At room temperature, most glasses are insulators but ion motion can cause significant AC dielectric loss; consequently glass ceramics are often preferred substrates in the electronics industry. Glasses become ionic conductors at higher temperatures ($\sim$100°C for silicate glasses with significant modifier ion content; larger ions and higher charge reduce conductivity). The phenomenon of fast ion conduction, observed in some crystalline ceramics, also occurs in glasses.

The mixed alkali effect is a characteristic of ionic conduction and diffusion. **Figure 7** plots the conductivity of glasses containing Na and K against concentration; a pronounced minimum occurs where Na:K = 50:50, explained by the different sites the two ions occupy. Sodiums hop easily between equivalent sodium sites but mixed sites create an energy barrier. The loss of vibrational coupling between adjacent ions may also reduce coordinated hopping. The mixed alkali effect is most pronounced below T_g, the cation sites being unable to relax.

Both crystalline and glassy semiconductors display valence and conduction bands, and a bandgap. Interband states exist even in undoped glasses however, particularly near the band edge. Chalcogenide glasses, based on S, Se, Te with, for example, Ge, Si, As, Sb, Ga, and glasses with high concentrations of transition metals in mixed valence states (e.g., V, Fe) can be semiconducting, electrons hopping between adjacent ions in different oxidation states in the latter case. Chalcogenide glasses have typical semiconductor characteristics, for example, photoconductivity and xerography; a-Si is a common component of solar cells. They also display switching behavior. Low voltages give small currents but higher voltages can induce crystalline filaments of higher conductivity. If crystallization is reversible, a memory switch results.

Group Theory

R Dirl and P Weinberger, Technische Universitat Wien, Vienna, Austria

Introduction

The theory of groups can be developed as an entity independent of its applications as it avoids confusion concerning what is proper to group theory itself and what is special to its applications. The mixture of theory and applications tends, in many cases, to obscure the boundary between them. From this viewpoint, perhaps the most important aspect of group-theoretical applications to physics or chemistry is to consistently disentangle the various concepts. The three major issues are the algebraic structure of the group in question, its corresponding representation theory usually referring to the field of complex numbers $\mathbb{C}$ (as commonly accepted in the quantum theory) and finally, what is essential to the actual physical application.

Properties of Groups

Although some basic knowledge of the group theory is assumed, basic properties are repeated here, thereby also establishing notation and conventions. Let $G = \{e, g, g', g'', \ldots\}$ be a group which is assumed to be finite (e.g., point groups), countable infinite (e.g., crystallographic space groups), or compact continuous (e.g., the three-dimensional proper rotation group $SO(3, \mathbb{R})$ whose corresponding universal covering group SU(2) plays a fundamental role for the spin degree of freedom). Recall that a group G is defined by a set of elements endowed with a certain algebraic structure. Its composition law

$$gg' = g'' \qquad [1]$$

must satisfy the associative law for ordered triplet $g, g', g'' \in G$ of group elements. Likewise, the existence of the unit element and uniquely defined inverses for each $g \in G$ must be guaranteed. Group–subgroup relations of the type $H \subset G$ imply that the group H forms a subset of G, which itself satisfies the group properties and hence is called a subgroup of the group G. A subgroup $N \subset G$ is called a normal subgroup if the conjugation

$$gNg^{-1} = N \qquad [2]$$

maps the subgroup N onto itself for all $g \in G$. Normal subgroups play a fundamental role not only when dealing with images of groups but also when studying features, such as faithfulness, of group representations.

The order of a group, which, loosely speaking, is equal to the number of its elements, is usually denoted by the symbol $|G|$. This symbol implies, for finite groups, the number of its elements, in the case of countable abelian groups, the group volume of their dual groups, and in the case of compact continuous groups, their group volume where the latter are endowed with appropriate Haar measures.

Specific relationships between different groups can be established by means of mappings of the type $\varphi : G \to H$, where G and H are two groups and $\varphi(G) = H$ defines the mapping in detail. Once the mappings satisfy the composition law of the image group H,

$$\varphi(g)\varphi(g') = \varphi(g'') \qquad [3]$$

then such mappings are called homomorphisms, and the associated kernel, denoted by $\ker_{\varphi(G)}$, defines a nontrivial normal subgroup of the pre-image group G. In mathematical terms,

$$\ker_{\varphi(G)} = \{g \in G \mid \varphi(g) = e \in H\} \lhd G \qquad [4]$$

$$G/\ker_{\varphi(G)} \sim H \qquad [5]$$

where the entry $G/\ker_{\varphi(G)}$ denotes the factor group and the special symbol $\lhd$ emphasizes that the subgroup $\ker_{\varphi(G)}$ must form a normal subgroup of the group G. A homomorphism is said to be an isomorphism if and only if the $\ker_{\varphi(G)}$ is trivial, that is, it consists of the identity element of G only. The mapping $\varphi : G \to H$ is called automorphism if and only if the group G is mapped onto itself. For more details on algebraic properties of groups and more advanced concepts, such as extensions of groups, the reader is referred to the "Further reading" section.

Properties of Representations

Every homomorphism $\varphi : G \to T(G)$ of a given group G into a group of nonsingular transformations $T(G) = \{T(g) \mid g \in G\}$ that map an underlying linear n-dimensional vector space $V^n_{\mathbb{K}}$ over the field $\mathbb{K}$ onto itself is called a representation of the group G if and only if the corresponding homomorphism property

$$T(g)T(g') = T(gg') = T(g'') \qquad [6]$$

is satisfied for all group elements $g, g' \in G$. Such a general representation is called a linear representation of the group G if and only if the linearity condition is satisfied. To be strict, one assumes that

$$T(g)(a\boldsymbol{v} + b\boldsymbol{w}) = aT(g)\boldsymbol{v} + bT(g)\boldsymbol{w} \qquad [7]$$

for all vectors $\boldsymbol{v}, \boldsymbol{w} \in V_{\mathbb{K}}^{n}$ and all $a, b \in \mathbb{K}$. In many applications, especially in quantum mechanics, one assumes $\mathbb{K} = \mathbb{C}$, sometimes one restricts $\mathbb{K} = \mathbb{R}$, whereas for some applications in crystallography, one even restricts $\mathbb{K} = \mathbb{Z}$, where the symbol $\mathbb{Z}$ denotes the ring of integers. For instance, one is inevitably led to the ring of integers when discussing the automorphisms of Bravais lattices. The restriction to the elements of the full rotation group $O(3, \mathbb{R}) = \mathrm{SO}(3, \mathbb{R}) \times \mathscr{C}_2$, where the symbol $\mathscr{C}_2 = \{E, I\}$ denotes that the inversion group does not influence the statement. It merely restricts the elements of $\mathrm{GL}(3, \mathbb{Z})$ to the elements of point groups $\mathscr{P}(T_{\text{Bravais}})$, which are finite subgroups of $O(3, \mathbb{R})$.

Matrix Representations

Every homomorphism $\vartheta : G \to D(G)$ of a given group G into a group of nonsingular matrices represented by $D(G) = \{D(g) \mid g \in G\}$, which are assumed to be finite-dimensional, is called a matrix representation of the group G if and only if the corresponding homomorphism property

$$D(g)D(g') = D(gg') = D(g'') \qquad [8]$$

is satisfied for all group elements $g, g' \in G$. Every matrix representation $\vartheta(G) = D(G)$ of the group G is called faithful if $\ker_{\varphi(G)}$ of the homomorphism is trivial. Every matrix representation of any group G is called unitary if and only if

$$D(g)^{-1} = D(g)^{\dagger} \qquad [9]$$

for all group elements $g \in G$. In the case of finite, countable, or compact continuous groups, it is assumed that every nonsingular matrix representation can be transformed by means of suitable intertwining matrices into unitary ones, if $\mathbb{K} = \mathbb{C}$ is assumed. However, this statement does not make sense if, for instance, $\mathbb{K} = \mathbb{Z}$, the ring of integers, is chosen. In this context, it should be noted that matrix groups are entities in their own right, which need not have any carrier space in order to be able to define them.

Unitary Operator Representations

A homomorphism $\varepsilon : G \to U(G)$ of a given group G into a group of unitary operators, represented by $U(G) = \{U(g) \mid g \in G\}$, that maps an underlying Hilbert space $\mathscr{H}$ over the field $\mathbb{C}$ onto itself is called a unitary operator representation of the group G if and only if the corresponding homomorphism property

$$U(g)U(g') = U(gg') = U(g'') \qquad [10]$$

$$\langle \phi, \psi \rangle_{\mathscr{H}} = \langle U(g)\phi, U(g)\psi \rangle_{\mathscr{H}} \qquad [11]$$

is satisfied for all group elements $g, g' \in G$, together with $U(g^{-1}) = U(g)^{\dagger}$ for all $g \in G$. Here the symbol $\langle ., . \rangle_{\mathscr{H}}$ denotes the scalar product of the $\mathscr{H}$. The most prominent application of this concept concerns the quantum mechanical problems, where the symmetry operations of any Hamiltonian H have to be realized as unitary operators in order to conform to the fundamental rules of quantum mechanics, such as the invariance of the expectation values of operators with respect to unitary conjugation operations.

Unitary Irreducible Matrix Representations

The so-called unitary irreducible matrix representations play the most important role in the vast majority of group-theoretical applications. Hereafter, these representations are called unirreps. Their basic properties are

$$D^{\xi}(g)D^{\xi}(g') = D^{\xi}(gg') \qquad [12]$$

$$D^{\xi}(g^{-1}) = D^{\xi}(g)^{\dagger} \qquad [13]$$

$$\frac{1}{|G|} \sum_{g \in G} D^{\xi}_{ab}(g) D^{\lambda}_{rs}(g)^{*} = \frac{1}{n(\xi)} \delta_{\xi\lambda} \delta_{ar} \delta_{bs} \qquad [14]$$

$$\sum_{\xi \in \mathscr{A}(G)} \sum_{m,n=1}^{n(\xi)} D^{\xi}_{mn}(g) D^{\xi}_{mn}(g')^{*} = |G| \delta_{gg} \qquad [15]$$

where the following notations have been introduced and further conventions have been adopted. Let $D^{\xi}(G) = \{D^{\xi}(g) \mid g \in G\}$ denote an $n(\xi)$-dimensional G unirrep. Moreover, [12] represents the composition law, [13] represents the unitarity condition, [14] illustrates the orthogonality relations, and [15] the completeness relations of G unirreps. Finally, the symbol $\mathscr{A}(G) = \{\xi, \lambda, \ldots\}$ denotes the set of G irrep labels, whilst the subscripts a, b, and likewise r, s, or eventually m, n label the rows and columns of the corresponding G unirreps.

Schur's lemma *Let G be a group and $D^{\alpha}(G)$ with $D^{\beta}(G)$ two given G unirreps. Moreover, let S be a matrix such that*

$$D^{\alpha}(g)S = SD^{\beta}(g) \qquad [16]$$

holds true for all group elements $g \in G$. Now, by applying the orthogonality relations [14] *of the G unirreps and assuming that equivalent G unirreps are chosen to be, by definition, always identical, one arrives at the following well-known result*:

$$S = \begin{cases} O_{\alpha,\beta} & \text{for } \alpha \nsim \beta \\ \delta 1_{\alpha,\alpha} & \text{for } \alpha = \beta \end{cases} \qquad [17]$$

where, in particular, the notation $\alpha \sim \beta$ signifies inequivalent G unirreps and alternatively $\alpha = \beta$ equivalent G unirreps, respectively.

Here the entry $O_{\alpha,\beta}$ denotes the rectangular $n(\alpha) \times n(\beta)$ null matrix, and the entity $1_{\alpha,\alpha}$ the square $n(\alpha) \times n(\alpha)$ unit matrix. Here, only the factor $\delta \in \mathbb{C}$ can be chosen arbitrarily. Schur's lemma, as a special case of the so-called Wigner–Eckart theorem, is one of the most frequently used group-theoretical tools in quantum mechanical applications.

Reducible Representations

Let $D(G) = \{D(g) \mid g \in G\}$ be an n-dimensional matrix representation of the group G. This implies that the composition law [8] is satisfied. Every unitary similarity transformation of the G matrix representation, $D(G)$, defined by some n-dimensional unitary matrix $W \in U(n)$ leads to an equivalent matrix representation of the group G:

$$F(g) = WD(g)W^{\dagger} \qquad [18]$$

$$F(g)F(g') = F(gg') \qquad [19]$$

What is common to these equivalent matrix representations $D(G) \sim F(G) \sim \cdots$ are the so-called characters of the corresponding equivalent matrix representations, which by construction are identical:

$$\chi(g) = \text{tr } D(g) = \text{tr } F(g) = \cdots \qquad [20]$$

Accordingly, every set of characters $\{\chi(g) \mid g \in G\}$ is an invariant and loosely speaking, the unique fingerprint of the G matrix representations. Sets of characters, say $\{\chi(g) \mid g \in G\}$ and $\{\tilde{\chi}(g) \mid g \in G\}$ of any given group G are either identical (and, hence, the corresponding matrix representations are equivalent), or different (and the corresponding matrix representations are inequivalent). Thus, this provides an important and simple tool to distinguish matrix representations of any given group G uniquely. Apart from this, one may write

$$\text{tr } D^{\xi}(g) = \chi^{\xi}(g) \qquad [21]$$

$$\frac{1}{|G|} \sum_{g \in G} \chi^{\xi}(g)\chi^{\lambda}(g)^{*} = \delta_{\xi\lambda} \qquad [22]$$

which represent the orthogonality relations of the so-called simple characters that are uniquely assigned to the corresponding G unirreps. These follow immediately from the orthogonality relations [14] by simply carrying out the trace operation for the G unirreps.

A G matrix representation $D(G)$ is called reducible if and only if this matrix representation can be decomposed by means of suitable unitary similarity matrices into a direct sum of small dimensional G matrix representations. Conversely, a G matrix representation $D(G)$ is called irreducible if this matrix representation cannot be decomposed into a direct sum of smaller-dimensional G matrix representations. Note, in passing, that due to the restriction to consider merely finite, countable, and compact continuous Lie groups, one need not distinguish between reducible and completely reducible G matrix representations, since reducibility implies complete reducibility provided that the field $\mathbb{K} = \mathbb{C}$ coincides with the field of complex numbers.

Irreducibility criterion Let $D(G)$ be an m-dimensional G matrix representation. Its corresponding set of characters $\{\chi(g) \mid g \in G\}$, where $\text{tr } D(g) = \chi(g)$ is assumed, has to satisfy

$$\frac{1}{|G|} \sum_{g \in G} |\chi(g)|^2 = \begin{cases} 1, & D(G) \text{ is irreducible} \\ M > 1, & D(G) \text{ is reducible} \end{cases} \qquad [23]$$

where the integer $M > 1$ is uniquely defined by the G matrix representation in question. This criterion is simply applicable and widely used in many practical applications of group-theoretical methods.

Decomposition of reducible matrix representations The decomposition of a reducible m-dimensional G matrix representation $D^{\text{red}}(G)$ into a direct sum of its irreducible constituents is a significant problem. The consistent sequence of the corresponding decomposition formulas may be summarized as follows:

$$D^{\text{red}}(g) = \sum_{\xi \in \mathscr{A}(G)} \oplus m(\text{red}|\xi) D^{\xi}(g) \qquad [24]$$

$$m(\text{red} \mid \xi) = \frac{1}{|G|} \sum_{g \in G} \chi^{\text{red}}(g)\chi^{\xi}(g)^{*} \qquad [25]$$

$$\frac{1}{|G|} \sum_{g \in G} |\chi(g)|^2 = \sum_{\xi \in \mathscr{A}(G)} m(\text{red}|\xi) n(\xi) = M \in \mathbb{Z}^{+} \qquad [26]$$

$$W^{\dagger} D^{\text{red}}(g) W = \sum_{\xi \in \mathscr{A}(G)} \oplus m(\text{red}|\xi) D^{\xi}(g) \qquad [27]$$

$$\{W\}_{j;\xi wa} = W_{j;\xi wa} = \{\boldsymbol{W}_{\boldsymbol{a}}^{\xi \boldsymbol{w}}\}_{\boldsymbol{j}} \qquad [28]$$

$$D^{\text{red}}(g) \boldsymbol{W}_{\boldsymbol{a}}^{\xi \boldsymbol{w}} = \sum_{\boldsymbol{b}=\boldsymbol{1}}^{\boldsymbol{n}(\xi)} \boldsymbol{D}_{\boldsymbol{ba}}^{\xi}(\boldsymbol{g}) \boldsymbol{W}_{\boldsymbol{b}}^{\xi \boldsymbol{w}} \qquad [29]$$

Several remarks should be made on this set of formulas. First, it should be noted that the unitary m-dimensional similarity matrix W is nonsymmetrically indexed. The row index of W is given by $j = 1, 2, \ldots, m$, whereas its column index is fixed by the ordered triplets (ξ, w, a), where the G irrep label $\xi \in \mathscr{A}(G)$ together with the so-called multiplicity index $w = 1, 2, \ldots, m(\text{red}|\xi)$, and finally the row index $a = 1, 2, \ldots, n(\xi)$, of the G unirrep $D^{\xi}(G)$ have to be taken into account. This nonsymmetrical indexing is common to all types of similarity matrices, for instance, subduction matrices, or Clebsch–Gordan matrices as a special case of subduction matrices. Second, it should be realized that the columns $\{\boldsymbol{W}_{a}^{\xi w}\}$ of any similarity matrix may be regarded as symmetry adapted vectors, since the transformation formulas [29] represent the prototype of symmetrized states. The basic features of symmetrized states are that they are mutually orthonormal and they transform according to G unirreps. The computation of similarity matrices can be done by applying the so-called projection method, which is briefly discussed later, since the transformation formulas [29] suggest this method. Finally, it should be noted that due to Schur's lemma the similarity matrices W cannot be unique and, hence, have to be fixed by adopting appropriate conventions. The structure of unitary similarity matrices describing this ambiguity can be simply deduced by the following statement.

Schur's lemma applied to reducible representations Let G be a group and $\Phi \in \mathrm{GL}(m, \mathbb{C})$ an m-dimensional nonsingular but otherwise arbitrary matrix. Moreover, let $D^{\mathrm{red}\oplus}(G)$, which symbolizes the RHS of [27], be an m-dimensional reducible unitary G matrix representation that is already decomposed into a direct sum of its irreducible constituents. Assume that

$$[\Phi, D^{\mathrm{red}\oplus}(g)] = O \qquad [30]$$

for all group elements $g \in G$. By applying Schur's Lemma to this general situation, one immediately arrives at the following result:

$$\Phi = \sum_{\xi \in \mathscr{A}(G)} \oplus (1_{\alpha,\alpha} \otimes \Phi^{\xi}(m(\text{red}|\xi))) \qquad [31]$$

where the submatrices $\Phi^{\xi}(m(\text{red}|\xi)) \in \mathrm{GL}(m\ (\text{red}|\xi), \mathbb{C})$ are otherwise arbitrary. Of course, if $\Phi \in U(m)$, then $\Phi^{\xi}(m(\text{red}|\xi)) \in U(m(\text{red}|\xi), \mathbb{C})$ must be satisfied. The latter condition reflects the ambiguity of similarity matrices, since W and its counterpart $W\Phi$ are equally well suited to describe identically the decomposition [27], where the phase matrices of the type [31] can be chosen arbitrarily.

The second type of ambiguities emerges from the nonuniqueness of each G unirrep whose dimension is greater than 1. Since every similarity transformation of the type

$$F^{\xi}(g) = W^{\xi\dagger} D^{\xi}(g) W^{\xi} \qquad [32]$$

by means of an arbitray unitary matrix $W^{\xi} \in U(n(\xi))$, yields equivalent G unirreps, they are equally well suited to be used in any application. One then arrives at the following formulas:

$$\bar{W}^{\dagger} D^{\mathrm{red}}(g) \bar{W} = \sum_{\xi \in \mathscr{A}(G)} \oplus m(\text{red} \mid \xi) F^{\xi}(g) \qquad [33]$$

$$\bar{W} = W\Psi \qquad [34]$$

$$\Psi = \sum_{\xi \in \mathscr{A}(G)} \oplus (1_{\alpha,\alpha} \otimes \Phi^{\xi}(m(\text{red}|\xi))) \qquad [35]$$

where, for the sake of brevity, $m(\text{red} \mid \xi) = m(\alpha)$ has been employed; for $m(\alpha) = 0$, the corresponding terms vanish. The combination of both types of ambiguities, namely the occurrence of phase matrices due to Schur's lemma and the transfer to equivalent G unirreps, have led to many unnecessary controversies in the literature. Accordingly, it is generally advised that when comparing results emerging from different sources, one should check whether the intertwining matrices W can be identified by means of phase matrices of the type [31]. If this fails, then the results of at least one source are wrong.

Subduced Representations

Let $H \subset G$ be a given group–subgroup relation, where, for the sake of simplicity, the index $s \in \mathbb{Z}^{+}$ of the subgroup G in the supergroup G is assumed to be finite. Note that in the case of group–subgroup relations between space groups and sectional layer or penetration rod groups, which are briefly discussed later, this simplifying constraint would be violated. To unify the discussion, let formally

$$G = \sum_{j=1}^{s} a_j H \qquad [36]$$

be the left coset decomposition of the group G with respect to the subgroup H, where, for the sake of distinction, coset representatives $a_j \in G$ are underlined. Cosets $a_j H$ are unique, whereas coset representatives $a_j \in G$ are never unique unless the subgroup is trivial.

By definition, the restriction of any given G matrix representation, say $D(G) = \{D(g) \mid g \in G\}$, to the elements of the subgroup H is called subduced matrix representation. Symbolically,

$$D(G)\downarrow H = \{D(h) \mid h \in H\} \qquad [37]$$

which means that only the elements of the subgroup $h \in H$ have to be taken into account. Of course, if $D(G) = D^{\xi}(G)$ forms a G unirrep, then the subduced matrix representation $D^{\xi}(G)\downarrow H$ will in general be reducible. Hence, if a complete set of H unirreps, say $\{L^{\lambda}(H) \mid \lambda \in \mathscr{A}(H)\}$, are known, the corresponding decomposition of the H matrix representations $D^{\xi}(G)\downarrow H$ can be carried out along the lines discussed previously:

$$D^{\xi}(g)\downarrow H \sim \sum_{\lambda \in \mathscr{A}(H)} \oplus m(\xi|\lambda) L^{\lambda}(h) \qquad [38]$$

$$m(\xi|\lambda) = \frac{1}{|H|} \sum_{h \in H} \chi^{\xi}(h) \chi^{\lambda}(h)^{*} \qquad [39]$$

$$W^{\xi\dagger} D^{\xi}(h) W^{\xi} = \sum_{\lambda \in \mathscr{A}(H)} \oplus m(\xi|\lambda) L^{\lambda}(h) \qquad [40]$$

The generalization of these decomposition formulas to the more general situation of reducible G matrix representations subduced to H matrix representations, say $D(G)\downarrow H$, can be readily deduced from formulas [38], [39], and [40].

Clebsch–Gordan Coefficients

The problem of computing for any group G with a fixed complete set of G unirreps, say $\{D^{\xi}(G) \mid \xi \in \mathscr{A}(G)\}$, corresponding Clebsch–Gordan matrices may be viewed as a special case of constructing, for subduced matrix representations, suitable similarity matrices that transform the subduced representation into a direct sum of its subgroup constituents.

General outer direct-product groups General outer direct-product groups are groups of the type $G_1 \otimes G_2$ where the given groups G_1 and G_2 are assumed not to be isomorphic. Its group elements are, by definition, the ordered pairs (g_1, g_2), where $g_1 \in G_1$ and $g_2 \in G_2$ are chosen independently. In mathematical terms,

$$G_1 \otimes G_2 = \{(g_1, g_2) \mid g_1 \in G_1;\ g_2 \in G_2\} \qquad [41]$$

$$(g_1, g_2) * (g_1', g_2') = (g_1 g_1', g_2 g_2') \qquad [42]$$

where its composition law, given by [42], is an immediate consequence of the definition of the outer direct-product set. Moreover, the order $|G_1 \otimes G_2|$ of the outer direct-product group $G_1 \otimes G_2$ is given by the product of the orders $|G_1|$ and $|G_2|$ of the respective groups G_1 and G_2.

Special outer direct-product groups Let G be a group and the specific construction

$$G \otimes G = \{(g, g') \mid g, g' \in G)\} = G^2 \qquad [43]$$

its corresponding outer direct-product group, whose group elements are again the ordered pairs (g, g'), where, analogously to the general situation, the group elements $g, g' \in G$ are to be chosen independently. Its composition law is again given by the rule

$$(g, g') * (\tilde{g}, \tilde{g}') = (g\tilde{g}, g'\tilde{g}') \qquad [44]$$

and shows, amongst others, that for the order of the outer direct-product group, $|G \otimes G| = |G|^2$ must be valid. Obviously, the subset

$$G \boxtimes G = \{(g, g) \mid g \in G\} = G^{[2]} \sim G \qquad [45]$$

must form a subgroup of the outer direct-product group $G \otimes G$ which is isomorphic to the original group G. It is common to denote the special group $G \boxtimes G$ as a twofold Kronecker product group. The generalization to n-fold outer direct-product groups G^n and n-fold Kronecker product groups $G^{[n]}$ is immediate.

Unirreps of special outer direct-product groups The G^2 unirreps of the special outer direct-product group $G \otimes G = G^2$ are simply obtained by the construction of ordered pairs of direct matrix products of G unirreps, say $D^{\xi}(G)$ and $D^{\eta}(G)$, where $\xi, \eta \in \mathscr{A}(G)$. Accordingly, one can summarize that

$$D^{\xi \otimes \eta}(g, g') = D^{\xi}(g) \otimes D^{\eta}(g') \qquad [46]$$

$$(\xi \otimes \eta) \in \mathscr{A}(G^2) \qquad [47]$$

$$\dim D^{\xi \otimes \eta}(g, g') = n(\xi) n(\eta) \qquad [48]$$

for all $(g, g') \in G^2$, where especially the elements $(\xi, \eta) = (\xi \otimes \eta)$ of the index set $\mathscr{A}(G^2)$ of the outer direct-product group G^2 are denoted by the symbols $(\xi \otimes \eta)$ to emphasize the outer direct-product group structure. Now, if one restricts G^2 to its Kronecker product subgroup $G^{[2]}$,

$$\begin{aligned} D^{\xi \otimes \eta}(G^2)\downarrow G^{[2]} &= D^{\xi,\eta}(G) \\ &= \{D^{\xi,\eta}(g) = D^{\xi}(g) \otimes D^{\eta}(g) \mid g \in G\} \end{aligned} \qquad [49]$$

then one arrives at $n(\xi)n(\eta)$-dimensional G matrix representations, which in general are reducible.

Clebsch–Gordan matrices By definition, the corresponding similarity matrices are nothing but the unitary Clebsch–Gordan matrices whose matrix elements are the Clebsch–Gordan coefficients. In

mathematical terms

$$D^{\xi,\eta}(g) \sim \sum_{\zeta \in \mathscr{A}(G)} \oplus m(\xi,\eta|\zeta) D^{\zeta}(g) \qquad [50]$$

$$m(\xi,\eta \mid \zeta) = \frac{1}{|G|} \sum_{g \in G} \chi^{\xi}(g) \chi^{\eta}(g) \chi^{\zeta}(g)^{*} \qquad [51]$$

$$C^{\xi,\eta\dagger} D^{\xi,\eta}(g) C^{\xi,\eta} = \sum_{\zeta \in \mathscr{A}(G)} \oplus m(\xi,\eta|\zeta) D^{\zeta}(g) \qquad [52]$$

$$\{C^{\xi,\eta}\}_{jk;\zeta wa} = C^{\xi,\eta}_{jk;\zeta wa} = \left(\begin{array}{cc|c} \xi & \eta & \zeta w \\ j & k & a \end{array}\right) \qquad [53]$$

where, as already pointed out, the corresponding Clebsch–Gordan coefficients $C^{\xi,\eta}_{jk;\zeta wa}$ are nonsymmetrically indexed. The row index of Clebsch–Gordan matrices $C^{\xi,\eta}$ are given by the ordered pairs (j,k), where $j = 1,2,\ldots,n(\xi)$ and $k = 1,2,\ldots,n(\eta)$, whereas their column indices are fixed by the ordered triplets (ζ,w,a), where the G irrep label $\zeta \in \mathscr{A}(G)$ together with the so-called multiplicity index $w = 1,2,\ldots,m(\xi,\eta|\zeta)$, and finally the row index $a = 1,2,\ldots,n(\zeta)$ of the relevant G unirreps $D^{\zeta}(G)$ have to be taken into account. The round bracket symbol occurring on the RHS of [53] is frequently used to symbolize Clebsch–Gordan coefficients but many other types of symbols may appear in applications.

Needless to repeat that Clebsch–Gordan matrices are not unique, which is not only due to Schur's lemma but also to their representation dependence. Apart from this, it is worth stressing the possible appearance of the so-called multiplicity index w in the case of twofold Kronecker product decompositions. In fact, the appearance of the multiplicity index w depends on the structure of the group G in question. A group G is called simple reducible if and only if the multiplicities $m(\xi,\eta|\zeta)$ occurring in the so-called Clebsch–Gordan series [52] are at most 1. Accordingly, a group G is called simple reducible if and only if

$$0 \leqslant m(\xi,\eta|\zeta) \leqslant 1 \qquad [54]$$

is satisfied for all G irrep labels $\xi,\eta,\zeta \in \mathscr{A}(G)$. Groups of this type are, for instance, SU(2) or its homomorphic image $SO(3,\mathbb{R})$, and certainly abelian groups, whereas in particular three-dimensional crystallographic space groups $\mathscr{G}$ are nonsimple reducible. This has as an important consequence that an additional ambiguity arises in the computation of Clebsch–Gordan coefficients and their potential applications.

Induced Representations

By definition, induced matrix representations are obtained by assuming a given group–subgroup relation, say $H \subset G$ with [36] as its left coset decomposition, and extending by means of the so-called induction procedure a given H matrix representation $D(H)$ to an induced G matrix representation $D^{\uparrow G}(G)$. To be more strict, induced G matrix representations are defined by the following expressions:

$$D^{\uparrow G}_{\underline{a},\underline{b}}(g) = \delta_{\underline{a}H,g\underline{b}H} D(\underline{a}^{-1} g \underline{b}) \qquad [55]$$

$$\delta_{\underline{a}H,g\underline{b}H} = \left\{ \begin{array}{ll} 1, & \underline{a}^{-1} g \underline{b} \in H \\ 0, & \text{otherwise} \end{array} \right\} \qquad [56]$$

$$\dim D^{\uparrow G}(G) = |G:H| \dim D(H) \qquad [57]$$

where, in part, a matrix representation has been employed and the notation $|G:H| = s$ has been introduced to stress the fact that the dimensions of the induced G matrix representations increase by the index of H in G. Moreover, if $D(H)$ defines a reducible H matrix representation, then the corresponding induced G matrix representation $D^{\uparrow G}(G)$ must be reducible in any case. Conversely, if $D(H) = D^{\lambda}(H)$ defines an H unirrep, then the corresponding induced G matrix representation $D^{\lambda\uparrow G}(G)$ still need not necessarily be a G unirrep. On the contrary, induced G matrix representations of the type $D^{\lambda\uparrow G}(G)$ are in general reducible and may be decomposed into direct sums of G unirreps in the same manner as before. The corresponding decomposition formulas read

$$D^{\lambda\uparrow G}(g) \sim \sum_{\zeta \in \mathscr{A}(G)} m(\lambda\uparrow G|\zeta) D^{\zeta}(g) \qquad [58]$$

$$m(\lambda\uparrow G|\zeta) = \frac{1}{|G|} \sum_{g \in G} \chi^{\lambda\uparrow G}(g) \chi^{\zeta}(g)^{*} \qquad [59]$$

$$m(\lambda\uparrow G|\zeta) = m(\zeta\downarrow H|\lambda) \qquad [60]$$

$$S^{\lambda\uparrow G\dagger} D^{\lambda\uparrow G}(g) S^{\lambda\uparrow G} = \sum_{\zeta \in \mathscr{A}(G)} m(\lambda\uparrow G|\zeta) D^{\zeta}(g) \qquad [61]$$

$$\{S^{\lambda\uparrow G}\}_{\underline{a}k;\zeta wa} = S^{\lambda\uparrow G}_{\underline{a}k;\zeta wa} \qquad [62]$$

where the matrix elements $S^{\lambda\uparrow G}_{\underline{a}k;\zeta wa}$ of the subduction matrices $S^{\lambda\uparrow G}$ are nonsymmetrically indexed. The row indices of $S^{\lambda\uparrow G}$ are given by the ordered pairs $(\underline{a},\ k)$ where $\underline{a} \in G:H$ and $k = 1,2,\ldots,n(\lambda)$, whereas their column indices are fixed by the ordered triplets (ζ,w,a), where the G irrep label $\zeta \in \mathscr{A}(G)$ together with the so-called multiplicity index

$w = 1, 2, \ldots, m(\lambda \uparrow G|\zeta)$, and finally the row index $a = 1, 2, \ldots, n(\zeta)$ of the relevant G unirreps $D^{\zeta}(G)$ have to be taken into account. Finally, the relations [60] describe the Frobenius reciprocity law, which, for instance, is extensively discussed in several textbooks.

Group-Theoretical Methods in Physics

Up to now, exclusively group-theoretical aspects, such as their algebraic structure and associated properties, and representation-theoretic aspects with special emphasis on the decomposition of reducible representations into direct sums of their irreducible constituents have been dealt with. This section discusses how group-theoretical methods can be applied in physical applications. The physical applications cover a wide range of, not only quantum mechanics but also classical applications (e.g., classical mechanics or hydrodynamics are possible candidates for these methods). Here the discussions are confined to standard applications in quantum mechanics.

Symmetry Groups of Hamiltonians

The first task is to construct a unitary operator representation of a given group, say G, with respect to the Hilbert space $\mathscr{H}$, which is the carrier space for the considered Hamiltonian H in question. Accordingly, it is assumed that there exits a homomorphism $\varepsilon : G \to U(G)$ of the given group G into a group of unitary operators which are represented by $U(G) = \{U(g) \,|\, g \in G\}$ that map the underlying Hilbert space $\mathscr{H}$ over the field $\mathbb{C}$ onto itself.

The group G being represented by the corresponding unitary operator group $U(G) = \{U(g) \,|\, g \in G\}$ is called a symmetry group of the Hamiltonian H if and only if the Hamiltonian commutes with all unitary operators:

$$[H, U(g)] = O \quad \forall g \in G \tag{63}$$

Moreover, assume that the eigenvalue problem for the Hamiltonian H has been solved, which implies that not only the corresponding eigenvalues, denoted by $\lambda \in \mathbb{R}$, but also suitably orthonormalized eigenstates $\{\Phi_j^{\lambda} \,|\, j = 1, 2, \ldots, \deg \lambda\}$ for each eigenvalue are known. The existence of a symmetry group G of the Hamiltonian H implies

$$\begin{aligned} & H\Phi_j^{\lambda} = \lambda \Phi_j^{\lambda} \\ \Leftrightarrow\, & H(U(g)\Phi_j^{\lambda}) = \lambda(U(g)\Phi_j^{\lambda}) \end{aligned} \tag{64}$$

that the corresponding eigenspaces $\mathscr{H}^{\lambda} \subset \mathscr{H}$, which are uniquely associated with the eigenvalues $\lambda \in \mathbb{R}$ the Hamiltonian H, have to be G-invariant subspaces of the original Hilbert space $\mathscr{H}$. Clearly, the "bigger" and the "more noncommutative" the symmetry group G, the more useful the symmetry group G. Once the so-called symmetry adapted states, which are discussed below, are known, the application of Schur's lemma leads at least to a partial solution of the eigenvalue problem. Obviously, if every G-invariant subspace $\mathscr{H}^{\lambda}$ turns out to be irreducible, then the eigenvalue problem for H is completely solved, and the degeneracy of the eigenvalues is sometimes said to be generic with respect to the group G. Conversely, if some of the subspaces $\mathscr{H}^{\lambda}$ are reducible, then the degeneracy of the corresponding eigenvalues is sometimes said to be nongeneric with respect to the group G.

Symmetrization of States

One of the most popular group-theoretical applications in quantum mechanics consists of symmetry, adapting given sets of states, say $\{\Phi\} = \{\Phi_1, \Phi_2, \ldots, \Phi_n\}$. In mathematical terms, it implies that, out of the given set of states $\{\Phi\}$, some new sets of states be constructed systematically whose elements transform according to given G unirreps and are mutually orthonormal. Such bases are usually called G-symmetrized states or simply symmetry-adapted states. The standard method to achieve the symmetry adaptation of states is the so-called projection method. The set of operators

$$\{E_{jk}^{\xi}\} = \{E_{jk}^{\xi} \,|\, \xi \in \mathscr{A}(G);\ j, k = 1, 2, \ldots, n(\xi)\} \tag{65}$$

$$E_{jk}^{\xi} = \frac{n(\xi)}{|G|} \sum_{g \in G} D_{jk}^{\xi}(g)^* U(g) \tag{66}$$

are the so-called units of the corresponding group algebra $\mathscr{A}(G)$ whose general elements are arbitrary linear combinations of the group elements. Clearly, if and only if G is finite, then $|\{E_{jk}^{\xi}\}| = |G|$, which, loosely speaking, remains valid if the group G is countable or even compact continuous but has to be refined correspondingly, since the group volumes of their dual groups have to be taken into account. In fact, this represents a topological subtlety. Apart from this, one has

$$\{E_{jk}^{\xi}\}^{\dagger} = E_{kj}^{\xi} \tag{67}$$

$$E_{jk}^{\xi} E_{mn}^{\eta} = \delta_{\xi\eta} \delta_{km} E_{jn}^{\xi} \tag{68}$$

$$U(g) E_{jk}^{\xi} = \sum_{\ell=1}^{n(\xi)} D_{\ell j}^{\xi}(g) E_{\ell k}^{\xi} \tag{69}$$

$$\sum_{\xi \in \mathscr{A}(G)} \sum_{k=1}^{n(\xi)} E_{kk}^{\xi} = 1_{\mathscr{H}} \tag{70}$$

where the extra symbol $1_{\mathscr{H}}$ denotes the unit operator of the underlying Hilbert space $\mathscr{H}$. It follows from [67] and [68] that the operators $\{E^{\xi}_{kk} \mid \xi \in \mathscr{A}(G);\ k = 1, 2, \ldots, n(\xi)\}$ are projection operators, whereas the remaining operators are shift operators that intertwine mutually orthogonal subspaces that belong to any given $\xi \in \mathscr{A}(G)$ but different $k = 1, 2, \ldots, n(\xi)$.

Step 1 First, one proves that the n-dimensional subspace which is the linear hull of the set of functions $\{\Phi_1, \Phi_2, \ldots, \Phi_n\}$ denoted by $\mathscr{H}_n$ is in fact a G-invariant subspace. For simplicity, assume that the set of functions $\{\Phi\}$ forms an orthonormal basis. Accordingly, $\langle \Phi_j, \Phi_k \rangle_{\mathscr{H}} = \delta_{jk}$ for all pairs Φ_j, Φ_k of basis functions. By virtue of the transformation law given by the expressions

$$U(g)\Phi_j = \sum_{k=1}^{n} D^{\Phi}_{kj}(g)\Phi_k \qquad [71]$$

$$D^{\Phi}(g) \sim \sum_{\xi \in \mathscr{A}(G)} m(D^{\Phi}(G)|\xi) D^{\xi}(g) \qquad [72]$$

$$\begin{aligned} \dim D^{\Phi}(G) &= n \\ &= \sum_{\xi \in \mathscr{A}(G)} m(D^{\Phi}(G)|\xi) n(\xi) \end{aligned} \qquad [73]$$

one defines an n-dimensional G matrix representation, which in general forms a reducible representation. Relation [73] presents the obvious dimension check to be carried out from the outset.

Step 2 Let $m(D^{\Phi}(G)|\xi) > 0$, then one knows that the corresponding subspaces constructed by means of the projection operators

$$\mathscr{H}^{\xi,k}_n = E^{\xi}_{kk}\mathscr{H}_n \qquad [74]$$

$$\dim \mathscr{H}^{\xi,k}_n = m(D^{\Phi}(G) \mid \xi) \qquad [75]$$

have the same dimension for each $k = 1, 2, \ldots, n(\xi)$, as otherwise the projection method would contain inconsistencies.

Step 3 Next, one constructs for the fixed G irrep label $\xi \in \mathscr{A}(G)$ (where $m(D^{\Phi}(G)|\xi) > 0$ is assumed) and for a fixed row index, say $k = k_0 = 1$, an orthonormalized basis of the $m(D^{\Phi}(G)|\xi)$-dimensional subspace $\mathscr{H}^{\xi,k_0}_n$ by applying the Gram–Schmidt orthonormalization procedure. Symbolically, as a result of the projection method,

$$E^{\xi}_{k_0k_0}\{\Phi\} \to \{\Psi^{\xi,w}_{k_0} \mid w = 1, 2, \ldots, m(D^{\Phi}(G)|\xi)\} \qquad [76]$$

$$\langle \Psi^{\xi,w}_{k_0}, \Psi^{\xi,v}_{k_0} \rangle_{\mathscr{H}} = \delta_{wv} \qquad [77]$$

Step 4 In order to obtain for the fixed G irrep label $\xi \in \mathscr{A}(G)$ (where $m(D^{\Phi}(G)|\xi) > 0$ is assumed) the remaining partner functions, one has to employ the corresponding shift operators:

$$\Psi^{\xi,w}_j = E^{\xi}_{jk_0}\Psi^{\xi,w}_{k_0}, \quad j = 1, 2, \ldots, n(\xi) \qquad [78]$$

$$\langle \Psi^{\xi,w}_j, \Psi^{\xi,v}_{\ell} \rangle_{\mathscr{H}} = \delta_{wv}\delta_{j\ell} \qquad [79]$$

$$U(g)\Psi^{\xi,w}_j = \sum_{\ell=1}^{n(\xi)} D^{\xi}_{\ell j}(g)\Psi^{\xi,w}_{\ell} \qquad [80]$$

Step 5 Finally, in order to obtain a complete basis of the n-dimensional G-invariant subspace $\mathscr{H}_n$ that consists of G-symmetrized states which are mutually orthonormal and which satisfy the transformation law [80], one has to repeat the steps described previously for all G irrep labels $\xi \in \mathscr{A}(G)$, where the corresponding multiplicities $m(D^{\Phi}(G)|\xi)$ are different from zero.

Coupling of Product States

Another important application of group-theoretical methods in quantum mechanics concerns the coupling of states, where the constituents are assumed to transform according to G unirreps, and where the coupled product states likewise should possess specific transformation properties. Let $\Psi^{\xi}_j \in \mathscr{H}_1$ and, equivalently, $\Phi^{\eta}_k \in \mathscr{H}_2$ be two sets of G-symmetrized states, where states of the type

$$\Lambda^{\xi\otimes\eta}_{jk} = \Psi^{\xi}_j \otimes \Phi^{\eta}_k \in \mathscr{H}_1 \otimes \mathscr{H}_2 \qquad [81]$$

should be transformed into such linear combinations, so that the new states transform according to G unirreps of the twofold Kronecker product group $G^{[2]}$ which is isomorphic to G. Starting from the transformation law

$$\begin{aligned} &U(g, g')\Lambda^{\xi\otimes\eta}_{jk} \\ &\quad = \sum_{j'=1}^{n(\xi)} \sum_{k'=1}^{n(\eta)} \{D^{\xi\otimes\eta}(g)\}_{j'k',jk}\Lambda^{\xi\otimes\eta}_{j'k'} \end{aligned} \qquad [82]$$

which refers to the special outer direct-product group $G \otimes G$, one readily infers that the product states [81] transform according to G^2 unirreps. The aim is to find such linear combinations of the states [81] such that they transform according to G unirreps. The desired transformation coefficients are just the

corresponding Clebsch–Gordan coefficients:

$$\Theta_a^{\xi\otimes\eta;\zeta,w} = \sum_{j=1}^{n(\xi)} \sum_{k=1}^{n(\eta)} \left(\begin{matrix} \xi & \eta \\ j & k \end{matrix} \middle| \begin{matrix} \zeta w \\ a \end{matrix} \right) \Lambda_{jk}^{\xi\otimes\eta} \quad [83]$$

$$U(g,g)\Theta_a^{\xi\otimes\eta;\zeta,w} = \sum_{b=1}^{n(\zeta)} D_{ba}^{\zeta}(g)\Theta_b^{\xi\otimes\eta;\zeta,w} \quad [84]$$

This type of coupling of product states is frequently used in describing atomic spectra, where the orbital angular momenta are coupled and independently, the spin degree of freedom. The corresponding scheme of coupled states is well known as LS coupling.

Selection Rules – Wigner – Eckart Theorem

The most important, and certainly the most frequently used, application of group-theoretical methods in quantum mechanics concerns the well-known Wigner–Eckart theorem. In order to formulate the Wigner–Eckart theorem, one has to define the so-called irreducible tensor operators with respect to the group G in question and a complete set of G-symmetrized states. The latter are formally abbreviated as $\{\Psi_\ell^{\xi,n}\}$, where the extra index $n \in \mathbb{N}$ subsumes the additional quantum numbers that are not correlated to the G irrep labels.

Irreducible tensor operators A set of operators denoted by the symbol $T^\beta = \{T_k^\beta \mid \beta \in \mathscr{A}(G);\ k = 1, 2, \ldots, n(\beta)\}$, which consists of $n(\beta)$ tensor components T_k^β, is called irreducible tensor operator of rank β with respect to the group G if and only if the following transformation law is satisfied for all group elements $g \in G$:

$$U(g)T_k^\beta U(g)^\dagger = \sum_{j=1}^{n(\beta)} D_{jk}^\beta(g)T_j^\beta \quad [85]$$

Note that an arbitrary operator cannot be identified with a component of an irreducible tensor operator with respect to the group G in question. The decomposition of an arbitrary operator into its irreducible tensor components with respect to the group G can be done along the lines of the symmetrization procedure discussed previously for arbitrary states of the Hilbert space $\mathscr{H}$.

Wigner–Eckart theorem Let G be a group, $\{D^\xi(G)\}$ a complete set of G unirreps, $\{\Psi_\ell^{\xi,n}\}$ a complete set of G–symmetrized states of the underlying Hilbert space $\mathscr{H}$, and finally T^β a given irreducible tensor operator of rank $\beta \in \mathscr{A}(G)$ with respect to the given group G. The crucial point of the Wigner–Eckart theorem consists of the fact that the matrix elements of T_k^β with respect to G-symmetrized states can be factorized in a specific manner, namely

$$\langle \Psi_\ell^{\xi,n}, T_k^\beta \Psi_j^{\zeta,m} \rangle_{\mathscr{H}} = \sum_{w=1}^{m(\beta,\zeta|\xi)} \left(\begin{matrix} \beta & \zeta \\ k & j \end{matrix} \middle| \begin{matrix} \xi w \\ \ell \end{matrix} \right)^* \langle \Psi^{\xi,n} || T^\beta || \Psi^{\zeta,m} \rangle_w \quad [86]$$

where the second factors $\langle \Psi^{\xi,n} || T^\beta || \Psi^{\zeta,m} \rangle_w$ occurring on the RHS of [86] are called reduced matrix elements of the G irreducible tensor operator. The reduced matrix elements $\langle \Psi^{\xi,n} || T^\beta || \Psi^{\zeta,m} \rangle_w$ by definition must not depend on the row indices k, j, ℓ of the corresponding G unirreps. Moreover, the reduced matrix elements $\langle \Psi^{\xi,n} || T^\beta || \Psi^{\zeta,m} \rangle_w$ contain the "physics," whereas the Clebsch–Gordan coefficients are pure group-theoretical entities which have nothing to do with the physics of the problem considered, and hence are sometimes called geometrical factors. The proof of the Wigner–Eckart theorem relies, among others, upon the use of the orthogonality relations [14] of the G unirreps and of the Clebsch–Gordan series [52]. In the case of simple reducible groups (e.g., SU(2)), the corresponding Wigner–Eckart theorem reads

$$\langle \Psi_m^{j,n}, T_M^J \Psi_{m'}^{j',n'} \rangle_{\mathscr{H}} = \left(\begin{matrix} J & j' \\ M & m' \end{matrix} \middle| \begin{matrix} j \\ m \end{matrix} \right) \langle \Psi^{j,n} || T^J || \Psi^{j',n'} \rangle \quad [87]$$

where, in addition, the fact has been exploited that the corresponding SU(2) Clebsch–Gordan coefficients are real. The simplified version of the Wigner–Eckart theorem for simple reducible groups is likewise utilized to simplify the computation of the reduced matrix elements of irreducible tensor operators by applying the method of the so-called equivalent operators in the crystal field theory. The specifically simple form of the Wigner–Eckart theorem for the group SU(2) might not reflect the general complexity of the method; in general for nonsimple reducible groups, such as SU(3), or especially the three-dimensional crystallographic space groups, nontrivial multiplicities $m(\beta, \zeta|\xi) > 1$ occur and hence complicate the problem of the factorization of the considered matrix elements into Clebsch–Gordan coefficients and reduced matrix elements that explicitly depend on the multiplicity index w.

Selection rules Apart from this, the merits of Wigner–Eckart's theorem primarily rely upon the property that if the corresponding Clebsch–Gordan coefficients vanish, which exclusively emerges from the structure of the group G and the chosen G unirreps, the considered matrix elements also vanish. Thus, this conclusion follows exclusively from the Clebsch–Gordan coefficients and not from the actual form of the G-irreducible tensor operator; hence, in

all such cases, one need not compute the corresponding reduced matrix elements. Not surprisingly, this is an important statement when investigating selection rules, such as the Stark effect for the spectral properties of the hydrogen atom, or when dealing with electron–phonon interactions in solids. However, if the respective Clebsch–Gordan coefficients are nonzero, then one has to compute the corresponding reduced matrix elements, but which might be much more complicated than to simply compute directly the original matrix elements.

Group Theory in Materials Science, Applications

R Dirl and P Weinberger, Vienna University of Technology, Vienna, Austria

Applications in Materials Science

The potential applications of group-theoretical methods in solid-state physics – synonymous for materials science – depend on the various groups that are specific for this field. For instance, the compact continuous groups SU(2) or its homomorphic image $SO(3,\mathbb{R})$ are widely used in multiple scattering theory. Proper point groups as specific finite subgroups of $SO(3,\mathbb{R})$ are employed when investigating macroscopic properties of materials that are described by tensors of certain ranks. Crystallographic space groups containing Bravais vector lattices as countable subgroups are taken into account when describing bulk properties of materials. Moreover, sectional layer groups might turn out to be of decisive importance when discussing surface properties of materials, since they describe the symmetries of crystallographic planes. Finally, penetration rod groups may eventually become important when investigating one-dimensional defects in some materials.

Point Groups – Macroscopic Properties

Proper crystallographic point groups $\mathscr{P}(\mathscr{T}(\mathscr{L}))$ are, by definition, intersection groups of the type $SO(3,\mathbb{R}) \cap SL(3,\mathbb{Z})$ where the symbol $SL(3,\mathbb{Z})$ denotes the group of all integral 3×3 matrices with $\det \mathbb{Z}(z) = +1$ such that, in addition, a certain Bravais lattice $\mathscr{T}(\mathscr{L})$ is mapped by these matrices onto itself. Proper noncrystallographic point groups $\mathscr{P}$ are, by definition, finite subgroups of the proper rotation group $SO(3,\mathbb{R})$ which are not constrained by the invariance condition of Bravais vector lattices. Macroscopic properties of materials, such as stress or conductivity, are described by tensors of certain ranks which in the presence of symmetry are invariant with respect to the symmetry group G in question. For instance, the invariance condition implies, for a second rank tensor $\{T_{jk} \mid j,k = 1,2,3\}$,

$$\sum_{j,k=1}^{3} T_{jk} R_{jm}(R)\, R_{kn}(R) = T_{mn} \quad \forall R \in \mathscr{P} \qquad [1]$$

that, depending on the symmetry group $\mathscr{P}$, certain tensor components vanish for symmetry reasons. For instance, in cubic symmetry tensors of rank two are proportional to the three-dimensional unit matrix.

Crystallographic Space Groups

A proper description of bulk properties in solids requires the introduction of three-dimensional crystallographic space groups which, loosely speaking, can be seen as the invariance groups of three-dimensional periodic structures. The basic constituents of space groups are their underlying Bravais vector lattices $\mathscr{T}(\mathscr{L})$ and admissible crystallographic point groups $\mathscr{P}$ that leave the Bravais vector lattice $\mathscr{T}(\mathscr{L})$ invariant. Possible structures of space groups and their classification schemes are discussed later.

Bravais vector lattices Let $\{\boldsymbol{t}_1, \boldsymbol{t}_2, \boldsymbol{t}_3\}$ be a set of three linearly independent (noncoplanar) vectors of the Euclidean vector space $\boldsymbol{E}^3_{\mathbb{R}}$ where the latter is

regarded as the vector space component of the underlying Euclidean point space $\mathsf{E}^3_{\mathbb{R}}$. To simplify the notation, let $\boldsymbol{t} = (\boldsymbol{t}_1, \boldsymbol{t}_2, \boldsymbol{t}_3)$ be formally denoted as row vector and $\underline{n} \in \mathbb{Z}^3$ as column vectors with integral coefficients. Then, by definition,

$$\mathscr{T}(\mathscr{L}) = \{\boldsymbol{t} = \boldsymbol{t} \cdot \underline{n} \mid \underline{n} \in \mathbb{Z}^3\} \qquad [2]$$

$$\boldsymbol{t} = \boldsymbol{e}\, \mathbb{D}\,(\mathscr{L}) \qquad [3]$$

where the countable set of vectors denoted by $\mathscr{T}(\mathscr{L})$ determines uniquely a Bravais vector lattice which can be traced back by means of an appropriate three-dimensional nonsingular matrix $\mathbb{D}\,(\mathscr{L}) \in \mathrm{SL}(3, \mathbb{R})$ with $\det \mathbb{D}\,(\mathscr{L}) > 0$ to an orthonormalized basis $\boldsymbol{e}$ of the associated Euclidean vector space $\boldsymbol{E}^3_{\mathbb{R}}$. It is worth noting that the positive sign of the determinant guarantees the right-handedness of the associated coordinate system. Apart from this, the symbol $\boldsymbol{t} \cdot \underline{n}$ should be seen as formal scalar product and likewise $\boldsymbol{e}\, \mathbb{D}\,(\mathscr{L})$ are the formal multiplication of a row vector times a 3×3 matrix. Moreover, one can define

$$\boldsymbol{t}(z) = \boldsymbol{t}\mathbb{Z}(z) \quad \forall \mathbb{Z}(z) \in \mathrm{SL}(3, \mathbb{Z}) \qquad [4]$$

countable infinitely many vector bases for one and the same Bravais vector lattice $\mathscr{T}(\mathscr{L})$, since the group $\mathrm{SL}(3, \mathbb{Z})$ is countably infinite. Accordingly, the corresponding vector bases $\boldsymbol{t}(z)$ are equally well suited to describe one and the same Bravais vector lattice. Hence, the choice of standardized vector bases, such as vectors of the shortest lengths, is subject to certain conventions to achieve this goal.

Automorphisms of vector lattices – point groups To understand the structure of crystallographic space groups, one first has to understand the structure of crystallographic point groups $\mathscr{P}(\mathscr{T})$ that leave a certain Bravais vector lattice $\mathscr{T}(\mathscr{L})$ invariant. Obviously,

$$\mathrm{Aut}(\mathscr{T}) = \mathrm{GL}(3, \mathbb{Z}) \qquad [5]$$

which implies that the "automorphism group" $\mathrm{Aut}(\mathscr{T})$ is the most general group that leaves the Bravais vector lattice $\mathscr{T}$ invariant, where $\mathrm{GL}(3, \mathbb{Z})$ contains $\mathrm{SL}(3, \mathbb{Z})$ as normal subgroup of index two. To assure that the point group $\mathscr{P}(\mathscr{T})$ contains only orthogonal transformations, one demands the restricting condition

$$\mathscr{P}(\mathscr{T}) = \mathrm{O}(3, \mathbb{R}) \cap \mathrm{GL}(3, \mathbb{Z}) \qquad [6]$$

in order to guarantee a maximal set of orthogonal symmetry operations that leave the Bravais vector lattice $\mathscr{T}$ invariant. The action of the point group operations $R \in \mathscr{P}(\mathscr{T})$ onto the elements of the primitive vector basis $\boldsymbol{t}$ is given by

$$R\boldsymbol{t}_j = \sum_{k=1}^{3} Z_{kj}(R)\boldsymbol{t}_k \qquad [7]$$

where the additional condition $Z(R) \in \mathrm{GL}(3, \mathbb{Z})$ must be satisfied for all group elements $R \in \mathscr{P}(\mathscr{T})$ of the crystallographic point group. The actual form of the matrix representation $\{Z(R)\}$ is characteristic of the corresponding crystal class, once the associated crystal system has been determined for the Bravais vector lattice $\mathscr{T}$ in question.

Space groups – gross classification The easiest access to crystallographic space groups is to start from the locally compact continuous "Euclidean group" $E(3, \mathbb{R})$ which is composed of the locally compacts three-dimensional continuous translation group $T(3, \mathbb{R})$ and the full rotation group $O(3, \mathbb{R})$:

$$E(3, \mathbb{R}) = T(3, \mathbb{R}) \circledS O(3, \mathbb{R}) \qquad [8]$$

which symbolizes a semidirect product group between the translation group and the full rotation group. The Euclidean group $E(3, \mathbb{R})$ is the most general motion group whose corresponding transformations map the Euclidean vector space $\boldsymbol{E}^3_{\mathbb{R}}$ onto itself, such that not only the distance between two vectors, but also the angle between them remains invariant. The nonsingular transformations $\mathscr{M}(S \mid \boldsymbol{v})$ that are uniquely assigned to the groups elements $(S \mid \boldsymbol{v}), (X \mid \boldsymbol{w}) \in E(3, \mathbb{R})$ are given by the following expressions:

$$\mathscr{M}(S \mid \boldsymbol{v})\boldsymbol{x} = S\boldsymbol{x} + \boldsymbol{v} = \boldsymbol{x}' \in \boldsymbol{E}^3_{\mathbb{R}} \qquad [9]$$

$$\mathscr{M}(S \mid \boldsymbol{v})\mathscr{M}(X \mid \boldsymbol{w}) = \mathscr{M}(SX \mid \boldsymbol{v} + S\boldsymbol{w}) \qquad [10]$$

where the so-called Wigner–Seitz symbols are used to denote the group elements of the Euclidean group. In order to combine consistently the various notations, one may express an arbitrary element of the Euclidean vector space $\boldsymbol{E}^3_{\mathbb{R}}$ as follows $\boldsymbol{x} = \boldsymbol{e} \cdot \underline{x}$, where $\underline{x} \in \mathbb{R}^3$ are the corresponding column vectors with real-valued components. Finally, the composition law of the Euclidean group $E(3, \mathbb{R})$ is given by [10] in terms of the nonsingular transformations.

By definition, space groups (hereafter sometimes denoted by the shorthand notation $\mathscr{G}$) are countable subgroups of the Euclidean group $E(3, \mathbb{R})$ where the locally compact continuous translation group $T(3, \mathbb{R})$ is reduced to one of the noncountable infinitely many Bravais vector lattices $\mathscr{T}$ and where the full rotation group $O(3, \mathbb{R})$ is reduced to the utmost maximal crystallographic point group $\mathscr{P}(\mathscr{T})$ that leaves the underlying Bravais vector lattice $\mathscr{T}$ by its orthogonal transformations invariant. In mathematical

terms, one writes

$$\mathcal{G} = \{\mathcal{T}, \mathcal{P} \mid \mathcal{O}, \boldsymbol{w}_{\mathcal{P}}\} \qquad [11]$$

to symbolize space groups. Here, the entry $\mathcal{T}$ denotes the Bravais vector lattice and $\mathcal{P}$ its corresponding crystallographic point group which satisfies the group–subgroup relation $\mathcal{P}_{\min} \subseteq \mathcal{P} \subseteq \mathcal{P}_{\max}$, where $\mathcal{P}_{\min}$ and its corresponding counterpart $\mathcal{P}_{\max}$ are determined by the associated arithmetic class of space group types. Moreover, the symbol $\mathcal{O}$ denotes the chosen origin of the associated coordinate system and $\boldsymbol{w}_{\mathcal{P}} \in \boldsymbol{E}^3_{\mathbb{R}}$, the set of nonprimitive translations which are likewise called "fractional translations." They are uniquely assigned to the point group elements $R \in \mathcal{P}$. Accordingly,

$$\boldsymbol{w}_{\mathcal{P}} = \{\boldsymbol{w}_R = \boldsymbol{t} \cdot \underline{w}_R \mid R \in \mathcal{P}\} \qquad [12]$$

where the components $\underline{w}_R \in \mathbb{Q}^3$ of the fractional translations become rational numbers if the origin $\mathcal{O}$ of the space group G is suitably chosen. The corresponding space group elements are denoted by $(R \mid \boldsymbol{w}_R + \boldsymbol{t}) \in \mathcal{G}$, where again the Wigner–Seitz notation is employed. The composition law of each space group $\mathcal{G}$ must follow automatically from the composition law [10] the Euclidean group $E(3, \mathbb{R})$ due to their group–subgroup relation. To be more specific

$$\begin{aligned}(R \mid \boldsymbol{w}_R + \boldsymbol{t}) * (S \mid \boldsymbol{w}_S + \boldsymbol{v}) \\ = (RS \mid \boldsymbol{w}_{RS} + \boldsymbol{t}_{R,S} + \boldsymbol{t} + R\boldsymbol{v})\end{aligned} \qquad [13]$$

$$\boldsymbol{t}_{R,S} = \boldsymbol{w}_R + R\boldsymbol{w}_S - \boldsymbol{w}_{RS} \qquad [14]$$

where the closure relation for the space group $\mathcal{G}$ implies $\boldsymbol{t}_{R,S} \in \mathcal{T}$ for all point group elements $R, S \in \mathcal{P}$. This allows one to classify the space groups into two significantly different types, namely "symmorphic" and "nonsymmorphic" space group types. The criterion reads

$$\text{Symmorphic } \mathcal{G}: \quad \boldsymbol{t}_{R,S} = 0 \quad \forall R, S \in \mathcal{P} \qquad [15]$$

$$\text{Nonsymmorphic } \mathcal{G}: \quad \boldsymbol{t}_{R,S} \neq 0 \quad \exists R, S \in \mathcal{P} \qquad [16]$$

which simply shows that symmorphic space groups can be seen as semidirect product groups, whereas nonsymmorphic space groups are more general extensions. As a matter of fact, there exist 230 space group types which split into 73 mutually disjoint arithmetic classes, where each arithmetic class is led by a symmorphic space group type.

$\mathcal{G}$-Invariant atomic arrangements The simplest model for a crystal is the static arrangement of atoms (molecules, clusters, etc.) where it suffices to fix some atomic positions within one primitive cell $\mathcal{P}(\mathcal{T})$ and to exploit its space group symmetry to obtain an infinitely extended periodic structure. Here the symbol $\mathcal{P}(\mathcal{T})$ denotes the primitive cell of the Bravais vector lattice $\mathcal{T}$ that is nothing but the parallelepiped spanned by the primitive basis vectors $\boldsymbol{t}$. Atomic positions in $\mathcal{P}(\mathcal{T})$ are denoted by $\boldsymbol{x} \in \mathcal{P}(\mathcal{T})$ and are classified by the so-called "Wyckoff positions." Here, for simplicity $G = (R \mid \boldsymbol{w}_R + \boldsymbol{t}) \in \mathcal{G}$ a shorthand notation for the space group elements is introduced as

$$\mathcal{G}(\boldsymbol{x}_j) = \{G \in \mathcal{G} \mid \mathcal{M}(G)\boldsymbol{x}_j = \boldsymbol{x}_j\} \qquad [17]$$

$$\{\boldsymbol{x}_j(\mathcal{G})\} = \{\boldsymbol{x}_j(G) = \mathcal{M}(G)\boldsymbol{x}_j \mid G \in \mathcal{G} : \mathcal{G}(\boldsymbol{x}_j)\} \qquad [18]$$

Groups of the type $\mathcal{G}(\boldsymbol{x}_j)$ defined by [17] are called site groups. Infinite sets $\{(\boldsymbol{x}_j)\mathcal{G}\}$ defined by [18] are called single site atomic arrangements. Two positions, say $\boldsymbol{x}_j$ and $\boldsymbol{x}_k$, are called $\mathcal{G}$ equivalent if and only if, there exists at least one space group element $G \in \mathcal{G}$ such that $\mathcal{M}(G)\boldsymbol{x}_j = \boldsymbol{x}_k$. Their site groups are then conjugate subgroups with respect to the space group $\mathcal{G}$ in question. However, if one cannot find a space group element $G \in \mathcal{G}$ such that the previous condition holds, then the two positions are called $\mathcal{G}$ inequivalent. The union of mutually disjoint single site atomic arrangements defined by

$$\begin{aligned}\{\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n, \mathcal{G}\} \\ = \{\boldsymbol{x}_1(\mathcal{G})\} \cup \{\boldsymbol{x}_2(\mathcal{G})\} \cup \cdots \{\boldsymbol{x}_n(\mathcal{G})\}\end{aligned} \qquad [19]$$

is regarded as a multiple-site atomic arrangement which describes a periodic structure that possesses the space group $\mathcal{G}$ as its symmetry group. The notion of Wyckoff position is synonymous for connected subsets of the primitive cell $\mathcal{P}(\mathcal{T})$, whose points (vectors) possess image groups $\mathcal{P}(\boldsymbol{x}_j) \sim \mathcal{G}(\boldsymbol{x}_j)$ that are conjugated subgroups with respect to its crystallographic point group $\mathcal{P}$. Wyckoff positions may consist of isolated points, lines, planes, or compact subsets of $\mathcal{P}(\mathcal{T})$. This specific classification of points $\boldsymbol{x} \in \mathcal{P}(\mathcal{T})$ is of importance in physical applications. Since different elements or any fixed Wyckoff position must have the same point group symmetry, it may or may not lead to a change of energy when the atoms vary their positions within one Wyckoff position.

Space group–subgroup relations Group–subgroup relations between crystallographic space groups play a decisive role in structural phase transitions which are accompanied by changes in the symmetry. Usually, one assumes that the space group $\mathcal{H}$ of the distorted phase is a proper subgroup (of finite

index) of the space group $\mathcal{G}$ of the parent phase which implies that $\mathcal{H} \subset \mathcal{G}$. Due to the reduction of the symmetry at the phase transition, the distorted phase can appear in several homogeneous simultaneously coexisting states which have the same structure but different orientations and/or locations in space. Let $\mathcal{G} = \{\mathcal{T}, \mathcal{P} \mid \mathcal{O}, \boldsymbol{w}_{\mathcal{P}}\}$ be the superspace group and $\mathcal{H} = \{\mathcal{S}, \mathcal{Q} \mid \mathcal{O}', \boldsymbol{w}_{\mathcal{Q}}\}$ be the subspace group of the former. In fact, three significant different types of group–subgroup relations are possible, namely

$$\text{translationsgleiche}: \quad \mathcal{S} = \mathcal{T}, \ \ \mathcal{Q} \subset \mathcal{P} \qquad [20]$$

$$\text{klassengleiche}: \quad \mathcal{S} \subset \mathcal{T}, \ \ \mathcal{Q} = \mathcal{P} \qquad [21]$$

$$\text{general}: \quad \mathcal{S} \subset \mathcal{T}, \ \ \mathcal{Q} \subset \mathcal{P} \qquad [22]$$

where by means of "Hermann's theorem," it can be shown that every general group–subgroup relation between space groups can be traced back to various chains of maximal *translationsgleiche* or *klassengleiche* subspace groups. Group–subgroup relations of infinite index are given by V Kopsky and D B Litvin in 2002 in the International Tables for Crystallography, Volume E, Subperiodic Groups, where sectional layer groups and penetration rod groups are discussed as subgroups of three-dimensional crystallographic space groups.

Space Group Unirreps

This section focuses on the representation theory of space groups with special emphasis on their unirreps. It is well known that space group unirreps can be constructed systematically by applying Mackey's induction procedure, which is exhaustively discussed by C J Bradley and A P Cracknell in 1972 in The Mathematical Theory of Symmetry in Solids. Mackey's induction procedure relies, among others, on the assumption that the given group G possesses a normal subgroup N whose unirreps are known. Specifying these assumptions to space groups, it implies that one should start from the well-known one-dimensional $\mathcal{T}$ unirreps, since every crystallographic space group $\mathcal{G}$ contains a Bravais vector lattice $\mathcal{T}$ as its natural normal subgroup.

Reciprocal vector lattices In order to be able to define the $\mathcal{T}$ unirreps, one has to define first the corresponding reciprocal vector lattice $\mathcal{T}^\star$ together with its corresponding "Brillouin zone" $\mathcal{B}(\mathcal{T}^\star)$

$$\mathcal{T}^\star = \{\boldsymbol{K} = \boldsymbol{K} \cdot \underline{n} \mid \underline{n} \in \mathbb{Z}^3\} \qquad [23]$$

$$\boldsymbol{t}_j \cdot \boldsymbol{K}_l = 2\pi\delta_{jl} \qquad [24]$$

By definition, the vectors $\boldsymbol{K} = \{\boldsymbol{K}_1, \boldsymbol{K}_2, \boldsymbol{K}_3\}$, formally written as row vectors, form the basis of the corresponding reciprocal lattice $\mathcal{T}^\star$, where $\mathcal{T}$ is the underlying direct vector lattice. The Brillouin zone $\mathcal{B}(\mathcal{T}^\star)$ is the counterpart of the Wigner–Seitz cell of the underlying direct vector lattice. The primitive cell $\mathcal{P}(\mathcal{T}^\star)$ is spanned as parallelepiped by the basis vectors $\boldsymbol{K}$. Recall that $\mathcal{P}(\mathcal{T}^\star)$ and its symmetrical counterpart $\mathcal{B}(\mathcal{T}^\star)$ are equally well suited to describe the basic domains of the reciprocal vector lattice $\mathcal{T}^\star$.

$\mathcal{T}$ Unirreps Since $\mathcal{T}$ forms an abelian group, its unirreps over the field $\mathbb{C}$ of complex numbers are one-dimensional, which implies that they are unimodular numbers. In fact,

$$D^{\boldsymbol{k}}(E|\boldsymbol{t}) = \mathrm{e}^{-i\boldsymbol{k}\cdot\boldsymbol{t}} \qquad [25]$$

$$\boldsymbol{k} = \alpha\boldsymbol{K}_1 + \beta\boldsymbol{K}_2 + \gamma\boldsymbol{K}_3 \qquad [26]$$

where not only $\boldsymbol{k} \in \mathcal{B}(\mathcal{T}^\star)$ but also $\boldsymbol{t} \in \mathcal{T}$ should be taken into account. It is to be noted that the $\mathcal{T}$ irrep label $\boldsymbol{k} \in \mathcal{B}(\mathcal{T}^\star)$ varies continuously over the Brillouin zone. For instance, in the case of primitive cubic Bravais vector lattices, the corresponding continuous parameters have $-1/2 < \alpha, \beta, \gamma \leqslant +1/2$ their domains of definitions to avoid double counting of eventually superfluous $\mathcal{T}$ irrep labels.

Periodic boundary conditions Once the so-called "periodic boundary conditions" are imposed to any given Bravais vector lattice $\mathcal{T}$, it implies that only finite homomorphic image of the originally countable Bravais vector lattice are considered. This reduces the originally compact continuous Brillouin zone $\mathcal{B}(\mathcal{T}^\star)$ to a finite set of vectors. Hence, the original continuous parameters α, β, γ become discrete and lose their continuity properties. Usually, periodic boundary conditions are introduced to avoid mathematical difficulties that arise from the fact that the $\mathcal{T}$ unnirreps (see eqn [25]) are normalized to delta functions. On the other hand, they reduce to ordinary Kronecker delta functions if periodic boundary conditions are imposed. Closely related to these difficulties is the fact that Bloch functions, which are associated with infinitely extended crystals, cannot be normalized to unity, since their ℓ_2 norms do not exist for fundamental reasons.

Little group unirreps The next step in Mackey's induction procedure consists of determining the corresponding little group $\mathcal{G}(\boldsymbol{k}) \subseteq \mathcal{G}$ for each $\mathcal{T}$ irrep label $\boldsymbol{k} \in \mathcal{B}(\mathcal{T}^\star)$. Once this is done, the corresponding

$\mathscr{G}(\boldsymbol{k})$ unirreps are computed. To summarize,

$$\mathscr{G}(\boldsymbol{k}) = \{G \in \mathscr{G} \mid D^{\boldsymbol{k}}(G^{-1}(E|\boldsymbol{t})G) = D^{\boldsymbol{k}}(E|\boldsymbol{t})\} \quad [27]$$

$$\mathscr{P}(\boldsymbol{k}) \sim \mathscr{G}(\boldsymbol{k})/\mathscr{T} \subseteq \mathscr{P} \quad [28]$$

$$\mathscr{P}(\boldsymbol{k}) = \{R \in \mathscr{P} \mid R\ \boldsymbol{k} = \boldsymbol{k} + \boldsymbol{K}(\boldsymbol{k}, R)\} \quad [29]$$

where, in particular, it is assumed that $\boldsymbol{K}(\boldsymbol{k}, R) \in \mathscr{T}^{\star}$ for all point group elements $R \in \mathscr{P}$. The homomorphic images $\mathscr{P}(\boldsymbol{k})$ of the little groups $\mathscr{G}(\boldsymbol{k})$ are usually called "little co-groups." It is to be noted that

$$\boldsymbol{K}(\boldsymbol{k}, RS) = \boldsymbol{K}(\boldsymbol{k}, R) + R\boldsymbol{K}(\boldsymbol{k}, S) \quad [30]$$

must be valid for all point group elements $R, S \in \mathscr{P}(\boldsymbol{k})$ as, otherwise, the closure condition for the little co-group $\mathscr{P}(\boldsymbol{k})$ would be violated. The closure condition [30] plays an important role when symmetrizing plane waves or any other type of wave functions. It is seen in this context that the reciprocal lattice vectors $\boldsymbol{K}(\boldsymbol{k}, R) \in \mathscr{T}^{\star}$ may only occur if and only if, the associated $\boldsymbol{k} \in \mathscr{B}(\mathscr{T}^{\star})$ belongs to the surface of the Brillouin zone $\mathscr{B}(\mathscr{T}^{\star})$ as otherwise they are zero.

Apart from this, corresponding $\mathscr{G}(\boldsymbol{k})$ unirreps are usually obtained by computing suitable $\mathscr{P}(\boldsymbol{k})$ unirreps. Provided the underlying space group G is symmorphic, suitable $\mathscr{P}(\boldsymbol{k})$ unirreps have to be ordinary vector unirreps. However, if the underlying space group $\mathscr{G}$ is nonsymmorphic, suitable $\mathscr{P}(\boldsymbol{k})$ unirreps are the so-called projective $\mathscr{P}(\boldsymbol{k})$ unnirreps. Nevertheless, the use of projective representations is merely an auxiliary tool which simplifies the construction of $\mathscr{P}(\boldsymbol{k})$ unirreps significantly. Accordingly, suitable $\mathscr{P}(\boldsymbol{k})$ unirreps are constrained by the following condition:

$$D^{\xi}(R)D^{\xi}(R) = \mathscr{F}^{\boldsymbol{k}}(R, S)D^{\xi}(RS) \quad [31]$$

$$\mathscr{F}^{\boldsymbol{k}}(R, S) = \exp(-\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{t}_{R,S}) \quad [32]$$

for all point group elements $R, S \in \mathscr{P}(\boldsymbol{k})$ and where the special translations $\boldsymbol{t}_{\underline{R},\underline{S}} \in \mathscr{T}$ are defined by [14]. As previously noted, these vectors vanish, if the space group $\mathscr{G}$ is symmorphic, and hence the corresponding $\mathscr{P}(\boldsymbol{k})$ unirreps are ordinary vector representations. However, if the space group $\mathscr{G}$ is nonsymmorphic, the corresponding $\mathscr{P}(\boldsymbol{k})$ unirreps may be projective representations, since some $\boldsymbol{t}_{\underline{R},\underline{S}} \in \mathscr{T}$ may be nonzero. By definition, the constructions

$$D^{\xi,\boldsymbol{k}}(R|\boldsymbol{w}_R + \boldsymbol{t}) = \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{t}}D^{\xi}(R) \quad [33]$$

$$\dim D^{\xi,\boldsymbol{k}}(\mathscr{G}(\boldsymbol{k})) = n(\xi) \quad [34]$$

$$D^{\xi,\boldsymbol{k}}(R|\boldsymbol{w}_R + \boldsymbol{t})D^{\xi,\boldsymbol{k}}(S|\boldsymbol{w}_S + \boldsymbol{v}) = D^{\xi,\boldsymbol{k}}(RS|\boldsymbol{w}_{RS} + \boldsymbol{t}_{R,S} + \boldsymbol{t} + R\boldsymbol{v}) \quad [35]$$

define ordinary vector $\mathscr{G}(\boldsymbol{k})$ unirreps, provided that suitable $\mathscr{P}(\boldsymbol{k})$ unirreps are constructed. Note in particular that $\xi \in \mathscr{A}(\mathscr{P}(\boldsymbol{k}))$ define the complete sets of all $\mathscr{P}(\boldsymbol{k})$ irrep labels. In summary, the set of ordered pairs

$$\mathscr{A}(\mathscr{G}(\boldsymbol{k})) = \{(\boldsymbol{k}, \xi) | \xi \in \mathscr{A}(\mathscr{P}(\boldsymbol{k}))\} \quad [36]$$

define complete sets of $\mathscr{G}(\boldsymbol{k})$ unirreps for each $\boldsymbol{k} \in \mathscr{B}(\mathscr{T}^{\star})$.

Full space group unirreps The final step is, among others, to restrict the Brillouin zone $\mathscr{B}(\mathscr{T}^{\star})$ to a suitable subset, sometimes called "representation domain," $\Delta\mathscr{B}(\mathscr{T}^{\star}, \mathscr{P})$, in order to avoid double counting of equivalent $\mathscr{G}$ unirreps. This is done by taking only one representative (arm) from each $\boldsymbol{k}$-vector star $S(\boldsymbol{k})$ defined by

$$S(\boldsymbol{k}) = \{\boldsymbol{k}_R \in \mathscr{B}(\mathscr{T}^{\star}, \mathscr{P}) \mid \boldsymbol{k}_R = R\boldsymbol{k};\ R \in \mathscr{P}\} \quad [37]$$

$$|S(\boldsymbol{k})| = |\mathscr{P} : \mathscr{P}(\boldsymbol{k})| \quad [38]$$

It is worth noting that the order $|S(\boldsymbol{k})|$ of any star is a divisor of the order $|\mathscr{P}|$ of the corresponding crystallographic point group $\mathscr{P}$. The union set of all these representative $\boldsymbol{k}$ vectors defines the representation domain $\Delta\mathscr{B}(\mathscr{T}^{\star}, \mathscr{P})$. As commonly accepted in physics, one takes a simply connected continuous subset $\Delta\mathscr{B}(\mathscr{T}^{\star}, \mathscr{P})$ of the original Brillouin zone $\mathscr{B}(\mathscr{T}^{\star})$ in order to avoid unnecessary difficulties when dealing, for instance, with the so-called "compatibility relations," whichever have been discussed for the first time by L P Bouckaert *et al.*, in 1936.

The actual final step in Mackey's induction procedure consists in inducing the full $\mathscr{G}$ representations from the $\mathscr{G}(\boldsymbol{k})$ unirreps given by [33]. A general theorem guarantees that the corresponding induced $\mathscr{G}$ representations are automatically irreducible. The induction formulas read

$$D^{(\boldsymbol{k},\xi)\uparrow\mathscr{G}}_{\underline{R},\underline{S}}(G) = \delta_{\underline{R}\mathscr{P}(\boldsymbol{k}),R\underline{S}\mathscr{P}(\boldsymbol{k})}D^{\boldsymbol{k},\xi}(\underline{A}^{-1}G\underline{B}) \quad [39]$$

$$G = (R \mid \boldsymbol{w}_R + \boldsymbol{t}) \quad [40]$$

$$\underline{A} = (\underline{R}|\boldsymbol{w}_{\underline{R}}) \quad [41]$$

$$\underline{B} = (\underline{S}|\boldsymbol{w}_{\underline{S}}) \quad [42]$$

$$\delta_{\underline{R}\mathscr{P}(\boldsymbol{k}),R\underline{S}\mathscr{P}(\boldsymbol{k})} = \begin{cases} 1, & \underline{R}^{-1}R\underline{S} \in \mathscr{P}(\boldsymbol{k}) \\ 0, & \text{otherwise} \end{cases} \quad [43]$$

$$\dim D^{(\boldsymbol{k},\xi)\uparrow\mathscr{G}}(\mathscr{G}) = |\mathscr{P} : \mathscr{P}(\boldsymbol{k})| \cdot n(\xi) \quad [44]$$

where the specific space group elements $\underline{A} = (\underline{R}|\boldsymbol{w}_{\underline{R}})$ and $\underline{B} = (\underline{S}|\boldsymbol{w}_{\underline{S}})$ are coset representatives of the space group $\mathscr{G}$ with respect to the corresponding little

group $\mathscr{G}(\boldsymbol{k})$. Specifying the conjugation $\underline{A}^{-1}G\underline{B}\in\mathscr{G}$ by taking into account [33] and [43], one immediately arrives at the following final formulas for $\mathscr{G}$ unirreps:

$$D^{(\boldsymbol{k},\xi)\uparrow\mathscr{G}}_{\underline{R}a,\underline{S}b}((R|\boldsymbol{w}_R+\boldsymbol{t})) = \delta_{\underline{R}\mathscr{P}(\boldsymbol{k}),R\underline{S}\mathscr{P}(\boldsymbol{k})}\mathrm{e}^{-\mathrm{i}\underline{R}\boldsymbol{k}\cdot\boldsymbol{t}}\Phi^{\boldsymbol{k}}_{\underline{R},\underline{S}}(R)D^{\xi}_{ab}(\underline{R}^{-1}R\underline{S}) \quad [45]$$

$$\Phi^{\boldsymbol{k}}_{\underline{R},\underline{S}}(R) = \exp\bigl(-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{t}_{\underline{R},\underline{S}}(R)\bigr) \quad [46]$$

$$\boldsymbol{t}_{\underline{R},\underline{S}}(R) = \boldsymbol{t}_{\underline{R}^{-1},R} + \boldsymbol{t}_{\underline{R}^{-1}R,\underline{S}} - \underline{R}^{-1}\boldsymbol{t}_{\underline{R},\underline{R}^{-1}}\in\mathscr{T} \quad [47]$$

Clearly, if $\mathscr{G}$ defines a symmorphic space group, then the corresponding phase factors $\Phi^{\boldsymbol{k}}_{\underline{R},\underline{S}}(R)$ defined by [45] reduce to 1, since the special translation vectors $\boldsymbol{t}_{R,S}$ are zero-vectors. However, if $\mathscr{G}$ defines a nonsymmorphic space group, then some of the phase factors defined by [45] are nontrivial and lead to quite different expressions for its corresponding $\mathscr{G}$ unirreps.

Operator Representations of Space Groups

Usually, space group symmetry and space group representations are applied in the one-particle approximation to Hamiltonians that describe the motion of an electron in periodic structures quantum mechanically. The first step consists of defining a homomorphism $\varepsilon:\mathscr{G}\to U(\mathscr{G})$ of the given space group $\mathscr{G}$ into a group of unitary operators $U(\mathscr{G})$ that map the underlying Hilbert space $\mathscr{H}=L^2(\mathbb{R}^3)$ onto itself (here the spin degree of freedom has been neglected):

$$U(\mathscr{G}) = \{U(G)|G\in\mathscr{G}\} \quad [48]$$

$$[U(G)\Phi](\boldsymbol{x}) = \phi(\mathscr{M}(G^{-1})\boldsymbol{x}) \quad [49]$$

$$U(G)U(G') = U(GG') \quad [50]$$

In this context, it is worth noting that every mapping $\mathscr{M}(G):\mathbb{R}^3\to\mathbb{R}^3$ is nonsingular but likewise nonlinear, if and only if the translational part $\boldsymbol{t}\in\mathscr{T}$ contained in $G=(R|\boldsymbol{w}_R+\boldsymbol{t})$ is nonzero, whereas the uniquely associated unitary operator representation is linear with respect to the Hilbert space $L^2(\mathbb{R}^3)$ in any case. The one-particle Hamiltonian reads

$$H = \frac{1}{2m}P^2 + V(X) \quad [51]$$

where the potential is responsible for the symmetry of the problem. Apart from this, space groups and their representation theory are likewise utilized in order to simplify systematically the diagonalization of the force matrix in the "harmonic approximation" when dealing with lattice vibrations in classical point mechanics.

Bloch Theorem – Energy Bands

The eigenvalue problem of periodic one-particle Hamiltonians, where the spin degree of freedom is neglected, presents one of the most popular examples where group-theoretical methods are applied. Taking into account that every space group $\mathscr{G}$, whether $\mathscr{G}$ is symmorphic or nonsymmorphic, contains a countable translational group $\mathscr{T}$ as a normal subgroup, one may use, as a first step, the translational symmetry of the Hamiltonian represented by the vanishing commutators

$$[H, U(E|\boldsymbol{t})] = 0 \quad \forall\boldsymbol{t}\in\mathscr{T} \quad [52]$$

to simplify the eigenvalue problem. According to a general theorem of functional analysis, the countable set $U(\mathscr{T})=\{U(E|\boldsymbol{t})|\boldsymbol{t}\in\mathscr{T}\}$ of mutually commuting unitary operators and the Hamiltonian H can be diagonalized simultaneously.

Bloch theorem Bloch's theorem predicts partly the form of the common eigenfunctions of the periodic Hamiltonian. It leads to the following well-known and extensively used statement:

$$\Psi^{\boldsymbol{k}}(\boldsymbol{x}) = \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}w(\boldsymbol{k},\boldsymbol{x}) \quad [53]$$

$$w(\boldsymbol{k},\boldsymbol{x}) = w(\boldsymbol{k},\boldsymbol{x}+\boldsymbol{t}) \quad \forall\boldsymbol{t}\in\mathscr{T} \quad [54]$$

These eigenfunctions are called "Bloch functions," of the Hamiltonian, and the unitary translational operators have the form given by [53] and [54]. The translational symmetry has been utilized for this factorization. The eigenvalue problem reads

$$H\Psi^{\boldsymbol{k}} = E(\boldsymbol{k})\Psi^{\boldsymbol{k}} \quad [55]$$

where the eigenfunctions are assumed to be Bloch functions. What remains to be done in practical applications is the determination of the periodic Bloch factors

$$w(\boldsymbol{k}):\mathscr{P}(\mathscr{T})\to\mathbb{C} \quad [56]$$

for every $\boldsymbol{k}\in\mathscr{B}(\mathscr{T}^{\bigstar})$, which is a problem in its own right. Simple manipulations yield the following noncountable infinite set of decoupled partial differential equations for the unknown Bloch factors:

$$H(\boldsymbol{k}) = \frac{1}{2m}(\boldsymbol{Q}+\hbar\boldsymbol{k})^2 + V(X) \quad [57]$$

$$H(\boldsymbol{k})w(\boldsymbol{k}) = E(\boldsymbol{k})w(\boldsymbol{k}) \quad [58]$$

for all $\boldsymbol{k}\in\mathscr{B}(\mathscr{T}^{\bigstar})$ where, in particular, the operator $\boldsymbol{Q}=-\mathrm{i}\hbar\nabla$ is the usual differential operator but its domain of definition is the Hilbert space $L^2(\mathscr{P}(\mathscr{T}))$

together with periodic boundary conditions which give rise to a pure point spectrum of the operator $\boldsymbol{Q}$ in contrast to $\boldsymbol{P} = -\mathrm{i}\hbar\nabla$ that possesses a continuous spectrum with respect to $L^2(\mathbb{R}^3)$. To recapitulate, if one does not introduce periodic boundary conditions for the original eigenvalue problem, admissible vectors $\boldsymbol{k} \in \mathscr{B}(\mathscr{T}^\star)$ vary continuously over the Brillouin zone, whereas the spectrum of the momentum operator $\boldsymbol{Q}$ is discrete and coincides with the corresponding reciprocal lattice $\boldsymbol{K} \in \mathscr{T}^\star$. Assuming that [58] has been solved for all $\boldsymbol{k} \in \mathscr{B}(\mathscr{T}^\star)$, then [55] reads

$$H\Psi_s^{\boldsymbol{k},n} = E_n(\boldsymbol{k})\Psi_s^{\boldsymbol{k},n} \qquad [59]$$

where $n \in \mathbb{N}$ is usually called the "band index," where $s = 1, 2, \ldots, \deg E_n(\boldsymbol{k})$ describes possible degeneracies of the eigenvalues $E_n(\boldsymbol{k})$. The band index n is a countable index, since the Hamiltonians $H(\boldsymbol{k})$ given by [57] possess pure point spectra for fixed $\boldsymbol{k} \in \mathscr{B}(\mathscr{T}^\star)$.

Energy bands To define energy bands in terms of functions of the following type $E_n : \mathscr{B}(\mathscr{T}^\star) \to \mathbb{R}$, one has, in principle, two different possibilities. Either one defines these functions by assuming the strict ordering

$$1.\quad E_1(\boldsymbol{k}) < E_2(\boldsymbol{k}) < \cdots < E_n(\boldsymbol{k}) < E_{n+1}(\boldsymbol{k}) < \cdots \qquad [60]$$

$$2.\quad E_n(\boldsymbol{k}) = \text{analytic functions} \qquad [61]$$

or one demands that these functions be analytic functions. The second possibility is usually preferred, since it leads to smooth functions with respect to the variable $\boldsymbol{k} \in \mathscr{B}(\mathscr{T}^\star)$, whereas the first possibility may lead to cusps with band contacts and hence accidental degeneracies. Obviously, the second possibility may likewise lead to band crossings, which indicate the same type of accidental degeneracies.

Wannier functions Assume that the eigenfunctions $\{\Psi_s^{\boldsymbol{k},n}\}$ are orthonormal with respect to the scalar product of the underlying Hilbert space $\mathscr{H}$:

$$\langle \Psi_s^{\boldsymbol{k},n}, \Psi_s^{\boldsymbol{k}',n'} \rangle_{\mathscr{H}} = \delta(\boldsymbol{k} - \boldsymbol{k}')\delta_{nn'}\delta_{ss'} \qquad [62]$$

where the entries $\delta(\boldsymbol{k} - \boldsymbol{k}')$ define the delta functions. This implies that for the infinite system, that is, system without periodic boundary conditions, Bloch functions cannot be normalized to unity. This is one of the main reasons for the introduction of periodic boundary conditions, since then the delta-functions reduce to ordinary Kronecker deltas, which means that the corresponding Bloch functions become square-integrable functions. In the case of infinite systems, Wannier functions are defined as

$$\Omega_s^{n,\boldsymbol{t}} = \frac{1}{\sqrt{|\mathscr{B}(\mathscr{T}^\star)|}} \int_{\mathscr{B}(\mathscr{T}^\star)} \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{t}} \Psi_s^{\boldsymbol{k},n} \qquad [63]$$

$$\langle \Omega_s^{n,\boldsymbol{t}}, \Omega_{s'}^{n',\boldsymbol{t}'} \rangle_{\mathscr{H}} = \delta_{\boldsymbol{t},\boldsymbol{t}'}\delta_{nn'}\delta_{ss'} \qquad [64]$$

which are square integrable and orthonormal with respect to all labels $\boldsymbol{t}$, n, s respectively. These functions are localized around the positions $\boldsymbol{t} \in \mathscr{T}$ but have infinitely many oscillations to achieve their mutual orthogonality. Whether the Bloch functions $\Psi_s^{\boldsymbol{k},n}$ are directly taken to construct [63] or specific linear combinations (U matrix approach) of $\{\Psi_s^{\boldsymbol{k},n} \mid s = 1, 2, \ldots, \deg E_n(\boldsymbol{k})\}$ are considered, turns out to be problem of its own right and is sensitively influenced by the physical problem.

Energy bands – full space group symmetry More information is gained regarding the degeneracy of the eigenvalues $E_n(\boldsymbol{k})$ and their corresponding eigenfunctions $\{\Psi_s^{\boldsymbol{k},n}\}$, if the full space group symmetry is exploited. The correspondingly refined eigenvalue equation reads

$$H\Psi_{\underline{R}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n} = E_n^\xi(\boldsymbol{k})\Psi_{\underline{R}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n} \qquad [65]$$

$$E_n^\xi(\boldsymbol{k}) = E_n^\xi(\underline{R}\boldsymbol{k}) \quad \forall \underline{R} \in \mathscr{P} : \mathscr{P}(\boldsymbol{k}) \qquad [66]$$

$$\deg E_n^\xi(\boldsymbol{k}) = |\mathscr{P} : \mathscr{P}(\boldsymbol{k})| \cdot n(\xi) \qquad [67]$$

where the eigenfunctions $\Psi_{\underline{R}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}$ are written as $\mathscr{G}$-symmetry-adapted functions, the eigenvalues $E_n^\xi(\boldsymbol{k})$ are labeled by the band index n and the $\mathscr{G}$ irrep labels. Apart from this, the formula [67] for the degeneracies of the eigenvalues is valid, if and only if there is no accidental degeneracy caused by band crossings. The symmetry properties (see eqn [66]) of the eigenvalues explain why energy band calculations are restricted to subsets of $\boldsymbol{k}$ vectors, namely $\boldsymbol{k} \in \Delta\mathscr{B}(\mathscr{T}^\star, \mathscr{P})$, where the symbol $\Delta\mathscr{B}(\mathscr{T}^\star, \mathscr{P})$ denotes the so-called representation domain of the Brillouin zone $\mathscr{B}(\mathscr{T}^\star)$. Note that $\Delta\mathscr{B}(\mathscr{T}^\star, \mathscr{P})$ presents, loosely speaking, the $|\mathscr{P}|$th part (simply connected subwedge) of the Brillouin zone. The restriction to $\Delta\mathscr{B}(\mathscr{T}^\star, \mathscr{P})$ guarantees the uniqueness and completeness of the corresponding $\mathscr{G}$-irrep label set $\mathscr{A}(\mathscr{G})$:

$$\mathscr{A}(\mathscr{G}) = \{(\boldsymbol{k}, \xi) \mid \boldsymbol{k} \in \Delta\mathscr{B}(\mathscr{T}^\star, \mathscr{P});\ \xi \in \mathscr{A}(\mathscr{P}(\boldsymbol{k}))\} \qquad [68]$$

Compatibility relations It was in the famous article of L P Bouckaert *et al*. in 1936 where for the first time continuity properties of $\mathscr{G}$-symmetry-adapted eigenfunctions were discussed. The basic idea was

to change smoothly the continuous parameters $\boldsymbol{k}\in\Delta\mathscr{B}(\mathscr{T}^{\bigstar},\mathscr{P})$ in the vicinity of some $\boldsymbol{k}$-vectors and study the transformation properties of the corresponding $\mathscr{G}$-symmetry-adapted eigenfunctions $\Psi_{\underline{R}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}$ at different $\boldsymbol{k}$-positions, say $\boldsymbol{k}$ and $\boldsymbol{k}'=\boldsymbol{k}+\varepsilon$. In addition, the authors studied whether the assigned eigenvalues, say $E_n^{\xi}(\boldsymbol{k})$ and $E_n^{\xi}(\boldsymbol{k}+\varepsilon)$ may or may not split, depending on the relationship of the associated little co-groups $\mathscr{P}(\boldsymbol{k})$ and $\mathscr{P}(\boldsymbol{k}+\varepsilon)$. The important result culminated in the so-called compatibility relations which allow one to make some predictions on the splitting of energy bands. To summarize, if and only if $\mathscr{P}(\boldsymbol{k})=\mathscr{P}(\boldsymbol{k}+\varepsilon)$, then, because of $D^{\boldsymbol{k},\xi}(\mathscr{P}(\boldsymbol{k}))\downarrow\mathscr{P}(\boldsymbol{k}+\varepsilon)=D^{\boldsymbol{k},\xi}(\mathscr{P}(\boldsymbol{k}))$ it follows that $E_n^{\xi}(\boldsymbol{k}+\varepsilon)$ must not split. Conversely, if and only if, $\mathscr{P}(\boldsymbol{k})\subset\mathscr{P}(\boldsymbol{k}+\varepsilon)$, and if, in addition, $D^{\boldsymbol{k},\xi}(\mathscr{P}(\boldsymbol{k}))\downarrow\mathscr{P}(\boldsymbol{k}+\varepsilon)$ becomes reducible, then the corresponding eigenvalue $E_n^{\xi}(\boldsymbol{k}+\varepsilon)$ may split, unless accidental degeneracies occur. The compatibility relations are an indispensable tool when calculating energy bands or phonon dispersion relations, since in many situations the numerical accuracy may be insufficient to decide whether eigenvalues degenerate or not.

Space Group Symmetrized States

As already noted, the $\mathscr{G}$-symmetrized eigenfunctions $\{\Psi_{\underline{R}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}\}$, which are normalized to unity, are mutual orthogonal and, by definition, transform according to the $\mathscr{G}$ unirreps. One simply proves that the eigenfunctions

$$\Psi_{\underline{R}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}(\boldsymbol{x})=\mathrm{e}^{\mathrm{i}\underline{R}\boldsymbol{k}\cdot\boldsymbol{x}}w_a^{\xi,n}(\underline{R}\boldsymbol{k},\boldsymbol{x}) \qquad [69]$$

retain their structure to form Bloch functions, where the lattice periodic Bloch factors carry the transformation properties with respect to the correspondingly conjugated little co-groups $\mathscr{P}(\underline{R}\boldsymbol{k})=\underline{R}\mathscr{P}(\boldsymbol{k})\underline{R}^{-1}$. Turning back to the penultimate step of the induction procedure, one has the forms

$$\Psi_{\underline{E}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}(\boldsymbol{x})=\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}w_a^{\xi,n}(\boldsymbol{k},\boldsymbol{x}) \qquad [70]$$

$$U(R\,|\,\boldsymbol{w}_R)\Psi_{\underline{E}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}=\sum_{b=1}^{n(\xi)}D_{ba}^{\boldsymbol{k},\xi}(R)\Psi_{\underline{E}b}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n} \qquad [71]$$

which represents the special case $\underline{R}=E$ where, especially, $G=(R|\boldsymbol{w}_R)\in\mathscr{G}(\boldsymbol{k})$ with $R\in\mathscr{P}(\boldsymbol{k})$ and $\boldsymbol{t}=0$. This yields the subset of the eigenfunctions that must transform according to the corresponding $\mathscr{G}(\boldsymbol{k})$ unirreps. Accordingly, one can define

$$[U(R\,|\,\boldsymbol{w}_R)\Psi_{\underline{E}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}](\boldsymbol{x})$$
$$=[\Psi_{\underline{E}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}](\mathscr{M}(R\,|\,\boldsymbol{w}_R)^{-1}\boldsymbol{x}) \qquad [72]$$

$$=\mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}[V^{\boldsymbol{k}}(R|\boldsymbol{w}_R)w_a^{\xi,n}(\boldsymbol{k})](\boldsymbol{x}) \qquad [73]$$

where $R\in\mathscr{P}(\boldsymbol{k})$ is assumed. It is worth noting that definition [72] is used to assign uniquely via definition [73] to each unitary operator $U(R|\boldsymbol{w}_R)$ for every $\boldsymbol{k}$-vector belonging to $\Delta\mathscr{B}(\mathscr{T}^{\bigstar},\mathscr{P})$ an isometrical operator $V^{\boldsymbol{k}}(R|\boldsymbol{w}_R)$ where, especially, the constraints $R\in\mathscr{P}(\boldsymbol{k})$ must not be forgotten. To summarize,

$$[V^{\boldsymbol{k}}(R|\boldsymbol{w}_R)w_a^{\xi,n}(\boldsymbol{k})](\boldsymbol{x})$$
$$=\mathrm{e}^{-\mathrm{i}R\boldsymbol{k}\cdot\boldsymbol{w}_R}\mathrm{e}^{\mathrm{i}\boldsymbol{K}(\boldsymbol{k},R)\cdot\boldsymbol{x}}w_a^{\xi,n}(\boldsymbol{k},R^{-1}(\boldsymbol{x}-\boldsymbol{w}_R)) \qquad [74]$$

where every set of operators $V^{\boldsymbol{k}}(\mathscr{P}(\boldsymbol{k}))=\{V^{\boldsymbol{k}}(R|\boldsymbol{w}_R)|R\in\mathscr{P}(\boldsymbol{k})\}$ forms a generalized unitary operator representation with respect to the Hilbert space $L^2(\mathscr{P}(\mathscr{T}))$, since these operators leave the $L^2(\mathscr{P}(\mathscr{T}))$ scalar product invariant. Rather straightforward manipulations yield

$$V^{\boldsymbol{k}}(R|\boldsymbol{w}_R)V^{\boldsymbol{k}}(S|\boldsymbol{w}_S)=\mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{t}_{R,S}}V^{\boldsymbol{k}}(RS|\boldsymbol{w}_{RS}) \qquad [75]$$

for all point group elements $R,S\in\mathscr{P}(\boldsymbol{k})$. In fact, the operator representation $V^{\boldsymbol{k}}(\mathscr{P}(\boldsymbol{k}))$ defines the so-called "projective multiplier" representations, since the occurrence of the factor system [32] on the RHS of [75] shows, among others, that they must be projective ones. The notion multiplier representation comes from the extra factor $\mathrm{e}^{-\mathrm{i}\boldsymbol{K}(\boldsymbol{k},R)\cdot\boldsymbol{x}}$ on the RHS of [74], where the special reciprocal vectors $\boldsymbol{K}(\boldsymbol{k},R)\in\mathscr{T}^{\bigstar}$ may occur, if and only if the vectors $\boldsymbol{k}\in\Delta\mathscr{B}(\mathscr{T}^{\bigstar},\mathscr{P})$ belong to the surface of the corresponding Brillouin zone $\mathscr{B}(\mathscr{T}^{\bigstar})$. Accordingly,

$$V^{\boldsymbol{k}}(R|\boldsymbol{w}_R)w_a^{\xi,n}(\boldsymbol{k})=\sum_{b=1}^{n(\xi)}D_{ba}^{\boldsymbol{k},\xi}(R)w_b^{\xi,n}(\boldsymbol{k}) \qquad [76]$$

which represents the transformation properties of the lattice-periodic $\mathscr{P}(\boldsymbol{k})$-symmetrized Bloch factors. It is to be noted that even in the case of symmorphic space groups the extra factors $\mathrm{e}^{-\mathrm{i}\boldsymbol{K}(\boldsymbol{k},R)\cdot\boldsymbol{x}}$ on the RHS of [74] occur and hence crucially enter into the discussions when constructing $\mathscr{G}(\boldsymbol{k})$-symmetrized functions as the penultimate step in the induction procedure. Point symmetrized states have been extensively discussed by S L Altmann and P Herzig in 1994.

Symmetrized plane waves A brief comment on the construction of symmetrized plane waves is made here. By virtue of the previous discussions, it is immediately clear that the construction of all $\mathscr{P}(\boldsymbol{k})$-symmetrized bases of the image Hilbert space $L^2(\mathscr{P}(\mathscr{T}))$ is sufficient to obtain symmetrized plane waves, since the last step in the induction procedure consists in inducing from $\mathscr{G}(\boldsymbol{k})$-symmetrized bases, the $\mathscr{G}$-symmetrized bases. As noted before, an orthonormalized basis of the Hilbert space $L^2(\mathscr{P}(\mathscr{T}))$ is

defined by the plane wave basis $\{\Phi^K \mid K \in \mathscr{T}^\star\}$:

$$\Phi^K(\boldsymbol{x}) = \frac{1}{\sqrt{|\mathscr{P}(\mathscr{T})|}} \mathrm{e}^{-\mathrm{i}\boldsymbol{K}\cdot\boldsymbol{x}} \qquad [77]$$

$$\langle \Phi^K, \Phi^{K'} \rangle_{L^2(\mathscr{P}(\mathscr{T}))} = \delta_{K,K'} \qquad [78]$$

Now, let Φ^K be a fixed plane wave. To achieve $\mathscr{P}(\boldsymbol{k})$-symmetrization, one must apply for the chosen $\boldsymbol{k} \in \Delta\mathscr{B}(\mathscr{T}^\star, \mathscr{P})$, the corresponding set of unitary operators $V^k(\mathscr{P}(\boldsymbol{k}))$ to the fixed plane wave Φ^K which induces a $\mathscr{P}(\boldsymbol{k})$ matrix representation, which in general should be decomposed into a direct sum of its irreducible constituents. The definition [74] yields

$$\begin{aligned}[V^k(R|\boldsymbol{w}_R)\Phi^K](\boldsymbol{x}) &= \mathrm{e}^{-\mathrm{i}R\boldsymbol{k}\cdot\boldsymbol{w}_R}\mathrm{e}^{-\mathrm{i}\boldsymbol{K}(\boldsymbol{k},R)\cdot\boldsymbol{x}}\Phi^K(R^{-1}(\boldsymbol{x}-\boldsymbol{w}_R)) \\ &= \mathrm{e}^{-\mathrm{i}R(\boldsymbol{k}+\boldsymbol{K})}\Phi^{R\boldsymbol{K}+\boldsymbol{K}(\boldsymbol{k},R)}(\boldsymbol{x}) \end{aligned} \qquad [79]$$

which illustrates among others, the importance of the specific reciprocal lattice vectors $\boldsymbol{K}(\boldsymbol{k}, R) \in \mathscr{T}^\star$, where the latter inevitably occur if the corresponding $\boldsymbol{k}$-vector $\boldsymbol{k} \in \Delta\mathscr{B}(\mathscr{T}^\star, \mathscr{P})$ belongs to the surface of the Brillouin zone $\mathscr{B}(\mathscr{T}^\star)$. To summarize, even in the case of symmorphic space groups, nontrivial multiplier representations may be realized. Once the $\mathscr{P}(\boldsymbol{k})$ matrix representations are decomposed into their irreducible constituents, the last step of the induction procedure consists in passing over from the corresponding $\mathscr{G}(\boldsymbol{k})$ unirreps to $\mathscr{G}$ unirreps in order to construct the correspondingly symmetrized plane waves.

Selection rules for space groups Let $\mathscr{G}$ be a space group and $\{\Psi_{\underline{R}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}\}$ be some $\mathscr{G}$-symmetrized eigenfunctions of the Hamiltonian H in question. Moreover, let $T^{(\boldsymbol{k}_o,\lambda_o)\uparrow\mathscr{G}} = \{T_{\underline{S}s}^{(\boldsymbol{k}_o,\lambda_o)\uparrow\mathscr{G}} \mid \underline{S} \in \mathscr{P} : \mathscr{P}(\boldsymbol{k}); s = 1, 2, \ldots, n(\lambda_o)\}$, an irreducible $\mathscr{G}$-tensor operator of rank $(\boldsymbol{k}_o, \lambda_o)\uparrow\mathscr{G}$. According to the Wigner–Eckart theorem, one expects

$$\begin{aligned}&\langle \Psi_{\underline{R}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}, T_{\underline{S}s}^{(\boldsymbol{k}_o,\lambda_o)\uparrow\mathscr{G}}\Psi_{\underline{R}'a'}^{(\boldsymbol{k}',\xi')\uparrow\mathscr{G},n'} \rangle \\ &= \sum_{w=1}^{m((\boldsymbol{k}_o,\lambda_o),(\boldsymbol{k}',\xi')|(\boldsymbol{k},\xi))} \left(\begin{matrix} (\boldsymbol{k}_o,\lambda_o) & (\boldsymbol{k}',\xi') \\ \underline{S}s & \underline{R}'a' \end{matrix} \middle| \begin{matrix} (\boldsymbol{k},\xi)w \\ \underline{R}a \end{matrix} \right)^* \\ &\quad \times \langle \Psi^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n} \| T^{(\boldsymbol{k}_o,\lambda_o)\uparrow\mathscr{G}} \| \Psi^{(\boldsymbol{k}',\xi')\uparrow\mathscr{G},n'} \rangle_w \end{aligned} \qquad [80]$$

where the absolute square of the matrix elements describes, apart from a time dependent factor, "Fermi's golden rule," namely the transition probability from the initial state $\Psi_{\underline{R}'a'}^{(\boldsymbol{k}',\xi')\uparrow\mathscr{G},n'}$ to the final state $\Psi_{\underline{R}a}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}$, provided that the interaction operator is described by the irreducible $\mathscr{G}$ tensor operator component $T_{\underline{S}s}^{(\boldsymbol{k}_o,\lambda_o)\uparrow\mathscr{G}}$. The appearance of nontrivial multiplicities

$$m((\boldsymbol{k}_o,\lambda_o),(\boldsymbol{k}',\xi')|(\boldsymbol{k},\xi)) > 1$$

causes additional difficulties, since not only the determination of suitable Clebsch–Gordan coefficients becomes more complicated, but also the dependence of the reduced matrix elements causes additional problems. These problems might be the main reason why the application of the Wigner–Eckart theorem in solid-state physics has not been popular. Basic material concerning space group unirreps and Clebsch–Gordan coefficients for space groups were cited by A P Cracknell *et al.*, in 1979 and 1980. Important applications, such as infrared absorptions or Raman spectroscopy, of this topic are discussed by J L Birman and J F Cornwell in 1974 and 1984, respectively.

What Group Theory Provides

Finally, the usefulness of group-theoretical methods, especially in solid state physics, when applied to simplify certain tasks, is summarized. Here, exclusive comments on group-theoretical tools and methods which refer to space groups, subgroups of space groups, and eventually certain homomorphic images of space groups are made. Possible applications of so-called magnetic space groups, spin groups, and other groups to describe the symmetries of more complex periodic, or even quasiperiodic structures, such as the symmetry properties of quasicrystals, are not discussed here.

- *Bravais vector lattices and sublattices*. Group theory presents an effective tool to identify vector lattices and their sublattices, which are useful for determining not only their crystal system and their crystal class, but also their correlations to standardized lattices. Standardized lattices have basis vectors of the shortest length and specific orientation.
- *Deformed and distorted lattices*. By definition, deformed lattices are obtained by continuously varying the lattice parameters, whereas distorted lattices have lattice matrix that is post-multiplied by a nonsingular matrix which describes the distortion. The proper identification of such lattices is of vital importance in practical applications, for instance, in relaxation processes.
- *Subgroups of space groups of finite index*. Group–subgroup relations of space groups of finite index are of interest in structural phase transitions that are accompanied with changes in symmetry. The knowledge of admissible chains of subgroups from the determination of all intermediate groups is vital in such discussions, since they allow one to

predict the preferred chains of admissible structures of the intermediate phases.

- *Coset and double cosets of space groups*. In phase transitions (with changing structures) which are accompanied with the loss of symmetries, it turns out that simultaneously coexisting domain states are generated whose positions and orientations in space are directly related to the coset decomposition of the parent space group with respect to the subspace group (and correspondingly conjugated subspace groups) which describes the symmetry of the domain states. Likewise, double coset decompositions are used to describe the so-called ordered domain states.
- *Sectional layer and penetration rod groups*. The systematic determination of the symmetries of crystallographic planes, which are subsumed under the notion of sectional layer groups, as subgroups of three-dimensional space groups, plays an essential role in the analysis of the physical properties of two-dimensional surfaces. Likewise, the symmetries of crystallographic lines denoted as penetration rod groups are of interest when describing one-dimensional defects.
- *Point group symmetries of tensors*. Macroscopic properties, such as electrical conductivity, are usually described by tensors of certain ranks. In the presence of some symmetries, for example, point group symmetries, the invariance of such tensors with respect to point groups leads to restrictions as regards their nonzero components.
- *Space group unirreps*. The computation of space group unirreps by means of Mackey's induction procedure can be carried out systematically for every space group in question. Likewise, this approach allows one to gain more insight into the constructions of space–group-symmetrized states.
- *Space group Clebsch–Gordan coefficients*. Knowledge of sets of space group Clebsch–Gordan coefficients allows one not only to study selection rules when calculating transition probabilities, but also to construct systematically product states that transform according to the Kronecker product of the space group in question.
- *Bloch theorem*. One of the most prominent applications of group-theoretical methods in solid-state physics is presented by the Bloch theorem. This theorem allows one to predict the functional form of the common eigenfunctions of the mutually commuting translational operators which represent the Bravais vector lattice and the periodic Hamiltonian, where the latter is assumed to commute with the translational group.
- *Spectral properties of periodic Hamiltonians*. Once, the entire space group symmetry of the periodic Hamiltonian is taken into account, more information gained not only as regards the point group symmetries of the energy eigenvalues, but also systematic construction of the corresponding eigenstates.
- *Compatibility relations*. The continuity behavior of the energy eigenvalues and their associated eigenfunctions in the vicinity of some $\boldsymbol{k}$-vectors can be described by some specific subduction rules of the corresponding $\mathscr{P}(\boldsymbol{k})$ unirreps when passing over continuously to some adjacent $\boldsymbol{k}$-vectors with lower symmetry. Thus, group theory provides a necessary condition which decides whether the eigenvalues do not split or alternatively may eventually split.
- *Transformation properties of states*. An important task in applications, for instance energy band calculations, concerns determining according to which representation the lattice periodic Bloch factors transform. Every careful treatment of this problem inevitably leads to multiplier or even projective multiplier representations of the corresponding little co-groups provided that in the latter case the underlying space group is nonsymmorphic.
- *Symmetrized states*. The systematic construction of space group symmetry-adapted functions follows closely along the lines of Mackey's induction procedure for space group unirreps. For instance, symmetrized plane waves may be useful when calculating matrix elements of some interaction operators.
- *Symmetrized operation*. In order to apply the Wigner–Eckart theorem to space groups, irreducible space group tensors are required. However, in many cases the interaction operators do not represent irreducible space group tensors. Nevertheless, group theory allows one to decompose any operator into a sum of its irreducible space group tensor components. The corresponding method closely resembles the symmetry adaptation of states, apart from some minor modifications.
- *Wigner–Eckart theorem*. The application of the Wigner–Eckart theorem to problems which possess space group symmetry requires not only the, knowledge of space group symmetry adapted states and irreducible space group tensors, but also the corresponding space group Clebsch–Gordan coefficients. Due to the fact that space groups are nonsimple reducible groups, additional difficulties may arise because of the occurrence of nontrivial multiplicities.
- *Magnetic groups – co-representations*. The inclusion of the so-called "antiunitary" operators, for instance, the time reversal operator, requires, substantial extension of the concept of groups to the so-called magnetic groups, and their representations to co-representations.

Applications of Group Theory

Group theory was originally used extensively in evaluating the so-called energy band structures along special symmetry directions, that is for computing the eigenvalues corresponding to a special $\boldsymbol{k}$-vector from the three-dimensional Brillouin zone of a particular bulk system. The reasons were quite clear, namely the dimension of the secular matrix could be reduced substantially and therefore the computing times for inversion or diagonalization procedures were drastically shortened. Furthermore, respective compatibility relations guaranteed an unambiguous classification of energy bands along the rays in the Brillouin zone. The usefulness of such classifications was, in particular, evident in photoemission experiments and studies involving the Fermi surfaces.

With increasing speed of computers, in particular, with the innovation of architectures utilizing vectorizations, efforts at directly deriving the physical properties grew. This implied, for example, in most cases summations over all occupied states, that is, the use of Brillouin zone integrals by means of sophisticated sampling techniques. Thus, no longer were individual $\boldsymbol{k}$-states of interest, but so was the sum over all these states. Consequently, the incentive for using group theory, shifted from projecting particular states to theoretical means of reducing the computational efforts in evaluating Brillouin zone integrals.

Nowadays, most theoretical descriptions of problems in materials science, nanoscience, etc., are based on Kohn's density-functional theory, that is, on the use of effective (single-particle) Hamiltonians (H_{eff}, Kohn–Sham Hamiltonians). In particular, since the interest in solid-state physics shifted to systems with surfaces and interfaces, mostly group-theoretical means for two-dimensional translationally invariant systems are applied. It turned out that in two kinds of applications, namely in Brillouin zone integrations and in reduction of angular momentum coupling constants, the use of group theory is very valuable indeed. These two applications are discussed below and are meant to illustrate the contemporary use of group theory in solid-state physics.

Brillouin Zone Integrations

Taking the density of states as the simplest physical observable,

$$\begin{aligned} n(\varepsilon) &= -\frac{1}{\pi}\operatorname{Im}\mathcal{G}(\boldsymbol{r},\boldsymbol{r},\varepsilon) \\ &= -\frac{1}{\pi}|\mathcal{T}|^{-1}\sum_{\boldsymbol{k}}\operatorname{Im}\mathcal{G}(\boldsymbol{k};\varepsilon) \qquad [81] \end{aligned}$$

$$= -\frac{1}{\pi}|\mathcal{B}(\mathcal{T}^{\bigstar})|^{-1}\int \operatorname{Im}\mathcal{G}(\boldsymbol{k};\varepsilon)\,\mathrm{d}\boldsymbol{k} \qquad [82]$$

where the Green's function $\mathcal{G}(\boldsymbol{r},\boldsymbol{r},\varepsilon)$ is the diagonal configuration space representation of the resolvent of H_{eff}, $(z-H_{\text{eff}})^{-1}$ and $\mathcal{G}(\boldsymbol{k};\varepsilon)$ the corresponding lattice Fourier transformed Green's function, and $|\mathcal{T}|$ the order of the translational group. It should be noted that in eqn [81] a symmorphic space group is assumed and $|\mathcal{B}(\mathcal{T}^{\bigstar})|$ refers to the volume of the corresponding Brillouin zone $\mathcal{B}(\mathcal{T}^{\bigstar})$.

Suppose now that an appropriate matrix representation is used for $\mathcal{G}(\boldsymbol{r},\boldsymbol{r},\varepsilon)$ and $\mathcal{G}(\boldsymbol{k};\varepsilon)$, which, of course, depends largely on the applied quantum mechanical approach: Korringa–Kohn–Rostoker method (KKR), linear combination of muffin-tin orbitals (LMTO), or by using directly the effective Hamiltonain in the formulation of $n(\varepsilon)$ by means of a pseudopotential approach, or the linearized augmented plane wave method), then eqn [81] can be rewritten as

$$\begin{aligned} n(\varepsilon) &= -\frac{1}{\pi}|\mathcal{B}(\mathcal{T}^{\bigstar})|^{-1}\int \operatorname{Im}\operatorname{tr}\left[\underline{\mathcal{G}}(\boldsymbol{k};\varepsilon)\,\mathrm{d}\boldsymbol{k}\right] \\ &= -\frac{1}{\pi}|\mathcal{B}(\mathcal{T}^{\bigstar})|^{-1}\operatorname{Im}\operatorname{tr}\left[\int \underline{\mathcal{G}}(\boldsymbol{k};\varepsilon)\,\mathrm{d}\boldsymbol{k}\right] \qquad [83] \end{aligned}$$

where $\underline{\mathcal{G}}(\boldsymbol{k};\varepsilon)$ refers to the matrix representation of the Green's function and tr denotes the trace. In most of the methods mentioned above, the matrix representations are related in essence to angular momentum representations, that is they are expressed in terms of spherical harmonics.

Let $\mathcal{P}$ be the point group of the underlying (three-dimensional) lattice $\mathcal{T}$ and suppose $\underline{\mathbb{D}}(S)$ contains blockwise the irreducible representations of $S\in\mathcal{P}$. If $\Delta\mathcal{B}_E\ (\mathcal{T}^{\bigstar},\mathcal{P}) = \Delta\mathcal{B}_E$ as shorthand notation denotes an irreducible wedge of the Brillouin zone of volume $|\Delta\mathcal{B}_E(\mathcal{T}^{\bigstar},\mathcal{P})| = |\Delta\mathcal{B}_E|$, then any other wedge $\Delta\mathcal{B}_S(\mathcal{T}^{\bigstar},\mathcal{P})$ of the Brillouin zone is defined by

$$\Delta\mathcal{B}_S(\mathcal{T}^{\bigstar},\mathcal{P}) = \{S\boldsymbol{k}\,|\,\boldsymbol{k}\in\Delta\mathcal{B}_E|\} \qquad [84]$$

where $S\in\mathcal{P} : \mathcal{P}(\boldsymbol{k})$ is sufficient such that the union of the mutually disjoint subsets, (formally written as a sum here) can be written as follows:

$$\mathcal{B}(\mathcal{T}^{\bigstar}) = \sum_{S\in\mathcal{P}}\Delta\mathcal{B}_S(\mathcal{T}^{\bigstar},\mathcal{P}) \qquad [85]$$

It is seen from eqn [83] that

$$\underline{\mathcal{G}}(S^{-1}\boldsymbol{k};\varepsilon) = \underline{\mathbb{D}}(S)^{\dagger}\underline{\mathcal{G}}(\boldsymbol{k};\varepsilon)\underline{\mathbb{D}}(S) \qquad [86]$$

that is for a rotated $\boldsymbol{k}$ vector, the corresponding Green's function matrix is related to the original one by means of a similarly transformation.

The Brillouin zone integral in eqn [83] can, therefore, be expressed as

$$\frac{1}{|\mathscr{B}(\mathscr{T}^{\bigstar})|}\int \underline{\mathscr{G}}(\boldsymbol{k};\varepsilon)\,\mathrm{d}\boldsymbol{k} = \frac{1}{|\Delta\mathscr{B}_E|}\sum_{S\in\mathscr{P}}\mathbb{D}(S)^{\dagger}\left[\int_{\Delta\mathscr{B}_E}\underline{\mathscr{G}}(\boldsymbol{k};\varepsilon)\,\mathrm{d}\boldsymbol{k}\right]\mathbb{D}(S) \quad [87]$$

which, of course, results in a very large reduction of computing time, even if the order of the point group is rather small. In the case of a relativistic description, (Kohn–Sham–Dirac Hamiltonians) in the presence of an effective magnetization, the proper rotational invariance group of the corresponding Hamilton should be used. This is one of the rare cases when antiunitary operators are practically important. Of course, the same type of procedure as in eqn [87] can be applied when only two-dimensional translational symmetry is applied.

Reduction of Angular Momentum Coupling: The Point Group Symmetry of Single-Particle Densities

Let $\bar{\rho}(\boldsymbol{r})$ be the (shape-truncated) charge density in the cell $\mathscr{W}(\mathscr{T})$ (which may denote the corresponding Weigner–Seitz cell or any other type of primitive cell) centered at a particular origin $\boldsymbol{R}_0$ of given lattice or of any particular site in an arbitrary ensemble of scatterers,

$$\bar{\rho}(\boldsymbol{r}) = \rho(\boldsymbol{r})\sigma(\boldsymbol{r}) = \sum_L \bar{\rho}_L(r)Y_L^*(\hat{\boldsymbol{r}}) \quad [88]$$

where $\sigma(\boldsymbol{r})$ is the so-called shape function given by

$$\sigma(\boldsymbol{r}) = \left\{\begin{array}{ll} 1, & \boldsymbol{r}\in\mathscr{W}(\mathscr{T}) \\ 0, & \boldsymbol{r}\notin\mathscr{W}(\mathscr{T}) \end{array}\right\} \quad [89]$$

which usually is expanded into spherical harmonics as

$$\sigma(\boldsymbol{r}) = \sum_L \sigma_L(r)Y_L(\hat{\boldsymbol{r}}) = \sum_{l=0}^{\infty}\sum_{m=-l}^{l}\sigma_{lm}(r)Y_{lm}(\hat{\boldsymbol{r}}) \quad [90]$$

where the expansion coefficients are determined by

$$\sigma_L(r) = \int_{\mathscr{W}(\mathscr{T})}\mathrm{d}\hat{\boldsymbol{r}}\,\sigma(\hat{\boldsymbol{r}})Y_L^*(\hat{\boldsymbol{r}}) \quad [91]$$

It should be noted that the $\bar{\rho}_L(r)$ are the coefficients of the shape-truncated charge density, that is,

$$\bar{\rho}_L(r) = \sum_{L',L''}C_{L''L}^{L'}\rho_{L'}(r)\sigma_{L''}(r) \quad [92]$$

$$C_{L,L''}^{L'} = \int \mathrm{d}\Omega Y_L(\Omega)Y_{L'}^*(\Omega)Y_{L''}(\Omega) \quad [93]$$

Table 1 Table of nonvanishing azimuthal quantum number terms

Plane	*n*	*Two-dimensional lattice*
(1 0 0)	4	Quadratic lattice
(1 1 0)	2	Rectangular lattice
(1 1 1)	3	Hexagonal lattice

Since $\rho(\boldsymbol{r})$ is a real function, in eqn [88] one needs to evaluate only terms $\bar{\rho}_{l,-m}(r)$ for $m\geqslant 0$ and then make use of the relation

$$\bar{\rho}_{l,-m}(r) = (-1)^m\bar{\rho}_{l,m}(r)^* \quad [94]$$

Furthermore, for a system with inversion symmetry with respect to $\boldsymbol{R}_0$,

$$\bar{\rho}_{lm}(r) = 0, \quad \forall l = \text{odd} \quad [95]$$

If the z-axis of the coordinate system is an n-fold rotational symmetry axis, the selection rule

$$m = \ldots, -n, 0, n, \ldots \quad [96]$$

applies, which in turn implies for example, that for simple cubic systems, there are only very few nonvanishing terms, namely those shown in **Table 1**.

Reviewing eqn [93], it is obvious that even very simple group theory can help substantially in reducing the number of terms to be evaluated. This kind of application is a very transparent example of reducing angular momentum coupling constants and is desperately needed whenever the so-called full-potential approaches are applied.

Much more advanced procedures are used whenever spectroscopic intensities are to be calculated, since then 3j-, 6j- or even higher coupling constants occur, depending, of course, on the type of excitation to be investigated.

Nomenclature

$\mathscr{B}(\mathscr{T}^\star)$	Brillouin zone
$\mathbf{\Delta}\mathscr{B}(\mathscr{T}^\star, \mathscr{P})$	irreducible subwedge of $\mathscr{B}(\mathscr{T}^\star)$
$C^{L'}_{L,L''}$	Gaunt coefficient
$\boldsymbol{D}^{\boldsymbol{k}}(\boldsymbol{E}\|\boldsymbol{t}) = \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{t}}$	$\mathscr{T}(\mathscr{L})$-unirreps
$\boldsymbol{D}^{(\boldsymbol{k},\mathscr{E})\uparrow\mathscr{G}}(\mathscr{G})$	space group unirrep
$\boldsymbol{D}^{(\boldsymbol{k},\mathscr{E})\uparrow\mathscr{G}}$	matrix element of space group element
$(R\|\boldsymbol{w}_R + \boldsymbol{t})$	of space group unirrep
$\mathscr{G} =$	shorthand and extended space group
$\{\mathscr{T}, \mathscr{P}\|_o, \boldsymbol{w}_\mathscr{P}\}$	symbol
$\mathscr{G}(\boldsymbol{k}) \subseteq \mathscr{G}$	little group
$\boldsymbol{H}$	periodic one-particle Hamiltonian
$\mathscr{P}(\boldsymbol{k}) \sim \mathscr{G}$	little co-group
$(\boldsymbol{k})/\mathscr{T} \subseteq \mathscr{P}$	
$\mathscr{P}(\mathscr{T})$	point group of $\mathscr{T}(\mathscr{I})$
$\mathscr{P}(\mathscr{T})$	primitive cell of $\mathscr{T}(\mathscr{I})$
$(R\|\boldsymbol{w}_R + \boldsymbol{t})$	Wigner–Seitz symbol for space group element
$\boldsymbol{t} = (t_1, t_2, t_3)$	vector basis of Bravais vector lattice
$\mathscr{T}^\star$	reciprocal vector lattice
$\mathscr{T}(\mathscr{L})$	Bravais vector lattice
$\boldsymbol{w}_\mathscr{P} =$	set of fractional translations
$\{\boldsymbol{w}_R \| R \in \mathscr{P}\}$	
$\mathscr{W}(\mathscr{T})$	Wigner–Seitz cell of $\mathscr{T}(\mathscr{L})$
$\mathbb{Z}(z) \in \boldsymbol{SL}(3, \mathbb{Z})$	integral 3×3-matrix with determinant 1
$\mathbf{\Psi}^{\boldsymbol{k}}(\boldsymbol{x}) =$	Bloch function
$\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}} w(\boldsymbol{k}, \boldsymbol{x})$	
$\mathbf{\Psi}^{\boldsymbol{k},n}_s$	Bloch eigenfunction of periodic Hamiltonian
$\mathbf{\Psi}^{(\boldsymbol{k},\xi)\uparrow\mathscr{G},n}_{\underline{R}_a}$	$\mathscr{G}$-symmetrized eigenfunctions of periodic Hamiltonian
$\Phi^{\boldsymbol{k}}(\boldsymbol{x}) =$	plane wave basis of Hilbert space $L^2(\mathscr{P}(\mathscr{T}))$
$\dfrac{1}{\sqrt{\lvert\mathscr{P}(\mathscr{T})\rvert}}\, \mathrm{e}^{\mathrm{i}\boldsymbol{K}\cdot\boldsymbol{x}}$	
$\mathbf{\Omega}^{n,\boldsymbol{t}}_s$	Wannier functions

Harmonic Generation Frequency Conversion

M Bellini, Istituto Nazionale di Ottica Applicata, Florence, Italy

Introduction

The ability to manipulate the frequency of laser light emission is essential in order to extend the range of possible spectroscopic investigations of matter in its different forms. Although the number of available laser lines is continuously growing, thanks to the introduction of new active materials operating in different spectral ranges, the extension toward the short-wavelength region of the electromagnetic spectrum would have been seriously limited without the advent of harmonic generation techniques, which rely on the nonlinear interaction between matter and intense laser light to generate new optical frequencies at integer multiples of the pump frequency.

With ordinary light sources, the electric fields associated to radiation are normally small and can be safely neglected when compared to the typical local fields (of atomic, molecular, or crystal origin) inside materials. The electrons in atoms or the nuclei in molecules just explore the bottom of their potential wells (where the shape is approximately parabolic) under the influence of the external optical field, and their motion is harmonic with the same frequency of the forcing light (**Figure 1**). The oscillating dipoles in the material are then the sources of reemitted radiation, whose spectral content is the same as the incident one. Many properties of light propagation in matter (such as refraction, reflection, dispersion, scattering, and birefringence) can be readily explained in this regime of linear optics. However, when the light field is so intense that it becomes a non-negligible fraction of the internal field, the linear approximation breaks down and the electrons or nuclei start exploring the anharmonic parts of their potential wells.

In this regime, their motion is no longer harmonic and can be expanded in a Fourier series containing frequencies at integer multiples of the forcing frequency. Such new frequencies are also present in the radiation field emitted by the material and constitute the harmonics of the fundamental driving field.

In this article, the basics of harmonic generation are presented concisely, with an attempt to illustrate the fundamental physical mechanisms which are responsible for the processes at play. A few examples are given: from the simple case of second harmonic generation (SHG), dating back to the dawn of the laser era, to the production of high-order harmonics in the extreme ultraviolet (XUV) and soft X-rays, which relies on the high-peak intensities available with the current pulsed laser systems.

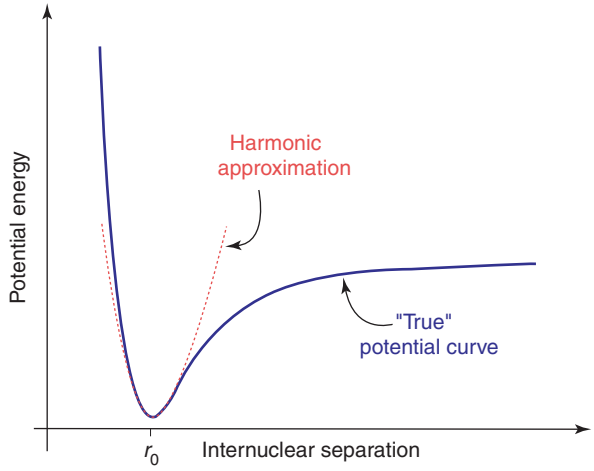

Figure 1 Potential curve illustrating the vibrational motion of nuclei in a molecule. The bottom of the curve can be well approximated by a parabolic potential and the motion is harmonic if only small amplitude oscillations are induced by an external field.

Nonlinear Polarization and Susceptibilities

Consider the case where light is sufficiently off resonance such that its interaction with matter does not induce any change in the population of the energy eigenstates of the material system (i.e., no absorption takes place), but only provokes a perturbation of the motion of electric charges within the atoms or molecules. In this nonresonant process, the material is transparent to the incident radiation, but the change in charge distribution due to the oscillating light field results in an induced electric dipole moment which, in turn, acts as a new source to emit secondary electromagnetic waves: the induced polarization $\boldsymbol{P}$ is the source term, which has to be introduced in Maxwell equations leading to the inhomogeneous wave equation:

$$\nabla^2 \boldsymbol{E} - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\boldsymbol{E} = \mu_0 \frac{\partial^2}{\partial t^2}\boldsymbol{P}$$

in order to describe the subsequent field evolution. The general form for the component at frequency ω of the polarization vector $\boldsymbol{P}$ can be written as

$$\boldsymbol{P}(\omega) = \sum_n \boldsymbol{P}^{(n)}(\omega)$$

where the nth-order polarization has the following expression:

$$\boldsymbol{P}^{(n)}(\omega) = \varepsilon_0 \chi^{(n)}(\omega_1, \omega_2, \ldots, \omega_n)\boldsymbol{E}(\omega_1)\boldsymbol{E}(\omega_2)\cdots\boldsymbol{E}(\omega_n)$$

and

$$\omega = \sum_{i=1}^{n} \omega_i$$

The quantities $\chi^{(n)}(\omega_1, \omega_2, \ldots, \omega_n)$ are known as the nonlinear optical susceptibilities of order n of the medium, and they are $(n+1)$th-order tensors that relate an n-fold product of vector components E_j to a certain component of the nth-order polarization $\boldsymbol{P}^{(n)}(\omega)$.

In the ordinary linear regime, the Fourier component of the polarization for a medium reduces to

$$\boldsymbol{P}^{(1)}(\omega) = \varepsilon_0 \chi^{(1)}(\omega)\boldsymbol{E}(\omega)$$

with the obvious meaning that, in this first-order approximation, the polarization at a given frequency is linearly proportional to the field component of the same frequency: a monochromatic incident light can only induce a monochromatic secondary wave at the same frequency. For anisotropic media, $\chi^{(1)}(\omega)$ is a 3×3-element second-order tensor, it reduces to a complex function of the frequency for isotropic materials.

In the general case, the expression for $\boldsymbol{P}^{(n)}(\omega)$ shows that, thanks to nth-order nonlinearities, it is possible to mix n waves at different frequencies to obtain an induced polarization and reemitted radiation at a different frequency: sums and differences among the frequencies of the incoming beams can be performed this way. In the particular case where only one field at frequency ω enters the material, a susceptibility of order n can produce new radiation at $n\omega$, the nth harmonic of the incident field.

The ratio of two successive orders of polarization can be roughly estimated by

$$\left|\frac{P^{(n+1)}}{P^{(n)}}\right| = \frac{|\chi^{(n+1)}||E|}{|\chi^{(n)}|} \approx \left|\frac{E}{E_{\mathrm{m}}}\right|$$

where E is the amplitude of the applied optical field, and E_{m} is the characteristic value of the internal electric field in the material. If the major mechanism contributing to the nonlinear polarization is the distortion of the electronic cloud of an atomic or molecular system (as in the case of optical harmonic generation), then E_{m} is the average magnitude of the binding field experienced by the electrons ($\sim 10^{11}\,\mathrm{Vm}^{-1}$ for the hydrogen atom). For ordinary light sources, the ratio $|E/E_{\mathrm{m}}|$ is normally so small that nonlinear polarization terms can be safely neglected, but when a laser light of high spectral intensity is used, the laser field may become a significant fraction of the material field, and the second, third, and higher nonlinear order terms start playing an important role, causing part of the incident light to be converted in the corresponding harmonic. From the above expression, one can also deduce that the nth-order polarization, hence the field emitted at $n\omega$, is proportional to the nth power of the ratio between E and E_{m} (normally much smaller than 1), so that the probability of generating higher harmonics is expected to drop exponentially with the corresponding order in this perturbative approach.

From the fact that the susceptibility tensors must remain unchanged upon the symmetry operations allowed for the medium, one can simply conclude that for all isotropic media and centrosymmetric crystals, the even-order susceptibilities ($\chi^{(2)}, \chi^{(4)}, \ldots, \chi^{(2n)}$) must be zero. Consequently, the generation of even-order harmonics is only possible in materials which lack inversion symmetry, while odd-order nonlinear effects can be exhibited by any media, although at different degrees of efficiency.

If the field amplitudes do not change much in a propagation length shorter than a wavelength (the so-called slowly varying amplitude approximation) and if nonlinearities are not too strong (so that the field amplitude at the pump frequency stays almost

constant throughout the interaction), then one can find a simple expression for the wave equation of the plane-wave field and the induced nonlinear polarization P^{NL} oscillating at the new frequency ω':

$$\frac{\partial}{\partial z} E(z,\omega') = -\frac{\mathrm{i}\mu_0 \omega'^2}{2k'} P^{\mathrm{NL}}(z,\omega')\ \mathrm{e}^{\mathrm{i}\Delta k z}$$

where one assumes linear polarizations (to reduce to a scalar equation) and collinear propagation along the z direction. The phase term $\mathrm{e}^{\mathrm{i}\Delta k z}$ accounts for the phase drift between the induced polarization and the generated electric field at ω', and depends on the mismatch in their propagation vectors

$$\Delta k = k' - k_{\mathrm{p}}$$

where $k_{\mathrm{P}} = \sum_i \omega_i n(\omega_i)/c$ and $k' = \omega' n(\omega')/c$, with $n(\omega)$ the material refraction index at frequency ω.

In the case of harmonic generation of order q, this factor reduces to

$$\Delta k = k(q\omega) - qk(\omega)$$

Second Harmonic Generation

As a simple example, consider the case of second-order nonlinearity for the generation of radiation at twice the frequency of the incoming light. As seen before, symmetry considerations impose the process to take place in noncentrosymmetric crystals only.

The polarization vector

$$\boldsymbol{P}^{(2)}(2\omega) = \varepsilon_0 \chi^{(2)}(\omega,\omega)\boldsymbol{E}_1(\omega)\boldsymbol{E}_1(\omega)$$

is the source term that has to be inserted in the wave equation and leads to the following expression for the variation of the field amplitude at the second harmonic $E_2(z)$:

$$\frac{\partial}{\partial z} E_2(z) = -\frac{\mathrm{i}\omega d}{cn(2\omega)} E_1^2(z)\ \mathrm{e}^{\mathrm{i}\Delta k z}$$

where d corresponds to the component of the $\chi^{(2)}(\omega,\omega)$ tensor appropriate for the particular geometry of the laser-crystal interaction and

$$\Delta k = k(2\omega) - 2k(\omega) = \frac{4\pi}{\lambda}\left[n(2\omega) - n(\omega)\right]$$

is the phase mismatch factor, which takes into account the different phase velocities of the waves at ω and 2ω. If a negligible absorption and little production of the wave at 2ω are assumed, so that the pump field amplitude E_1 at frequency ω can be considered as almost constant, then the coupled wave equation can be integrated straightforwardly:

$$E_2(z) = -\frac{\mathrm{i}\omega d}{cn(2\omega)} E_1^2(0) \int \mathrm{e}^{\mathrm{i}\Delta k z}\,\mathrm{d}z$$

where the integration is done over the length of the medium between 0 and L. The integration yields, assuming that $E_2(0) = 0$:

$$E_2(L) = -\frac{\omega d}{cn(2\omega)} E_1^2(0)\,\frac{\mathrm{e}^{\mathrm{i}\Delta k L} - 1}{\Delta k}$$

and the output intensity of the second harmonic is proportional to

$$I_2(L) \propto d^2 I_1^2(0) L^2\,\frac{\sin^2(\Delta k L/2)}{(\Delta k L/2)^2}$$

Some simple observations can be made about this result: the total amount of generated light at the second harmonic is proportional to the square of the intensity at the fundamental frequency; the efficiency is proportional to $|\chi^{(2)}|^2$ and to L^2 but also contains a sinc^2 term involving L and Δk.

The dependence of the emitted intensity at the harmonic frequency on the propagation distance and phase-mismatch is quite general and does not depend on the particular harmonic order considered. As seen above, passing to higher harmonic orders normally involves a rapidly decreasing value of the nonlinear coefficient d and a different power dependence on the incident intensity I_1, but both the L^2 and the sinc^2 terms remain unchanged and play an important role in the harmonic generation of any order.

Only in the optimal condition of phase-matching, with $\Delta k = 0$, will the efficiency really depend quadratically on the medium length, and longer crystals will produce more second harmonic. Note, however, that in these conditions the coupling between the fundamental wave and the second harmonic may become so strong that the depletion of E_1 while it propagates along z has to be taken into account, and some of the assumptions made above are no longer valid. In this so-called depleted-pump regime, a set of coupled equations for the pump field at ω and for the second harmonic field at 2ω has to be solved, and one finds that a complete transfer of the pump energy into the second harmonic field can be achieved.

Phase-Matching

In the general case where $\Delta k \neq 0$, the intensity of the second harmonic field generated in a nonlinear

crystal varies periodically along the z-axis with a period $2\pi/\Delta k$, and at a propagation distance of

$$L_C = \frac{\pi}{\Delta k} = \frac{\lambda}{4}\frac{1}{n(2\omega) - n(\omega)}$$

it reaches the first maximum, at a peak efficiency inversely proportional to Δk^2 (**Figure 2**).

The physical explanation for this effect is connected to the fact that, due to dispersion, the incident wave at frequency ω and the second harmonic wave at 2ω propagate in the medium with different phase velocities ($v_1 = c/n(\omega)$ for the fundamental and $v_2 = c/n(2\omega)$ for the second harmonic). Consequently, the two waves fall out of step with increasing distance in the crystal and the second harmonic waves generated at different places do no longer superpose in phase: after a distance L_C, destructive interference starts developing and it becomes complete, with the full disappearance of the wave at 2ω, at a distance of $2L_C$. L_C is the coherence length for SHG and defines the medium thickness for optimized conversion efficiency under the conditions of $\Delta k \neq 0$. Large Δk values lead to small SHG peak intensities and rapid variations with the distance, so that efficiency is severely limited for crystals longer than L_C.

The condition of $\Delta k = 0$ is referred to as the phase-matching condition and is achieved when $n(2\omega) = n(\omega)$. For ordinary waves in a medium with positive dispersion:

$$n(2\omega) > n(\omega)$$

so one always gets $\Delta k \neq 0$, unless special conditions are met.

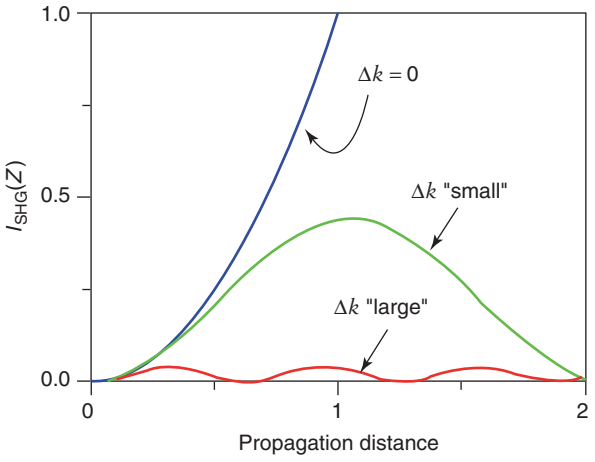

Figure 2 Intensity of the second harmonic field vs. propagation distance in the nonlinear medium. A quadratic growth is obtained for perfect phase-matching conditions ($\Delta k = 0$), while oscillations of decreasing amplitude and period arise for increasing Δk.

In a birefringent material, different polarizations see different refractive indices. "Ordinary" and "extraordinary" refractive indices can be different by up to ~ 0.1 for SHG crystals, so one can satisfy the phase-matching condition by choosing the extraordinary polarization for one wave and the ordinary polarization for the other. For a negative uniaxial crystal ($n_o > n_e$), one can achieve phase-matching at a particular frequency ω if the relation $n_o(\omega) = n_e(2\omega)$ is satisfied (**Figure 3**).

Furthermore, the extraordinary index n_e also depends on the propagation angle θ with respect to the optical axis of the crystal, so one can phase-match the fundamental and second harmonic waves at different ω just by adjusting the angle of incidence on the crystal: the phase-matching condition in this case becomes $n_o(\omega) = n_e(2\omega, \theta_m)$, where θ_m is the phase-matching angle (**Figure 4**). A geometric representation of this situation is obtained by plotting the index curves for the ordinary and extraordinary waves at the fundamental and second harmonic frequencies: the refraction index n_e or n_o for each wave can be found at the crossing of the curves with the k-vector. In the negatively uniaxial crystal case, the point of intersection between the n_o circle at ω with the n_e ellipse at 2ω indicates the phase-matching angle θ_m.

Note that in the quantum mechanical view of SHG, two photons of energy $\hbar\omega$ are absorbed during the excitation of the medium to a virtual state, and a

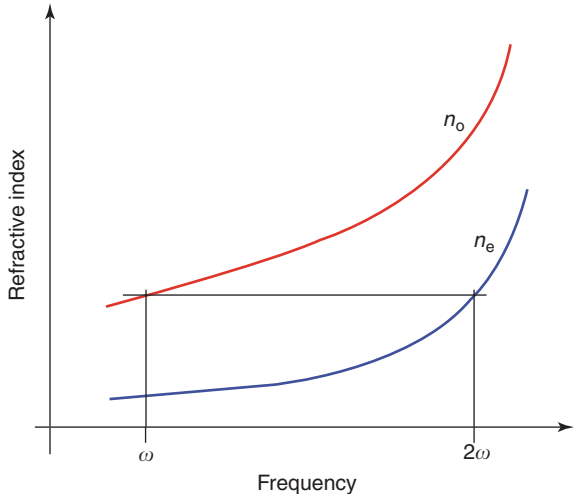

Figure 3 Phase-matching condition for a negative uniaxial crystal occurring for a particular frequency ω. In reality, the two curves for n_o and n_e represent the maximum and the minimum attainable index of refraction in the crystal, and the whole range in between the two curves can be covered by the extraordinary index n_e by changing the angle between the propagation vector and the optical axis of the medium. So, by choosing the appropriate angle, phase-matching can be obtained for different frequencies.

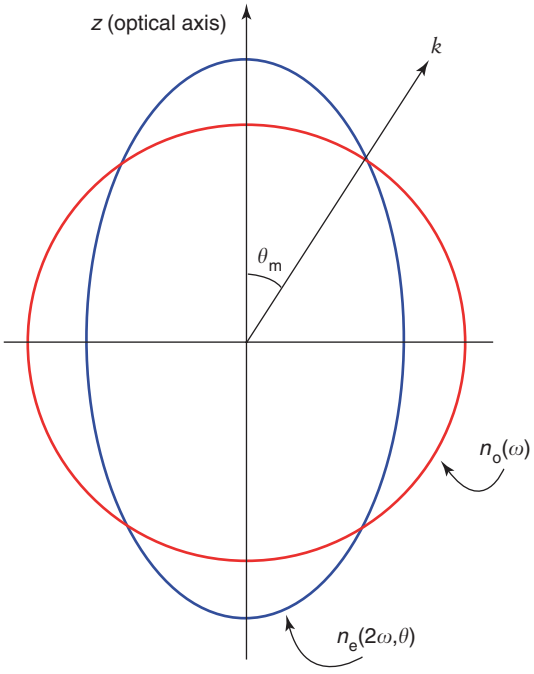

Figure 4 Geometric construction for the determination of the phase-matching angle θ_m in a negative uniaxial crystal.

single photon with an energy $2\hbar\omega$ is immediately re-emitted when the medium de-excites toward the ground state. In this framework, the phase-matching condition has the simple meaning of photon momentum conservation

$$\boldsymbol{k}_1 + \boldsymbol{k}_1 = \boldsymbol{k}_2$$

between the initial and the final states of the system.

Although it was discussed in the particular case of SHG, phase-matching is a much more general issue and is always present in all nonlinear optics phenomena where waves at new frequencies are to be generated with the highest possible efficiency. In the most general case of n waves with wave vectors $\boldsymbol{k}_i$ participating in the nonlinear process, one has to make sure that the total photon momentum is conserved in the interaction by making

$$\sum_{1}^{n} \boldsymbol{k}_i = 0$$

Quasi Phase-Matching

As seen before, when perfect phase-matching is not achieved, the fundamental and second harmonic fields slip out of phase after a propagation distance L_C and the conversion efficiency oscillates without growing monotonically with L^2 as it should do in the case of $\Delta k = 0$ (**Figure 5**). An alternative idea to improve the

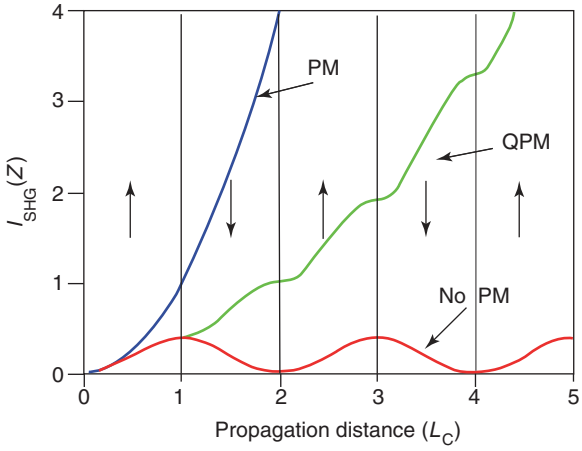

Figure 5 Intensity of the second harmonic field vs. propagation distance in the conditions of quasi-phase-matching. The sign of the nonlinear coefficient of the crystal is reversed for every coherence length L_C in order to get a monotonous increase of the second harmonic intensity. The perfect phase-matched condition and the mismatched situation are also shown.

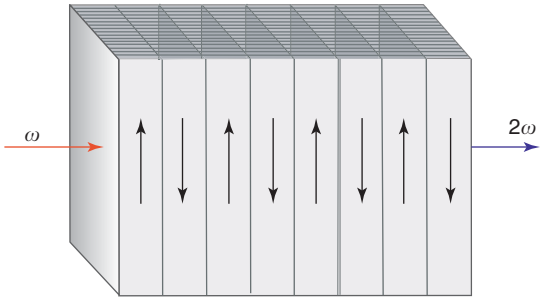

Figure 6 Schematic of SHG in a periodically poled crystal with several layers of alternatively oriented domains.

conversion efficiency is to adjust the phase of the nonlinear polarization appropriately after each coherence length: the best conditions are obtained by changing the sign of the nonlinear coefficient (and thus the sign of the polarization) with a periodicity L_C.

Under these circumstances, the nonlinear intensity starts growing monotonically, although less rapidly than in the case of perfect phase-matching, and long interaction lengths can be used to boost the conversion.

The condition of quasi-phase-matching (QPM) can be achieved in a so-called periodically-poled material, generally a ferroelectric crystal ($LiNbO_3$ is the currently most used one) where regions of periodically reversed polarization domains are permanently written by applying spatially shaped electric fields (**Figure 6**).

If technological limitations do not allow one to realize the right spacing between the inverted domains (it is currently difficult to obtain poling periods smaller than $\sim 5\,\mu m$), a higher order QPM can be

obtained, although with a lower conversion efficiency with increasing order, by flipping the nonlinear coefficients every 3 (third-order QPM), 5 (fifth-order QPM), or any odd number of coherence lengths.

High-Order Harmonic Generation

Current amplified pulsed laser systems can reach peak intensities $\sim 10^{15}$–$10^{20}\,\mathrm{W\,cm^{-2}}$ and, in these situations, the perturbative approach used above to model the nonlinear response of materials to radiation is no longer adequate. As a matter of fact, at a peak intensity of $3.5 \times 10^{16}\,\mathrm{W\,cm^{-2}}$, the electric field of the laser corresponds to the field which binds an electron to the proton in the ground state of a hydrogen atom: the assumption that successive terms in the expansion of the medium polarization in powers of the incident field get progressively smaller with the order cannot hold.

The most impressive consequence of the breakdown of the perturbative approach is the deviation from the expected exponential decay of the intensity of successive harmonic orders (**Figure 7**). The appearance of a so-called plateau, a region of the spectrum where several harmonics are generated with almost constant efficiency, is the characteristic feature of high-order harmonic generation (HHG) in gases.

Here, short and intense laser pulses are typically focused in a pulsed gas jet to produce coherent radiation in the extreme ultraviolet (XUV) and soft X-rays, a wavelength range (1–100 nm) where the lack of coherent sources has greatly limited the possibility of spectroscopic investigation so far (**Figure 8**).

As a consequence of the isotropy of the gaseous medium, only odd-order harmonics are generated, and one finds that the region of efficient production of high harmonics is limited by a so-called cutoff. The most energetic photons generated in the process possess a cutoff energy E_{cutoff}, which is experimentally found to follow the simple law:

$$E_{\mathrm{cutoff}} \approx I_{\mathrm{P}} + 3.2U_{\mathrm{P}}$$

where I_{P} is the ionization potential of the atoms in the gas jet, and U_{P} is the ponderomotive energy, which corresponds to the mean kinetic energy acquired by an electron in one cycle of oscillation in the laser field:

$$U_{\mathrm{P}} = \frac{e^2E^2}{4m\omega^2}$$

with e and m the electron charge and mass, respectively, E the amplitude of the laser field and ω its frequency.

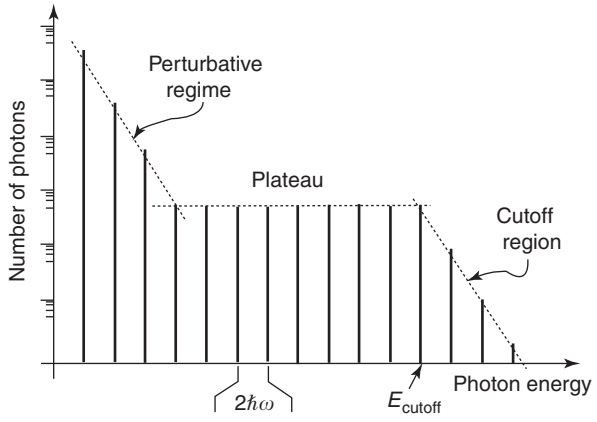

Figure 7 Schematic view of the typical behavior of high-order harmonic spectra. Only odd-order harmonic photons are generated with successive harmonics separated by twice the energy of the pump laser. The first harmonics follow the predictions of the perturbative approach, with intensities exponentially decreasing with the order. Then a plateau is formed and extends up to E_{cutoff}.

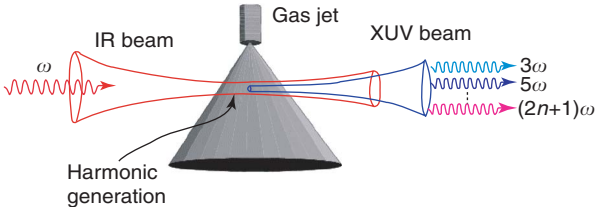

Figure 8 HHG in a gas jet.

It is evident that high laser intensities and high ionization potentials are required in order to reach very short wavelengths. Indeed, rare gas atoms and ultrashort pulses of very high peak intensity are normally used to generate high harmonics. A further advantage of using hard-to-ionize gases and short pulses is given by the requirement that neutral atoms survive long enough to experience the full peak pulse intensity instead of being completely ionized at the leading edge of the pulse itself. If $W(I)$ is the atomic ionization rate and τ_{p} the pulse duration, then the maximum effective intensity useful to produce harmonic photons is the so-called saturation intensity I_{s}, approximately given by $W(I_{\mathrm{s}})\tau_{\mathrm{p}} = 1$; $W(I)$ being a monotonously increasing function of I, higher saturation intensities can be reached with shorter laser pulses and, of course, with light noble gases having higher ionization potentials.

Three-Step Model

The standard picture of the HHG process can be easily visualized from a semiclassical perspective in a single-atom approach: in every half optical cycle of

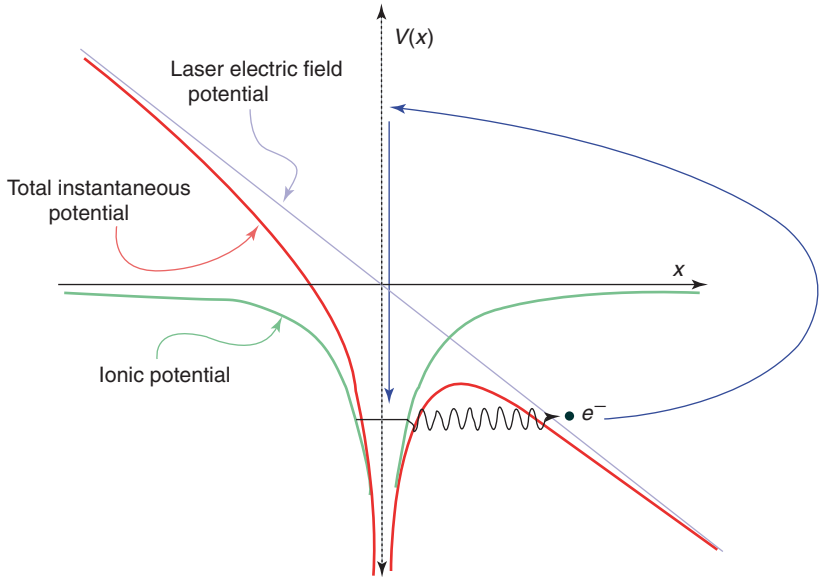

Figure 9 The three-step model for HHG. Electrons are first tunnel-ionized by the intense laser field, then they are accelerated during an optical cycle and finally recombine with the ion, thus releasing the accumulated kinetic energy in the form of harmonic photons.

the laser pulse, electrons undergo tunnel ionization through the potential barrier formed by the atomic potential and by the electric field potential of the laser itself; after being accelerated in the ionization continuum by the field, they may come back to the ion core and recombine to emit harmonic photons that release the accumulated kinetic and ionization energy (**Figure 9**).

Some of the most relevant features of harmonic radiation can be simply obtained by using this single-atom picture and solving the classical equations of motion for an electron, freed with zero velocity at different moments in an oscillating electric field. Depending on the phase of the field at the moment of ionization, the electron can either escape from the parent ion or oscillate in the field, and come back to the original position after a fraction of the optical period T. Only electrons ionized within $T/4$ after each field maximum contribute to the harmonic emission by recombining with the ion and converting their kinetic and potential energy into photons (**Figure 10**).

The experimentally found cutoff law can be simply obtained by noting that the maximum return kinetic energy (brought back by electrons which escape slightly after each field maximum every half optical cycle) corresponds to $\sim 3.17\ U_p$ (**Figure 11**). For the generation of harmonics with photon energies below the cutoff limit, there are always two different trajectories (corresponding to two different release times within each half cycle) that the electron can follow in the continuum, such that it returns to the ion core with the correct energy. These two trajectories, although giving rise to photons with the same energy, may correspond to quite different permanence times of the electrons under the influence of the laser field, and some of the spatial and temporal characteristics (phase-matching relations, defocusing, and frequency modulation) of the emitted harmonic radiation will thus be strongly affected.

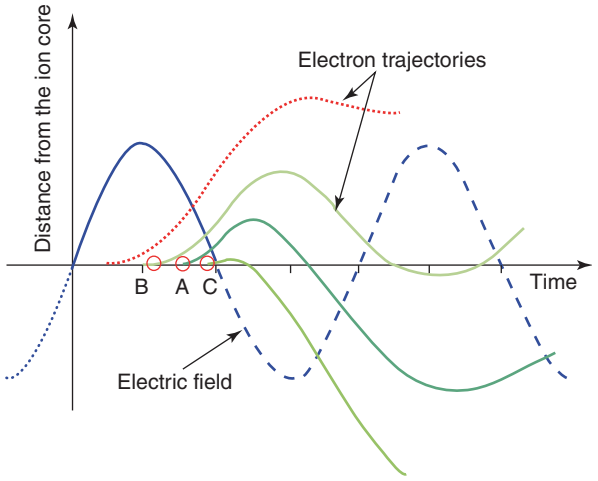

Figure 10 Schematic representation of the main electron trajectories involved in the HHG process (only the first half optical cycle is considered for simplicity, but things repeat with a $T/2$ periodicity). Electrons which are ionized when the absolute value of laser field amplitude is growing just escape from the ion and do not contribute to the process, while electrons released after the peak can come back to the core position and recombine to emit harmonic photons. Electrons ionized in A return with the maximum kinetic energy and generate the most energetic photons in the cutoff region. Electrons released in B and C follow different trajectories in the continuum but return with the same kinetic energy, thus both contribute to the generation of the same harmonic.

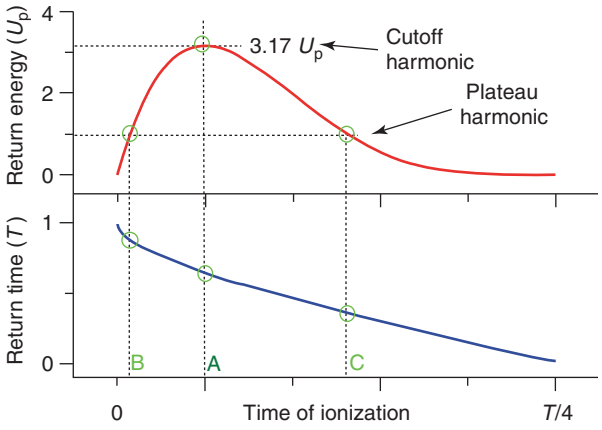

Figure 11 Upper curve: plot of the return kinetic energy for electrons ionized at different times during the optical cycle. The origin of the time axis is fixed at the peak of the field amplitude for each half optical cycle. A single trajectory, corresponding to electrons emitted in A, is responsible for the emission of a cutoff harmonic, while two distinct trajectories (originating in B and C contribute to the generation of a harmonic in the plateau. Lower curve: time (here indicated as the "return time") that the electrons spend oscillating in the continuum before re-combining with the ion. Plateau harmonics mainly come from two classes of electrons with distinct return times.

Harmonic emission during a single pump pulse is thus seen to be composed of a train of XUV photon bunches, essentially released twice every optical cycle of the laser field. This temporal structure translates into the characteristic spectral structure of high-order harmonics, with peaks corresponding to the odd orders, separated by twice the laser frequency.

The semiclassical model also offers a simple explanation for other experimentally observed characteristics of harmonic radiation. A linear polarization of the laser is needed to make sure that the electron oscillating in the field may "hit" the ion and recombine with it when it comes back after the oscillation in the continuum; experiments have shown that just a small degree of ellipticity is sufficient to completely inhibit the generation of harmonics. It is also clear that, although the expressions for E_{cutoff} and U_p seem to favor long-wavelength pump pulses for the generation of high harmonics, actually, the longer time that it takes for the electron to return to the ion (proportional to the pump laser wavelength) implies a significant spreading of the electron wave packet during its oscillation and a final lower overlap with the ion wave function, which in turns causes the probability of recombination to decrease.

Phase-Matching in High-Order Harmonic Generation

The three-step model is a good way to understand the single-atom response of the gas medium to the intense electric fields of the laser. However, when the global response of the system is considered, propagation effects have to be included. Phase-matching is again an essential condition for efficient generation of high-order harmonics to take place. In this case, the fundamental and the harmonic field can fall out of phase for several reasons: besides the usual dispersion in the neutral gaseous medium (which may, however, contain both linear and nonlinear contributions, due to the high intensities involved), the geometrical dephasing due to the focusing of the Gaussian laser beam can introduce an additional phase shift, as well as the dispersion introduced by the generated free electrons, and the so-called dipole-phase variation. In order to achieve sufficiently high conversion efficiency, the phase shift between the polarization of the qth harmonic and the generated harmonic field has to be kept as constant as possible over all the interaction region.

As for the dispersion by the neutral medium, the corresponding phase shift on a propagation distance z has the usual form

$$\Delta\varphi_{\text{ND}} = \frac{2\pi q z}{\lambda}\left(n(q\omega) - n(\omega)\right)$$

and the refraction indices at the two frequencies clearly depend both on the gas density in the jet and on the fraction of neutral atoms left after the partial ionization by the laser pulse.

The dispersion caused by free electrons produced in the interaction becomes important as soon as the intensity approaches the saturation intensity I_s and has to be accounted for by introducing the index of refraction

$$n_{\text{el}}(\omega) = \sqrt{1 - \frac{\omega_P^2}{\omega^2}}$$

where $\omega_P(z,t)$ is the so-called plasma frequency, which is proportional to the local free-electron density: the corresponding phase shift is approximately given by

$$\Delta\varphi_{\text{el}} \approx \frac{z\omega_P^2}{2cq\omega}\left(q^2 - 1\right)$$

The on-axis phase shift across the focus of a Gaussian beam is $\varphi(z) = \tan^{-1}(2z/b)$, where b is the laser confocal parameter. The phase shift due to this geometrical effect is then

$$\Delta\varphi_{\text{G}} = (1-q)\tan^{-1}\left(\frac{2z}{b}\right)$$

Finally, one finds that the laser-induced polarization has an intrinsic intensity-dependent phase which arises

from the phase of the wave function of the electrons which generate a particular harmonic. The two main electronic trajectories contributing to the dipole moment of a given plateau harmonic induce a phase which is proportional to the intensity of the laser driving field, and to the amount of time the electron has spent in the continuum. For each trajectory (labeled by j), this leads to an intensity-dependent variation of the phase

$$\Delta\varphi_{\mathrm{D},j} = -\alpha_j I(z,t)$$

which sum up to a total dipole phase:

$$\Delta\varphi_{\mathrm{D}} = \sum_j \Delta\varphi_{\mathrm{D},j}$$

All these contributions to the phase slip between the induced polarization and the generated harmonic field have to be combined to give a total phase-mismatch

$$\Delta\varphi = \Delta\varphi_{\mathrm{ND}} + \Delta\varphi_{\mathrm{el}} + \Delta\varphi_{\mathrm{G}} + \Delta\varphi_{\mathrm{D}}$$

which should not vary much in the medium length. Unfortunately, most of the above terms have a complicated dependence on the detailed spatio-temporal dynamics of the atom–laser interaction, and the task of keeping $\Delta\varphi$ fixed is normally a very difficult one, unless special simplifications can be made in order to neglect one or more of the contributions to the total phase-mismatch. Using collimated laser beams or propagation in hollow fibers can null the geometrical phase shift, while keeping a low ionization level can eliminate the free-electron contribution to dispersion. When the experimental conditions are achieved so that positive and negative terms partially cancel out in the expression for $\Delta\varphi$, a strong enhancement in the conversion efficiency of a particular high-order harmonic can be obtained.

Hartree and Hartree–Fock Methods in Electronic Structure

G C Strinati, Università degli Studi di Camerino, Camerino (MC), Italy

Introduction

The Hartree and Hartree–Fock methods represent good starting points for the calculation of eigenvalues and eigenfunctions of complex atoms, molecules, and solids. They provide a conceptually simple and practical prescription to deal with many-body interactions in these systems, although their implementation may not be sufficient to get an appreciable agreement with experimental data under many circumstances.

The success of these methods rests essentially on the very reasonable physical intuition on which they are based, and also their mathematical foundation is sound. In addition, in spite of their limitations (to cure which more sophisticated methods have been devised), the Hartree and Hartree–Fock methods have also been useful in establishing calculation procedures (such as the very idea of "self-consistency") that have been later applied to other widely used methods (such as the local density approximation to the density-functional theory). Besides, the "mean-field" approach (with which the Hartree–Fock method is sometimes synonymous) is regarded as being nonperturbative, in the sense that it does not treat the interaction term of the many-body Hamiltonian as a perturbation to the kinetic term. This fact acquires importance both for atoms and condensed matter systems at the relevant densities, whereby the average kinetic and interaction energies are of the same order.

In a sense, the Hartree and Hartree–Fock methods can be regarded as reference methods for many-body calculations in complex systems. In many cases, in fact, their utility as reference methods is far more appreciated than the practical results which can be directly produced by the methods themselves. Finally, extensions of the methods have been successfully

applied to include broken-symmetry situations (for instance, in magnetic and superconducting systems).

Need for Nonperturbative Approximations

For atoms with more than one electron, the Schrödinger equation cannot be solved in practice without recourse to numerical approximations. It is then important to develop approximation methods for calculating the energy eigenvalues and wave functions of stationary states.

The Hamiltonian H of a system of N electrons in atoms, molecules, and solids contains two parts, namely, the kinetic energy of the particles plus the interaction with the nuclei (H_1), and their mutual interaction energy (H_2):

$$H = H_1 + H_2 \qquad [1]$$

with

$$H_1 = \sum_{i=1}^{N} h(q_i) \quad \text{and} \quad H_2 = \frac{1}{2}\sum_{i\neq j}^{N} v(q_i, q_j) \qquad [2]$$

Here, the indices (i, j) label the particles, $q = (\boldsymbol{r}, \sigma)$ is a collective coordinate including spatial position $\boldsymbol{r}$ and spin σ, $h(q)$ is the Hamiltonian relative to each particle, and $v(q, q')$ is the mutual interaction energy between two particles (which is usually taken to be the repulsive Coulomb potential).

Perturbative methods are normally constructed to deal with (at least part of) the interaction energy as the perturbation. It turns out, however, that the perturbation theory in the interaction part of the Hamiltonian is nonanalytic. This is also expected on physical grounds, from the fact that the behavior of the system should completely change if the interaction $v(q, q')$ changes its sign. It is for these reasons that nonperturbative methods (such as the Hartree and Hartree–Fock methods) acquire great value. Furthermore, for a neutral atom (where N equals the atomic number Z) with large enough Z, the Z dependence of the two-body Hamiltonian H_2 (namely, $ZN(N-1)/2 \approx Z^3$) becomes comparable with the corresponding dependence of the one-body Hamiltonian H_1 (namely, $Z^2N = Z^3$). This is an additional indication that the perturbation theory in the two-body Hamiltonian H_2 is bound to fail even in practice, at least for large enough systems.

Note that, in the absence of the electron–electron interaction H_2, the many-body problem decouples into a one-body problem for each electron in the external potential due to the nuclei. The Hartree and Hartree–Fock methods succeed specifically in reducing the many-body problem to a one-body problem, while including at least part of the effects of the electron–electron interaction.

Hartree Self-Consistent Field

The original motivation of the Hartree and Hartree–Fock methods was to obtain an average (central) field in atomic problems. A similar requirement is also present in crystals for the one-electron periodic potential, with the purpose of calculating band structures and obtaining the corresponding Bloch wave functions.

Hartree's idea (originally devised on physical considerations) was to reduce the many-electron Schrödinger equation

$$H\Phi(q_1, q_2, \ldots, q_N) = E\Phi(q_1, q_2, \ldots, q_N) \qquad [3]$$

(E being the total energy) to the equation for only one electron in its own central field, obtained from the nuclear potential and the wave functions of the other electrons. The one-electron wave functions obtained in this way are then made consistent with the fields from which they are calculated. The resulting self-consistent field thus represents, as closely as possible, the average effect of the other electrons on one electron.

The Hartree method rests on writing the many-electron wave function of eqn [3] in the form

$$\Phi(q_1, q_2, \ldots, q_N) = u_{\alpha_1}(q_1)u_{\alpha_2}(q_2)\cdots u_{\alpha_N}(q_N) \qquad [4]$$

Here, the single-electron wave functions $u_{\alpha_i}(q)(i = 1, \ldots, N)$ are assumed to be different from each other and normalized as follows:

$$\langle u_{\alpha_i}(q)|u_{\alpha_i}(q)\rangle = 1 \qquad [5]$$

with the Dirac's convention for the matrix elements. Note that the requirement for the wave function to be antisymmetric in all the electrons is not taken into account in the Hartree wave function [4].

The single-electron wave functions $u_{\alpha_i}(q)$ can be obtained by an optimization procedure based on the variational principle (as recognized only later by Slater and Fock). One thus calculates the average values

$$\langle \Phi|H_1|\Phi\rangle = \sum_{i=1}^{N} \langle u_{\alpha_i}(q)|h(q)|u_{\alpha_i}(q)\rangle \qquad [6]$$

and

$$\langle \Phi|H_2|\Phi\rangle = \frac{1}{2}\sum_{i\neq j}^{N} \langle u_{\alpha_i}(q)u_{\alpha_j}(q')|v(q, q')|u_{\alpha_i}(q)u_{\alpha_j}(q')\rangle \qquad [7]$$

in terms of the wave function [4]. Minimization of $\langle\Phi|H_1|\Phi\rangle + \langle\Phi|H_2|\Phi\rangle$ with respect to alternative $u_\alpha(q)$ and subject to the normalization constraint [5] then yields the Hartree differential equation(s)

$$h(q)u_{\alpha_i}(q) + \sum_{j\neq i}\langle u_{\alpha_j}(q')|v(q,q')|u_{\alpha_j}(q')\rangle u_{\alpha_i}(q) = \varepsilon_i u_{\alpha_i}(q) \qquad [8]$$

where ε_i are Lagrange multipliers (with the dimension of energy) introduced to enforce the constraints [5].

Equation [8] has the form of the Schrödinger equation for one electron moving under the influence of the nuclear potential and the density distribution $\sum_{j\neq i} u^*_{\alpha_j}(q')u_{\alpha_j}(q')$ of the remaining electrons. This density distribution has to be obtained self-consistently by solving the same equation. Implementation of the method thus requires recourse to successive approximations. The ensuing iterative procedure starts with a first "guess" of the single-electron wave functions with which the effective Hamiltonian of eqn [8] is computed. The Hartree equation is then solved numerically to obtain new approximations to the single-electron wave functions. Starting from these new wave functions, the effective Hamiltonian of eqn [8] is recalculated and the eigenvalue equation solved once again. This iteration is continued until the effective Hamiltonian computed from the new single-electron wave functions at the end of the cycle agrees with the one of the previous cycle within a given accuracy, thereby terminating the iteration.

Recourse to successive approximations makes the Hartree method nonlinear and renders its solution effectively of infinite order in the interaction Hamiltonian, thus overcoming the problems mentioned above with the (finite-order) perturbation theory.

Satisfying Pauli Principle

The Hartree wave function [4] satisfies the Pauli principle only in a partial way, in the sense that the single-electron wave functions are required to be all different from each other, thereby preventing two electrons from occupying the same single-particle state. However, the Pauli principle requires more stringently the many-electron wave function to be antisymmetric with respect to the interchange of any pair of electrons. The required antisymmetrization is achieved in a reasonably compact form for any number of electrons with a Slater-determinant formulation by

$$\Phi(q_1, q_2, \ldots, q_N) = \frac{1}{\sqrt{N!}}\begin{vmatrix} u_{\alpha_1}(q_1) & u_{\alpha_2}(q_1) & \cdots & u_{\alpha_N}(q_1) \\ u_{\alpha_1}(q_2) & u_{\alpha 2}(q_2) & \cdots & u_{\alpha_N}(q_2) \\ \cdots & \cdots & \cdots & \cdots \\ u_{\alpha_1}(q_N) & u_{\alpha_2}(q_N) & \cdots & u_{\alpha_N}(q_N) \end{vmatrix} \qquad [9]$$

in the place of eqn [4] (the factor $\sqrt{N!}$ has been introduced to preserve the normalization). The Hartree–Fock wave function [9] thus contains $N!$ terms, of which the Hartree wave function [4] represents the diagonal one.

Hartree–Fock Equations

The averages [6] and [7] need to be recalculated at this point with the wave function [9] that obeys the Pauli principle. With the same variational procedure that has led to eqn [8], one now obtains the Hartree–Fock integro-differential equation(s):

$$h(q)u_{\alpha_i}(q) + \sum_j[\langle u_{\alpha_j}(q')|v(q,q')|u_{\alpha_j}(q')\rangle u_{\alpha_i}(q) - \langle u_{\alpha_j}(q')|v(q,q')|u_{\alpha_i}(q')\rangle u_{\alpha_j}(q)] = \varepsilon_i u_{\alpha_i}(q) \qquad [10]$$

The modification due to Fock (originating from the Pauli principle) has introduced the so-called exchange term on the left-hand side of eqn [10]. Correspondingly, the operator acting on the single-particle wave function $u_{\alpha_i}(q)$ is no longer purely differential as in eqn [8], but now also contains an integral part. Note that the exchange term of the Hartree–Fock operator, being of purely quantum-mechanical origin, lacks the intuitive interpretation of the (direct) Hartree term based on classical physics. Note further that the restriction $j\neq i$ has been removed from the sum in eqn [10], since the two terms with $i=j$ within brackets cancel each other. Despite the presence of these additional features, however, the Hartree–Fock equation still fails to include a correlation between electrons of either spin resulting from the Coulomb interaction.

From the above considerations, one anticipates that the Hartree approximation (whereby the exchange term in eqn [10] is neglected), being based on a classical self-consistent picture, should work better when classical considerations can give a good answer. This typically occurs when macroscopic effects are dominant, such as when the forces are slowly varying. Consistent with this expectation, one readily verifies from eqn [10] that for a short-range interaction $v(q, q')$ (as in nuclear physics or with the Hubbard Hamiltonian in a solid), the direct (Hartree) and exchange (Fock) terms are comparable in magnitude.

For a long-range interparticle potential (as in atomic physics), on the other hand, the exchange contribution is usually much smaller than the direct one, so that it is often neglected in determining the self-consistent energy levels of atoms.

The Hartree–Fock eqn [10] obviously shares with the Hartree eqn [8], the nonlinearity and self-consistency of the solution, and thus the need for iterative methods.

The total energy E of the original Schrödinger eqn [3] can be obtained from the solution of the Hartree–Fock eqn [10] by projecting on alternative wave functions $u_{\alpha_i}(q)$ and summing over i. One obtains

$$\sum_{i=1}^{N} \varepsilon_i = \langle \Phi|H_1|\Phi \rangle + 2\langle \Phi|H_2|\Phi \rangle = E + \langle \Phi|H_2|\Phi \rangle \qquad [11]$$

where $\langle \Phi|H_2|\Phi \rangle$ now contains the exchange besides the Hartree contribution [7]. Note that the total energy E is not merely the sum of the single-particle eigenvalues ε_i of eqn [10]. The average interaction energy $\langle \Phi|H_2|\Phi \rangle$ is, in fact, subtracted from this sum to avoid double counting of the interaction energy. In addition, the ground-state energy is obtained by considering the lowest N single-particle eigenvalues ε_i in eqn [11] (with occupancy consistent with the Pauli principle). Correspondingly, the remaining single-electron wave functions with higher energies represent unoccupied or "virtual" single-particle states. The value of the total energy E obtained in this way for the ground state constitutes an upper bound for the true ground state of the many-electron system, in accordance with the variational principle from which the Hartree–Fock eqn [10] has been obtained.

It remains to give a physical interpretation to the eigenvalues ε_i, which were originally introduced as Lagrange multipliers to enforce the (ortho) normalization constraints on the single-electron wave functions.

Koopmans' Theorem

Koopmans' theorem provides an interpretation to the Hartree–Fock eigenvalues ε_i as ionization potentials, in the sense that energies of the occupied states in the single-determinant approximation for the many-electron ground state represent the energy (with opposite sign) required to remove an electron from that state.

The central hypothesis of Koopmans' theorem is that one removes a particular single-electron wave function, say $u_{\alpha_{\tilde{i}}}(q)$, from the ground-state configuration [9] for N electrons, while leaving all other $(N-1)$ single-electron wave functions unchanged. By taking the difference between the total energies [11] corresponding to these N and $(N-1)$ electron configurations, one obtains

$$E(N) - E(N-1) = \varepsilon_{\tilde{i}} \qquad [12]$$

In physical terms, one says that Koopmans' theorem, by assuming a "frozen orbital" approximation, neglects the relaxation of the wave functions in the $(N-1)$ electron state. In practice, this neglect of relaxation results in very positive ionization potentials, even though Koopmans' ionization potentials constitute, in general, a reasonable first approximation to the experimental values.

The approximation of frozen orbitals is expected to be more appropriate when the electron is removed from an "outer" than from an "inner" level. By the same token, the approximation is expected to be a poor one in solids when screening (relaxation) effects are important. The valence and conduction bands of diamond constitute a notable example of a situation where "correlation effects" beyond the Hartree–Fock approximation produce important corrections to Koopmans' theorem results. As shown in **Figure 1**, the sets of valence and conduction bands of diamond get considerably closer to each other when including correlation effects on top of the Hartree–Fock results. In particular, the bandgap is reduced in this way from 15.0 to 7.4 eV, a value quite close to the experimental 7.3 eV.

Another famous example when screening (not taken into account by the Hartree–Fock–Koopman scheme) is important to account for the experimental data is provided by the ΔSCF (self-consistent field) calculations of Bagus and Schaefer for a deep excitation in a diatomic molecule. In a ΔSCF calculation, the "frozen orbital" approximation is relaxed in such a way that, after removal of one electron from a particular single-electron wave function (hole), the Hartreee–Fock single-electron wave functions for the remaining $(N-1)$ electrons are recalculated self-consistently. Bagus and Schaefer have shown that results in good agreement with the experimental data can be obtained, when one requires the deep-hole wave function to be localized at one of the two atoms of the diatomic molecule O_2, while it fails when the hole wave function is delocalized spreading over the whole molecule (as it is usually assumed for Hartree–Fock calculations with molecules).

Results for Atoms

The first numerical calculations for atoms were made direcly by Hartree and his students. Quite generally,

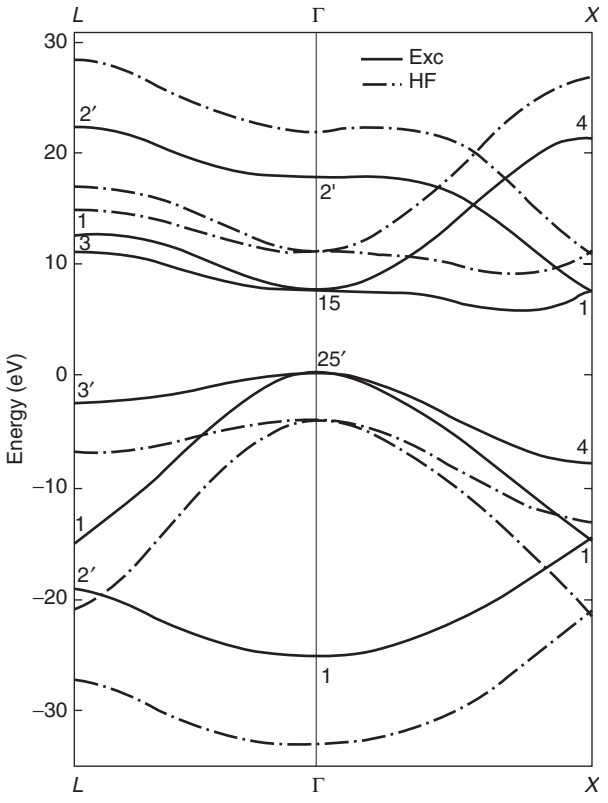

Figure 1 Valence and conduction bands of diamond including correlation effects (full lines) on top of Hartree–Fock results (dashed-dotted lines), along two symmetry directions in the Brillouin zone. (Reprinted with permission from Strinati G, Mattausch HJ, and Hanke W (1982) Dynamical aspects of correlation corrections in a covalent crystal. *Physical Review B* 25: 2867–2888; © American Physical Society.)

the first problem one encounters, when applying the Hartree or Hartree–Fock method to atoms, is that the potential due to the other electrons is not spherically symmetric, due to departures of the charge distribution from spherical symmetry. Including departures from spherical symmetry in atomic calculations would be rather difficult and probably not very useful, as it would not correspond to an improvement of the final results. Accordingly, Hartree did not use the actual nonspherically symmetric potential field but an average of this field over all directions in space, with the result that each electron moves in an effective central field.

The Hartree method provides good radial wave functions as a first approximation to the atomic structure problem and as the starting point for more refined calculations. With the inclusion of the Fock term, it turns out that the typical error of the Hartree–Fock energy for an atom (ion) is only $\sim 1\%$. The Hartree–Fock wave functions, on the other hand, may not be so accurate in some regions of configuration space which, however, do not play an important role in the variational integral from which the energy is obtained. As a consequence, matrix elements (required, for instance, to calculate transition rates) may sometimes have a substantial error when calculated in the Hartree–Fock approximation.

Standard tabulations of the Hartree–Fock results exist (see Clementi and Roetti), which gather the best results obtained for the ground state (and even for some excited states) of atoms. From these tables, one can get both total and single-particle (orbital) energies, as well as the form of the single-particle wave functions. Usually, Slater-type radial orbitals of the form $\chi(r) = Ar^{\nu-1}e^{-\eta r}$ (where $r = |\mathbf{r}|$, ν is a positive integer, η a positive number, and A a normalization constant) are chosen as a basis for these calculations, thereby determining the coefficients c_p of the expansion $u(r) = \sum_p c_p \chi_p(r)$ for the radial part $u(r)$ of the single-particle wave functions.

Results for Molecules

The Hartree–Fock approximation plays an especially important role in quantum chemistry, where it is also used as the starting point for more elaborate (configuration interaction) calculations that include the effects of electron correlations.

For molecules, the Hartee–Fock approximation is applied to the electronic equation that depends parametrically on the nuclear coordinates in the spirit of the Born–Oppenheimer approximation. In practice, for molecules it would be rather difficult to solve the Hartree–Fock integro-differential equations as one does for atoms, due to the reduced symmetry. Instead, for molecules one prefers (Roothaan) to introduce a finite set of known basis functions for the expansion of the single-particle wave functions, thus converting the Hartree–Fock equations into a set of algebraic equations for the expansion coefficients. These equations are then solved by standard matrix techniques using an iterative procedure. The basis functions are usually taken to spread over the whole molecule, with their symmetry properties classified in accordance with the symmetry group of the molecule.

The basis functions for this expansion, although linearly independent, are in general not orthogonal to each other, which results in the presence of an overlap matrix in the matrix equation. In particular, two types of basis functions are commonly used, the Slater-type and Gaussian-type functions. The use of Slater functions would in principle be preferable, since they more correctly describe the qualitative features of molecular orbitals. However, the calculation of two-electron integrals employing functions centered at the positions of different nuclei is easier to evaluate with Gaussian functions.

In literature, the results of a large number of Hartree–Fock calculations for molecules are available, especially as far as their total energy is concerned. For specific molecules (such as H_2), there also occurs good agreement between Koopmans' and experimental values of the ionization potential, although this agreement originates from a fortuitous cancellation of correlation and relaxation effects (both neglected by the Koopmans' approximation). For other molecules (such as N_2), however, the Hartree–Fock approximation is not sufficiently accurate even for a qualitative understanding of the ionization phenomena. Restricted Hartree–Fock calculations provide, instead, reasonable approximations to the experimental values for the equilibrium geometry of molecules, whose prediction is one of the most common uses of electronic structure calculations. ("Restricted" ("unrestricted") spin orbitals are constrained to have the same (different) spatial function(s) for up and down spins.)

In the case of unrestricted molecular orbitals, the equations to be solved (called the Pople–Nesbet equations) are analogous to the Roothaan's equations for the case of restricted molecular orbitals, but entail two coupled matrix eigenvalue problems to be solved simultaneously. A well-known example, when unrestricted Hartree–Fock calculations are preferred to the restricted ones, is the case of molecular dissociation. In this case, a lower energy is often obtained by allowing each doubly occupied molecular orbital to split into two spin orbitals with different spatial factors under a bond-breaking deformation of the molecule.

Results for the Homogeneous Electron Gas

Before discussing the Hartree–Fock calculations for solids, it is worth mentioning the results for the homogeneous electron gas (with which some metals such as Na and K are sometimes associated, at least to a first approximation).

When the potential contained in the single-particle Hamiltonian h of eqn [2] is constant, the Hartree–Fock eqn [10] can be solved exactly with plane waves $e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$ (where $\boldsymbol{k}$ is a wave vector), without the need for a self-consistent procedure (even though the corresponding energy eigenvalues $\varepsilon(\boldsymbol{k})$ are not free-electron eigenvalues). For a Coulomb interparticle potential (which requires the inclusion of a uniform positive compensating background), one then obtains, for the average (ground-state) energy per particle, the expression

$$\frac{E}{N} = \frac{2.21}{r_s^2} - \frac{0.916}{r_s} \qquad [13]$$

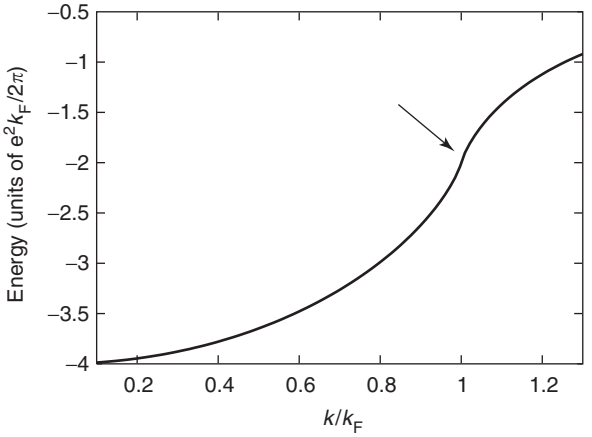

Figure 2 Hartree–Fock part $\varepsilon(\boldsymbol{k}) - \boldsymbol{k}^2/(2m)$ of the single-particle eigenvalues for a homogeneous electron gas vs. the magnitude $k = |\boldsymbol{k}|$ of the wave vector. The singularity at the Fermi wave vector k_F is evidenced by the arrow. (Adapted with permission from Fuchs HD, *et al.* (1992) *Solid State Communications* 82: 225.)

in units of Rydbergs. Here $r_s = r_0/a_0$ with $4\pi r_0^3 n/3 = 1$ (n being the density and a_0 the Bohr radius). In expression [13], the competition between the (positive) kinetic energy and the (negative) exchange energy contributions results in a minimum occurring for negative values of the total energy. For values of r_s corresponding to metals (typically in the range from 2 to 6), the exchange energy in eqn [13] is comparable in magnitude to the kinetic energy, thus confirming the need for nonperturbative calculations in condensed matter systems.

In spite of the simplified procedure, a shortcoming occurs with the Hartree–Fock result of the homogeneous electron gas. The Hartree–Fock part $\varepsilon(\boldsymbol{k}) - \boldsymbol{k}^2/(2m)$ of the eigenvalues (m being the electron mass) shown in **Figure 2** versus $k = |\boldsymbol{k}|$ has, in fact, a log-singularity in the first derivative at the Fermi wave vector k_F (related to the density via $k_F = (3\pi^2 n)^{1/3}$). This singularity, in turn, implies that the corresponding density of states vanishes at the Fermi energy, resulting for instance, in the vanishing of the electronic specific heat.

It is actually the neglect of screening (not taken into account in the Hartree–Fock approximation) that is responsible for the failure of the Hartree–Fock approximation with the homogeneous electron gas.

Results for Solids

In crystalline solids, where the atomic positions are related by translational symmetry, the solutions of the Hartree–Fock eqn [10] satisfy the Bloch theorem, and are thus labeled by a wave vector $\boldsymbol{k}$ (restricted to the first Brilluoin zone) and a band index.

In analogy with atoms, whereby the Hartree–Fock method is exploited to determine an average central potential, a simplified version of the Hartree–Fock method for solids (the X_α method) has been proposed by Slater, by setting up an average potential field in which all electrons move. In this way, the nonlocal exchange potential is replaced by a local one that depends on the local density, like constant $\times\, n(\boldsymbol{r})^{1/3}$. In addition, in analogy with molecules, the basis functions for full Hartree–Fock calculations are taken of the form of Bloch sums in terms of orbitals centered at the lattice sites.

Owing to its failure for the homogeneous electron gas, the Hartree–Fock approximation has long been viewed as a poor approximation for metals. *Ab initio* calculations of energy bands in solids with the Hartree–Fock method have thus been mostly performed for insulators with the Fermi level lying within the bandgap (the example of the energy bands of diamond has already been shown in **Figure 1**). Only recently the Hartree–Fock method has been applied to 3D transition metals, by truncating the long-range part of the Coulomb potential and thus effectively mimicking correlation effects.

In spite of these improvements, band structure calculations for solids have preferably been performed by alternative methods, such as the local density approximation to the density-functional theory of Hohenberg, Kohn, and Sham, and more recently by introducing correlation effects with the so-called GW approximation. It is nevertheless remarkable that both these alternative methods rely on the idea of a self-consistent field originally developed for the Hartree approach.

Successes and Limitations

It is worth summarizing the achievements of the Hartree–Fock method by spelling out its successes and limitations.

Among its successes, one should mention that: (1) The Hartree–Fock method is based on the variational principle, and, as such, has a sound physical–mathematical justification. (2) The method provides an approximate separation of variables of the original interacting N – electron problem, in that it enables one to solve N coupled one-electron problems in the place of one problem with N coupled electrons. (3) Even from a numerical point of view, the method provides reasonable order-of-magnitude estimates of single-particle eigenvalues.

Limitations of the Hartree–Fock methods concern instead: (1) The error in the single-particle eigenvalues, interpreted in conjunction with Koopman's theorem, which can admittedly be too large to allow for a detailed comparison with the experimental data, especially for systems where relaxation effects (screening) are relevant. (2) The first-principle extension of the method to excited states, which is not obvious since the excited states should (by construction) be orthogonal to the ground state.

Unrestricted Hartree–Fock Calculations

When discussing the results for molecules, it has already been mentioned that unrestricted Hartree–Fock calculations are sometimes preferred to the restricted ones for dealing with specific problems.

More generally, the technical term "unrestricted" refers to the fact that one allows for self-consistent field wave functions of a lower symmetry than that of the Hamiltonian. For instance, in spin-symmetry unrestricted self-consistent field solutions, the electrons on the average can be kept further apart than in the restricted solutions, thereby reducing their mutual Coulomb interaction.

It is sometimes said that "unrestricted" self-consistent field calculations enable one to incorporate part of the electron correlations within a self-consistent field scheme. This is due to the fact that a broken-symmetry ansatz effectively introduces nodes in the Hartree–Fock wave function, which amounts, in turn, to the introduction of some sort of correlation over and above the Hartree–Fock approach.

A notable example is the Hartree–Fock calculation for the Hubbard model in a crystal. In this case, the ordinary Hartree–Fock approach (with a spin-independent occupancy of the single-particle levels) merely produces the constant shift $nU/2$ of the independent-electron band eigenvalues (obtained in the absence of the electron–electron interaction). Here, n ($0 \leqslant n \leqslant 2$) is the average density per site, and U is the site interaction characteristic of the Hubbard Hamiltonian. At the same time, the Hartree–Fock wave function coincides with the independent-electron case, corresponding to the paramagnetic phase of the system. On physical grounds, these results are expected to be correct only for small values of U (such that $U \ll t$, where t is the hopping matrix element between nearest-neighbor sites). If one, instead, enforces a broken-symmetry situation to the Hartee–Fock approach (making the average spin occupancy different on alternative sites of a bipartite lattice), the approach proves its ability to describe antiferromagnetic situations which are (at least qualitatively) correct also in the large-U limit.

Generalized Mean-Field Approaches

The Hartree–Fock method is sometimes synonymous with mean field methods. As such, the method can be

readily generalized to finite temperatures within a grand canonical ensemble, whereby the Fermi–Dirac distribution contains the self-consistently determined single-particle energy eigenvalues of the Hartree–Fock equation. Cases of a broken symmetry can further be described with suitable Hartree–Fock approaches. For instance, the Stoner criterion for ferromagnetism is obtained within the Hartree–Fock approximation to the Hubbard Hamiltonian. The Bardeen–Cooper–Schrieffer (BCS) theory of superconductivity can also be regarded as a generalized Hartree–Fock decoupling of the attractive interparticle interaction. In this case, "anomalous" averages associated with the broken gauge symmetry are considered besides the usual Hartree (direct) and Fock (exchange) averages.

Nomenclature

E	total many-electron energy
h	one-electron Hamiltonian
H	many-electron Hamiltonian
k	wave vector
k_F	Fermi wave vector
m	electron mass
n	average electron density
$n(r)$	local electron density
N	total number of electrons
r	spatial position of an electron
t	hopping matrix element of the Hubbard model
u	one-electron wave functions
U	site interaction energy of the Hubbard model
Z	atomic number
α	label of the one-electron wave functions
ε	Hartree and Hartree–Fock single-particle eigenvalues
σ	spin of an electron
Φ	many-electron wave function

Highly Porous Metals and Ceramics

A E Markaki, University of Cambridge, Cambridge, UK
P Colombo, University of Bologna, Bologna, Italy
T W Clyne, University of Cambridge, Cambridge, UK

Introduction

Porous cellular metals and ceramics are now being intensively studied. This has arisen partly from a growing appreciation that biomaterials must be thoroughly understood, not only to exploit them effectively, but also to develop biomimetic materials with attractive properties and biocompatible materials and structures. Since many natural and biological materials are cellular, often with relatively high-porosity levels (although sometimes these pores are, at least, partly filled with a fluid or a soft and compliant solid in the natural state), study of manufactured porous materials has become an important branch of materials science. In fact, various types of

porous materials, quite different from any biological system, are also being heavily investigated. Furthermore, certain well-established areas of porous material usage, such as filters, catalyst supports, and heat exchangers, are being subjected to renewed scrutiny, as novel porous materials and structures are developed.

Interest extends to both processing developments and to relationships between microstructure and properties. The concept of microstructure should be defined with care in highly porous materials, since it is sometimes used to refer only to the cell structure (i.e., the size, volume fraction, shape, etc. of the pores), whereas in practice, the microstructure of material constituting the cell wall may also be important. Distinctions can be drawn between different types of porous materials, based on their cell structure. The most significant classification is that between open-cell and closed-cell materials. An obvious difference is that open-cell foams are permeable to fluids, which has various implications, but there are also some rather systematic differences between the two types of materials, relating to various thermophysical and mechanical properties, and also to the applications for which they might be suitable.

However, further classification is probably needed. Some porous materials exhibit distinct, separate cells, but with some connectivity – as, for example, might result from rupturing of some cell walls. Such configurations differ noticeably from open structures having such high connectivity that it is difficult to delineate any individual cells. It might be argued that the latter should be termed "open-network materials," rather than "cellular materials." Open-network materials can, for example, be produced by assembling a set of fibers or fine wires. Such assemblies can be isotropic or they may be highly oriented – commonly either in-plane or uniaxially aligned – and hence exhibit pronounced anisotropy in both structures and properties. Ropes, cables, braided wires, etc. are effectively open-network materials of this type, as are various types of insulation blankets, filters, etc. There are many such products in commercial use, based on metallic, ceramic, or polymeric fibers, with or without strong interfiber bonding.

Classifying ropes, or bonded assemblies of short struts, as (open-network) materials brings into sharp focus the issue of whether such things should really be termed materials or structures. In fact, many highly porous materials should probably be treated as "quasimaterials," since they are in many ways genuinely intermediate between the two. An important feature of quasimaterials, and of highly porous materials in general, is that the "pore architecture" introduces extra degrees of freedom into microstructural design. In thinking about terminology and classification, it is instructive to consider the combinations of pore content, connectivity, and anisotropy exhibited by various actual and putative materials and quasimaterials. This is illustrated graphically in **Figure 1**, which presents data for a number of well-known products and natural materials. Void content is simply evaluated, while anisotropy can be characterized via observed variations with direction of a suitable property, such as Young's modulus E (see the section "Elastic constants and stiffness-critical lightweight structures"). Intercell connectivity is more difficult to quantify. In constructing **Figure 1**, the ease of permeation of fluids through the material (see the section "Fluid permeability and specific surface area") has been used as the indicator, represented by the specific permeability κ (in m^2), which is independent of the fluid used in the measurement. Good intercell connectivity leads to high permeability. However, the permeability drops as the scale of the structure becomes finer, so κ has been multiplied by the specific surface area (in m^{-1}), which rises as this occurs, to give a connectivity parameter designed to be scale independent, at least to a first approximation. **Figure 1** highlights the wide range of cell architectures obtainable. Of course, the scale of the structure is a further important variable.

Highly porous materials are also sometimes classified according to whether their cell structures are regular or stochastic (i.e., exhibiting random variations in cell size, shape, and distribution). This can affect certain characteristics, particularly mechanical properties, since it influences stress concentration effects and crack propagation paths. The distinction is not, however, a very rigid one, since porous materials which do not, strictly speaking, have regular or periodic cell structures may nevertheless exhibit a relatively narrow distribution of cell size and shape. Finally, some porous materials tend to exhibit bimodal distributions of pore size, so that, for example, the cell walls might themselves be porous. This can influence a wide range of properties. An illustration is presented in **Figure 2** of cell structures in four different types of highly porous materials, exhibiting a wide range of regularity, anisotropy, connectivity, and scale.

In this article, a brief outline is given of how various properties of highly porous materials are predicted and controlled. It is sometimes possible to apply conventional composite theory, with one of the constituents taken as having zero stiffness or strength or conductivity, etc. However, models of this type often breakdown for high porosity levels, particularly as the pores become contiguous (open-celled), and, in general, rather different approaches are needed in this regime, taking proper account of the cell architecture.

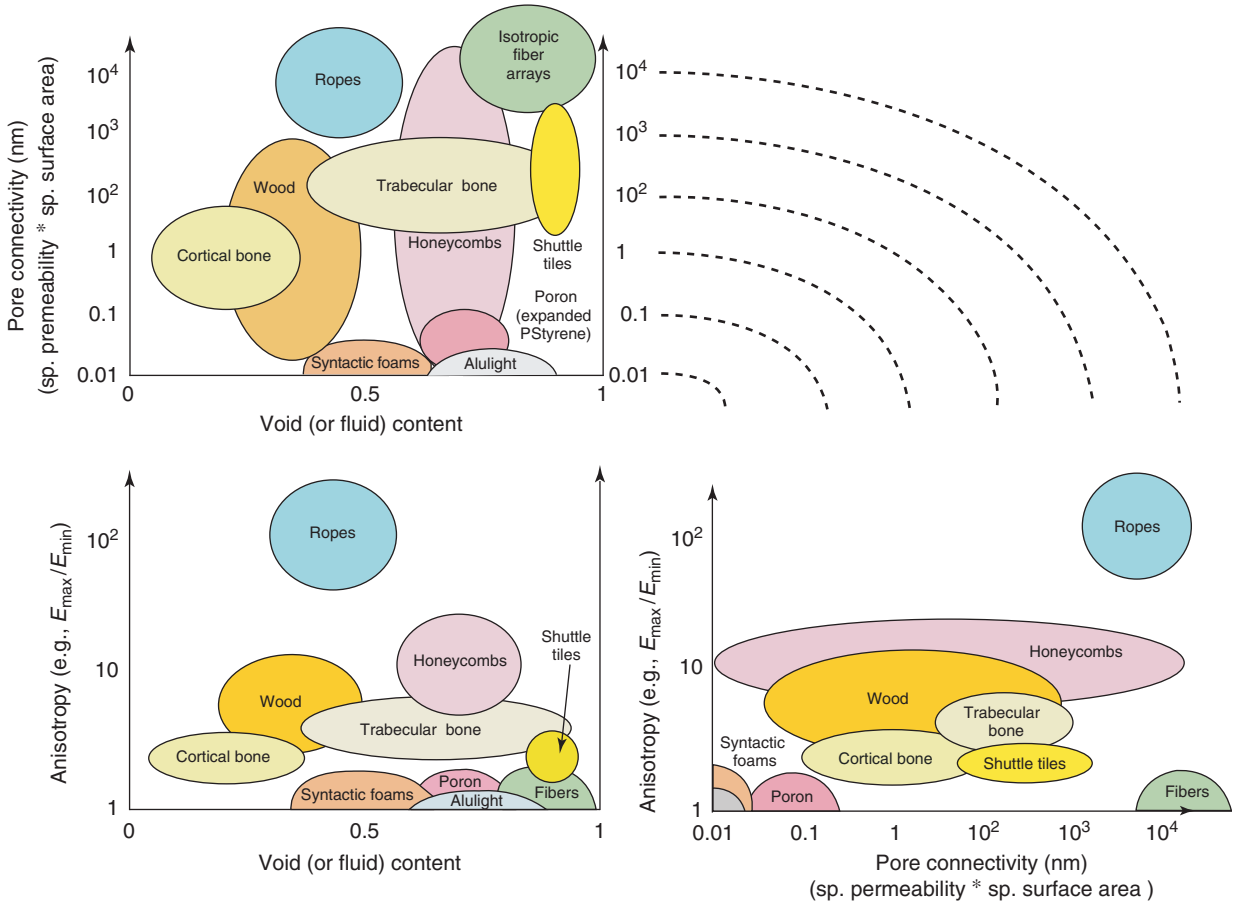

Figure 1 Semiquantitative map designed to aid classification according to pore architecture, showing the combinations of void content, anisotropy, and pore connectivity exhibited by a variety of highly porous materials. ("Alulight" is a closed-cell aluminum foam made via a gas generation route.)

Furthermore, porous materials may have interesting transport properties or potential for actuation characteristics and these often require rather specialized analysis. In outlining these structure–property relationships, reference is periodically made to the applications for which particular properties are most relevant. Of course, minimization of weight is a common motivation for using porous materials, and this is a key objective for many applications, but transport properties such as permeability and conductivity may also be of critical importance. Overall, the coverage is of necessity highly abbreviated and the bibliography provided will need to be consulted for any detailed information.

Mechanical Properties and Performance Requirements

Elastic Constants and Stiffness-Critical Lightweight Structures

The elastic constants of porous materials can be predicted using conventional composite theory models, with the "reinforcement"-ascribed zero stiffness (and zero Poisson ratio). For example, **Figure 3** shows how axial and transverse Young's modulus and Poisson ratio are predicted to vary with void content, and with void aspect ratio, according to the Eshelby method, which is based on assuming that ellipsoid-shaped inclusions (pores) are dispersed throughout the matrix. The following equation gives the elastic constants

$$\boldsymbol{C} = [\boldsymbol{C}_{\mathrm{m}}^{-1} - f\{(\boldsymbol{C}_{\mathrm{i}} - \boldsymbol{C}_{\mathrm{m}})[\boldsymbol{S} - f(\boldsymbol{S} - \boldsymbol{I})] + \boldsymbol{C}_{\mathrm{m}}\}^{-1}(\boldsymbol{C}_{\mathrm{i}} - \boldsymbol{C}_{\mathrm{m}})\boldsymbol{C}_{\mathrm{m}}^{-1}]^{-1} \quad [1]$$

where C is the stiffness tensor, the subscripts m and i refer to matrix and inclusions (pores), S is the Eshelby tensor (dependent on inclusion aspect ratio s), I is the identity tensor and f is the volume fraction of inclusions (pores). The model is known to be unreliable for high inclusion contents, but it, nevertheless, serves to illustrate a few simple points.

First, the specific stiffness of porous materials differs little from that of the matrix, since the Young's

modulus falls off in a broadly similar way to the density (rule of mixtures line). In fact, apart from the axial stiffness of a material with aligned, highly elongated pores, which approximates closely to the rule of mixtures line, the stiffness falls off more sharply than the density, so the specific stiffness of porous materials is, in general, lower than that of corresponding monolithic materials.

Second, porous materials can be quite significantly anisotropic in stiffness, if the pores are aligned and elongated. This is the case in many natural cellular materials. In fact, it is clear from the plot that the pores do not need to be highly elongated for this to be the case, since the $s = 3$ curves are fairly close to those for infinite aspect ratio. However, it is also worth noting that the plot suggests that elastic anisotropy is unlikely to be dramatic (greater than a factor of 2 or so). Some assumptions, such as those of the equal stress model, lead to much greater predicted anisotropy, but these are known to be very unreliable, at least for cylindrical inclusions (pores). On the other hand, experimental data for transverse stiffness often suggest that it is much lower than in the axial direction. For example, typical woods (with a void content of $\sim$20–40%) are often quoted as having an axial (parallel to grain) stiffness of $\sim$10 GPa, but a transverse value of only $\sim$1 GPa. For bone, the quoted anisotropy is usually lower, but is still substantial in some cases. Partial explanation for such discrepancies is often related to difficulties in measuring a true transverse stiffness. The strength (and creep resistance) is often dramatically lower under transverse loading (see below), so that inelastic straining commonly occurs at low applied loads

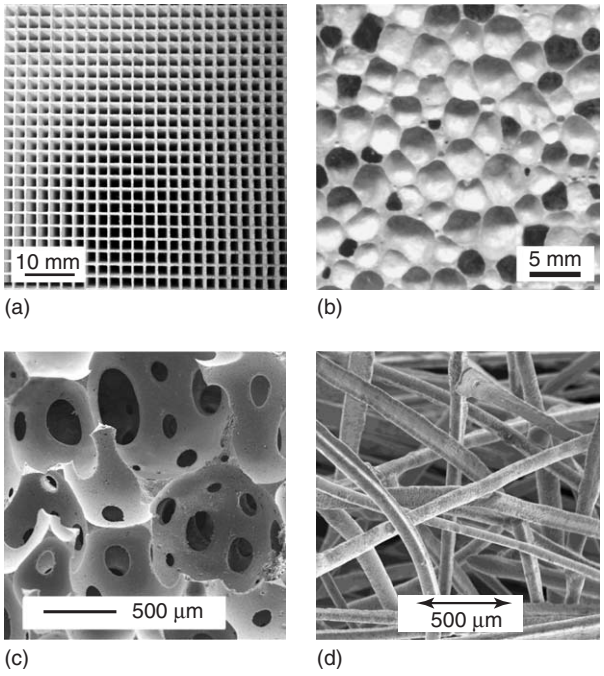

Figure 2 Microstructures of (a) a ceramic honeycomb, (b) a closed-cell metallic foam, (c) an open-cell SiOC foam, and (d) an open-network structure made by bonding metallic fibers together.

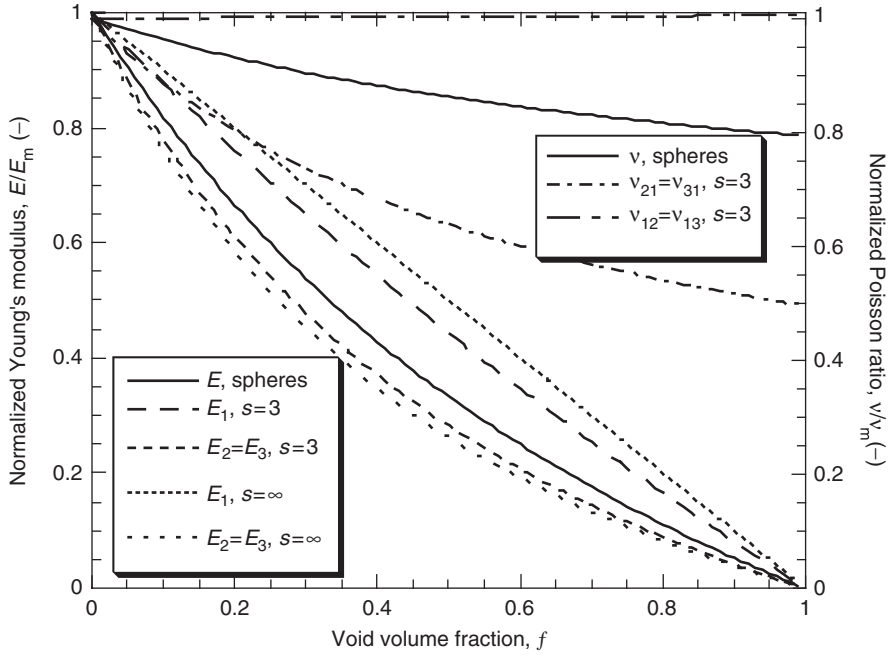

Figure 3 Predicted dependence on void content f, and void aspect ratio s, of the Young's modulus and Poisson ratio, obtained using the Eshelby method (eqn [1]).

during stiffness measurement. However, it should also be recognized that this type of model, which takes no account of the distribution of voids, and assumes that they have no contiguity (i.e., that the cells are all closed), may be very unreliable for high-void contents and for open-cell materials. Finally, it must be noted that these models assume the base material to be isotropic. For many natural materials, such as wood, the cell walls themselves exhibit high degrees of structural alignment, and hence are highly anisotropic, both elastically and in terms of strength. Obviously, such effects should be taken into account when predicting the effect of the presence of pores.

It can also be seen in **Figure 3** that the Poisson ratio may vary significantly when voids are introduced, although the relative changes are predicted to be smaller than those for stiffness. However, it should again be emphasized that, particularly at high-void contents, and with open-cell structures, geometrical aspects can assume much greater importance, and the "mean field" approach of the Eshelby method is certainly not well-suited for prediction of elastic constants at high-void contents. For highly porous materials of this type, geometrically specific models may be more appropriate. For example, consider the plots shown in **Figure 4**. These relate to porous materials composed of an isotropic (random) array of slender cylindrical fibers, bonded together at junction points – see **Figure 2d**. A model has been developed for such material, based on assuming that deformation arises solely from elastic-bending deflections of the fiber segments between junctions. The following simple equation is derived for the normalized Young's modulus

$$\frac{E}{E_{\mathrm{m}}} = \frac{9(1-f)}{32(L/D)^2} \qquad [2]$$

where L/D is the aspect ratio of fiber segments between joints. These stiffnesses, both measured and predicted, are well below those predicted by the Eshelby method for the void contents concerned. In general, open-cell materials are less stiff than closed-cell ones with similar void contents, while open-network materials are the least stiff. These discrepancies highlight some of the limitations of applying conventional composite theory approaches to highly porous materials, particularly if they have open-cell or open-network structures. It might also be noted that the model used to produce the plots in **Figure 4** predicts a Poisson ratio value of ~ 0.32, independent of void-content and fiber segment aspect ratio.

Finally, it should be emphasized that, while porous materials do not have superior specific stiffness to monolithic materials under uniaxial loading, they can exhibit dramatic advantages when subjected to bending moments or torques. The reason for this is

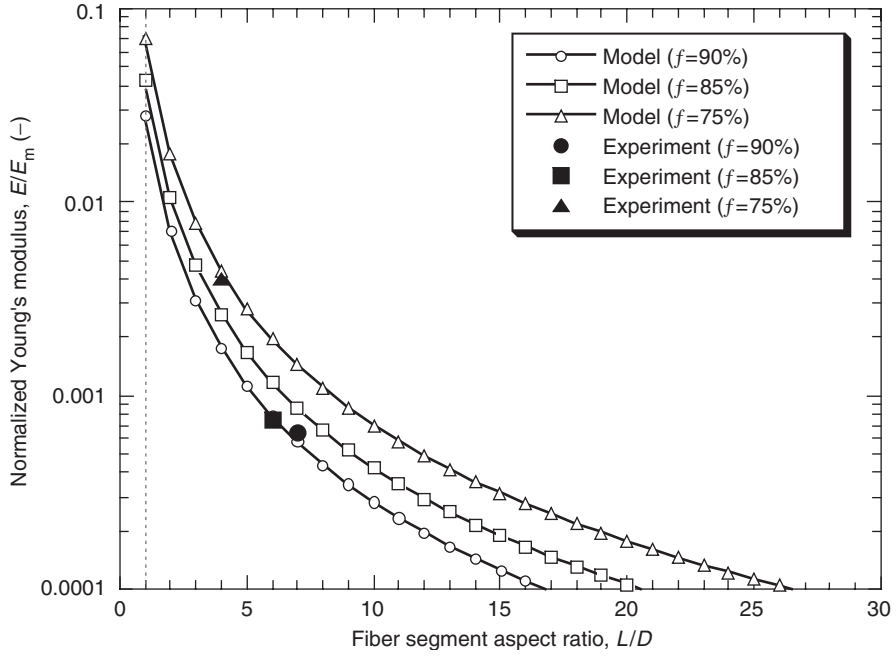

Figure 4 Predicted Young's modulus of an open-network porous material comprising an isotropic array of bonded fibers, as a function of the aspect ratio L/D, of fiber segments between junctions, according to eqn [2]. Curves are plotted for several void contents (f) and some corresponding experimental data are also shown.

that "bending stiffness" and "torsional stiffness" are raised, not only by the material having a higher Young's modulus, but also by it being located further from the neutral axis or neutral plane. Depending on the exact boundary conditions, the appropriate figure of merit for stiffness-critical weight minimization (E/ρ for uniaxial loading) is commonly $E^{1/2}/\rho$ or $E^{1/3}/\rho$ for bending, which can make highly porous materials attractive for construction of many types of stiff, lightweight structures. A simple example of this is sandwich panels, for which optimizing the design of highly porous core material is an important issue.

Strength, Fracture Mechanics, and Energy-Absorbing Structures

In general, pores are expected to cause both stress concentration effects and easier crack paths, leading to reductions in strength. In principle, a conventional fracture mechanics calculation should allow estimation of the effect of a dispersed set of (closed cell) pores on the strength and toughness. The passage of a crack through pores reduces the need for material to be fractured and hence reduces the fracture energy. Neglecting any effects of preferential crack paths or reductions in constraint near pores, the fracture energy should thus be proportional to the relative density ($1–f$), with no dependence on pore size. The stiffness falls off with increasing void content in a broadly similar manner (see the section "Elastic constants and stiffness-critical lightweight structures"). Pores will also act as crack-initiating flaws, reducing the stress required for the onset of fast fracture. In this role, the pore size is significant. To a zeroth approximation, the strength of a porous material could thus be written as a conventional fracture mechanics strength

$$\sigma_* = \left(\frac{G_c E}{\pi c}\right)^{1/2} \approx (1-f)\left(\frac{G_{cm} E_m}{\pi R}\right)^{1/2} \qquad [3]$$

where c is the flaw size, G_{cm} is the fracture energy of the base material and R is the radius of the crack-initiating (largest) pore, assumed to be spherical. This equation is plotted in **Figure 5**, which illustrates how high-porosity contents and large pores lead to low-fracture strengths. However, it should be recognized that experimental strengths (and fracture energies) tend to be very low for most highly porous metals and ceramics, even if the pores are relatively fine, and, in general, these predictions are over-estimates, particularly for metals. This is thought to be largely due to a tendency for cracks to preferentially follow high-porosity paths and for ductile tearing of ligaments between pores to occur readily as stress concentration effects operate. This can substantially reduce the effective toughness. While tensile strengths are higher if the pore (cell) structure is fine and regular, most experimentally measured values for highly porous materials are no higher than a few MPa, although some reported values for materials based on metal fibers are in the range of several tens of MPa.

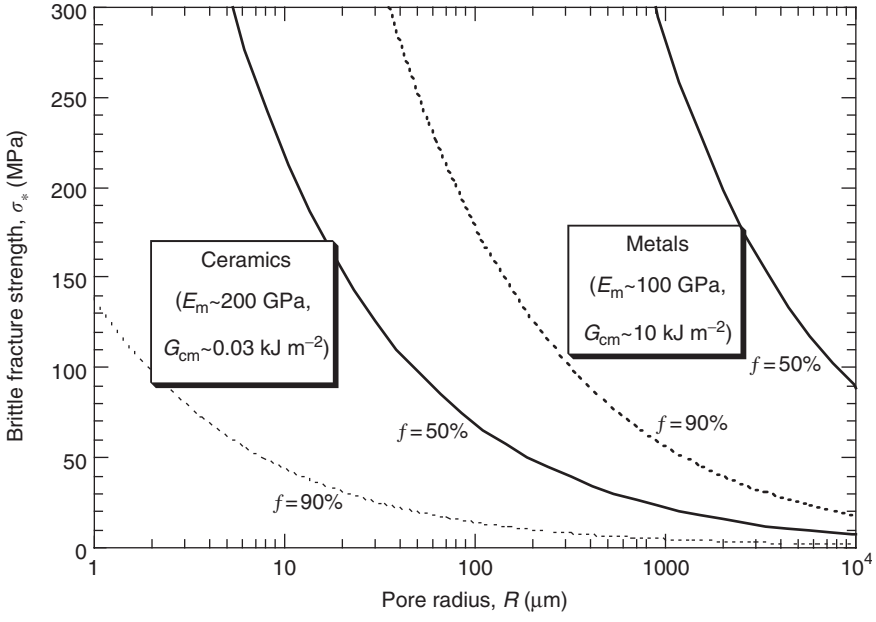

Figure 5 Predicted dependence of the fracture strength of porous metals and ceramics on void content and size, according to eqn [3].

Where highly porous materials are used in load-bearing situations, attempts are often made to ensure that they experience predominantly compressive loads (although it may be noted that this is not possible under bending and twisting moments, which is when their elastic properties can be most effectively exploited – see the section "Elastic constants and stiffness-critical lightweight structures"). Under uniaxial compression, highly porous materials tend to yield at relatively low stresses (from a few MPa up to a few tens of MPa) and then undergo quite large strains without the stress level rising much. This strain is associated with local plastic deformation and/or fracture and crushing events. Such deformation can be useful when substantial energy absorption is required without high stresses being generated, as in cushioning of impact events or redistribution of static or dynamic loading configurations. Of course, polymeric foams have long been used for such purposes, but they do not have high energy-absorbing potential and they also suffer from other drawbacks, such as susceptibility to fire. Metals offer particular promise in this regard, since very high local plastic strains can, in principle, be generated, due to the reduced constraint on individual cell walls or network members. This potential has not yet been fully exploited and further work is required on optimization of the energy-absorbing characteristics of highly porous metals. Some such material incorporates significant levels of ceramic in the cell walls (introduced to facilitate the processing) and this certainly impairs plasticity and energy absorption. On the other hand, there may be some situations in which predominance of brittle crushing processes over plastic deformation may be advantageous, since it will tend to result in reduced stress transfer to the component being protected.

Strength can be markedly anisotropic in porous materials. In highly aligned cellular materials, such as wood, factors of 10 between axial and transverse strengths are commonly observed. In materials such as wood and bone, this is partly attributable to the alignment of microstructural constituents (cellulose microfibrils, collagen, etc.) within the cell walls, as well as to the anisotropic cell geometry. However, even in the absence of such effects, strength anisotropy from cell or network geometry can be dramatic, with ropes providing a graphic example. The nature of the bonding in transverse directions is clearly relevant to the magnitude of the anisotropy and in some cases this can be very weak indeed.

Finally, it should be emphasized that the toughness and strength of highly porous materials is not a simple topic. While the presence of pores tends, in general, to promote premature yielding and fracture, there are situations in which the compressibility of porous materials represents a substantial advantage. For example, while the outstanding toughness and damage tolerance of wood arises partly from specific energy-absorbing mechanisms, notably fiber pullout, it is also partly due to the compressibility conferred by the presence of pores. This allows intrusive events, such as the introduction of screws, to take place without the large stress buildup and consequent macroscopic distortion or crack propagation which would tend to result with most fully dense materials, even those with relatively high toughness. Bone is also able to withstand screwing and similar fixation operations quite well, although they can sometimes cause cracking. It might also be argued that the damage tolerance and general mechanical versatility of ropes arises largely from their compressibility, or, at least, from the relative independence of individual strands, which is clearly associated with the presence of the free space. Unfortunately, most manufactured porous materials do not exhibit toughening mechanisms analogous to those operating in wood and bone, which are attributable to their complex, multi-scaled microstructures. Furthermore, the damage tolerance and flexibility of rope-like materials is achieved at the cost of very high compliance and low strength in transverse directions. The degree to which most manufactured porous materials benefit mechanically from their high compressibility has thus been rather limited, although it has been noted in some cases that they are suitable for screwing etc. Nevertheless, open-network quasimaterials of various types have excellent potential for offering attractive combinations of mechanical properties and their further development seems likely.

Transport Properties and Multifunctional Applications

Electrical and Thermal Insulation Characteristics

Since there is substantial resistance to the passage of both heat and electrical charge through pores (gaseous or vacuum), porous materials have long been of interest as insulators. However, there are important differences between the two cases for porous materials. In particular, pore connectivity is often an important issue for heat flow. The main reason for this is that convective heat transfer can be significant. There is a scale effect here, since natural thermal convection within closed cells tends to be significant only when the cells are relatively large (typically, $> \sim 10\,\text{mm}$). However, in open-cell materials natural convection can occur even with finer structures and forced convection can be an important heat transfer

mechanism (to such an extent that open-pore materials are often used as heat exchangers – see the section "Fluid permeability and specific surface area"). In the electrical case, on the other hand, the focus is entirely on current paths through the matrix, assuming that the breakdown field for ionization of gas in the pores is not reached. In this section, attention is concentrated on conductive transfer.

From a mathematical point of view, conduction of heat and of electrical charge are indistinguishable. The basic equations of unidirectional heat and current flow may be written as

$$q = -K\frac{\partial T}{\partial x} \qquad [4]$$

$$j = -\sigma\frac{\partial V}{\partial x} \qquad [5]$$

where q is the heat flux ($\mathrm{W\,m^{-2}}$) arising from a thermal gradient $\partial T/\partial x$ ($\mathrm{K\,m^{-1}}$) in a material of thermal conductivity K ($\mathrm{W\,m^{-1}\,K^{-1}}$), while j is the current density ($\mathrm{A\,m^{-2}}$), σ is the electrical conductivity ($\Omega^{-1}\,\mathrm{m^{-1}}$ or $\mathrm{S\,m^{-1}}$) and $\partial V/\partial x$ is the electric field ($\mathrm{V\,m^{-1}}$). It is common to use the resistivity ρ ($\Omega\,\mathrm{m}$), which is the reciprocal of the electrical conductivity. Both conductivities are proportional to the concentration of carriers, and to their mobility. For thermal conduction, either electrons or phonons can be effective carriers. Good thermal conduction is conferred by the presence of free electrons (metals) or by high phonon velocities (light, stiff materials) and large phonon mean free paths (few scattering centers, i.e., low levels of defects, grain boundaries, etc.). In contrast to this, only electrons or ions can act as carriers of electric charge. Since electrons are much more mobile than ions, materials with free electrons (metals) have vastly greater electrical conductivities than all other materials. Differences in thermal conductivity between different types of material are much less dramatic.

It therefore follows that, if the objective is electrical insulation, then most ceramics are effective anyway and there is little incentive to make them porous, unless a large volume is beneficial – for example, in increasing the thickness of a ceramic insulating layer while keeping its mass low. The electrical resistance of such a porous ceramic layer would probably be similar to a dense ceramic layer of the same thickness, although other electrical properties, such as dielectric characteristics, will often be substantially different. For metals, on the other hand, electrical conductivity will fall as the porosity is increased, but even highly porous metals are unlikely to be suitable for electrical insulation purposes. In addition, there may be interest in maximizing the electrical conductivity of porous metals, so as to facilitate electrical connections or allow resistance welding.

For thermal insulation purposes, however, there is interest in quantifying the conductivity of both ceramics and metals, as a function of porosity level and pore architecture. If the pores are treated as isolated ellipsoids, then the Eshelby method can again be employed, leading to the following equation for the conductivity (electrical or thermal)

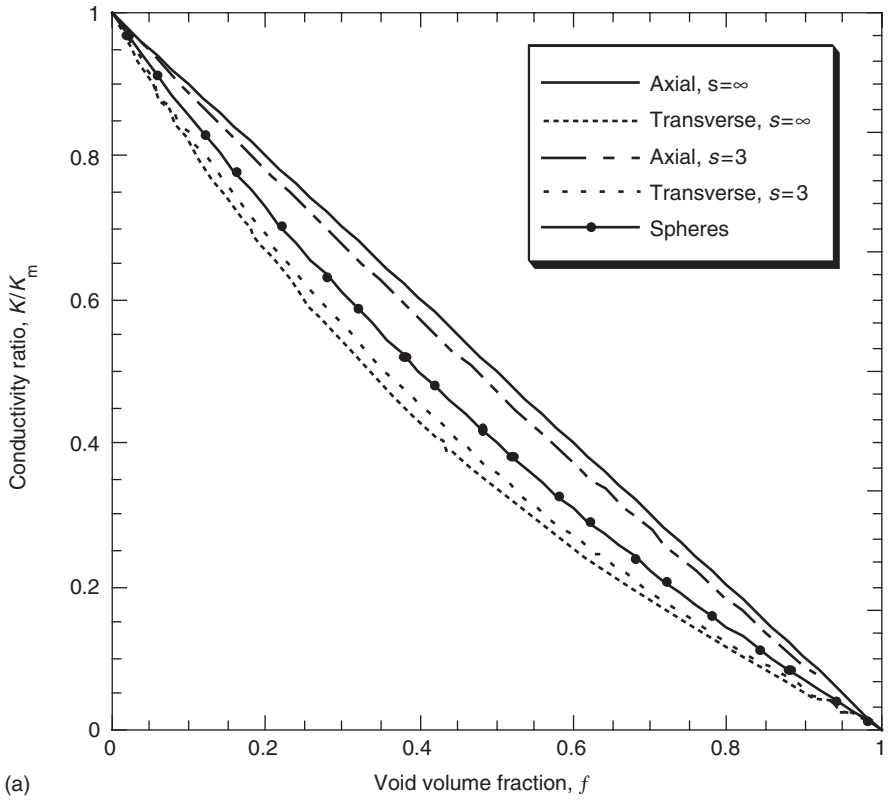
$$K = [K_{\mathrm{m}}^{-1} + f\{(K_{\mathrm{m}} - K_{\mathrm{I}})[S - f(S - I)] - K_{\mathrm{m}}\}^{-1}(K_{\mathrm{i}} - K_{\mathrm{m}})K_{\mathrm{m}}^{-1}]^{-1} \qquad [6]$$

which reduces for the case of spheres to the familiar Maxwell equation

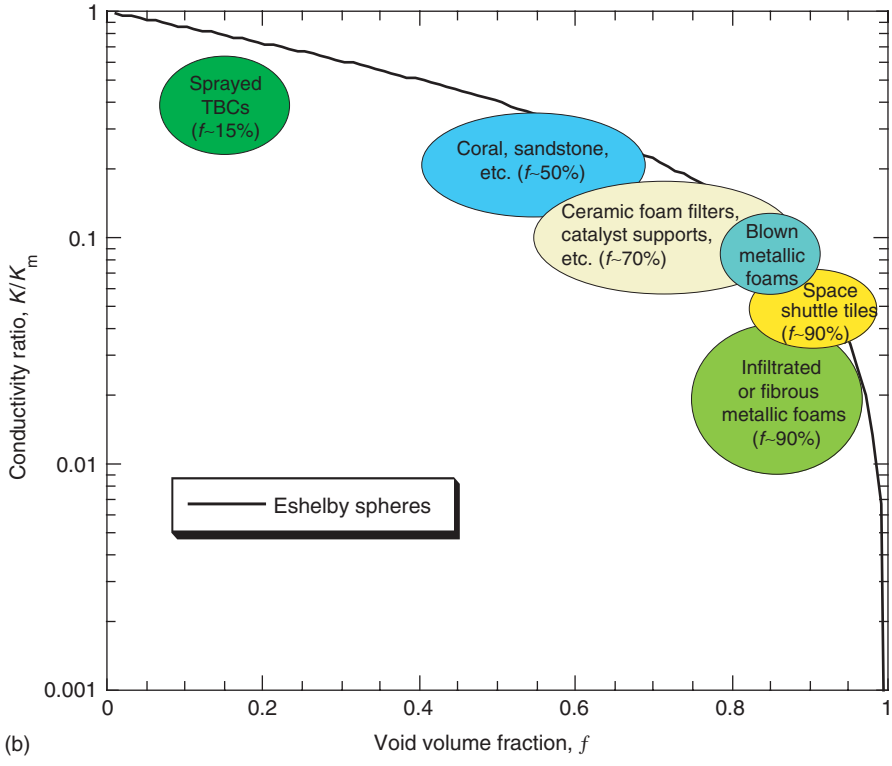
$$\frac{K}{K_{\mathrm{m}}} = \frac{2(1-f) + (K_{\mathrm{I}}/K_{\mathrm{m}})\,(1+2f)}{(2+f) + (K_{\mathrm{I}}/K_{\mathrm{m}})\,(1-f)} \qquad [7]$$

This Eshelby expression is very similar to that for the elastic constants (eqn [1]), but these are now second-rank tensors, rather than fourth rank. Predictions from eqn [6] are shown in **Figure 6a**, with the void conductivity taken as zero ($K_{\mathrm{air}} \sim 0.025\,\mathrm{W\,m^{-1}\,K^{-1}}$, compared with typical values of ~10–200 for metals and 1–150 for ceramics). As with the elastic constants, the reliability is rather poor at high-void contents ($> \sim 50\%$), when the structure will not in most cases approximate well to a matrix containing a set of isolated ellipsoidal voids and the pore architecture should be taken into account. In general, conductivities fall significantly below the Eshelby-predicted levels at high-void contents, as the conduction paths through the matrix become longer and more convoluted, particularly if the pore connectivity is high. This is illustrated by **Figure 6b**, which presents a normalized plot of thermal conductivity data for various porous metals and ceramics, with structures ranging from a set of layered splats to open three-dimensional fibrous networks. These include the silica fiber-based space shuttle tiles and plasma-sprayed zirconia thermal barrier coatings (TBCs). The latter exhibit normalized conductivities well below the Eshelby predictions, even though the void content is relatively low. This is a consequence of their layered structure, with many poorly bonded interfaces normal to the heat flow direction. (Note that the blown metallic foams have closed-cell structures, while the infiltrated and fibrous ones are open cell.)

With particular pore architectures, the behavior can often be predicted quite reliably using simple geometrical models. For example, electrical conduction through a bonded metallic-fiber array has been



(a)



(b)

Figure 6 (a) Predicted dependence of the conductivity ratio on void content, *f*, and aspect ratio, *s*, obtained using the Eshelby method (eqn [6]), and (b) typical experimental ranges for the thermal conductivity ratio of various porous metallic and ceramic materials, with the Eshelby prediction for spheres included for reference purposes.

represented using the model shown in **Figure 7a**, assuming symmetry about the current flow axis, with all fibers equally inclined to it. It is easily shown that the resistivity of such material is related to that of the fibers by

$$\rho = \frac{\rho_{\text{fib}}}{(1-f)\cos^2\theta} \qquad [8]$$

where θ is the inclination angle. A comparison is presented in **Figure 7b** between predictions from this equation and some experimental data. The resistivity of such material tends be much higher than that of pore-free metal, by several orders of magnitude, even when the porosity content is only $\sim 80\%$, and it can be seen that the model captures this effect. That the internal architecture is important in this case is clear from the predicted sensitivity to the fiber inclination angle.

However, it is important to recognize that such simple models are only expected to be reliable if the transport process is dominated by conventional conduction through an isotropic matrix. This is quite likely for electrical current flow through a porous metal, but for heat flow through metals or ceramics there may also be significant convective and/or radiative contributions, while heat conduction through gas in the pores can be relevant and may be affected by pore dimensions, gas pressure, etc. Prediction of the thermal conductivity values exhibited by the materials represented in **Figure 6b** thus requires modeling that takes into account both structural architecture and details of the heat transfer conditions.

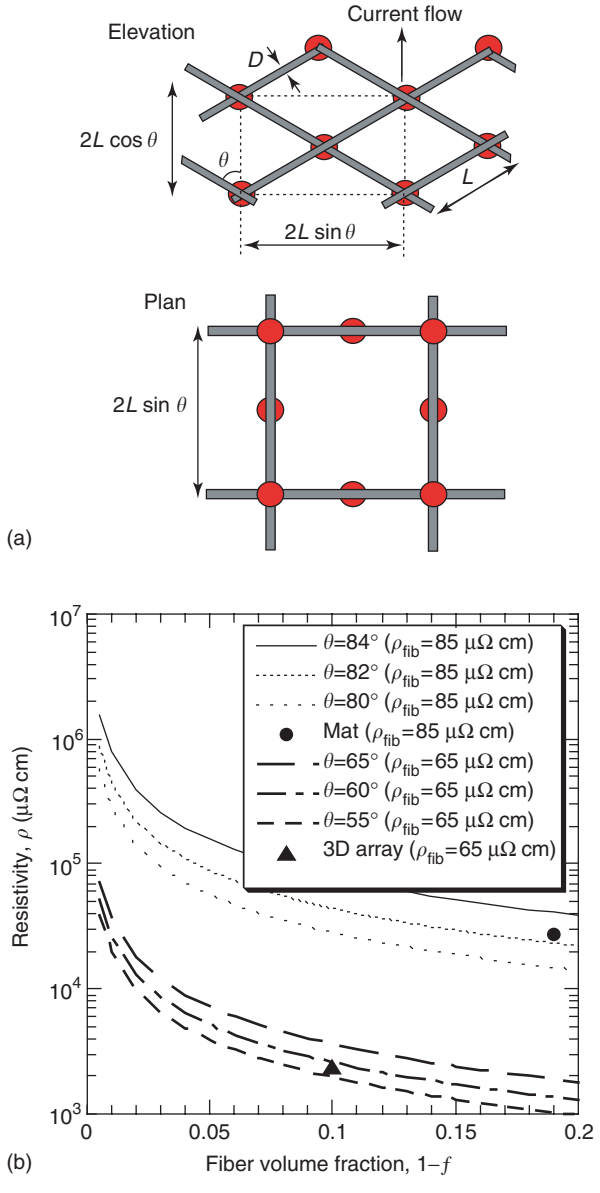


Figure 7 (a) Unit cell for a simple geometrical model of a bonded fiber array and (b) predicted resistivities compared with experimental data for two brazed materials – a mat made from long austenitic fibers (85 μΩ cm) and a 3D array material made from short ferritic fibers (65 μΩ cm).

Fluid Permeability and Specific Surface Area

The permeability of an open-celled porous material is an important property for several types of application. Permeation of fluids through such materials is a key issue for heat exchangers, filters, fuel cells, batteries, catalyst platforms, fuel tank baffles, fluid diffusers/mixers, and various types of textiles, as well as in many natural systems such as soils and rocks. The permeation process is clearly facilitated by high cell connectivity. The scale of the structure, which can be characterized by the specific surface area

$$S = \frac{A_{\text{sur}}}{V_{\text{tot}}} \qquad [9]$$

is also of importance. The resistance to fluid flow increases as the scale is refined, but a high surface area may be beneficial in some applications, including many electrochemical devices and combustion-related systems, such as solid fuel rocket propellants. For heat exchangers, there is expected to be an optimal specific surface area, allowing both rapid fluid permeation and efficient local heat exchange. This will also be true for filters, since the scale needs to be sufficiently fine to entrap the target bodies in the fluid stream, but not so fine that the entrapped bodies rapidly cause the permeability to fall as clogging occurs. Finally, it may be noted that encouragement of permeation is desirable in certain biomedical applications, such as porous surfaces of prosthetic implants into which bone growth is to be promoted.

Clearly, the permeation velocities of interest may cover a very wide range. Some example materials, designed for particular applications in which permeation and surface area are relevant, are shown in **Figure 8**.

Laminar flow of a fluid through a porous medium commonly conforms to Darcy's law, which may be written as

$$\frac{Q}{A} = \frac{\kappa}{\eta}\frac{\partial P}{\partial x} \qquad [10]$$

where Q is the volumetric flow rate ($m^3\,s^{-1}$), A is the sectional area (m^2), $\partial P/\partial x$ is the pressure gradient ($Pa\,m^{-1}$), η is the dynamic viscosity of the fluid (Pa s) and κ is the specific permeability (m^2). Permeability can thus be measured experimentally by recording the flow rate under a known pressure gradient. It should have the same value for all fluids.

Accurate prediction of permeability as a function of pore architecture is a relatively complex problem, but some simple models have been developed. The value of $\sqrt{\kappa}$ has dimensions of length and one approach involves equating this to some appropriate distance, such as the pore diameter or the hydraulic radius of the structure, defined as

$$R_h = \frac{f}{S} \qquad [11]$$

Such a rationale leads to the so-called Kozeny equations, of which the best known is probably the Blake–Kozeny equation. This is based on semi-empirical correlations for flow through packed beds and may be written as

$$\kappa \approx \frac{f^3}{4.2\,S^2} \qquad [12]$$

The specific surface area S, can be measured directly or can be estimated via a suitable geometrical

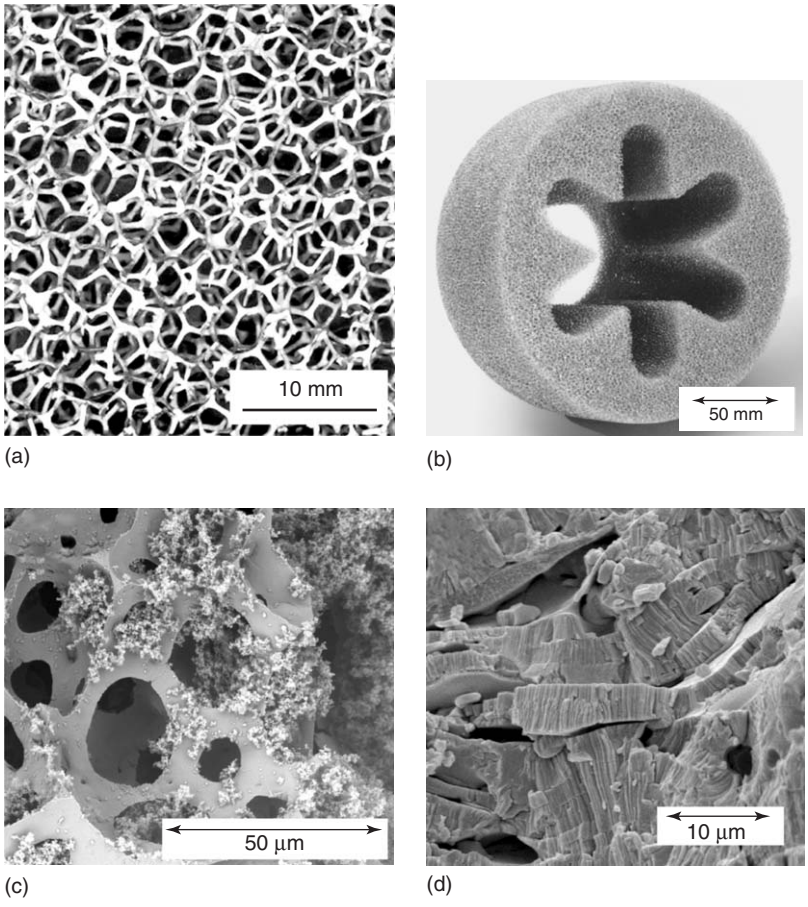

Figure 8 Examples of porous materials for specific applications: (a) microstructure of "Duocel" Al foam ($f \sim 90\%$), (b) rocket propellant component made of Duocel, (c) alumina filter ($f \sim 90\%$) with entrapped soot particles, and (d) plasma-sprayed zirconia thermal barrier coating (TBC), used in gas turbine engines ($f \sim 15\%$). model for the pore architecture, giving relationships such as the following

$$S \approx \frac{3.84}{D} \quad (f \approx 0.36) \quad \text{dense random packing of solid spheres (diameter } D\text{)} \qquad [13]$$

$$S = \frac{3\pi}{D(L/D)^2} \quad \left(f = 1 - \frac{3\pi}{4(L/D)^2}\right) \quad \text{cubic array of cylinders (diameter } D\text{, length } L\text{)} \qquad [14]$$

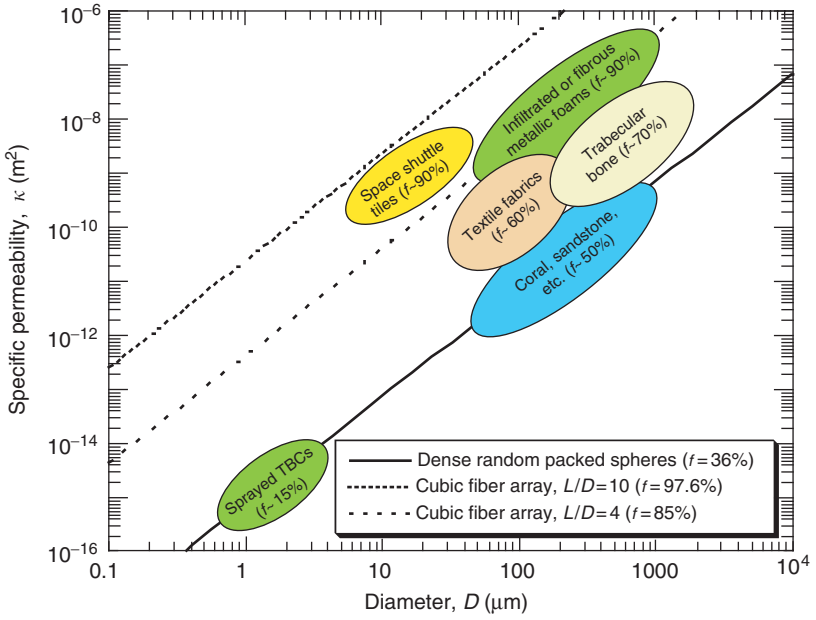

Figure 9 Plot of specific permeability against the structural length scale showing predictions from the Blake–Kozeny equation (eqn [12]), for a packed bed of spheres (eqn [13]) and for a cubic array of cylindrical fibers (eqn [14]), with two different aspect ratios between the joints. Also shown are the approximate ranges of experimental data obtained with various types of porous material.

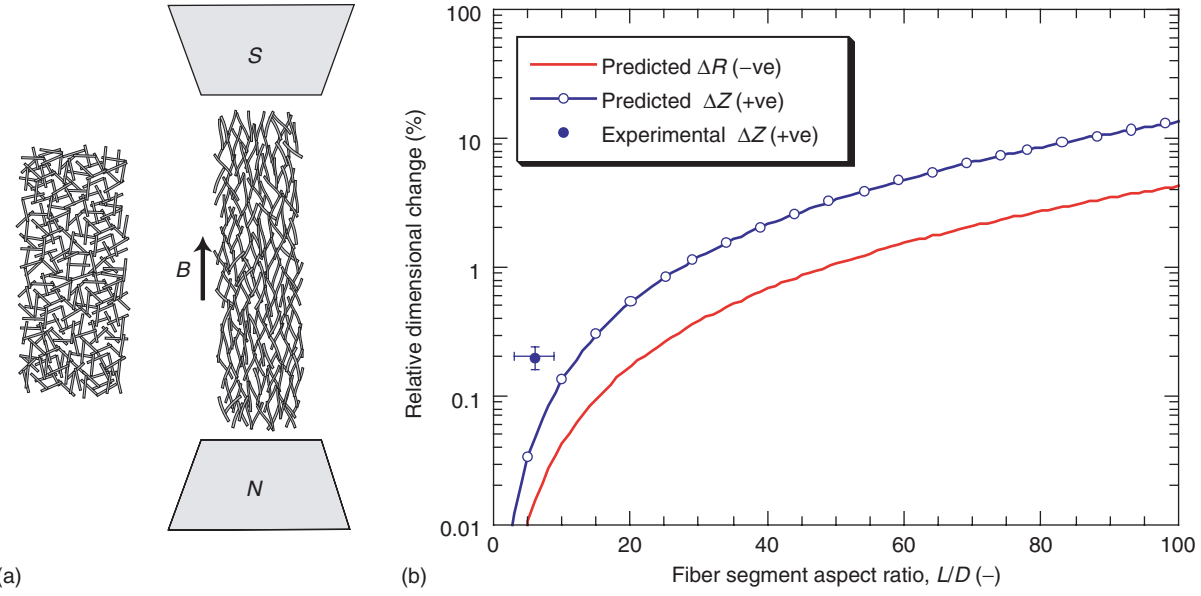

Figure 10 (a) Schematic depiction of how an isotropic porous material made by bonding of ferromagnetic fibers will tend to deform elastically in an applied magnetic field and (b) predicted (eqns [15] and [16]) and measured shape changes ($M_s = 1.6\,\text{MJ}\,\text{T}^{-1}\,\text{m}^{-3}$; $E_f = 210\,\text{GPa}$; $B = 1\,\text{T}$).

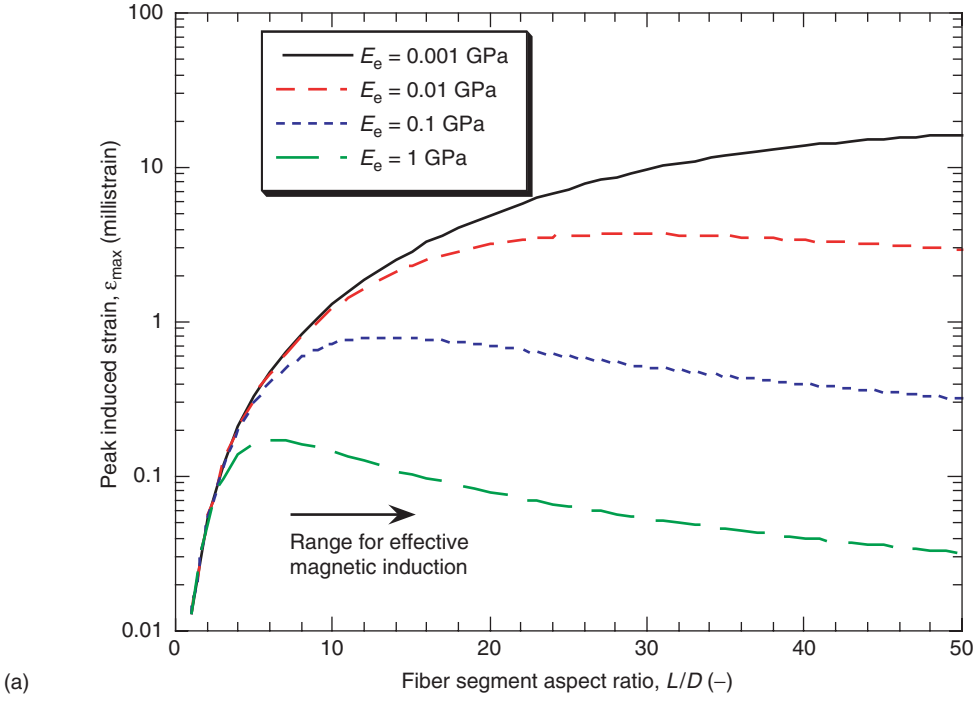
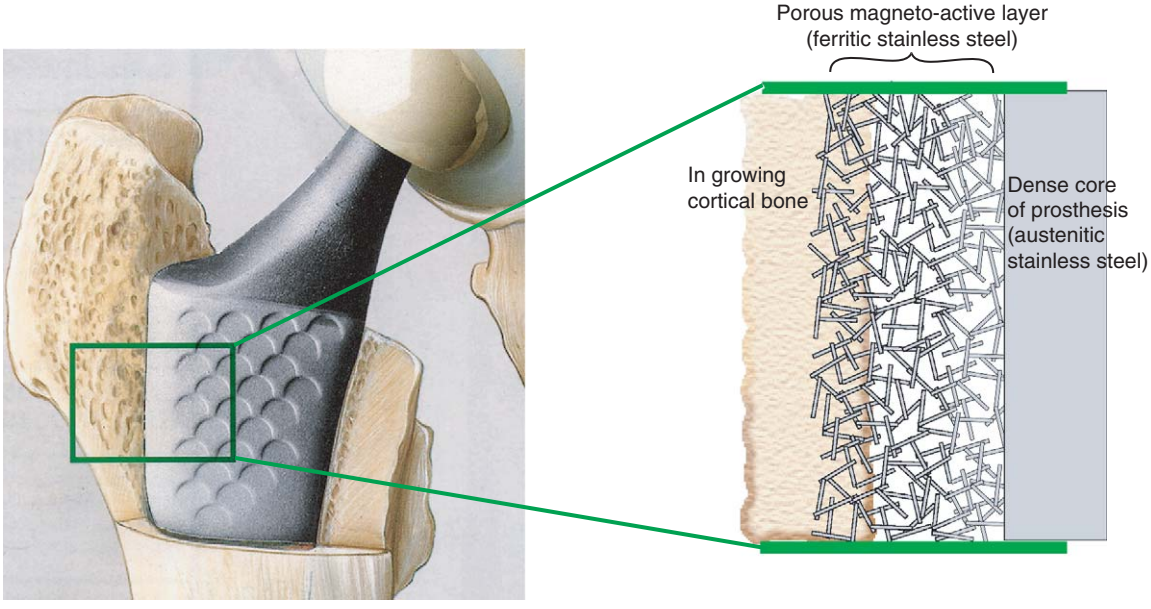
Relationships can also be derived for fiber bundles, planar random fiber arrays, woven fabrics, overlapping (poorly bonded) pancakes, etc. Predictions from the Blake–Kozeny equation, for the geometries of eqns [13] and [14], are shown in **Figure 9**, together with representative ranges of experimental data for various types of porous material. It can be seen that these data are, at least, broadly consistent with this simple model, with the permeability falling as the structural scale is refined, and as the void content is reduced. The product of permeability and specific surface area can be taken as a measure of pore



(a)



(b)

Figure 11 Estimated dependence (eqn [17]) on fiber segment aspect ratio, of the maximum strains induced in a compliant surrounding matrix when a ferromagnetic fiber array is subjected to an applied magnetic field and (b) an integrated prosthesis design, incorporating a porous surface layer in which mechanical straining could be induced in this way ($B = 1.5\,\mathrm{T}$; $M_s = 1.6\,\mathrm{MJ\ T^{-1}\ m^{-3}}$; $\theta = 30^\circ$; $E_f = 210\,\mathrm{GPa}$).

connectivity, as plotted in **Figure 1**, but it may be noted that all of the materials represented in **Figure 9** have a relatively high connectivity.

Correlations can be established between permeability and the efficiency of convective heat transfer, but such treatments are beyond the scope of the present article. However, it is worth noting that, in practice, the choice of materials and the design of pore architecture, for applications such as heat exchangers and fuel cell elements are often driven, not solely by transport phenomena optimization, but also by mechanical performance and high temperature stability requirements.

Magnetic Actuation and Magnetomechanical Devices

Porous materials have high potential for usage in various types of actuators, partly because of their relatively low stiffness. A high permeability may also be beneficial in some circumstances – for example, it might facilitate rapid temperature change, perhaps leading to shape changes via differential thermal contraction or the shape memory effect. There is also scope for magnetic actuation with certain types of pore architecture, particularly those containing slender members of ferromagnetic materials, which tend to align with an applied magnetic field. This concept is illustrated in **Figure 10a**, which shows how a material composed of bonded magnetic fibers would deform in such a field. Deformation of this type has recently been analyzed. The shape changes illustrated in **Figure 10a** are predicted to conform to the following equations

$$\frac{\Delta Z}{Z} = \left(\frac{16M_sB}{9E_f}\right)\left(\frac{L}{D}\right)^2 \qquad [15]$$

$$\frac{\Delta R}{R} = \left(\frac{-16M_sB}{9\pi E_f}\right)\left(\frac{L}{D}\right)^2 \qquad [16]$$

where M_s is the saturation magnetization of the fiber material, B is the applied magnetic field, E_f is the Young's modulus of the fiber, and L/D is the aspect ratio of the fiber segments between joints. Predictions are compared with experiment in **Figure 10b**. It can be seen that quite substantial macroscopic strains could be generated, particularly with relatively high fiber segment aspect ratios.

Estimates have also been made of the peak strains that could be induced in this way in a surrounding matrix, such as an embryonic network of bone cells growing into the fiber array. The analysis leads to the following equation for such strains

$$\varepsilon_{max} \approx \frac{12\pi M_sB \sin\theta(L/D)^2}{(9\pi E_f \tan\theta + 28E_e(L/D)^3)} \qquad [17]$$

Predictions are shown in **Figure 11a** for several matrix stiffness levels. Since such a bone network would have a stiffness of the order of 0.01–0.1 GPa, and since strains of at least around 1 millistrain are known to be required for effective mechanical stimulation of bone growth, it can be seen that this model suggests that such stimulation could be generated with a suitable external magnetic field ($B \sim 1.5$ T), provided the fiber segment aspect ratio was at least ~ 5–10. A possible prosthesis design allowing such an effect to be exploited is shown in **Figure 11b**.

Holography

P Ambs, Université de Haute Alsace, Mulhouse, France
J-P Huignard and B Loiseaux, Thales Research and Technology, Orsay, France

Introduction

Holography was discovered in 1948 by Denis Gabor who proposed to use this technique to improve the resolution in electron microscopy. Denis Gabor received the Nobel prize for this work in 1971. The word holography comes from Greek words meaning "total recording," and it is a technique for "wave front reconstruction" where both amplitude and phase of a wave front are recorded. The development of holography started in the beginning of the 1960s when coherent light sources became available with the invention of the laser. In 1962, E Leith and J Upatnieks made a major breakthrough with the invention of the off-axis reference beam optical holography. A few years later, in 1967, A Lohmann presented the first computer-generated hologram. The most spectacular application is the three-dimensional (3D) imaging, but there are now numerous applications where holography is even more useful for nondestructive testing, security, data storage, or for new optical elements, etc.

This article presents the basis of the holographic principles, and then the most commonly used optical setup to record and reconstruct holograms. A short review of the different recording materials and the applications, follows. The two last sections are dedicated to computer-generated holography and to the recent field of digital holography.

Principle of Holography

The purpose of holography is a wave front reconstruction. It is a two-step process, which involves first, the recording of the amplitude and phase of the wave front, and second, its reconstruction. All the available recording materials (photographic plates, photopolymers, photorefractive crystals, etc.) or recording devices (CCD or CMOS cameras) are only sensitive to the intensity of the wave front, and therefore all the phase information is lost. Since the interferences between two coherent waves reflect their phase differences, the idea of recording the whole wave is to record the intensity of the interferences between the desired wave front (object beam) and a known reference wave (reference beam). This can be easily illustrated by the following equation:

$O(x,y)$ called the object beam, is the wave to be recorded:

$$O(x,y) = |O(x,y)| \exp j\Phi(x,y)$$

$R(x,y)$ called the reference beam is a known wave that interferes with the object beam:

$$R(x,y) = |R(x,y)| \exp j\Psi(x,y)$$

$I(x,y)$ is the intensity of the interference pattern between the object and reference beams ($*$ indicates the complex conjugate), and using the simplified notations O and R, one obtains:

$$I(x,y) = |O+R|^2$$

$$I(x,y) = |O|^2 + |R|^2 + OR^* + O^*R$$

It is assumed that the recording medium is an ideal holographic material in which the amplitude transmittance $t(x,y)$ is proportional to the recorded intensity $I(x,y)$. To reconstruct the wave front, the hologram is illuminated by a wave identical to the reference beam and this is given by the following equation:

$$R(x,y)t(x,y) = |O|^2R + |R|^2R + O|R|^2 + O^*R^2$$

These last two terms of this development show that 3D imaging is possible since the complete amplitude and phase of the original wave front $O(x,y)$ is reconstructed. It can also be noted that due to the recording process, each point of the object contributes to the whole surface of the hologram. Therefore, even

a partially illuminated hologram reconstructs the image of the whole object, but the quality of the image is affected.

Principal Holographic Setups

In the previous section, the basic principle of holography was presented and in this section, the three principal setups that are used for optically recording and reconstructing holograms are detailed.

The In-line Hologram

The in-line configuration shown in **Figure 1** is also named the Gabor hologram since D Gabor first proposed this optical setup to demonstrate holography. The object is mostly transparent and may contain opaque particles. It is illuminated by a uniform coherent parallel beam and the transmitted wave is composed of two parts:

1. The wave directly transmitted by the object, noted as R, is constant and forms the reference.
2. The wave scattered by the particles, noted as O, and forms the object beam.

It is assumed that the intensity distribution $I(x, y)$ due to interference of O and R is recorded on a photographic plate whose transmittance $t(x, y)$ is proportional to the intensity and exhibits a constant offset t_0. Then, one has the following relation:

$$t(x, y) = t_0 + kI(x, y)$$

where k is a constant including the exposure time and the slope of the recording material.

To reconstruct the Gabor hologram, it is illuminated with a coherent parallel plane wave R (see **Figure 2**), and the wave transmitted by the hologram is given by

$$Rt(x, y) = R(t_0 + k|R|^2) + kR|O|^2 + k|R|^2O + kR^2O^*$$

The three terms of the reconstruction are presented in **Figure 2**. (1) $R(t_0 + k|R|^2 + k|O|^2)$ is the transmitted beam. (2) $k|R|^2O$ is the original object wave multiplied by a constant. It generates a reconstruction of the object located at its original position behind the hologram. It is a virtual image. (3) kR^2O^* is the complex conjugate of the original object. It generates a real image of the object in front of the hologram.

Application of the Gabor Holograms

The main application of the Gabor holograms is in the particle analysis. In conventional imaging systems, the combination of a large depth of field with a high resolution is not possible. This bottleneck can be

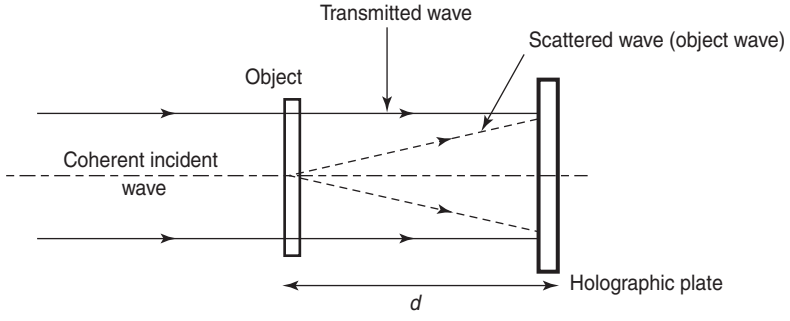

Figure 1 Recording a Gabor hologram.

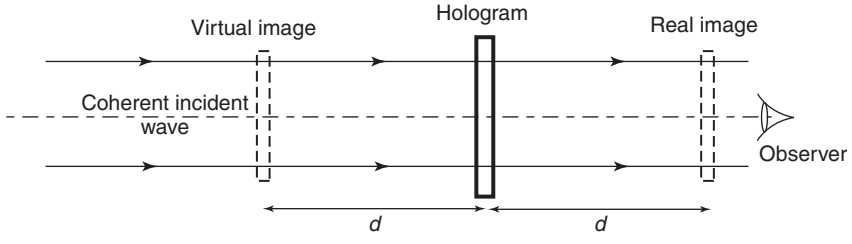

Figure 2 Reconstructing a Gabor hologram.

solved using a holographic recording that can store a high-resolution 3D image. The in-line hologram of the volume of moving particles is recorded using a triggered pulsed laser and the real 3D image can be analyzed by a conventional camera, which images the different planes of the volume. As an example of application, this setup was used to analyze the size and shape of droplets generated by injectors.

The Off-Axis Hologram

With the Gabor hologram, the three reconstructed wave fronts are on the same axis and they cannot be spatially separated. To solve this problem, E Leith and J Upatnieks proposed in 1962 the off-axis recording setup. In this case, the reference beam $R(x,y)$ and the object beam $O(x,y)$ are separated and interfering on the holographic plate under an angle α (see **Figure 3**). The object beam and the off-axis plane wave reference beam are respectively expressed by

$$O(x,y) = |O(x,y)| \exp j\Phi(x,y)$$

$$R(x,y) = |R(x,y)| \exp j2\pi\xi x$$

where

$$\xi = \frac{\sin \alpha}{\lambda}$$

As in previous relations $I(x,y) = |R+O|^2$ is the intensity of the interference fringes.

Following the above formalism, it is clear that when reconstructing this type of hologram with the off-axis reference beam as shown in **Figure 4**, it generates two spatially separated waves $W_1(x,y)$ and $W_2(x,y)$, respectively expressed by

$$W_1(x,y) = k|R|^2 O$$

where $W_1(x,y)$ is the original object wave multiplied by a constant factor and generates a virtual image of the object and $W_2(x,y)$

$$W_2(x,y) = kR^2 O^* \exp(j4\pi\xi x)$$

is the complex conjugate of the original object wave and generates a conjugate real image.

The three waves R, W_1, and W_2 are separated angularly and do not overlap as shown in the Gabor holograms. The off-axis setup is now the most common holographic recording configuration and it is used for reconstructing 3D images.

The Fourier Hologram

In this case, the object is planar and the purpose is to record the amplitude and the phase of its Fourier transform (FT). The holographic technique is used to record this complex wave front. The hologram is formed by the interference pattern between the FT of the object $O(u,v)$ and a tilted wave that is

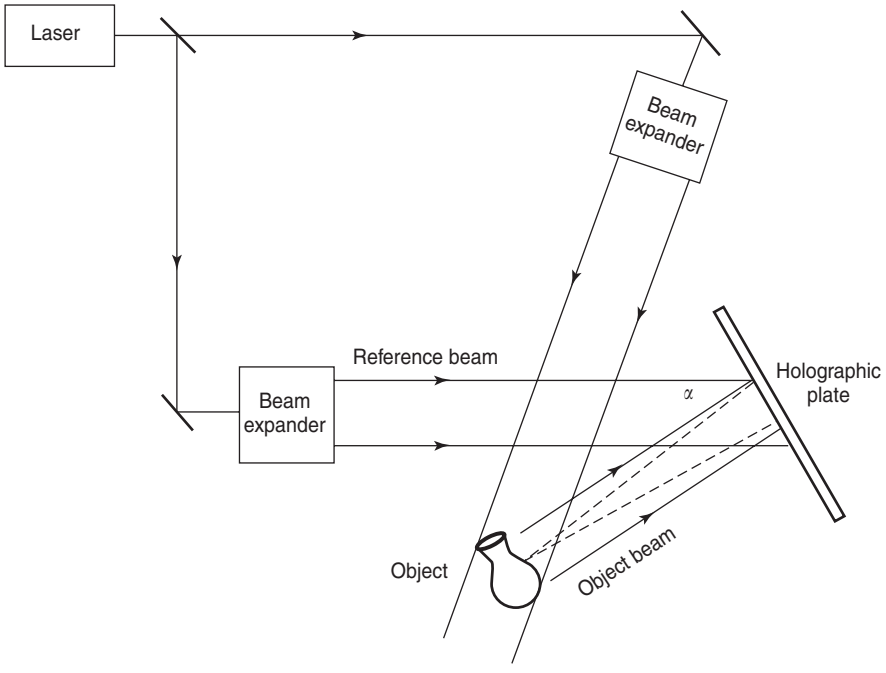

Figure 3 Recording an off-axis hologram.

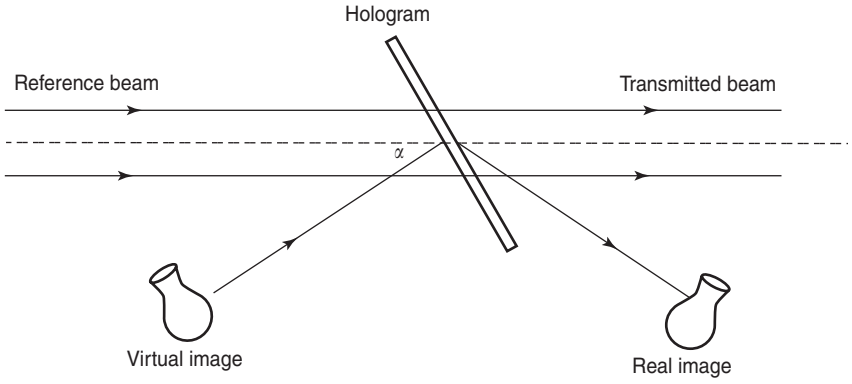

Figure 4 Reconstructing an off-axis hologram.

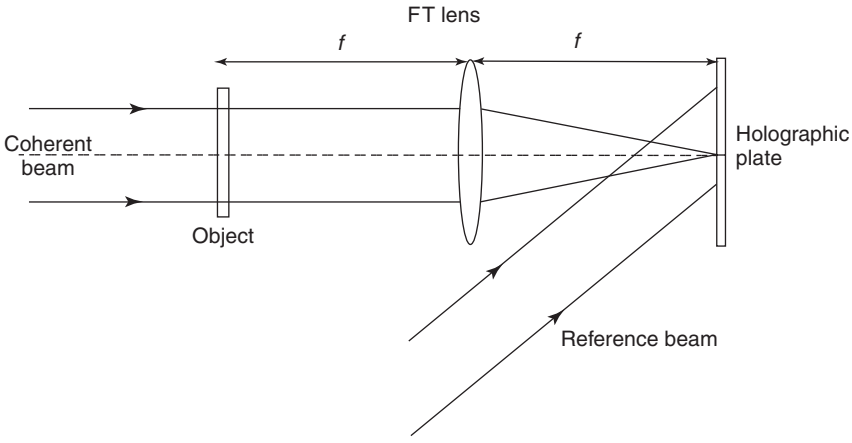

Figure 5 Recording a Fourier hologram.

the reference beam $R(u,v)$ (see **Figure 5**)

$$O(u,v) = FT[O(x,y)]$$
$$R(u,v) = \exp(j2\pi ua)$$

where a is a constant.

$I(u,v)$ is the intensity of the interferences between the object and the reference beams

$$I(u,v) = 1 + |O(u,v)|^2 + O(u,v)\exp(-j2\pi ua) + O^*(u,v)\exp(j2\pi ua)$$

For the reconstruction, the hologram is illuminated by a parallel plane wave (of amplitude unity to simplify) and the wave transmitted by the hologram is

$$U(u,v) = t_0 + kI(u,v)$$

The hologram is placed in the front focal plane of a lens (see **Figure 6**) and therefore the wave in the focal plane is the FT of $U(u,v)$

where

$$\begin{aligned} U(u,v) &= FT[U(u,v)] \\ &= (t_0 + k)\delta(x,y) \\ &\quad + kO(x,y) \otimes O(x,y) \\ &\quad + kO(x-a,y) + kO^*(-x+a,-y) \end{aligned}$$

where $\otimes$ represents the correlation operator.

This diffraction pattern is composed by a central order plus two terms:

1. $kO(x-a,\ y)$ is the $+1$ diffraction order that represents the original object beam separated by a distance a from the central order, and
2. $kO^*(-x+a,-y)$ is the -1 diffraction order that represents the complex conjugate of the original object beam separated by a distance $-a$ from the central order.

These two images of the object transparency are real.

Fourier holograms are not designed for 3D imaging; they have more specific applications such as optical correlation for pattern recognition, high-capacity

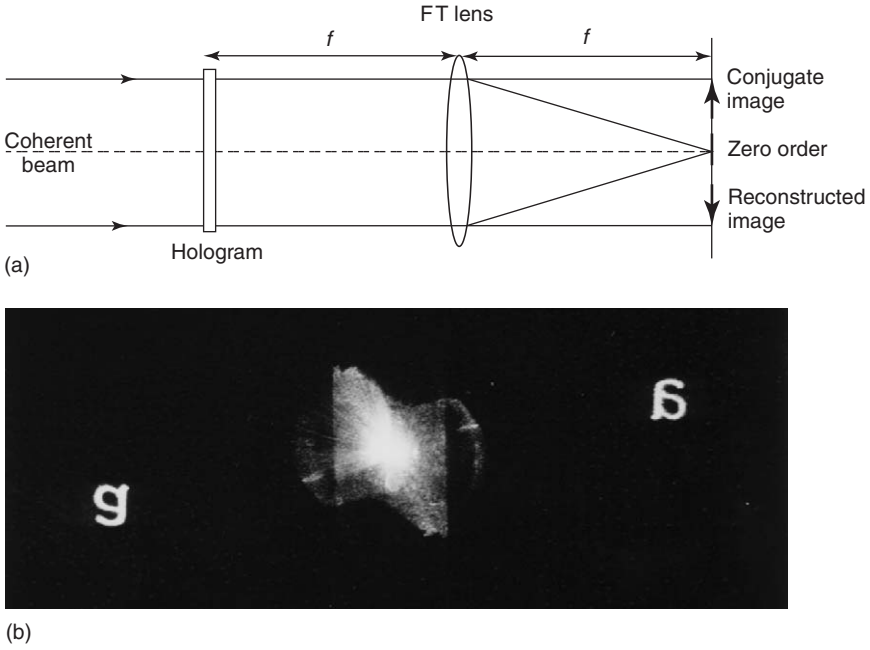

Figure 6 Reconstructing a Fourier hologram (a) the optical setup, and (b) the optical reconstruction of a Fourier hologram.

holographic data storage, 2D imaging, diffractive optical elements, and optical interconnections.

Hologram Characteristics and Recording Procedure

An important parameter of the holographic reconstruction is the diffraction efficiency. It is defined as the ratio between the light beam intensity of the desired reconstructed image and the intensity of the incident beam illuminated on the hologram during the reconstruction.

Depending on the recording material, the hologram can introduce an amplitude or a phase modulation. A spatial phase modulation is often preferred since the diffraction efficiency is higher and can reach hundred percent. If the recording material thickness is small compared to the fringe spacing, a thin grating is recorded and the Raman–Nath diffraction regime applies. The reconstruction produces a large number of diffraction orders and the efficiency gets reduced. On the other hand, a thick volume hologram is recorded if the thickness of the recording material is large compared to the fringe spacing. In such a case, a 3D grating is obtained and the Bragg diffraction regime applies. Phase volume holograms have two very attractive properties: (1) when illuminated by the reference beam, it reconstructs only one beam, and a diffraction efficiency of 100% can be theoretically reached, and (2) angular multiplexing of holograms is possible. In this case, the angle of incidence of the reference beam is different for each of these holograms, which are recorded in the same volume.

Each hologram is then addressed and reconstructed when illuminated by the reference beam with the corresponding incidence angle. It is also possible to multiplex holograms using different wavelengths. Holograms, which can be sequentially stored in the same volume location by varying the reference beam angle at each recording step, provide the capability of high-capacity data storage of digital pages of information.

Also, holograms recorded with the optical setup of **Figure 3** are of the transmission type. However, if a hologram can be recorded by two waves traveling in opposite directions and illuminating respectively the front face and the rear face of the recording medium, the fringes inside the recording medium will be parallel to its faces; this is a reflective type of hologram.

The requirements for optically recording holograms are imposed by the contrast and stability of the interference fringes. The illuminating laser source must be coherent with an adequate coherence length, and the optical setup is stable and isolated from the vibrations. Ideally, the recording media must not only have a high spatial resolution, typically higher than 1000 lines per mm, but also a linear response, a sensitivity range which can match the available laser wavelengths, and a low noise.

Most of the hologram recording materials are nonerasable, such as the commonly used materials listed below:

1. Silver halide emulsions have been used since the beginning of holography. After processing, the light intensity is then transformed into an amplitude modulation. However, it is possible to change this modulation into a phase modulation by bleaching the plate thus allowing for to reach a higher diffraction efficiency to be reached. The use of photographic emulsions implies a chemical wet processing. Silver halide emulsions fulfill most of the requirements for holographic recording media – they are relatively sensitive, have a large spectral response, and a high spatial resolution. Holographic emulsions were easily commercially available until all the large photographic material companies stopped their production several years ago. Now, only a few small companies are still producing holographic plates.
2. Dichromated gelatin is sensitized by ammonium dichromate imbedded into the gelatin, and it produces pure phase holograms. It is a very good material for holography with high resolution ($>10\,000$ lines per mm), a large change of refractive index modulation ($\Delta n > 0.1$), low absorption, and scattering. The use of dichromated gelatin is mastered at the industrial level with well-controlled processes to achieve $\sim 100\%$ diffraction efficiency.
3. Photopolymers are organic materials that transform the light intensity into a refractive index modulation through a photopolymerization process. This is a self-processing photochemical reaction and the hologram is recorded by illuminating the photopolymer, and no further processing is required. Of late, several companies have been selling their photopolymers which exhibit excellent characteristics for high-efficiency holographic components ($\Delta n > 5 \times 10^{-2}$).
4. Photoresists are also organic materials, which are well developed for microelectronic technologies. The illuminating light gives a relief modulation after wet development. Photoresists are used for the fabrication of the masters and for replicating the holograms by embossing.

Erasable holographic materials are suitable for dynamic holography, and the most commonly used materials in this category are photorefractive crystals. In this class of materials, the phase volume holographic grating is due to a photoinduced space charge field which modulates the crystal refractive index through the electrooptic effect. The index modulation can be erased by illuminating the crystal with a uniform beam intensity. Most of the photorefractive crystals also exhibit a dark storage time constant. A significant effort of research is still being done to investigate the phenomena involved in efficient hologram recording in the visible and near infrared spectral range. Photorefractive crystals permit the recording of dynamic holograms with time constants varying from nanoseconds to several seconds, and consequently, the diffracted wave front is probed in real time. Moreover, due to the nonlinear optical behavior of the material, there is an energy redistribution between the two recording beams. In other words, a low-intensity object beam can be amplified through an energy transfer from the reference beam. This unique property of the photorefractive crystals, due to self-diffraction mechanisms, opens up its applications to parametric image amplification, self-induced optical cavities, and phase conjugation with gain. Many other attractive applications can be realized based on the specific characteristics of photorefractive effects in a variety of crystals. Presently, the most important materials used in experiments are: $LiNbO_3$ iron doped; $BaTiO_3$; $KnbO_3$; Bi_{12}(Si, Ge, Ti)O_{20}; for visible and GaAs; InP or CdTe for the near IR. Besides the spectral sensitivity, they differ in terms of speed, dark storage time, diffraction efficiency, and a two-wave mixing gain coefficient.

Applications of Optical Holography

Holography has a large range of applications although it is not as commonly used as it was expected to be in its early stages in the 1960s. Several applications are listed below:

1. Display is the most spectacular and public-oriented application of holography. Large transmissive and reflective holograms have been recorded, and 3D images with a large depth of field have been reconstructed. Different varieties have been developed, particularly in hologram reconstruction with white light, such as the rainbow or color holograms. For color imaging, three holograms of the object are recorded successively on the same plate by three lasers emitting blue, red, and green light respectively. The recording media must have a high resolution and a broad spectral sensitivity range. Such color reflective holograms, reconstruct a 3D color object when illuminated by white light. Since holograms are difficult to reproduce, they are now used as a security feature, on banknotes for example. In this case, the original hologram is recorded optically on a photoresist and used to fabricate a master. The

embossing of a sheet of a reflective material produces the final hologram.

2. Holography also has industrial applications in nondestructive testing, thanks to holographic interferometry. The purpose of classical interferometry is to compare two wave fronts, though most of the time one wave front is tested with a reference one. The principle of the double exposure holographic interferometry is, first, to record holographically the wave front coming from an object at rest. Second, some constraints or stress (mechanical, thermal, etc.) are applied to the object and the new wave front coming from the object is also recorded on the same support. When the resultant hologram is illuminated, it reconstructs the two wave fronts that interfere together and the resultant fringe pattern reveals the modifications of the object with a slight change in its shape. Presently, the principle of holographic interferometry is still used, but the recording and processing are done electronically.
3. Holographic optical elements (HOEs) are also becoming an important industrial application. These elements are recorded optically, mainly on dichromated gelatin, and their purpose is to convert one wave front into another. They can implement, even simultaneously, complex optical functions such as focusing, deflecting, multiplexing, and spectral filtering. One of the applications of HOEs is the head-up display that is used in airplanes and recently in cars.
4. Holographic memories are under study in research laboratories, and an attempt to develop systems are now considered by a few companies. The data pages are written as holograms into a thick layer of photopolymer coated onto a rotating disk. The digital data can be recovered in parallel by reconstructing the holograms page-by-page. Therefore a high data rate can be achieved. The demonstrated capacity of such a 12 cm disk is presently 200 GB, but holographic memories of 1 TB could be expected in the future.

Computer-Generated Holograms and Diffractive Optics

The purpose here is the same as for optically recorded holography. It is to reconstruct a desired wave front, but the process is different since no physical recording process is involved. The wave front is entirely computed and this brings flexibility and versatility.

In the beginning, the word computer-generated hologram (CGH) was used, but presently, it is often referred to as a diffractive optical element (DOE). A Lohmann proposed the first CGH in 1967, and since then computation algorithms and fabrication methods have evolved following the progress of computers as well as the development of new fabrication technologies based on microlithography techniques. Presently, the DOEs can be classified into two classes: analytical-type DOEs and numerical-type DOEs.

Analytical-Type DOEs

The data composing such a DOE are in an analytical form and this is the case for diffractive lenses or gratings. These DOEs are pure phase elements and are fabricated accordingly. There are different approaches for the design of analytical-type DOEs, the direct DOE computation, the interferogram approach, and also the use of optical-design software.

Numerical-Type DOEs

The wave front to be reconstructed cannot be described by an analytical equation but must be computed using the propagation law. If the CGH illuminated by a plane wave reconstructs the desired wave front in the focal plane of a converging lens, the CGH will contain the inverse FT of the desired construction. If the CGH reconstructs without a lens at a given distance, then it will contain the inverse Fresnel transform of the desired reconstruction. The result of the Fourier or Fresnel transform is a 2D array of complex values. As for optically recorded holograms, the recording media are pure amplitude (mostly binary) or pure phase media, and therefore the complex data must be encoded to satisfy the requirements of the fabrication techniques. There are two types of encoding: first one is the cell-oriented encoding, and the second is the point-oriented encoding.

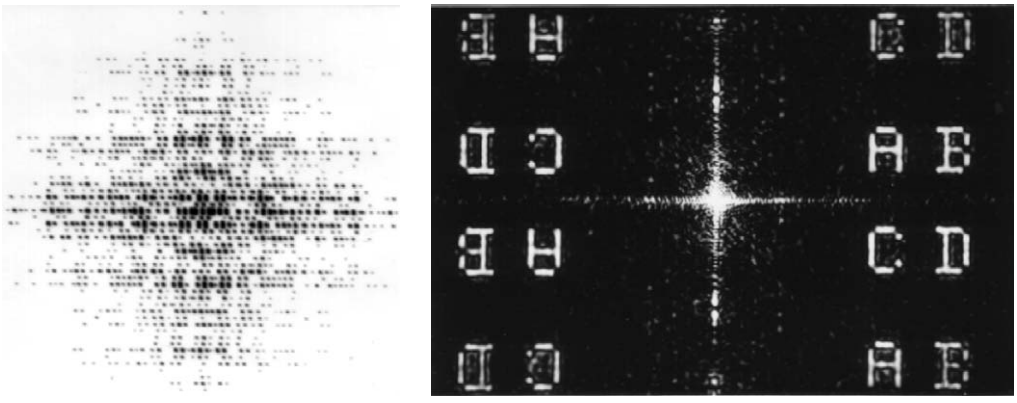
The first CGH presented by A Lohmann used a cell-oriented encoding that he called phase-detour encoding. The hologram is a 2D array of cells representing the array of complex values, and an aperture in each cell represents each complex value. The surface of this aperture is proportional to the amplitude of the complex value to be encoded and its position in relation to the center of the cell is proportional to the phase. An adequate ratio between the aperture width and the cell size introduces the right carrier frequency that allows the separation of the central order from the two reconstructed orders (see **Figure 7**). This encoding, known now as Lohmann's encoding, has given rise to several variations such as the encoding presented by W H Lee with two apertures per cell. The computation of these CGHs does not require powerful computers and is

not time-consuming since only one Fourier or Fresnel transform is calculated. Originally, these CGHs were first drawn on a sheet of paper with a computer-controlled pen plotter and then photoreduced on a high-resolution photographic film.

In the 1980s, thanks to the progress of computers in terms of power and memory capacity, several point-oriented encoding methods were developed. The principle of the three main methods is described below. For these algorithms, the desired reconstruction window is placed into a larger 2D array, therefore the hologram and also the reconstruction plane is larger than the reconstruction window. This extra space allows a better convergence of the computation algorithm due to the phase and amplitude freedom outside the reconstruction window. Amplitude CGHs construct the desired reconstruction, its complex conjugate, and a zero order. In order to separate these terms, the reconstruction window should be placed at some distance from the center of the reconstruction plane. For phase CGHs with more than three phase levels, only the desired reconstruction window appears in the reconstruction plane with no zero and no complex conjugate orders. However, this happens only if the computed phase levels are perfectly reproduced by the CGH.

The error diffusion algorithm consists of using a pulse width modulation technique for binarizing the hologram. In the case of binary amplitude CGHs, the real part of the Fourier or Fresnel transform is made positive by adding an offset, and then normalized. Each of these sampled real values are binarized and the error, that is, the difference between the binary value and the analog value, is divided and distributed with a weight to the unprocessed neighbors before proceeding to the next point. By choosing the weight and the direction of the error diffusion carefully, it is possible to separate the quantization noise from the desired reconstruction. This algorithm has given rise to a lot of related algorithms, such as the complex error diffusion algorithm (see **Figure 8**).

The next two encoding methods that are presented are iterative methods, they give better results in terms



(a) (b)

(a) (b)

Figure 8 Error diffusion encoding (a) the CGH and (b) the optical reconstruction.

of signal to noise ratio (SNR) but their computation is more time-consuming.

The direct binary search (DBS) algorithm presented by Seldowitz and co-workers in 1987 is based on the optimization of an error criterion by the use of a Monte Carlo technique. To begin with, a random hologram is generated, and the error criterion between the desired image and the reconstruction of this hologram is computed. The random CGH is then scanned, and a new error is computed after inversion of a new pixel. Pixel modification is retained only if the error decreases, and the error criterion is thereby minimized. This cycle is stopped when the error stops decreasing. The error criterion can be defined for amplitude, intensity, or a complex image, depending on the application using the CGH. For some applications, the CGH must reconstruct a wave front with a specified amplitude and phase, and the error must then be based on a complex-amplitude error criterion. However, in many other applications (display, memory, interconnect, etc.) the CGH reconstruction is detected by a quadratic detector, leaving the phase as a free parameter, and the error criterion can be based on amplitude or intensity errors. Since these errors use the phase freedom, the optimization algorithms converge better in this case. The original DBS algorithm was designed for binary CGHs; however, it can be extended to multilevel amplitude or phase CGHs at the expense of the computation time, since for each pixel, all levels must be tested.

The iterative Fourier transform algorithm (IFTA) presented in 1988 by F Wyrowski, is an iterative technique based on the Gerchberg–Saxton algorithm. Schematically, the principle of this method consists in going successively from the object plane to the spectrum plane by the application of constraints on the CGH (see **Figure 9**). To be recorded, the CGHs must be quantized and often binarized, but IFTA can also be used to compute multilevel amplitude or phase CGHs. In the Fourier domain, the spectrum of the object is thus constrained to be a binary function. The object constraint must correct the quantization noise by injection of the desired image intensity in the signal windows. The inverse FT of this spectrum gives back an object plane in which the object constraint is thus applied to match the desired image intensity in the signal windows. However, to avoid stagnation of the algorithm the quantization of the spectral plane must be progressive, as is illustrated in **Figure 9**, where three different steps of the binarization process are shown. In order to make its spectrum as uniform as possible, an equalizer can be applied to the desired signal. The simplest equalizer adds a random diffuser to the object plane.

Quality DOEs imply a very precise manufacturing with a perfect match between the computed phase and the actual phase of the component. To achieve these requirements, microlithography techniques are used to etch very precisely, in shape and depth, the chosen optical substrate such as quartz. Embossing techniques make cheaper DOEs, but the quality of their reconstruction is lower, particularly as the phase mismatch generates a zero order.

CGHs have a broad range of applications such as beam shaping, Fourier filtering, 2D or 3D display, optical interconnects, and complex optical functions generation (**Figure 10**).

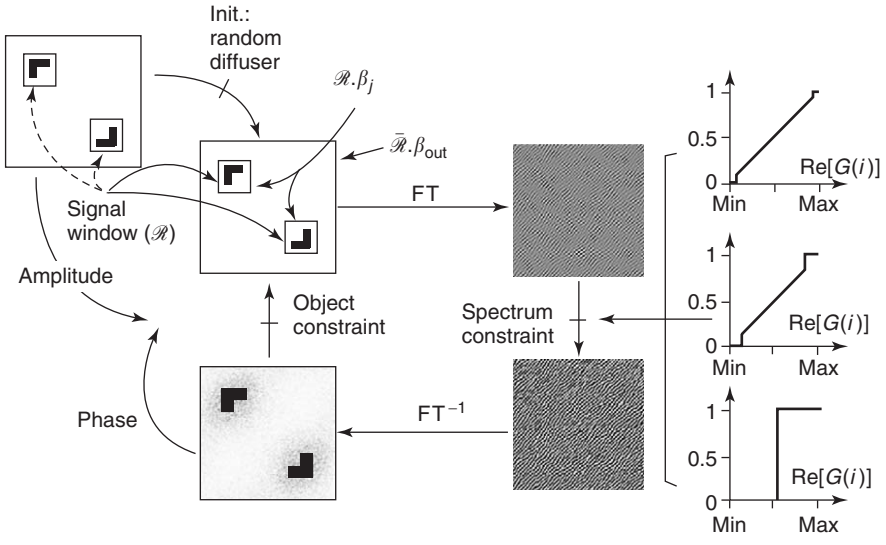

Figure 9 IFTA for computing a binary amplitude CGH. (After Wyrowski.)

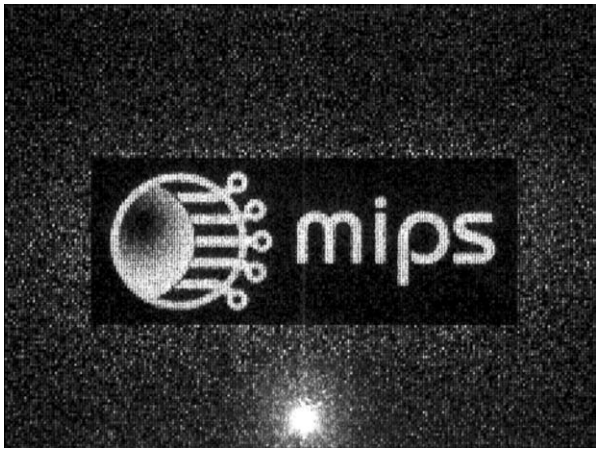

Figure 10 The optical reconstruction of an IFTA encoded binary amplitude CGH. Only the first reconstruction order is shown along with the zero order. The reconstructed image is 153×60 pixels, and a 256×256 pixel hologram was computed and replicated to fill an 800×600 array. This replication reduces the speckle noise into the reconstruction.

Digital Holography

In digital holography, the recording media is replaced by a high-resolution electronic camera. Using data from the recorded interference pattern, the object is reconstructed by a digital computer. Digital holography is a fast growing field, because it suppresses all the difficulties related to the processing of the traditional holographic recording media and brings in a lot of versatility and flexibility. Digital holography is now used in industrial applications requiring a quantitative measurement of a wave front where it is successfully replacing the classical setups. **Figures 11** and **12** show, respectively, the measurement of deformations and of vibrations using digital holography.

Imaging and Optical Processing

F Gori, University of Rome "Roma" Tre, Rome, Italy

Introduction

The most elementary treatment of imaging is based on geometrical optics. In this realm, the propagation of light is described through rays, the lines along which luminous energy is carried. Rays are rectilinear in homogeneous media, whereas they are bent toward the higher refractive index regions in nonhomogeneous media. A geometrical analysis gives a wealth of useful results but conceals the most subtle effects connected to wave propagation and diffraction. On analyzing these effects, it is found that an optical system acts as a low-pass filter with respect to the spatial frequency spectrum of the input. This, in turn, suggests that other filtering operations can be realized, thus introducing the idea of optical processing.

The basic elements of the geometrical analysis are considered first, using a matrix form that, to a certain extent, can be transferred into the ondulatory treatment. Then, the wave behavior and its implications for optical processing are examined.

Ray Matrices

The most common optical systems are endowed with a cylindrical symmetry. At the simplest level, rays are assumed to travel near the symmetry axis, say the z-axis, with little inclination with respect to it. This is known as the paraxial hypothesis. Attention is focused on the so-called meridional rays, that is, those contained in a plane passing through the z-axis.

At a typical plane orthogonal to the z-axis, a meridional ray can be specified (**Figure 1**) by a two-element matrix of the form

$$\begin{pmatrix} r \\ n\vartheta \end{pmatrix} \qquad [1]$$

where r is the distance between the intersection point and the z-axis, ϑ is the angle between the ray and the z-axis, and n is the local refractive index. The introduction of n into the matrix simplifies the formulas to follow.

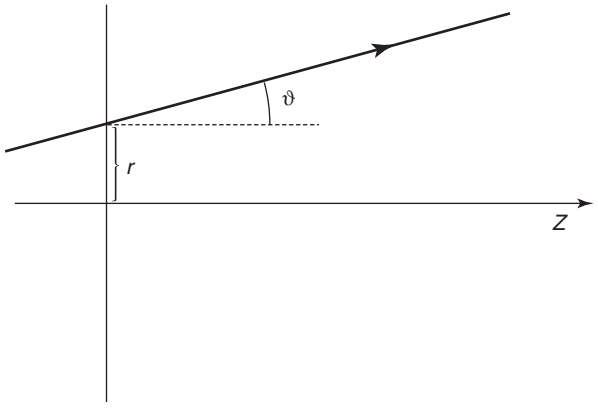

Figure 1 Specifying a meridional ray at a typical plane orthogonal to the symmetry axis (z-axis).

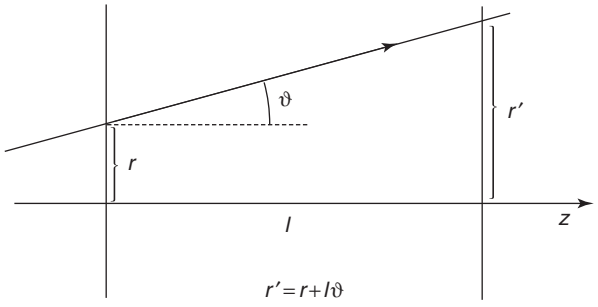

Figure 2 Effect of free propagation in a homogeneous slab of length l. The distance r varies, while the inclination θ remains unchanged.

An ordinary optical system is a sequence of homogeneous media (generally air and glasses) separated by spherical surfaces whose centers lie on the z-axis. Consider a meridional ray traveling within such a system. In the homogeneous sections (**Figure 2**), there is a continuous change of r (except for $\vartheta = 0$) without any change of ϑ. On the contrary, when the ray intersects a spherical surface between media with different refractive indices (**Figure 3**), the angle ϑ changes while r remains unaltered. These modifications are easily evaluated by means of geometrical considerations and by taking into account the

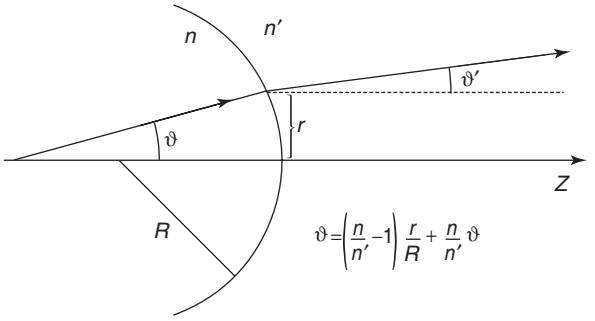

Figure 3 Ray passing through a spherical surface of radius R dividing two media with different refractive indices (n, n'). The inclination θ varies, while the distance r remains unchanged.

Snell–Cartesius law of refraction. Since the small-angle approximation can be used, the ray parameters change according to a projective transformation of the form

$$\begin{aligned} r' &= Ar + Bn\vartheta \\ n'\vartheta' &= Cr + Dn\vartheta \end{aligned} \qquad [2]$$

where the quantities A, B, C, and D depend on the optical system. This leads one to represent the relation between input and output rays in the matrix form

$$\begin{pmatrix} r' \\ n'\vartheta' \end{pmatrix} = \begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} r \\ n\vartheta \end{pmatrix} \qquad [3]$$

The so-called $ABCD$ matrix of a system can be derived starting from two basic ones. First, there is the matrix relating to free propagation in a homogeneous section of length l and refractive index n. This is denoted by M_{fp}. Second, there is the matrix, say M_{sph}, that describes the passage through a spherical surface dividing two media with refractive indices n (input side) and n' (output side). Let R be the radius of curvature of the surface. The usual convention is to take R as positive if the ray impinges on the convex side of the surface. Matrices M_{fp} and M_{sph} are easily evaluated and turn out to be

$$M_{\text{fp}} = \begin{pmatrix} 1 & l/n \\ 0 & 1 \end{pmatrix}, \qquad M_{\text{sph}} = \begin{pmatrix} 1 & 0 \\ (n-n')/R & 1 \end{pmatrix} \qquad [4]$$

Since in a typical optical system, there is a sequence of the above basic processes, the overall $ABCD$ matrix is obtained by multiplying the matrices pertaining to the single elements in the right order.

It is to be noted that the determinants of both M_{fp} and M_{sph} are equal to 1. The same holds true for any of their products, so that one can express, in a general way

$$AD - BC = 1 \qquad [5]$$

As a simple example, consider a lens with refractive index n in air (whose refractive index is ~ 1). Denote by R_1 and R_2, the radii of the first and the second limiting surfaces of the lens. On assuming the lens to be thin, the propagation from the first to the second limiting surface can be neglected. Using eqns [4], the $ABCD$ matrix, say M_{l}, of the lens is found to be

$$\begin{aligned} M_{\text{l}} &= \begin{pmatrix} 1 & 0 \\ -\left(\dfrac{1}{R_1} - \dfrac{1}{R_2}\right)(n-1) & 1 \end{pmatrix} \\ &= \begin{pmatrix} 1 & 0 \\ -1/f & 1 \end{pmatrix} \end{aligned} \qquad [6]$$

where f is the focal length of the lens.

The $ABCD$ formalism can be extended to optical systems including more sophisticated elements. For example, a GRIN (graded index) lens is made by a cylindrically symmetric medium in which the refractive index decreases parabolically as a function of the distance from the axis, according to a law of the form

$$n(r) = n_0 - \frac{n_2}{2} r^2 \qquad [7]$$

where n_0 and n_2 are positive constants. Equation [7] is assumed to hold for a certain range of values of r. It is further assumed that all rays of interest travel within such a range. Letting $\gamma^2 = n_2/n_0$, it can be shown that a GRIN lens of length l is characterized by a matrix of the form

$$M_{\text{GRIN}} = \begin{pmatrix} \cos \gamma l & (n_0\gamma)^{-1} \sin \gamma l \\ -(n_0\gamma) \sin \gamma l & \cos \gamma l \end{pmatrix} \qquad [8]$$

It should be noted that the present formalism does not account for the presence of any transversal limitation to the ray path (stops, pupils). Similar limitations are taken into account at a more refined stage of analysis. Furthermore, the behavior of rays whose inclinations with respect to the optical axis are not small can be studied by the so-called ray tracing process, in which the path of a ray is followed without introducing the small angle approximation. Ray tracing can also be applied to nonmeridional or skew rays. Powerful computer programs are available for this purpose.

Geometrical Imaging

The imaging condition requires that all rays starting from a fixed point of the input plane are led to pass through one and the same point at the output plane. Limiting to the meridional rays, this amounts to saying that the position r' has to be independent of the angle ϑ. The first of eqns [2] then gives the imaging condition

$$B = 0 \qquad [9]$$

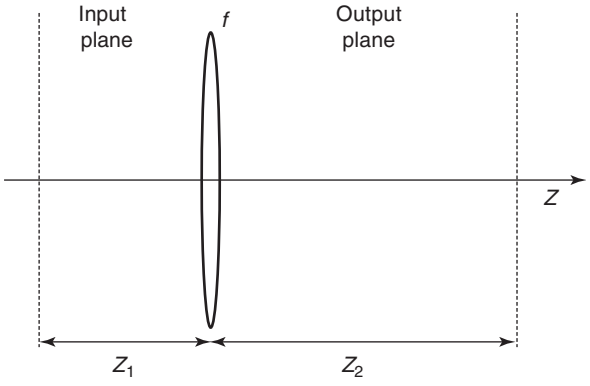

Figure 4 Geometrical imaging through a thin converging lens with focal length *f*.

If this condition is satisfied, then the relation between r and r' becomes

$$r' = Ar \qquad [10]$$

so that A is the magnification of the image with respect to the object.

A simple example is worked out by considering the case (**Figure 4**) in which three processes take place between the input and output planes: (1) free propagation in air for a length z_1, (2) passage through a lens with focal length f, and (3) free propagation in air for a length z_2. Using eqns [4] and [6], the $ABCD$ matrix for the system is evaluated as

$$M = \begin{pmatrix} 1 & z_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -1/f & 1 \end{pmatrix} \begin{pmatrix} 1 & z_1 \\ 0 & 1 \end{pmatrix} \qquad [11]$$

where, as before, the refractive index of air has been set ~ 1. On expanding the product,

$$M = \begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} 1 - z_2/f & z_1 + z_2 - z_1 z_2/f \\ -1/f & 1 - z_1/f \end{pmatrix} \qquad [12]$$

The imaging condition [9] now reads

$$z_1 + z_2 - z_1 z_2/f = 0 \rightarrow 1/z_1 + 1/z_2 = 1/f \qquad [13]$$

and this is nothing else but the well-known thin lens equation. According to eqns [12] and [13], the magnification is

$$A = 1 - z_2/f = -z_2/z_1 \qquad [14]$$

Wave Analysis

The question now is how the treatment has to be modified when one passes from a geometrical to a wave analysis. The coherent, monochromatic case is considered first. In a scalar description, the field is specified by a single function of the spatial coordinates. It is understood that the time dependence is of the form $\exp(-i\omega t)$, ω being the angular frequency. Again, using a paraxial hypothesis, the Fresnel approximation can be adopted. Basically, in the Fresnel approach, an approximate expression for spherical waves is introduced. More explicitly, consider the field distribution produced across a plane $z = \text{const.}$ by a point-like source placed at the origin of the reference frame. Denoting by R the distance from the origin of a typical point of such a plane, the field is proportional to $\exp(ikR)/R$, where k is the wave number, that is, $2\pi/\lambda$, λ being the wavelength. Let $R = \sqrt{z^2 + \rho^2}$, where ρ is the distance from the z-axis. For small ρ, that is, in a paraxial neighborhood of the z-axis, the following approximation can be used: $\exp(ikR)/R = \exp[ikz + ik\rho^2/(2z)]/z$. This gives rise to the celebrated Fresnel diffraction formula (see "Further reading" section). In most textbooks, such a formula is derived for free propagation only. Yet, it can also be used for propagation through an optical system described by an $ABCD$ matrix, as was shown by Collins long ago.

Denoting the position vectors at the input and output planes by $\boldsymbol{\rho}$ and $\boldsymbol{r}$, the Collins formula reads

$$V(\boldsymbol{r}) = -\frac{ie^{ikz_t}}{\lambda B} \exp\left(\frac{ikD}{2B} r^2\right) \times \int\int V_0(\boldsymbol{\rho}) \exp\left[\frac{ik}{2B}(A\rho^2 - 2\boldsymbol{r}\cdot\boldsymbol{\rho})\right] d^2\rho \qquad [15]$$

Here, V_0 and V are the (scalar) field distributions across the input and output planes respectively. Finally, z_t is the overall optical path between the two planes.

Fourier Transformation by Lenses

A fundamental property of lenses is their ability to perform Fourier transformations. To see this, reconsider the example of a single thin lens between two layers of air. Suppose $z_2 = f$. Then eqn [12] becomes

$$M = \begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} 0 & f \\ -1/f & 1 - z_1/f \end{pmatrix} \qquad [16]$$

Accordingly, eqn [15] gives

$$V(\boldsymbol{r}) = -\frac{ie^{ik(z_1+f)}}{\lambda f} \exp\left[\frac{ik}{2f}\left(1 - \frac{z_1}{f}\right) r^2\right] \times \int\int V_0(\boldsymbol{\rho}) \exp\left(-2\pi i \frac{\boldsymbol{r}}{\lambda f}\cdot\boldsymbol{\rho}\right) d^2\rho \qquad [17]$$

This can be written

$$V(\boldsymbol{r}) = -\frac{ie^{ik(z_1+f)}}{\lambda f} \exp\left[\frac{ik}{2f}\left(1 - \frac{z_1}{f}\right) r^2\right] \tilde{V}_0\left(\frac{\boldsymbol{r}}{\lambda f}\right) \qquad [18]$$

where the tilde denotes the Fourier transformation. It can then be seen that, whatever the value of z_1, in the back focal plane of the lens the field distribution contains a factor representing the Fourier transform of the input field. The frequency at which such a transform is evaluated, the so-called spatial frequency, is $\boldsymbol{r}/(\lambda f)$. The other function of r appearing on the right-hand side of eqn [18] represents, in the paraxial approximation, a spherical wave. Therefore, one can say that the field at the back focal plane of the lens is a spherical wave that is transversally modulated by the Fourier transform of the input field. It can be observed that the spherical wave term is irrelevant if only the intensity is of interest, because in that case the phase term disappears (the intensity being proportional to the squared modulus of the field).

It is seen from eqn [18] that a pure Fourier transform is performed by the lens, up to a known constant complex factor, if the input field is fed at the front focal plane of the lens ($z_1 = f$). This has important implications for optical processing. Note that in this case the $ABCD$ matrix becomes

$$M = \begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} 0 & f \\ -1/f & 0 \end{pmatrix} \qquad [19]$$

Wave Imaging

The treatment based on geometrical optics gives the imaging condition $B = 0$. There is no *a priori* guarantee that such a condition holds true when the imaging process is analyzed in terms of waves. This point is now discussed.

It is seen from eqn [15] that the case $B = 0$ has to be dealt with by means of a suitable limiting procedure. For the moment, B is assumed to be different from zero. On completing the square in the exponential within the integral, one can write eqn [15] in the form

$$V(\boldsymbol{r}) = -\frac{\mathrm{i}e^{\mathrm{i}kz_t}}{\lambda B}\exp\left[\frac{\mathrm{i}\pi}{\lambda B}(D - 1/A)r^2\right] \times \int\int V_0(\boldsymbol{\rho})\exp\left[\frac{\mathrm{i}\pi A}{\lambda B}(\boldsymbol{\rho} - \boldsymbol{r}/A)^2\right]\mathrm{d}^2\rho \qquad [20]$$

Thanks to eqn [5]

$$\frac{1}{B}\left(D - \frac{1}{A}\right) = \frac{C}{A} \qquad [21]$$

so that eqn [20] becomes

$$V(\boldsymbol{r}) = -\frac{\mathrm{i}e^{\mathrm{i}kz_t}}{\lambda B}\exp\left(\frac{\mathrm{i}\pi C}{\lambda A}r^2\right)\int\int V_0(\boldsymbol{\rho}) \times \exp\left[\frac{\mathrm{i}\pi A}{\lambda B}(\boldsymbol{\rho} - \boldsymbol{r}/A)^2\right]\mathrm{d}^2\rho \qquad [22]$$

Recall that one of the definitions of the (two-dimensional) Dirac delta function reads

$$\lim_{\alpha\to 0}\frac{-\mathrm{i}}{\alpha}\exp\left[\frac{\mathrm{i}\pi}{\alpha}(\boldsymbol{\rho} - \boldsymbol{\rho}_0)^2\right] = \delta(\boldsymbol{\rho} - \boldsymbol{\rho}_0) \qquad [23]$$

One can use this relation on passing to the limit for $B \to 0$ in eqn [22]. This gives

$$\lim_{B\to 0} V(\boldsymbol{r}) = -\frac{e^{\mathrm{i}kz_t}}{A}\exp\left(\frac{\mathrm{i}\pi C}{\lambda A}r^2\right)V_0\left(\frac{\boldsymbol{r}}{A}\right) \qquad [24]$$

It is interesting to compare the present result with the geometrical prediction. The field specified by eqn [24] accounts for the same magnification factor A predicted by the geometrical analysis. In general, however, it cannot be said to be an image of V_0 at the field level because it is multiplied by a quadratic exponential term that describes a spherical wavefront. The only exception occurs when $C = 0$. On the other hand, if the intensity only is of interest, the presence of the exponential term is immaterial.

It is not difficult to devise an optical system that gives rise to a perfect image at the field level. It has been seen that the passage from the front to the back focal plane of a single thin lens is associated to an anti-diagonal $ABCD$ matrix (see eqn [19]). Now, it is well known that the product of two anti-diagonal matrices leads to a diagonal one. This ensures that the condition $C = 0$ is met. Therefore, one considers the sequence of two thin lenses (**Figure 5**), whose focal lengths are denoted by f_1 and f_2, in which the back focal plane of the first lens coincides with the front focal plane of the second. Such a configuration is called telescopic. The overall $ABCD$ matrix of the system is

$$M = \begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} 0 & f_2 \\ -1/f_2 & 0 \end{pmatrix}\begin{pmatrix} 0 & f_1 \\ -1/f_1 & 0 \end{pmatrix} = \begin{pmatrix} -f_2/f_1 & 0 \\ 0 & -f_1/f_2 \end{pmatrix} \qquad [25]$$

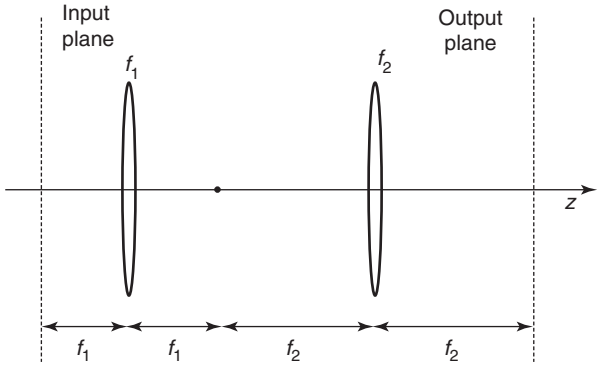

Figure 5 Wave imaging through a telescopic system.

This gives rise to a perfect image with magnification $-f_2/f_1$. Essentially, the same conclusion can be reached by noting that two cascaded Fourier transforms amount to replicating the input field up to a reversal of the coordinate axes.

Pupils

Up to now, it has been assumed that no transversal limitations were present. Obviously, in any real optical system there are diaphragms of various types. The procedure to take into account their effect is essentially to trace the paths of the rays in order to find the diaphragm that imposes the most severe limitation. The image of such a diaphragm formed by that part of the optical system that lies beyond it (along the light propagation direction) is called the exit pupil. Consider a point source at the entrance plane now. In the ideal case, its image would be a delta-like field distribution at the output plane. In other words, there would be a spherical wave converging to a certain image point with a position vector, say $\boldsymbol{r}_0$. In the actual case, such a wave is limited by the exit pupil. Denote by $H(\boldsymbol{r}, \boldsymbol{r}_0)$, the field across the output plane. Taking into account the first of eqns [4] and letting $n = 1$, eqn [15] becomes

$$H(\boldsymbol{r},\boldsymbol{r}_0) = -\frac{\mathrm{i}e^{\mathrm{i}k[d+r^2/(2d)]}}{\lambda d}\int\int p(\boldsymbol{\rho}) \times \exp\left[-\frac{\mathrm{i}k}{2d}(\boldsymbol{\rho}-\boldsymbol{r}_0)^2\right] \times \exp\left[\frac{\mathrm{i}k}{2d}(\rho^2 - 2\boldsymbol{r}\cdot\boldsymbol{\rho})\right]\mathrm{d}^2\rho \qquad [26]$$

where d is the distance between the exit pupil and the image plane. The first quadratic exponential function within the integral describes a spherical wave that converges toward the point $\boldsymbol{r}_0$. The function $p(\boldsymbol{\rho})$ is known as the transmission function of the exit pupil. For any field impinging on the pupil, it represents the pointwise ratio between the emerging and the incident fields. This function is either 1 (within the clear region of the pupil) or zero. Nonetheless, in most sophisticated cases, it could be a complex function whose modulus changes between zero and 1 in a continuous way. Rearranging terms in eqn [26], one obtains

$$H(\boldsymbol{r},\boldsymbol{r}_0) = \exp\left[\frac{\mathrm{i}k}{2d}(r^2 - r_0^2)\right]\int\int p(\boldsymbol{\rho}) \times \exp\left[-\frac{\mathrm{i}k}{d}\boldsymbol{\rho}\cdot(\boldsymbol{r}-\boldsymbol{r}_0)\right]\mathrm{d}^2\rho \qquad [27]$$

Since H gives the field at the output when the input is a delta-like function, it is called a coherent impulse response. For any reasonably good optical system, the integral is appreciable only in a small neighborhood of $\boldsymbol{r}_0$. Accordingly, the exponential in front of the integral can be approximated by 1 and eqn [27] can be written as

$$H(\boldsymbol{r},\boldsymbol{r}_0) = K\tilde{p}\left(\frac{\boldsymbol{r}-\boldsymbol{r}_0}{\lambda d}\right) \qquad [28]$$

where K is a constant. This means that the coherent impulse response is proportional to the Fourier transform of the pupil transmission function. Furthermore, it is shift-invariant, in the sense that it depends only on $\boldsymbol{r}-\boldsymbol{r}_0$.

It is now possible to write the image formation law for any coherent input field distribution. In fact, in a linear system endowed with a shift-invariant impulse response, the relation between input and output is simply a convolution. As a consequence, denoting again the input and output fields with V_0 and V, the image formation law reads

$$V(\boldsymbol{r}) = \int\int V_0(\boldsymbol{r}_0)H(\boldsymbol{r}-\boldsymbol{r}_0)\,\mathrm{d}^2r_0 \qquad [29]$$

Taking into account the convolution theorem for the Fourier transforms, it is seen that the optical system acts as a filter on the spatial frequency spectrum of the input field. The associated transfer function, which is the Fourier transform of H, is known as the coherent transfer function. Up to a multiplicative constant and a coordinate scale factor, it is given by the pupil function itself. Typically, the system behaves as a low-pass filter.

Incoherent Imaging

In many instances, the object to be imaged behaves as a spatially incoherent source. This means that any point-like element of the object radiates in an uncorrelated way with respect to the others. As a consequence, the image is obtained by summing up the intensity contributions due to the various elements. In other words, the image formation law is formulated as a relation between the intensities across the object and the image, instead of a relation between the associated fields. As for the temporal behavior of the radiation field, a quasi-monochromaticity hypothesis is adopted (a strictly monochromatic field would be spatially coherent). The so-called incoherent impulse response is then the squared modulus of the coherent impulse response [28] and the image formation process is described by the law

$$|V(\boldsymbol{r})|^2 = \int\int |V_0(\boldsymbol{r}_0)|^2|H(\boldsymbol{r}-\boldsymbol{r}_0)|^2\mathrm{d}^2r_0 \qquad [30]$$

This convolution relation implies, as in the coherent case, a filtering process. The corresponding incoherent

transfer function is the Fourier transform of $|H|^2$. Therefore, it is proportional to the autocorrelation of the pupil function. It is to be borne in mind that the quantity by which the process is described is the intensity, not the field. As a consequence, a comparison with the coherent case is difficult to establish.

Optical Processing

The basic ideas underlying the techniques of optical processing can be grasped by means of what has already been discussed with reference to the optical systems. For the sake of simplicity, refer to the telescopic setup examined in the section "Wave imaging" (**Figure 5**), assuming coherent monochromatic illumination. Furthermore, the magnification is supposed to be -1. Consider first the ideal case in which transversal limitations can be neglected. Then, through two cascaded Fourier transformations, the input field is replicated at the output plane up to a reversal of the coordinate axes. Suppose now that a circular diaphragm is centered at the origin of the intermediate plane, where the Fourier transform of the input field is displayed. This may be called the Fourier plane. The effect of the diaphragm is to cut off from the object spectrum, spatial frequencies above a certain maximum. In other words, the diaphragm acts as a low-pass filter. Much in the same way, one can perform other types of filtering operations by inserting suitable filters in the Fourier plane. Some examples are examined now.

Visualization of Phase Objects

Certain objects, when traversed by a coherent light field, alter essentially the transverse phase distribution of the field leaving the amplitude pattern unchanged except for a transversally uniform attenuation factor due to reflection. Simple examples are given by dielectric plates whose thickness changes from one point to another, by biological specimens in which the refractive index is spatially varying, or by turbulent fluid layers. Objects with this property are briefly called phase objects. Suppose an object of this type is present at the input plane of the telescopic system discussed above. Suppose further that the object is orthogonally illuminated by a coherent plane wave. Obviously, if one looks at the output plane, one sees a uniform illumination. The problem then arises as to how to transform the phase distribution into an intensity pattern, so that the phase changes can be detected by an intensity sensitive detector (visual system, photographic emulsions, TV-cameras, etc.). This problem, called the phase visualization problem, can be solved by introducing suitable filters in the Fourier plane. Typically, the phase variations across the objects to be visualized are much smaller than 2π. Consequently, the object spectrum seen at the Fourier plane has a strong peak centered at the origin. In addition, some energy is spread across the plane because of diffraction by the phase modulations. Then, a very simple way to visualize the phase object is to absorb the central peak by means of a small opaque disk. Only the diffracted light caused by the phase variations passes around the disk and reaches the output plane. There, an image of the phase distribution across the object is formed. This is known as the central stop method. From the experimental point of view, an even simpler procedure is to insert a knife edge in the Fourier plane to intercept the central spot as well as half the object spectrum. One then speaks of the Schlieren method.

A more sophisticated solution is the phase-contrast technique invented by Zernike and widely used in microscopy. In order to explain this technique, one may express the field emerging from a phase object under illumination by an orthogonal monochromatic plane wave. Such a field has the form

$$V_0(\boldsymbol{r}) = A\,\exp[\mathrm{i}\varphi(\boldsymbol{r})] \qquad [31]$$

where A is a constant and φ describes the phase structure. The associated intensity, namely,

$$I_0(\boldsymbol{r}) = |V_0(\boldsymbol{r})|^2 = |A|^2 \qquad [32]$$

does not contain any information about φ. One useful way to interpret this lack of information is obtained by observing that, for small values of φ, the field [31] can be written as

$$V_0(\boldsymbol{r}) = A[1 + \mathrm{i}\varphi(\boldsymbol{r})] \qquad [33]$$

so that the intensity reads as

$$I_0(\boldsymbol{r}) = |A|^2[1 + \varphi^2(\boldsymbol{r})] \simeq |A|^2 \qquad [34]$$

It can be said that the two terms appearing in the right-hand side of eqn [33] do not interfere with each other because they are in quadrature (dephased by $\pi/2$). Consider then the Fourier transform of V_0,

$$\tilde{V}_0(\boldsymbol{v}) = A[\delta(\boldsymbol{v}) + \mathrm{i}\tilde{\varphi}(\boldsymbol{v})] \qquad [35]$$

where $\boldsymbol{v}$ is the spatial frequency variable. Suppose now that, through the insertion of a suitable filter in the Fourier plane, the delta function is multiplied by a constant of the form $\mathrm{i}a$, where a is a real number whose modulus is not greater than 1. At the same time, it is required that $\tilde{\varphi}$ remains approximatively unchanged on passing through the filter. These two requirements can be satisfied if a small disk of a suitable material is put at the origin of the Fourier

plane. The transmission function of the corresponding filter is ia in a small region around the origin (the disk region), while it has the value 1 in the remaining part of the plane. As a consequence, the filter acts on the delta function, multiplying it by ia, whereas it leaves essentially unaltered $\tilde{\varphi}$, whose significant values are taken for frequencies different from zero. The output field can now be written as

$$V(\boldsymbol{r}) = \mathrm{i}A[a + \varphi(\boldsymbol{r})] \qquad [36]$$

and the associated intensity becomes

$$I(\boldsymbol{r}) = |A|^2[a^2 + 2a\varphi(\boldsymbol{r}) + \varphi^2(\boldsymbol{r})] \simeq |A|^2 \times [a^2 + 2a\varphi(\boldsymbol{r})] \qquad [37]$$

It is seen that the variations of the intensity are proportional to those of the phase. Therefore, one has a linear mapping of the phase structure. On reducing the value of $|a|$, the contrast of the image (pointwise ratio between the second and the first term in square brackets) is increased while the luminosity diminishes. A limiting case is obtained for $a = 0$. This corresponds to the central stop case. Instead of eqn [37], one obtains

$$I(\boldsymbol{r}) = |A|^2\varphi^2(\boldsymbol{r}) \qquad [38]$$

so that the mapping refers to the square of the phase.

Boundary Detection

In a number of instances, the problem faced is that f recognizing a certain pattern within an image. This task is made easier if the boundaries of the pattern are put into evidence. Such an operation can be performed through some process of mathematical derivation of the image. This, in turn, can be achieved by multiplicative operations on the spectrum, thanks to the derivative theorems for the Fourier transform. As a simple example, refer to a one-dimensional case in which the first derivative is sought. A filter whose transmission function is proportional to the spatial frequency is required

$$\tau(v) = \alpha v \ \mathrm{rect}\left(\frac{v}{v_{\mathrm{M}}}\right) \qquad [39]$$

where α and v_{M} are constants. The presence of the function rect, which equals 1 for $|v| \leqslant v_{\mathrm{M}}/2$ and zero otherwise, is due to the fact that, whatever the value of α, the linear dependence law can hold for a limited interval of values of v only. When such a filter is introduced in the Fourier plane, the output field is the convolution of the derivative of the input signal with a $\sin(\cdot)/(\cdot)$ function produced by Fourier transformation of the rect.

In the two-dimensional case, other types of operations can be performed, for example, the application of the Laplace operator. This modification too can be realized through a suitable filtering operation.

Holographic Filters

The previous examples show that in order to perform filtering operations, one needs to construct transparencies that alter, in a prescribed way, both the amplitude and the phase patterns across the Fourier transform of the input field. The amplitude can be controlled by a careful use of photographic emulsions. As for the phase, the thickness of a dielectric plate can, in principle, be tailored in such a way that the plate introduces, point by point, the required phase changes. This, however, is cumbersome from the experimental point of view. A more viable solution is to use holographic methods. As is well known, holography is a technique by which both the amplitude and the phase of a coherent field can be recorded in a medium, such as a photographic emulsion, which is sensitive to the intensity of the field. Furthermore, powerful methods of digital holography have been developed. In other words, the hologram can be synthesized with the aid of a computer. This makes it possible to design and realize a wide variety of filters.

Advantages and Limits of Optical Processing

Whenever the information to be processed is carried by a coherent (or nearly coherent) field, optical processing is invaluable. A typical example is the visualization of phase objects. As seen, such an operation can be performed with rather simple optical devices that work in real time. On the other hand, standard optical processors are affected by a certain lack of flexibility. Nonetheless, some reconfigurable filters (spatial light modulators) have been realized using, for example, liquid crystal valves. At present, the spatial resolution afforded by these devices is not very high, but the related technology is steadily advancing.

Images formed with incoherent light could also be treated by optical processors by first recording the image on a suitable transparency. In this case, however, the information is contained in the intensity distribution only. As a consequence, the processing can be done with a computer in a more convenient way.

Impedance Spectroscopy and Mobility Spectra

R A Gerhardt, Georgia Institute of Technology, Atlanta, GA, USA

Introduction

Impedance spectroscopy is a technique that has seen revolutionary changes in the last 30 years as a result of the development of computer automation, design of better frequency-response analyzers, and the ability to acquire data over many different frequency ranges. Most commercially available equipment today can collect real and imaginary impedance data from frequencies as low as a few microhertz and as high as a few gigahertz. Due to a large variance in material resistivities (e.g., $\rho > 10^{12}$ ohm cm^{-1} for insulators and $< 10^{-3}$ ohm cm^{-1} for semiconductors), different manufacturers specialize in the characterization of specific material types and the equipment specifications can vary widely.

Impedance spectroscopy, also referred to as IS/DS because of its close relationship to dielectric spectroscopy, involves the measurement of the current (I), voltage (V), and phase angle (θ) over a wide frequency range so that the impedance vector (Z^*) may be defined as follows:

$$Z^*(\omega) = V(\omega)/I(\omega) \qquad [1]$$

where $V(\omega) = V_m \sin(\omega t)$, $I(\omega) = I_m \sin(\omega t + \theta)$, $\omega = 2\pi f$, and θ is the phase difference between the current and the voltage.

Measurements can also be carried out in the time domain and then Fourier transformed into the frequency domain. Each measurement mode has advantages and disadvantages. The frequency domain is ideally suited for determining the steady-state response of the object under test, whereas the time domain is better suited for detecting time-dependent phenomena.

Equivalent Circuits

It is customary to analyze the measured impedance response in terms of the possible equivalent circuit components that can give rise to the frequency response observed. The circuit elements of interest are capacitors represented by C, resistors represented by R, and inductors represented by L. Most dielectric materials can be represented by a parallel RC circuit, whereas others are better represented by a series RC circuit. The presence of magnetic components introduces inductive components, and one may expect that series or parallel RL circuits may represent such materials.

It is useful to remember that if elements are in series, it is easier to write the impedance response. On the other hand, if the circuit elements are in parallel, it is more convenient to write the admittance and then convert it to the impedance. For example, the impedance of a series RC circuit is written as

$$Z^* = R + [1/j\omega C] \qquad [2]$$

whereas the impedance of a parallel RC circuit is given by

$$Z^* = 1/Y^* \qquad [3]$$

where $Y^* = (1/R) + j\omega C$.

Most modern equipment include some version of software that can be used to fit the most appropriate equivalent circuit to the experimentally measured results. However, the reader is urged to consider the physical mechanisms that may have contributed to the experimental data before concluding that a derived R or C is representative of the bulk of the material or device being measured (see the section "Data analysis" for more details).

Table 1 lists the simplest equivalent circuits and their corresponding impedance equations. Data acquired can be plotted in terms of frequency-explicit and frequency-implicit impedance plots. Frequency-explicit plots are often referred to as Bode plots. They are just simply real (Z') or imaginary impedance (Z'') plotted versus frequency. The magnitude of the impedance vector, which is equal to

$$|Z^*| = [Z'^2 + Z''^2]^{1/2} \qquad [4]$$

and the phase angle θ are also plotted versus the measured frequency. The magnitude of the impedance

Table 1 Simplest equivalent circuits and their impedance equations

Resistor		$Z^* = R1$
Capacitor		$Z^* = 1/j\omega C1$
Inductor		$Z^* = j\omega L1$
RC parallel		$Z^* = 1/[1/R1 + j\omega C1]$
RC series		$Z^* = R1 + (1/j\omega C1)$
RL parallel		$Z^* = 1/[1/R1 + 1/j\omega L1]$
RL series		$Z^* = R1 + j\omega L1$
LC series		$Z^* = j\omega L1 + 1/j\omega C1$
LC parallel		$Z^* = 1/[1/j\omega L1 + j\omega C1]$
LCR series		$Z^* = j\omega L1 + (1/j\omega C1) + R$

vector is useful for quickly assessing the presence of resistive components (flat with frequency), capacitive components (decrease with increasing frequency), and inductive components (increase with increasing frequency) (see **Figure 1** for representative frequency-explicit plots for a perfect resistor, a perfect capacitor, and a perfect inductor).

Frequency-implicit plots are better known as complex plots because the imaginary impedance is plotted versus the real impedance. These plots are often referred to as Nyquist plots or Cole–Cole plots and result in the formation of semicircles only under certain conditions. As shown in **Figure 2**, a semicircle will only appear on the complex impedance plots when the measured object can be represented by a parallel RC circuit or a parallel RL circuit. It should be noted that the imaginary part of these two circuits carries opposite signs. By established convention, a parallel RC circuit will display a semicircle in the first quadrant if the imaginary axis is labeled as negative (**Figure 2a**). In contrast, a parallel RL circuit will display an upside down semicircle in the fourth quadrant (**Figure 2d**). It may be added that a series RC circuit or a series RL circuit do not display semicircles in the complex impedance plane (**Figures 2b** and **2c**).

Microscopic Interpretation

If one is interested in determining the electrical process which has given rise to a particular set of impedance spectra, it is useful to remember that all materials are made up of charged entities at various length scales (see **Figure 3**). At the atomic level, one has protons and electrons. At the molecular level, there may be anions, cations, or charged molecules. At the nano-, meso-, and micro-structural levels within a single material, there may also be charged interfaces. The interface between the contacting electrode and the material surface often results in a space-charge polarization. Hence, the impedance response measured is dictated by the total number of impediments to the current flow that an AC signal encounters on its way from the high- to the low-voltage electrode. The impedance response measured is then a function of the frequency of the applied field, how that field interacts with each polarization process present in the material, and whether it is commensurate with the dimensions of the permanent or temporary dipoles formed and the strength of the signal.

Polarization Mechanisms

Figure 4 schematically displays the real and imaginary polarization response of a material as a function of the applied frequency. Upon the application of an electric field, atomic or electronic polarization is easily detectable in the optical frequency range, and this results in the resonance response displayed. The polarization strength is proportional to the number of electrons present and is governed by the equation below:

$$P = Zqd \qquad [5]$$

where Z is the atomic number, q is the charge constant $= 1.609 \times 10^{-19}$ coulombs m^{-1}, and d is the distance.

At the molecular level, dipole polarization can be due to temporary or permanent dipoles present in a material. Permanent dipoles are present in those materials that possess a center of positive charge different from that of a negative charge. This includes all ferroelectrics below their Curie temperature, all polar polymer molecules, and all polar liquids such as water. It may also occur by aliovalent doping of compounds. Temporary dipoles may occur in weakly bound polymers or in the electrostatic attachment of nanowires to patterned substrates. Molecular temporary dipoles also occur in ionically bonded materials, such as many oxides and fluorides.

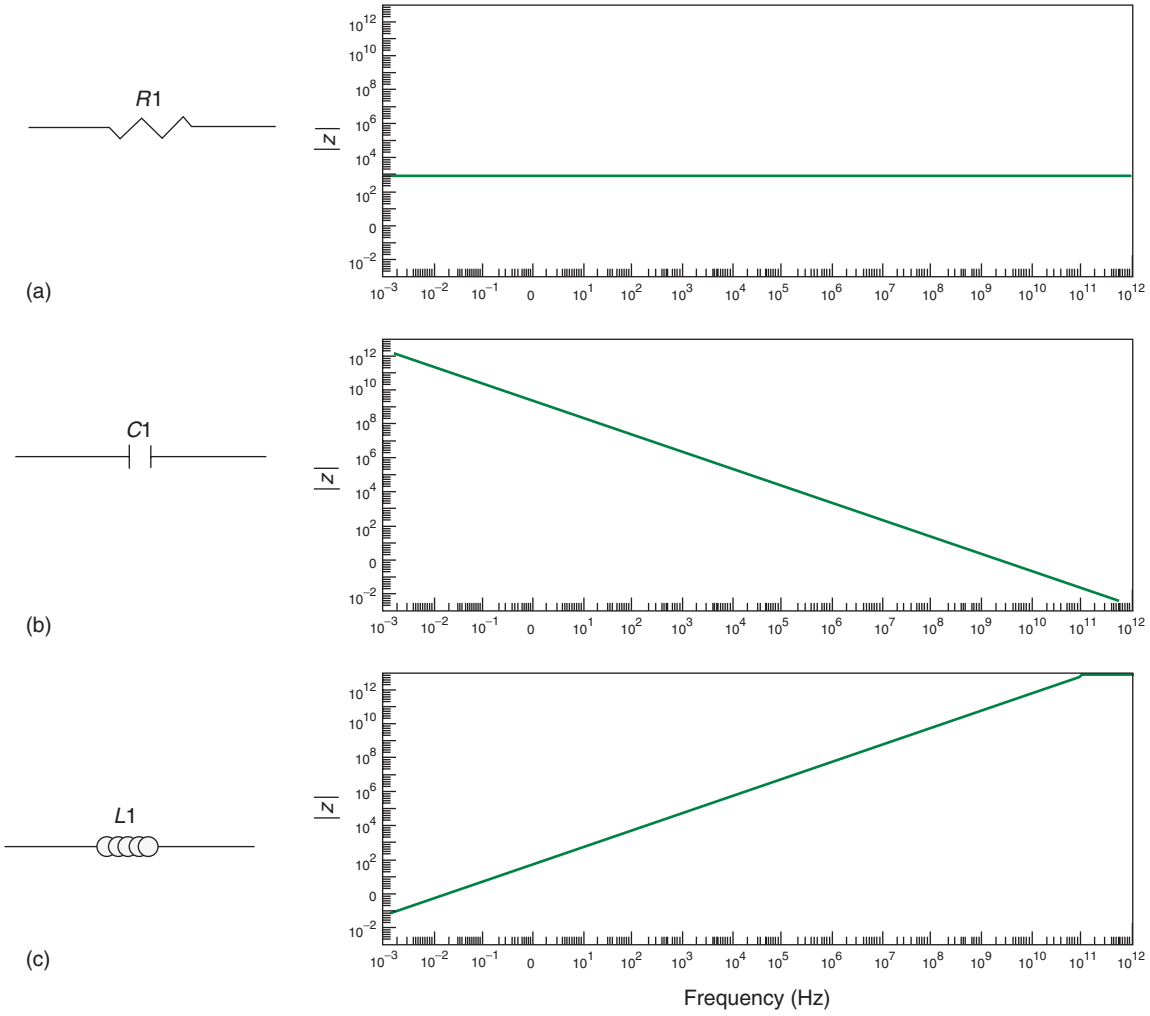

Figure 1 Representative impedance vector response for (a) a perfect resistor, (b) a perfect capacitor, and (c) a perfect inductor as a function of frequency.

Space-charge polarization occurs whenever the electrical response at an interface is dominated by a pile-up of charge carriers at that interface. This commonly occurs at the interface between the contacting electrode and the material under test, and is often assumed to occur only at very low frequencies. If the electrode contact is nonohmic or if the charge-transfer resistance is high, the space-charge polarization will overshadow any other processes that may be present in the material. Space-charge polarization may also occur at the interface between grains of phases with very different electrical properties or at the grain boundaries of a single-phase material, if the defect concentration is high or if there is segregation of impurities into or away from the boundaries. Space-charge polarization at the interface between two different materials is generally expressed in terms of the Maxwell–Wagner two-layer condenser model. These equations are discussed in the section, "Multiple relaxation."

Space-charge polarization at electrode–material interfaces is often diffusive in nature and can be represented by the Warburg impedance. This gives rise to a linear dependence of the conductivity on the frequency of the measurement, as described in the following equation:

$$Z^* = [A/(D\omega)^s](1 - \mathrm{j}) \qquad [6]$$

where A is a constant related to the valence state of the diffusing species and the concentration gradient, and s represents the diffusion exponent. For a perfect diffusion-controlled response, $s = 1/2$. This is often seen as a straight line at 45° from the real impedance axis.

Relaxation and Resonance Frequency Spectra

The frequency dispersion that allows transformation of the dielectric response from one polarization

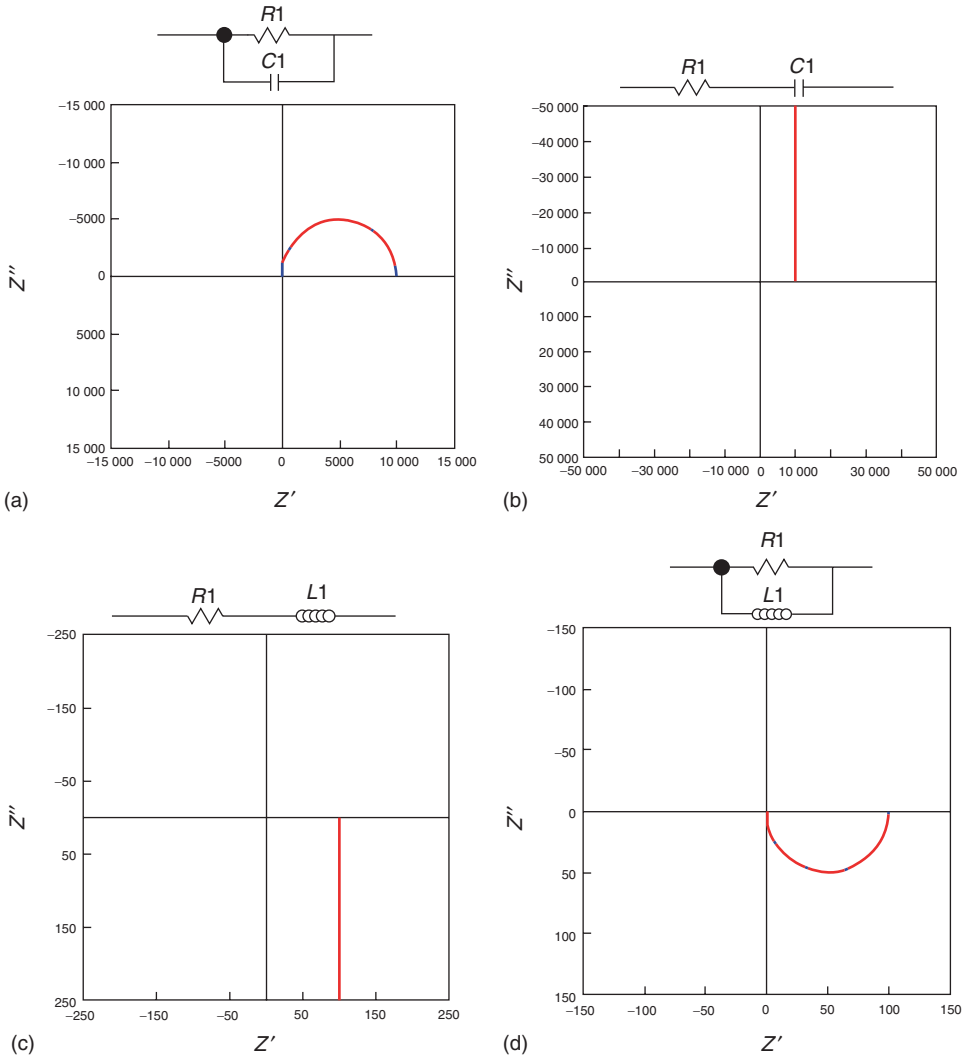

Figure 2 Equivalent circuits and representative complex impedance plots for (a) a parallel RC circuit, (b) a series RC circuit, (c) a series RL circuit, and (d) a parallel RL circuit.

mechanism to another is known as dielectric relaxation. The Debye equation describes this for essentially all relaxation processes even though it was originally developed to represent dielectric relaxation in polar liquids:

$$\varepsilon^* = \varepsilon_\infty + (\varepsilon_s - \varepsilon_\infty)/[1 + j\omega\tau] \qquad [7]$$

where ε_∞ represents the high-frequency dielectric permittivity, ε_s is the lowest frequency dielectric permittivity, ω is the angular frequency, and τ the relaxation time for the process. Cole–Cole and others have modified the Debye equation to account for deviations from the ideal Debye response. Cole and Cole introduced the α parameter as follows:

$$\varepsilon^* = \varepsilon_\infty + (\varepsilon_s - \varepsilon_\infty)/[1 + (j\omega\tau)^{1-\alpha}] \qquad [8]$$

Davidson and Cole introduced the β parameter, which accounts for deviations from ideality in the highest frequency region of the Debye relaxation. This modification is written as follows:

$$\varepsilon^* = \varepsilon_\infty + (\varepsilon_s - \varepsilon_\infty)/[1 + (j\omega\tau)]^\beta \qquad [9]$$

To account for both spreading of the relaxation time and deviations from ideality at high frequency, Havriliak and Negami combined the two parameters, as shown below:

$$\varepsilon^* = \varepsilon_\infty + (\varepsilon_s - \varepsilon_\infty)/[1 + (j\omega\tau)^{1-\alpha}]^\beta \qquad [10]$$

The differences between the Debye, Cole–Cole, and Davidson–Cole relaxation equations are depicted in **Figure 5**.

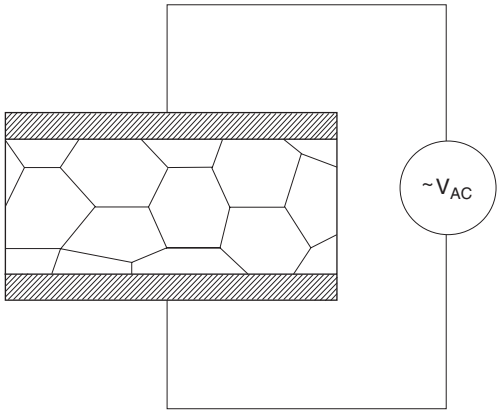

Figure 3 Schematic of experimental setup for a two probe parallel plate AC impedance measurement. The specimen cross section shows the presence of electrode–specimen interfaces and grain-to-grain interfaces which may have different response than the bulk grains of the material, any permanent dipoles present, any ionic polarization present, or any electronic polarization present.

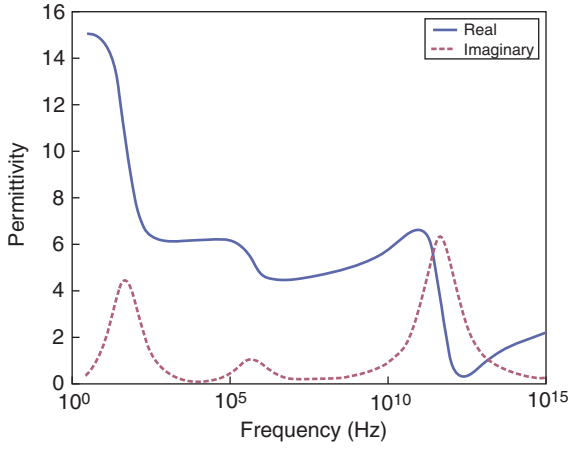

Figure 4 Schematic of the real and imaginary permittivity curves for a material that contains two dielectric relaxation processes and a single resonance process. Note that change in the real part results in the formation of a peak in the imaginary part.

Resonance spectra are hardly ever discussed in the context of IS. This is because ionic and electronic resonance generally occur at frequencies near the optical range and are best detected with optical spectroscopic methods such as IR, UV, and visible spectroscopy methods. NMR and EPR methods are also superb at detecting ionic resonances. Nevertheless, it is possible to observe resonance phenomena while making impedance measurements. Resonance behavior that occurs at the lower frequencies of impedance measurements is normally associated with parasitics in the measurement circuit, but may also be due to a nonlinear response of materials such as ferroelectrics and ferromagnetics. An equation that

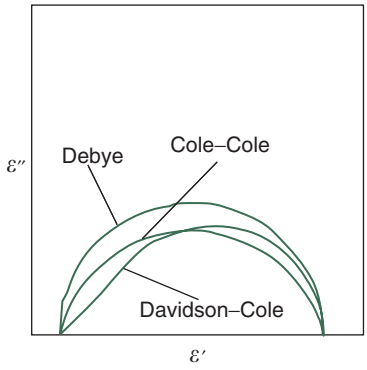

Figure 5 Simulated complex permittivity plots for representative Debye, Cole–Cole, and Davidson–Cole relaxations described by eqns [7]–[9].

can generate a resonance response is given by

$$\varepsilon^* = \varepsilon'_\infty + 1/2(\varepsilon'_s - \varepsilon'_\infty)/[(1 - (\omega/\omega_{res})) + (\beta/\omega_{res})] \quad [11]$$

where ε'_s and ε'_∞ are the permittivities at frequencies much lower and much higher than the resonant frequency ω_{res}, and β represents the strength of the restoring force that gives rise to resonance. **Figure 6** displays the frequency-explicit and frequency-implicit graphs of the dielectric resonance equations.

Various Representations of the Dielectric Function

A fact not often recognized is that the dielectric relaxation equation, originally developed by Debye for relaxation in polar liquids, provides another way of interpreting impedance data. This is possible because dielectric permittivity is inversely related to impedance, as shown below:

$$Z^* = 1/j\omega C_0 \varepsilon^* \quad [12]$$

Therefore, it follows that measured impedance data can be converted into permittivity and vice-versa, provided that the geometric capacitance, C_0, of the sample measured is known. Recalling that admittance, Y^*, is the inverse of impedance and that electric modulus, M^*, is the inverse of permittivity, it then becomes possible to analyze the same measured data in four different formalisms without the use of any adjustable parameters. **Table 2** lists all the important relationships between these four dielectric functions. Performing the conversions mentioned is advantageous because polarization or conductivity processes that may be hidden in the impedance, for example, may become fully detectable in the

$\tan\delta = \varepsilon''/\varepsilon'$	$\tan\delta = Z''/Z'$

admittance plane. **Figure 7** displays the impedance and admittance of a series RC circuit. It can be seen that it does not show a semicircle in the impedance plane but shows one in the admittance plane, although this one appears in the fourth quadrant if one keeps the same sign convention as for the impedance. Likewise, a series RL circuit also displays a semicircle in the admittance plane but not in the impedance plane (see **Figure 2c**) but this semicircle will appear in the first quadrant. It should then become clear that using a multiplane analysis can be extremely useful when more than one relaxation process may be active within a measured frequency range. It should be added that mathematical transformations need to be done with caution, as the data on either extreme of the frequency range of a given impedance analyzer tend to carry a higher error. Hence, taking the inverse can amplify the size of the errors. Nevertheless, it is an extremely useful tool for determining the most appropriate model that can help identify the relaxation process more easily. Moreover, once the relaxation process has been identified, the data can then be used to obtain the activation energy for that particular process.

Temperature Dependence

Most relaxation phenomena are thermally activated. As a result, the relaxation time can be expressed in terms of an Arrhenius-type temperature dependence:

$$\tau = \tau_0 \exp(E/kT) \qquad [13]$$

where τ_0 is the relaxation frequency at infinite temperature, E is the activation energy for the relaxation process, k is Boltzmann's constant, and T is temperature in degrees kelvin. In addition, when a relaxation process occurs, $\omega_{max}\tau = 1$; therefore, one can use the frequency at which a peak occurs at a given temperature as a way of determining the activation energy of the process. **Figure 8a** schematically displays a dielectric loss process that changes peak frequency as temperature is changed. The linearized version of eqn [13] is used to obtain the activation energy as depicted in **Figure 8b**.

Similarly, conductivity processes may display peaks in the imaginary impedance or imaginary admittance, which could then be used to estimate the activation energy for that process in the same fashion as described above. More often, the activation energy for conduction, in a given system, is obtained by taking the intercept of the impedance semicircle with the real axis, as displayed in **Figure 9**, and converting that to conductivity and plotting the calculated conductivity versus inverse temperature. Either type of analysis is only accurate when the resistance and capacitance of the relaxation processes being measured are both independent of frequency. A truly bulk response will always have constant R and C at a given temperature. This is not the case for space-charge polarization under biasing conditions or diffusion-controlled processes. In both of these cases, the number of mobile charge carriers will change the values of R and may also affect the value of C.

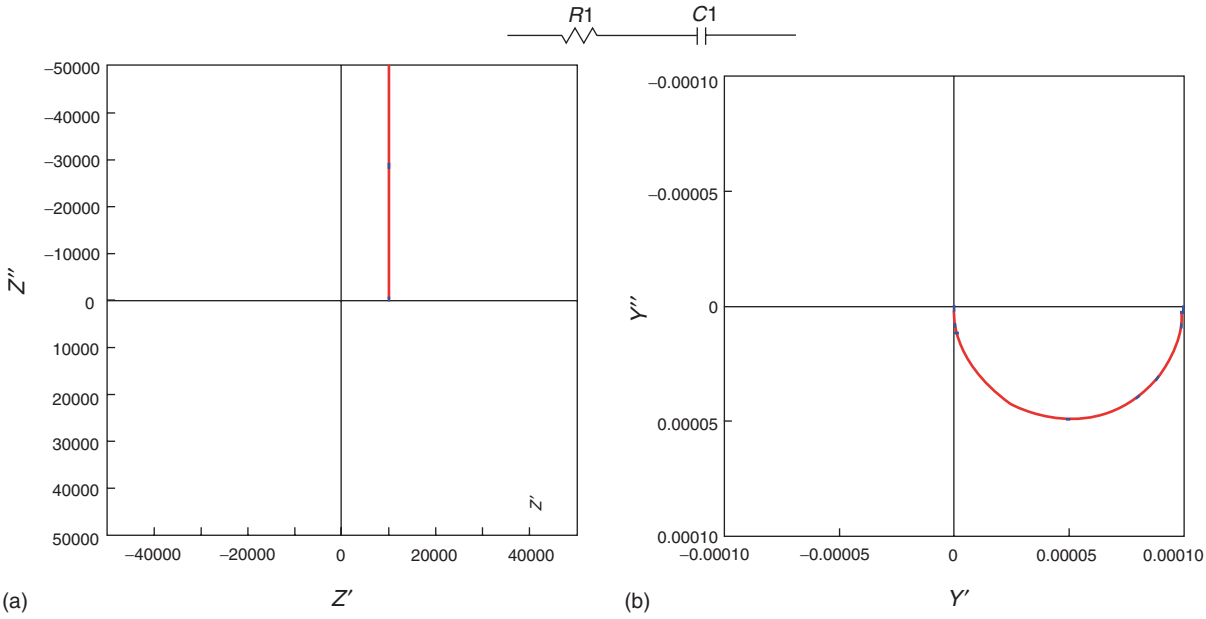

Figure 7 Complex impedance (Z'' vs. Z') and complex admittance (Y'' vs. Y') plots for a series RC circuit.

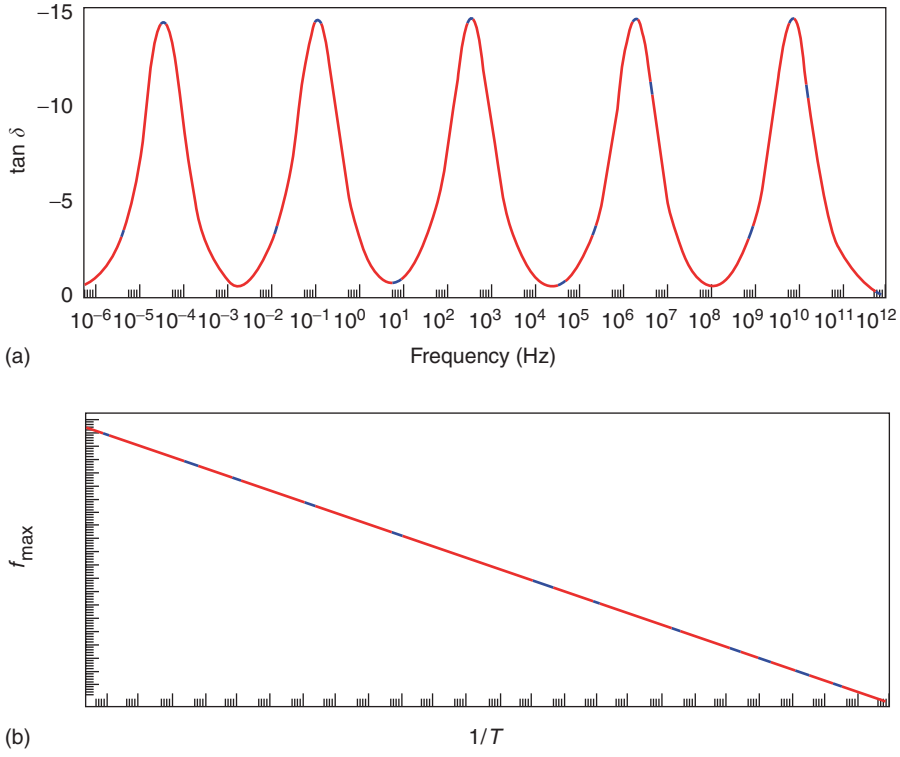

Figure 8 (a) Schematic of a dielectric loss ($\tan\delta$) process at different temperatures. Loss peaks shift to higher frequency (f_{max}) as the temperature is increased. (b) Plot of f_{max} versus the reciprocal temperature allows determination of the activation energy for the dielectric loss process.

Multiple Relaxations

If one refers back to **Figure 4**, it should not be surprising to realize that most experimentally measured spectra will be made up of more than one relaxation process. Examples include: (1) a Debye-type dielectric polarization process and a parallel leakage current, (2) a solid-state ionic material with different response at the grain boundaries than

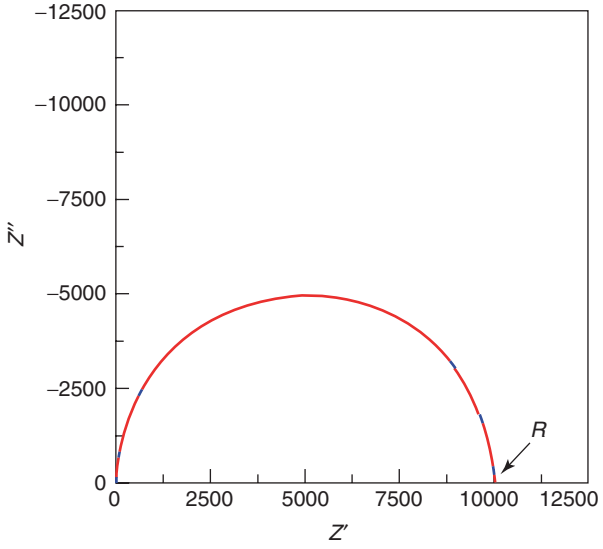

Figure 9 The intercept of the complex impedance semicircle with the real Z' axis is used to determine the resistivity of a conduction process. This must be done for different temperatures in order to obtain the activation energy for the conductivity process.

within the bulk grains, (3) a semiconducting material with space-charge polarization at the electrode/material interface, and (4) bulk response and interfacial responses of multiphase systems.

For the defect dipole case, the easiest way to represent this is to modify the Debye equation by adding a leakage current, σ, as follows:

$$\varepsilon^* = \varepsilon_\infty + \{(\varepsilon_s - \varepsilon_\infty)/[1 + j\omega\tau]\} - j\sigma/\omega \quad [14]$$

The corresponding equivalent circuit will contain a series RC circuit in parallel with a leakage resistor, which is also in parallel with the bulk capacitance. The different dielectric functions for this situation are displayed in **Figure 10**. **Figure 10a** shows that the leakage path can totally dominate the impedance spectra, while dielelctric permittivity plane (shown in **Figures 10b** and **10d**) hints at the presence of the dielectric relaxation, which is even better displayed in the modulus plane as depicted in **Figure 10c**.

In all of the remaining cases, the simplest equivalent circuit to represent them contains two parallel RC circuits in series, as shown in **Figure 11a**. The physical meaning of each of these circuit elements is, however, quite different for each of these cases. **Table 3** lists some of the possible physical processes that may be represented in each of these cases.

Irrespective of the source of the frequency dependence, when the difference between the relaxation times of the two processes present is large, that is, more than one or two orders of magnitude, or either the R or C is very small, one of the processes may be overshadowed by the other in the impedance plane. This is when a multiplane analysis should be used, as different processes can be best displayed in different dielectric functions, according to their R,C,L values. To illustrate this point, **Figures 11–13** are presented.

Figures 11b–11f display the complex impedance spectra for a bulk ionic conductor with $C1 = 1$ pF, which may have different electrical responses at the grain boundaries (with $C2 = 1$ nF) depending on the ratio of the bulk resistance $R1 = R_g$ and the effective resistance at the grain boundaries labeled $R2 = R_{gb}$. The following cases are presented: (1) $R_g = R_{gb}$, (2) $R_g < R_{gb}$, (3) $R_g \ll R_{gb}$, (4) $R_g > R_{gb}$, and (5) $R_g \gg R_{gb}$. These figures illustrate that only looking at the impedance plane may prevent identification of the presence of a second process. Taking the impedance graphs from **Figures 11d** and **11f** which correspond to cases 3 and 5 and converting them to admittance, dielectric permittivity, and electric modulus clearly reveals the existence of more than one process (see **Figures 12a–12d**). Another way, which may also reveal the presence of more than one process when the time constants are quite different, is to use logarithmic scales, as suggested by Jonscher.

When making measurements of a semiconducting material, it is important to pay attention to whether the electrode contact is ohmic or not. If the electrode contact is nonohmic or the charge transfer between the semiconductor and the electrode is inefficient, then an additional semicircle may be observed, which may be interpreted to be related to the space-charge polarization at that interface. **Figures 13a** and **13b** show the complex impedance graphs for a semiconductor in contact with a blocking electrode. The image on the left shows the response for a given size electrode whereas the image on the right displays the effect of changing the electrode size, which affects the semicircle due to the electrode but not the response of the bulk material.

The situation is again different for the impedance response of a multiphase material. The two-layer condenser, first proposed by Maxwell and Wagner to represent a layered material, contains layers of a material with conductivity σ_1 and dielectric permittivity ε_1 that are placed with alternating layers of a material with conductivity σ_2 and dielectric permittivity ε_2, and thicknesses of d_1 and d_2. This gives rise to the Maxwell–Wagner dielectric relaxation equations given below:

$$\varepsilon'_{M-W} = (\varepsilon_\infty)^{M-W}\{1 + [k/(1 + \omega^2\tau^2)]\} \quad [15]$$

and

$$\varepsilon''_{\mathrm{M-W}} = (\varepsilon_\infty)^{\mathrm{M-W}}\{[\tau/\omega\tau_1\tau_2] + [k\,\omega\tau/(1+\omega^2\tau^2)]\} \quad [16]$$

where

$$k = [(\varepsilon_s)^{\mathrm{M-W}} - (\varepsilon_\infty)^{\mathrm{M-W}}]/(\varepsilon_\infty)^{\mathrm{M-W}}$$

$$\tau = [\varepsilon_1 d_2 + \varepsilon_2 d_1]/[\sigma_1 d_2 + \sigma_2 d_1]$$

It goes without saying that quite different spectra will be obtained depending on what the values of σ_1, ε_1, σ_2, ε_2 are. The basic interpretation is that the response at the highest frequencies represents the "effective" response of the bulk of the material, whereas the response at the lowest frequencies takes into account the interfaces between the two materials. It should be added that it may be necessary to consider additional processes such as defect relaxation within the more insulating type material and/or additional

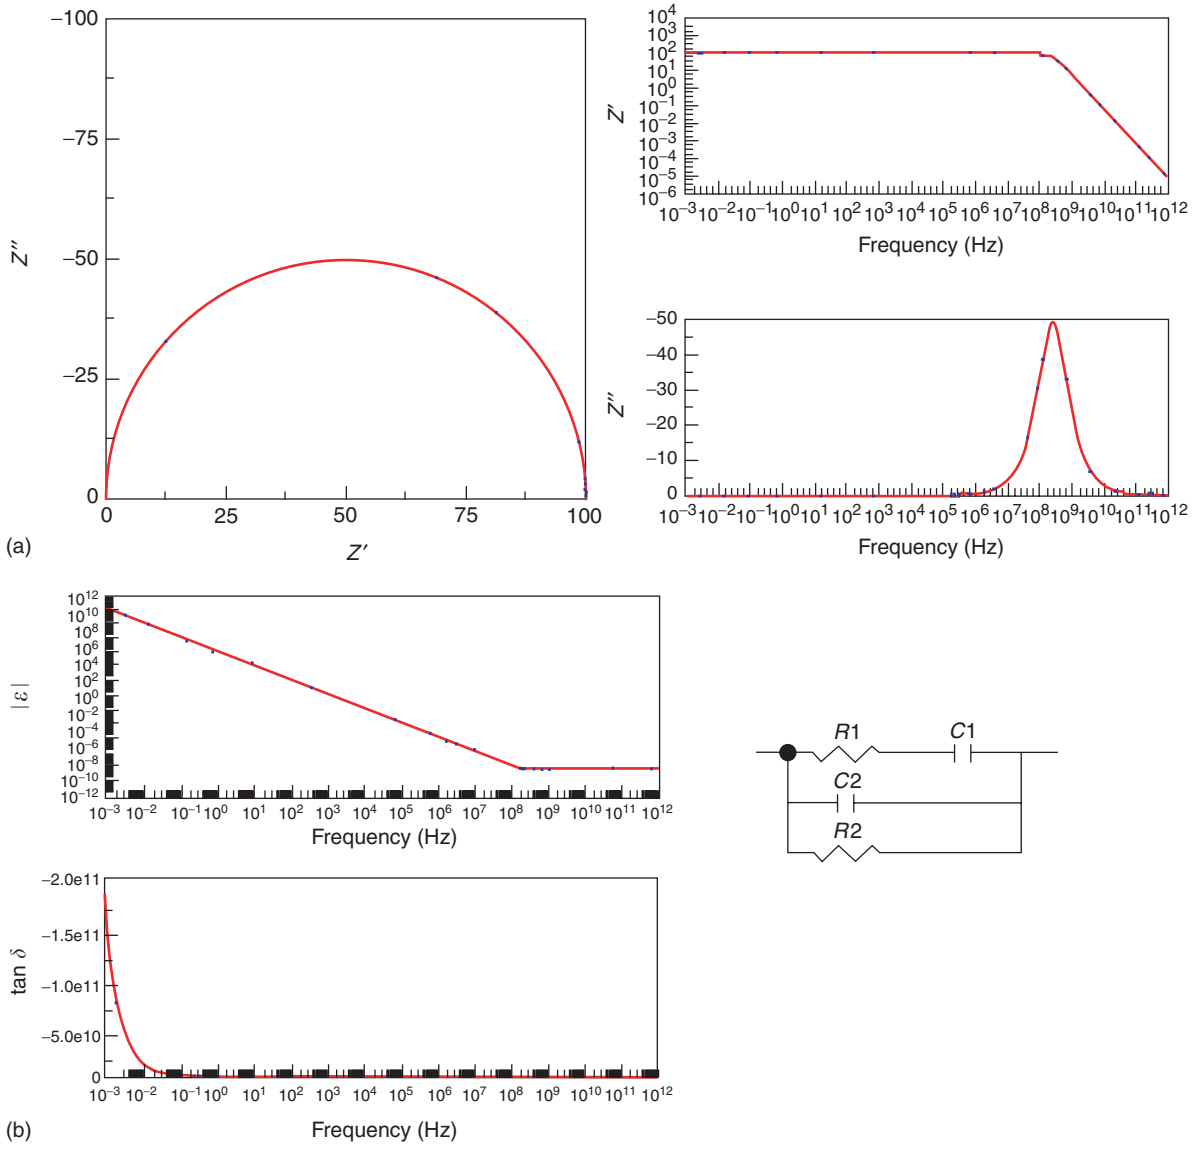

Figure 10 (a) Impedance plane response for a Debye relaxation with a measurable parallel leakage current process. The frequency implicit complex plot is dominated by the current leakage process; however, the frequency explicit real part shows both processes. (b) Frequency explicit dielectric permittivity and dissipation factor plots for a dielectric relaxation with a parallel leakage current. The equivalent circuit for such a combination of processes is also shown where *R*1 and *C*1 represent the leakage process and *R*2 and *C*2 represent the Debye relaxation. space-charge polarization processes at the interfaces of the more conducting material.

Data Analysis

Some guidelines have already been provided, but additional details will be given here. The most important concept is that of the geometric capacitance. The correct way of obtaining the capacitance of a conducting process is to use the intercept of the impedance curve with the real axis to obtain R for that process. To obtain the capacitance, the peak frequency must be identified (as was done in **Figure 8a**) so that the following equation can be used:

$$C = 1/\omega R \qquad [17]$$

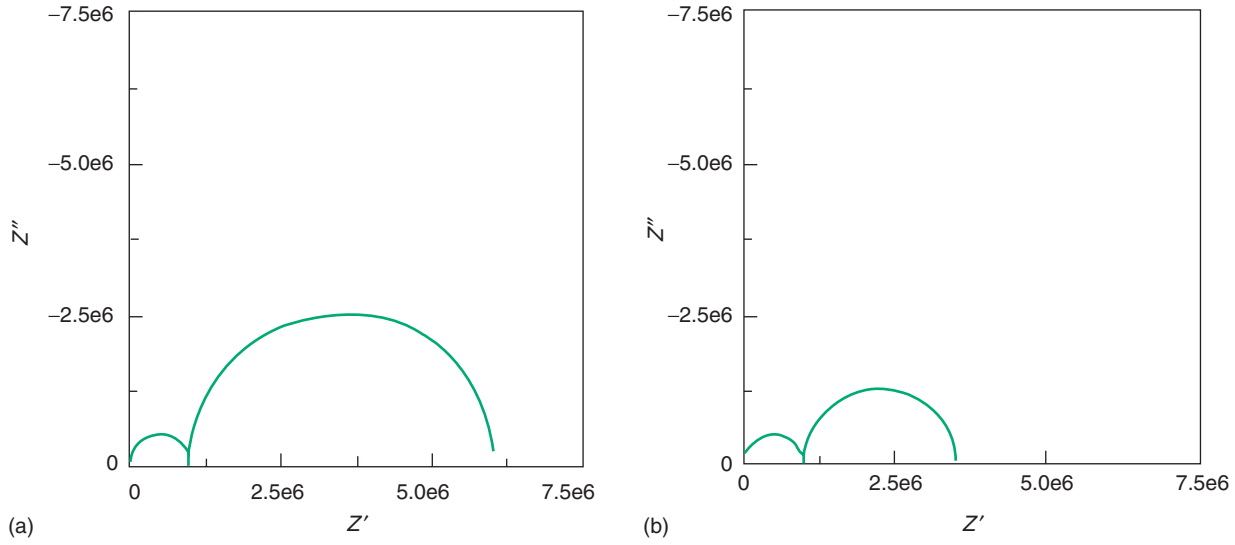

Figure 13 Complex impedance plots for an arbitrary semiconducting material system with a nonohmic or inefficient charge transfer electrodes. The only difference between (a) and (b) is the size of the electrodes used to measure the impedance. Note that while the high-frequency semicircle (due to a bulk process) remains unchanged, the low-frequency semicircle changes in proportion to the interfacial geometry.

Table 4 Effect of physical dimensions on measured capacitance

Dielectric constant	*Physical dimensions t*(m) *with* $A = 5 \times 10^{-5}\,m^2$	*Measured capacitance* (F)
2	1×10^{-3}	8.85×10^{-13}
2	1×10^{-6}	8.85×10^{-10}
2	1×10^{-9}	8.85×10^{-7}
10	1×10^{-3}	4.43×10^{-12}
10	1×10^{-6}	4.43×10^{-9}
10	1×10^{-9}	4.43×10^{-6}
100	1×10^{-3}	4.43×10^{-11}
100	1×10^{-6}	4.43×10^{-8}
100	1×10^{-9}	4.43×10^{-5}
1000	1×10^{-3}	4.43×10^{-10}
1000	1×10^{-6}	4.43×10^{-7}
1000	1×10^{-9}	4.43×10^{-4}

If one is interested in characterizing the bulk electrical properties of a given material or device, the measured capacitance should be of the same order of magnitude as that expected for the physical dimensions of the sample or device measured. This means that if such an analysis gives a capacitance that is not in agreement with the expected capacitance, then the measured data is not related to the bulk of the material or the device and is most probably related to some type of space-charge polarization mechanism. **Table 4** lists the expected capacitances for materials with different dielectric constants and physical dimensions. Note that changing the physical dimensions can change the value of the geometric capacitance drastically. Additional confirmation, that a measured process is related to a bulk process, can be obtained by varying the applied voltage or changing the size of the electrode contacts. The response for a bulk process should be the same, irrespective of the values of these. Instead, if they scale with these variables, it may be possible to separate electrode contact effects from internal interface effects. In cases where the impedance is so large that the intercept with the real axis is not available, the capacitance of the material will only be able to be obtained from either the real dielectric permittivity or the real electric modulus spectra. In most cases, the value is almost constant as a function of frequency. The only time that a semicircle will appear in both of these functions is when a dipolar-type relaxation is present.

Separating individual processes present in the bulk becomes a little bit more difficult. For example, separating the dipolar relaxation from the ionic conductivity in a good ionic conductor is not possible at temperatures where the ionic conductivity is high. However, carrying out measurements at lower temperatures suppresses the ionic conductivity and allows the detection of the defect dipole relaxation. Likewise, if a material has a large fraction of electronic conductivity and only a small fraction of ionic conductivity, detecting the latter is almost impossible within a single set of experiments. In such cases, the usage of blocking electrodes and/or controlled atmospheres to enhance or diminish a particular type of charge carrier will aid in the interpretation.

Electromagnetic Simulation Software

In recent years, a large number of commercially available software packages have become available. Many of the software packages come complete with electrostatic and electromagnetic modules. They are used mostly to model the performance of devices, but physical arrangements of structures (at various length scales) are also possible. Most commercially available simulation software is finite element based (FEA) or finite time difference based (FTDT). Some progress has been made on implementing these packages to help simulate impedance data at the microstructural level, but much more work needs to be done before they become commonplace.

Recent Advances (What to Expect in the Future)

IS of solid-state materials continues to be used in a wide variety of fields and the number of applications continues to grow. Besides being useful as a way of determining the bulk electrical properties of materials and devices, it can also be used as a way to determine: (1) the sensitivity and selectivity of gas sensors, (2) the degree of biocompatibility of new biomedical implants, (3) methods of quality control, and (4) nondestructive characterization of microstructures.

More recent developments include magneto-impedance measurements, photostimulated-impedance measurements, and bioimpedance measurements of tissue. These new methods will be a great help to the burgeoning fields of spintronics, giant magnetoresistance, electrooptical devices, and biomedical engineering. In addition, impedance measurements can be taken at all length scales; localized measurements have been acquired using macro-, micro-, and nano-sized electrodes for a number of years. However, simultaneous impedance and topographical data acquisition in an AFM/STM has the potential to revolutionize the usage of IS in the future. Single frequency impedance amplitude and phase image scans have been collected using the tapping mode or the conductive AFM mode, and are being related to topographical images in order to understand what role different features play. Recent experiments have considered Schottky barriers in single-crystal semiconductors, ionic conductivity in mixed conductors, and electron transfer in molecular wires and carbon nanotubes. It is anticipated that, with further developments in probe tips, many more exciting scanning impedance microscopy experiments will be conducted.

Concluding Remarks

Attempts to simplify the many facets of IS have been made throughout this article. The author has purposely excluded discussion of more complex equivalent circuits, as these only modify the basic concepts described here. Electrochemical impedance spectroscopy (EIS), which is mainly used to study corrosion of metallic materials, was also excluded, as there are many excellent reviews available in the literature. Readers are urged to carefully review the extensive literature in the subject matter of their interest, keeping in mind some of the guidelines presented here.

Incommensurate Phases

J M Perez-Mato, Universidad del Pais Vasco, Bilbao, Spain

Introduction

Incommensurate phases are thermodynamically stable phases that do not have lattice periodicity although they possess a long-range order. Their diffraction patterns exhibit sharp Bragg peaks but, in contrast with conventional (commensurate) crystalline solid phases, their indexation requires more than three Miller indices. They can be classified into two groups according to their structural properties: modulated structures and composite structures. The first ones can be described as a distortion of an underlying average crystal structure with conventional lattice periodicity.

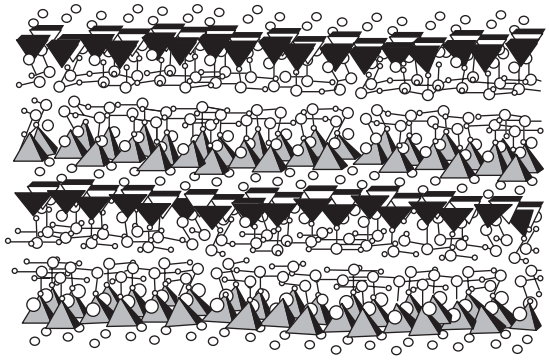

Figure 1 Incommensurate structure of $Bi_2Sr_2[Sr,Ca]Cu_2O_{8+x}$. (Reproduced from Calestani G, Rizzoli C, Francesconi MG, and Andreetti GD (1989) *Physica C* 161: 598–606, with permission from Elsevier.)

This distortion or modulation may involve any atomic parameter (atomic positions, atomic occupation probabilities, etc.), its periodicity being incommensurate with the lattice of the basic structure. This formally means that, at least in one direction, the ratio of the period of the modulation with respect to that of the basic structure is an irrational number. As an example, **Figure 1** depicts an approximate representation of the incommensurate modulated structure of the high-T_c superconductor $Bi_2Sr_2[Sr, Ca]Cu_2O_{8+x}$. In this material, some atomic displacements from the reference average structure are extremely large (more than 1 Å in the case of the oxygen atoms within the Bi_2O_2 layers). In general, atomic displacements due to the modulation are usually ~ 0.1 Å.

Incommensurate composite structures, on the other hand, are built by several crystalline subsystems whose basic lattice periodicities are incommensurate with one another. In the simplest and most common case, the number of subsystems is two. In general, their mutual interaction causes, in each of the subsystems, a modulation with the periodicity of the other one. In this sense, a composite structure is a set of modulated incommensurate structures forming a single phase. As an example, the basic features of a urea inclusion compound are shown in **Figure 2**. The urea forms a lattice with large hexagonal channels where a second subsystem of organic chains accommodates. The chains are ordered along the channels according to a basic periodicity, which is independent of the one of urea. The set of chains can be considered as a guest within the host urea. But both host and guest form a coherent single system, and a non-negligible incommensurate modulation in each subsystem, with the average periodicity of the other one, exists.

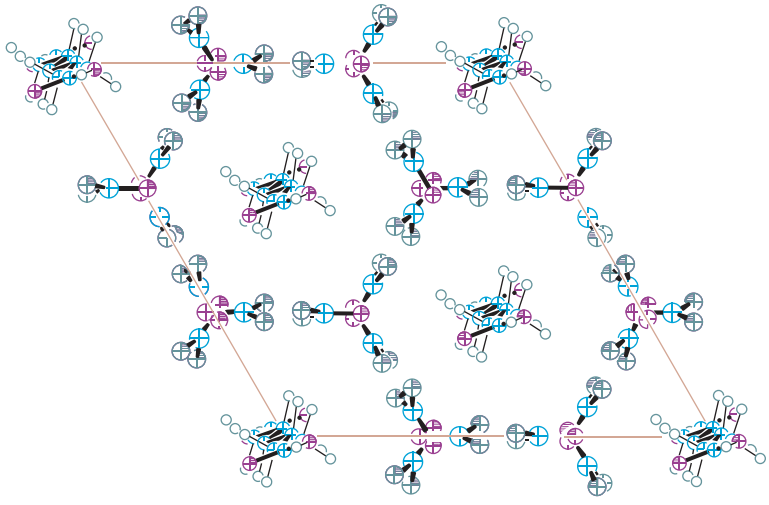

Figure 2 View of a urea inclusion compound with octanedioic acid as guest subsystem. (Courtesy of G Madariaga and I Peral.)

Strictly speaking, the definition given above for incommensurate phases would also include quasicrystals. These latter are usually distinguished by the fact that they exhibit, in their diffraction diagram, a noncrystallographic point group. However, it is now generally accepted that noncrystallographic symmetry is not essential for the concept of a quasicrystalline state, and for instance, aperiodic quasicrystalline tilings with crystallographic point groups can be designed. In fact, the conceptual borders between these three types of incommensurate phases (modulated, composites, and quasicrystals) have become progressively blurred. Nevertheless, if quasicrystals are also included within the same category, one rather speaks of aperiodic crystals instead of incommensurate phases or incommensurate crystals.

In this article, the fundamental crystallographic and physical properties of incommensurate phases in the restricted sense explained above, that is, disregarding quasicrystals, are briefly summarized.

Crystallography of Incommensurate Phases

An example of the diffraction diagram of a simple incommensurate modulated phase is shown in **Figure 3**. One can distinguish a lattice of intense Bragg reflections, the so-called main reflections, which can be indexed in a conventional way with a set of three reciprocal unit cell vectors. There are, however, additional weaker reflections, the so-called satellite reflections, separated from a neighboring main reflection by vectors of type mq, with m an integer

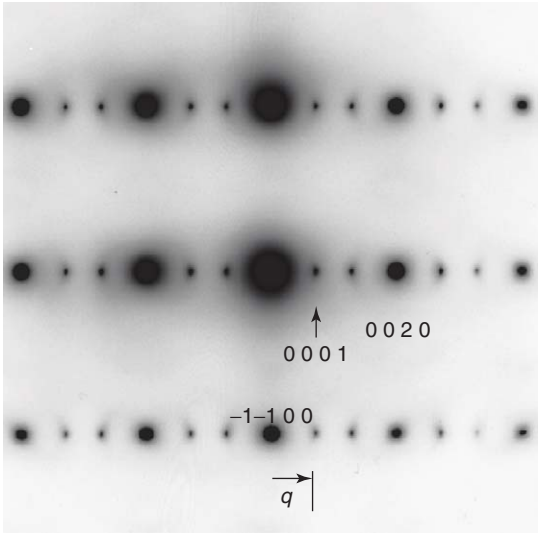

Figure 3 Electron diffraction diagram ($\langle -1, 1, 0 \rangle$ zone axis) of the incommensurate modulated $Ni_{2.667}In_{0.667}Te_2$. (Courtesy of RL Withers.)

and q a unique specific vector. These satellite reflections are the signature of a distortion with periodicity $2\pi/|q|$. Hence, the indexation of the diffraction vectors H associated to the observed Bragg reflections requires four vectors:

$$H = ha^* + kb^* + lc^* + mq;\ h,k,l,m \text{ integers} \quad [1]$$

For a given choice of the four indexation vectors, if q is rationally independent of the basis $\{a^*, b^*, c^*\}$, the indexation [1] is unique and unambiguous, and the system is incommensurate. Obviously, one could always find, within experimental resolution, a much smaller reciprocal unit cell of three vectors capable of indexing all reflections. This, however, would be impractical as the resulting cell in direct space would be too large, and most of the Bragg reflections associated with this lattice would be absent. Hence, the incommensurability of q is more a matter of efficiency and simplicity of the description, rather than a rigorous mathematical property. However, in many cases, the formal incommensurability of q is clearly evidenced by its temperature variation.

Note that, strictly speaking, the set of points described by eqn [1] is not discrete. The reason why one can talk of an unambiguous indexation and a discrete set of Bragg peaks lies on the empirical fact that the set of observed diffraction vectors H is limited to small indices (h,k,l,m).

As an example of an incommensurate composite, a simple case is considered where the two subsystems have two lattice vectors in common, a and b. The incommensurability is then restricted to the z direction. The basic structures of the two subsystems have two different lattice parameters, c_1 and c_2, so that c_1/c_2 is irrational in the practical sense mentioned above. In the diffraction diagram, as shown in the example of **Figure 4**, one can distinguish the main reflections of the two subsystems which can be indexed with their respective reciprocal unit cells (a^*, b^*, c_1^*) and (a^*, b^*, c_2^*). Since both subsystems are modulated with the periodicity of the other one, additional satellite reflections are also present. The vectors c_2^* and c_1^* act as modulation wave vectors of the subsystem 1 and 2, respectively. If q is denoted as the vector c_2^*, then again all Bragg reflections H in the diffraction diagram can be indexed in the form of eqn [1], as shown in **Figure 4**. Satellites with index l and m different from zero cannot be explained but by the presence of the mutual modulation of both subsystems.

In general, an incommensurate phase may have several independent modulation wave vectors $\{q_j, j = 1, \ldots, d\}$. The indexation of the diffraction vectors then requires $(3 + d)$ indices and one speaks

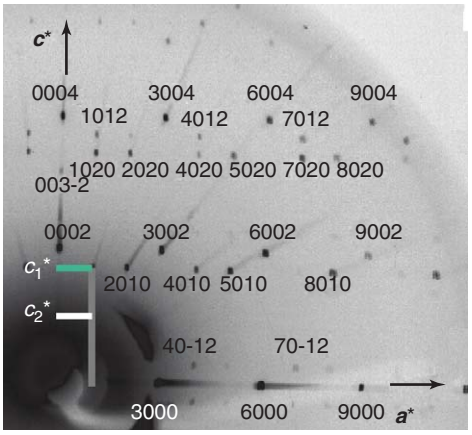

Figure 4 X-ray diffraction diagram of the incommensurate composite $Ba_{1+x}(Cu_xRh_{1-x})O_3$ with $x \approx 0.161$. The two incommensurate $\boldsymbol{c}^*$ parameters and the four integer indexation of the Bragg peaks are shown. (Courtesy of J Darriet.)

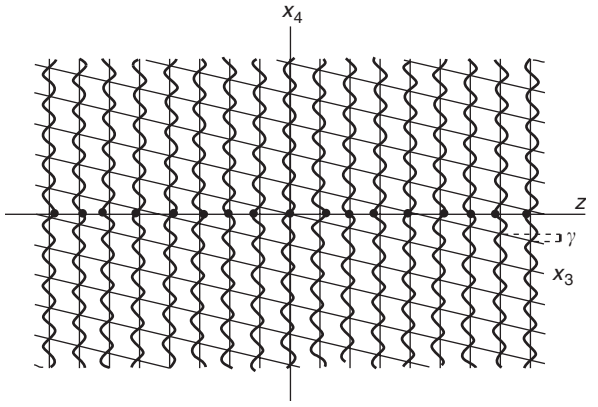

Figure 5 Projection on the plane x_3x_4 of the superspace density of a monoatomic structure with an incommensurate longitudinal sinusoidal modulation along the z-axis with wave vector $\boldsymbol{q} = \gamma \boldsymbol{c}^*$. Resulting aperiodic atomic positions are indicated by filled circles. (Courtesy of L Elcoro.)

of an incommensurate phase with a Fourier module of rank $(3+d)$.

The quantitative description of incommensurate phases cannot be done using the tools of conventional crystallography. Instead, a very efficient methodology has been developed introducing the concept of superspace. The real aperiodic structure is embedded within a $(3+d)$-dimensional space, the so-called superspace, as a section of a $(3+d)$-dimensional periodic structure. This allows the recovery of periodic crystallography, albeit in $(3+d)$ dimensions, and a straightforward description of the symmetry of these phases as a space group defined in superspace.

The superspace construction for the description of incommensurate phases is very easy to understand if one considers the Fourier spectrum of such systems. In general, one can say that their scattering density $\rho(\boldsymbol{r})$ can be developed in discrete Fourier series $\rho(\boldsymbol{r}) = \sum_H F(\boldsymbol{H})\exp(-\mathrm{i}2\pi \boldsymbol{H}\cdot\boldsymbol{r})$ with the set of diffraction vectors given by $\boldsymbol{H} = \sum_{i=1}^{n} h_i \boldsymbol{k}_i$, where $n = 3 + d$ (for simplicity, a notation is used that does not distinguish among the indexation basis vectors). A function in n variables can then be defined as

$$\rho_s(x_1, x_2, \ldots, x_n) = \sum_H F(\boldsymbol{H})\exp(-\mathrm{i}2\pi \sum_{i=1}^{n} h_i x_i) \quad [2]$$

where $F(\boldsymbol{H})$ are the Fourier amplitudes of the real 3D structure $\rho(\boldsymbol{r})$, and h_i the n indices of the corresponding vector $\boldsymbol{H}$. The n "phases" $(x_1, \ldots, x_n)$ define an n-dimensional superspace. By definition, the superspace density $\rho_s(x_1, \ldots, x_n)$ is periodic for each of its n variables with period 1, and directly defines the structure in real space $\rho(\boldsymbol{r})$ through the simple equation

$$\rho(\boldsymbol{r}) = \rho_s(\boldsymbol{k}_1\cdot\boldsymbol{r}, \ldots, \boldsymbol{k}_n\cdot\boldsymbol{r}) \quad [3]$$

Hence, a knowledge of the periodic superspace density within a single n-dimensional "primitive unit cell" and of the vector basis used in the indexation is sufficient for obtaining the aperiodic density in real space.

Note that the superspace is, in principle, an abstract space without a predefined metric. However, traditionally a particular metric is introduced which allows one to interpret eqn [3] from a geometrical viewpoint, so that the section of the superspace density $\rho_s(x_1, \ldots, x_n)$ given by eqn [3] does not only represent the real structure, but it does keeping its real space metric. In this way, the real space is imagined as a subspace of the defined superspace. In the following, this convention will be maintained. The Fourier spectrum of the incommensurate structure can then be interpreted as the projection in real space of the Fourier spectrum of the superspace density. Each vector $(h_1, \ldots, h_n)$ belonging to its reciprocal lattice has a component in real space that coincides with the real space diffraction vector $\boldsymbol{H} = \sum_{i=1}^{n} h_i \boldsymbol{k}_i$ and a perpendicular component in the complementary subspace, usually called internal space. For 1D modulated structures, the convention is to choose the metric so that the coordinates $x_4, \ldots, x_n$ corresponding to the modulation wave vectors $\boldsymbol{q}_i$, $i = 1, \ldots, d$ are associated to the internal space.

In **Figures 5** and **6**, two examples of the superspace description of incommensurate structures are depicted. They represent the projection on the plane x_3x_4 of a monoatomic structure with a sinusoidal and a

sawtooth longitudinal modulation along the z-axis, respectively. In both cases, the modulation wave vector can be expressed as $\boldsymbol{q} = \gamma \boldsymbol{c}^*$. The z-coordinates of the aperiodic point-like atomic sites along the z-axis in real space are represented by black dots, and are defined by the intersection with the real space z-axis of the sinusoidal or sawtooth lines representing the periodic superspace density. These two graphic examples illustrate the basic principle of the superspace construction. The section corresponding to the real space is irrationally oriented with respect to the superspace periodic lattice, making the real structure aperiodic. However, there is a one to one correspondence between all atomic sites in real space and points within a single unit cell in superspace. Each atomic position in real space is equivalent, by a lattice translation in superspace, to a single point within a primitive unit cell of the superspace density. The infinite set of all these points within a single n-dimensional unit cell defines the set of occupied atomic positions in real space. The superspace formalism would not be of any use if these points within the superspace unit cell would be more or less random and one should give the coordinates of all of them to define the structure. The crucial property of the superspace description (implicit in the discreteness of the diffraction diagram) is that, in general, these points form, in superspace, dense sets that can be described with few parameters. These sets are called atomic domains or atomic surfaces. In many cases, these atomic domains are continuous along the internal space, as the example of **Figure 5**. However, discontinuous atomic domains may also exist as in **Figure 6**, where the presence of a discontinuous sawtooth modulation yields in real space only two different interatomic distances along the modulation direction. More complex situations have also been hypothesized as, for instance, atomic domains with fractal character.

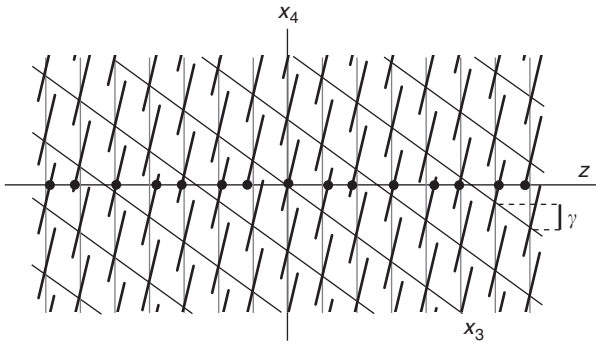

Figure 6 Projection on the plane x_3x_4 of the superspace density of a monoatomic structure with an incommensurate longitudinal sawtooth modulation along the z-axis with wave vector $\boldsymbol{q} = \gamma \boldsymbol{c}^*$. The resulting interatomic distances along z are restricted to two possible values. (Courtesy of L Elcoro.)

Once the phase problem has been solved and phases can be assigned to the experimental structure factor moduli $|F(\boldsymbol{H})|$, the superpace density can be retrieved from experimental diffraction data by means of so-called Fourier maps given by eqn [2]. **Figure 7** represents a section of the superspace density on the plane x_2x_4 corresponding to the bismuth and oxygen atoms of the Bi_2O_2 layers in $Bi_2Sr_2[Sr, Ca]Cu_2O_{8+x}$ (see **Figure 1**) as obtained from neutron diffraction experiments. The highly anharmonic modulations of both cations can be clearly seen. The strong oxygen modulation is discontinuous and the atomic domains form a sawtooth function. The flexibility of oxygen content in this compound is reflected in a variable size along the internal coordinate x_4 of these oxygen domains.

The symmetry associated to an incommensurate phase is given by a so-called superspace group. It can

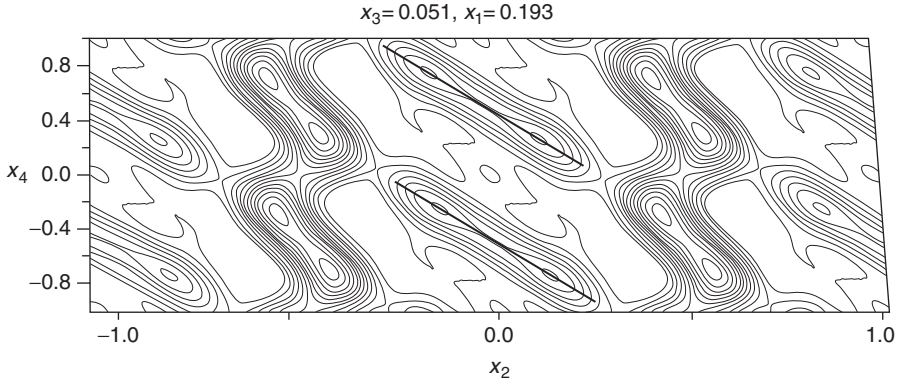

Figure 7 Fourier map corresponding to an x_2x_4 section showing the modulations of bismuth and oxygen in the Bi_2O_2 layers of $Bi_2Sr_2[Sr,Ca]Cu_2O_{8+x}$.The oxygen atomic domains are also drawn. (Reproduced with permission from Perez-Mato JM, Etrillard J, Kiat JM, Liang B, and Li CT (2003) Competition between composite and modulated configurations in $Bi_2Sr_2CaCu_2O_{8+x}$ and its relation to oxygen stoichiometry. *Physical Review B* 67: 024504; © American Physical Society.)

be easily derived from the properties of the corresponding Fourier spectrum, but it is difficult to visualize in direct space. It is described by operations that transform the real space structure in a new atomic configuration, different from the original one but physically indistinguishable. In superspace, these operations have a simple interpretation as space group operations in the n-dimensional superspace describing the symmetry of the superspace density $\rho_s(x_1, \ldots, x_n)$. However, not all n-dimensional space groups make sense as superspace groups. By definition, their rotational part should maintain the real space invariant. It is important to note that the superspace groups are not fortuitous geometrical relations, but they are thermodynamically stable in the sense that they are maintained within the whole range of a thermodynamic phase. They may only be broken via a phase transition, and in this sense, they are well-defined symmetries.

The Physical Origin of Incommensurate Phases

The systematic quantitative analysis of incommensurate phases started in 1976 with the study of Na_2CO_3 by de Wolff and collaborators. At this time, the existence of incommensurate modulated phases seemed an exceptional phenomenon. Four decades later, it is known that incommensurate phases are nearly ubiquitous and may appear in the phase diagram of systems of any type. During these years, the structure of more than 100 modulated crystals and about 50 modulated composites have been quantitatively characterized using the superspace approach, while the observation of modulated phases has been reported in many more. Incommensurate phases have been found in ionic, covalent, and molecular crystals, and also in alloys and metallic systems. Even numerous single chemical elements are now known to exhibit incommensurate phases at high pressures, either single modulated or composite. Incommensurate distortions are also present in important materials as high-T_c superconductors or ferroelectric relaxors.

An incommensurate configuration may be not only thermally stabilized, but it can also be the actual ground state of some systems. The mechanisms capable of producing the stabilization of modulated phases are quite various, and this variety of possible causes may be at the origin of the abundance of these phases in all types of materials. Incommensurate phases may in fact be stabilized through temperature, pressure, or composition.

The modulated structures of some metallic systems are attributed to a charge-density wave (CDW) mechanism, analogous to the Peierls transition. In a 1D metal, for instance, it may be energetically favorable to introduce a lattice modulation with a period π/k_F, k_F being the Fermi wave vector. This distortion opens up a gap just at the Fermi level, which decreases the electronic energy and may successfully compete with the increase of elastic energy. In general, for an arbitrary band filling, k_F is not commensurate with the underlying lattice and the modulation is incommensurate. In three dimensions, the phenomenon requires some additional (difficult to fulfil) topological conditions. In order to produce a significant gap at the Fermi level through the presence of a distortion with one or a few primary wave vectors, the topology of the Fermi surface must be such that these wave vectors connect significant dense sets of points at the Fermi surface. This is the so-called nesting condition and can only be satisfied by very peculiar Fermi surface topologies (see **Figure 8**). The nesting condition is easier to happen in systems closer to lower dimensionalities, that is, strongly anisotropic materials. Thus, typical CDW systems have chain or layer structures. Examples are transition-metal dichalcogenides, such as $NbSe_3$, NbS_3. It must be noted that this CDW–Peierls mechanism does not imply, in general, that the resulting incommensurate phase would be a semiconductor or insulator, as the gap may not be fully realized.

In some compounds, the incommensurate modulation is the result of the ordering of a minority component or of some vacancies. This modulation is then mainly occupational, that is, the occupation probability of some atomic sites varies along the modulation. In many cases, it may result in discontinuous atomic domains. This situation is rather common in nonstoichiometric compounds.

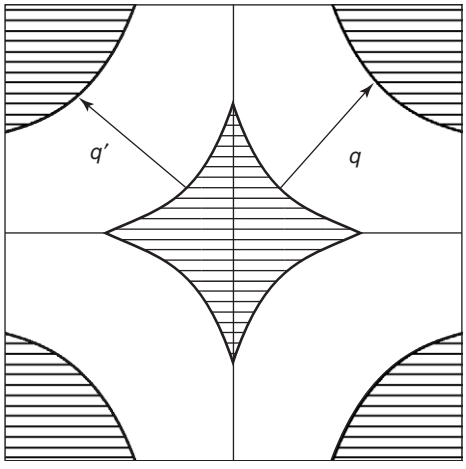

Figure 8 Scheme of a 2D Fermi surface fulfilling nesting conditions for two wave vectors.

Valence considerations and the bond valences sum rules, developed by ID Brown, have also been used to explain the stabilization of many incommensurate phases. In the case of metals such as calaverite ($Au_{1-p}Ag_pTe_2$), the need of a fluctuating valence for Au has been argued to be at the origin of the modulation. In other cases, as in Na_2CO_3, however, the requirement is of a single optimal valence for a particular cation, which is the main cause of the modulation. The average nonmodulated configuration can lead to chemically unfavorable sites for specific cations, yielding bond valence sums with significant deviations from the ideal values. As the ideal valences can be achieved by means of quite different coordination geometries, a modulation involving a correlated distortion of the coordination polyhedra corresponding to the problematic atomic sites may optimize the local chemistry of the structure. This has been shown to happen in many incommensurate insulators.

In some cases, the existence of a modulated phase can be understood using simple steric arguments and can be considered to be a purely lattice phenomenon with no direct involvement of the electronic degrees of freedom. For instance, in many materials rather rigid atomic polyhedra share vertices or edges and form an infinite framework. These framework structures possess, in many cases, specific distorting modes that are compatible with the rigidity of the polyhedral units forming the framework. These so-called rigid unit modes (RUMs) are candidates for being low frequency and even unstable modes of the system. They are usually constrained to specific modulation wave vectors within the Brillouin zone, that is, isolated points, lines, or surfaces. If the strongest instability of the systems corresponds to one RUM with a wave vector not fully fixed by symmetry, its freezing on the structure yields, in general, an incommensurate modulated phase of lower energy.

Similarly, in other cases, such as the family of orthorhombic compounds A_2BX_4, with K_2SeO_4 as an emblematic example, the optimal packing of some rigid ionic groups yields interstices, which are too large to accommodate the remaining atoms (cations). A modulation, either commensurate or incommensurate, can then palliate the problem optimizing the coordination of these interstitial sites. All A_2BX_4 compounds have a conspicuous soft phonon branch, which can be attributed to this steric effect. **Figure 9** schematizes the calculated variation of this phonon branch for different effective sizes of one of the two independent A cations. The branch is stabilized for larger A cations, while for small cation sizes, as those of potassium or rubidium, it softens and may even become unstable. In this latter case, an incommensurate frozen modulation of the wave vector around

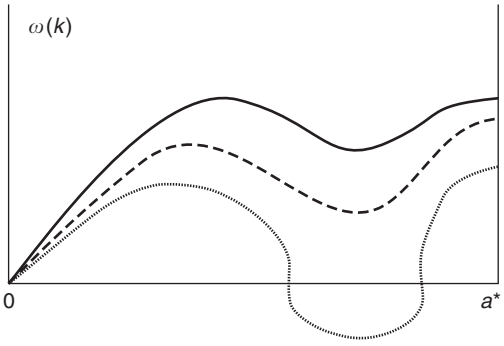

Figure 9 Scheme of the variation of the soft-mode branch in orthorhombic A_2BX_4 compounds as a function of the effective size of one of the independent A cations after the calculations in Etxebarria I, Perez-Mato JM, and Madariaga G (1992) *Physical Review B* 46: 2764. The branch lowers and becomes unstable at an incommensurate wave vector as the size increases. Imaginary frequency values are represented as negative.

$(2/3)\,a^*$ minimizes the energy. Clearly, a mismatch between the A cation size and the corresponding atomic site produced by the optimal accommodation of the more voluminous ionic units of the structure is at the origin of the incommensurate instability in these materials.

When atomic size effects are mainly involved in the incommensurate instability, thermal effects are very important as temperature can significantly change the effective size of atoms and the incommensurate phase is limited to some temperature range. For instance, in the case of A_2BX_4 compounds, the incommensurate modulation appears at a thermal phase transition as the temperature is lowered and the effective volume of the A cations decreases. In fact, the experimental soft phonon branch of K_2SeO_4 changes as the temperature is lowered in a form similar to the one given in **Figure 9**, which corresponds to a change of the size of the A cation.

It has become commonplace to talk about the existence of competing interactions as the ultimate origin of incommensurate phases. As practically all cohesive properties of any system could be traced back to the presence of competing interactions (repulsion–attraction), this does not seem very informative. In fact, the term "competing interactions" is used here in the sense that the basic interactions in these systems favor not one, but several incompatible and competing periodicities. The system is then frustrated and adopts a compromise configuration given by the incommensurate modulated structure. This simple concept is underlying the microscopic models developed to study the basic properties of the incommensurate phases. Among them, the so-called ANNNI model (axial next nearest neighbor Ising model) is the one that has been more thoroughly studied. This is essentially a 3D Ising model with

ferromagnetic nearest-neighbor coupling on one plane, while in the perpendicular direction, a ferro and antiferromagnetic coupling, J_1 and J_2, for nearest and next nearest neighbor, respectively, compete and favor different periodicities along this axis. **Figure 10** shows the approximate topology of the resulting mean-field phase diagram as a function of temperature and the relative strength of the ferromagnetic and antiferromagnetic interactions. The ground state is either ferromagnetic or commensurate modulated with a fourfold unit cell. At high temperatures the full disordered paramagnetic phase is stable, but as temperature is lowered, the system exhibits numerous phase transitions between different modulated phases including incommensurate ones. Similar results are obtained for more complex models as the so-called discrete frustrated Φ^4 model (DIFFOUR) where spins are substituted by more realistic local continuous variables on double wells.

Although the ANNNI model was initially designed to reproduce the properties of modulated magnetic materials, it has been successfully applied to understand the properties of purely structural modulated compounds, where the spin is associated to a local mode described as a pseudospin variable. In fact, a ferroelectric material, betaine calcium chloride dihydrate (BCCD), exhibits properties which strikingly reproduce those associated to the ANNNI model and some of its derivatives. On decreasing the temperature, the material passes through more than ten intermediate modulated phases, including two incommensurate ones, as the modulation wave vector locks into decreasing commensurate values before the system acquires a final ferroelectric nonmodulated configuration. This step-like decrease of the modulation wave vector, as the temperature is lowered, is given, under certain mathematical conditions, the name "Devil's staircase."

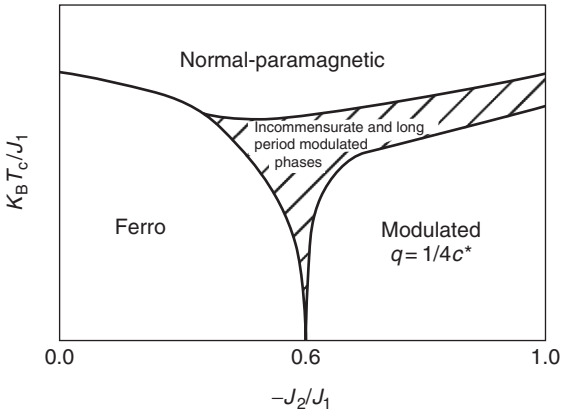

Figure 10 Schematic phase diagram of the ANNNI model within the mean field approximation.

The stabilization mechanism of incommensurate composites can also be quite varied. There are composites, as the inclusion compounds, where the interactions between the subsystems are rather weak, limited to molecular forces. Their mutual modulations are, therefore, in this case, rather small. In other compounds, the interaction is much stronger and there may even exist chemical bonding between atoms belonging to different subsystems, as in $(LaS)_{1.13}TaS_2$.

One could expect that by their own definition, nonstoichiometry is an essential component of composites. Two incommensurate atomic subsystems yield necessarily a noninteger ratio between their respective compositions. However, the interaction between both subsystems can be so strong that the actual modulation may include chemical substitution, yielding a perfectly stoichiometric (but incommensurate) composite. The family of commensurate and incommensurate trigonal compounds of general formula $A_{1+x}[A'_xB_{1-x}]O_3$ is a nice example, where this type of chemical interaction between the subsystems plays a dominant role. **Figure 4** above shows a typical diffraction pattern of one of these compounds, and **Figure 11** illustrates their main

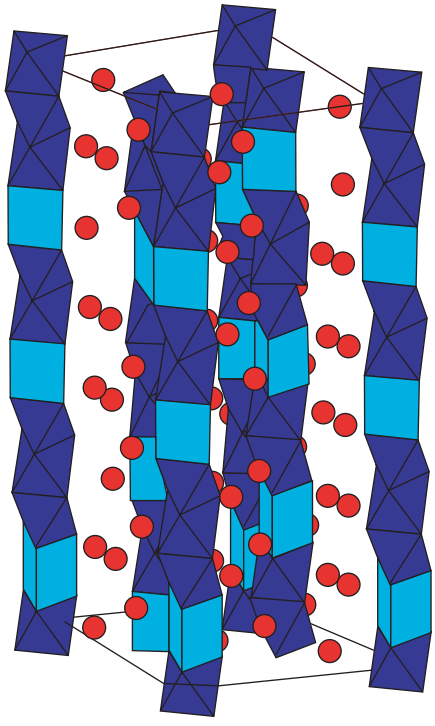

Figure 11 Approximate structure of a composite of type $A_{1+x}[A'_xB_{1-x}]O_3$ with $x \approx 3/11$.The sequence of octahedra and prisms along the $[A'_xB_{1-x}]O_3$ columns is aperiodic but locally follows the sequence $\langle 3\,1\,3\,1\,2\,1 \rangle$ corresponding to the exact commensurate composition $x = 3/11$. The periodicity and this commensurate composition are lost by "faults" in this sequence.

structural features. These trigonal materials are closely related to the 2H hexagonal perovskites ABO_3. The groups $A'O_3$ and BO_3 forming columns along the trigonal axis constitute the first subsystem, while the second subsystem is given by the cations A forming chains among these columns. The mismatch between the two subsystems is produced by the excess of A cations, in a ratio $1+x$ with respect to the number of $[A', B]O_3$ units. However, stoichiometry is maintained through the substitution of B cations by divalent A′ cations, the composition of the second subsystem being $[A'_xB_{1-x}]O_3$ (A and B are typically divalent and tetravalent, respectively). Hence, the presence of the A′ cations within the columns $[A', B]O_3$, visible in **Figure 11** through their trigonal prismatic oxygen coordination, can be considered the fundamental modulation of the $[A', B]O_3$ subsystem. In some cases, A′ and B cations can be the same element in two oxidation states and then one can talk of a valence modulation. Thus, stoichiometry is ensured, but the system is incommensurate, as the sequence of octahedra and prisms along the $[A', B]O_3$ columns is, in practice, aperiodic for x values not assimilable to simple fractions.

Landau Phenomenology

There are a significant number of compounds that, after becoming incommensurate at a thermal phase transition, remain incommensurate up to the lowest accessible temperatures (for instance PbO). In most cases, however, the range of the incommensurate phases stabilized by temperature is usually limited by two commensurate phases, a high-temperature or parent (nonmodulated) phase, and a low-temperature "lock-in" phase, where the modulation wave vector "locks" into a certain rational value $\boldsymbol{q}_c$. In the generalized Landau theory of phase transitions, extended to include incommensurate phases, both the lock-in and the incommensurate phase are usually described using the same order parameter. It is homogeneous in the first case and modulated in the second one.

One of the simplest and most common situations occurs when the lock-in wave vector lies within a symmetry line of the Brillouin zone and the associated order parameter is 2D. The order parameter can then be considered a complex number, $Q = \rho\exp(i\theta)$, representing the complex amplitude of the primary distorting mode in the lock-in phase. The incommensurate phase is then described by a space-dependent order parameter $Q(x)$ along the direction of the wave vector. This is the case of the A_2BX_4 compounds and many other incommensurate insulators. The corresponding Landau free energy includes two essential terms: a Lifshitz invariant of type $(Q\partial Q^* - Q^*\partial Q)$ (where ∂ means a derivative with respect to x), and an umklapp term, $Q^p + Q^{*p}$, of relatively low order p. These terms favor inhomogeneous and homogeneous configurations of the order parameter, respectively. The Lifshitz invariant is the essential cause of the stability of the incommensurate phase, while the second one favors the lock-in phase. The properties predicted by this generalized Landau potential agree rather well with the experimental results. As temperature is lowered, after a second-order transition from the parent to the incommensurate phase, the competition between the Lifshitz and the umklapp terms drives the modulation from an initial sinusoidal configuration into a strong anharmonic regime, the so-called soliton regime, previous to the lock-in phase transition. In this soliton regime, the modulation is soliton-like with regions, periodic along the modulation direction, where the order parameter is approximately constant (i.e., regions approximately commensurate corresponding to the lock-in phase) separated by coherent periodic discommensurations, where the phase $\theta(x)$ of the complex order parameter changes rapidly to the next "constant" value. In the simplest approximation, this step-like behavior of the phase $\theta(x)$ satisfies the sine-Gordon equation, a well-known equation in nonlinear physics. The density of the discommensurations, the so-called soliton density n_s, can be taken as an order parameter with respect to the lock-in phase. A zero soliton density would correspond to the lock-in phase while $n_s = 1$ is associated to the perfect sinusoidal modulation. Hence, the system approaches the lock-in phase in two rather different and complementary ways: (1) approaching the modulation wave vector to the commensurate value $\boldsymbol{q}_c$, and (2) transforming progressively the structural modulation into a step function corresponding to $n_s = 0$. Experimentally, the lock-in transition has a discontinuous character and takes place before either the modulation wave vector or n_s can reach their limit values. However, soliton regimes in the incommensurate phase with n_s as low as 0.2 have been detected.

Figure 12 shows the measured diffracted intensity around the satellite $(6\ 0\ 1\ -1)$ of Rb_2ZnCl_4 at 6 K above the lock-in transition, well within the soliton regime. The modulation wave vector in this case is about $(1/3-0.018)\boldsymbol{c}^*$. The signature of the strong anharmonic step-like atomic modulations is the presence of very high-order satellites around the stronger first-order $(m = -1)$ satellite. Satellites up to $m = 7$ can be observed. The rather relative strong intensity of the satellites with $m = 5$ and 7 is due to symmetry restrictions on the atomic modulations that favor Fourier components of order $6n \pm 1$. Note that at

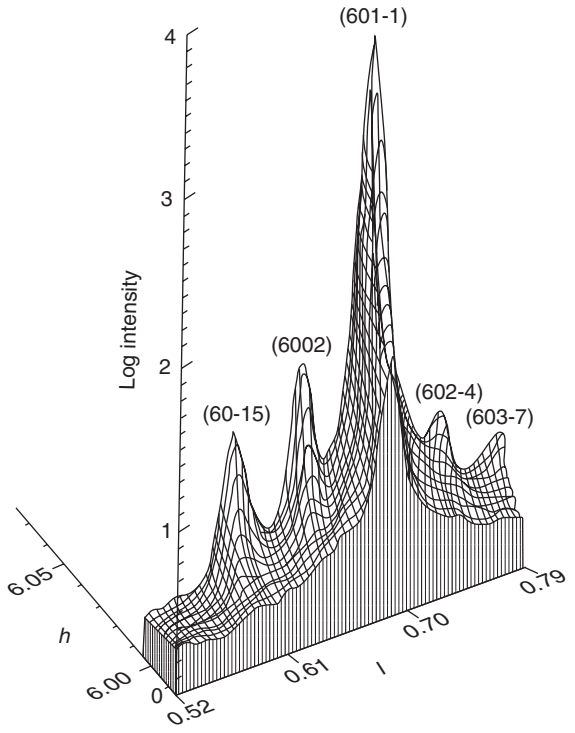

Figure 12 X-ray intensity diffracted by R_2ZnCl_4 around the satellite (6 0 1 $-$1) at 198 K showing intense high-order satellites close to the lock-in phase transition. the lock-in phase transition where the modulation wave vector takes the commensurate value $(1/3)\boldsymbol{c}^*$, all the satellites observed in the figure will collapse into a single superstructure reflection centered at $6\boldsymbol{a}^* + (2/3)\boldsymbol{c}^*$.

The incommensurate phases that include a Lifshitz invariant in the Landau free-energy density are usually called type I, and type II otherwise. The simplest cases of type II phases are those for which the lock-in commensurate structure is associated with a 1D order parameter whose wave vector is null. The modulated order parameter in the incommensurate phase is, therefore, also usually taken as 1D. The free-energy density lacks a Lifshitz invariant, but the incommensurate modulation of the order parameter can be explained in this case by the coupling of the order parameter with a "secondary" mode. If $\eta(x)$ is called the x-dependent order parameter and $\xi(x)$ another local degree of freedom, a term of the type $(\partial\eta\xi - \eta\partial\xi)$ in the free-energy density, if allowed, favors a modulated configuration. It plays a similar role as a Lifshitz invariant and in fact, it can lead, as in thiourea, to a soliton regime similar to those observed in type I materials. The incommensurate phase will be given in this case by a modulation of

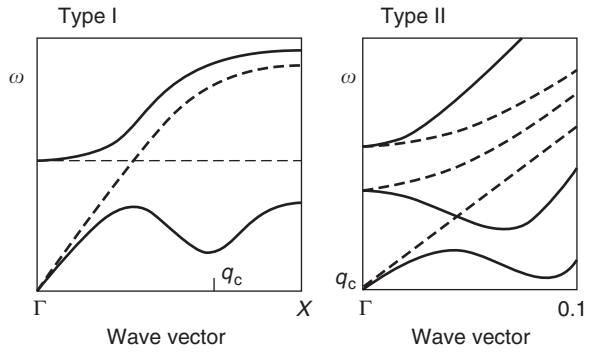

Figure 13 Idealized scheme of the soft-mode branch for the simplest cases of type I and type II incommensurate systems above the normal-incommensurate phase transition, including its possible coupling with an acoustic branch.

not only the nominal order parameter $\eta(x)$ but also of the secondary mode $\xi(x)$.

From a lattice dynamics viewpoint, a Landau free energy of type I describes a thermal soft-mode mechanism with a lock-in wave vector having no additional symmetry compared with the neighboring incommensurate wave vector, while a type II describes a soft-mode having the lock-in value $\boldsymbol{q}_c$ at a point of higher symmetry. This difference is schematically represented in **Figure 13**. In both cases, either the Lifshitz invariant or the alternative mixed coupling term places the minimum of the soft-mode branch off the commensurate value $\boldsymbol{q}_c$. While in type I, one can neglect the change of the mode eigenvector as the modulation wave vector changes and locks into $\boldsymbol{q}_c$, in type II a strong change of the modulation eigenvector is an essential part of the approach to the lock-in phase. The hybridization of the soft-mode branch with the secondary mode necessarily disappears at the lock-in into $\boldsymbol{q}_c = 0$. A strong coupling with an acoustic branch may also play a fundamental role in the phase-transition mechanism. This possibility has also been included in the schemes of **Figure 13**. In type I crystals as K_2SeO_4, in contrast with the earlier models, the anticrossing with the acoustic branch of the soft mode branch is an essential part of the physics of the transition and can even explain the incommensurate minimum of the hybridized soft-phonon branch.

Specific Physical Properties

Incommensurate phases possess, in principle, low-energy lattice dynamical excitations (zero-gap branches) in addition to the acoustic phonons. They are usually termed phasons and correspond in the superspace description to fluctuations of the superstructure along the internal subspace. The incommensurability

of the structure ensures that the phase of the structural modulation associated to each independent incommensurate vector $q_i, i = l, \ldots, d$ can be shifted without changing the structure globally and, therefore, without energy cost. In the superspace, this means that any section parallel to the one corresponding to the real space, but shifted along the internal space, describes a physically equivalent structure with the same energy. This is the cause of these peculiar phason degrees of freedom. Phason branches have been detected experimentally in several materials although they may be overdamped in many cases. One of the main discussions has been to assess the existence of a gap in these phason branches. In principle, for an ideal incommensurate system it should be zero, but defects or the underlying average lattice may produce some pinning of the modulation and the opening of a gap. A pinning of the modulation also exists if the modulation is not analytical, that is, when the atomic domains are discontinuous along the internal space. This "break of analyticity" may happen, for instance, in the soliton regime as the modulation becomes step-like when approaching the lock-in phase. It also exists in strong interacting composites. On the other hand, in the sinusoidal regime, close to the second-order normal-incommensurate transition, pinning effects of any sort are expected to be minimal.

The strong pinning effects expected in the soliton regime are considered to be the cause of special thermal hysteresis effects observed around the lock-in phase transition and termed global hysteresis. Also so-called memory effects associated to annealings within the incommensurate phase have been attributed to pinning effects produced by mobile lattice defects.

It has been argued that the existence of the phason degrees of freedom in the incommensurate phase can increase, compared with other structural phase transitions, the size of the critical region around the normal-incommensurate phase transition where universal critical behavior could be observed. Although the reasoning behind this expectation has been the object of much controversy, it is indeed an empirical fact that the normal-incommensurate phase transitions are among the few structural phase transitions, if not the only ones, where fully consistent fluctuation-driven asymptotic universal critical behavior has been measured. A thoroughly studied example is the continuous normal-incommensurate phase transition in Rb_2ZnCl_4 at about 304 K. Results of NMR, synchrotron X-ray scattering, specific heat measurements, and other techniques are all fully consistent and have demonstrated an asymptotic critical behavior corresponding to the universal class associated to the 3D XY model in a temperature interval as large as 15 K below the transition temperature (see **Figure 14**).

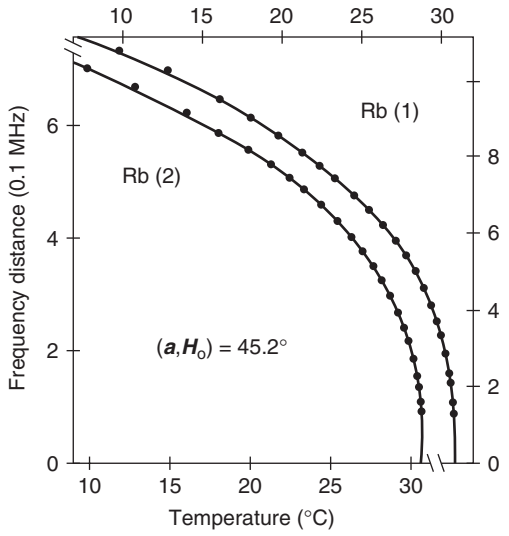

Figure 14 Temperature dependence of the width of the continuous distribution of quadrupolar perturbed NMR frequencies of the two symmetry-independent Rb atoms in the incommensurate phase of Rb_2ZnCl_4. This width is proportional to the amplitude of the order parameter. The fit curves correspond in both cases to a power law with $\beta = 0.35$. Nomenclature

$\boldsymbol{a}^*, \boldsymbol{b}^*, \boldsymbol{c}^*$	basis of reciprocal unit cell associated to the average periodic structure of a modulated structure
$F(\boldsymbol{H}), \lvert F(\boldsymbol{H})\rvert$	structure factor and its modulus for the diffraction vector $\boldsymbol{H}$
$\boldsymbol{H}$	diffraction vector of a Bragg reflection
(h,k,l,m)	set of four integers indexing a Bragg reflection of an incommensurate phase of rank $(3+1)$
$\boldsymbol{q}$	primary wave vector of a modulation
$\{\boldsymbol{q}_1,\ldots,\boldsymbol{q}_d\}$	set of primary modulation wave vectors for an incommensurate modulated structure of rank $(3+d)$
$\boldsymbol{r}$	position vector in real space
$\rho(\boldsymbol{r})$	scattering density in real space (electronic or nuclear, depending on the radiation source) corresponding to an incommensurate phase
$\{\boldsymbol{k}_1,\boldsymbol{k}_2,\ldots,\boldsymbol{k}_n\}$	basis of vectors indexing the diffraction diagram of an incommensurate phase of rank n
$(x_1,x_2,\ldots,x_n)$	position vector in superspace
$\rho_s(x_1,x_2,\ldots,x_n)$	superspace density
$(h_1,h_2,\ldots,h_n)$	set of n integers indexing a diffraction vector of an incommensurate phase of rank n
k_F	Fermi wave vector
$\boldsymbol{q}_c$	modulation wave vector of a lock-in phase
$Q(x)$	local complex order parameter in a simple type I incommensurate phase as a function of the x coordinate along the modulation direction
$\rho(x)$	amplitude of $Q(x)$
$\theta(x)$	phase of $Q(x)$
n_s	soliton density
∂	partial derivative with respect to x
$\eta(x)$	one-dimensional order parameter of a type II incommensurate phase as a function of the x coordinate along the modulation direction
$\xi(x)$	real amplitude of a secondary mode in a type II incommensurate phase as a function of the x coordinate along the modulation direction

Insulators, Electronic States of

F Casula and G Mula, Cagliari University, Cagliari, Italy

Introduction

Materials are traditionally classified according to their conduction properties: they are called metals if their conductivity persists even to the lowest temperatures, insulators if they do not. In the former case electrons flow freely under an applied DC field, in the latter they do not, but undergo static polarization.

In quantum mechanics, however, this distinction is somewhat blurred, since materials are usually understood in terms of a band theory picture, that is, in terms of the solution of a many-electron problem within the one-electron approximation. Within this approximation, electrons behave as independent particles embedded in a mean field which includes their interactions. Theoretical calculations thus make no distinction between metals and insulators: solids in which all occupied energy bands happen to be completely filled are insulators, and solids in which at least one occupied energy band happens to be only partly filled are metals. It is on the basis of this picture that it has been possible, at least since the 1980s, to deal on a first-principles basis with any kind of materials, irrespective of their conduction properties, including, of course, the ever more relevant case of semiconductors.

This quantum approach has led to reliable quantitative predictions for a wide range of materials and of materials properties. The decisive breakthrough has been achieved essentially, thanks to the advent of density-functional methods. These methods are based on a theorem, formulated by Hohenberg and Kohn in 1964, which states that all the ground-state properties of a system of interacting electrons, possibly embedded in an external potential $v(\boldsymbol{r})$, are completely determined by the electronic charge density $\rho(\boldsymbol{r})$. This theorem leads to an extraordinary simplification of the many-electron problem, since one needs to deal with only three spatial variables instead of the $3N$ variables needed to specify the ground-state wave function of a system of N interacting electrons. Hohenberg and Kohn also proved that

the ground-state energy of an interacting electron gas is a unique functional of $\rho(\boldsymbol{r})$, thereby paving the way for the subsequent advances in 1965 by Kohn and Sham (KS), who were able to build self-consistent equations for a fictitious system of noninteracting electrons with the same electron density as the interacting one. Solving these equations also gives, in principle, the exact solution to the full problem.

Thanks to this approach, the band theory has been shown to be able to successfully explain even the limiting cases of insulating behavior, namely carbon, solid noble gases, and alkali halides. The validity of the one-electron picture has been thus assessed independently of the type of chemical bond, whether covalent, ionic or molecular, and some of these band structure results for insulators are discussed in the following, while referring to other articles in this encyclopedia for more information on band-theory density-functional methods.

Successful as it can be, however, this theoretical framework cannot be the whole story, since in many cases, for example, when the insulating behavior is dominated by disorder (the so-called Anderson insulators), or by electron correlation (the so-called Mott insulators), the band approximation fails to give a consistent account of the ground-state properties. In particular, it fails to explain polarization and localization, the two basic phenomenological features that characterize insulators. The following sections present very recent theoretical developments which have made it possible to understand localization and polarization as two aspects of the same phenomenon, within a unified approach that deals on the same basis with all insulators, irrespective of what determines the insulating behavior – independent or correlated electrons, crystalline characteristics or disorder.

Band Structure Results for Insulators

Basically, energy band calculations for insulators are done according to the same methods which are used for semiconductors. In principle, accurate values for equilibrium electronic properties in condensed matter (such as, e.g., volume, bulk modulus, elastic constants), as well as for linear response (such as phonon spectra) and other thermodynamical properties, can be obtained by solving KS equations within the local density approximation (LDA), independently of whether the material studied is metallic, semiconductor or insulating.

Excitation properties, however, are often inaccurately determined both in semiconductors and insulators, due to the fact that LDA works well only for the ground state. The optical gap, in particular, is usually severely underestimated, as has been shown in the early 1980s by the extensive LDA calculations on group IV elements performed by M L Cohen and co-workers and published in *The Physical Review*. Nevertheless, besides obtaining very accurate results for the cohesive energies and the equilibrium structures, they were able to state unambiguously the insulator or semiconductor quality of both C and Si respectively, in the diamond structure, in spite of the somewhat poor results for their band gaps (4.1 and 0.5 eV for C and Si, respectively, against the experimental values of 5.49 and 1.17 eV). In order to consider the achievements of the band structure calculations in the field, it may be recalled that the semimetallic character again of carbon, but in graphite structure, was already obtained in the sixties by F Bassani and G Pastori and confirmed ever since. A further confirmation of the band picture of the electronic properties of these materials is the overall success of the energy gap corrections introduced via Green's function approaches (GW approximation).

Similar considerations hold for rare-gas solids, whose experimental gaps range from 9.3 eV in Xe to 21.7 eV in Ne. By taking into account the closed-shell character of the constituents atoms, it is not difficult to understand in a band picture that conduction states will result from free-electron like bands, widely separated from valence bands for orthogonality reasons. Again, LDA estimation of the energy gap can be as poor as 11.5 eV for Ne, to be improved up to 22.2 eV after the introduction of self-interaction corrections – as was done by M R Norman and J P Perdew in 1983 – but the insulating behavior cannot be questioned.

A third class of wide-gap crystals can also be considered, that is, alkali halides, which are characterized by huge values of the Madelung potential, and, therefore, by large energy separation between valence and conduction bands. Experimental bandgaps can be as large as 13.6 eV in LiF and smaller but still very large in iodides, where typical values are $\sim$6.0 eV. From the theoretical point of view, for example, considered the results for NaCl by Norman and Perdew, quoted above, which obtained for the gap a clear-cut value of 9.2 eV, to be compared with the experimental values of 8.5–9.0 eV. Despite the successes of the band theory in explaining the electronic properties of insulators, some problems remain, mainly connected to the description of the ground state. In a band theory framework, the difference in DC conductivity between metals and insulators is explained with reference to the spectrum of the electronic excitations, that is, to the availability of low-lying unoccupied energy levels. However, it makes no mention of localization, that is, of the

qualitative difference in the ground-state electrons organization which has to account for the fact that electrons in metals are able to flow freely under an applied DC field, while electrons in insulators are not. Neither can the band theory readily explain why finite macroscopic metallic samples subject to an electric field only show a polarization due to surface phenomena (screening by free carriers), while in analogous situations insulator samples show a material-dependent polarization which is a true bulk phenomenon.

These difficulties stem from the fact that electron states, being eigenfunctions of Hamiltonian operators subject to periodic Born–von Karman boundary conditions, are delocalized, and qualitatively rather similar, in both metals and insulators, so that it is a real challenge to detect differences between these two classes of materials just by looking at their one-electron ground-state wave functions.

Localization and Polarization in Insulators and Metals

W Kohn was the first, in 1964, to answer this challenge by pointing out that an essential characteristic of insulators is the disconnectedness of their ground-state many-body wave function, meaning its breaking up into a sum of functions which are localized in disconnected regions. This feature forbids the free flow of charge in insulators under the application of a DC field, so that electrons can be polarizable while remaining bound. Kohn demonstrated this result in a crystalline system of independent electrons, but argued that the same kind of disconnectedness should also hold quite generally, in any insulator.

Kohn's theory correctly points out that electronic localization in insulators is a feature of the ground-state wave functions, which, for an N-particle system, are disconnected in a high-dimensional configuration space. Therefore, localization cannot be seen by looking at the charge density, which is a function in three-dimensional space. His approach, however, leaves alone the problem of macroscopic polarization, which until 1992 even failed to have a proper definition as a bulk property independent of surface termination. Since 1992, a new theory of polarization has been developed which builds on the concept that polarization must be understood as a global property of the many-body ground-state wave function as a whole. According to this viewpoint, localization is just another aspect of polarization, and can be rightly regarded as the cause of insulating behavior since it is a physical observable completely independent of the periodic charge distribution of the valence electrons.

The 1992–93 Breakthrough

What happened around 1992 is that people came to realize that the classic definition of macroscopic polarization as the dipole of a macroscopic sample, divided by its volume, simply does not hold when periodic boundary conditions are applied (though polarization derivatives had been successfully addressed for many years and for many materials in the framework of linear-response theory). Under these conditions, which are almost mandatory in most computational condensed matter physics, the dipole of a macroscopic charge distribution cannot be evaluated since its expression for finite systems, while perfectly valid, does not have a well-defined thermodynamic limit independent of surface termination. The clue to a solution of this problem came from realizing that nobody ever measures the "absolute" macroscopic polarization of a material as a bulk property, but only polarization differences. Therefore, the modern theory of polarization only deals with finite polarization differences, avoiding any definition of absolute polarization.

Consider for example, a possible experimental arrangement for measuring the macroscopic polarization in a piezoelectric material, in which the crystal is uniaxially strained while being short-circuited in a capacitor. The induced macroscopic polarization is obtained by integrating the transient macroscopic current flowing through the sample. It must be stressed that polarization in a zero field is considered here, as is mandatory if one wants to preserve crystal periodicity.

This approach is also relevant for the analysis, at zero field, of the effective charges of lattice dynamics, as well as of ferroelectric polarization. Basically, all these situations lead to considering macroscopic polarization differences, given expressions like

$$\Delta \boldsymbol{P}_{\text{bulk}} = \int \mathrm{d}\lambda \, \frac{\delta \boldsymbol{P}^{(\lambda)}_{\text{bulk}}}{\delta \lambda} \qquad [1]$$

where λ may be thought of as an adiabatic time in the piezoelectric case, or as the amplitude of the distortion for ferroelectric materials. In all cases, $\delta \boldsymbol{P}^{(\lambda)}_{\text{bulk}}/\delta\lambda$ is just the spatially averaged adiabatic current flowing through the bulk.

Focusing on the current instead of the charge is a crucial step for a proper definition of macroscopic polarization as a physical observable in extended systems. The introduction of an integration over λ in the expression for $\Delta \boldsymbol{P}_{\text{bulk}}$ is equivalent to assuming a parametric dependence in the system Hamiltonian. This feature allows the introduction of a Berry's phase formulation, and leads to a satisfactory solution of the problem.

Though a parametric Hamiltonian could not properly be regarded as isolated, since the presence of a parameter is an expression of the coupling with "the rest of the universe" (to use Michael Berry's expression), this trick allows calculations to be done assuming just this isolation. As a trade-off it is observed that the macroscopic polarization can indeed be regarded as a proper physical observable, but only when defined as a Berry phase, that is as a gauge-invariant geometric phase which is observable even if it cannot be expressed in terms of the eigenvalues of any operator.

Berry Phase

Consider a generic parametric Hamiltonian $H(\xi)$ such that

$$H(\xi)|\Psi(\xi)\rangle = E(\xi)|\Psi(\xi)\rangle \qquad [2]$$

where ξ defined in a suitable domain and $|\Psi(\xi)\rangle$ is the ground state of the system, nondegenerate for any ξ. The phase difference $\Delta\phi_{ij}$ between ground eigenstates belonging to two different values of ξ can then be defined as

$$e^{-\Delta\phi_{ij}} = \frac{\langle\Psi(\xi_i)|\Psi(\xi_j)\rangle}{|\langle\Psi(\xi_i)|\Psi(\xi_j)\rangle|} \qquad [3]$$

$$\Delta\phi_{ij} = -\mathrm{Im}\log\langle\Psi(\xi_i)|\Psi(\xi_j)\rangle \qquad [4]$$

Since the phase of any quantum-mechanical state vector is arbitrary, this phase difference cannot have any physical meaning. However, when one considers a discretized closed path in the space of the parameter ξ, one immediately realizes that the total phase difference $\gamma = \sum_{\mathrm{cycle}} \Delta\phi_{i,i+1}$ along the path must be independent from the (arbitrary) phase choices at each point in the path, since in the end all of them cancel out. γ is called a Berry phase because it is a gauge-invariant quantity, meaning that it is a physical observable, albeit a rather anomalous one, since it obviously cannot be expressed in terms of the eigenvalues of Hermitian operators.

It can be seen that the Berry phase is relevant to the modern theory of polarization because it substitutes an ill-defined (when periodic boundary conditions are applied) dipole expression with a computable gauge-invariant quantity. An alternative, of course, would be to define macroscopic polarization for finite systems and to proceed to the elimination of surface effects through suitable limiting procedures as the system size goes to infinity.

Berry Phase Theory of Polarization

Evaluating polarization for finite systems is, in principle, fairly straightforward: for instance, one can introduce the position operator as $\boldsymbol{R} = \sum \boldsymbol{r}_i$ and compute the electric dipole as $\boldsymbol{d} = q_e\langle\Psi_0|\boldsymbol{R}|\Psi_0\rangle$. This expression, however, becomes meaningless when periodic boundary conditions are imposed, since in the resulting Hilbert space $\boldsymbol{R}$ becomes a forbidden operator. The problem, obviously, is that when one applies $\boldsymbol{R}$ to a function obeying these conditions, that is to a periodic function, one gets a new function which is no longer periodic and, therefore, does not belong to the given Hilbert space.

A way out of these difficulties was found by Resta in 1992, when he introduced expression [1] to calculate finite changes in bulk polarization. According to classical electrodynamics, the polarization current $\delta\boldsymbol{P}^{(\lambda)}_{\mathrm{bulk}}/\delta\lambda$ in eqn [1] can be expressed as

$$\frac{\delta\boldsymbol{P}^{(\lambda)}_{\mathrm{bulk}}}{\delta\lambda} = \frac{1}{V}\int_V \mathrm{d}\boldsymbol{r}\, \boldsymbol{j}^{(\lambda)}_{\mathrm{bulk}} = \boldsymbol{J}^{(\lambda)} \qquad [5]$$

where V is the volume of the system, $\boldsymbol{j}^{(\lambda)}_{\mathrm{bulk}}$ is the current density in the bulk, with λ playing the role of time. The right-hand side could be expressed as the adiabatic limit of a Kubo formula, which usually involves a summation over the excited eigenstates. It is more convenient, however, to arrive at a form which only depends on the ground-state wave function. To this end, one imposes the following boundary conditions:

$$\Psi^{(\lambda)}_{\boldsymbol{k}}(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_i + \boldsymbol{L}, \ldots, \boldsymbol{x}_N) = e^{i\boldsymbol{k}\cdot\boldsymbol{L}}\Psi^{(\lambda)}_{\boldsymbol{k}}(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_i, \ldots, \boldsymbol{x}_N) \qquad [6]$$

to label the N-body wave function $\Psi^{(\lambda)}_{\boldsymbol{k}}$. (This way of introducing boundary conditions has recently come to be called "twisted," to avoid confusion with all the other usages of the word "phase" that appear in quantum and statistical physics.) One also introduces the wave function $|\Phi^{(\lambda)}_{\boldsymbol{k}}\rangle = e^{-i\boldsymbol{k}\cdot\boldsymbol{X}}|\Psi^{(\lambda)}_{\boldsymbol{k}}\rangle$ (it is none other than the many-body analog of the cell-periodic part of the single-electron Bloch function). If $\Psi^{(\lambda)}_{\boldsymbol{k}}$ is the ground-state of Hamiltonian $\boldsymbol{H}^{(\lambda)}$, then $\Phi^{(\lambda)}_{\boldsymbol{k}}$ is the ground-state of the Hamiltonian

$$\boldsymbol{H}^{(\lambda)}(\boldsymbol{k}) = e^{-i\boldsymbol{k}\cdot\boldsymbol{X}}\boldsymbol{H}^{(\lambda)}e^{i\boldsymbol{k}\cdot\boldsymbol{X}} \qquad [7]$$

which can be obtained from $\boldsymbol{H}^{(\lambda)}$ by performing a gauge transformation $\boldsymbol{p}_j \to \boldsymbol{p}_j + \hbar\boldsymbol{k}$ on the momentum of each particle. The $\boldsymbol{k}$-dependence has thus been transferred from the boundary conditions to the Hamiltonian. Using functions $\Phi^{(\lambda)}_{\boldsymbol{k}}$, the Kubo formula for the adiabatic current $\boldsymbol{J}^{(\lambda)}_{\boldsymbol{k}}$ can indeed be expressed, for

strictly periodic boundary conditions, in a form which depends only on the ground-state wave function:

$$\boldsymbol{J}_{\boldsymbol{k}}^{(\lambda)} = 2q_{\mathrm{e}}\mathrm{Im}\langle \partial_{\boldsymbol{k}}\Phi_{\boldsymbol{k}}^{(\lambda)}|\partial_{\lambda}\Phi_{\boldsymbol{k}}^{(\lambda)}\rangle \qquad [8]$$

which, substituted in eqn [1] through eqn [5], finally gives

$$(\Delta \boldsymbol{P}_{\mathrm{el}})_i = \frac{\mathrm{i}q_{\mathrm{e}}}{(2\pi)^3}\int \mathrm{d}\boldsymbol{k}\int_0^1 \mathrm{d}\lambda\Big[\langle \partial_{\lambda}\Phi_{\boldsymbol{k}}^{(\lambda)}|\partial_{\boldsymbol{k}_i}\Phi_{\boldsymbol{k}}^{(\lambda)}\rangle - \langle \partial_{\boldsymbol{k}_i}\Phi_{\boldsymbol{k}}^{(\lambda)}|\partial_{\lambda}\Phi_{\boldsymbol{k}}^{(\lambda)}\rangle\Big] \qquad [9]$$

Equation [9], where the $\boldsymbol{k}$-integration is over all the twisted boundary conditions, gives the net polarization change along the path parametrized by λ. Through a further manipulation, one can obtain the following expression, which only depends on the end points $\lambda = 0$ and $\lambda = 1$,

$$\Delta \boldsymbol{P}_{\mathrm{el}} = \boldsymbol{P}_{\mathrm{el}}^{(1)} - \boldsymbol{P}_{\mathrm{el}}^{(0)} \qquad [10]$$

with

$$\boldsymbol{P}_{\mathrm{el}}^{(\lambda)} = \frac{\mathrm{i}q_{\mathrm{e}}}{(2\pi)^3}\int \mathrm{d}\boldsymbol{k}\ \langle \Phi_{\boldsymbol{k}}^{(\lambda)}|\partial_{\boldsymbol{k}}\Phi_{\boldsymbol{k}}^{(\lambda)}\rangle \qquad [11]$$

The last three equations give the many-body generalization, as given in 1994 by Ortiz and Martin, of the polarization theory originally formulated in 1993 by King-Smith and Vanderbilt for independent electrons. In the *tour-de-force* leading to eqn [11], it is assumed that the ground-state is isolated from the excited states by a finite energy gap, and that there are no long-range correlations. Besides, it should be pointed out that while eqn [9] gives the exact change in polarization along the chosen path, eqns [10] and [11] only give it modulo a "quantum," whose value can be taken as a multiple of $|q_{\mathrm{e}}|L/V = |q_{\mathrm{e}}|/L^2$. This quantization of charge transport for an insulating system with periodic boundary conditions only occurs in the thermodynamic limit; for finite sizes and periodic boundary conditions, there are exponentially small corrections which destroy the exact quantization. In some way, the difference between eqns [8] and [10] can be regarded as a trade-off for getting an expression which only depends on the end points $\lambda = 0$ and $\lambda = 1$.

Resta, in 1998, gave an alternative formulation of the modern polarization theory which makes use of the unitary many-body phase operator

$$\hat{U}(\boldsymbol{k}) = \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}} \qquad [12]$$

where $\boldsymbol{k}$ is an arbitrary vector and $\boldsymbol{R}$ is the usual position operator. At variance with $\boldsymbol{R}$, $\hat{U}(\boldsymbol{k})$ is a perfectly admissible operator for Hilbert spaces defined by periodic boundary conditions, provided $\boldsymbol{k}$ components are restricted to integer multiples of $2\pi/L$, with L the imposed periodicity. One may introduce the special notations $\boldsymbol{\kappa}^{(\alpha)}$ for three useful vectors $\boldsymbol{k}$ in this class (which are chosen to be proportional to the three Cartesian unit vectors)

$$\boldsymbol{\kappa}_{\beta}^{(\alpha)} = \frac{2\pi}{L}\delta_{\alpha\beta} \qquad [13]$$

and for the three related ground-state expectation values:

$$z_N^{(\alpha)} = \langle \Psi_0|\hat{U}(\boldsymbol{\kappa}^{(\alpha)})|\Psi_0\rangle \qquad [14]$$

From these expectation values one can get, in the usual way, their phases. Explicitly,

$$z_N^{(\alpha)} = |z_N^{(\alpha)}|\mathrm{e}^{\mathrm{i}\gamma_N^{(\alpha)}} \qquad [15]$$

$$\gamma_N^{(\alpha)} = \mathrm{Im}\log z_N^{(\alpha)} \qquad [16]$$

Resta showed that the above phases are, in the thermodynamic limit, just the components of macroscopic polarization. One has

$$\boldsymbol{P}_{\alpha} = \frac{q_{\mathrm{e}}\gamma_N^{(\alpha)}}{2\pi L^2} = \frac{q_{\mathrm{e}}}{2\pi L^2}\mathrm{Im}\log z_N^{(\alpha)} \qquad [17]$$

It is worth remembering at this point that $\hat{U}(\boldsymbol{k})$ is not a one-body operator written in a many-body notation: since the integrations in eqn [14] require the full many-body wave function, a one-body density matrix would not be enough. It may be surprising that polarization, a quantity intuitively connected to the average of the electric dipole over the charge density, is not expressible in terms of the one-body density matrix. Again, here one has a trade-off between the elimination of size effects (obtained through the use of periodic boundary conditions) and the fact that macroscopic polarization, in extended systems under periodic boundary conditions, is no longer a function of the electron density. This is why there is a need to extract the information about macroscopic polarization from the phase of the many-body wave function instead of getting it from the charge density.

Another feature worth mentioning is that in eqn [17] there is no $\boldsymbol{k}$-integration, at variance with eqn [11]. Expressions like eqn [17] are usually called "single-point" formulas.

Berry Phase Theory of Localization

As has been already noted, W Kohn was the first to emphasize that even within quantum mechanics,

electron localization must be the cause for insulating behavior. His solution, the disconnectedness of the ground-state many-body wave function, remained unchallenged for ~ 35 years, and still must be regarded as an important part of a correct understanding of the problem. In 1999, however, Resta and Sorella (RS) reconsidered the problem and provided a solution which, besides being in many respects simpler than the previous one, was revolutionary in the sense that it allowed one to understand macroscopic polarization and electron localization as two aspects of the same phenomenon.

To summarize this development, it is convenient to refer to the formal tool that has been introduced in the preceding pages, namely the many-body phase operator. Its ground-state expectation value is a complex number which vanishes in metals and is finite in insulators. It has already been noted that its phase is a measure of macroscopic polarization. RS, in addition, showed that a measure of the localization length in 1D insulators can be given by the expression

$$\xi = \frac{L\sqrt{D}}{2\pi N} \qquad [18]$$

where D is a dimensionless parameter given by

$$D = -\lim_{N\to\infty} N \log|z_N|^2 \qquad [19]$$

RS showed analytically that, for a one-dimensional independent electron model of an insulator, ξ is finite, whereas for metals it diverges (even before taking the limit $N\to\infty$). They also argued that the same should hold for interacting electrons, though the divergent behavior for metals should occur only after taking the limit.

Since the same parameter, $z_N^{(\alpha)}$ as given by eqn [14], gives a measure, through eqn [17], of macroscopic polarization and, through eqns [18]–[19], of electron localization, it is apparent that polarization and localization are just two sides of the same coin. Maybe it is worth stressing again that $z_N^{(\alpha)}$ is a pure ground-state property, whose phase gives, in suitable units, a measure of the (α) component of the polarization, and whose modulus leads to a definition of localization length quite able to make a sharp distinction, in the thermodynamic limit, between metals and insulators.

To complete the picture, it must be pointed out that the following year Souza, Wilkens, and Martin (SWM) extended the above analysis to the case of many dimensions and of correlated electron systems. They also proved that the new definition of localization length corresponds to a well-defined ground-state physical observable, and suggested experimental measurements that could actually be performed. In this process, they were also able to connect the localization length to DC conductivity, that is, to the physical property the vanishing of which signals the onset of an insulating phase.

SWM introduced a statistical approach based on the definition of cumulants as the series-expansion coefficients of $\log C(\alpha)$, the characteristic function being

$$\mathbf{C}(\alpha) = \int \mathrm{e}^{-\mathrm{i}\alpha \cdot \mathbf{R}} p(\boldsymbol{R})\, \mathrm{d}\boldsymbol{R} \qquad [20]$$

where $\boldsymbol{R}$ are the electron coordinates and $p(\boldsymbol{R})$ is the probability distribution. Through this very powerful technique, they were able to recover the Berry phase definition of the electronic polarization as the first cumulant $\langle r_i \rangle_c$, where "c" stands for "cumulant," as well as the square of localization length as the second cumulant $\langle r_i r_i \rangle_c = \langle (r_i)^2 \rangle - \langle r_i \rangle^2$. A detailed illustration of such a generalization is not given here; however, the link with RS formalism is pointed out:

$$\langle r_i r_i \rangle_c = -\frac{1}{N}\left(\frac{L}{2\pi}\right)^2 \log|z_N^{(i)}|^2 \qquad [21]$$

valid in the thermodynamic limit. Moreover, SWM obtained a fundamental connection to the electrical conductivity

$$\langle r_i r_j \rangle_c = \frac{\hbar L^3}{\pi q_e^2 N} \int_0^\infty \frac{\mathrm{d}\omega}{\omega} \mathrm{Re}\ \sigma_{ij}(\omega) \qquad [22]$$

namely a fluctuation–dissipation relation, which allows one to estimate the localization length, that is, a ground-state property, by a measurement over the excited states, such as conductivity. Clearly in insulators, where $\lim_{\omega\to 0} \mathrm{Re}\ \sigma_{ii}(\omega) = 0$, the localization length has a finite asymptotic value, as expected, at variance with conductors where $\lim_{\omega\to 0} \mathrm{Re}\ \sigma_{ii}(\omega) > 0$ and, therefore, the localization length turns out infinite. Another interesting feature can be obtained by observing that, in insulators, there is no absorption below the optical gap ε_g, and therefore,

$$\langle r_i r_i \rangle_c < \frac{\hbar^2 L^3}{\pi q_e^2 N \varepsilon_g} \int_0^\infty \mathrm{d}\omega\ \mathrm{Re}\ \sigma_{ii}(\omega) = \frac{\hbar^2}{2 m_e \varepsilon_g} \qquad [23]$$

where the sum rule for the oscillator strengths has been taken into account. This is obviously the result usually stated in the band theory, that the larger the gap the stronger the insulating character of a crystal.

Conclusions

The modern theory of the electronic states in insulators heavily rests upon the same first-principle density-functional approach which works for metals and semiconductors. Most electronic properties of insulators are well described by this approach, and even the very distinction between insulators and semiconductors can be related to their bandgap values. However, basic ground-state properties such as localization and polarization remained in an unclear state until 1964, when a fundamental paper by W Kohn showed that electron localization depends on the disconnectedness of the ground-state wave function. Substantial advances came only many years later, first through the modern theory of polarization, based on a Berry's phase, then from Resta–Sorella's discovery that the use of the many-body phase operator eqn [12] allows one to view macroscopic polarization and electron localization as two aspects of the same phenomenon. The fact that this operator extracts, in a very compact and effective way, the connectedness properties of the many-body wave function, can be regarded as a direct connection between Kohn's insight and the modern approach.

Future developments in this field appear to depend on advances in the density-functional theory (DFT), for instance, by settling the basic problem that, though in DFT, by definition, the density of the fictitious noninteracting KS system equals the density of the interacting one, the KS system and interacting one can have, in principle, different polarizations. The current understanding of this problem is that, at least in weakly correlated systems, $z_N^{(\alpha)}$ for the noninteracting KS system is a good approximation for the $z_N^{(\alpha)}$ to the interacting system. This assumption seems to be well supported, up to now, from the available experimental evidence.

A further open issue is whether the theory can be extended to discriminate between normal metals and superconductors, an extension which would probably amount to introducing a suitably defined new kind of "anomalous" density. Finally, there is the need for more computational studies to check the predictions of the theory and its extension to disordered systems.

Insulators, Impurity and Defect States in

A M Stoneham and A L Shluger, University College London, London, UK

Introduction

Serious studies of materials are often serious studies of defects, for control of properties of materials implies control of defects or impurities. Understanding the electronic structure of defects in insulators has helped the development of microelectronic devices, the photographic process, solid electrolytes, and the applied surface physics of sensors and catalyst substrates. This understanding is based on ideas founded on a synthesis of theories, modeling, and experiment.

Defining the Issues

When a new material is created, which defects are important? Will there be vacancy-interstitial pairs (Schottky defects) or just vacancies of several types (Frenkel defects)? Will there be nonstandard ionic charge states, such as Fe^{3+} ions in FeO? Could one species move on to the sites of another, for example, As antisites on Ga sites in GaAs? Can the material be doped with electrically active impurities? Are there understandable trends of properties from material to material in some class, such as II–VI compounds? Electronic structure is subtle and varied, with the key ideas identified by a mix of theory and experiment.

In most insulators Coulomb energies dominate, so antisite defects are not energetically easy, and charge

transfer across sublattices is difficult, instead nonstoichiometry is common. Thus vacant lattice sites (vacancies), ions placed at normally unoccupied sites (interstitial ions), foreign ions present as impurity or dopant, and ions with charges different from those of the host ions are prevalent defect types. Electronic defects may arise either as ions with charges deviating from those on lattice ions, or from excitation of electrons from filled valence bands to empty conduction bands. When a valence-band electron is missing, one has an electron hole (hole) and its behavior can be compared with that of an electron in a normally empty conduction band. The electron and hole together can form a transient neutral species, the "exciton." In the absence of macroscopic electric fields, ionic lattices must be electrically neutral overall, implying that one charged defect must be compensated by another charged defect or defects to satisfy the electroneutrality condition locally or over the whole sample. The charges of defects and of the regular lattice particles, defined with respect to the neutral ideal lattice, are called "effective charges."

Complexity is the norm for advanced materials. When solid-state lasers degrade and mechanical properties change under irradiation, defect processes occur in parallel on timescales from picoseconds upwards. In a composite material, defect phenomena may occur in the matrix, the fiber, or the interface. When a metal is oxidized, interfacial, diffusional, and impurity processes coexist. Separating these processes by experiment alone may not be feasible. The proper use of electronic structure theory establishes priorities, and is used to organize massive amounts of data to identify what is novel and point to significant issues.

Which Electronic Structure Parameters Are of Interest?

Defects control the properties and performance of materials and devices in various ways. For luminescence, whether of rare earths in oxides or sulfides or CsI:Na, the spectroscopic properties of impurities, optical absorption, and luminescence energies are of the outmost importance. Bragg grating formation in silica fibers is associated with the optical absorption of induced defects. Defect species in gate dielectrics, such as those listed in **Table 1**, influence device performance. These defects may initiate degradation, trap charge, or create fixed charge, which scatters carriers in the Si substrate. Their electron- and hole-trapping energies and cross sections are of main interest. Many radiation-induced processes in insulators involve forming self-trapped excitons and holes, so the electron coupling to lattice deformation plays a crucial role.

The raw data of defect studies describe spectroscopic observations and their dependence on time and other parameters, such as dopant concentration, temperature, pressure, irradiation power, and dose. Carefully obtained data provide the basis for formulating defect models. **Figure 1** shows several such models for major paramagnetic defects in irradiated fused silica. The most reliable models knit together the best-available experimental data from many sources with solid-state physics theory, often aided by detailed calculations. Some of the key ideas underpinning modern calculations of the electronic structure of defects in insulators are reviewed here. The article starts with outlining some of the theoretical methods used to study defect electronic structures. Then it reviews some of the concepts necessary for understanding the electronic properties of point defects in crystalline and disordered solids and at interfaces.

Theoretical Methods for Defect Electronic Structure

Even simple answers can be useful answers. At one level, electrons and holes can be treated only implicitly. Born's model of ionic solids as polarizable point ions, interacting through transferable interatomic

Table 1 Possible defect types and their impact on device performance

Origin of defect	*Defect type*	*Possible role*
Imprecise stoichiometry	Vacancies or interstitials, annealing-induced	Fixed charge, SILC; motion under applied field
Growth-related impurities from fabrication or diffusion	Precursor related: e.g., Cl, H	Fixed charge; time dependence of operating device
	Source/drain related: e.g., B, P	
Features of polycrystallinity	Grain boundaries and associated defects, e.g., vacancies	Charge, diffusion
Amorphous structure	Structure-induced traps	Leakage current
Interface	Wrong bonds, relaxation with associated dipoles, roughness	Dipole, charge, electric field

(b) An oxygen vacancy with an unpaired electron on a dangling bond of a three-coordinated Si atom. (c) A nonbridging oxygen atom trapping a hole; the partially filled *p*-orbitals of the oxygen atom are shown. (d) A bridging peroxy linkage center formed by incorporation of an oxygen atom at a regular Si–O–Si bond. (e) A peroxy radical center formed by attachment of an oxygen ion to a regular oxygen site.

potentials, was the basis for describing cohesion, dielectric, and vibrational properties of perfect solids. The large Coulomb energies are the reason why accurate defect studies were first practical for ionic crystals. Nevertheless, polarization energies are large too (for an ion of charge $Z+2$ substituting for a Mg^{2+} ion in MgO, Madelung terms are $\sim 24 \times Z\,\text{eV}$ and polarization $\sim 6 \times Z^2\,\text{eV}$) and explain why so many charge states of impurities can be stable. Mott and Littleton's systematic way of calculating the Coulomb and polarization contributions to defect formation energies in ionic solids forms the basis of many current state-of-the-art codes.

Modeling Simple One-Electron Systems

For nonpolar semiconductors, "effective mass theory" is superb, often working well beyond its justification using empirical bulk properties. For ionic crystals, point ions are a surprisingly good start, but "pseudopotential methods" were necessary to explain why, and to give the "ion-size corrections" needed for accurate trends over the whole series of alkali halides. The F center (electron at an anion vacancy) was the first deep trap to be predicted well over a very wide range of halide and oxide hosts, and the same techniques were successful in modeling states of self-trapped excitons.

For most systems, however, the "many-electron treatment" is essential. Here both first-principles and empirical theories are often used. Empirical methods help most in new situations where what is important is not certain, for more complex systems, where computer power and technique is yet to be sufficient for the best methods, or for extrapolation across a broad range of materials. Many of the problems addressed empirically today will be solved by far better methods tomorrow.

By choosing first-principles methods, one is not reliant on parametrized theories or fitting possibly inaccurate experiments. These theories can be applied more reliably to hypothetical materials, defects for which data are not available, or for extreme temperature, pressure, and irradiation conditions. Computational techniques for modeling defects in solids exist in a form of computer codes, implementing a model of a solid with a defect, and methods for calculation of defect structure and properties.

Most first-principles methods are based on Hartree–Fock and density-functional theory (DFT). DFT states that the ground-state properties of a system are given by the charge density, and state-of-the-art methods allows one to compute the charge density and energy self-consistently, using various effective exchange-correlation potentials that account for the quantum mechanical interactions between electrons. The local density approximation (LDA) takes the exchange-correlation potential from the uniform electron gas theory at the density for each point in the material. The generalized gradient approximation (GGA) includes the effects of local gradients in the density.

The main computer models of a point defect in a crystal include a periodic model, an embedded cluster, and molecular cluster models. They differ by the boundary conditions imposed on a system wave function. The periodic model was first developed for calculating the electronic structure and properties of ideal crystals, whereas the cluster model evolved from molecular calculations (**Table 2**). Within the periodic model, a unit cell with a defect is periodically translated. It is ideal if one is interested in the ground-state properties of neutral defects, which weakly perturb the surrounding lattice. Many molecular cluster models treat a defect with surrounding

Table 2 Comparison of computational methods used in defect calculations

Models	*Methods*	*Properties*
Molecular cluster: molecule represents local defect environment in a solid	Density-functional theory and *ab initio* and semi-empirical Hartree–Fock theory in localized basis sets	Can predict local defect structure, vibrational, optical, and EPR properties providing intermediate and long-range order are not important.
Embedded cluster: local defect environment is treated quantum-mechanically and the rest of the solid structure treated classically	Density-functional theory and *ab initio* and semi-empirical Hartree–Fock theory in localized basis sets	Can predict local defect structure, ionization energies, electron and hole affinities, vibrational, optical, and EPR properties, and diffusion parameters. Can treat infinite amorphous structures.
Periodic: defects are repeated periodically in a lattice	Density-functional theory, Hartree–Fock theory, tight-binding methods in plane wave and localized basis sets	Can predict local defect structure, electrical levels, vibrational and EPR properties, and diffusion parameters providing the interaction between periodically translated defects is small. Treats amorphous structures as periodic arrangement of disordered cells.

atoms simply as a molecule or cluster. They disregard the effects of the rest of the atoms outside the cluster, but apply semi-empirical fixes to the atoms at the cluster surface to diminish their adverse effect. This major problem is addressed and partially solved in "embedded cluster" models, where a cluster with a defect is embedded in an infinite solid. This allows one to self-consistently include the effect of the polarizable environment into the cluster treatment of a defect, which is particularly important for charged defects in insulators.

Both static Hartree–Fock and DFT methods are ground-state theories, in the form of an effective one-particle Schrödinger equation (the Kohn–Sham equation in the case of DFT). The eigenvalues of these equations are often interpreted as electron energies and their differences as optical excitation energies. This interpretation is linked to an intuitive picture of independent electrons occupying well-defined energy levels. However, this is a gross simplification: the electrons are not independent, and when, for example, an electron is removed to form a hole, all remaining electrons respond by changing their electronic states. This electron relaxation and other quantum-mechanical contributions must be taken into account for energy differences to be calculated correctly. One can retain the picture of one-particle energy levels, but these particles are quasi-electrons and quasi-holes, which embody the effects of interaction with all the other particles.

The concept of quasiparticles is often used to represent the electronic states of an insulator with a defect schematically, as shown in **Figure 2**. Such energy

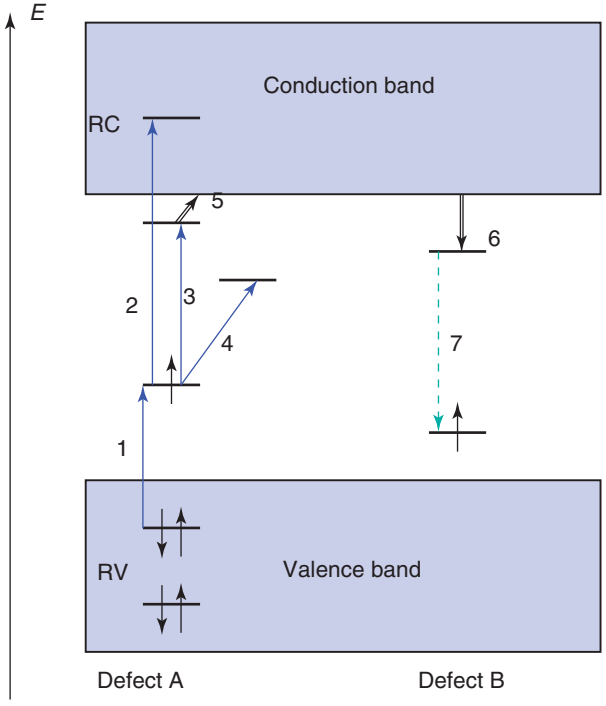

Figure 2 The quasiparticle energy diagram representing total energies of a solid with two defects A and B. The defect A produces local single-occupied and unoccupied states within the bandgap, and resonant states (denoted RV and RC) in the valence and conduction band, respectively. The defect B is characterized only by two local states in the gap. The arrows 1–4 correspond to optical transitions between states in the defect A. The arrow 5 corresponds to thermal ionization of an electron from the excited state of the defect A into the conduction band. Process 6 is nonradiative trapping of an electron from the conduction band on an empty state of the defect B. Process 7 is the de-excitation of the defect B, which may be either radiative or nonradiative.

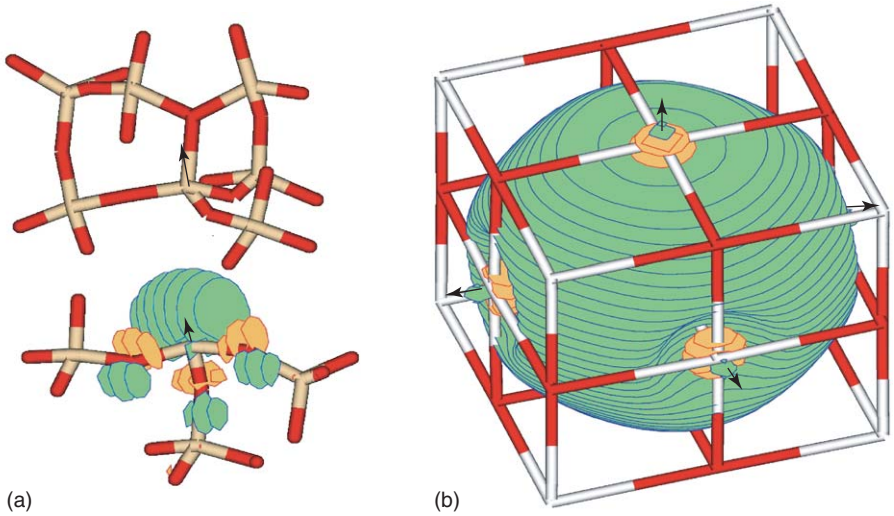

Figure 3 The geometric configurations and electronic states of positively charged oxygen vacancies in oxides. (a) The relaxed configuration of the positively charged oxygen vacancy, E_1' center, in α-quartz; red are oxygen ions. The envelope of the density of the unpaired electron mostly localized on a *p*-orbital of one Si ion is shown pointing into the vacancy. The arrows indicate the direction and relative values of the displacements of the two Si ions surrounding the vacancy. (b) The relaxed configuration of the positively charged oxygen vacancy, F^+ center, in MgO; red are oxygen ions. The envelope of the density of the unpaired electron localized on an *s*-orbital inside the vacancy is shown. Note that the electron density of the unpaired electron propagates much further out from the vacancy. Depressions in the envelope show that the unpaired electron avoids the core electrons of surrounding Mg ions. The arrows indicate the symmetric displacements of the six nearest-neighbor Mg ions surrounding the vacancy. This radial displacement of the six Mg ions is often used as a configuration coordinate, Q, in considering the spectroscopic properties of the F^+ center.

diagrams usually include the highest valence band and the lowest conduction band of the system. Point defects and impurities may induce occupied and unoccupied states in the gap and so-called resonant states in the valence and conduction bands of the system. The wave functions of localized states are often strongly localized in the defect area (**Figure 3**) and the corresponding quasi-electron energies are located in the bandgap of the solid. The resonant states differ from the ordinary band states in that they are localized in the defect region with the major wave function component decaying exponentially from the defect, but their quasi-electron energies are located within the occupied or unoccupied bands. Quasiparticle energy diagrams similar to that shown in **Figure 2** are used to summarize pictorially the electronic structure and processes involving optical excitation, luminescence, ionization, and energy transfer between defects.

Coupling of Electrons and Lattice Deformation

One of the issues crucial for the understanding of defect properties is how defect electrons couple to the motion of nearby ions or, alternatively, the way defect electrons apply forces to host ions. The static polarization and distortion of the host lattice affects defect formation and transition energies; the dynamics leads to transitions between electronic states and to defect diffusive motion. Optical spectra change qualitatively: the optical line width, the existence of a zero-phonon line, and the Stokes shift, the energy difference between optical absorption and emission energies, give direct measures of this coupling. Although any of a large number of atomic displacements might influence a defect in a solid, often a very specific combination of displacements is especially important. For example, the radial displacement of the nearest neighbors to the defect can be represented by a single configuration coordinate Q, as illustrated in **Figure 3**. It is noted that it is most unlikely that the coordinate Q will be one of the dynamically independent normal vibrational modes q. It is almost certain that normal modes of many different frequencies will be needed to make up Q. Moreover, the precise mode combinations making up Q will depend on the defect electronic state (it will be different in the excited state of defects shown in **Figure 3**). Yet, this configuration coordinate model is surprisingly effective, giving an invaluable tool for showing what happens after electronic excitation, and a simple language for describing defect processes. An example of such a diagram is given in **Figure 4**.

A central issue for optical and electronic materials is how they recover after excitation. A good X-ray phosphor emits the most visible light after excitation and degrades least from defect production. A

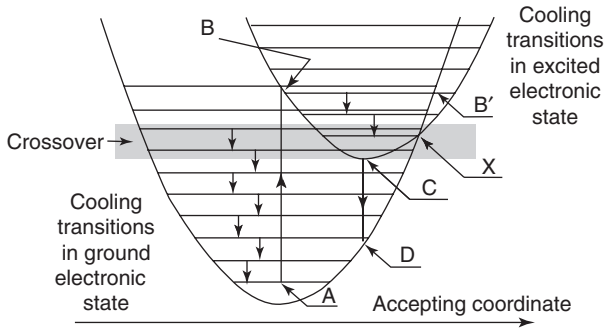

Figure 4 Configuration coordinate diagram. The figure shows the main characteristic energies and transitions, both radiative and nonradiative. Accepting coordinate represents one of the configuration coordinates effective in vibrational energy dissipation. The vertical arrow A–B corresponds to a vertical (so-called Franck–Condon) transition between the ground and excited states of the system represented by two harmonic energy surfaces. Horizontal lines indicate vibrational energy levels with small arrows showing transitions between these levels (cooling transitions) dissipating the excess vibrational energy (relaxation energy). The transition C–D between the lowest vibrational state in the excited state back to the ground-state energy surface corresponds to the Franck–Condon deexcitation with photon emission (luminescence or phosphorescence). It is accompanied by further cooling transitions in ground electronic state. The area near the crossing point X is where the system can cross nonradiatively from the excited to the ground state. In this case the relaxation energy, which is the energy difference between X and A or between C and A, is dissipated into lattice vibrations. The zero-phonon transition energy is the energy difference between C and A.

solid-state laser needs both population inversion and a lack of wasteful competing processes; carrier capture in semiconductors determines what defects and materials are acceptable; photographic (not to mention the photosynthetic) processes have their own demands. In such cases, nonradiative transitions are central, a role evident from over half a century of theory.

In nonradiative decay, excitation energy is transformed into heat, defect production, or to excitation of other electrons, the so-called Auger processes which are especially important at higher carrier densities. The most common manifestation of nonradiative decay of an excited state concerns suppression of luminescence. Can one tell, from optical absorption data, whether luminescence will occur from the absorption data alone or not? Huang and Rhys's seminal study showed one possible criterion: the larger the excitation energy, the faster the optical transition and the slower the nonradiative decay, since larger numbers of phonons would be needed (see **Figure 4**). Dexter, Klick, and Russell developed other criteria relating to the final state energy achieved by optical excitation and the energy at which the ground and excited electronic states intersected on the configuration coordinate diagram: the energy surfaces, rather than some matrix element, controlled the result. This led Bartram and Stoneham to show that simple expressions could be given for branching ratios at critical steps, and that these ideas – which could be applied to much more complex cases – correctly predicted behavior over a wide range of systems.

Self-Trapping and Localization

Landau made the remarkable suggestion of self-trapping: an electron could be so strongly coupled to the lattice that, even without a defect, it would lead to lattice distortion and be effectively immobilized. The suggestion was the basis of the important ideas of small polarons (incoherent hopping of localized carriers, as in some transition metal oxides, rather than the long mean-free-path motion of carriers in Si or metals), and even of the recently observed barrier to self-trapping. The observed small polarons (e.g., self-trapped holes in halides in **Figure 5**) show both the soundness of Landau's idea and (since naive belief in the band theory appears to be violated) the importance of theorists learning from experiment too. Distortion and polarization dominate too in negative-U behavior, where a charge disproportionation is exothermic (so the positive vacancies in Si decay from $2\,V^{+}$ to $V^{0}+V^{2+}$; for all free atoms, disproportionation is endothermic).

Localization can correspond to carrier or exciton trapping by an isolated defect (extrinsic trapping). If there is an attractive perturbation A at a defect site, then, for large enough A, a bound state emerges for the extra electron, hole, or exciton. Both impurity-induced potentials and electron–phonon interaction play crucial roles in this localization. Extrinsic electron trapping near defects is quite rare in insulators because electron polarons are not easily formed in these materials. However, exciton trapping by impurities is very common in most insulators.

As well-established examples of extrinsic hole trapping, one can consider holes trapped near cation vacancies in MgO (so-called V^{o} and V^{-} centers) and holes trapped near Ge and Al impurities in α-quartz. In particular, cation vacancies in MgO have an effective negative charge of $-2e$ with respect to the lattice and, therefore, attract positive holes. When one hole is trapped, a paramagnetic V^{-} center is formed, which is well studied experimentally using electron paramagnetic resonance and optical spectroscopy. Similar centers occur in CaO, SrO, and BaO, in the fourfold-coordinated oxides such as BeO and ZnO and in related sulfides, selenides, and tellurides. In MgO, at low temperatures the hole is

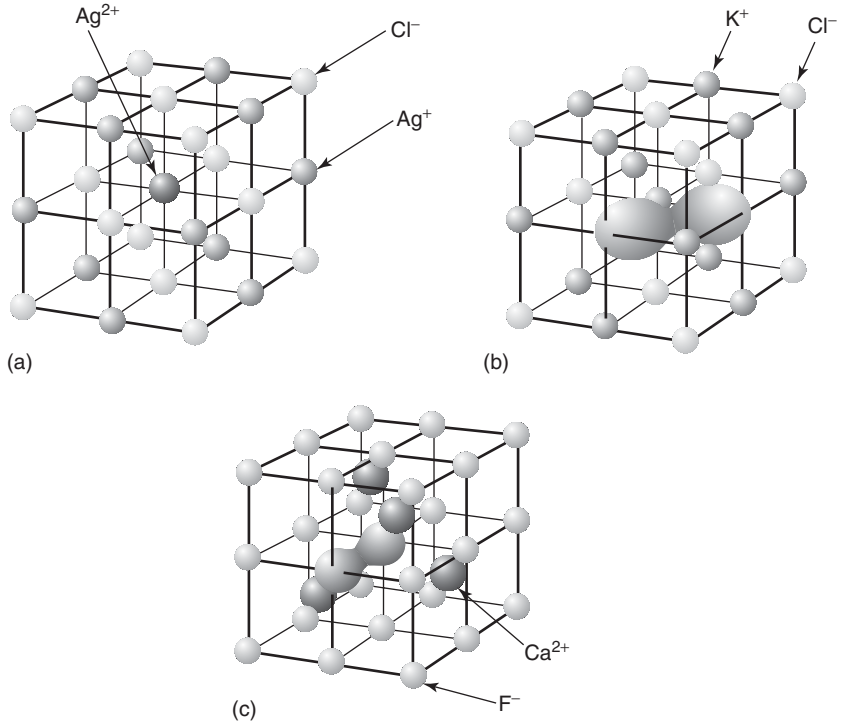

Figure 5 Atomic structure of the self-trapped hole centers in halides: (a) AgCl – the hole is localized on a silver ion; (b) alkali halides of NaCl structure – the hole is localized on two halogen ions forming a Cl_2^- molecule; (c) CaF_2 – the hole is localized on two fluorine ions forming a F_2^- molecule. Note that in (b)–(c) the X_2^- (X = F, Cl) molecular ion occupies two nearest anion lattice sites. In all cases, the hole localization is accompanied by a strong distortion of the surrounding lattice (not shown in the figure).

strongly localized on one of the six oxygen ions surrounding the vacancy. As the temperature rises, the hole moves more and more rapidly among the equivalent oxygens until it appears delocalized at room temperature. The nature of optical transitions in this center is characteristic to many other hole centers in oxides: there are two types of optical transitions. One is internal to the O^- ion on which the hole is localized. This is a crystal-field transition, since the transition energy is largely determined by the electric field at the O^- ion due to the Mg^{2+} vacancy. The other, more important, transitions involve charge transfer of the hole to other neighbors of the vacancy. These are analogous to electron excitation from resonant states in the valence band into the unoccupied hole state shown in **Figure 2**. Similar charge transfers are important in determining the color of gemstones.

Extensive experimental and theoretical studies show that excitons self-trap in both α-quartz (the most stable crystalline polymorph of SiO_2) and amorphous SiO_2. However, EPR studies show that holes and electrons do not self-trap in α-quartz. Yet, in high-purity Ge-doped quartz, low-temperature irradiation leads to the formation of a hole center localized at an oxygen site next to Ge. This formation of the localized hole centers associated with Ge impurity can be described as "extrinsic self-trapping," where both impurity-induced potential and electron–phonon interaction play crucial roles in the hole localization. In amorphous SiO_2, two types of localized hole centers have been determined that are free from pre-existing lattice defects such as vacancies, interstitials, or impurities, and are trapped by some precursor states induced by the disorder of amorphous structure. This example demonstrates that the mechanisms of localization processes in amorphous solids are more complicated than in crystalline materials due to coexistence of electron–phonon interaction, structural defects, and static potential fluctuations. It is not straightforward to distinguish the polaron self-trapping experimentally due to strong electron–phonon interaction from charge trapping by structural defects in an amorphous structure.

Defects in Disordered Materials

Defect structures and processes in amorphous materials have been studied extensively, partly as fundamental research on model amorphous materials, and partly to understand their extremely important role in technology. For example, the mechanisms and

kinetics of relaxation of electronic excitations in SiO_2 are crucial in micro- and opto-electronics applications. There are at least three basic fallacies concerning amorphous systems. First, it is wrong to assume there is only a single amorphous structure for a given composition, since the method of preparation can have significant effects. Second, it is wrong to think that the mean energies of defect formation or of trap ionization in an amorphous structure are sufficient to understand the behavior: the form and tails of the distribution are equally important. Third, one should not assume that crystals and amorphous systems of the same composition have the same values for defect and trap energies.

Structural disorder in amorphous materials generally means that all sites are different. In most experimental studies, the effect is hidden in broadening of the spectral features, and only rarely has disorder been implicated in the formation of different structural types of the same defect. Predicting defect properties and relative abundance of different defect configurations generally requires considering not one or several, as in crystals, but a statistical ensemble of structural sites. Additional factors include the sample history and the mechanism of defect formation. This provides new challenges for both theoretical and experimental analyses of defects in amorphous materials.

Surfaces and Interfaces

No discussion of defects could be complete without mention of interfaces. Their structures are rarely, if ever, the ideal terminations of perfect crystal structures, and the variety of reconstructions is becoming clearer as new microscopies (e.g., the atomic force microscope) develop. Defects or impurities at surfaces and interfaces are especially important for most applications. It is the impurities close to grain boundaries, which are most strongly involved in the operation of solid-state gas sensors, and the framework of the Debye–Hückel theory is central. The space charge in silver halides relates to their photographic effectiveness; the Mott and Gurney theory provides the basic framework. Defects at the interface between silicon and gate dielectrics control the reliability of microelectronic devices. Ceramists recognize the importance of segregation in oxides, where experiment shows that Mg in alumina gives dramatic improvements in sintering.

Defects also influence adhesion. What controls the variation from one oxide to another of the adhesion of a nonreactive metal? Why (a related question) does liquid Cu wet some oxides (NiO, urania, chromia) but not other similar oxides (MgO, thoria, alumina)? The answer lies largely in the defect populations and basic electrostatics: charged defects close to the highly polarizable metal have lower energy; those close to the unpolarizable vacuum have higher energy. The operation of gas sensors relies on electron transfer across interfaces, as does the operation of contacts to semiconductors (whether conventional or organic) and electrodes.

Yet, another issue, specific for microelectronics applications, is that the dielectric of interest can be in contact with the electrode(s) – semiconducting (e.g., silicon) or metallic – which provides a source of extra electrons. Also, a dielectric film can be placed in the electric field between the two electrodes, which may alter the defect charge states. Charged defects can cause substantial random fields, which may alter breakdown thresholds locally. Typically, for 100 ppm of charged defects, there will be random fields of order $10^5\,V\,cm^{-1}$. Defects can be involved in stress-induced leakage currents (SILC) and dielectric breakdown. In such cases, the defect offers a channel for electron transfer across the dielectric: an electron tunnels from one electrode into an oxide defect; there are then relaxation processes or a sequence of defect processes, and the electron can then tunnel to the other electrode. What can one say about the defects responsible, their electrical energy levels and relaxation energies (differences in energy for electron capture and emission)? Can one give useful estimates of electron and hole trapping cross sections? Will there be any field-stimulated diffusion of defects?

To define which charge state of an intrinsic defect (e.g., vacancy) or incorporated defect species is favored, consider the common case of an oxide film grown on silicon, the source or sink of electrons being the bottom of the silicon conduction band at the Si/SiO_2 interface. Hence, the chemical potential of the electron can be chosen at the bottom of the Si conduction band or at the silicon mid-gap energy. Electrons are assumed to be able to tunnel elastically or inelastically from/to these states to/from defect states in the oxide and create charged species. Most calculations use experimental information to estimate the energy of an electron at the bottom of the conduction band of Si with respect to the defect states.

The key point about defect states in a dielectric from the device point of view is to control the dependence of the defect charge state on the position of the system Fermi energy. It is useful to distinguish two charge-state levels: the thermodynamic level, E_{th}, and the transient level, E_{tr}. The thermodynamic charge-state level corresponds to the system Fermi energy for which a defect changes its charge in

thermal equilibrium. E_{th} is defined as a difference of total energies of systems of N and $N+1$ electrons, each in its fully relaxed ground state: $E_{th} = E(N+1) - E(N)$. Thus, if E_F is the energy required to remove an electron from some electron reservoir (e.g., Si at the Si/SiO_2 interface), $E_{th} - E_F$ is the energy required to add an electron from the reservoir to the lowest unoccupied charge-state level.

Taking into account that the electrical measurements and the electronic processes are fast compared with the time needed for the system to come to equilibrium, another transient level is introduced, which is consistent with the Frank–Condon principle. E_{tr} is defined as the energy required for trapping an electron or a hole in the geometry of the system as it was prior to the trapping. Thus, E_{tr} are obtained as the differences of the total energies of the system with N and $N+1$ electron, but in the local atomic geometries, which correspond to one of these systems. For example, $E_{tr}(0/-) = E(-) - E(0)$ denotes the energy required to add an electron to the neutral defect calculated using the neutral defect geometry.

Once the charge-state levels are calculated, the dependence of the defect charge state on the electrode Fermi energy can be introduced via a correction term $q \times E_F$, where E_F is varied in the energy range from that of the maximum of the last valence band of the oxide to the bottom of the first conduction band. The results are presented as plots of E_{th} versus E_F or E_{tr} versus E_F calculated for different values of E_F. The crossing points of the corresponding lines determine the regions where one charge state of a defect is more favorable than the other. Although the Fermi energy remains unknown in the experiment, such diagrams allow one to identify some critical cases and help in the analysis of the experimental data. The same approach is used to determine the dependence of the defect formation energies on the position of the Fermi energy.

Insulators, Optical Properties of

Y Toyozawa, University of Tokyo, Tokyo, Japan

Band Model and Optical Properties

Insulators are characterized, and contradistinguished from metals, by the existence of a forbidden energy band of finite width, a bandgap, between the highest filled band (the valence band) and the lowest empty band (conduction band). The existence of a bandgap can be confirmed by the optical transparency, that is, a vanishing absorption constant, up to a finite energy a little below the bandgap ε_g, except in the lower energy region where the absorption due to lattice vibrations may arise.

The energy difference between the first absorption peak and the bandgap ε_g, from where the continuous spectrum of band-to-band transitions starts, is due to the Coulomb binding energy between the excited electron in the conduction band and the positive hole left behind in the valence band, a typical example of "configuration interaction" – a step beyond the

one-electron approximation of the band model – or of "final state interaction" in the optical spectrum. This bound electron–hole pair is called "exciton," which means a quantum of excitation.

Exciton Model and the Optical Spectrum Near the Absorption Edge

The relative motion of the electron and the positive hole with orbital radius larger than the interatomic distance can be described in the effective mass approximation, and if their effective masses m_e and m_h and hence the reduced mass $m_r = (m_e^{-1} + m_h^{-1})^{-1}$ are isotropic, the binding energies form a hydrogen-like series: $B_n = Ry_{ex}/n^2 (n = 1, 2, \ldots)$, $Ry_{ex} = (m_r/m)(\varepsilon_0/\varepsilon_e)^2 Ry$ where $Ry = 13.6\,\text{eV}$ is the Rydberg energy, m the electron mass in vacuum, ε_0 the dielectric constant of vacuum, and ε_e the electronic dielectric constant $\varepsilon(\omega)$ at $\hbar\omega \sim O(Ry_{ex}) \ll \varepsilon_g$ which is contributed only from electronic transitions except when B_n is as small as the phonon energies. The exciton radius is given by $a_n = a_{ex} n^2$, $a_{ex} = (m/m_r)(\varepsilon_e/\varepsilon_0) a_H$ where $a_H = 0.052$ nm is the orbital radius of the electron in the ground state of a hydrogen atom. This Wannier model of an exciton is valid for insulators with relatively small bandgap (less than a few eV) and hence with large values of $\varepsilon_e/\varepsilon_0$ and a_{ex}/a_H of the order of 10. In insulators with a larger bandgap, the exciton radius is smaller than or comparable with the interatomic (intermolecular) distance, and the Frenkel model of intra-atomic (intramolecular) excitation (as in rare gas solids and aromatic molecular crystals), or the model of charge transfer to neighboring atoms (from an anion to neighboring cations as in ionic crystals) is more appropriate at least for an exciton in its ground state ($n = 1$).

In the Wannier model, the matrix element of the optical transition is given as a product of that for the interband transition and the amplitude of the hydrogen-like wave function $F_n(\boldsymbol{R}_m)$ of the relative motion at the origin $\boldsymbol{R}_m = 0$ (probability amplitude that the electron and the hole are found on the same site), which is nonvanishing only for the s-like states ($\ell = 0$ where ℓ is the angular momentum). Thus, the intensity of the ns exciton line at $\hbar\omega = E_n = \varepsilon_g - B_n$ in the absorption spectrum is proportional to the square of the above amplitude, namely to n^{-3} ($n = 1, 2, \ldots$) as known in the hydrogen atom. Noting that the product of the intensity and the number density of states $|dE_n/dn|^{-1} \propto n^3$ is independent of n and hence of energy $\hbar\omega$, one finds that the absorption spectra consisting of higher exciton lines overlapping with each other (due to their finite widths) tends to a plateau of constant height as $n \to \infty$. It can also be shown analytically that this asymptotic height is in exact accordance with that of the continuous spectrum of band-to-band transition with the Coulomb-enhancement factor $(\hbar\omega - \varepsilon_g)^{-1/2}$ which cancels out the density of states effect $(\hbar\omega - \varepsilon_g)^{+1/2}$. The resulting absorption spectrum around the band edge is shown schematically in **Figure 1a** where the n-dependence of the width γ_n of discrete lines does not affect the above mentioned continuity.

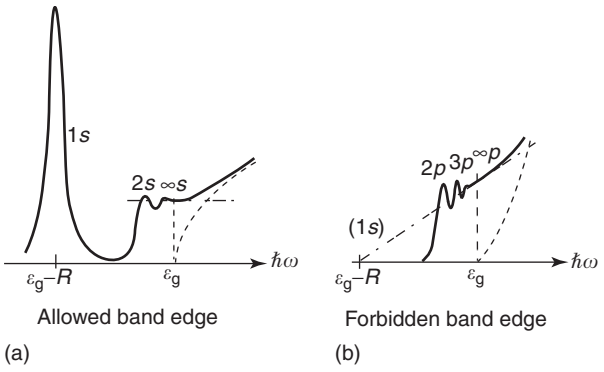

Figure 1 The effect of Coulomb interaction on the fundamental absorption edge. The broken lines represent the interband absorption edge without the Coulomb effect. (Reproduced with permission from Toyozawa Y (2003) *Optical Processes in Solids.* Cambridge: Cambridge University Press; © Cambridge University Press.)

In the case that the matrix element of band-to-band transition vanishes at the band edge ε_g due to a reason of symmetries of band wave functions, one has to consider its values above the edge. Correspondingly, one has to use the gradient $\nabla_R F_n(\boldsymbol{R}_m)$ of the hydrogen wave function at the origin, which is nonvanishing only for the p-like states ($\ell = 1$). Thus, np exciton lines ($n = 2, 3, \ldots$) appear at $\hbar\omega = E_n = \varepsilon_g - B_n$ of the absorption spectrum with intensities proportional to $(n^{-3} - n^{-5})$, with $n = 1$ missing. It can be shown, as before, that the broadened exciton lines asymptotically merge smoothly (inclusive of the finite slope extrapolating to the $n = 1$ position) to the continuous spectra of the Coulomb enhanced band-to-band transition around ε_g. The absorption spectra in this case of the forbidden band edge is schematically shown in **Figure 1b**. The intensity of the absorption spectra is smaller than that in the allowed band edge case mentioned above by a factor $(a/a_{ex})^2$, where a is the interatomic distance. Absorption spectra in alkali halides and cuprous oxides shown in **Figures 2a** and **2b** belong to the cases (a) and (b), respectively, of **Figure 1**.

Insulators with small bandgaps become intrinsic semiconductors except at low temperatures. The existence of thermally excited free carriers causes a metallic screening of a long-range electron–hole

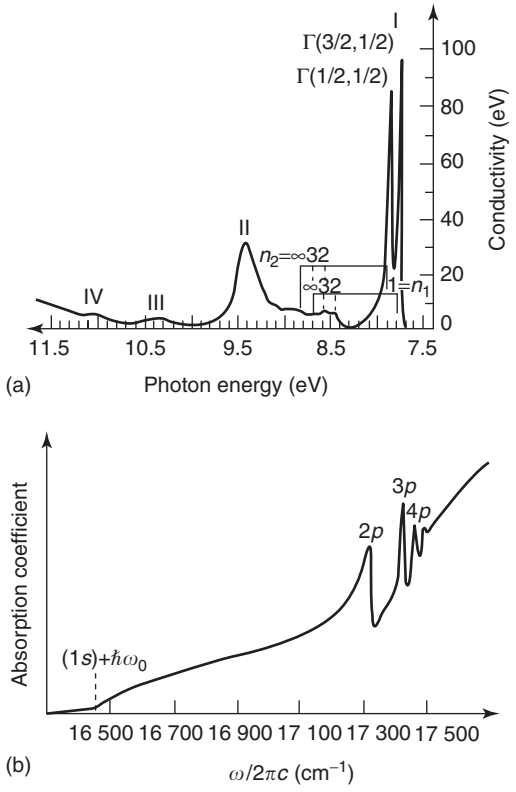

Figure 2 (a) Fundamental absorption spectrum of KCl crystal 10 K. (Reproduced with permission from Tomiki T (1969) *Journal of the Physical Society of Japan* 26: 738.) (b) The yellow series excitons at the fundamental absorption edge of Cu_2O crystal at 4.2 K. Coulomb interaction into a short-range one, thus affecting the interband optical spectra in such a way that the discrete exciton lines merge into the continuous spectra of interband transition as temperature rises. Moreover, the free carriers give rise to their own optical absorption (intraband optical transition) in the infrared region.

Dipole–Dipole Interaction Contributing to the Translational Motion of an Exciton

As a composite particle consisting of an electron in the conduction band with effective mass m_e and a positive hole in the valence band with effective mass m_h, the exciton has effective mass $m_{ex} = m_e + m_h$ and translational kinetic energy $\hbar^2 K^2/2m_{ex}$ near the bottom of the exciton band. Finite bandwidths of the valence, conduction, and hence exciton bands are due to the overlaps of wave functions between neighboring atoms.

The width of the exciton band is contributed by another type of interaction energy, the dipole–dipole interaction. Take the Frenkel exciton in which this interaction predominates, and consider how the intra-atomic excitation at the nth atom is transferred to the mth site. Consider the state $\Phi_n = \phi_p(\boldsymbol{r}_n - \boldsymbol{R}_n)\prod_{\ell(\neq n)}\phi_s(\boldsymbol{r}_\ell - \boldsymbol{R}_\ell)$ where all atoms are in the s-like ground state except the nth atom which is in a p-like excited state. The excitation transfers to the mth atom through the matrix element

$$H_{nm} \equiv (\Phi_n, H\Phi_m) = \int\int \mathrm{d}\boldsymbol{r}_n \mathrm{d}\boldsymbol{r}_m \phi_p(\boldsymbol{r}_n - \boldsymbol{R}_n)\phi_s(\boldsymbol{r}_m - \boldsymbol{R}_m) \times v_{nm}\phi_s(\boldsymbol{r}_n - \boldsymbol{R}_n)\phi_p(\boldsymbol{r}_m - \boldsymbol{R}_m)$$

where H denotes the total Hamiltonian of the system consisting of N atoms with one electron per atom. Note that due to the orthogonality of atomic wave functions ϕ_s and ϕ_p and the neglect of overlaps of wave functions between different atoms, only the Coulomb interaction $v_{nm} = e^2/4\pi\varepsilon_0|r_n - r_m|$ remains among the total Hamiltonian H. Due to the same reasons, one can take only the lowest dipole–dipole terms in the multipole expansion of the long-range Coulomb interaction, namely $H_{nm} = (\boldsymbol{m}^2/R_{nm}^3 - 3(\boldsymbol{m}\cdot\boldsymbol{R}_{nm})^2/R_{nm}^5)/\ 4\pi\varepsilon_0 \equiv D\ (\boldsymbol{R}_{nm})$, where $\boldsymbol{m} \equiv \int \mathrm{d}\boldsymbol{r}\phi_p\ (\boldsymbol{r})(-e\boldsymbol{r})\phi_s(\boldsymbol{r})$ is the transition dipole moment. The Hamiltonian H is diagonalized with the wave function of the Frenkel exciton given by $\Psi_K^{(e)} = N^{-1/2}\sum_n \exp(\mathrm{i}\boldsymbol{K}\cdot\boldsymbol{R}_n)\Phi_n$, namely $H_{KK'} = \delta_{KK'}E_K^{(e)}$, with diagonal energy being $E_K^{(e)} = (\Psi_K^{(e)},\ H\Psi_K^{(e)}) = E^{(g)} + \varepsilon + D_K$ where $E^{(g)}$ is the ground-state energy of the entire system, $\varepsilon = \varepsilon_p - \varepsilon_s$ the atomic excitation energy in the crystal and $D_K \equiv \sum_{n(\neq 0)} D(\boldsymbol{R}_n)\exp(-\mathrm{i}\boldsymbol{K}\cdot\boldsymbol{R}_n)$. Thus, the dipole–dipole interaction contributes to the K-dependence of the exciton energy.

One must be careful in summing up the long-range dipole–dipole interaction $D(\boldsymbol{R}_n) \propto R_n^{-3}$ because of the slow convergence, especially when K is much smaller than the reciprocal of the interatomic distance a. Dividing the summation into the inner region $R_n < R_c$ and the outer region $R_n > R_c$ where R_c is chosen so as $a \ll R_c \ll K^{-1}$, and replacing the latter summation by integration, one obtains $D_K \equiv \sum_{n(\neq 0)}^{R_n<R_c} D(\boldsymbol{R}_n) - (N_0/3\varepsilon_0)[m^2 - 3(\boldsymbol{m}\cdot\boldsymbol{K})^2/K^2]$, which is singular at $\boldsymbol{K} = 0$ since it tends to different values depending on the direction in which $\boldsymbol{K}$ approaches 0. In a typical case that each atom is situated in the environment of cubic symmetry, the first summation vanishes. One has triply degenerate atomic p-states p_x, p_y and p_z so that one has a 3×3 matrix of the $\boldsymbol{K}$-dependent part: $(D'_K)_{ij} = -(N_0\mu^2/3\varepsilon_0)[\delta_{ij} - 3K_iK_j/K^2]$. It is diagonalized by taking the coordinate system with the

z-axis along the direction of $\boldsymbol{K}$. In fact, one obtains a longitudinal wave $\boldsymbol{m}\|\boldsymbol{K}$ with energy $(D'_K)_{33} = (2/3)(N_0\mu^2/\varepsilon_0)$, and two transverse waves $\boldsymbol{m}\perp\boldsymbol{K}$ with energy $(D'_K)_{11} = (D'_K)_{22} = -(1/3)(N_0\mu^2/\varepsilon_0)$. Their energy difference, $N_0\mu^2/\varepsilon_0$, agrees with $\hbar$ times the longitudinal–transverse splitting $D_{\mathrm{lt}} = \omega_1 - \omega_{\mathrm{t}}$ of polarization waves which originates from the depolarizing field. Under the coexistence of many oscillators, ε_0, is to be replaced by the residual dielectric constant ε'_j which is contributed by the oscillators other than the one (j) under consideration. Note that this dielectric constant is different from ε_{e}, which governed the electron–hole relative motion.

The Effect of Spin and the Interplay of Exchange and Spin–Orbit Interactions

To be more realistic, one must consider the electron spin in addition to its orbital motion. Each atomic state characterized by (n, ℓ, m) is doubly degenerate with up and down spins, $s = \pm 1/2$. The simplest closed shell atom consists of two ns electrons with configuration $(ns)^2$, and its optically allowed excited state consists of the configuration $(ns)(np)$. The two electrons in the excited state can have either antiparallel (as in the ground state) or parallel spins, with energy difference $2\Delta_{\mathrm{exch}}(>0)$ where $\Delta_{\mathrm{exch}} = \int\int \mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{r}'\phi_p(\boldsymbol{r})\phi_s(\boldsymbol{r})(\mathrm{e}^2/4\pi\varepsilon_0)|\boldsymbol{r}-\boldsymbol{r}'|^{-1}\phi_s(\boldsymbol{r}')\phi_p(\boldsymbol{r}')$ is the exchange energy. The singlet state is above the triplet state because one is concerned with the e–h (instead of the e–e) system. The optical transition to the triplet excited state is forbidden because of its total spin state $S = 1$ $(\boldsymbol{S} \equiv \boldsymbol{s}_1 + \boldsymbol{s}_2)$ different from that of the ground state $S = 0$. Noting that Δ_{exch} is the special case $(n = m)$ of H_{nm} in the preceding section and that the dipole–dipole interactions vanish for the triplet state but are to be multiplied by 2 for the singlet state (because two electrons participate), one can incorporate the exchange and dipolar energy into a single form, $2\delta_{S,0}|F_n(0)|^2[\Delta_{\mathrm{exch}} + D_k]$, where multiplication by the squared amplitude of the wave function of e–h relative motion at the origin is required only where the interaction remains in the Wannier exciton. The total energy of the Wannier exciton with the principal quantum number n, spin quantum number S, and translational wave vector $\boldsymbol{K}$ is then given by

$$E_{n,S}(\boldsymbol{K}) = \varepsilon_{\mathrm{g}} - B_n + \hbar^2\boldsymbol{K}^2/2m_{\mathrm{ex}} + 2\delta_{S,0}|F_n(0)|^2[\Delta_{\mathrm{exch}} + D_K]$$

Another term to be considered is the spin–orbit interaction $H_{\mathrm{s.o.}} = \lambda\boldsymbol{l}\cdot\boldsymbol{s}$. One can diagonalize it together with the total angular momentum $\boldsymbol{j} \equiv \boldsymbol{l} + \boldsymbol{s}$ by making use of the identity $2\boldsymbol{l}\cdot\boldsymbol{s} = (\boldsymbol{j}^2 - \boldsymbol{l}^2 - \boldsymbol{s}^2) = j(j+1) - 1\cdot 2 - (1/2)\cdot(3/2)$. Thus, the atomic state with $\ell = 1$ are split into $j = 3/2$ and $j = 1/2$ with spin–orbit energies $+\lambda/3$ and $-2\lambda/3$, respectively. According to this quasi-atomic model, the valence band of alkali halide which consists of p-orbitals of halogen is split to the upper $(j_{\mathrm{v}} = 3/2)$ and lower $(j_{\mathrm{v}} = 1/2)$ branches while the conduction band consisting of s-orbital of alkali is not split ($j_{\mathrm{c}} = 1/2$ only). Hence, the absorption edge of band-to-band transition appears at $\varepsilon_{\mathrm{g}} - \lambda/3$ and $\varepsilon_{\mathrm{g}} + 2\lambda/3$ with the intensity ratio 2:1 reflecting the degeneracy $2j_{\mathrm{v}} + 1$. This $\boldsymbol{j}$–$\boldsymbol{j}$ coupling scheme is no more valid for exciton lines because of finite exchange-dipolar interaction, $\Delta_n \equiv 2\delta_{S,0}|F_n(0)|^2[\Delta_{\mathrm{exch}} + D_0]$ mentioned above. As Δ_n/λ increases the intensity ratio decreases, tending to 0 since the lower exciton state tends to a pure spin-triplet ($S = 1$) which is optically forbidden ($\boldsymbol{L}$–$\boldsymbol{S}$ coupling). In materials with small spin–orbit coupling constants as are realized with light atom constituents, the triplet exciton is optically almost forbidden. The continuous change from the $\boldsymbol{j}$–$\boldsymbol{j}$ to $\boldsymbol{L}$–$\boldsymbol{S}$ and again to $\boldsymbol{j}$–$\boldsymbol{j}$ coupling schemes has been observed in the alloy system $CuCl_{1-x}Br_x$ in which λ varies continuously from negative to positive values with Δ_{exch} staying always small as composition x varies from 0 to 1, as is shown in **Figure 3**. The $\boldsymbol{L}$–$\boldsymbol{S}$ coupling scheme is realized only around the composition x where λ changes sign, the $\boldsymbol{j}$–$\boldsymbol{j}$ coupling scheme with intensity ratio 1:2 and 2:1 is observed on its left and right sides, respectively.

The quasi-atomic model mentioned above has been improved to the crystalline field model in which the symmetry of the crystal is fully taken into account. The anisotropic exchange energy introduced thereby as an independent material parameter has in fact been observed in some materials.

Participation of Phonons in the Electronic Excitation

The wave vector of a photon with energy enough for the electronic excitation across a bandgap of 10 eV is $\sim 10^8\,\mathrm{m}^{-1}$ which is much smaller than the reciprocal lattice $\sim 10^{10}\,\mathrm{m}^{-1}$. One can thus assume that the wave vector (pseudo or crystal momentum divided by $\hbar$) is conserved in the optical transition, namely $\boldsymbol{k}_{\mathrm{c}} - \boldsymbol{k}_{\mathrm{v}} = 0$ or $\boldsymbol{K}_{\mathrm{ex}} = 0$. In addition, it has been tacitly assumed so far that the bottom of the conduction band and the top of the valence band are at the origin, $\boldsymbol{k}^m_{\mathrm{c}} = 0$ and $\boldsymbol{k}^m_{\mathrm{v}} = 0$, which, however, is not always the case. If one or both of them are not at the origin, the absorption edge of band-to band transition appears around the indirect

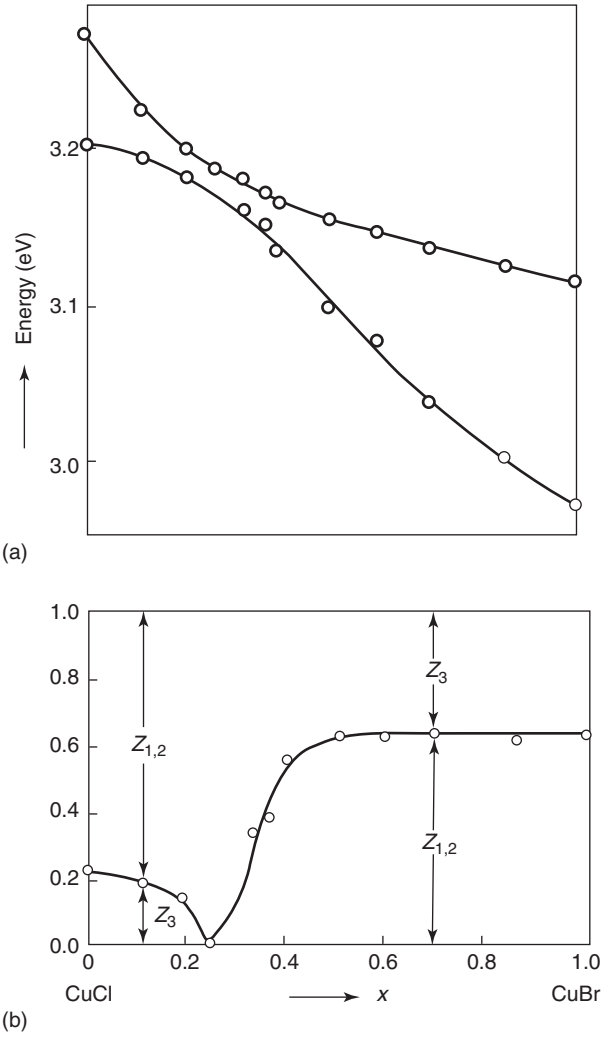

Figure 3 (a) Observed energies, and (b) intensity ratio of $Z_{1,2}$ and Z_3 excitons in mixed crystal: $CuCl_{1-x}Br_x$ as functions of the concentration x. (Reproduced with permission from Kato Y, Yu CI, and Goto T (1970) *Journal of the Physical Society of Japan* 28: 104.)

gap $\varepsilon_g = \varepsilon_c(\boldsymbol{k}_c^m) - \varepsilon_v(\boldsymbol{k}_v^m)$, but with the participation of phonons with wave vector $\boldsymbol{k}_{id} \equiv \boldsymbol{k}_c^m - \boldsymbol{k}_v^m$ to satisfy the conservation of the wave vector. Hence, the exact absorption edge appears at $\varepsilon_g - B_n' \pm \hbar\omega_s(\pm\boldsymbol{k}_{id})$ according as a phonon is absorbed or emitted, where B_1' is the binding energy of the exciton formed at $\boldsymbol{K} = \boldsymbol{k}_{id}$ and $\omega_s(\boldsymbol{k})$ is the circular frequency of the sth mode lattice vibration with wave vector $\boldsymbol{k}$. The absorption spectrum rises with the square root of energy from each edge reflecting the density of states of the exciton band, with the intensity proportional to the square of the indirect exciton–phonon interaction matrix element and the temperature dependent factor $\bar{n}_s$ and $\bar{n}_s + 1$ for absorption and emission of a phonon, respectively, where $\bar{n}_s = [\exp\{\hbar\omega_s(\pm\boldsymbol{k}_{id})/\ k_B T\} - 1]^{-1}$ is the thermal average of the number of phonons. Such indirect exciton edges are observed in germanium and silicon ($\boldsymbol{k}_c^m \neq 0$), silver halides ($\boldsymbol{k}_v^m \neq 0$), and thallous halides ($0 \neq \boldsymbol{k}_c^m \neq \boldsymbol{k}_v^m \neq 0$). Similar phonon-mediated exciton edge arises even when $\boldsymbol{k}_c^m = \boldsymbol{k}_v^m = 0$, provided the exciton transition matrix element vanishes at $\boldsymbol{K}_{ex} = 0$, as is realized with the 1s exciton in Cu_2O (see **Figure 2b**).

The widths γ of direct exciton absorption peaks, introduced phenomenologically as damping constants of oscillators, are microscopically attributed to the rate τ^{-1} of scattering of the optically created exciton $\boldsymbol{K}_{ex} = 0$ to $\boldsymbol{K}_{ex} \neq 0$ by absorbing or emitting a wave number conserving phonon, which is of the same origin as the indirect exciton transition mentioned above. An indirect exciton absorption band is, therefore, supposed to be the tail part of the broadened peaks of a direct exciton. As a second-order process, the $\boldsymbol{K} = 0$ exciton is the intermediate state which is resonant and nonresonant to the incident photon in the direct and indirect transitions, respectively.

In fact, one can incorporate both aspects in a unified expression for a multicomponent exciton absorption spectrum. For a multiband scheme of excitons with energy $E_{\lambda K}$, one can write the spectral line shape as the sum of asymmetric Lorentzians: $F(E) = \sum_\lambda \bar{f}_\lambda \pi^{-1}[\bar{\Gamma}_{\lambda 0} + \bar{A}_\lambda(E - \bar{E}_{\lambda 0})]/[(E - \bar{E}_{\lambda 0})^2 + \bar{\Gamma}_{\lambda 0}^2]$ which is in accordance with the result of the classical model of damped oscillators ($\hbar\gamma_\lambda \leftrightarrow \bar{\Gamma}_{\lambda 0}$) for the direct exciton peaks, except for the asymmetry terms with $\bar{A}_\lambda$ (the degree of asymmetry) in the numerator, and the fact that the quantities crowned with bars are the renormalized (in the phonon field) quantities dependent on a variable E, the photon energy (though not shown explicitly). The shape of the indirect absorption edge is contained implicitly in the functional form of the width $\bar{\Gamma}_{\lambda 0}(E)$, which is proportional to the combined density of states of excitons and phonons in the final state of indirect transition. The asymmetry term $\bar{A}_\lambda(E - \bar{E}_{\lambda 0})$ in the numerator originates from the interference of the direct exciton peak λ with its background continuum of indirect exciton transitions to other exciton bands $\lambda'(\neq\lambda)$ – a solid-state version of the Fano effect well known in atomic spectroscopy. Such multicomponent asymmetric Lorentzian peaks have, in fact, been observed as shown in **Figure 2b**. The asymmetry here is due to the interference of the direct exciton peak with the background continuum of phonon-assisted optical transition to the 1s exciton band to which the direct transition is forbidden. Phonon sidebands of the direct exciton peak (as are observed in some ionic crystals) are also contained implicitly in the functional form of $\bar{\Gamma}_{\lambda 0}(E)$.

Absorption Bands of Extrinsic Origin below the Bandgap

While (chemically) pure and (physically) perfect insulators are transparent in the spectral region below the first exciton peak (in the direct bandgap case), impure or imperfect insulators have various absorption bands due to the electronic transitions at impurity (guest) atoms or point defects of a lattice. The localized electron(s) is subject to a strong interaction with phonons (stronger than the mobile exciton is) particularly when its orbital radius is comparable with the lattice constant, and once excited, it causes significant displacements of nearby atoms to their new equilibrium positions (lattice relaxation). From this "relaxed excited state," the electron returns to the ground state emitting a photon (luminescence) or nonradiatively. The peak of the emission band is displaced from that of the absorption band (Stokes shift), both bands being more like Gaussian shapes as can be described by the configuration coordinate model. Examples are Tl-like atoms in alkali halides which are known as phosphorescence centers of high efficiency, and the F-centers (an electron captured at an anion vacancy) in alkali halides which are subject to a variety of photochemical reactions resulting in the color changes of the crystal.

The impurities and imperfections sometimes give rise to bound excitons as can be confirmed by the optical absorption bands just below the intrinsic exciton absorption peaks. For example, the α and β absorption bands in alkali halides correspond to exciton formation around an anion vacancy and an F-center, respectively. Shallow bound excitons, as are realized at donors in direct gap semiconductors (such as CdS), have large oscillator strengths of the order of the number of host atoms covered by their extended wave functions, the effect known as "giant oscillator strength."

Intrinsic Photoluminescence and Its Correlation with the Urbach Rule

The optically created exciton will be thermalized around the bottom of the exciton band from where it will emit a photon with energy smaller (in the indirect case) than or equal (in the direct case) to the absorption edge. In the direct case, the exciton is gradually converted into a photon during its thermalization through the polariton bottleneck. In any case, the emission spectrum from this "mobile exciton" is a sharp line.

In some materials, the exciton becomes self-trapped by the lattice distortion caused by itself. The emission spectrum of this self-trapped exciton is a broad Gaussian with a significant Stokes shift from the exciton absorption peak (direct gap case) or edge (indirect case), similar to the localized center mentioned before. In the configuration coordinate model, the self-trapped state is separated by a potential barrier from the free or mobile state, and which of them is more stable depends on whether the exciton–phonon coupling constant g, a material constant, is greater or smaller than a critical value g_c.

In contrast to different behaviors of the emission spectrum in the weak and strong coupling cases, the line shape of the exciton absorption band varies continuously as a function of g. For instance, the low energy tail of the exciton absorption spectrum in many insulators has been found to obey the Urbach rule: $\exp[-\sigma(E_0' - E)/k_B T]$ except at low temperatures where E_0' is the convergence point of semi-logarithmically plotted line contours at various temperatures T, and the steepness coefficient σ is the material constant. This exponential tail has been ascribed to momentarily localized exciton states under a fluctuating field of lattice vibrations, with σ being given by a constant (different values for direct and indirect gap cases) times g^{-1}. While empirical values of σ and g derived therefrom are rather evenly distributed over a variety of insulating materials, the observed emission spectrum of the exciton is distinctly different according as g is smaller ($\rightarrow$ sharp line almost resonant to the absorption peak in the direct gap case) or larger ($\rightarrow$ broadband with a significant Stokes shift) than the critical value g_c in accordance with the theoretical prediction from the observed value of σ.

Optical Excitation of Inner Shell Electrons

Synchrotron radiation has facilitated the spectroscopic studies over a vast energy range extending up to the X-ray, corresponding to electronic transitions from different inner atomic states (much deeper than the outermost orbital state responsible for the valence band) to the empty conduction band. Below the ionization continuum of each inner state, there appear exciton lines as in the valence band excitation. However, the exciton here can be viewed as a localized excitation since the width of the energy band formed by the inner atomic state is negligibly small. Moreover, the positive hole in the inner state is subject to decay processes such as (1) radiative recombination, and (2) Auger recombination with an electron in the upper filled band (inclusive of the valence band) which are the main causes of a lifetime broadening of the exciton line, except in shallow inner bands (next below the valence band) in some

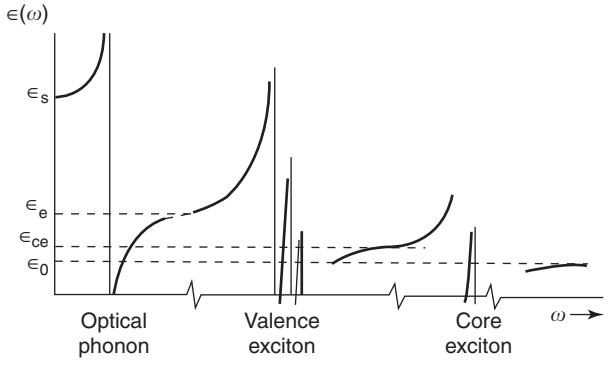

Figure 4 Typical dispersion of dielectric constant $\varepsilon(\omega)$ of an ionic crystal. At frequencies far higher than those of optical phonons but a little below the bandgap, dispersion appears due to excitons associated with the valence band hole. At even higher frequencies, dispersions appear due to excitons associated with the inner shell holes. (Reproduced with permission from Toyozawa Y (2003) *Optical Processes in Solids*. materials in which (1) is insignificant and (2) is impossible because of insufficient energy of electronic recombination against the ionization of valence electrons. Whether the optical spectrum belongs to the band edge allowed or forbidden type, depends on the symmetry of the inner atomic state. The electron–hole exchange energy with its possible interplay with spin–orbit interaction appears here in the same way as before.

Typical dielectric dispersion in the entire ω-region of an ionic crystal is shown schematically in **Figure 4**, in the idealistic situation of no damping (vanishing line width).

Integrated Circuits

M Van Rossum, IMEC, Leuven, Belgium

Introduction

The performance of a complex electronic circuit usually scales with the number of its components. In the early days of electronics, circuits were bulky assemblies of vacuum valves (invented by Lee de Forest in 1906), resistors, and capacitors fixed on a metal frame, and connected with soldered copper wires. The invention of the transistor by Bardeen, Brattain, and Shockley in 1947 already contained the seed of further circuit miniaturization, but it would take more than 10 years before this potential was fully recognized. In 1959, Jack Kilby from Texas Instruments and Robert Noyce from Fairchild independently filed patents for an electronic circuit whose components were fabricated on a single piece of semiconductor material (germanium for Kilby and silicon for Noyce). Kilby's circuit measured 0.2×0.8 inches and had 12 components, connected together with tiny gold wires. To quote his own words, "what we didn't realize then was that the integrated circuit would reduce the cost of electronic functions by a factor of a million to one, nothing had ever done that for anything before." Today, integrated circuits (ICs) may contain tens of millions of transistors per square centimeter. Jack Kilby received the Nobel prize for his invention in 2000 (**Figure 1**).

IC Materials

The vast majority of ICs are fabricated on single crystal silicon. Although not the best semiconductor material, silicon is still unrivaled thanks to its crystalline perfection, its excellent combination of electrical and thermomechanical properties, as well as the outstanding quality of its natural oxide, SiO_2. For some low-cost applications where data speed is not an issue, polycrystalline silicon films deposited on glass can also be used. The most recent IC technology is silicon-on-insulator (SOI), which consists of a thin monocrystalline silicon film, isolated from the bulk silicon substrate by an intercalated SiO_2 layer.

Over the years, other substrate materials have found a role in niche technologies, targeting applications for which silicon is not the optimal choice. The most important IC technology after silicon is based on III–V compound semiconductors. Prominent among them is gallium arsenide (GaAs), which is a better semiconductor than silicon although less robust from a manufacturing point of view. Due to its high electron mobility and high bulk resistivity, it is the substrate of choice for high-frequency circuits. As a direct bandgap material, gallium arsenide is also an efficient light emitter and therefore well suited for optoelectronic devices, a domain where silicon cannot compete since its own bandgap is indirect. GaAs can be combined with indium, phosphorous, or antimony to tune the band structure for specific applications. Indium phosphide (InP), another III–V compound, is a convenient substrate for many epitaxial films made from ternary or even quaternary III–V alloys. A new player in this area is gallium nitride (GaN), well-suited for power electronics and optoelectronics. GaN is not available as a bulk substrate and must be grown on sapphire or silicon carbide (SiC). Together with SiC and diamond, it belongs to a special class of wide bandgap semiconductors, which are fit for high-voltage device fabrication. However, their present materials quality is lagging far behind silicon and the commercial future of these technologies is still unclear.

IC substrates are usually produced as circular wafers, a few hundred micrometers in thickness, cut from as-grown cylindrical ingots of various diameters. Silicon wafers are commercially available with diameters up to 300 mm, whereas other semiconductor substrates are significantly smaller. Silicon ICs can be classified into two groups based on the type of transistors they contain. Bipolar circuits use bipolar junction transistors as their principle elements. Metal oxide semiconductor ICs contain mainly *n*- and *p*-type metal-oxide semiconductor field-effect transistor (MOSFET) as their active components and are the dominant technology for logic circuits (i.e., processors and memories, also called digital circuits). Today, the most common architecture for digital electronics is complementary MOS (CMOS), which uses a combination of a *p*-MOSFET and *n*-MOSFET as its basic device to minimize the power consumption during switching.

IC Technology

The making of an IC typically proceeds through three standard stages: (1) fabricating individual devices, (2) wiring the devices together to form the circuit, and (3) encapsulating the IC in a package. The full sequence of the fabrication steps required to produce a complete circuit is called the process flow. Different IC technologies therefore require different process flows. In the following, the focus will be on CMOS technology because of its dominant position in the IC market.

Device Fabrication

Starting from a clean substrate, the first stage of IC fabrication – commonly called front-end process – is to form individual devices. The devices are produced through several levels of patterning, each level consisting of a well-defined combination of photolithography, deposition and etching steps. For a MOSFET, the typical front-end sequence is the following:

1. doping and isolation of the transistor wells and junctions
2. growth of the gate insulator
3. patterning of the gate electrode
4. formation of the metal contacts

In total, a CMOS process may require several hundred individual steps. The most important ones are outlined below.

The transistor well The well is the region of the substrate containing the transistor body. Since current must pass through the device, the well must be doped to provide charge carriers (electrons or holes). After the device area has been delineated by photolithography and isolated from its surroundings by thin grooves (so-called shallow trenches), etched into the substrate and filled with a dielectric material, dopants are introduced into the well region. For *n*-type MOSFETs, the well must be *p*-doped whereas *p*-MOSFETs need *n*-doped wells. In the early days of MOS technology, diffusion of impurities from a gaseous or solid-state source was the standard doping technique. However, with present deep-submicron device dimensions, this method has been replaced by ion implantation, which offers far better flexibility, precision and depth control. Ions of boron (for *p*-type), phosphorous or arsenic (for *n*-type) are accelerated by an electric field and gain a kinetic energy of a few tens of kiloelectronvolts, allowing them to penetrate some hundred nanometers into the substrate. Several implantation steps are usually required to reach the desired dopant profile. The as-implanted region has high electrical resistance due to the radiation-induced lattice damage, which can range from isolated point defects to complete amorphization. The high defect density prevents the dopants from occupying substitutional lattice sites, thereby leaving them electrically inactive. In order to activate the dopants, damage must be removed by a high-temperature annealing step (typically between 800 and 1000°C). This can be done in a conventional furnace, but a short thermal pulse produced by halogen lamps (the so-called rapid thermal process or RTP) is often preferred in order to minimize the motion of the implanted species during annealing.

The gate insulator The thinnest feature of the transistor is the gate insulator, which consists of a few nm of silicon dioxide (SiO_2) deposited directly on top of the transistor well. The gate oxide is formed by thermal oxidation of the silicon surface, which involves heating the substrate above 900°C in an oxygen atmosphere (dry oxidation) or a mixture of oxygen and water (wet oxidation). Trace amounts of other gases are often added to improve the electrical quality of the oxide. Both the temperature gradients and the gas flow pattern in the furnace must be accurately controlled to obtain a very thin and uniform oxide. Short thermal pulses produced by rapid thermal processing can also be used. Although the as-grown oxide layer is structurally amorphous, the high quality of its chemical bonds with the silicon surface limits the density of interface defects to very low levels (less than $10^{10}\,\mathrm{cm}^{-2}$). The quality of the gate oxide and of the Si/SiO_2 interface is a crucial factor to ensure the good electrical behavior of the MOSFET. However, there are now indications that further shrinking of the devices will push SiO_2 toward its application limit. For very thin oxides, direct carrier tunneling through the gate insulator produces a sizable current leakage and unwanted power dissipation. This problem can, in principle, be overcome by introducing "high-*k* insulators," that is, gate dielectrics with a higher polarizability than SiO_2. These materials would allow the physical thickness of the insulator to increase (thereby keeping tunneling currents at an acceptable level), while maintaining a strong capacitive coupling between the gate and the channel. At this time, refractory metal oxides such as HfO_2 as well as some ferroelectrics are potential candidates for replacing silicon dioxide in future ICs.

Gate, source, and drain The gate electrode sits on top of the oxide and regulates the current inside the transistor channel. It is made of doped polycrystalline silicon (usually designated as "poly"), which is a reasonably good conductor and can be patterned into very narrow lines. Today, the most advanced commercial transistors have a physical gate length of $\sim 50\,\mathrm{nm}$. Since the gate is the narrowest feature on any IC, its formation involves the most demanding steps of the front-end process flow. First, a blanket layer of poly is deposited by chemical vapor deposition (CVD), after which the gate fingers are defined by a lithography step and patterned by dry etching. In order to achieve the right threshold voltage for the transistor, the poly-gate on the NMOS is *n*-doped whereas on PMOS it is *p*-doped. Both doping steps

are performed by ion implantation and annealing. In a MOSFET, the current input and output electrodes are called source and drain. They are defined by local implantation of complementary doping species (*n* for *p*-well and *p* for *n*-well) very close to the surface, thereby forming shallow *p–n* or *n–p* junctions, depending on the transistor type. Fine-tuning of the junction profiles requires additional implantation steps followed by annealing.

Contacts Metals are needed for electrical contacts to the three device electrodes. The contact material must exhibit low electrical resistance and be chemically compatible with silicon in order to avoid interface degradation over time. For many years, metal silicides have been used extensively on the source and the drain: first titanium disilicide ($TiSi_2$), and more recently cobalt disilicide ($CoSi_2$) and nickel monosilicide (NiSi). The silicide layers are formed by solid-state reaction of a deposited metal film with the underlying silicon; therefore, it is important that the reaction should not consume too much silicon. In the same way, a polycrystalline silicide layer or polycide is formed on top of the poly in order to contact the gate electrode and to reduce the gate series resistance (**Figures 2** and **3**).

Interconnects

Connecting the individual transistors is an essential step in the production of an IC. The process flow needed for interconnect fabrication is called the back-end sequence. Since the early days of IC technology, aluminum-based alloys have been used as the interconnect metal. This choice was dictated by the low resistivity of aluminum, its high ductility, easy etching behavior, and good coverage of nonplanar geometries. The latter property is particularly important, since complex ICs normally require many levels of wiring stacked on top of each other, giving rise to a multilayer structure called the multilevel interconnect scheme. To improve the electrical reliability of the wires, particularly with respect to electromigration, aluminum–silicon and aluminum–silicon–copper alloys are preferred over pure aluminum. However, in the late nineties the series resistance of aluminum-based lines became a bottleneck for circuit performance. After more than 30 years of use, the aluminum wires were finally abandoned in favor of a copper-based metallization scheme. Copper conducts about 60% better than aluminum, but patterning it into submicron wires is difficult because traditional plasma etch techniques do not work on copper. A novel process called "damascene" had to be introduced, due to its similarity with the well-known metal inlaid technique that goes back to the Middle Ages. Following this process, the conductor wires are embedded in a dielectric film deposited on the silicon substrate or on a previous interconnect layer. Copper lines are formed by electroplating the metal inside preformed trenches, which have been etched into the dielectric. The formation of a multilevel damascene scheme requires special polishing techniques (called chemical mechanical polishing or CMP) to planarize each interconnect layer by removing the excess metal outside the trenches (**Figure 4**).

Packaging

Packaging the IC serves a twofold purpose: to protect the chip against mechanical damage and corrosion, and to provide electrical connections with the outside circuitry. An IC package consists of a sealed box which is either from ceramic material (for hermetic sealing) or from a plastic mold (for low-cost packaging). Metallic pins are attached to the base plate of the package, to be inserted in the printed circuit board. After completing the back-end process, the backside of the chip is fixed to the package base plate using a conductive paste or metal solder. Next, the bonding pads of the chip are connected to the package pins. The most common technique is wire bonding: thin aluminum or gold wires are thermally bonded to the IC pads and to the pins, sometimes with the help of ultrasonic vibrations. Wire bonding is cheap and reliable, but cannot handle the increasing density of bonding pads in the most recent IC generations. Flip-chip bonding is now an increasingly popular alternative. Microscopic solder balls are first deposited on the IC bonding pads. The chip is then positioned face down to the package base plate, so that the solder balls can be attached directly to the pin pads. Since this method does not use wires, it offers both higher connection density and better reliability than the traditional bonding schemes. After wiring, the upper lid of the package is sealed or molded to the base plate for final encapsulation (**Figure 5**).

Processing Techniques

Photolithography

Photolithography uses a beam of photons to transfer a pattern written on an optical mask to the substrate surface. In a complex IC process, a wafer will go through the photolithographic step in the order of 20–30 times. Photolithography is, therefore, the key technology of IC fabrication and an essential driver behind the miniaturization trend commonly known

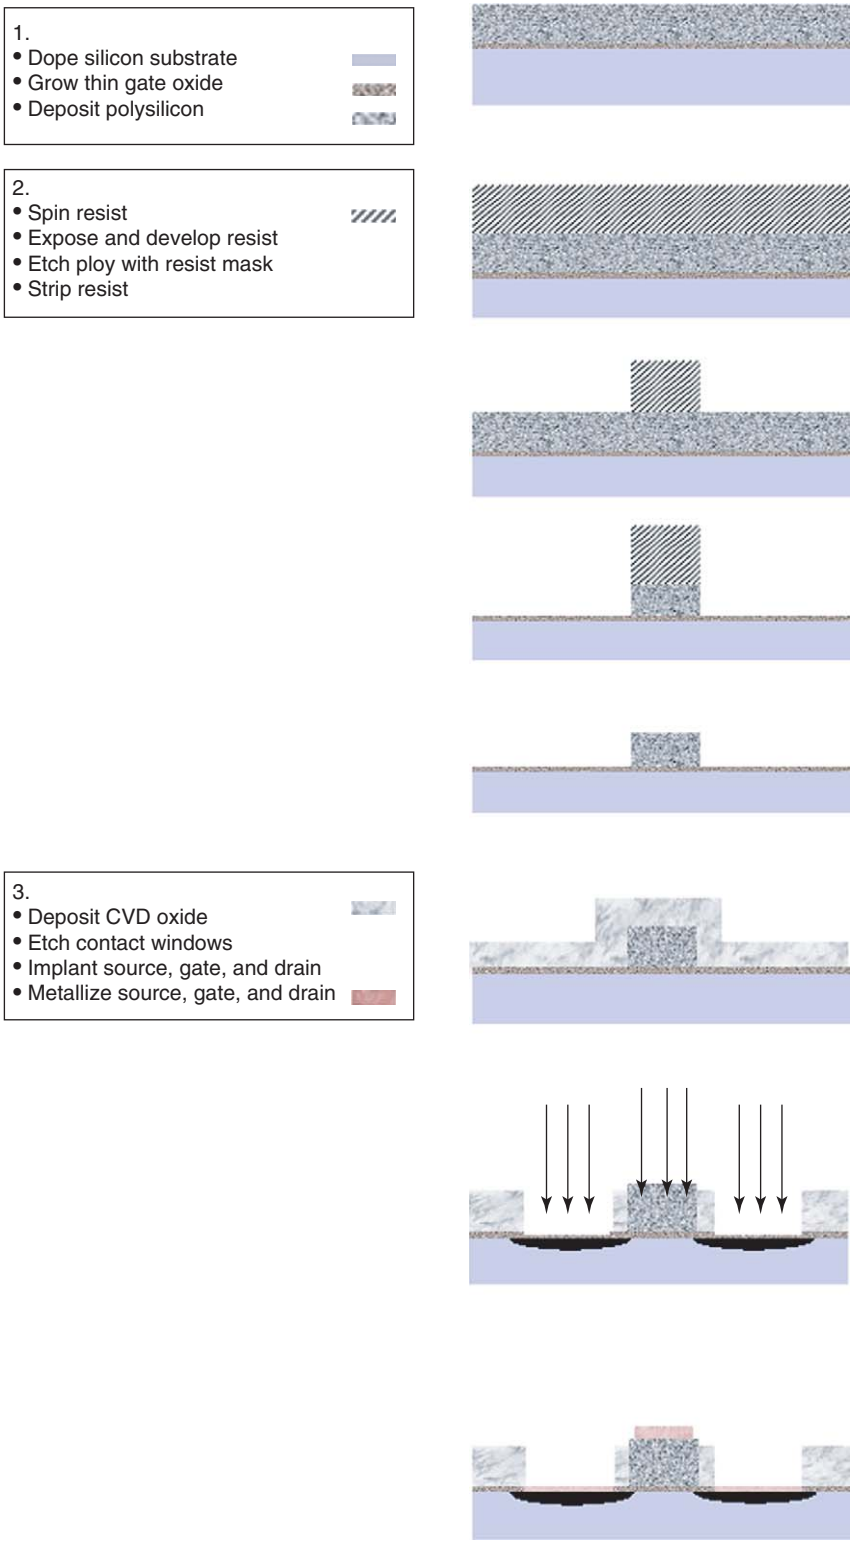

Figure 2 Schematic process flow for an MOS transistor.

as Moore's law. It was introduced almost simultaneously with the invention of the IC in 1959, but in the meantime, the minimum dimensions on the masks have decreased by several orders of magnitude, forcing continuous improvement in lithography tools and processes.

A standard lithography sequence involves a large number of steps. The wafer is initially cleaned and

heated to remove any moisture from its surface. After deposition of an adhesion promotor, a liquid polymer called photoresist is spun on the surface while the wafer is kept rotating at high speed. After a thermal bake-out, the substrate is introduced in an optical projection tool called stepper/scanner. A light beam passing through the mask is focused on the wafer through a reduction lens system to produce the desired image in the photoresist. In order to achieve high resolution, only a small portion of the mask is imaged once, but the small image field is repeated over the surface of the wafer by a combination of stepping and scanning operations. During exposure, the photoresist material undergoes some light-triggered chemical reactions, which cause the illuminated regions to be either more or less acidic. If they become more acidic, the material is called a positive

photoresist, while in the reverse case it is a negative photoresist. The resist is then developed in an alkali solution such as sodium hydroxide (NaOH), which removes either the exposed (positive photoresist) or the unexposed (negative photoresist) polymer. After development, the wafer is finally "hardbaked" at high temperature in order to solidify the remaining photoresist. The resist can then be used as a patterning mask for etching, deposition or implantation. After patterning, the resist is stripped from the wafer with appropriate solvents.

The optical resolution of the lithography system is the main factor determining the smallest device size that can be fabricated at any time. The ability to form a clear image of a very small feature is limited by the wavelength of the light and the ability of the lens system to capture enough diffraction orders of the illuminated mask. Although theoretically the Rayleigh diffraction limit determines the maximal achievable resolution, in practice, it is possible to use special (but costly) tricks called resolution enhancement techniques that improve resolution beyond the Rayleigh limit by a factor of 2 or more. Current state-of-the-art photolithography tools use deep ultraviolet light (DUV) with wavelengths of 248 and 193 nm, allowing feature sizes below 100 nm to be printed with good yield. Extreme ultraviolet (EUV) systems using 13 nm radiation are presently under development for introduction by the end of this decade. Because such short wavelength radiation cannot be diffracted by lens systems or absorbed by bulk masks, the EUV technology will require a transition from diffractive to fully reflective optics.

Dry Etching

The aim of the etching process is to remove material from the IC surface in the areas left uncovered after photoresist development. For most patterning steps, dry (plasma) etching is now the standard procedure, while "wet" etching using liquid chemicals is still used to clean wafers. The main advantage of dry etching is its ability to achieve sharp etch profiles with nearly vertical sidewalls. This creates features with a high aspect ratio, as required by the relentless miniaturization of the circuit elements. A hot plasma formed by RF excitation of a neutral gas species is directed on the wafer by a static electric field. The radicals in the gas react with the substrate material to form volatile byproducts which are either evacuated from the etch chamber or deposited on the chamber walls. The mixture normally consists of a hydrogenated hydrocarbon diluted in an inert gas. However, the gas composition depends on the material to be etched, and will be different for silicon, metals or SiO_2. The strength of the DC field also plays a role in the etch process. A strong field increases the kinetic energy of the ions, and therefore enhances the amount of physical etching, which depends on mechanical sputtering. On the other hand, low-energy ions will act essentially by chemical etching, which proceeds through surface reactions resulting in smoother patterns. In this way, the etching mechanism can be tuned to optimize the shape of the patterned structures.

Deposition Techniques

PVD In standard silicon processing, physical vapor deposition (PVD) uses target sputtering rather than target evaporation because of its better step coverage. For aluminum interconnect layers, plasma-induced sputtering is the most convenient technique. The sputtered metal lands on the wafer surface where it forms a thin metal film, which can be further etched into wires. The film thickness is proportional to the width of the conductor lines, and usually lies in the range of a few hundred nanometers. Plasma sputtering can also be employed to deposit nonmetallic layers, especially insulators, although for the latter, CVD is the preferred method.

CVD Chemical vapor deposition is a process by which a thin film is deposited on a substrate by chemical reaction in a gas at an elevated temperature. If required, the reaction temperature can be lower by using plasma-enhanced CVD (PECVD). Over the years, CVD has become very popular due to its versatility, speed of deposition, and excellent step coverage. CVD can be used for metal, semiconductor, and insulating films. The structure of the deposited film can be monocrystalline, polycrystalline, or amorphous. The lattice structure depends primarily on the substrate, the reaction rate, and the temperature. Selective deposition is also possible, by choosing precursor gases that react preferentially with specific surfaces. CVD is the preferred method to deposit polycrystalline silicon, as well as various types of oxide films used for isolation of the interconnect layers. These interlayer dielectrics are grown by CVD at low pressure (LPCVD). Thin metallic layers such as titanium nitride (TiN), which are used as seed layers for copper electroplating or as a seal between the interlayer dielectrics, are also deposited by CVD.

Epitaxy Epitaxy is a process by which a deposited film is forced into a high degree of crystallographic alignment with the substrate lattice. Several epitaxy techniques are now available, such as molecular beam epitaxy (MBE), epitaxial CVD, or atomic layer

epitaxy (ALE). In all cases, the deposition process must be slow enough to allow the atoms to rearrange themselves on the surface according to the lattice orientation of the substrate. Contamination of the surface by impurities must be kept minimal, since it will disturb the epitaxial alignment. Epitaxial layers are now widely used in IC technology and the number of applications is still growing. In the early days, the epitaxy process was limited to deposition of silicon on silicon (homoepitaxy). Today, an increasing number of devices require thin film heteroepitaxy, for example, growing a binary alloy such as silicon–germanium (SiGe) epitaxially on the silicon wafer. For layers with high Ge concentration, the epitaxy is made difficult by the lattice mismatch between the substrate and the thin film. However, using appropriate techniques, the epitaxial layer can be grown pseudomorphically, meaning that the distance between the film atoms will adapt itself spontaneously to the bond length of the substrate material.

Physics of Integrated Circuits

Integration Density: Moore's Law

Moore's original statement, made in 1965, was modestly presented as an educated guess at the expected development of ICs over the next ten years. Or, to put it in his own words: "With unit cost falling as the number of components per circuit rises, by 1975 economics may dictate squeezing as many as 65.000 components on a single silicon chip" (see Further Reading Section). Almost four decades later, unit cost is still falling with the number of components, and as long as this favorable trend persists, the "law" will remain firmly in place. The continuation of Moore's law is made possible by the relentless shrinking of the MOSFET dimensions. Now, spanning more than two orders of magnitude, the downscaling of the MOSFET is a truly unique occurrence in the history of technology. The physical base for this miniaturization is a set of scaling rules defined some years after Moore's initial paper. In essence, the scaling algorithms tell us that the transistor performance (mainly its gate delay time and overall power dissipation) will improve with decreasing dimensions, provided the rules are properly applied. However, a point has been reached where the presence of nonscaling quantities such as the thermal voltage kT/q and the semiconductor bandgap (together with some others) can no longer be neglected. These nonscaling parameters are giving rise to so-called "short-channel" effects, such as threshold voltage shifts and many others, which tend to degrade the transistor switching speed and lower its power efficiency. These disturbing effects can be acted upon with specific counter-measures, partly technological and partly design-related. Up to now, device engineers have been remarkably successful in alleviating the negative impact of short-channel effects. However, it appears increasingly difficult to define a universal approach similar to the early scaling laws, and a certain amount of specialization in the circuit technologies (such as distinguishing between high-speed and low-power applications) is becoming unavoidable.

Speed and Power

Power and speed issues are strongly linked by the scaling rules. The width, length, and gate oxide thickness all scale roughly equally by a common factor. Therefore, the primary effect of the device scaling is to reduce all the capacitances, which provides a proportional decrease in power consumption and RC delays. However, not all the vertical dimensions of the circuit scale down by the same factor. In particular, the thickness of the interconnect lines cannot change as fast due to fundamental technology limitations. This increases the fringe capacitance from the metal side to the substrate, as well as the capacitance between adjacent line segments. Compounding this problem, the decreasing wire width raises the series resistance of the lines. As a result, RC delays in the lines tend to become more important with respect to transistor delays. This can be counteracted by optimizing the interconnect layout, and by introducing low-k dielectrics as the insulating layers between the copper wires.

The scaling rules also impact on the power consumption of the IC. There are two main sources of power dissipation: dynamic switching power due to the charging and discharging circuit capacitances, and static dissipation from leakage currents. When CMOS devices switch, the output is either charged up to the transistor bias voltage, or discharged down to the ground. The power dissipated during switching is therefore proportional to the switching speed and to the capacitive load. Decreasing the clock frequency of the circuit is, therefore, an efficient way to lower the dynamic power consumption.

Static power dissipation is linked with two types of leakage currents: reverse-bias diode leakage on the transistor drains, and subthreshold leakage through the channel when the transistor is turned off. Diode leakage must be tackled through process optimization, mainly by improving the quality of the junctions. Subthreshold current is a more complex issue. The process parameter that predominantly affects its value is the threshold voltage, since reducing the latter exponentially increases the subthreshold current.

Static power dissipation can, however, be reduced by shrinking the transistor size, and by lowering the supply voltage.

Applications

Most ICs belong to one of three main categories: memories, microprocessors, and custom ICs.

Memories

Random-access memory (RAM) A type of computer memory that can be accessed randomly; that is, any byte of memory can be accessed without disturbing the other bytes. RAM is the most common type of memory found in computers and other information processing devices. There are two basic types of RAM: dynamic RAM (DRAM) and static RAM (SRAM). Both are volatile memories, meaning that they lose their contents when the electrical power is turned off. RAM circuits are organized in cells, with each cell storing a binary 1 or 0. DRAM cells are very simple, consisting basically of one transistor and one capacitor for charge storage. Because this capacitor leaks, a DRAM needs to be refreshed thousands of times per second. This makes DRAM relatively slow and power-hungry. However, due to the small cell size, DRAM is best-suited for high-density storage (**Figure 6**). SRAMs are more complex, with 4–6 transistors per cell, providing a stable storage, which does not need to be refreshed. SRAM is very fast and power-efficient, but the complexity of its cell makes it much more expensive than DRAM. Due to its high cost, SRAM is used mainly as a memory cache.

Read-only memory (ROM) Computers almost always contain a read-only memory that holds instructions to boot the operating system and perform diagnostics. ROM is nonvolatile, that is, it does not need electrical power to keep its data stored. Like RAM, ROM memories are random-access, but they cannot change their content during the computer operation. However, some types of ROM allow changing the content by special procedures. The most common ones are erasable programmable read-only memory (EPROM), electrically erasable programmable read-only memory (EEPROM) and FLASH EEPROM. FLASH (not an acronym) memories, which store the information bits in a second transistor gate called the floating gate, have become increasingly popular in recent years. They can be erased and reprogrammed in blocks instead of one byte at a time, which is faster and less power consuming than other EEPROMs. PCs have their basic input-output system (BIOS) stored on a flash memory chip so that it can easily be updated if necessary. Flash memory is also very common in communication appliances and portable devices such as cellular phones and smartcards.

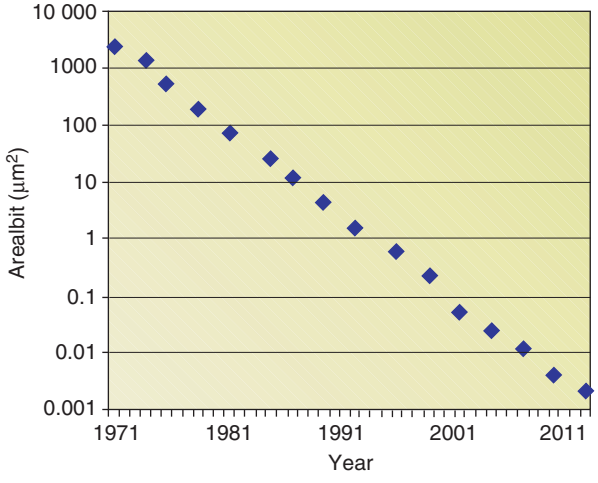

Figure 6 Moore's law in action: evolution of the chip area / bit for a standard DRAM memory cell.

Microprocessors and Custom ICs

Microprocessors Also called central processing unit (CPU), microprocessors are ICs that can execute instructions by running a software program. Although computer microprocessors have become a benchmark for the IC industry, they only represent a small part (~2% in unit sales) of the total CPU market. By far, the largest, by number, are the embedded microprocessors (also called microcontrollers), which can be found in many consumer products, ranging from toys to automobiles.

Custom ICs In contrast to standard memories and microprocessors, custom ICs are specially designed for specific product applications. The main types are:

- *Application-specific ICs (ASICs)*. They are meant to achieve optimal performance in terms of speed and/or power consumption. ASICs are custom-designed for a specific application, either full custom (meaning that the design is made from scratch) or starting from standard cells or gate arrays, where the designers can take advantage of pre-existing blocks.
- *Field-programmable chips*. These are special chips that can be reconfigured by the customer. The most popular ones are field-programmable gate arrays (FPGAs). Their circuits are diced into regular arrays, which can be disconnected by blowing microscopic fuses. In this way, the desired functionality is "burned into" the IC. This process is reversible, meaning that the original connections can be

restored and a new pattern burned. Although FPGAs are usually slower and less power-efficient than ASICs, they have become very popular due to their flexibility and ease of programming.

- *Analog/RF ICs*. Even if digital signal processing today represents the largest market for the semiconductor industry, there is also a wide variety of ICs handling analog and high-frequency signals. Some chips process both digital and analog information and are called mixed-mode ICs. Typical applications are amplifiers, mixers, multiplexers, and analog-to-digital converters. Wireless communication devices make heavy use of these components, which can be found in every cellular phone set.

Interaction of Light and Matter

G Nienhuis, Universiteit Leiden, Leiden, The Netherlands

Introduction

Light is electromagnetic radiation in the visible part of the spectrum. Radiation and matter are the main physical objects in the world. Their behavior is described by electromagnetism and mechanics, with Maxwell's equations and Newton's laws as basic ingredients. Radiation is the only means by which one can obtain information on the remote parts of the universe. In general, without interaction between light and matter, the world would not only be invisible, but dead as well. Radiation from the Sun is by far the main source of energy on Earth, and serves as the basis of life. This energy source is tapped by the process of photosynthesis, which starts out as the interaction of photons with individual molecules. The interaction of light and matter is discussed both at the microscopic level of atoms and molecules, and at the macroscopic level, in terms of the optical properties of materials.

Transition Driven by Broadband Light

Atoms and molecules have discrete energy levels, as a result of the quantum-mechanical nature of the motion of the electrons. Consider atoms with a lower level 1 and an upper level 2, with an energy separation $E_2 - E_1 = \hbar\omega_0$, with ω_0 the transition frequency. The atoms are driven by a light field that is nearly resonant with the transition $1 \leftrightarrow 2$, which means that the frequency ω of the field is close to the transition frequency. Then the two levels are coupled by the light field. When the atom is initially in state 1, it will start oscillating in a linear superposition of the states 1 and 2. For a conventional light source, with a broad spectrum, Einstein argued that the atom can make three types of transitions between the states, each one at a fixed rate. An atom in the lower state 1 can become excited while absorbing a photon, at a rate BIn_1 that is proportional to the intensity per unit frequency I (also called the spectral intensity). An atom in the upper state 2 can go spontaneously to the lower state at a rate An_2, while emitting a photon. However, using arguments of thermal equilibrium, Einstein showed that emission of a photon must also occur in a stimulated way, at a rate BIn_2 that is also proportional to the spectral intensity. The emitted photon will have the same properties (frequency and propagation direction) as the photons in the incident beam. The coefficient A is called the Einstein coefficient for spontaneous emission, and B is the Einstein coefficient for stimulated transitions. These coefficients are properties of the atom, and also depend on the specific transition. The transitions in the energy level scheme are sketched in **Figure 1**.

As a result of these considerations, the number of atoms n_1 and n_2 in the states 1 and 2 must obey the rate equations

$$\frac{\mathrm{d}}{\mathrm{d}t}n_2 = -\frac{\mathrm{d}}{\mathrm{d}t}n_1 = BI(n_1 - n_2) - An_2 \qquad [1]$$

The three terms on the right-hand side describe absorption, stimulated emission, and spontaneous

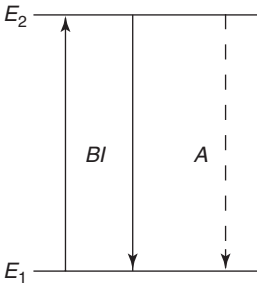

Figure 1 Energy level scheme of two states of an atom. The indicated transitions are absorption and stimulated emission (solid lines) at a rate BI, and spontaneous emission (dashed line) at rate A.

emission. Radiative transitions correspond to the creation or annihilation of photons. At absorption, a photon disappears from the light beam, whereas stimulated emission adds a photon to the beam. Therefore, the net rate of absorption of photons from the beam (direct absorption minus stimulated emission) is equal to $N_A = BI(n_1 - n_2)$. Spontaneously emitted photons can go in all directions, at a rate $N_E = An_2$. The balance between the number of excited atoms and the number of photons is best seen when the above equation is written as $dn_2/dt = N_A - N_E$. The efficiency of absorption as compared to spontaneous emission is measured by the ratio $s = BI/A$, which is called the saturation parameter.

When initially all atoms are in the lower state, the time-dependent solution for the populations of the two states are

$$\begin{aligned} n_1(t) &= \frac{n}{1+2s}[1 + s(1 + e^{-(1+2s)At)})] \\ n_2(t) &= \frac{ns}{1+2s}[1 - e^{-A(1+2s)t}] \end{aligned} \qquad [2]$$

with $n = n_1 + n_2$ the total number of atoms. It is seen that the populations approach their steady-state value exponentially. These expressions also hold for a single atom. Then the populations n_1 and n_2 must be interpreted as the probabilities that the atom is in the state 1 or 2. In this case, $n = n_1 + n_2 = 1$. Then the steady-state values are given by $n_2 = 1 - n_1 = s/(1 + 2s)$, which approaches the maximal value 1/2 for high intensity.

Transition Driven by Monochromatic Light

In modern optics, broadband light sources are commonly replaced by lasers, with a coherent and practically monochromatic output. Then the dynamics of the driven transition is quite different. The strength of the atom–field coupling is indicated by the product of the amplitude of the oscillating electric field of the light and the electric dipole moment of the transition. This product (which is an energy) is expressed as $\hbar\Omega$, so that Ω is a frequency, commonly called the Rabi frequency. Quantum mechanically, the state of a single two-level system is described by a wave function ψ, which is a linear superposition $\alpha_1\psi_1 + \alpha_2\psi_2$ of the wave functions ψ_1 and ψ_2 corresponding to the two states. The populations are $n_1 = \alpha_1\alpha_1^*$ and $n_2 = \alpha_2\alpha_2^*$. The product $\sigma_+ = \alpha_2\alpha_1^* = \sigma_-^*$, which is called the optical coherence of the atom, also has a direct physical significance, since it is proportional to the oscillating electric dipole induced by the field. The coupling between this dipole and the electric field determines the work that the field exerts on the atom, which is related to the net absorbed power. For monochromatic light, the behavior of the population and the coherence is given by the coupled equations

$$\begin{aligned} \frac{d}{dt}n_2 &= -\frac{d}{dt}n_1 = -An_2 + \frac{i}{2}\Omega(\sigma_+ - \sigma_-) \\ \frac{d}{dt}\sigma_+ &= -\left(\frac{1}{2}A - i\Delta\right)\sigma_+ + \frac{i}{2}\Omega(n_1 - n_2) \end{aligned} \qquad [3]$$

where $\Delta = \omega - \omega_0$ is the frequency detuning of the light from atomic resonance.

For monochromatic driving light, these equations [3] replace the rate equations [1] above. They closely resemble the Bloch equations for the behavior of a magnetic dipole in an oscillating magnetic field, as it appears in the theory of (nuclear or electronic) magnetic resonance. In analogy, the present equations are often called the optical Bloch equations. The steady state for the populations obeys the same expressions $n_2 = 1 - n_1 = s/(1 + 2s)$ as in the broadband case, provided that the saturation parameter is now defined as $s = \Omega^2/(A^2 + 4\Delta^2)$. Since s is proportional to Ω^2, it is also proportional to the square of the field amplitude, and thereby proportional to the intensity I. The variation of this parameter with the frequency ω reflects the absorption profile of the atom, with its maximum at atomic resonance. Even though the steady-state populations have the same form as in the broadband case, the way in which n_1 and n_2 approach their steady-state value is quite different in these two cases. For monochromatic radiation, the exponential behavior of eqn [2] is replaced by a damped oscillatory behavior (Rabi oscillations). A comparison of the approach to the steady state for monochromatic and broadband excitation is shown in **Figure 2**. When $\Omega \gg A$, that is, for strong saturation, the excited-state population is well approximated by the expression

$$n_2(t) = \tfrac{1}{2}[1 - e^{-3At/4}\cos(\Omega t)]$$

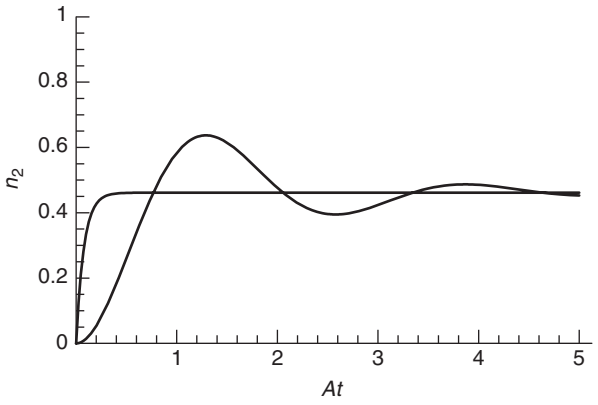

Figure 2 Time dependence of excited-state population in a broadband field (monotonic curve) and a monochromatic field (oscillating curve) at resonance. The saturation parameter amounts to $s = 6$ in both cases.

whereas for broadband radiation one finds from eqn [2] that $n_2(t) = [1 - \exp(-2Ast)]/2$.

The equations so far hold for a closed transition, where no other states than these two get populated. In practice, the population of the upper level can get transferred to many different states, in particular, for systems more complex than atoms. This leads to all kinds of radiative or radiation-free decay processes, with the final result that the absorbed light energy gets transformed in other forms of energy. But also for atoms the simple picture given above is a simplification, since an energy level is usually composed of a number of substates, which can be selectively addressed by light with a specific polarization. Moreover, at high intensities, transitions can occur under the absorption of two or more light quanta at the same time, so that light with a frequency ω can excite a transition with a transition frequency in the neighborhood of 2ω.

Propagation of Light in Gas Medium

When light with a frequency ω propagates through a dielectric medium, the electric field at each position induces a density of electric dipole moment, which is called the dielectric polarization $\boldsymbol{p}$. For not too high intensities, saturation can be ignored, and the polarization is proportional to the electric field. Then the dielectric medium is said to be linear. However, as seen above, the proportionality constant can depend strongly on the frequency ω, in particular, when this is near an atomic resonance frequency ω_0. When the electric field is expressed in the form of a plane wave as $\boldsymbol{E}(z,t) = 2\ \mathrm{Re}\ \boldsymbol{E}_0 \mathrm{e}^{\mathrm{i}kz - \mathrm{i}\omega t}$, and the polarization as $\boldsymbol{P}(z,t) = 2\ \mathrm{Re}\ \boldsymbol{P}_0 \mathrm{e}^{\mathrm{i}kz - \mathrm{i}\omega t}$, the response of the medium to the field is expressed as $\boldsymbol{P}_0 = \varepsilon_0 \chi(\omega) \boldsymbol{E}_0$, with χ the frequency-dependent susceptibility of the medium. For a dilute gas, the polarization is just the sum of the induced dipoles of the individual atoms. From the optical Bloch equations, one finds the electric dipole moment of each atom, and multiplication with the atom density ρ gives the polarization $\boldsymbol{P}$. This gives the expression

$$\chi(\omega) = -\varrho|\mu|^2 \frac{1}{\varepsilon_0 \hbar} \frac{1}{\Delta + iA/2}$$

with μ the strength of the atomic transition dipole. This expression is reliable near resonance, when the detuning Δ is small compared with the frequency ω. The susceptibility can be separated in its real and imaginary part, as $\chi = \chi_1 + \mathrm{i}\chi_2$. The presence of an imaginary part indicates that $\boldsymbol{E}$ and $\boldsymbol{P}$ are not in phase, so that the field exerts work on the medium, and the light intensity cannot be constant. Maxwell's equations show that the frequency ω and the wave number k are related by the dispersion relation $c^2k^2 = \omega^2(1 + \chi(\omega))$, with c the velocity of light in vacuum. The factor $1 + \chi = (n + \mathrm{i}\kappa)^2$ serves as the square of a complex refractive index. For a real frequency ω, the wave number $k = (n + \mathrm{i}\kappa)\omega/c$ is complex, and the field $\boldsymbol{E}$ decays as a function of z as $\exp(-\omega\kappa z/c)$. An incident beam loses energy while propagating through the medium, and the intensity I (which is proportional to the absolute square of the field amplitude) decreases as $\exp(-2\omega\kappa z/c)$. This is the solution of Beer's law of absorption $\mathrm{d}I/\mathrm{d}z = -\alpha_0 I$, with $\alpha_0 = 2\omega\kappa/c$ the unsaturated absorption coefficient.

For an atomic vapor, the loss factor κ is proportional to the absorption profile of the atoms. The absorbed energy is reemitted in the form of fluorescence radiation. For more complex media, the absorbed energy can be dissipated by all kinds of radiative or nonradiative ways, and turned into heat, or stored in some form of chemical energy.

When the light drives a transition where the population of the upper state n_2 is higher than n_1, the work exerted on the medium by the field is negative, so that the field actually gains energy. This is the situation of population inversion, which cannot occur in thermal equilibrium. It requires a pump mechanism to feed atoms in the upper state 2. The result is a negative value of χ_2, and thereby of κ, and the beam grows in intensity during propagation. This is the basis of laser action, where stimulated emission on the transition outweighs absorption.

Linear Optics in Continuous Media

Matter interacting with light can often be described as a continuum. This is true provided that the

wavelength of the light is large compared with the interatomic distance. The optical properties of the medium are then characterized by macroscopic coefficients, and the electric and magnetic fields in the medium obey a version of Maxwell's equations that contain these coefficients. Dielectric materials in general have a susceptibility $\chi(\omega)$ that specifies the dielectric polarization $\boldsymbol{P}$ for a given electric field $\boldsymbol{E}$. The frequency dependence of χ indicates that the response of the medium to the field is not instantaneous, but that its time dependence can be expressed as an integral over the past

$$\boldsymbol{P}(t) = \int_0^\infty \mathrm{d}\tau\, f(\tau)\, \boldsymbol{E}(t-\tau)$$

in terms of a memory function $f(\tau)$. When a monochromatic field $\boldsymbol{E}$ is substituted, a monochromatic polarization results with the same frequency, and the susceptibility is found as

$$\varepsilon_0\chi(\omega) = \int_0^\infty \mathrm{d}\tau\, f(\tau)\mathrm{e}^{\mathrm{i}\omega\tau}$$

in terms of the Fourier transform of the memory function. The principle of causality is expressed by stating that the response of a system to an external cause cannot precede the cause in time. In the case of a dielectric response, this is expressed by the fact that the response function $f(\tau)$ vanishes for negative values of the time delay τ. Applying the elementary theory of complex functions then leads to relations between the real and imaginary part of the susceptibility, in the form

$$\chi_2(\omega) = -\frac{1}{\pi}\mathscr{P}\int_{-\infty}^{\infty} \mathrm{d}\omega' \frac{\chi_1(\omega')}{\omega'-\omega},$$
$$\chi_1(\omega) = \frac{1}{\pi}\mathscr{P}\int_{-\infty}^{\infty} \mathrm{d}\omega' \frac{\chi_2(\omega')}{\omega'-\omega}$$

with $\mathscr{P}$ indicating the principal value of the integration. The Kramers–Kronig relations, which hold for all cases of linear response, show that the real and imaginary part of the susceptibility are determined by one another. Moreover, since the response function f is real, it is easy to show that $\chi_1(-\omega) = \chi_1(\omega)$, and $\chi_2(-\omega) = -\chi_2(\omega)$, so that $\chi_1(\omega)$ is an even function of the frequency, whereas $\chi_2(\omega)$ is odd.

Due to the frequency-dependence of the susceptibility, the velocity of a light wave becomes a slightly ambiguous concept. In a wave with frequency ω and wave number k, the crests and the troughs propagate with the velocity $v_{\mathrm{ph}} = \omega/k$, which is called the phase velocity. In a medium with refractive index n, the phase velocity is $v_{\mathrm{ph}} = c/n(\omega)$. A wave packet with a finite spatial extent is not monochromatic, and it must be a superposition of waves with at least slightly varying frequencies. When the frequency distribution is centered in the neighborhood of the frequency ω_0, the packet propagates with the group velocity $v_{\mathrm{gr}} = \mathrm{d}\omega/\mathrm{d}k$, where the derivative is taken at the value ω_0. The dispersion relation $\omega n(\omega) = ck$ leads to the expression for the group velocity $v_{\mathrm{gr}} = c/n_{\mathrm{gr}}$, with $n_{\mathrm{gr}} = n + \omega \mathrm{d}n/\mathrm{d}\omega$ the group refractive index. In specific ranges of the frequency, the phase velocity can be larger than the speed of light c, but the group velocity, which is the velocity of a physical signal, must be smaller than c.

For a monochromatic field, the dielectric properties of a material are expressed in the linear relation $\boldsymbol{D} = \varepsilon(\omega)\boldsymbol{E}$, where the dielectric displacement is defined by $\boldsymbol{D} = \varepsilon_0\boldsymbol{E} + \boldsymbol{P}$. The coefficient $\varepsilon(\omega)$ is called the dielectric permittivity (or dielectric constant) of the medium, which is related to the susceptibility as $\varepsilon(\omega) = \varepsilon_0(1 + \chi(\omega))$. The previous section indicates how the absorption depends on the imaginary part of the susceptibility. When the dielectric permittivity is separated into its real and imaginary parts as $\varepsilon(\omega) = \varepsilon_1(\omega) + \mathrm{i}\varepsilon_2(\omega)$, the Kramers–Kronig relations give

$$\varepsilon_1(\omega) = \varepsilon_0 + \frac{1}{\pi}\mathscr{P}\int_{-\infty}^{\infty} \mathrm{d}\omega' \frac{\varepsilon_2(\omega')}{\omega'-\omega}$$

A conducting medium, such as a metal, can in some respects also be described by a permittivity. The current density $\boldsymbol{j}$ is proportional to the local electric field, so that $\boldsymbol{j} = \sigma\boldsymbol{E}$, with σ the electric conductivity. Both the current and the displacement appear in the Ampère–Maxwell equation

$$\boldsymbol{\nabla} \times \boldsymbol{H} = \boldsymbol{j} + \frac{\partial \boldsymbol{D}}{\partial t}$$

with $\boldsymbol{H}$ the magnetic field. For monochromatic fields at frequency ω, the right-hand side takes the form $[\sigma - \mathrm{i}\omega\varepsilon(\omega)]\boldsymbol{E}$, so that the conductivity is equivalent to a contribution $\mathrm{i}\sigma/\omega$ to the dielectric constant. This contribution has a pole at zero frequency.

For high frequencies, well above the resonances in the material, $\varepsilon(\omega)$ must approach the vacuum value ε_0, since the electrons in the material can no longer follow the rapid oscillations. The asymptotic behavior can be estimated by noting that an electron (with charge $-e$) in a rapidly oscillating field $2\,\mathrm{Re}\,\boldsymbol{E}\mathrm{e}^{-\mathrm{i}\omega\mathrm{t}}$ will undergo an oscillating force $-2e\,\mathrm{Re}\,\boldsymbol{E}\mathrm{e}^{-\mathrm{i}\omega\mathrm{t}}$. This in turn produces an oscillation in position $\boldsymbol{r}_0 + 2\,\mathrm{Re}\,\boldsymbol{b}\mathrm{e}^{-\mathrm{i}\omega\mathrm{t}}$, with the amplitude $\boldsymbol{b} = -e^2\boldsymbol{E}/m\omega^2$, and m the mass of the electron. This oscillating charge corresponds to a dielectric polarization. When the effective number density of electrons is

given as N, the effective susceptibility of the medium is $\chi(\omega) = -e^2N/(m\omega^2\varepsilon_0)$. In practice, only the loosely bound electrons have to be taken into account here. This estimates the high-frequency limit of the susceptibility, and thereby the approach of the dielectric constant to ε_0.

In nonisotropic media, such as crystals with a low symmetry, the direction of the dielectric polarization $\boldsymbol{P}$ is not necessarily parallel to the direction of the electric field $\boldsymbol{E}$. Such a situation can be described by the linear relation $\boldsymbol{P} = \varepsilon_0\tilde{\chi}^{(1)}(\omega) \times \boldsymbol{E}$, where now $\tilde{\chi}^{(1)}(\omega)$ is a susceptibility tensor that takes the form of a 3×3 matrix. The symmetry properties of this matrix reflect the crystal symmetry. In this case, for each direction of the wave vector $\boldsymbol{k}$ of a plane wave, the medium has two different refractive indices, each one corresponding to a specific polarization of the light. The material is then birefringent: light incident on such a crystal can be split into two refracted beams, each one with a different polarization.

Nonlinear Optics

When an intense light beam traverses a gaseous medium, the dipole polarization is affected by saturation. The dipole polarization is then given by the relation $\boldsymbol{P}_0 = \varepsilon_0\chi_{\text{sat}}(\omega)\boldsymbol{E}_0$, with

$$\chi_{\text{sat}}(\omega) = -\varrho|\mu|^2\frac{1}{\varepsilon_0\hbar}\frac{1}{\Delta + \mathrm{i}A/2}\frac{1}{1+2s}$$

The presence of the saturation parameter s, which is proportional to the intensity, causes the susceptibility to decrease with the intensity. Saturation intensity I_{sat} is defined by rewriting the saturation parameter as $s = I/2I_{\text{sat}}$. The saturation factor in the susceptibility also modifies the absorption law, which now takes the form

$$\frac{\mathrm{d}I}{\mathrm{d}z} = -\frac{\alpha_0 I}{1 + I/I_{\text{sat}}}$$

The effective absorption coefficient decreases for increasing intensity, so that the medium becomes more transparent at higher intensities. When $I \ll I_{\text{sat}}$, Beer's law is recovered, with the linear absorption coefficient α_0, while for high intensities $I \gg I_{\text{sat}}$, the intensity decreases linearly with z, according to the rule $I(z) \simeq -(z - z_0)\alpha_0 I_{\text{sat}}$. By the same token, the effective refractive index at high intensity deviates less from unity than at intensities well below the saturation intensity.

Characteristic for saturation is that the response of the medium (the dielectric polarization) is no longer linear in the electric field. In many cases of nonlinear response, it is convenient to consider an expansion of the response in powers of the field, of the type

$$P = \varepsilon_0(\chi^{(1)}E + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \cdots)$$

with $\chi^{(n)}$ higher-order susceptibilities. For simplicity, for the moment the vector character of the field is ignored, thereby ignoring polarization effects. More complex effects can arise when a medium is irradiated by several light beams at different frequencies. Due to the different frequencies of oscillation, components of P with various frequencies will arise.

As an example, consider a light field that is composed of two fields with different frequencies

$$E(t) = 2\ \mathrm{Re}(E_1\mathrm{e}^{-\mathrm{i}\omega_1 t} + E_2\mathrm{e}^{-\mathrm{i}\omega_2 t})$$

so that its square contains terms proportional to all combinations $\exp(\pm\mathrm{i}\omega_i t \pm \mathrm{i}\omega_j t)$, with $i, j = 1, 2$. Each of these terms contributes to the second-order dielectric polarization, which is expressed as the sum of terms $2\ \mathrm{Re}\ P(\omega)\exp(-\mathrm{i}\omega t)$, where the oscillation frequency ω can attain all values that arise from addition or subtraction of the two field frequencies ω_1 and ω_2. Five possible terms are found. Two terms $P(2\omega_i) = \varepsilon_0\chi^{(2)}(2\omega_i)E_i^2$ for $i = 1$ or 2 express second-harmonic generation, where the dielectric polarization oscillates at twice the frequency of a field component. One term $P(\omega_1 + \omega_2) = 2\varepsilon_0\chi^{(2)}(\omega_1 + \omega_2)E_1E_2$ describes a polarization component oscillating at the sum frequency, and another term $P(\omega_1 - \omega_2) = 2\varepsilon_0\chi^{(2)}(\omega_1 - \omega_2)E_1E_2^*$ oscillates at the frequency difference. The physical processes are called sum-frequency and difference-frequency generation. Finally, there is a nonoscillating contribution $P(0) = \varepsilon_0\chi^{(2)}(0)(E_1E_1^* + E_2E_2^*)$. The process by which an optical field can create a constant dielectric polarization is referred to as optical rectification. In **Figures 3** and **4**, the processes of sum-frequency and difference-frequency generation are illustrated in terms of energy-level diagrams of the medium.

Each one of the oscillating polarization components can cause radiation. This radiation will be efficient only in directions where the contributions from different parts in space are in phase, so that constructive interference occurs. This is the condition of phase matching. For plane waves, this means that the wave vectors of the beams obey the same sum rule as the frequencies. For instance, for sum-frequency generation, the field at frequency $\omega_3 = \omega_1 + \omega_2$ will be emitted in the direction for which the wave vector is $\boldsymbol{k}_3 = \boldsymbol{k}_1 + \boldsymbol{k}_2$. The detailed study of these conditions, combined with the polarization directions of the driving and the emitted radiation is the subject of the field of nonlinear optics. It will be

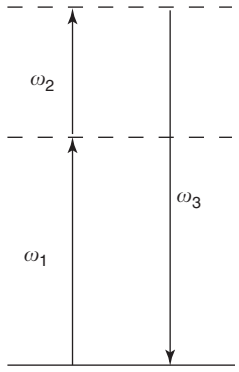

Figure 3 Process of sum-frequency generation in an energy-level diagram. Absorption of two photons with frequencies ω_1 and ω_2 leads to emission of a single photon with frequency $\omega_3 = \omega_1 + \omega_2$.

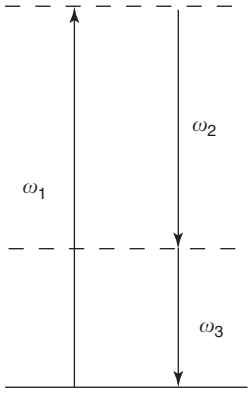

Figure 4 Process of difference-frequency generation in an energy-level diagram. Absorption of a photon with frequency ω_1 and stimulated emission of a photon with frequency ω_2 leads to emission of a photon with frequency $\omega_3 = \omega_1 - \omega_2$.

obvious that the number of combinations increases rapidly with the order of nonlinearity and the number of driving fields. For a medium with inversion symmetry, which can be mapped onto itself by space inversion, the second-order susceptibility $\chi^{(2)}$ must be zero for symmetry reasons. To see this, it is sufficient to consider the system consisting of the medium and the two input fields. Inversion of the entire system changes the sign of the input fields, while the medium does not change when it is inversion symmetric. The second-order expressions show that the output field (the created polarization) remains the same, whereas it changes sign under the inversion. Since the output is equal to its inverse, it must vanish.

Any nonlinear optical process can also take place in a spontaneous version. The description of these processes requires a quantum mechanical version of the corresponding classical theory. In the photon picture in a nonlinear crystal, a pump photon at frequency ω_1 can give rise to the emission of two photons with frequencies ω_2 and ω_3, with $\omega_1 = \omega_2 + \omega_3$, even when no beam at these frequencies is prepared. The process is called spontaneous parametric downconversion. It will be efficient in directions where phase matching is respected. This process is important in the emerging field of quantum information, since under proper circumstances the created pair of photons can be in a highly entangled state. These states display strong correlations that violate Bell's inequalities, and that cannot be explained in terms of classical physics.

Photonic Crystals and Optical Lattices

Photonic crystals are materials in which the refractive index is a periodic function of space, where the period is of the order of a wavelength. They can be designed and fabricated by modern lithographic or mechanical techniques. The optical properties of these materials can be compared with the electronic properties of crystal lattices. The dispersion relation between frequency and wavenumber is strongly affected by the structure. This is not easy to realize in the optical domain, and the first realizations concerned the microwave region. Situations of special interest occur when the periodicity gives rise to forbidden regions in frequency, where the density of modes vanishes. These regions are analogous to energy gaps in the electronic density of states. These optical bandgaps give rise to special effects, since light in that frequency region cannot propagate through the medium. As regarded from the outside, this implies that the medium should be highly reflecting in that region, whereas an excited atom placed inside cannot decay spontaneously when its resonance frequency falls within the gap. The analogy between electromagnetic waves in photonic material and electron propagation in crystals creates an interesting playground, where expertise from one field can be applied in the other one.

A comparable analogy between optics and condensed matter physics is found in the area of optical lattices. They are formed when atoms are trapped in the periodic optical potential wells that arise when pairs of light beams with different propagation directions interfere. These potentials describe the dipole forces that light with an intensity or a polarization gradient exerts on atoms. When one atom is trapped in each one of the periodic array of potential wells, an optical lattice is formed. In practice, it is not easy to obtain high atomic filling factors. Since the well depths are modest, and the optical forces are weak, the kinetic energy of the atoms must be quite low. The long-range periodicity is imposed by the light field,

and the interatomic interactions play no role. In this way, lattices are formed that are free from defects, and with a lattice symmetry that can be easily tailored by varying the number or the propagation direction of the composing light beams.

Photonic crystals and optical lattices display an attractive duality between light and matter. The periodic structure is provided by the material structure in the case of photonic crystals, and by the light beams for optical lattices. The waves in these structures are matter waves for an optical lattice, and light waves in a photonic crystal. A comparison between the developments in both fields gives a beautiful illustration of the use of analogies between neighboring domains of physics.

Intermetallic Compounds, Electronic States of

O Gourdon, D Gout, and G J Miller, Iowa State University, Ames, IA, USA

Introduction

Intermetallic compounds provide a rich and diverse resource to study the relationships among chemical composition, atomic structure, electronic structure, and physical properties. Since the majority of chemical elements are "metals," even with thermodynamic constraints, the numbers, types, and complexity of intermetallic compounds are immense, which is readily apparent in *Pearson's Handbook of Intermetallic Phases*. An understanding of the electronic states of an intermetallic compound can provide insights into the chemical bonding factors influencing composition and structure as well as the electronic underpinnings of its electrical and magnetic behavior. Experimental determination of electronic states, largely through photoelectron spectroscopy, demands pure samples, which can be a challenge to obtain because most metals react readily with oxygen. On the other hand, there is a great deal of effort on quantum mechanical calculations of the electronic structure. This article provides an overview of a comprehensive general picture of electronic states in intermetallic compounds, including brief descriptions of specific examples.

What Are Intermetallic Compounds?

At first glance, the answer seems obvious: intermetallic compounds are chemical substances formed when two or more metallic elements combine with a definite composition. They typically have small heats of formation (ca. -50 to $-10\,\mathrm{kJ\,mol^{-1}}$) when compared to salts and polymeric compounds (ca. -500 to $-100\,\mathrm{kJ\,mol^{-1}}$), but frequently show finite ranges in composition for a single phase, called homogeneity widths. Some melt congruently without decomposition into different phases, while many decompose peritectically into a liquid phase and another solid with a different composition. Concerning their structures, the various metal constituents are usually ordered in different sublattices, each with its own distinct population of atoms. In this way, elements of differing sizes or electronegativities can combine to give new compounds. Often, the corresponding structures are distinct from those of the component elements, but this is not necessary.

One important aspect of the definition is the combination of "metallic" elements. Chemical substances are classified as either metals or nonmetals, and many periodic tables of the elements include a zigzag line, with metals on the left and nonmetals on the right. A closer examination of the elements near this line reveals numerous unusual trends in structural and physical properties, such that in addition to the classification as normal metals, semiconductors and insulators, there are also "metametals" and "semimetals."

The different classification schemes for "metals" show the following characteristics.

1. Normal metals (alkali, alkaline earth, noble (Cu, Ag, Au) and many "transition metals"):
   (a) Ductile materials based on close-packed structures with high coordination numbers (12, 8 + 6) and high symmetry (cubic or hexagonal).
   (b) Typically electropositive elements with low first ionization potentials and low electron affinities.
   (c) Increasing electrical resistivities with increasing temperature; values $\sim 1\,\mu\Omega\,\text{cm}$.
   (d) Temperature-independent paramagnetism. Examples include the alkali, alkaline earth, noble (Cu, Ag, Au), and many "transition metals."
2. Metametals (Zn, Cd, Hg, Ga, In, Tl, Pb, and β-Sn as assigned by W Klemm in the 1950s):
   (a) Ductile materials based on nearly close-packed structures with moderately high symmetry (hexagonal and orthorhombic) and coordination numbers (6 + 6; 4 + 8).
   (b) Higher electronegativities than normal metals (except Pt and Au).
   (c) Increasing electrical resistivities with increasing temperature; values ~ 10–$100\,\mu\Omega\,\text{cm}$.
   (d) Temperature-independent diamagnetism. W. Klemm in the 1950s assigned Zn, Cd, Hg, Ga, In, Tl, Pb, and β-Sn to this category.
3. Semimetals (Sb, Bi, Te, Po):
   (a) Brittle materials based on network structures with low densities.
   (b) Larger electronegativities than most normal metals and metametals.
   (c) Decreasing electrical resistivities with increasing temperature; values $\sim m\Omega\,\text{cm}$.
   (d) Temperature-independent diamagnetism.

These classifications depend largely on their electrical properties and, therefore, are linked closely with their electronic states, which are depicted by their positions in the periodic table, shown in **Figure 1**. The electronic behavior of an element is related to the valence atomic orbitals, which are utilized for chemical bonding, and leads to three primary categories of metallic elements (*P*# = *Pettifor number*, see below):

1. A (*s* or *sd*): alkali and alkaline-earth elements, excluding Be and Mg (*P*#: 7–16), and A′ (*fsd*): rare-earth and actinide metals (*P*#: 17–48);
2. T (*ds*): early half of the transition metal series (*P*#: 49–∼60), and T′ (*dsp*): late half of the transition metal series (*P*#: ∼58–72); and
3. M (*sp* or *spd*): post-transition elements including Be, Mg, and Al (*P*#: 73–83), and M′ (*sp* or *spd*): semimetals (*P*#: 84–92).

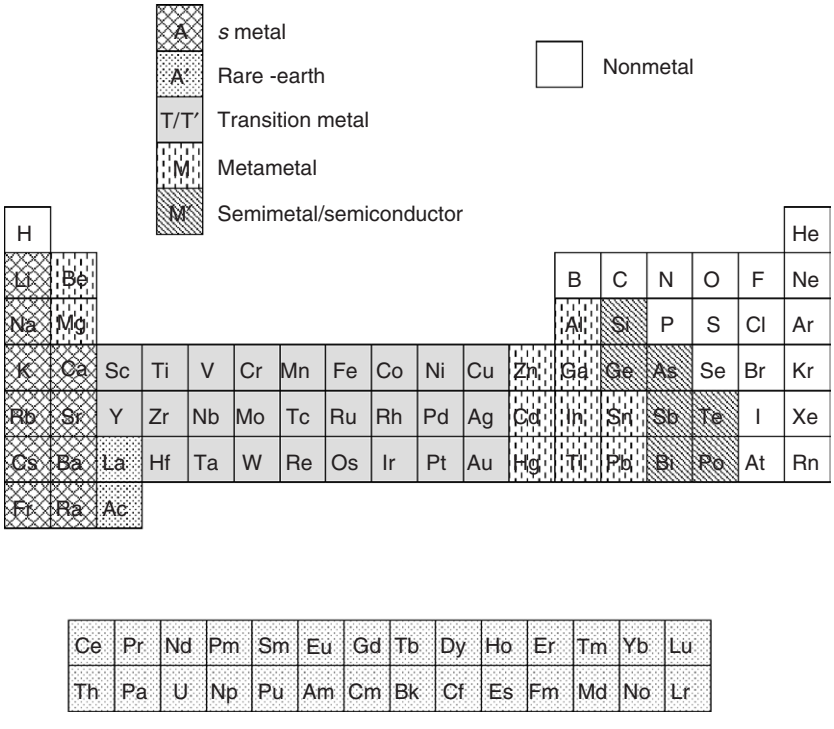

Figure 1 The periodic table of elements showing the different categories of metals based on the nature of the valence orbitals.

Periodic trends are especially important – whether the focus is on the main group (*sp*) or transition (*ds*) elements, the valence energy levels (E_{ns}, E_{np}, E_{nd}) drop linearly with the atomic number across a horizontal series. Among the main group elements, the valence *s* and *p* orbitals become less tightly bound as the valence period increases (except between 4*s* and 3*s* due to the presence of 3*d* orbitals). Furthermore, from left to right across a horizontal series, $E_{np} - E_{ns}$ increases so that *sp* hybridization is more important for lower nuclear charges. Within the transition series, the valence $(n+1)s$ orbital is less tightly bound than the *nd* orbitals, while the energies of 4*d* are lower than those of 3*d* orbitals. Thus, $E_{(n+1)s} - E_{nd}$ increases from 3*d* to 4*d* elements, but then drops going to 5*d* elements due to relativistic effects. These variations in valence state energies affect numerous properties, for example, the colors of Cu, Ag, Au; the onset of semiconducting behavior at high pressures in Ca and Sr; as well as the distortion of the hexagonal close-packed structures of Zn and Cd. To represent the general as well as subtle changes in atomic electronic structure, Pettifor developed a phenomenological numerical coordinate by placing the chemical elements in an order representative of their atomic properties and giving each element the number in the sequence – the Pettifor number (*P*#). This scheme has proved quite useful in separating different structural classes – in the periodic table, it nicely separates the different classifications of metals.

Furthermore, the term "intermetallic compound" is occasionally used interchangeably with "alloys," but they do differ from conventional metal alloys in a number of important ways. Conventional alloys consist basically of a disordered solid solution of two or more metallic elements with similar sizes and chemical characteristics. They do not have any particular chemical formula, and are best described as consisting of a base material to which certain percentages of other elements have been added. For example, type 304, a popular grade of stainless steel, has the composition Fe–18%Cr–8%Ni. An intermetallic compound, on the other hand, is based upon a definite atomic ratio, with a fixed or narrow range of chemical composition. **Figure 2** shows the Al–Ni phase diagram as an example of a binary system showing solid solutions and intermetallic compounds.

Elements such as B, Si, Ge, P, As, and Se, themselves nonmetals, as well as C, when combined with metallic elements are considered to form "intermetallic compounds" because their structures resemble those of other intermetallics, and they form with definite compositions. The elements H, N, O, S, and halogens are not considered to give intermetallic

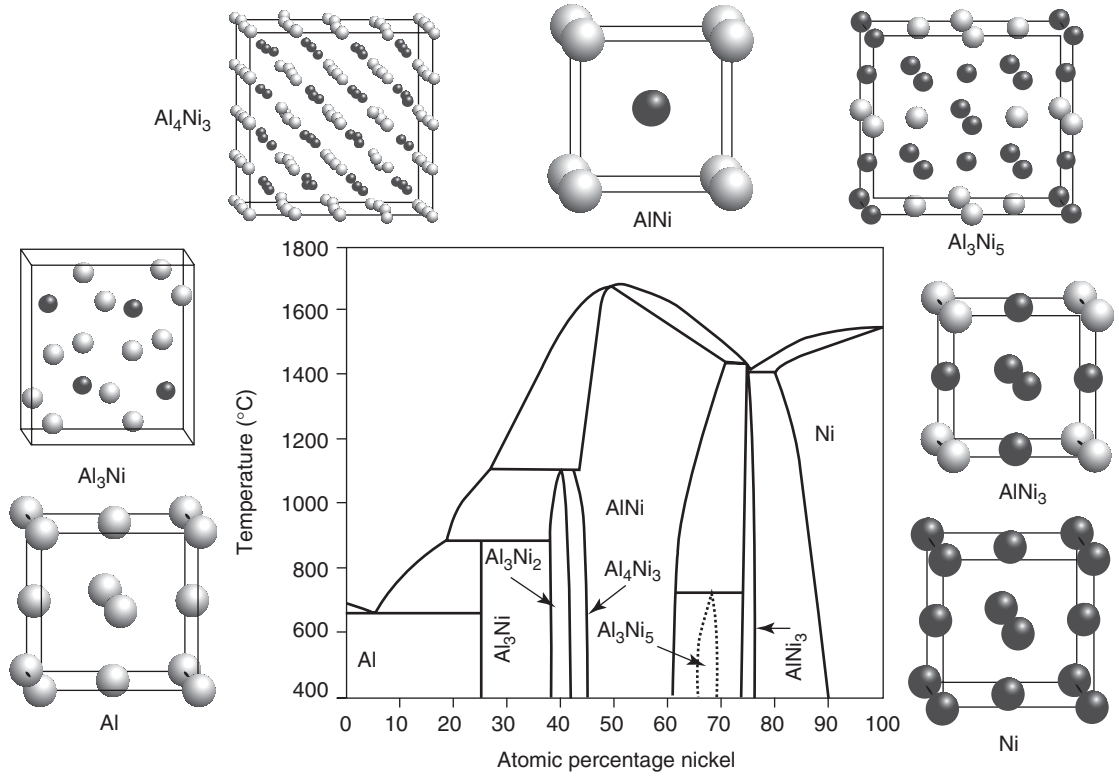

Figure 2 Al–Ni phase diagram and structures of various intermetallic compounds in this binary system. Light-colored spheres are Al; dark-colored spheres are Ni.

compounds, although numerous sulfides and some halides show a metallic character. The smaller elements, for example, H, B, C, N, and O can often occupy interstitial sites in intermetallic compounds, which greatly affect their mechanical, chemical, and physical properties.

The atoms in conventional alloys are linked through relatively weak interatomic interactions, often called "metallic bonds," with the atomic nuclei placed in a "gas" of valence electrons that are able to move relatively freely, which explains their ductility, electrical conductivity, and temperature-independent paramagnetism. In contrast, chemical bonding in intermetallic compounds may show significant polar covalent character, which can produce strong interatomic interactions, brittle mechanical behavior, transport properties ranging from semiconducting to superconducting, and various magnetic interactions leading to complex magnetic structures. However, in intermetallic compounds whose mechanical and electronic properties resemble those of alloys, the individual elements tend to occupy different positions within the crystal lattice. This condition, which is referred to as "ordering," often leads to abrupt changes in the physical properties of the material.

Classifying Electronic States in Intermetallic Compounds

One useful tool for assigning compounds into different categories is a van Arkel–Ketelaar triangle, which maps compounds according to two related chemical coordinates using an electronegativity scale based upon the average one-electron valence shell energy of the ground-state free atom, called the configuration energy (CE). In this map, shown in **Figure 3**, the horizontal coordinate is the average CE of the constituents, while the vertical coordinate is the difference, so that metallic substances lie to the left. The transition from metallic to nonmetallic behavior involves either increasing electronegativity in general, or increasing electronegativity difference between constituents. Since CE represents the average energy of a valence electron, CE correlates with the separation between the energies of the valence *s* and *p* orbitals, and so influences the way atoms will interact with one another. Low CE values give small $E_{np} - E_{ns}$ values and broad, frequently overlapping energy bands. In many cases, the electronic states for these systems behave like nearly free electron states. Moreover, valence *d* orbitals are important for the properties of transition elements and valence *f* orbitals for the rare-earth and actinides – changes in the band filling of these orbitals affect the structure, cohesive energies, thermodynamic properties, and magnetic character. Unlike valence *s* and *p* orbitals, the valence *d* and *f* orbitals give narrower energy bands, and have more atomic-like character in compounds. The 4*f* orbitals in rare-earth elements and their compounds are generally localized, while the 5*f* orbitals in actinides have a greater role in chemical bonding.

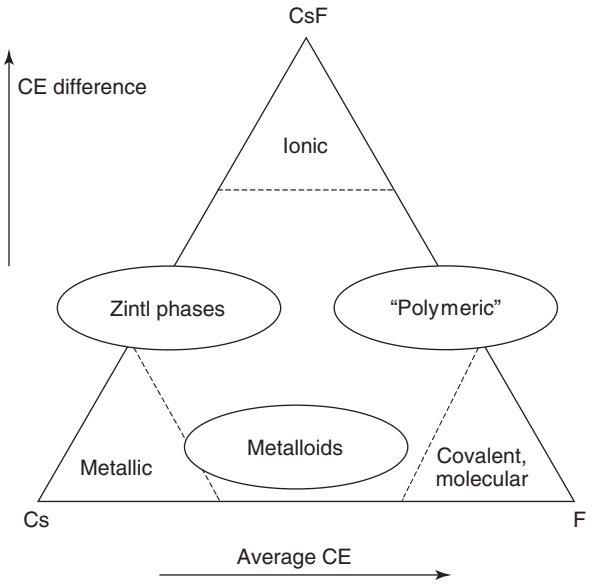

Figure 3 The van Arkel–Ketelaar triangle based on configuration energies of the atomic components.

This qualitative picture implies a variation in the description of states from a nearly free electron (NFE) model to a tight-binding (TB) model. In NFE, the electronic states are treated as linear combinations of plane waves (the eigenstates for a free electron gas). The arrangement of positively charged atomic nuclei creates a potential that perturbs the free electron states. The extension of this approach is toward pseudopotentials, which makes the valence states orthogonal to the core atomic states. In TB, the electronic states are treated as linear combinations of atomic orbitals (the one-electron eigenstates of free atoms). Pseudopotential methods as well as TB methods have been used to study metals and semiconductors – the TB methods lead to useful chemical insights by virtue of starting from atoms, and have provided valuable understanding even for systems in which NFE would be entirely appropriate.

To calculate the electronic densities of states (DOS), multi-electron terms in the total electronic energy may be treated either in the local density approximation (LDA) or in the local spin density approximation (LSDA) and the one-electron terms can be treated scalar relativistically. For the heavier elements, spin–orbit

coupling should also be considered. For many ground-state properties (structure, cohesive energy, magnetism, and electronic transport), the LDA is quite effective. Numerous recipes exist for calculating the exchange and correlation terms. An especially valuable analysis of the DOS is through the crystal orbital Hamilton population (COHP) analysis, which allows states to be identified according to the bonding, nonbonding, or antibonding character of the interatomic interactions (COHP values are, respectively, less than, equal to, or greater than zero).

Experimental determination of electronic states can be carried out by photoelectron spectroscopy, which is a surface-sensitive technique. de Haas–van Alphen effect gives information about the Fermi surface in reciprocal space, but demands quite pure samples. Hall effect measurements provide information about the charge carriers. Other methods, such as specific heat and magnetic susceptibility studies on metals, can give values of the DOS at the Fermi level.

Electronic Interactions between Different Metallic Types

An examination of Pearson's *Handbook of Intermetallic Phases* shows that the predominant classes of intermetallic compounds involve the following combinations of metallic elements using the designations in **Figure 1**: (1) A′–T′; (2) A–M and A–M′; (3) T–T′; (4) (T, T′)–(M, M′); and (5) (A, A′)–(T,T′)–(M,M′). Very few examples exist for (A,A′)–(A,A′), (M,M′)–(M,M′), (A,A′)–T, T–T, and T′–T′. This observation guides our emphasis to the important electronic interactions: (1) *d–d*; (2) *d–sp*; and (3) *sp–sp*.

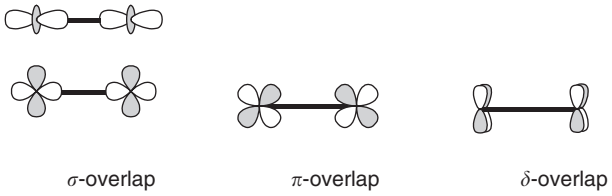
The two most important factors influencing the electronic DOS are the relative energies of the atomic orbitals of the different constituents and the strengths of the interatomic orbital interactions leading to bandwidths, that is, band dispersion. Energy gaps, pseudogaps, and peaks in the DOS arise from these two fundamental characteristics. Since the majority of intermetallic compounds show metallic properties, the "perfect" screening of conduction electrons means that there is essentially no charge transfer between different elements. Therefore, the "common band" model is most appropriate for analyzing the DOS. Additional factors include composition and the coordination environments surrounding each element in a structure.

d–d Interactions

Intermetallic compounds involving just transition metals are technologically important due to their mechanical, chemical, and physical properties. Some of the strongest chemical bonds in condensed phases are found among these compounds, as measured by their cohesive energies. The electronic states of transition metals exhibit a partially occupied, narrow valence *d* band that lies near the bottom of a broad valence *s* or *sp* band. Since the valence *d* electrons remain relatively tightly bound to their parent atoms, the appropriate method to treat the *d–d* electronic interactions is the TB model. When different transition metals combine to give an intermetallic compound, the primary effect is the way the different *d* orbitals interact – the valence *s* or *sp* band remains broad, and contributes to the chemistry and physics of these materials by adjusting the extent of filling of the *d* bands. The *d–d* orbital interactions break down into σ, π, and δ types of orbital overlap, with σ overlap the greatest and δ overlap the lowest (**Scheme 1**).

The *d–d* π interactions are important for the structural variation of the transition metals in the 4*d* and 5*d* periods (h.c.p.–b.c.c.–h.c.p.–f.c.c.) (b.c.c. – body-centered cubic; f.c.c. – face-centered cubic; h.c.p. – hexagonal close-packed). These overlaps affect the shape of the *d*-band DOS – see **Figure 4**, which compares the DOS curves for a b.c.c. and f.c.c. 4*d* transition metal. The local environments in the two structures both have cubic symmetry, and the local *d* orbitals are split into e_g and t_{2g} levels. The local coordination environment of the b.c.c. structure creates a region of low, nonzero DOS values close to six valence *s* and *d* electrons between two regions of high DOS values. This region of low DOS is called "quasigap" or "pseudogap." COHP analysis of the DOS shows that *d–d* bonding states are below the pseudogap while antibonding states lie above. On either side of six valence *s* and *d* electrons, close packed (h.c.p., f.c.c.) structures are preferred. Trends in effective nuclear charge and occupation of bonding versus antibonding states help explain the trend that across a period of transition metals, the *d* bandwidth slightly increases and then sharply decreases while the *d* band center steadily decreases. These trends have profound influences on the states of transition metal intermetallics.

When two different transition metals form an intermetallic compound, the shape of the DOS will



Scheme 1

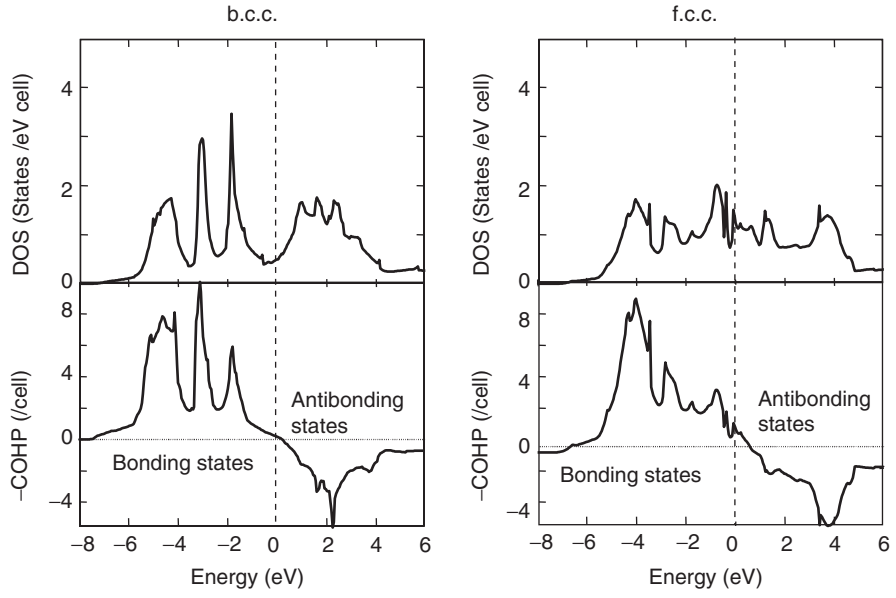


Figure 4 DOS and nearest-neighbor COHP analysis for the b.c.c. and f.c.c. structures of a typical 4*d* transition metal. The energy zero corresponds to six valence *s* and *d* electrons. In the COHP curves, metal–metal bonding states occur for –COHP > 0; antibonding states for –COHP < 0.

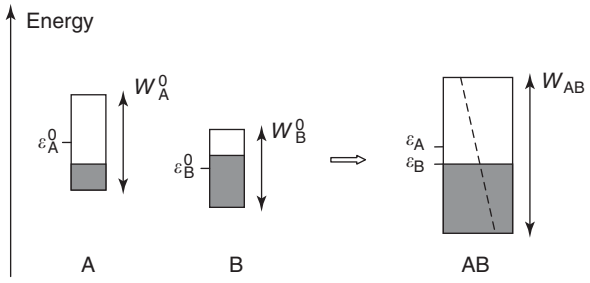

Scheme 2

depend on both the structure and the electronic characteristics of the component elements. In the case of disordered alloys AB, the "common band" model is appropriate for understanding heats of formation and trends in cohesive energies with respect to metals A and B (see **Scheme 2**). In this model, the valence *d* band of each transition metal is characterized by an energetic center (ε_M^0; M = A, B), a bandwidth (W_M^0; M = A, B), and band filling (N_M electrons; $0 \leqslant N_M \leqslant 10$; A, B; indicated by the shaded regions in **Scheme 2**). The resulting *d* band for the disordered alloy AB has a bandwidth given by $W_{AB} = \bar{W}[1 + 3(\Delta\varepsilon/\bar{W})^2]^{1/2}$ ($\bar{W} = (W_A^{AB} + W_B^{AB})/2$; $\Delta\varepsilon = \varepsilon_A - \varepsilon_B \langle \varepsilon_A^0 - \varepsilon_B^0 \rangle$, band filling of $\bar{N} = (N_A + N_B)/2$. To construct this *d* band for the alloy AB, there is "renormalization" of the average band energies ($\varepsilon_M^0 \rightarrow \varepsilon_M$; M = A, B) to keep local charge neutrality (i.e., no effective charge transfer) and the bandwidths ($W_M^0 \rightarrow W_M^{AB}$; M = A, B) due to changes in atomic volumes from the element to the alloy. In this *d* band, states below the band center $\bar{\varepsilon}$ are mostly from metal B, while those above $\bar{\varepsilon}$ are mostly from metal A (as indicated by the dashed line for the AB bnad). Therefore, electrons flow from A to B because B is more electronegative than A ($\varepsilon_A^0 < \varepsilon_A^0$), but also flow back from B to A through orbital overlap in alloy AB.

The common band model predicts that the most stable intermetallic compounds and alloys would arise from combinations of transition metals at opposite ends of the transition metal series and that the highest cohesive energies exist for AB systems with $\bar{N} : 5$. Specifically, the cohesive energy for AB, $U^{AB} : -k\bar{N}(10 - \bar{N})W_{AB} + cW_{AB}^2$ (*k*, *c* are positive constants) has an attractive part related to band filling and a repulsive part related to the number of nearest neighbors, which is proportional to the square of the bandwidth. The expression for the heat of formation of AB is more complicated, but takes the form $\Delta H_f^{AB} : f(\bar{N}(10 - \bar{N}))\,(\Delta N)^2$ where $\Delta N = N_B - N_A$. Negative heats of formation occur for $\bar{N}$ between 3.33 and 6.67 electrons per atom. For an intermetallic compound AB, with an ordering of A and B atoms, this model is appropriate for adjacent elements (small $\Delta\varepsilon$ values), but is less appropriate as this energy difference increases. For larger $\Delta\varepsilon$ values, a pseudogap can open in the DOS, as seen in **Figure 5** for TiFe, which adopts the CsCl-structure type. The DOS curves of Ti and nonmagnetic Fe show features as expected – a lower band center and a narrower

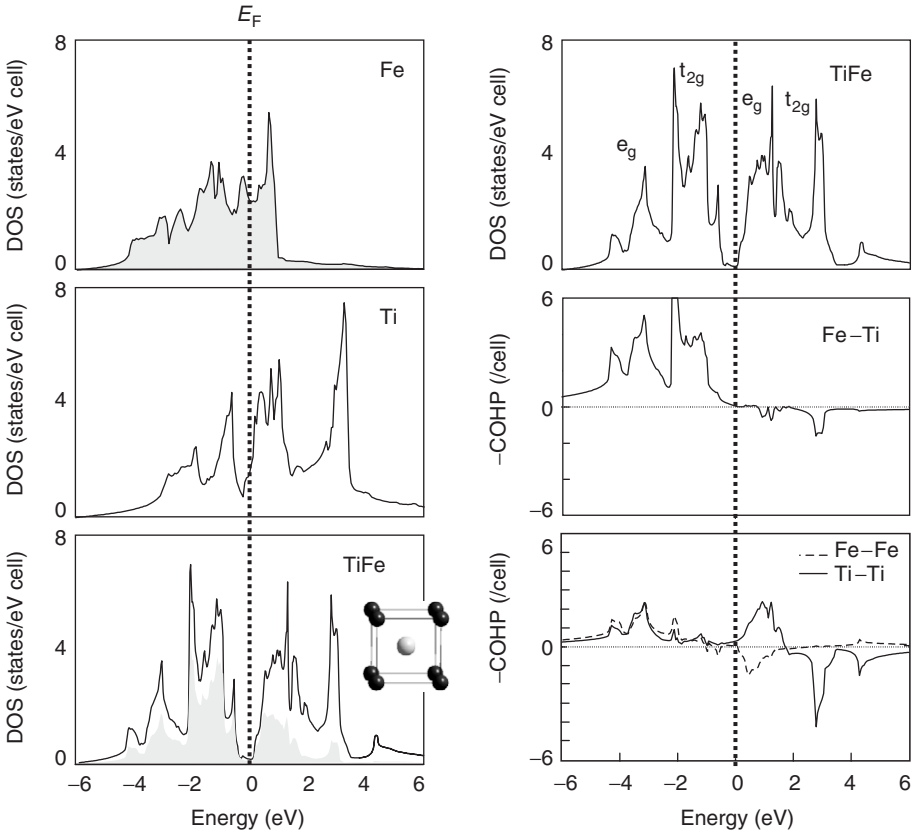

Figure 5 Left: DOS curves of nonmagnetic Fe, Ti, and TiFe. The shaded regions in the DOS of TiFe are Fe states. Right: Assignment of the peaks in the DOS of TiFe into local e_g and t_{2g} levels as well as COHP analyses for Ti–Fe, Ti–Ti, and Fe–Fe near-neighbor interactions.

bandwidth for Fe. In TiFe, the *d* bandwidth is wider than that for either element, but the shape shows a pseudogap at the center of the *d*-band and the Fermi level falls in this pseudogap. States below this pseudogap are mostly Fe-orbitals, while those above are mostly Ti-orbitals. Nevertheless, TiFe is not held together by "ionic" forces because the perfect screening of the valence electrons negates any charge transfer – there is a "renormalization" of the energies of each transition metal. The DOS shows aspects of the local coordination, but the principle factor creating the pseudogap in TiFe is the energy difference between the band centers of Ti and Fe. COHP analysis of the DOS of TiFe shows that states below the Fermi level are Ti–Fe bonding; those above are Ti–Fe antibonding. The homonuclear Fe–Fe and Ti–Ti interactions are weaker (longer distances) and bonding below the Fermi level, but the crossover from bonding to antibonding interactions does not occur at the pseudogap. Therefore, another aspect of the pseudogap in intermetallic compounds is the creation of bonding states below the gap and antibonding states above. Therefore, many stable intermetallic compounds show low DOS values at the Fermi level, which can be accounted for by certain metal–metal interactions through a COHP analysis of the DOS.

Trends in the features of DOS curves depend on the types of interactions, the relative magnitudes of orbital overlaps and atomic electronegativities. **Figure 6** shows the trends in DOS and COHP curves for TiRu, TiRh, and TiPd, which follows the structural trend b.c.c.–f.c.c.–h.c.p., but with ordered arrangements of metals. A pseudogap is noticeable in all cases for six states per formula, although it is less clear in the TiRh and TiPd cases. TiRu adopts the CsCl structure with eight nearest-neighbor Ti–Ru interactions and 12 second nearest-neighbor homonuclear (Ti–Ti and Ru–Ru) contacts. In TiRh and TiPd, there are six heteroatomic (Ti–Rh or Ti–Pd) and six homoatomic (Ti–Ti, Rh–Rh, Pd–Pd) nearest-neighbor contacts, which interferes with the pseudogap. Additionally, the bandwidths become narrower as the 4*d* metal becomes more electronegative. Again, there is no charge transfer between Ti and the 4*d* metal, in accordance with the common band model.

If the DOS value at the Fermi level is sufficiently high, then the structure is susceptible to an electronic distortion, which will perturb the electronic states

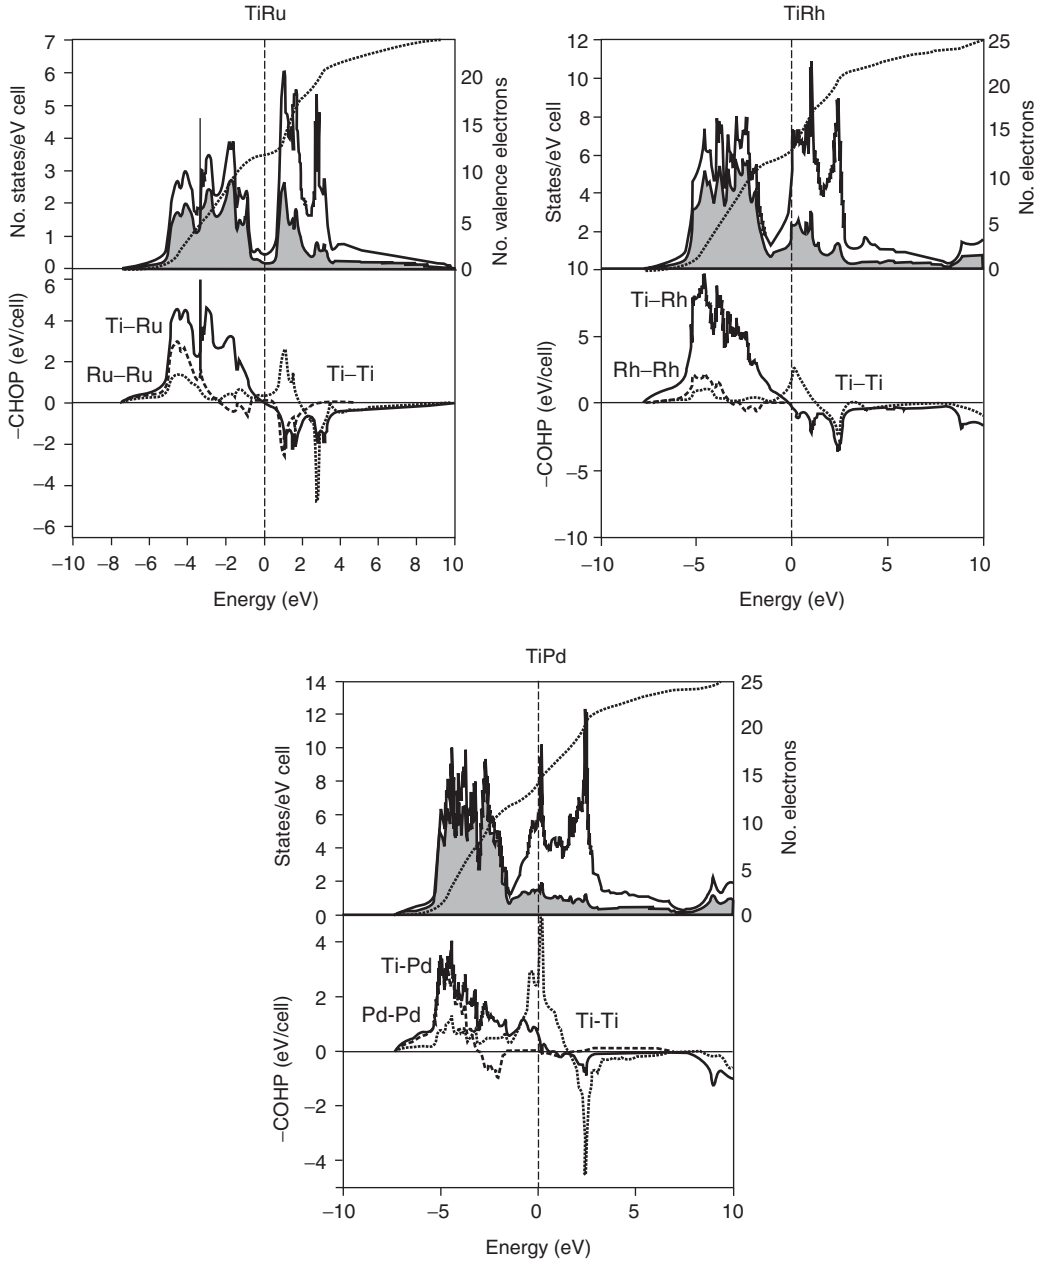

Figure 6 DOS and COHP analyses of the 3*d*–4*d* intermetallic compounds, TiRu, TiRh, and TiPd. Shaded regions of the DOS are states from the electronegative metal (Ru, Rh, Pd). Fermi levels are indicated by the dashed lines.

near the Fermi level and lower the total electronic energy. This effect can happen in one of two ways: (1) a structural distortion, as in VIr (which distorts away from the cubic CsCl-structure type); or (2) ferromagnetism. For ferromagnetism to occur, the local exchange energy must also be sufficiently large, and this occurs for some of the 3*d* elements, which have the smallest spatial extent. The Stoner criterion states that ferromagnetism is preferred when $IN(E_F) > 1$, where I is the intra-atomic exchange energy (chemists will think about the so-called "pairing energy" – the energy penalty in putting two electrons into the same atomic orbital) and $N(E_F)$ is the value of the DOS at the Fermi level. Since $N(E)$ is typically inversely proportional to the bandwidth W, when either intra-atomic or inter-atomic interactions lead to narrow bands, and the local exchange is sufficiently large, ferromagnetism frequently occurs – the 3*d* elements Fe, Co, and Ni as well as compounds involving Mn are especially susceptible.

d–(*s*)*p* Interactions

Intermetallic compounds between transition metals and main group metals display interesting magnetic, superconducting, mechanical, and structural properties. In most cases, the electronic states near the Fermi level of these compounds are dominated by the *d* orbitals of the transition metal component. Their electronic structures arise from two dominant factors: (1) the expansion of the transition metal lattice due to the insertion of the main group (*sp*) element; and (2) the interaction between the valence *d* bands on the transition metal with the *sp* bands of the main group element. Three categories occur (see **Figure 7**): (1) where the *d* levels lie much deeper in energy than the main group atom (e.g., PdLi); (2) where the opposite is true (e.g., "PdF"); and (3) the intermediate case where the two are of similar energy (e.g., PdB). In the first two cases, there is a rather weak interaction between the two sets of orbitals. The transition metal *d* band is narrower than in the pure metal, as a result of stretching the metal lattice to accommodate the nonmetal. These two cases do differ, however: (a) PdF is quite "ionic," involving charge transfer from metal *d* states to the low-lying fluorine-located bands – note that the Fermi level drops from the top of the *d* band; (b) PdLi utilizes the common band picture, but the Fermi level rises above the top of the Pd 4*d* band – note the significant contribution from Li valence states in the region of the Pd 4*d* band. A similar example is the case of CsAu, which is an unusual example of a red, transparent, semiconducting intermetallic compound – its photoelectron spectrum shows a band gap of 2.6 eV. The case of PdB is most interesting because strong mixing occurs between the two sets of orbitals. These bands can be separated into bonding, nonbonding, and antibonding regions between the metal and nonmetal. Changes to the DOS will occur on composition – the strongest interactions will typically involve transition metal–main group metal, but the DOS will depend on the concentration of different orbitals. In transition metal-rich compounds, the metal *d* band will dominate and be broadened by T–T interactions; in main group metal-rich compounds, the metal *sp* bands may now become apparent.

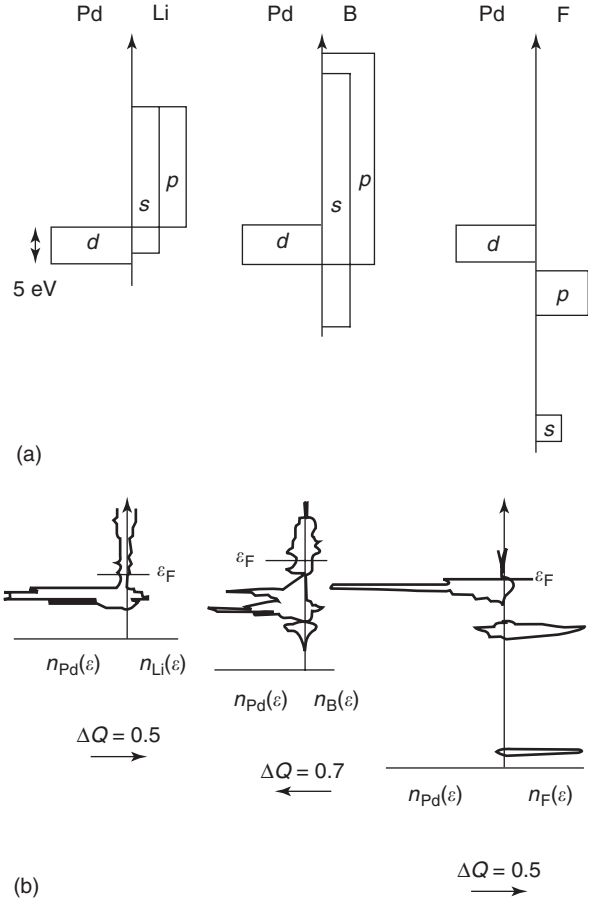

Figure 7 Schematic (a) and calculated (b) partial densities of states for the atomic components in the three examples: PdLi, PdB, and PdF. (Reprinted with permission from Gelatt CD, Jr., Williams AR, and Moruzzi VL (1983) Theory of bonding of transition metals to nontransition metals. *Physical Review B* 27: 2005–2013; © American Physical Society.)

One factor governing the atomic arrangements in intermetallic compounds is the relative strengths and concentrations of heteroatomic (between different elements) and homoatomic (between identical elements) interactions. As the molar concentration of the transition metal increases, the *d* band will become wider and may adjust its position depending on the relative electronegativity of the main group metal. For example, in the Ni–Al system, one can see the influence of composition on the DOS in **Figure 8** for three different examples. As there is an increased dilution of Ni in Al, the Ni 3*d* bands become narrower and pull away below the Fermi level.

Main group elements show extensive structural diversity as the number of valence *s* and *p* electrons changes. For less than the half-filled band situation, for example, among group 13 elements like Al and Ga, clusters based on octahedra, square pyramids, and tetrahedra are common. Such clusters can be used to visualize structures through condensation of vertices, edges, or faces and create new understanding of electronic and bonding characteristics, as in transition metal trialuminides, MAl_3 (M = rare-earth element, Ti, Zr, Hf, V, Nb, Ta). As the number of valence electrons increases in this family, the network of Al-based polyhedra changes from octahedra to square pyramids. The DOS shows a pseudogap at the Fermi level (see **Figure 9** for $TaAl_3$ as an example), which is largely influenced by the bonding states of the Al polyhedra. Nevertheless, M–Al orbital

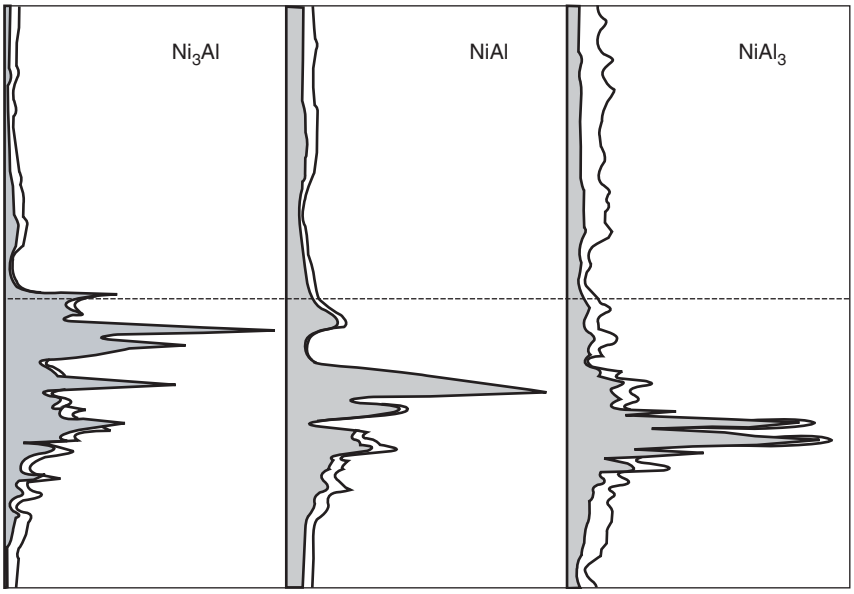

Figure 8 DOS curves for Ni_3Al, NiAl, and $NiAl_3$ presented with the Fermi level set as the energy reference. The shaded regions indicate the Ni 3*d* and 4*s* components to the DOS and Ni 3*d* states are labeled.

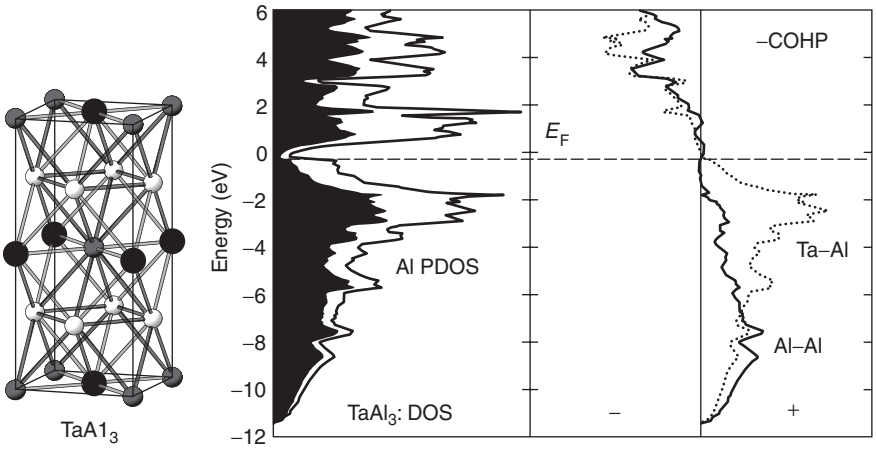

Figure 9 Structure, DOS, and COHP analysis for $TaAl_3$. Large, dark spheres are Ta; small shaded spheres are Al. The shaded regions in the DOS are Al states, and the Fermi level is marked by a dashed line. In the COHP curves, the solid line shows Al–Al interactions; the dotted line shows Ta–Al interactions.

interactions also split the 5 M *d* levels into two sets (e_g below t_{2g}), which also contributes to the observed pseudogaps in the DOS curves as well as the preferred structures and electronic properties. In fact, such compounds are called *d–p* covalent intermetallics – COHP analysis of the DOS in $TaAl_3$ shows maximum bonding character for both Al–Al and Ta–Al interactions.

Pseudogaps occur in intermetallics for reasons based on structure and atomic electronegativities. Another important growing class of compounds is the set of half-metallic ferromagnets, of which the "semi-Heusler alloys" represent significant examples ("semi-Heusler" alloys, ABX, consist of cubic closest packed X atoms with B atoms in all octahedral holes and A atoms ordered in one-half of the tetrahedral holes of the close packed array of X "Heusler" alloys, A_2BX, have all tetrahedral holes filled). These compounds are cubic intermetallic phases combining main group metals (Sn and Sb) with two different transition metals (one early T – Ti, Zr, Hf, V, Nb; one late T′ – Fe, Co, Ir, Ni, Pt). Their electronic properties, and therefore, their electronic states, depend strongly on the number of valence electrons: 18-electron examples such as TiCoSb are diamagnetic semiconductors, 17-electron examples are metallic and

Pauli paramagnetic, whereas 19- or 22-electron examples show half-metallic ferromagnetic behavior. Half-metallic ferromagnetism originates when the nonmagnetic electronic structure is susceptible to splitting of the majority and minority spin densities of states, and the Fermi level falls in an energy gap for either spin, as seen in the LSDA DOS for VCoSb, a 19-electron example, in **Figure 10** (VCoSb is a weak ferromagnet because there is an energy gap at nine states for both spin states; a half-metallic ferromagnet shows an energy gap just in the minority spin band, as seen in NiMnSb). The nonmagnetic DOS at the Fermi level for 19 electrons (VCoSb) is large, and is susceptible to ferromagnetism within the Stoner criterion. The lowest energy valence orbitals are from Sb, then from Co, finally from V since the atomic electronegativities increase from V to Co to Sb. The gap in the DOS at 18 valence electrons originates from these valence orbitals, the symmetry of the local coordination environments and metal–metal interactions: (1) Sb has four valence orbitals and the five Co 3*d* orbitals make nine low-lying orbitals to be filled for 18 electrons; (2) the tetrahedral coordination of Sb around Co and octahedral coordination around V keep the Co 3*d* levels low and split by a small amount; (3) V–Co orbital interactions help to keep a band gap at 18 electrons, which accounts for the properties of TiCoSb. In these examples, the gap opens through *d*–*d* interactions between the two different transition metals – note the strength of early-late *d*–*d* interactions, just as mentioned in an earlier section.

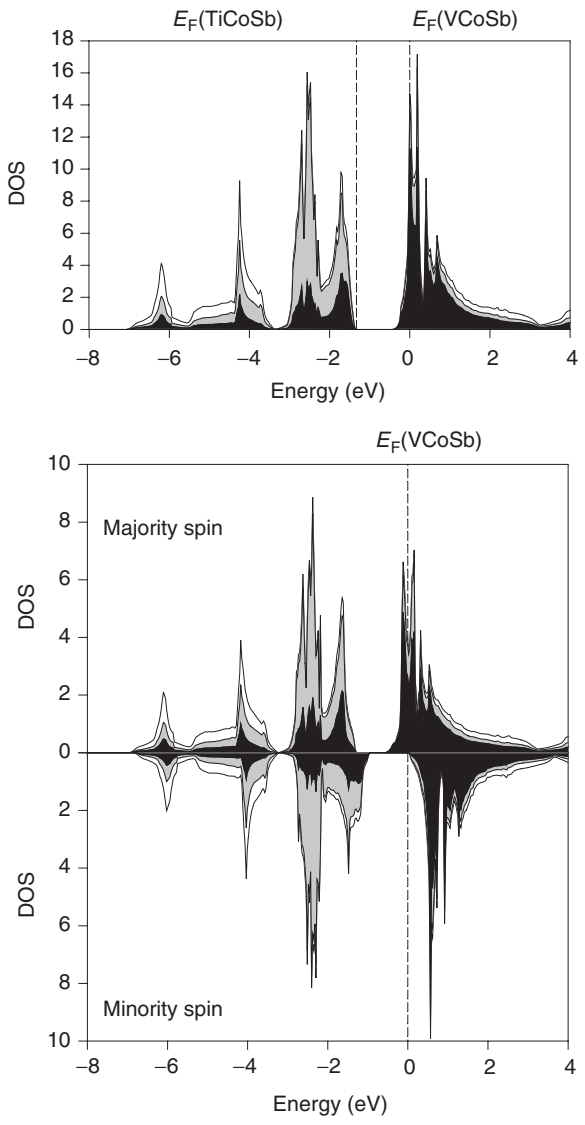

Figure 10 Nonmagnetic (top) and LSDA (bottom) DOS for VCoSb, a semi-Heusler alloy. The dashed line indicates the Fermi level – note the bandgap in the minority spin states. Black regions are V orbitals; gray regions are Co orbitals; white regions are Sb orbitals.

sp–sp Interactions

Due to the widely different electronegativities of these elements, theoretical determinations of their electronic states range from NFE through pseudopotentials to TB models. There are three principle types of interactions (see **Figure 1**): A–A, A–M, and M–M. A–A interactions are best modeled by the NFE because the active metals have the lowest $E_{np} - E_{ns}$ values and diffuse valence atomic orbitals. The more electronegative main group metals (M) require pseudopotential or TB models because $E_{np} - E_{ns}$ increases and the valence atomic orbitals become contracted. In intermetallic structures, coordination environments surrounding A-type elements involve several atoms and often resemble densely packed structures, whereas those around M-type elements show lower coordination numbers and some directional bonding character. As the electronegativity difference between main group elements increases, the DOS develops a structure, that is, peaks and pseudogaps (or gaps), as seen for the three hypothetical compounds: "NaMg," "NaAl," and "MgAl" in **Figure 11**. A–M compounds constitute an important class of compounds called "polar intermetallics," in which orbital interactions within the network of electronegative M atoms typically maximizes bonding interactions. If the local structure around the M atoms obey classical valence rules, then these compounds are called "Zintl phases." Subtle electronic effects can arise from valence *d* orbitals: for alkaline earth elements, there can be contributions of $(n-1)d$ orbitals to *ns* bands, especially under pressure, whereas for Cu, Ag, Au, Zn, Cd, and Hg, $(n-1)d$ orbitals can hybridize with the valence *ns* and *np* bands.

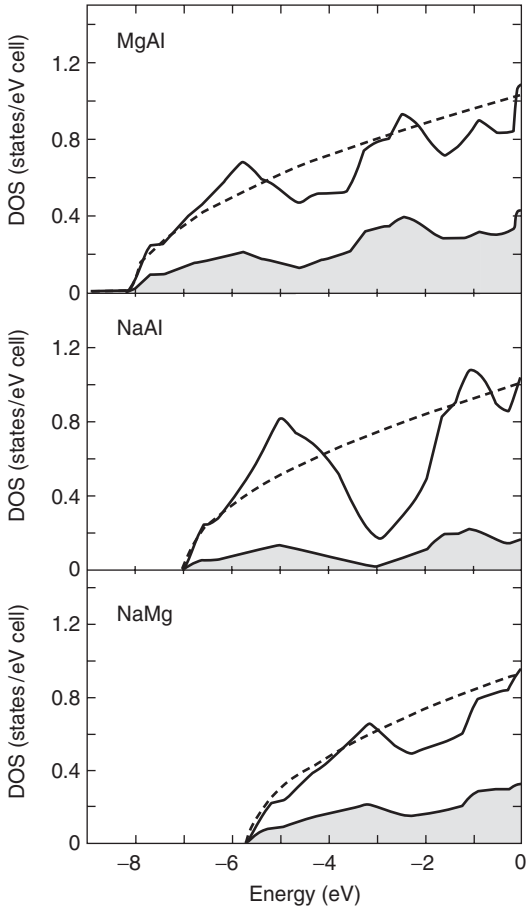

Figure 11 DOS curves for NaMg, NaAl, and MgAl, and the shaded regions are states from the more electropositive element. The dashed line shows a free-electron type DOS.

Hume–Rothery "electron compounds" are formed between noble metals and *sp* metals – in these systems, the noble metal *d* band is filled, so that the dominant orbital interactions will be *sp*–*sp* interactions. There are five phases that Hume–Rothery identified as controlled by electron count: (1) h.c.p. (3 subcategories: ζ ($c/a = 1.633$), ε ($c/a = 1.55$–1.58), and η ($c/a = 1.77$–1.78)); (2) f.c.c.; (3) b.c.c./CsCl-type (β-brass); (4) β-manganese; and (5) γ-brass. TB models account for the structural variations very well, which attests to the importance of orbital interactions influencing these structures. Analysis of the DOS and band structure for CuZn reveal, however, that optimized metal–metal bonding is not the driving force here (**Figure 12**). As Pettifor and co-workers have shown, the structural trend is driven by van Hove singularities in the DOS (places where the band structure has zero slope, which occur at the bottom or top of energy gaps at Brillouin zone boundaries). The band structure shows that the valence *d* bands are well below the Fermi level, but, nevertheless, hybridize with the NFE-like *sp* bands. Numerous quasicrystalline and approximant systems (Li–Cu–Al, Mg–Zn–Al) have been interpreted as similar "electron compounds," but the NFE gives little structural chemical information.

Zintl phases involve combinations of electropositive and electronegative main group metals, for example, LiAl, in which the electronegative element forms a structure based on the octet rule if one assumes that the electropositive element donates all of its valence electrons. The octet rule demands that

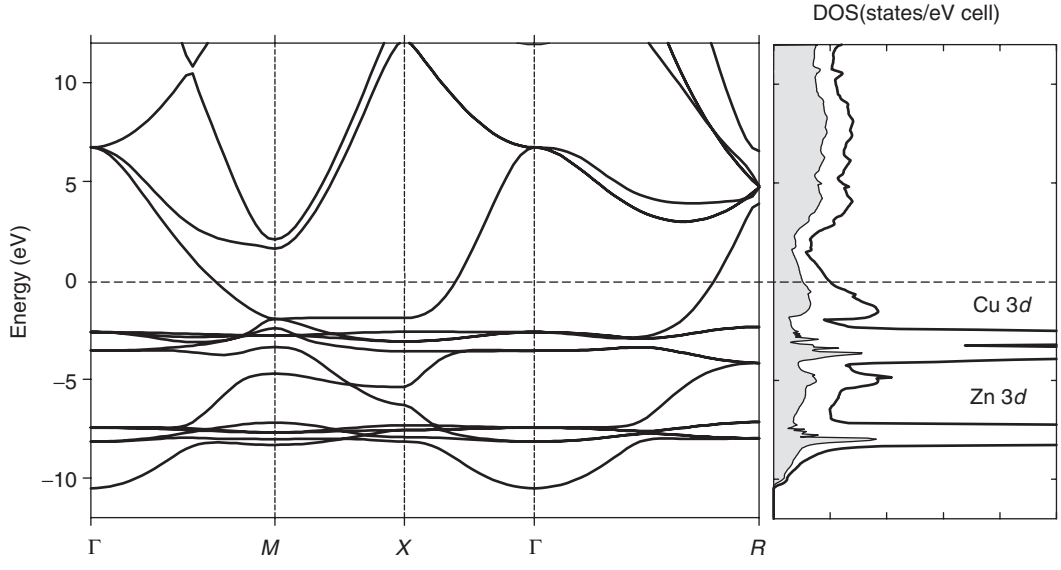

Figure 12 Energy bands and DOS for CuZn (β-brass structure). Shaded region in the DOS comes from valence *s* and *p* orbitals of Cu.

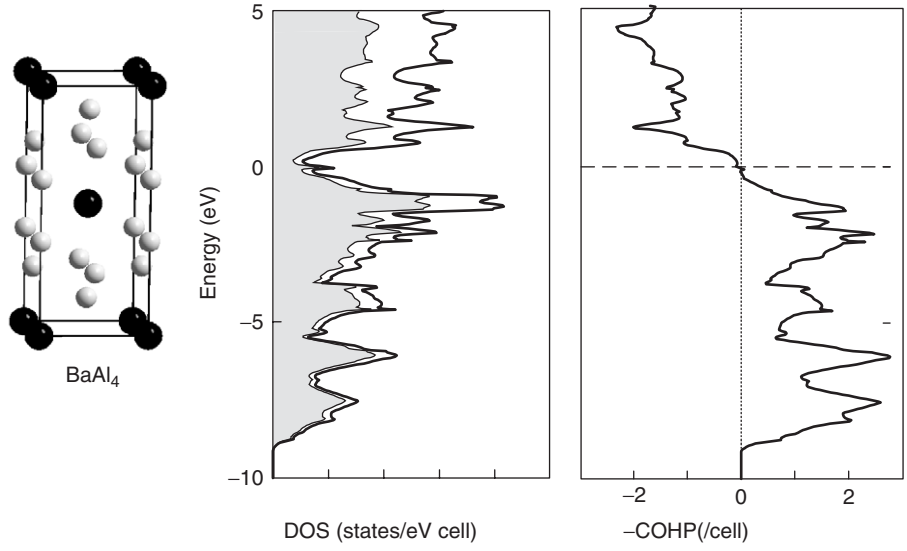

Figure 14 Structure, DOS, and Al–Al COHP analysis for $BaAl_4$. Shaded region is Al orbitals.

eight bonding or nonbonding valence electrons surround main group (*sp*) elements in stable structures. Thus, the structure of LiAl has a diamond network of four-bonded Al atoms, which is formulated as "Al^-," isoelectronic with Si. The DOS of Zintl phases show either a gap or pseudogap at the Fermi level with bonding states within the electronegative metal network fully occupied (**Figure 13**). So, "classical" Zintl phases are defined as follows: They are compounds that (1) contain an alkali or alkaline earth metal and an electronegative main group element that is a metal, semimetal, or small-gap semiconductor; (2) are electronically balanced or close-shell compounds, that is, the number of valence electrons provided by the constituents equals the number of electrons needed for two-center, two-electron covalent bonds in the structure; (3) are semiconductors or poor conductors; (4) are either diamagnetic or show a very weak temperature-independent paramagnetism; and (5) are typically brittle.

Among the *sp* class of intermetallic compounds, the Hume–Rothery phases behave as normal metals while Zintl phases are typically semiconductors. "Polar intermetallics" represent an intermediate class of compounds, formed between active metals with electronegative metals, but the DOS shows a pseudogap near the Fermi level. COHP analysis of the DOS indicates optimized bonding in the electronegative component and the active metal behaves like a cation, but typically does not donate its full complement of valence electrons. The structure of the electronegative component, however, cannot be explained by the octet rule – there is substantial delocalized bonding. The most prolific example of this

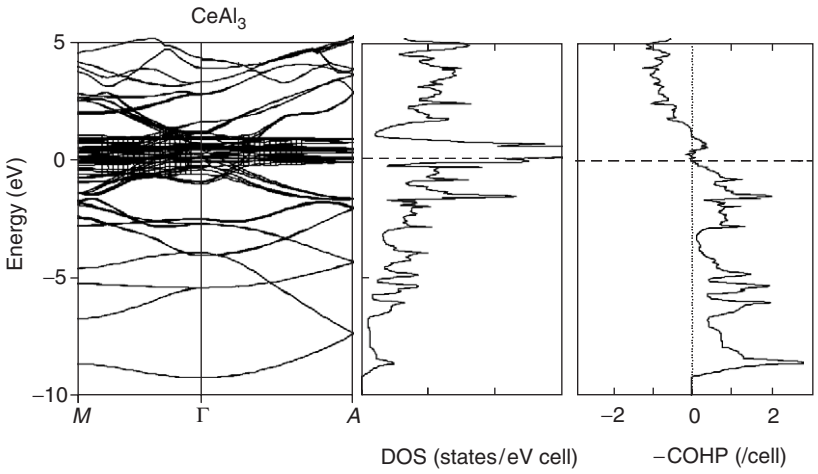

Figure 15 Band structure, DOS, and Al–Al COHP analysis for $CeAl_3$.

structural class is the $BaAl_4$-type, whose structure is adopted by hundreds of examples involving transition metals as well (**Figure 14**). There are numerous subcategories based on how different elements are arranged: $ThCr_2Si_2$, $CaBe_2Ge_2$, $BaNiSn_3$ are three common examples.

In polar intermetallics where the active metal is among the rare-earth elements, the predominant interatomic interactions involve 6*s* and 5*d* valence orbitals of the rare-earth with the valence *s* and *p* orbitals of the main group element. If there is significant hybridization between the valence 4*f* orbitals and the *sp* orbitals of the main group metals, then interesting properties may arise, for example, "heavy fermion" behavior. Valence fluctuations in the rare-earth element are also important for this situation, while a COHP analysis of the *sp*–*sp* interactions shows nearly maximum bonding within the main group framework. This is frequently observed for Ce, but is also possible with Yb, with an *f* band that mixes with states near the crossover from bonding to antibonding characteristics (**Figure 15**).

Summary

Describing the electronic states of intermetallic compounds requires an understanding of the distinct electronic structures of the various types of metallic elements. These elements combine in many different ways, and the nature of these interactions can be addressed using different quantum mechanical approximations, varying from the NFE model to the TB theory. Fundamental factors controlling the electronic states include (1) composition, (2) relative electronegativities of elements, which control the relative valence orbital energies, and (3) coordination environments (structure and atomic arrangements). Depending on the nature of these interactions, conducting properties can vary from metallic to semiconducting while magnetic properties can range from itinerant ferromagnetism to diamagnetic. Valence fluctuations and heavy fermion behavior are possible for rare-earth compounds, and 5*f* orbitals contribute to the chemical bonding interactions in actinide compounds.

Introduction

Originally the advent of microelectronics gave rise to the need for rapid and accurate analysis of thin film structures. Generally, these planar structures were formed in silicon or germanium by either energetic ion implantation of dopants to create electrically active regions and/or by thermal reactions between thin metal films which were deposited onto them. Ion-beam modification (e.g., ion implantation) was a new technique in the early sixties, and interactions between metal films and silicon required analysis. For example, the number of ions implanted per square centimeter (ion dose) and the thicknesses of metal layers required careful control to meet the specifications of integrated circuit technology. Rutherford backscattering spectrometry (RBS) and MeV ion-beam analyses were developed in response to the needs of the microelectronics and forensic disciplines. In turn, integrated circuit technology provided the electronic sophistication used in the instrumentation in ion-beam analysis. It was a synergistic development of analytical tools and the fabrication of integrated circuits.

Rutherford backscattering analysis is the measurement of the energies of ions scattered back from the surface and near the surface, the outer micron, of a sample. **Figure 1** shows a depiction of a general ion-scattering chamber where samples are typically analyzed. Monoenergetic helium ions or protons with energies ranging from 1 to 5 MeV are used to analyze thin film materials ranging from integrated circuits to biomedical materials. Only moderate vacuum levels ($\sim 10^{-6}$ torr) are required so that sample exchange is rapid; it allows the analysis to be done in a relatively brief period of time (~ 20 min or less). Under unique conditions, inorganic materials can be analyzed with minimum damage to the sample. In this case, RBS is considered nondestructive. This is in contrast to surface sensitive techniques such as Auger electron spectroscopy (AES), where surface erosion by sputtering is required for depth analysis. Another salient feature of RBS is that the scattering cross sections are well known, and this results in an analytical technique that is extremely quantitative. The scattering cross section is a measure of the probability of a detectable

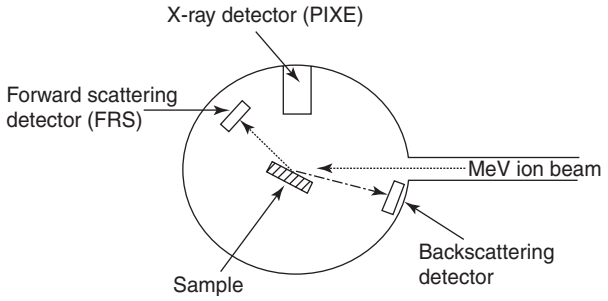

Figure 1 Schematic diagram of the target chamber and detectors used in ion-beam analysis. The backscattering detector is mounted close to the incident beam and the forward scattering detector is mounted so that when the target is tilted, ion recoils can be detected at angles of $\sim 30^{\circ}$ from the beam direction. The X-ray detector faces the sample and receives X-rays emitted from the sample.

interaction between the incident beam and the material under investigation. In other analytical techniques, such as secondary ion mass spectroscopy (SIMS), the cross sections are not well defined. The relative ion yields can vary over three orders of magnitude depending on the nature of the surface. Rutherford backscattering has been a convenient way to calibrate SIMS, which in turn, is more sensitive to the detection of trace elements than backscattering. Hence, these two techniques are complementary.

Ion-beam analysis grew out of early nuclear physics research on cross sections and reaction products involved in atomic collisions. In this work, million volt accelerators were developed and used extensively. As the energies of the incident particles increased, the lower energy accelerators became available for use in analytical applications. The early nuclear physics research used magnetic spectrometers to measure the energies of the particles. This analytical procedure was time consuming, and the advent of the semiconductor nuclear particle detector allowed simultaneous detection of all particle energies. The semiconductor detector is a Schottky barrier (typically, a gold film on silicon) or shallow diffused p–n junction with the active region defined by the high-electric field in the depletion layer. The active region extends tens of microns below the surface of the detector, so that in almost every application, the penetration of the energetic particles is confined within the active region. The response of the detector is linear with the energy of the particles providing a true particle energy spectrometer.

Analysis of ion-implanted layers and metal–silicon interactions (i.e., silicide formation) was carried out with Rutherford backscattering at 2.0 MeV energies and with semiconductor nuclear particle detectors

for decades. Rutherford backscattering became well established and was utilized in materials analysis in national, university, and eventually industrial laboratories across the world.

The recent interest in the use of implanted hydrogen to induce cleaving of thin layers of Si, has renewed the interest and importance of quantifying the amounts of hydrogen in Si and other single-crystalline substrates. Other areas such as solid-state chemistry of hydrogen production and storage have also required quantifying the amounts of hydrogen in thin films. Both these areas have led to the development of forward scattering, in which one quantifies the light-element content by measuring the energy of the recoiling hydrogen atom. The helium ion is heavier than that of hydrogen. In this case, the sample is tilted in a manner that the emerging hydrogen recoil energy can be measured with the use of a nuclear particle detector. The only modification to the RBS target chamber geometry is the tilt of the target and the position of the detector (see **Figure 1**). These forward recoil techniques have, of course, become more sophisticated with the use of heavy incident ions and detectors, which measure both the energy and the mass of the recoiling particles.

The analysis of thin film layers on species implanted into silicon is an almost ideal experimental situation for RBS because the masses of the thin films and/or atoms of implanted species and metal layers most often exceed the mass of Si. In Rutherford backscattering, the mass of the atom must be greater than that of the silicon target to separate the energy signals from the target atom from those of the silicon. However, there are few exceptions, such as carbon, nitrogen, and oxygen. The resonance analysis of these species is carried out in the same experimental chamber as used in RBS, but the energy of the incident helium ions is increased to energies where there are resonances in the backscattering cross sections. These resonances increase the yield of the scattered particle by nearly two orders of magnitude and provide high sensitivity to the analysis of oxygen and carbon in silicon. The use of these high energies, 4.3, 3.05, and 3.7 MeV for the helium–carbon, helium–oxygen, helium–nitrogen resonances, respectively, is called resonance scattering or non-Rutherford scattering. Insertion of a semiconductor X-ray detector into the analysis chamber allows the measurement of particle-induced X-rays. Particle-induced X-ray emission (PIXE) is a technique that can be used for nondestructive, simultaneous elemental analysis of bulk solids, thin films, liquids, and low specific volume gases. Like other fluorescence spectroscopies, PIXE is based on the emission of characteristic X-rays from an element. This reaction, however, is a direct result of the bombardment by MeV/amu ions (most often, protons or alpha particles). The use of proton and alpha beams as the probe-beam source offers several advantages over other fluorescence techniques in that it provides (1) a higher rate of data accumulation across the entire spectrum, and (2) better overall sensitivities, especially for the lower atomic number elements. This is due to a lower background noise.

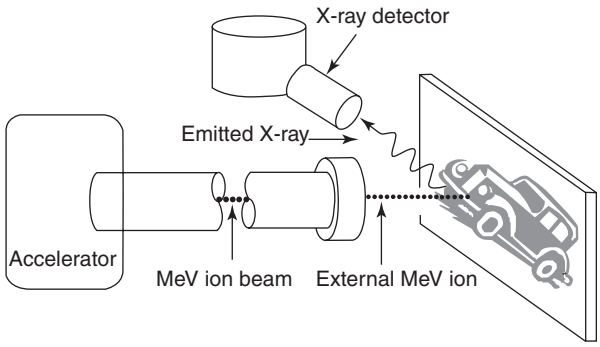

Figure 2 Schematic diagram of the setup for proton-induced X-ray emission. Protons of 3.5–5 MeV are produced in an accelerator, and travel in vacuum to the thin window at the end of the beam line. The protons have sufficient energy to pass through the window and travel in air to the painting. The emitted X-rays are detected by the X-ray detector.

Often the occasion arises such that the sample to be analyzed is too fragile or too large to fit into the ion-scattering chamber. A good example of this is the analysis of art work and archaeological artifacts. This situation requires the use of external PIXE analysis where the proton or alpha particles travel in vacuum to the thin window at the end of the beam line. The particles have sufficient energy (normally 3.5–5 MeV) to exit through the window (**Figure 2**) and to travel in air to the sample under investigation. For example, a 4 MeV proton can travel $\sim$25 cm in air before it loses all its energy in collisions with air molecules along its path. Consequently, the protons can be taken out into the air for external beam analysis.

The remaining portion of this article reviews the major techniques used in materials analysis that involve the use of MeV ion beams: Rutherford backscattering, channeling, resonance scattering, forward recoil scattering, and PIXE.

Rutherford Backscattering Spectrometry

In this section, the development of RBS analysis starts with an overview of the experimental target chamber. This is followed by a discussion of the particle kinematics, which determine mass identification and depth resolution, and then concludes with examples of the RBS analysis.

Target Chamber

In a typical scattering chamber (**Figure 1**), the sample is located so that its surface is on an axis of rotation of a goniometer such that the beam position does not shift across the sample as the sample is tilted with respect to the incident ion beam. The backscattering detector is mounted as close to the incident beam as possible such that the average backscattering angle, ϑ, is close to 180°, typically 170°, with a detector solid angle of 5 msr. In some cases, annular detectors are used with the incident beam passing through the center of the detector aperture in order to provide larger analysis solid angles. The sample can also be rotated into a glancing angle geometry when the forward scattering detector is used. In this case, a thin foil is placed in front of the detector to block the helium ions while allowing the hydrogen ions to pass through with only minimal energy loss. The stopping power (energy loss) of MeV helium ions is 10 times that of the recoiling hydrogen ions. In addition, the X-ray detector is placed such that the detector window (i.e., the entrance to the active region) is in full view of the sample surface bombarded with the incident ions. The vacuum requirements in the target chamber are comparable to those in the accelerator beam lines. Enhanced vacuum levels reduce the probability that the ion beam will lose energy along its path to the sample, and also minimizes deposition of contaminants and hydrocarbons on the surface during analysis.

In traditional backscattering spectrometry using helium ions, the energy resolution of the solid-state particle detector is typically 17 keV. This resolution can be improved to 10 keV with special detectors and detector cooling. The output signal, which is typically millivolts in pulse height is processed by silicon integrated circuit electronics and provides an energy spectrum in terms of number of particles versus energy. A multichannel analyzer records the number of backscattered particles versus a given energy in a specific channel. Hence, the energy scale is divided into channel numbers. To make the conversion from channel number to energy requires a simple energy calibration.

Scattering Kinematics

During ion-beam analysis, the incident particle penetrates into the target and undergoes inelastic collisions, predominantly with electrons, and loses energy as it penetrates to the end of its range. The range of 2.5 MeV helium ions is ~10 μm in a target of silicon atoms, the range of comparable energy protons is ~10 times that of the helium ions.

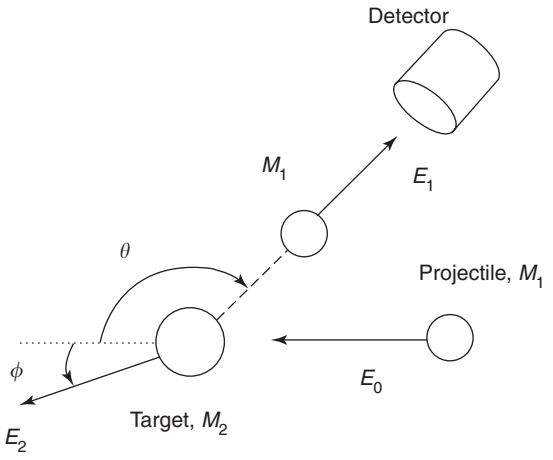

Figure 3 A schematic representation of an elastic collision between a particle of mass M_1 and initial energy E_0 and a target atom of mass M_2. After the collision, the projectile and target atoms have energies of E_1 and E_2, respectively. The angles θ and ϕ are positive as shown. All quantities refer to the laboratory frame of reference.

During the penetration of the helium ions, a small fraction undergoes elastic collisions with the target atom, which defines the backscattering signal. **Figure 3** shows a schematic representation of the geometry of an elastic collision between a projectile of mass M_1 and energy E_0 with a target atom of mass M_2 initially at rest. After collision, the incident ion is scattered back through an angle ϑ and emerges from the sample with an energy E_1. The target atom, after collision, has a recoil energy E_2. There is no change in target mass, because nuclear reactions are not involved and energies are nonrelativistic. The ratio of the projectile energies for $M_1 < M_2$ is given by

$$K = \frac{E_1}{E_0} = \left[\frac{(M_2^2 - M_1^2 \sin^2 \vartheta)^{1/2} + M_1 \cos \vartheta}{M_2 + M_1}\right]^2 \qquad [1]$$

The energy ratio $K = E_1/E_0$, called the kinematic factor, shows how the energy of the backscattered particle is a function of the incident particle and target atom masses, the scattering angle, and incident energy.

For a direct backscattering through 180°, the energy ratio has its lowest value given by

$$\frac{E_1}{E_0} = \left(\frac{M_2 - M_1}{M_2 + M_1}\right)^2 \qquad [2]$$

For incident helium ions $(M_1 = 4)$ at $E_0 =$ 2.8 MeV, the energy E_1 of the backscattered particle for silicon $(M_2 = 28)$ is 1.58 MeV and for silver $(M_2 = 108)$, the energy is 2.41 MeV. The energy E_2 transferred to the target atom has a general relation

given by

$$\frac{E_2}{E_0} = \frac{4M_1M_2}{(M_1 + M_2)^2}\cos^2\phi \qquad [3]$$

For scattering through an angle of $\vartheta = 180°$, the energy E_2 transferred to the target atom has its maximum value of

$$\frac{E_2}{E_0} = \frac{4M_1M_2}{(M_1 + M_2)^2} \qquad [4]$$

The ability to identify different mass species depends on the energy resolution of the detector which is typically 17 keV full width at half maximum (FWHM). For example, Ag has a mass $M_2 = 108$ and In has a mass $M_2 = 115$. The difference between $K_{Ag} = 0.862$ and $K_{In} = 0.870$ is 0.008. For 2.8 MeV helium ions, the difference in backscattering energy is 22 keV which is larger than the detector-system resolution, indicating that signals from Ag and In on the surface can be resolved. The difference between gold and tungsten K values, however, is 0.005, and hence at 2.8 MeV energies, it is not possible to resolve the signals between gold and tungsten. Conventional RBS systems using a 17 keV detector system can resolve signals from, and identify the elements of masses up to ~90. These systems can also resolve isotopes up to a mass of 55. For example, all of the silicon isotopes can be identified.

For the examples above, the detectors were assumed to be pristine and the system electronics to have negligible effects on the detectors. This is generally not the case. The system's electronics can contribute slightly to the value of the resolution. With an extended use and age, the worthiness of the detector resolution deteriorates and hence degrades the overall detector–system resolution.

Scattering Cross Section

The identity of target elements is established by the energy of the scattered particles after an elastic collision. This is done by measuring the yield Y, the number of backscattered particles for a given value of incident particles Q. The detector's solid angle is given as Ω. The areal density, the number of atoms per unit area, N_S determined from the scattering cross section $\sigma(\vartheta)$ by

$$N_S = \frac{Y}{\sigma(\vartheta)Q\ \mathrm{d}\Omega} \qquad [5]$$

This is shown schematically in **Figure 4**. A narrow beam of fast particles impinges on a thin uniform target that is wider than the beam. At a scattering angle θ from the direction of incidence, an ideal detector is located that counts each particle scattered in the differential solid angle $\mathrm{d}\Omega$. In the simplest approximation, the scattering cross section is given by

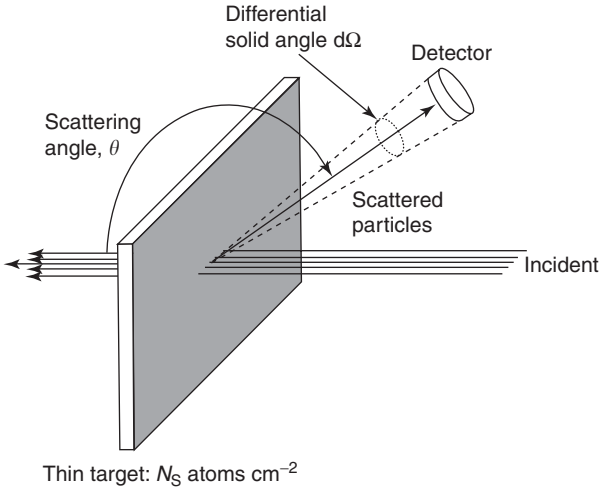

Figure 4 Layout of a scattering experiment. Only primary particles that are scattered within the solid angle dΩ spanned by the solid-state detector are counted. (Adapted and redrawn from Feldman LC and Mayer JW (1986) *Fundamentals of Surface and Thin-Film Analysis*. New York: North-Holland.)

$$\sigma(\vartheta) = \left(\frac{Z_1Z_2e^2}{4E}\right)^2 \frac{1}{\sin^4(\vartheta/2)} \qquad [6]$$

which is the scattering cross section originally derived by Rutherford. For 2 MeV helium ions incident on silver, $Z_2 = 47$ at 180°, the cross section is 2.9×10^{-24} cm^2 or 2.9 barns (where 1 barn = 10^{-24} cm^2). The distance of closest approach is $\sim 7 \times 10^{-3}$ nm which is smaller than the K-shell radius of silver (10^{-1} nm). This means that the incident helium ion penetrates well within the innermost radius of the electrons, so that one can use an unscreened Coulombic potential for the scattering. The distance of closest approach is sufficiently large so that penetration into the nuclear core does not occur and hence, nuclear reactions need not be considered.

The cross sections are relatively large such that one can detect sub-monolayers of most heavy-mass elements on silicon. For example, the yield of 2.0 MeV helium ions from 10^{14} cm^{-2} silver atoms (~1/10 of a monolayer) is 800 counts for a current of 100 nA for 15 min and detector area of 5 msr. This represents a large signal for a small amount of atoms on the surface.

Depth Scale

Light ions, such as helium, lose energy through inelastic collision with atomic electrons. In backscattering

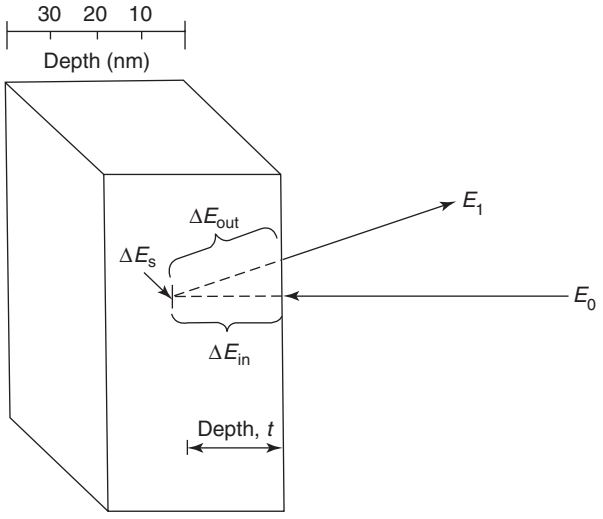

Figure 5 Energy loss components for a projectile that scatters from depth t. The particle loses energy ΔE_{in} via inelastic collisions with electrons along the inward path. There is energy loss ΔE_S in the elastic scattering process at depth t. There is energy lost to inelastic collisions ΔE_{out} along the outward path. For an incident energy E_0, the energy of the exiting particle is $E_1 = E_0 - \Delta E_{in} - \Delta E_S - \Delta E_{out}$.

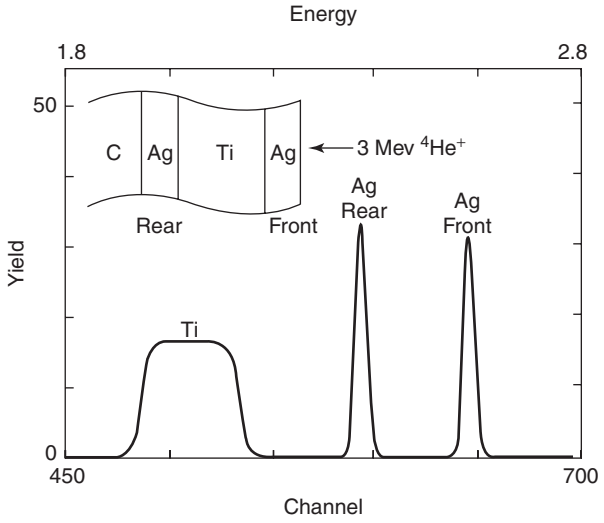

Figure 6 Backscattering spectrum of a Ti film (150 nm) with thin layers of Ag (3 nm) on the front and back surfaces of the titanium. The signals from the front and back layers of Ag are shown and are well separated in energy from each other by nearly the same energy width as the Ti signal.

spectrometry, where the elastic collision takes place at depth t below the surface, one considers the energy loss along the inward path and on the outward path as shown in **Figure 5**. The energy loss on the way in is weighted by the kinematic factor, and the total is given by the relationship

$$\Delta E = \Delta t\left(K\frac{\mathrm{d}E}{\mathrm{d}x}\bigg|_{\mathrm{in}} + \frac{1}{|\cos\vartheta|}\cdot\frac{\mathrm{d}E}{\mathrm{d}x}\bigg|_{\mathrm{out}}\right) = \Delta t[S] \quad [7]$$

where $\mathrm{d}E/\mathrm{d}x$ is the rate of energy loss with distance and $[S]$ is the energy loss factor. The particle loses energy ΔE_{in} via inelastic collisions with electrons along the inward path. There is energy loss ΔE_S in the elastic scattering process at depth t. There is energy loss due to inelastic collisions ΔE_{out} along the outward path. For an incident energy E_0, the energy of the exiting particle is $E_1 = E_0 - \Delta E_{in} - \Delta E_S - \Delta E_{out}$.

An example illustrating the influence of depth on analysis is given in **Figure 6**, which shows two thin silver layers on the front and back of a titanium film. The scattering from silver at the surface is clearly separated from Ag at the back layer. The energy width between the Ag signals, is closely equal to that of the energy width of the Ti signal. This signal is nearly square shaped because Ti exists from the front to the back surface. The depth scales are determined from energy loss values, which are given in a tabular form as a function of energy. It is often expressed as a stopping cross section in terms of $[S]$, the energy loss factor, which is given in units of $\mathrm{eV\,cm^{-1}}$. The depth resolution is given by dividing the detector resolution by the energy loss factor. For 2.0 MeV helium in silicon, one might expect a depth resolution of $\sim$20 nm for 180° scattering geometries. This can be reduced to values of $\sim$5 nm for glancing incident and exit angles. The resolution degrades as the particle transverses into the sample.

A typical use of RBS is to determine how the composition varies as a function of depth. The variation of composition with depth is used to characterize thin films and thin film reactions. For example, RBS is used to characterize the migration of Ti through a thin film of Ag after annealing in an NH_3 ambient. **Figure 7** (dashed line) shows the as-deposited spectrum for an Ag/Ti bilayer structure on a layer of SiO_2 on a silicon substrate. After a thermal anneal at 500°C in an ammonia ambient for 30 min (**Figure 7**, solid line), the RBS signal clearly shows how the composition varies as a function of depth. A computer simulation of the spectrum in **Figure 7** shows that the Ag layer contains a residual Ti concentration of <1 at.%. Rutherford backscattering spectra can be analyzed with the use of available analysis programs (e.g., Rutherford Universal Manipulation Program (RUMP). This software provides a layer-by-layer signal analysis of thin film materials and it gives the operator the ability to input: tilt angle, detector solid angle, detector resolution, individual isotopes, enhanced cross section for light elements, such as carbon and oxygen. RUMP has the ability to be used to analyze forward recoil spectra (see section "Elastic recoil spectrometry").

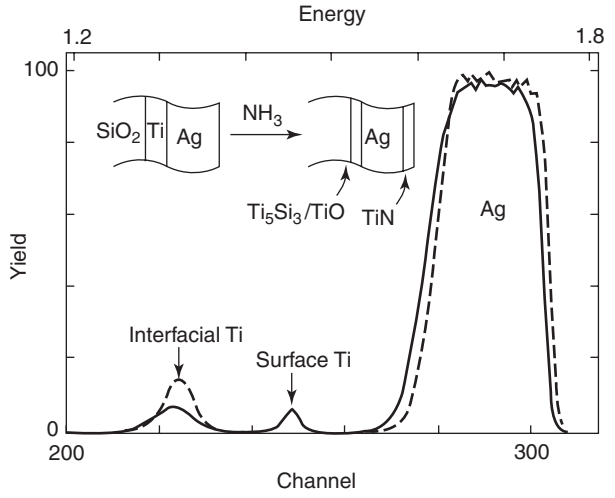

Figure 7 Ag encapsulation on SiO_2 prepared from Ag(120 nm)/Ti(22 nm) bilayers. RBS spectra show the depth distribution of Ag and Ti before and after annealing at 500°C in an ammonia ambient for 30 min. The spectra were obtained using a 2.0 MeV He^{+2} beam and a scattering angle of 170°.

Rutherford backscattering analysis is most often done in unison with one or more analytical techniques. **Figure 8** shows the backscattering spectrum from a single crystalline Si wafer implanted with 9×10^{15} Au^+ ions cm^{-2} at 3.6 MeV and the corresponding cross-sectional transmission electron microscopy (X-TEM) micrograph. The RUMP simulation of the Au RBS spectrum confirms the common depth scale. Two distinct regions of Au precipitates (dark spots) are present, coinciding in position with the two peaks in the Au backscattering profile. This example also shows the complementary nature of RBS and X-TEM analysis.

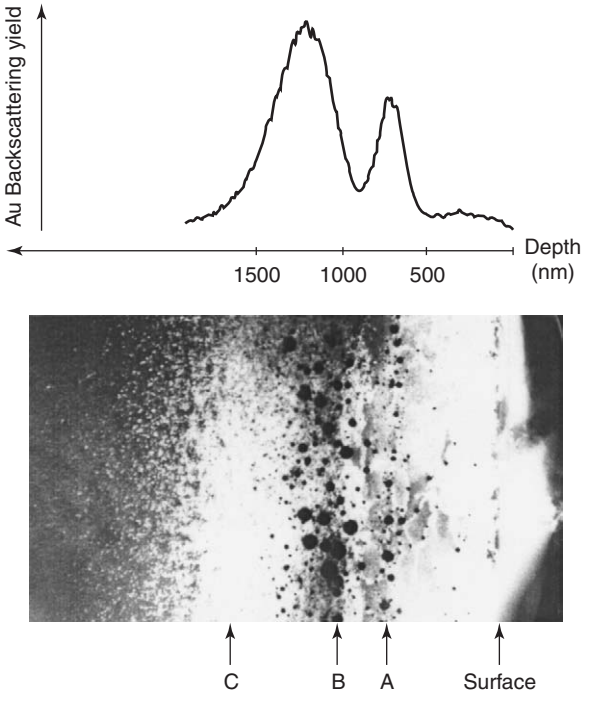

Figure 8 X-TEM micrograph of the 3.6 MeV Au^+ 8.6×10^{16} ions cm^{-1} implanted sample displaying the multiple precipitate layers which corresponds with the two Au peaks in the RBS spectrum. The depth scale is applicable to both X-TEM micrograph and the RBS spectrum. (From PhD dissertation of Alford TL.)

Ion Channeling

When a single-crystal sample is mounted on a goniometer such that a major crystallographic axis of the sample is aligned within ~0.1 or 0.5° of the incident beam, the crystal lattice can steer the trajectories of the incident ions penetrating into the crystal. It is this steering of the incident energetic beam that is known as ion channeling; the atomic rows and planes are guides that steer the energetic ions along the channels between rows and planes. The channeled ions do not approach close enough to the lattice atoms to be backscattered. Hence, the range (the total distance that an ion penetrates a solid) is increased several fold. In comparison, the reduced probability of scattering results in a two-orders of magnitude reduction in the yield.

Figure 9 shows schematically a random and aligned spectrum for MeV helium ions incident on

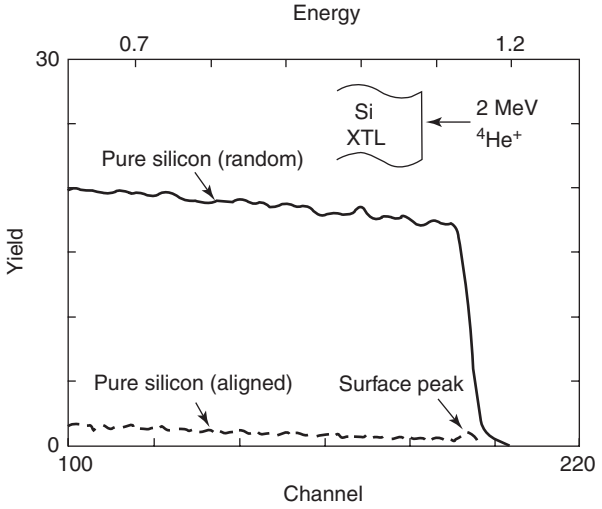

Figure 9 Random and aligned (channeled) backscattering spectrum from a single-crystal sample of silicon. The aligned spectrum has a peak at the high-energy end (near channel 195) of the Si signal. This peak, called the surface peak, represents helium ions scattered from the outer layers of Si that are exposed to the incident beam. The yield behind the peak is 1/40 of the random yield because the Si atoms are shielded from close encounter elastic collisions from the ion beam that is channeled along the axial rows of the Si crystal.

silicon. The characteristic feature of the aligned spectrum is the peak (near channel 195) at the high-energy end of the spectrum. This peak is a result of ions scattered from the outermost layer of atoms directly exposed to the incident beam. This peak is referred to as the surface peak. Behind the surface peak, at lower energies, the aligned spectrum drops to a value of 1/40 of the silicon random spectrum indicating that ~97% of the incident ions are channeled and do not make close-impact collisions with the lattice atoms. The rise in the aligned spectrum at lower energies represent the ions that are dechanneled, deflected from the steering by the lattice atoms, which can then collide in close impact collisions with the lattice atoms and hence directly contribute to the backscattering spectra. The ratio between the aligned minimum yield and random yield for the same channel number gives the χ_{min} value. The crystalline quality is given by the values of χ_{min} at a specific energy, for example, which equals 0.028 for Si when using 2.0 MeV helium ions.

Channeling phenomena is also important in the areas of ion implantation and epitaxial growth. In each case, the incident ions can be steered along the lattice planes and rows. Channeling measurements can determine the amount of lattice disorder when displaced atoms are located within the channels, they can measure the number of impurity atoms that are located sufficiently far from substitutional lattice sites so that they are accessible to backscattering from the channeled ions. Channeling also provides angular relationships between substrates and epitaxial layers.

During ion implantation, channeling leads to a deeper penetration of the incident ions when compared to the depths typically incurred for nonchanneled ions. The resulting implanted distribution of the channeled ions is a skewed Gaussian and not the typical Gaussian depth distributions characterized by nonchanneled energetic ions. **Figure 10** shows a plot of range of channeled ion and randomly aligned ions incident on a crystalline solid substrate.

The application of channeling to RBS is used to determine the amount of damage in ion-implanted single crystal silicon and the lattice location of ion-implanted dopant atoms. One important example of the contribution of channeling to integrated circuit technology is the analysis of damage evolution during ion implantation. **Figure 11** shows the channeling backscattering spectra obtained from H^+-implanted Si at different implantation doses. The peaks in the spectra of the implanted samples indicate the lattice damage induced by the hydrogen implantation. The difference in height of these peaks corresponds to the different H^+-implantation doses. At

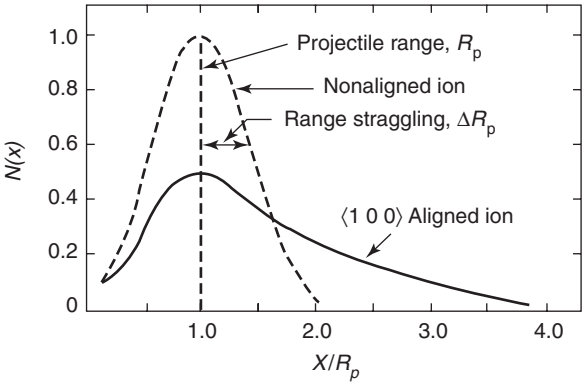

Figure 10 Distributions for channeled ions implanted along the ⟨1 0 0⟩ axis of Si. The dashed line shows the Gaussian distributions for incident ions aligned away from any channeling direction. (Adapted from Mayer W and Lau SS (1990) *Electronic Materials Science*. New York: Macmillan.)

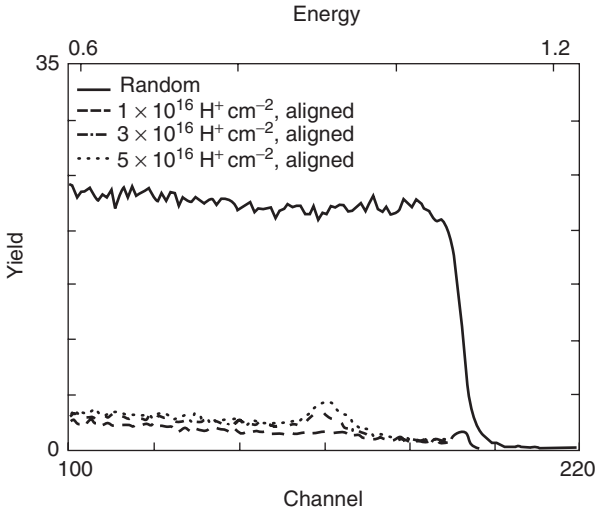

Figure 11 2 MeV He^{2+} RBS channeling (aligned) spectra of the ⟨1 0 0⟩ Si wafer, implanted with 40 keV H^+ ions at different doses. Also shown for comparison is a random spectrum.

low H^+-implantation dose, no damage peak is observed. The backscattering yield of the peaks at higher energies is quite low ($4\% < \chi_{min} < 9.5\%$ of the random signal), revealing the high crystal quality of the silicon layer above the implantation damage region. The creation of a submicron damage layer by H^+ implantation facilitates the slicing of thin high-quality silicon layers, which is essential for the production of silicon-on-insulator (SOI) and flexible displays.

Another example of channeling is the characterization of extended damage and eventual amorphization. **Figure 12** shows random and channeling spectra from silicon single-crystal samples implanted to doses of 0.4, 1.1, 1.8, and $2.3 \times 10^{15}\,cm^{-2}$ using 2.4 MeV Au^+ ions. As the implant dose increases,

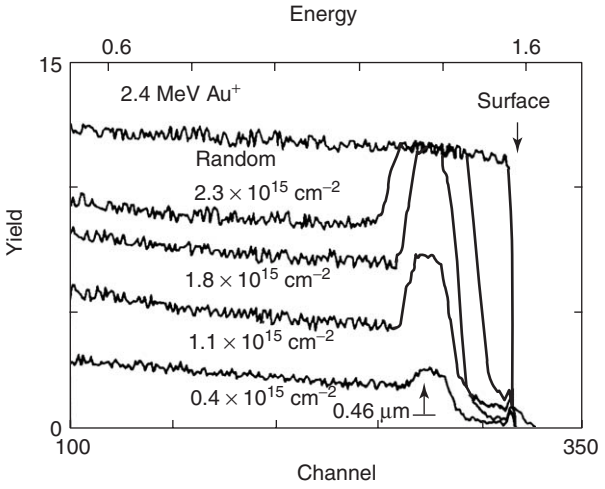

Figure 12 Random and aligned channeling ⟨100⟩ spectra from Si single crystals implanted with 2.4 MeV Au^+ to fluences of 0.4, 1.1, 1.8, and 2.3×10^{15} ions cm^{-2}. Note that only the Si signals are shown. (From PhD dissertation of Alford TL.)

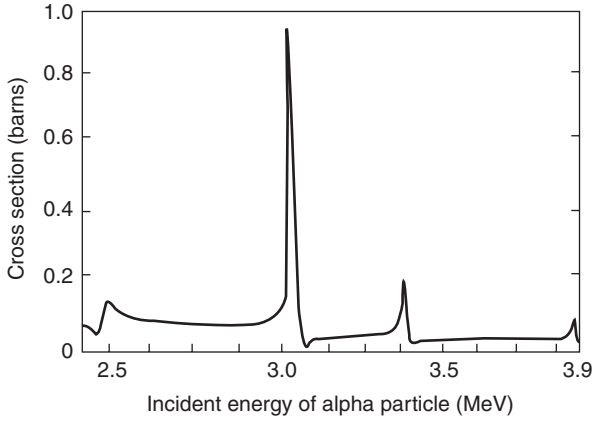

Figure 13 Elastic cross section of helium ions scattered from oxygen atoms. The pronounced peak in the spectrum ~3.04 MeV represents the resonance scattering cross section that is often used in the detection of oxygen. (Adapted from Tesmer JR and Nastasi M (eds.) (1995) *Handbook of Modern Ion Beam Materials Analysis*. Pittsburgh: Materials Research Society).

more silicon matrix atoms are displaced from the lattice sites; hence, the resulting damage profile increases as well. For the high doses, the damage-profile reaches the yield of the random spectrum. This is an indication of amorphous layer formation. Comparison of **Figures 11** and **12** reveals the usefulness of ion channeling to characterize both low and high amounts of damage in single crystals.

Ion Resonances

At energies of a few million electronvolts, nuclear reactions and strong deviations from Rutherford scattering should not play a role in the backscattering analyses. One of the exceptions is the strong increase (resonance) in the scattering cross section at 3.04 MeV for ^4He ions incident on ^{16}O, as shown in **Figure 13**. This reaction can be used to increase the sensitivity for the detection of oxygen as well as other light elements such as carbon and nitrogen.

The oxygen resonance cross section versus energy is shown in **Figure 13**. The resonance that occurs at 3.04 MeV shows a strong peak. In order to evaluate the amount of oxygen in a thin film of $TiAl_xN_yO_z$ on SiO_2/Si substrate, the oxygen resonance technique using 3.05 MeV $^4He^{2+}$ ion beam was employed (**Figure 14**). The RUMP simulation is overlapped with the real spectrum. The enhanced oxygen peak near channel 200 is a direct consequence of O resonance at 3.05 MeV and corresponds to oxygen atoms present in the thin film.

Carbon also has a resonance in its cross section leading to 100-fold increase in the backscattering signal. This resonance has been very convenient for

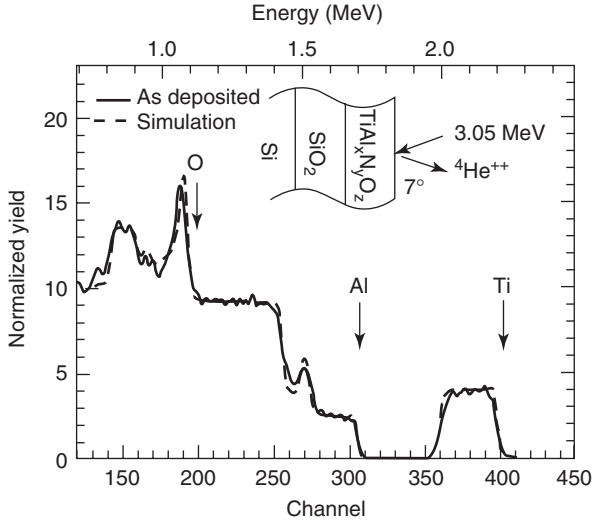

Figure 14 Backscattering spectrum (3.05 MeV He^{2+}, 7° tilt) and simulation of as-deposited $TiAl_xN_yO_z$ thin film on SiO_2/Si substrate.

analyzing 1% carbon in silicon–germanium films. The resonance for nitrogen is not as pronounced, but has been used extensively.

The use of elastic nuclear resonances provides a useful means of enhancing the sensitivity toward light elements using the same experimental setup as for Rutherford backscattering. Quantitative information about light-element concentrations is only obtainable under certain conditions. By using resonance near the peak value of the cross section, one may enhance sensitivity; however, this may result in a loss of precision, defined as day-to-day repeatability of the measurement. Conversely, using resonance in

an energy regime in which the cross section varies less rapidly may more accurately predict the actual composition than standard RBS, but prove less useful for low concentrations. Russell and co-workers in 1996, not only gave guidelines to the application of resonance analysis importance of film thickness and composition, and the variation in the incident beam energy toward the selection of the appropriate resonance regime, but also presented common sources of error. An excellent account of the effects of detector resolution, straggling, and film thickness was given by DeCoster and co-workers in 1992.

Elastic Recoil Spectrometry

The quantification of low Z elements is typically problematic due to the dependence of the scattering cross section σ on Z^2, when scattering occurs under Rutherford conditions. This has motivated the use of (α,α) resonances to enhance sensitivity in light-element profiling, requiring in turn that the necessary cross section data exist for the backscattering geometries found in different analytical laboratories. Elastic recoil spectroscopy detection (ERD) is another technique that is also similar to RBS in that the incident ion scatters from atoms in the matrix. What is unique about this technique is that the detected particles are not the backscattered particles, but light atomic weight species being forward scattered. ERD utilizes energy loss (ΔE) in the filter as a means to discriminate between signals from different atomic species present, for instance hydrogen, deuterium, and tritium in a single sample. The two techniques RBS and ERD are complementary techniques. For a given incident ion, ERD is sensitive to elements lighter than the incident beam, whereas RBS is sensitive to elements heavier than that of the incident beam.

The detection of H is not attainable with other techniques, such as SIMS. As with RBS, the depth resolution of ERD spectroscopy is based on the fact that the incident ion is slowed as it transverses the solid on both the inward and the outward paths. In a similar manner, the forward scattered ion also loses energy as it exits the solid. Hence, depth information is also obtainable for the forward scattered particle.

ERD uses the same relevant parameters (tilt angle, detector solid angle, detector resolution, and individual isotopes) as used in RBS. In the case of ERD, an energetic, higher atomic number particle impinges onto a target of a lower atomic number or a substrate containing lower atomic number atoms. Naturally, the lower-Z particle can only be recoiled in the forward direction, and, therefore, thick targets have to be bombarded at an oblique angle to allow detection of the recoil. The thin targets allow the transmission of the recoil through the target material.

In the case of thin targets, the incident ion also has a finite probability of undergoing a forward scattering event from the target into the detector. To minimize the effect of the forward scattered incident ion, a filter is typically placed in front of the detector to filter out scattered incident particles. The filter thickness ($\sim$25–100 μm of Mylar) is selected such that forward scattered, higher atomic number particles can be stopped while allowing the lower atomic number particle to recoil through the filter and into the detector. Due to kinematic reasons and straggling in this foil, the depth resolution is somewhat worse than that obtainable with RBS.

A more advanced application of the ERD technique is the use of high-energy heavy ions, such as 26 MeV Si^+. **Figure 15** shows a schematic of a typical high-energy scattering geometry. In this case, a number of target atoms lighter than the incident ion can be recoiled and detected. A salient feature of the use of high-energy ions requires that the detector has the capability to discriminate between particles of different atomic number. In this case, the foil that screens forward recoiled ions must be properly selected to minimize overlap between signals due to recoiling light elements. **Figure 16** shows the ERD spectrum for the as-deposited Cu–Ti alloy and spectra from the same film annealed in an ammonia ambient at 450°C, 550°C, and 650°C. The surface positions corresponding to O and N are indicated by the arrows. Approximately 1×10^{15} cm^{-2} nitrogen or

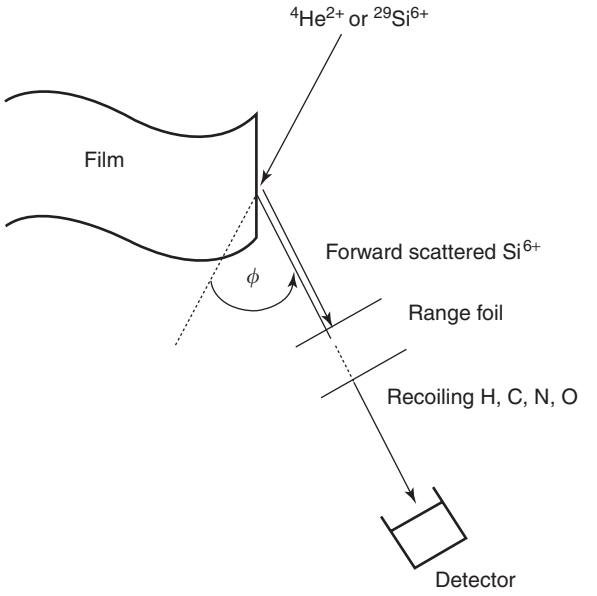

Figure 15 Schematic diagram of the elastic recoil detection process.

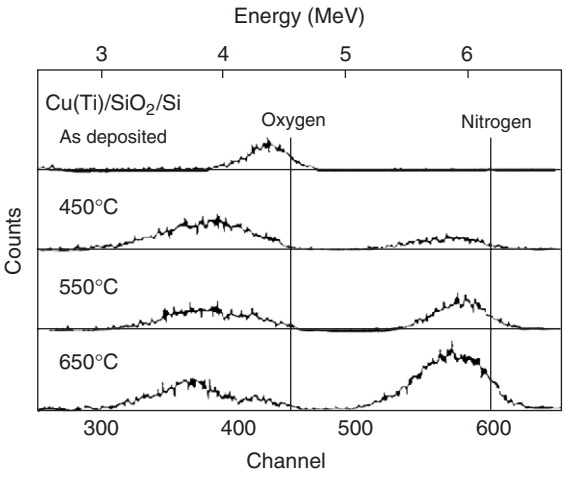

Figure 16 ERD spectra of N and O for as-deposited Cu(Ti) and for films annealed at 450°C to 650°C.

oxygen is observed in the as-deposited film by this technique. The nitrogen signal increases in area with increasing anneal temperature, indicating that the amount of nitrogen in the near-surface region of these films is steadily increasing. The N signal at 450°C is broad and flat, suggesting that a distinct N-containing layer does not exist. The height of the N signal increases up to 650°C but remains constant upon further annealing to 700°C. Also shown in the figures are signals due to oxygen. Note that the area of the major O signal remains approximately constant with annealing temperature, but shifts to lower energies. This corresponds to the oxygen-rich region being located deeper in the sample. A small step in the O signal is apparent at the two highest temperatures, with the step having its high-energy edge at the appropriate energy corresponding to the surface position of oxygen. This indicates that oxygen exists in two layers, one with a relatively small amount of oxygen located at the surface and the other with a large amount of oxygen located at a greater depth within the film.

Particle-Induced-X-Ray Emission

The PIXE analysis is based on the spectrometry of the radiation released during the filling of vacancies of inner atomic levels. These vacancies are produced by bombarding a sample with energetic (a few million electronvolts) ions. The binding energies of the electrons in the outer layers of the electron shell of an atom are of the order of some electronvolts, and radiation produced from the rearrangement of electrons in these levels is around the visible wavelength region. On the other hand, the binding energies of the inner levels are of the order of some kilo electronvolts, and, therefore, any radiation produced from processes involving these levels will typically be in the X-ray region. More importantly, as the electron energy levels of each element are quantized and unique, the measurement of the X-ray energy offers the possibility of determining the presence of a specific element in the bombarded sample. Furthermore, the number of X-rays measured of that specific energy is proportional to the amount of that element in the sample material.

The relative simplicity of the method and the penetrative nature of the X-rays yield a technique that is sensitive to most elements (for $Z > 10$) down to a few parts per million (ppm) and can be performed quantitatively from first principles. The databases for PIXE-analysis programs are typically so well developed as to include accurate, fundamental parameters, allowing the absolute precision of the technique to be $\sim 3\%$ for major elements and 10–20% for trace elements. A major factor in applying the PIXE technique is that the bombarding energy of the projectiles is a few orders of magnitude more than that of the binding energies of the electrons in the atom, and as the X-rays are produced from the innermost levels, no chemical information is obtained in the process. The advantage of this is that the technique is also not matrix dependent, and offers quantitative information regardless of the chemical states of the atoms in the sample. The major application of the technique is to determine trace-element concentrations. The nondestructive nature of this technique makes it attractive in the analysis of fragile artifacts or precious art.

In short, the technique is described schematically in **Figure 17**. A beam of energetic ions interrogates the sample. Ion–electron collisions result in the ejection of inner-shell electrons from atoms in a sample. This unstable condition of the atom cannot be maintained, and these vacancies are filled by outer-shell electrons. This means that the electrons make a transition in energy in moving from a higher energy level to a lower energy level, and this difference in energy can be released in the form of characteristic X-rays, of which the energy identifies that particular atom. In a competing process, called Auger electron emission, this energy can also be transferred to another electron that is ejected from the atom and can be detected by an electron detector. Therefore, the step from ionization to X-ray production is not 100% efficient, this efficiency being called the fluorescence yield, and has to be included in the database for quantitative measurements. The X-rays that are emitted from the sample are measured using an energy dispersive detector that has a typical energy resolution of $\sim 2.5\%$ (150 eV at 6 keV).

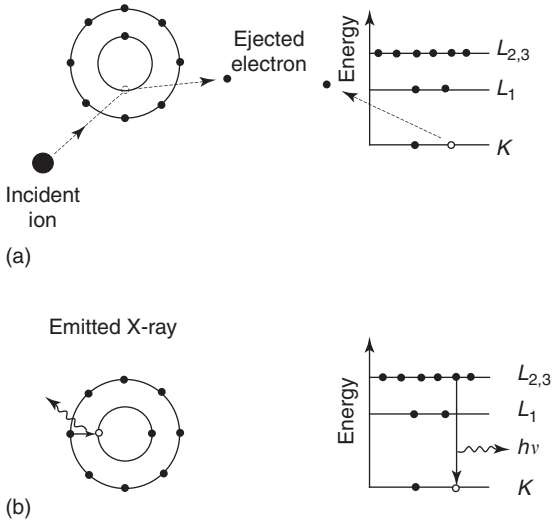

Figure 17 A schematic representation of X-ray generation by energetic particle excitation and the corresponding energy level diagrams. (a) A beam of energetic ions is used to eject inner-shell electrons from atoms in a sample. (b) These vacancies are filled by outer-shell electrons. The electrons make a transition in energy in moving from one level to another; this energy is released in the form of characteristic X-rays, of which the energy identifies that particular atom. The X-rays that are emitted from the sample are measured with an energy dispersive detector.

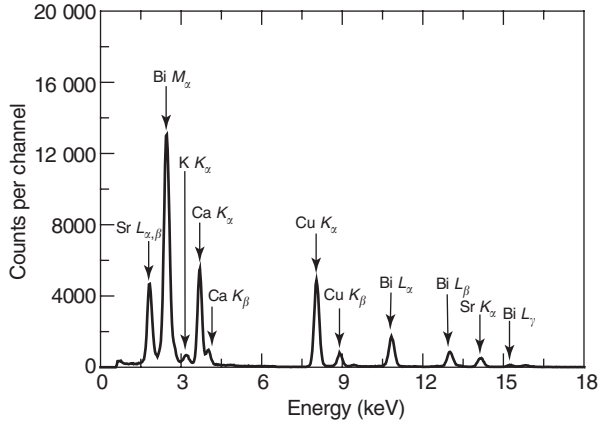

Figure 18 PIXE spectrum of a (Bi, Sr, Ca, Cu, O) superconductor taken with 1.7 MeV incident H^+ ions. (Data from K Streib at ASU.)

By convention, the transition filling vacancies in the innermost shell are called *K* X-rays, those filling the next shell are *L* X-rays, etc. The energies of the *L* X-rays are normally much lower than those of the *K* X-rays, and similarly *M* X-rays have much lower energies than the *L* X-rays. Due to the structure of the electron shells, there are naturally more possible transitions yielding *L* X-rays and even more possibilities of yielding *M* X-rays, and, therefore, it becomes more complex to measure the higher-order X-rays, and typically, the analytical method is limited to these three sets of X-rays from the elements. The limitation of detecting elements with $Z < 10$ is due to the low energies of the soft X-rays from the light elements that are absorbed before reaching the detector. This effect can also be put to good use in the technique, where the high yield of low-energy X-rays that originate from the major elements of a sample can be filtered using a selection of filters in front of the detector. Although the stopping of the bombarding ion is depth dependent, the X-ray energy measured gives no direct indication of the depth at which it was produced; therefore, the technique does not provide depth distribution information.

Typically, PIXE measurements are performed in the vacuum of a typical ion scattering chamber but it can also be performed in air with some limitations. Ion currents needed are typically around a few nanoamperes, and the current is normally not a limiting factor in applying the technique. The low-beam current also results in no or insignificant beam damage to samples during the analysis; hence, PIXE is a nondestructive analytical method sensitive to trace-element concentration levels.

The convenience of PIXE is most often compared to that of XRF (X-ray fluorescence) spectroscopy. **Figure 18** displays a spectrum taken from a bismuth strontium calcium copper oxide superconductor using PIXE analysis. This spectrum was taken with 1.7 MeV protons incident upon the sample and a 25 μm mylar filter between the sample and the detector. This filter blocks protons that are scattered from the sample from entering the detector and still allows the passage of most of the X-rays. However, the filter attenuates a small fraction of the radiation. Given that the mylar filter used in the acquisition of this spectrum is thinner, the low-energy lines are more prominent than if the filter were 50 or 100 μm. **Figure 19** displays a spectrum taken from the same sample; however, in this case, the incident radiation is molybdenum **K**α (17.48 keV) X-rays. This spectrum is taken in air and results in a small argon peak at the low-energy end of the spectrum. The radiation incident upon the sample excites some of the argon atoms present in the air before it reaches the sample. Note the presence of a molybdenum peak from the incident radiation at the high-energy end of the spectrum.

A comparison of the two spectra illustrates the advantages of PIXE over XRF. PIXE is capable of exciting X-ray lines across a wider range of energies than XRF, and is therefore capable of detecting a wider range of elements in a single spectrum. Also

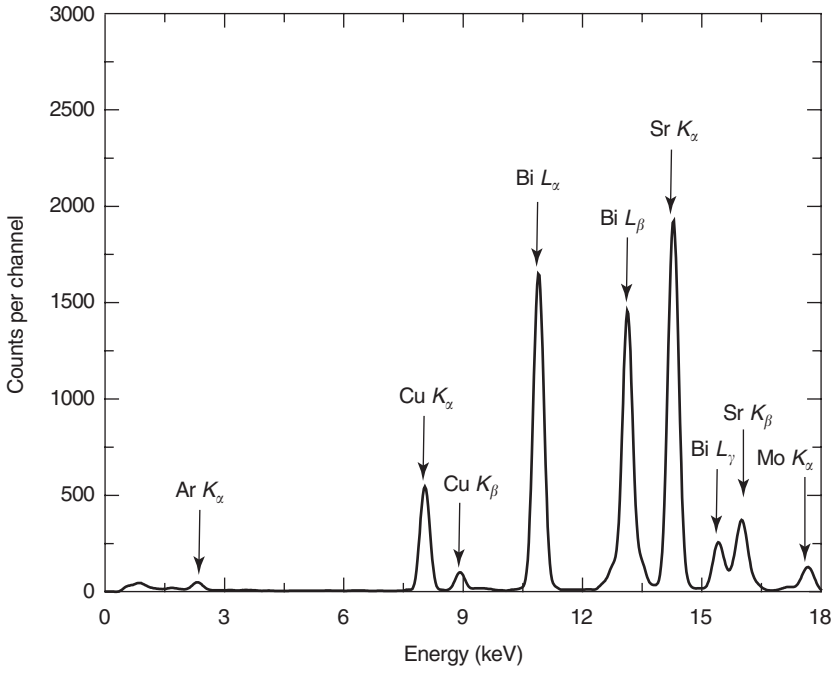

Figure 19 XRF spectrum of (Bi, Sr, Ca, Cu, O) superconductor taken with Mo K_α radiation incident on the sample. All the major peaks are indicated. The Mo peak is Mo K_α radiation scattered from the sample. The Ar K_α radiation is from air in the sample chamber (Data from K Streib at ASU.)

notice the lack of artifacts, such as argon peaks and secondary target peaks present in the XRF spectrum. This is another advantage of PIXE over XRF.

Closing Remarks

Ion-beam analysis is a mature technology that has stood the test of time. It is used in universities, national laboratories, and industry. Ion-beam analysis has also spread from semiconductor technology to fields as diverse as archaeology to the biomedical industry. References are provided to cover the basic concept and development (see the section on "Further reading").

Ion Transport in Biological Membranes

M Baruscotti, Università degli Studi di Milano, Milan, Italy
G Thiel, Darmstadt University of Technology, Darmstadt, Germany
A Moroni, Università degli Studi di Milano, Milan, Italy

All living cells are surrounded by lipid membranes that are impermeable to ions and any large or charged molecules. With this, lipid barrier cells are able to separate a well-defined ionic environment inside the cell, the cytoplasm, from the extra cellular solution and also from internal compartments. The purpose of internal compartmentation is that biochemical reactions with different ionic requirements can occur simultaneously without interfering. A schematic representation of the main cellular compartments of a typical animal cell is illustrated in **Figure 1**. The maintenance of these compartments and the integrity of the membranes is an absolute requirement for cellular life.

As much as the separation of compartments by membranes is important for cell function, a tightly controlled and selective communication between the individual compartments is required. Such a communication cannot occur via simple diffusion across the lipid membrane, because this process is much too slow. Cells have therefore evolved specific transport proteins, which facilitate the diffusion of ions and solutes through the membrane in a selective and regulated fashion.

Ion channel proteins represent a very efficient mechanism of facilitated diffusion. Due to the architecture of the channel pore (see section "Structure and function of transport proteins"), these transporters allow ions to cross membranes at rates which approach diffusion in water.

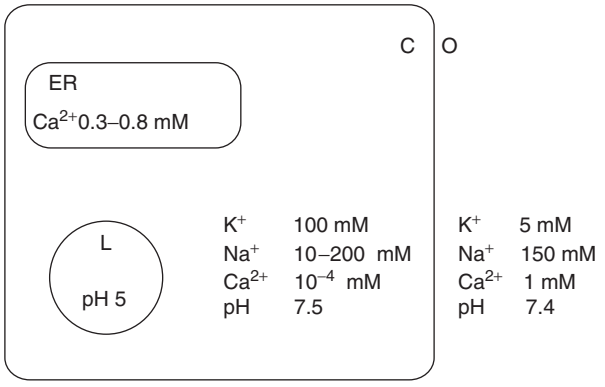

Figure 1 Concentration of main cations and pH in a typical animal cell and in some selected endo-compartments. O, external solution; C, cytoplasm; ER, endoplasmic reticulum; L, lysosome.

Diffusion is a passive process and occurs energetically only downhill. However, cells often have to concentrate ions in different compartments and in order to do this they have to move ions against their concentration gradient (see **Figure 1**). To this purpose cells utilize a class of transport proteins, termed pumps, which drive active, energy-consuming transport across the membranes. Active transport of a solute against its concentration gradient is driven by the energy released in the hydrolysis of a high-energy molecule, ATP. The pumps are therefore also called ATPases.

Transport of solutes against their gradient does not necessarily require the presence of a primary active transport system. The movement of solutes can also be coupled to the movement of other molecules down their respective electrochemical gradients (secondary active transport). In this case, the potential energy stored in ionic gradients (by the ATPases) can be utilized to transport other solutes. An example for this type of transporter is the Na^+/glucose co-transport. The concentration of sodium [Na^+] is kept low in the cytoplasm by the primary active transport system (the Na^+/K^+ ATPase). The glucose molecules are driven by secondary active transport by a Na^+/glucose co-transporter.

The best understood transporters to date, in terms of structure and function, are ion channels. This has two reasons. One reason is their key role in important physiological reactions such as nerve activity and muscle contraction. However, more significant for their understanding is their high turnover rate which allows them to be investigated at the single protein level. Two techniques, the planar lipid bilayer and the patch clamp technique, have greatly improved our understanding of ion transport through channels. The main features of the two methods are illustrated in **Figure 2**. The characteristic of the former approach is that the performance of a channel protein, even those from intracellular membranes, can be measured in a completely artificial system, in which all components such as the composition of the lipids and of the solutions are under the control of the experimenter, while the latter method allows one to measure channels in their native environment.

Both techniques report essentially the same kind of activity from ion channels. **Figure 3** illustrates a typical patch clamp recording of single-channel fluctuations in a membrane. The channel fluctuates between an open and a closed state. When it opens, it gives rise to a current, measured in picoampere (pA), with the

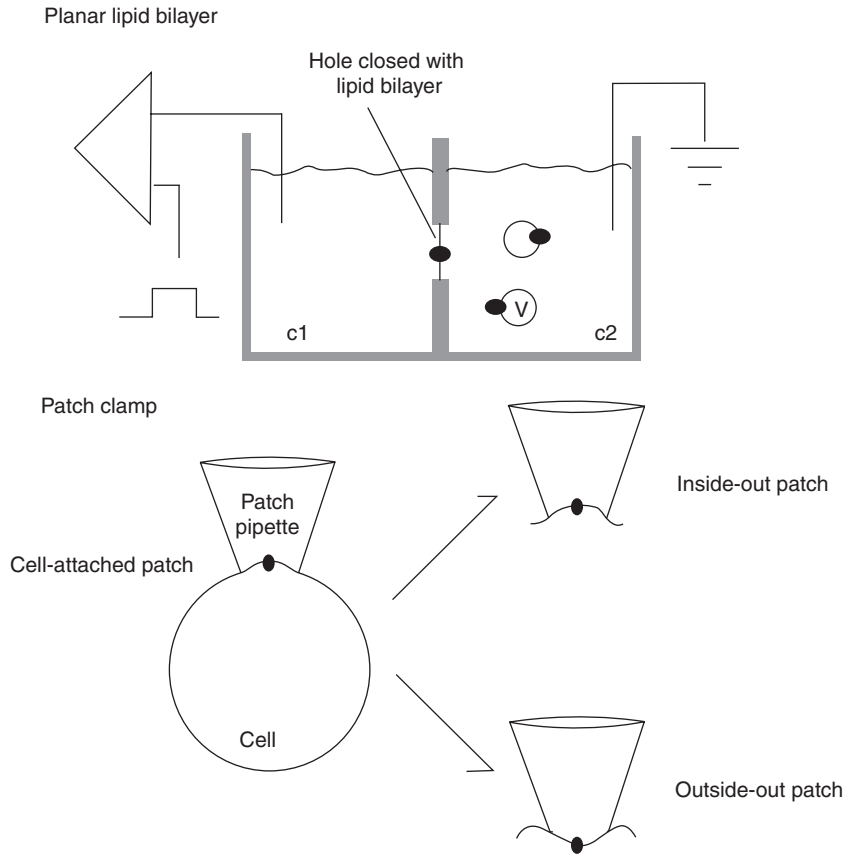

Figure 2 Sketch of main experimental techniques for single-channel recording. Planar lipid bilayer: two chambers (c1, c2) are connected by a small hole. This hole is sealed by a lipid bilayer reflecting a biological membrane. Vesicles (v) containing a channel protein (black dot) are made to fuse with this bilayer. This results in an incorporation of the channel protein into the bilayer. The activity of this channel can be recorded as a current between the two chambers. Patch clamp: A patch clamp pipette is sealed against the membrane of a cell. The current through a channel (here indicated by black dot) can be recorded. With different procedures, the membrane patch underneath the electrode can be isolated from the cell resulting in different orientations.

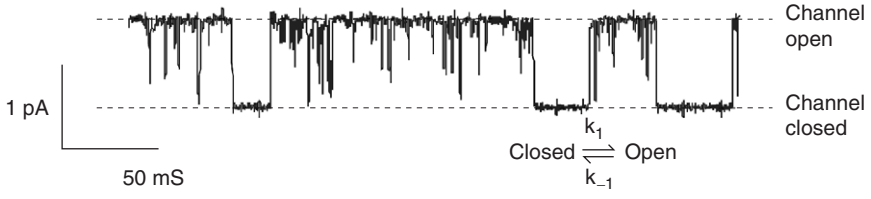

Figure 3 Example of single-channel fluctuations of K^+ channel. Opening of the channel pore allows a current flux of constant amplitude. The length which a channel spends in the open or closed state is variable. In the simplest case, the channel fluctuates in a stochastic manner with k_1 and k_{-1} between open and closed states.

characteristic open-channel amplitude. A single-channel current of 1 pA as in **Figure 3** corresponds to a flow of 6×10^6 ions per second.

In the simplest case, the conductance of an open channel behaves like an Ohmic resistor increasing linearly with the driving force. The slope of the current/voltage relation is a measure of the conductance of a channel. The conductance is characteristic of each individual channel proteins. In the case of potassium channels, they are in the range of picosiemens (pS).

The possibility of measuring and controlling the solution composition on both sides of the membrane allows examining the selectivity of these proteins. If a channel were perfectly selective for only one ion, the measured equilibrium voltage should match that predicted from the Nernst equation. Any other behavior indicates that the channel is either less selective or even, in the extreme case, not selective at all for a given ion. Channels of the latter kind have been described but they are a minority among the

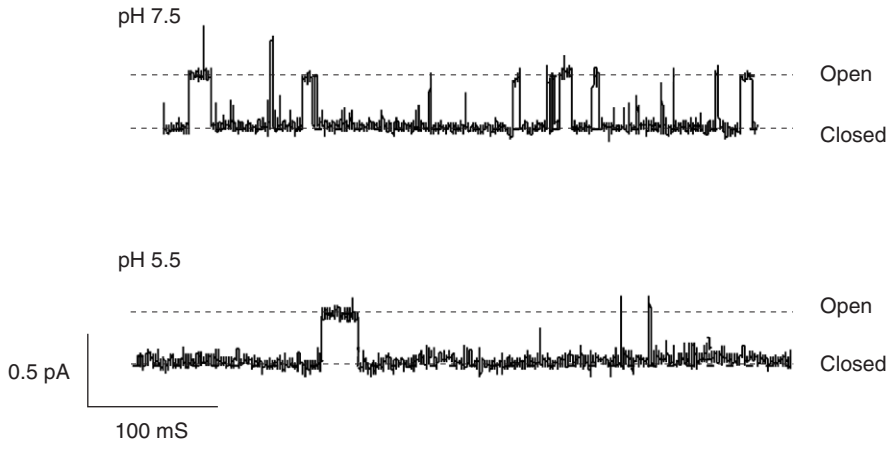

Figure 4 Effect of different pH on single K^+ channel gating. Activity of the same channel measured with a different pH on the cytoplasmic side of the membrane patch. Note that acidification increases the duration of the closed state.

physiologically relevant channels, which are in general highly selective. Experiments performed in the way indicated above show, for example, that K^+ channel are 1000 times more selective to K^+ than to Na^+. According to their selectivity, ion channels are classified as K^+, Na^+, Ca^{2+}, Cl^-, and H^+ channels.

The current flow through a channel is determined by the open-channel amplitude and by the relative time the channel stays open. As illustrated in the characteristic example in **Figure 3**, all channels fluctuate in a stochastic manner between an open and a closed state. In the simplest case, the mean dwell time of the open and the closed states are single exponentials so that the probability of a channel to be open (P_o) is given by

$$P_o = \tau_o/(\tau_o + \tau_c) \quad [1]$$

where τ_c and τ_o are the time constants for the closed and open times respectively.

While this simple kinetic model is suitable for the description of most channels, a detailed analysis of many ion channels has shown much more complex kinetic models. The analysis of the single-channel open and closed dwell times thus has led to models which include many more closed and open states organized in serial and/or parallel arrangement.

One of the important features of ion channels is that they are regulated. This guarantees that their activity is well integrated into the general physiological functions of a cell. In order to increase or decrease the current flux, channels increase or decrease their open probability, respectively. An increase in open probability can be achieved via a prolongation of the mean open dwell times or by a shortening of the mean closed dwell times or by both.

Several factors have been found to regulate ion channels in the physiological context. These include physical factors such as membrane voltage and mechanical stress. In addition, a large number of chemical modifications acting from either side of the membrane are known. **Figure 4** illustrates as an example the regulation of channel activity performed by pH on one side of the membrane. The data show that lowering of the pH results in a prolongation of the closed times, while the open times are not affected. As a result, the activity of the channels drops in a pH-dependent manner. This is mostly due to a titratable amino acid in the channel protein. As in the case of modulation by pH, most channel proteins harbor specific binding sites for their modulators.

Several different channels have been found to be regulated by chemical modification. The more general factors known to regulate channel activity in the plasma membrane of cells from the cytoplasmic side are, for example, phosphorylation/dephosphorylation, Ca^{2+}, pH, and cyclic nucleotides.

So far, the function of ion channels only at the single-protein level have been seen. From this information, one can easily extrapolate to the behavior of the ensemble of many channels of the same type in the membrane. From the aforementioned channel function, it can be deduced that the time-averaged current (I) through a channel is given by the product of the single-channel current (i) and the open probability (P_o):

$$I = i^* P_o \quad [2]$$

In this sense, the statistically weighted open-channel current is a perfect representation for the ensemble of the same kind of channels in a membrane. This only needs to be multiplied by the real number of

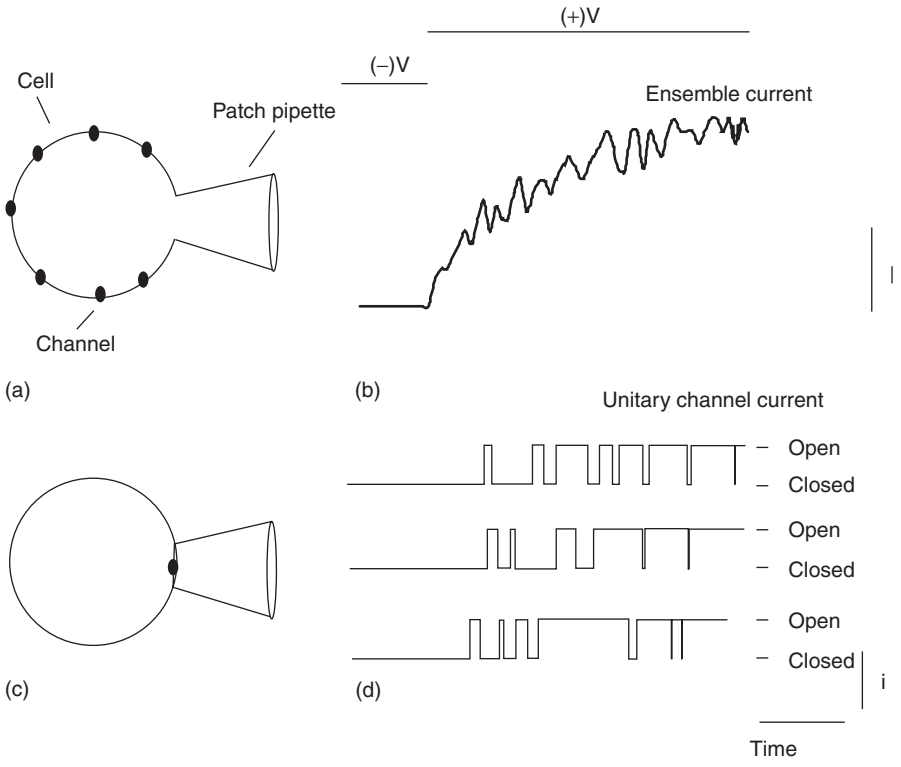

Figure 5 Relationship between single-channel activity and ensemble membrane current. Single-channel fluctuations (d) from a cell-attached recording (c, see **Figure 2**). The three simulated channel fluctuations are responses to a depolarizing voltage step (from (–)V to (+)V). The ensemble current (b) is obtained by averaging 30 sweeps as in (d). The same ensemble current (as in (b)) would be measured in the recording configuration illustrated in (a). Here the membrane underneath the patch pipette is ruptured to give a low resistance access to the cell interior.

channels in the membrane (N) to obtain the entire behavior of all channels in the membrane:

$$I = i^{*}P_{o} * N \qquad [3]$$

From an experimental point of view, it is sometimes more convenient to measure and analyze directly the ensemble currents in a membrane without any attention to the single channels. This can be achieved as illustrated in **Figure 5**. In this patch clamp configuration, referred to as "whole cell" configuration, the sum of currents through the ensemble of ion channels in the membrane is recorded. But in essence, the data between the statistical analysis of a single channel and the recording of ensemble currents are interchangeable.

Structure and Function of Transport Proteins

The first information on how membrane transport devices work came from physiological flux measurements. Physiologists traditionally divided transport mechanisms into two classes, carriers and pores. Carriers were responsible for transport which at high substrate concentration reached saturation, while pores were identified as mediating membrane transport which did not show any saturation kinetics. A carrier was essentially viewed as a molecule diffusing back and forth across the membrane while carrying small molecules or ions bound to specific sites, whereas a pore was a narrow, water-filled tunnel, permeable to few ions and molecules small enough to fit through the hole.

The numerous membrane proteins which have been purified, and the related genes which have been cloned, show that the carrier proteins are too large to diffuse or spin around at the predicted rate. The new view of carrier transport is that the protein is fixed in the membrane while exposing the transport-binding sites alternatively at the two sides of the membrane by small motions. Although the first crystal structure of a carrier appeared in the year 2000, nevertheless the specific mechanisms by which several carrier devices (transporters and pumps) work still await to be proved combining different experimental approaches, such as electrophysiology, molecular biology, and crystallography.

The view of pores as water-filled tunnels has been firmly established for a class of proteins which is now known as ion channels. The early identification of

these pores as proteins that span the membrane and the subsequent identification of the genes that codify for them have focused the work of electrophysiologists, biophysicists, and molecular biologists since the 1980s on ion channel structure–function relationships, creating a solid background of knowledge on how these channel proteins operate. The understanding of the structure and function of ion channels culminated in the landmark determination of the crystal structure of a K^+ channel, the bacterial channel KcsA, by Roderick MacKinnon. For his work on structure determination of several bacterial K^+ channels, MacKinnon received the Nobel Prize for chemistry in the year 2003.

The atomic structures of K^+ channels have especially improved the understanding of two main properties of ion channels: selectivity and gating.

Selectivity

A potassium channel can conduct K^+ ions one thousand times better than Na^+ ion. It is assumed that, in order to allow the protein channel to discriminate one ion from the other, the ions have to pass the cell dehydrated. In this situation, the atomic ray of Na^+ is smaller than that of K^+ (0.95 Å and 1.3 Å, respectively) implying that the Na^+ ions are not excluded on the basis of their dimension and that the selection process probably involves some kind of interaction with specific binding sites in the protein. The second striking characteristic of K^+ channels is that they pass K^+ ions at high speed, 10 e6, close to the diffusion limit. How can a protein interact with an ion and nevertheless allow its passage at the speed of ion diffusing in water? The atomic structure achieved for the bacterial potassium channel KcsA provides a deep understanding of K^+ selectivity and the ion conduction process.

Figure 6 reports the structure of the KcsA channel. The K^+ channel pore is formed by four identical subunits surrounding a central ion conduction pathway (two of the four subunits are shown in **Figure 6a**). Each subunit contains two transmembrane α-helices, termed inner (nearest the ion pathway) and outer helices, and a tilted shorter pore helix (in red) pointing toward the ion pathway and keeping in place the selectivity filter (in gold). The selectivity filter discriminates between potassium and other ions. It is the narrowest part of the ion permeation pathway, and is located in the extracellular third of the ion pathway. Inside the selectivity filter, the K^+ ion encounters four binding sites, which are created by evenly spaced layers of carbonyl oxygen atoms and a single layer of threonine hydroxyl oxygen atoms. At these sites a K^+ ion binds in a dehydrated

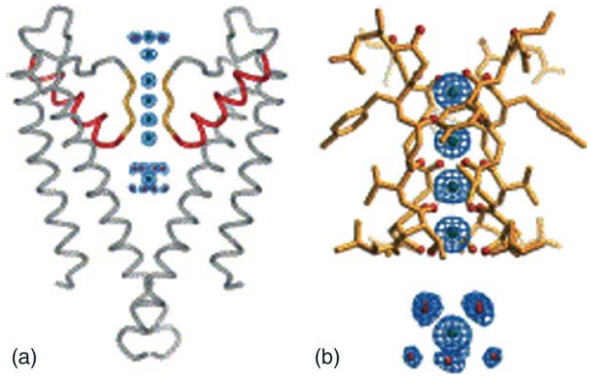

Figure 6 Ion conductance through a potassium channel pore, as deduced from the crystal structure of the bacterial channel KcsA. (a) Two of the four subunits from the pore of KcsA are shown, with the extra cellular side on top. Each subunit is formed by an outer helix that contacts the lipid membrane, an inner helix that faces the permeation pathway, a pore helix (red), and a selectivity filter (yellow). Blue mesh shows electron density for K^+ ions (green) and water molecules (red) along the pore. (b) Enlargement of the selectivity filter showing four dehydrated K^+ ions inside the filter and one hydrated K^+ ion outside (bottom). state, surrounded by eight oxygen atoms from the protein, four "above" and four "below" each ion (**Figure 6b**). The arrangement of protein oxygen atoms in each binding site is very similar to the arrangement of water molecules around hydrated K^+ ion observed in the central cavity (**Figure 6b**). Potassium ions therefore diffuse from water into the selectivity filter where the energetic cost of dehydration is compensated. Sodium ions, on the other hand, do not enter the selectivity filter because the dehydrated Na^+ ions have a radius of 0.9 Å, and their coordination is precluded in this rigid structure. The precise ion coordination required for selectivity does not prevent their rapid diffusion through the pore. This is due to the fact that the selectivity filter contains more than one ion and the repulsion between closely spaced ions helps to overcome the affinity that each ion has for its binding site.

Gating

While the pore of a channel is designed to achieve minimal energy barriers to ensure a fast flow rate, other parts of the channel are responsible in determining whether the channels are open or closed, and they do so by propagating conformational changes to the ion-permeating pathway inside the pore. Potassium channels differ in relation to the various ways in which they are gated, that is, the way they change from a nonconductive to a conductive state. Some K^+ channels are ligand-gated, which means that the pore opening is energetically coupled to the binding of an

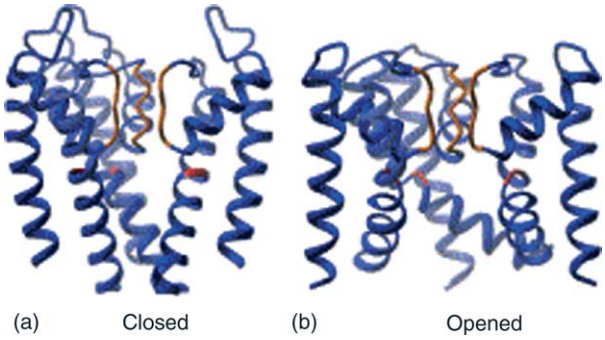

Figure 7 The pore gating of a potassium channel. Left: structure of the bacterial channel KcsA, crystallized in the closed conformation. Right: structure of the bacterial channel MthK crystallized in the open conformation. Three subunits are shown for each channel with the selectivity filter yellow and gating hinge in red. Figure 8 Electrical circuit representing the cell membrane. The lipid bilayer is modeled by a capacitance (C_M), while the different families of ionic channels are represented by conductances (g_x). The electromotive forces (E_X) generated by asymmetric ionic concentrations are included in the battery elements. Note that g_{Na} and g_k are variable conductances due to their time and voltage dependence.

ion, a small organic molecule, or even a small protein. Other K+ channels are voltage-gated, and the pore opening is energetically coupled to the movement of a charged voltage sensor within the membrane electric field. Diversity in gating is achieved by diverse structural domains attached in a modular fashion to the conserved pore domain. Binding of ligands as well as displacement of the voltage sensor by voltage changes must result in a global conformational change of the channel protein which is eventually transduced to the pore unit, causing the pore to open (and close). The recent crystallization of several K^+ channels (both in the open and closed conformation) has explained the conformational changes which underlie the pore opening in K^+ channels.

The pores of KcsA, crystallized in the closed configuration, and MthK, crystallized in the open configuration, are compared in **Figure 7**. The prominent difference between these two structures is the position of their inner helices. In KcsA they form a bundle at the cytoplasmic side of the pore that prevents free ion flow, while in MthK the inner helices are bent at a hinge point, allowing free ion flow between the cytoplasm and the selectivity filter. These structures are probably representative of the closed- and open-pore configurations of many different K^+ channels, as suggested by the amino acid conservation in the inner helices sequences of all K^+ channels (in particular of a glycine at the hingepoint) (**Figure 7**).

The Cell Membrane as an Equivalent Circuitry of Parallel Ion Channels with Variable Conductance: An Explanation for Complex Changes of Membrane Voltage

In this section, the functional roles of ion channel proteins are discussed with the aim of integrating their individual properties. This aims to explain their concerted contribution to the overall cell activity.

The concerted activity of ion channels may here be described for electrically excitable cells such as neurons and muscle cells. In general these cells can be found in two different conditions, namely at rest or excited. In the resting condition, the cell membrane voltage is stable over long periods of time; during electrical excitation, the cell undergoes a transient depolarization, a phenomenon called action potential (AP).

Both situations can be explained by a dynamic interplay of different ion channels in the plasma membrane. A physical model of the main elements in the plasma membrane of such a cell is presented in **Figure 8** where an equivalent circuit of a cell membrane built on capacitance, variable resistors, and batteries is presented. In this simple circuit, each resistor represents a specific type of ion channel, that is for K^+ or Na^+, with a variable internal resistance. The branch with the conductance g_L represents the ensemble of other conductances such as channels for Cl^- and Ca^{2+}. The variability of the resistor reflects the ability of the ion channels to undergo changes in activity. An important detail of this model is that the activity of the channels is sensitive, in a distinct way, to voltage. Hence through the voltage coupling of the channels via the membrane, the activity of each channel has an effect on the activity of the others. Due to their different distribution across cell membranes, the main ionic species involved in electrical activity (i.e., Na^+, K^+, Ca^{2+}) have different thermodynamic equilibrium (see **Figure 1**). These electrochemical gradients are a source of potential energy.

In the model they are represented by specific battery voltages, which are determined by the Nernst potential (E_X) of the respective ion. Cells consume this energy difference when ionic channels open and ions can freely diffuse. Due to its dielectric properties, the lipid component of the cell membrane is represented by a capacitor (C_M). Large and fast changes in the membrane voltage will hence cause currents to charge this capacitor.

At rest, cells have an internal potential of $-60/-80$ mV with respect to the extracellular environment. The precise value of the resting potentials is determined mainly by two factors: a relatively high K^+ (g_{K+}) and Cl^- (included in g_L) permeability of the cell membrane due to active K^+ and Cl^- channels and the respective battery voltages of E_{Cl}^- and E_{K+}. E_{Na+} does not contribute to the resting voltage since Na^+ channels are generally closed at rest ($g_{Na+} = 0$). Hence, the membrane current (I) at rest can be described according to the Ohms law by

$$I = g_{K+} * (V - E_{K+}) + g_{Cl}^- * (V - E_{Cl}^-) \qquad [4]$$

This resting state is drastically modified when cells become electrically active, that is, when they fire an AP. A simple physical description of an AP would be a wave of potential that travels at a rate of 1–100 m $*s^{-1}$ along excitable membranes, and conveys information from one point to another. The peak of the moving wave corresponds to a physical location where the membrane polarity is inverted (the intracellular part is positive up to $+40/+60$ mV with respect to the external), while the adjacent regions are still (region ahead) or have already returned (region before) to the resting hyperpolarized value.

The Hodgkin and Huxley (HH) model presented the first mechanistic explanation of the AP. This original model has now undergone major revision; however, the basic ideas can still be used to unravel how the concerted work of different ionic channels can bring about the AP. HH's interpretation of the molecular mechanisms underlying the complex event of an AP consists of a voltage-coupled interplay of two conductances: the Na^+ and K^+ channels. The elements that confer the circuit its active properties (i.e., the capacity of generating an AP) are the variable conductances (g_x) which are disposed in parallel (**Figure 8**). In the original HH model, the number of conductances is limited to three: g_{Na} and g_K that are the true, time- and voltage-dependent components, and a fixed g_L that represents a pathway for leakage currents. The last elements to consider are the source of electromotive forces E_x which complete each conductance branch with the electrochemical energy associated with the specific ionic flow and determined by the Nernst equation. The two dominant elements, the Na^+ and K^+ channels, have very distinct voltage- and time-dependent properties which can be summarized as follows: the Na^+ channels open transiently very fast upon a depolarization of the membrane. The K^+ channels in contrast open slowly upon depolarization. Because of their electrocoupling, the activity of one reflects back on the other and vice versa. Once the appropriate set of time- and voltage-dependent variables for each channel is defined, the mathematical solution of the circuit will appropriately simulate the electrical activity of the cell.

A more intuitive description of an AP can be attempted by describing the events that take place in a membrane region that is invested by an AP wave. If one could take a look at the intracellular side of the membrane, a situation would be observed where an already depolarized, positively charged region, is followed by a region in an electrically resting state of about $-70/-80$ mV. This situation would generate a depolarizing flow of positive charges toward the negative region; this event is the key element in the generation of APs. If the depolarization is not strong enough, then the resting K^+ conductance will soon buffer this perturbation and reestablish the correct resting potential, but if the depolarization reaches a threshold it will trigger a cascade of events that generates an AP. This is the reason why biophysicists describe the AP as an all-or-nothing event. It has already been seen that a great number of ion channels are gated by voltage, and this concept is crucial to the understanding of the AP mechanism. The threshold corresponds to a critical value of potential at which Na channels start opening, and thus generate an inward-going current that further depolarizes the membrane by a positive feedback mechanism that drives the membrane potential toward the equilibrium of Na^+ ions (E_{Na}). This depolarization activates two additional events: the inactivation of Na^+ channels and the activation of K^+ channels. Na^+ channels are dually gated by voltage: the positive electric field acting on these transmembrane proteins initially induces a conformational change that forces the channels to an open, conductive state, but soon after the channels relax to a nonconductive state. The voltage-gated K^+ channels involved in the AP differ from the resting ones in that the former are normally closed at resting, but open upon depolarization. K^+ channels activate with a slower kinetics compared to that of Na^+ channels, and, according to the acting electrochemical gradient, they generate an outward-going K^+ ions efflux, that repolarizes the cell to the resting state, and thus terminate the AP signaling. The electrical activity of a cell can now be summarized in three general

components: first, a trigger phase that moves the potential to the threshold; second, the activation of an inward-going current that rapidly depolarizes the cell, and finally the third part driven by a potassium outflow that terminates the electrical event. The above events are an over-simplification of a reality that is often more complex and thus adaptable; nature has evolved molecules with slightly different properties so that an array of elements is available to better accomplish the different functional requirements of excitable cells. Indeed APs can simply represent a piece of information that needs to be transferred from one point to another with high fidelity, but in many cases they must locally trigger crucial events such as a neurotransmitter release or a muscle contraction. Often, when spatial transferring of information is required, a simple system, based on limited population of channels (HH model), is perfectly fit for the function. Neuronal exocytosis and muscle contraction require the contribution of at least one more class of channels: the Ca^{2+} channel family. Ca^{2+} ions are key elements in inducing both the activation of the synaptic release machinery, and in allowing the physical interaction between the sliding filaments of muscle fibers.

Ion channels can be largely modulated by several effectors, for example calcium, second messengers such as cyclic nucleotides, phosphorylation, interaction with other proteins, and more (see above). As an example of the functional importance of these modulations, the activity of cardiac pacemaker cells are described here (**Figure 9**). These cells exhibit spontaneous voltage oscillations (**Figure 9a**) that determine the cardiac rate.

The most striking property of these cells is the slowly depolarizing or pacemaker phase (between arrows in **Figure 9a**) that, while moving the cell membrane toward the threshold (dotted line), allows for cardiac chamber refilling. This phase is generated by the intervention of several ionic channels and transporters, with the most important one being a specific current named I_f or pacemaker current. The I_f is modulated by the neural autonomic system that can increase (sympathetic branch) or decrease (parasympathetic branch) the current availability at any given potential (**Figure 9b**). The functional effect of this modulation is the modification of the slope of the diastolic depolarization that becomes steeper or shallower thus determining the autonomic-induced modulation of the heart rate (**Figure 9a**).

So far, the role of ion channels in underlying important physiological functions have been described; one can now appreciate why ion channels are important targets for drug-based therapy. Indeed in the year 2003, 15% of the top 100 best-selling drugs on the market were designed to specifically interfere with

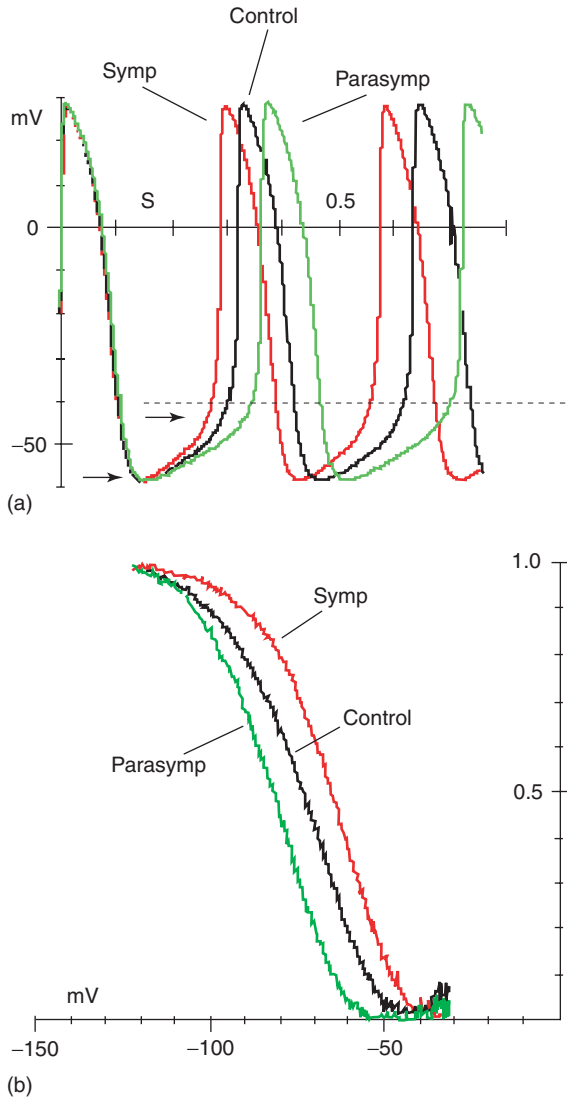

Figure 9 Heart rate modulation by autonomic system. (a) Spontaneous APs of pacemaker cells in control and during autonomic-induced modulation. (b) Fractional availability (*y*-axes) of the pacemaker current as a function of the applied voltage. The amount of available current modifies the slope of the pacemaker depolarization and thus the heart rate. (Modified with permission from Accili EA, Robinson RB, and Di Francesco D (1997) Properties and modulation of I_f in newborn versus adult cardiac SA node. *American Journal of Physiology, Heart and Circulatory Physiology* 272: H1549–H1552; and from Accili EA, Proenza C, Baruscotti M and Di Francesco D (2002) From funny current to HCN channels: 20 years of excitation. *News in Physiological Sciences* 17: 32–37; The American Physiological Society.)

ion-channel proteins. Several diseases such as epilepsy, long QT syndrome, cystic fibrosis, myopathies (but the list is in constant expansion) have been found to depend on abnormalities of genes coding for these proteins. For this reason, a new group of diseases has now been named after their molecular origin channelopathies. A still far to come, yet enticing possibility, is a strategy devised by ion-channel biologists which is

based on the "use" of ion-channel proteins as molecular tools for therapy of cardiac rhythm alteration. To date, cardiac electronic pacemakers have been widely used in the treatment of rhythm disorders. However, recent research suggests the possibility of developing therapeutic approaches based on "biological pacemakers" in which the ability of generating spontaneous cardiac electric activity could be restored by manipulating the level of ion channels expressed in a specific desired region of the heart.

Ionic and Mixed Conductivity in Condensed Phases

J Maier, Max-Planck-Institut für Festkörperforschung, Stuttgart, Germany

Introduction: Hopping Process

While a quantum mechanical particle such as a quasi-free-electron can tunnel through a barrier by interference of the states on both sides of the barrier (denoted by x and x'), that is, by seizing the hindrance in a wave-like way, the transport of a heavy particle such as an ion has to rely on the ensemble fraction with energy high enough to reach the final state (hopping). On the one hand, under favorable circumstances protons may also tunnel, while on the other hand electrons that strongly polarize their environment (large polarons) behave almost classically as ions.

In most cases of interest (consider A as an ion with charge z_A), the hopping of A from x to x' ($x' = x + \Delta x$) may be written as

$$A(x) + V'(x') \rightleftharpoons V(x) + A'(x') \qquad [1]$$

(The dash takes account of the possibility for A to have a different structural environment at x'.) In cases where A denotes an ion on a regular site in a crystal, V is the vacancy that serves as a jump partner, while in cases where A refers to an excess ion sitting on interstitial sites, V denotes the vacant interstitial site. In crystals, V (in the first case) or A (in the second case) are usually dilute with the energy levels of these sites being well defined. The concentration of the respective reaction partner is then approximately constant and the corresponding rate equation for the hopping process is pseudo-monomolecular. In amorphous solids, the sites are less defined, which also holds for the spatial energy distribution; in polymers, melts, or liquids, these sites and energy distributions are time dependent. In these cases, one would better speak of smeared-out density of states, as far as thermal excitations are concerned. The rate constant for the hopping rate equation is decisively influenced by the activation free enthalpy. The parameters k and $\Delta G^{\neq}$, for example, for the forward reaction (index $\rightarrow$) related through (prefactor k_0 is proportional to the attempt

frequency Γ_0)

$$\vec{k} = k_0 \exp\left(-\frac{\Delta \vec{G}^{\neq}}{RT}\right) \qquad [2]$$

refer to the built-in part of the forward rate constant and its activation free energy, respectively. This expression has to be complemented by the factor $\exp(-\vec{\alpha}\,\Delta\phi\, z\, F/RT)$ in order to take account of the applied electric field. The parameter $\Delta\phi$ is that part of the external voltage that drops from x to x' and the term $\vec{\alpha}\,\Delta\phi$ measures the portion of $\Delta\phi$ that is relevant for the forward reaction (distance between saddle point and initial state). The relations for the backward reaction are analogous ($\vec{\alpha} + \vec{\alpha} = 1$). This leads to the Butler–Volmer equation which describes the charge transfer from x to x' for an asymmetric free-energy profile. In the homogeneous bulk region (and also in the space charge region sufficiently far from the interface, i.e., $A = A'$), the built-in profile is symmetrical, that is, $\vec{k} = \overleftarrow{k} = k$, $\vec{\alpha} = 1/2 = \overleftarrow{\alpha}$ and $\Delta\vec{G} = \Delta\overleftarrow{G}$. The result for the rate represented by the current density i_j of carrier j in x-direction

$$\begin{aligned} i_j &= -2k_j c_j z_j F \sinh\frac{z_j F \Delta\phi}{2RT} \\ &\simeq -\sigma_j \frac{\Delta\phi}{\Delta x} \end{aligned} \qquad [3]$$

can be simplified to Ohm's law (bottom part) for $\Delta\phi \ll RT/z_j F$; the conductivity σ_j of the carrier is proportional to its mobility u_j ($u_j \propto k_j$), (molar) concentration (c_j) and (molar) charge ($z_j F$) and given as

$$\sigma_j = z_j F u_j c_j \qquad [4]$$

Allowing also for a concentration variation during the process and generalizing to three dimensions, the Nernst–Planck equation is arrived at

$$i_j = -D_j z_j F \nabla c_j - \sigma_j \nabla\phi \qquad [5]$$

where the diffusion coefficient (D) and conductivity (σ) are related through the Nernst–Einstein equation. Close to equilibrium, this equation corresponds to the result obtained by linear irreversible thermodynamics,

$$i_j = -\frac{\sigma_j}{z_j F}\nabla\tilde{\mu}_j \qquad [6]$$

which assumes the current to be proportional to the gradient in the electrochemical potential $\tilde{\mu} = \mu + zF\phi$ (chemical potential + (molar charge × electrical potential)). The latter relation is more general concerning the concentration range, while the former (as regards the diffusion term) is more general as far as the magnitude of this driving force is concerned. In cases where the current of a given species is also generated by secondary driving forces (e.g., by $\nabla\tilde{\mu}$ of a different particle), cross terms occur for which the Onsager–Casimir symmetry relations are valid. As regards the determination of the conductivity, the first task is to determine the carrier concentration as a function of the control parameters. This is feasible by solving the defect model for the system under consideration.

Equilibrium Charge Carrier Concentrations

Pure Compounds and Dilute Bulk

Figure 1 displays the fundamental charge carrier formation reaction in an "energy level" diagram for a fluid (H_2O) and an ionic crystal (AgCl). These levels refer to effective standard (electro) chemical potentials or – in the case of the "Fermi levels" that are positioned within the gap – full (electro) chemical potentials. (As long as the bulk is considered, $zF\phi$ can be neglected and one can refer to μ instead of $\tilde{\mu}$.) As long as – in pure materials – the gap remains large compared to RT, the Boltzmann form of the chemical potential of the respective charge carrier (defect) is valid which has the form

$$\mu_j = \mu_j^\circ + RT \ln\left(\frac{c_j}{c_j^\circ}\right) \qquad [7]$$

As outlined below, this relation holds largely independent of the charge carrier situation and the form of the energy level distribution. If the levels are smeared out or if there is a band of levels, μ_j° refers to an effective level (i.e., band edges in nondegenerate semiconductors or an appropriately averaged energy when dealing with fluids or disordered solids).

The coupling of the ionic level picture and the electronic level picture for AgCl (**Figure 2**) is established via the thermodynamic relation $\tilde{\mu}_{Ag^+} + \tilde{\mu}_{e^-} = \mu_{Ag}$, and hence via the component potential which reflects the precise position in the phase diagram.

The meaning of μ° becomes obvious, if for simplicity one considers an elemental crystal (with defect j). For the formation of N_j identical defects (among N regular positions), a local free enthalpy of $N_j \Delta g_j^\circ$ is required in the interaction-free case; including also the configurational contribution, the Gibbs energy of the defective crystal (G_P refers to the perfect crystal) reads

$$G = G_P + N_j \Delta g_j^\circ - k_B T \ln\left(\frac{N}{N_j}\right) \qquad [8]$$

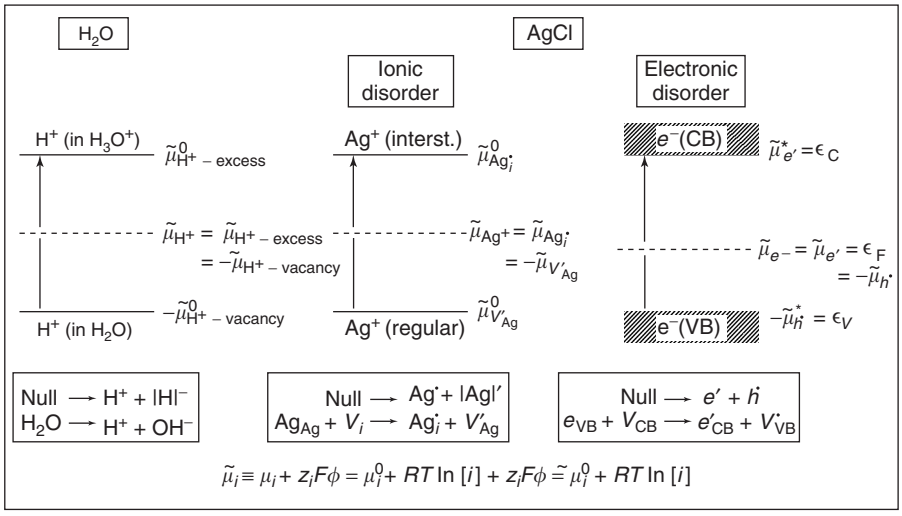

Figure 1 Electronic and ionic disorder in ionic solids and water in "physical" (top) and "chemical" language (bottom).

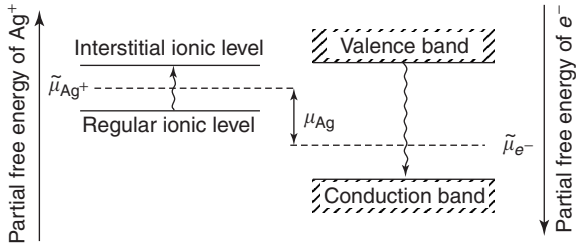

Figure 2 Coupling of ionic and electronic levels in AgCl.

The configuration term describes the number of combinations of N_j elements out of N choices without repetition. The calculation of Δg°, the free energy to form a single defect, requires an atomistic consideration. If one refers to ionic defects in crystals, it is essentially composed of lattice energy, polarization energy, and vibrational entropy terms. In more general terms, N_j is the number of defects and N the number of particles that can be made defective. Owing to the infinitely steep decrease of the configurational term with N_j, a minimum in $G(N_j)$ (see **Figure 3**) is observed in the elemental crystal, if the chemical potential of j, that is, $\mu_j \equiv \partial G/\partial(N_j/N_m)$, which follows as

$$\begin{aligned}\mu_j &= \mu_j^\circ + RT\ln\frac{N_j}{N-N_j}\\ &\simeq \mu_j^\circ + RT\ln\frac{N_j}{N}\\ &= \mu_j^\circ + RT\ln\frac{n_j}{n}\end{aligned} \qquad [9]$$

vanishes ($n \equiv N/N_m$, $n_j \equiv N_j/N_m$, N_m = Avogadro's number; $\mu_j^\circ = N_m \Delta g_j^\circ$). It is noteworthy that the strict result (top) which is formally valid for higher concentrations also is of the Fermi–Dirac type. This is due to the fact that one refers to combinations without repetition, that is, double occupancy is excluded and hence the sites are exhaustible similarly as is the case for quantum states in electronic problems. (Combinations with repetitions lead to Bose–Einstein distribution.)

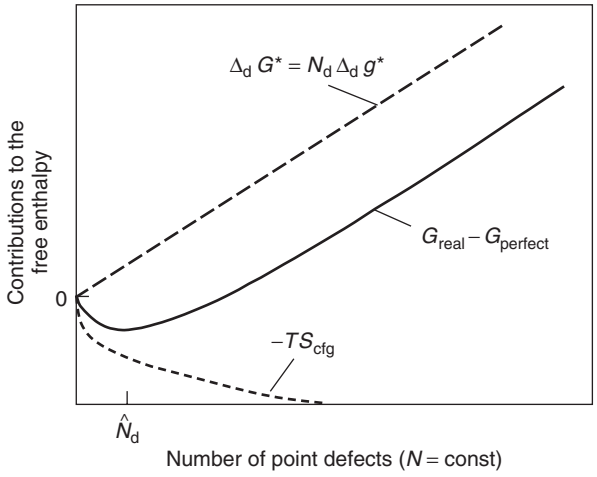

Figure 3 Contributions to the free enthalpy of the solid by defect formation with a constant total number of sites.

In a situation in which the levels are broadened to a more or less continuous zone (e.g., electrons in semiconductors and ions in fluids), the parameters N_j and μ_j° of the Fermi–Dirac form have to be attributed to an infinitely small level interval. Denoting the partial free energy level by ϵ, this integral ranges from ϵ_j to $\epsilon_j + d\epsilon_j$ and the total (molar) concentration

follows from integration:

$$n_j = \int_{\text{zone}} \frac{D(\epsilon_j)\,\mathrm{d}\epsilon_j}{1+\exp(|\epsilon_j-\mu_j|/RT)} \qquad [10]$$

whereby the molar density of states $D\ (\epsilon_j)$ appears in the integrand. At equilibrium, μ_j is independent of ϵ_j. Considering without the restriction of generality, the almost empty zone and the lower edge of this zone designated as ϵ_j, one can neglect the unity in the denominator of the above equation for all levels more distant from μ_j than ϵ_j' which leads to the Boltzmann expression $n_j \simeq \bar{n}_j(T)\exp(-|\epsilon_j'-\mu_j|/RT)$. The effective value $\bar{n}_j$ is given by

$$\bar{n}_j(T) = \int_{\text{zone}} \mathrm{d}\epsilon_j \left[D(\epsilon_j)\exp\left(-\frac{|\epsilon_j-\epsilon_j'|}{RT}\right)\right] \qquad [11]$$

$\bar{n}_j$ being usually weakly temperature dependent. It is worth noting that, owing to the high dilution, changes of the parameters with occupation have been ignored (for electrons in semiconductors, this is called the "rigid band model").

As anticipated above, the Boltzmann form of the chemical potential results with μ° representing an effective value. If n is identified with $\bar{n}_j$, the effective value μ_j° is given by ϵ_j'. As long as one refers to dilute conditions, considerable freedom of normalization is left with respect to the concentration measure.

In ionic compounds, charged defects occur pairwise, the formation of which is subject to disorder reactions (and electroneutrality conditions). Then, only the reaction combination of chemical potential vanishes, that is, $\sum_j \nu_{rj}\mu_j = 0$ (identical to $\sum_j \nu_{rj}\tilde{\mu}_j = 0$ since $\sum_j \nu_{rj}z_j = 0$), where ν_{rj} is the stoichiometric coefficient of j in the respective disorder reaction r (cf. **Figure 1**, bottom). Boltzmann expressions can be written for the individual carriers, if the formation energies and the configuration entropies are considered to be independent.

The application of chemical thermodynamics elegantly permits treatment of a variety of ionic and electronic disorder equations that simultaneously occur in a given solid. This is not only possible for the internal disorder equations (such as Schottky, Frenkel, anti-Frenkel, anti-Schottky, electron–hole formation) but also for external reactions such as the interaction of an oxide with the oxygen partial pressure and hence the stoichiometric variation. Under Boltzmann (i.e., dilute) and Brouwer (i.e., two majority carriers) conditions, an adequate expression is arrived at for any charge carrier concentration as a function of the control parameters (temperature T, doping content, component partial pressure P), namely

$$c_j(T,P) = \alpha_j^{\beta_j} P^{N_j} \prod_r K_r(T)^{\gamma_{rj}} \qquad [12]$$

($N_j, \gamma_{rj}, \alpha_j, \beta_j$ being simple rational numbers; the total pressure is assumed to be constant.) For multinary compounds (i.e., m components) at complete equilibrium $(m-1)$, component partial pressures are to be considered. This solution is only a sectional solution within a window in which the majority carriers situation (Brouwer condition) does not change. The power-law equation defines van't Hoff diagrams characterized by

$$-\frac{\partial \ln c_j}{\partial 1/RT} = \sum_r \gamma_{rj}\Delta_r H^\circ \qquad [13]$$

according to which, for not too extended T-ranges (i.e., $\Delta_r H^\circ$, the reaction enthalpy of the defect reaction γ, is constant), straight lines are observed in the ln c_j versus $1/T$ representation, as well as Kröger–Vink diagrams characterized by straight lines in the plots ln c_j versus ln P with slopes

$$\frac{\partial \ln c_j}{\partial \ln P} = N_j \qquad [14]$$

Figure 4 displays the defect chemistry within the phase width of the oxide MO. At low oxygen partial pressure (P_{O_2}), vacant oxygen ions ($V_O^{\bullet\bullet}$) and

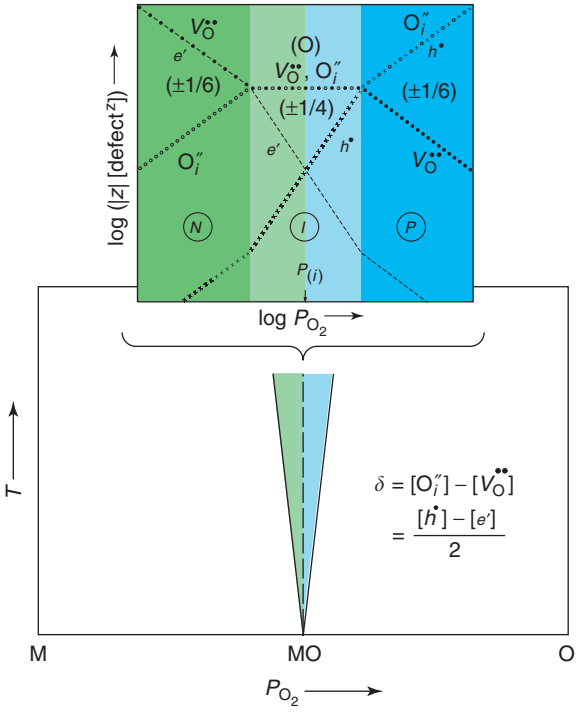

Figure 4 Internal redox and acid–base chemistry in a solid $MO_{1+\delta}$ within the phase width at a given temperature T (disorder in the M-sublattice assumed to be negligible).

reduced states (e') are in the majority ($2[V_O^{\bullet\bullet}] \simeq [e'] \gg [O_i''], [h^\bullet]$) (*N*-regime) whilst oxygen interstitials (O_i'') and oxidized states ($h^\bullet$) dominate for very high P_{O_2} ($2[O_i''] \simeq [h^\bullet] \gg [e'], [V_O^{\bullet\bullet}]$) (*P*-regime). At intermediate P_{O_2}, usually ionic disorder prevails ($[V_O^{\bullet\bullet}] \simeq [O_i''] \gg [e'], [h^\bullet]$) (*I*-regime); the alternative situation that electronic disorder predominates ($[e'] \simeq [h^\bullet] \gg [V_O^{\bullet\bullet}], [O_i'']$) is usually scarce. Exactly at the Dalton composition (i.e., at $P_{O_2}^{(i)}$ where $2[O_i''] = 2[V_O^{\bullet\bullet}] = [e'] = [h^\bullet]$), the "nonstoichiometry" δ in $MO_{1+\delta}$ (i.e., $[O_i''] - [V_O^{\bullet\bullet}] = \frac{1}{2}[h^\bullet] - \frac{1}{2}[e']$) is precisely zero. For $\delta \gg 0$, a *p*-conductor (mobility of $h^\cdot$ is usually much greater than for O_i'') is referred to, for $\delta \ll 0$, one refers (mobility of e' is usually much greater than for $V_O^{\bullet\bullet}$) to an *n*-conductor, while at $\delta \simeq 0$, mixed conduction is expected (only if the ionic concentrations are much larger than the electronic ones, pure ion conduction results). Usually, the entire diagram is not observed, as there are limits of experimentally realizing extreme P_{O_2} values as well as limits with respect to the phase stability (formation of higher oxides or lower oxides, if not of the metal).

Figure 5 gives three examples: SnO_2 as an oxygen-deficient material, La_2CuO_4 as an example of a *p*-type conduction, and PbO as an example of *I*-regime exhibiting mixed conduction. (In PbO, most probably, the counterdefect to O_i'' is $Pb_i^{\bullet\bullet}$ rather than $V_O^{\bullet\bullet}$; the results, however, are not different then.) The slopes directly follow from simple mass action considerations.

The model example of AgCl shall be considered in more detail. It also exhibits predominant ionic disorder, but now the decisive disorder reaction is the Frenkel reaction of the Ag sublattice (i.e., the formation of silver ion vacancy, V'_{Ag}, and interstitial silver ion, $Ag_i^\bullet$). The role of P_{O_2} is played by the chlorine partial pressure. The mass action law for the interaction with Cl_2 reads $[Ag_i^\bullet]P_{Cl_2}^{+1/2}[e'] = \text{constant}$, the mass action constant for the Frenkel reaction being $[Ag_i^\bullet][V'_{Ag}] = K_F$ and that for the band–band transfer $[e'][h^\bullet] = K_B$. Since $[Ag_i^\bullet] \simeq [V'_{Ag}] \gg [e'], [h^\cdot]$, it follows as solution $[V'_{Ag}] = [Ag_i^\bullet] = \sqrt{K_F}$, $[e'] \propto P_{Cl_2}^{-1/2}$, $[h^\bullet] \propto P_{Cl_2}^{+1/2}$.

Doping Effects

Dopants, as irreversibly introduced structure elements such as Cd^{2+} substituting Ag^+ to form the

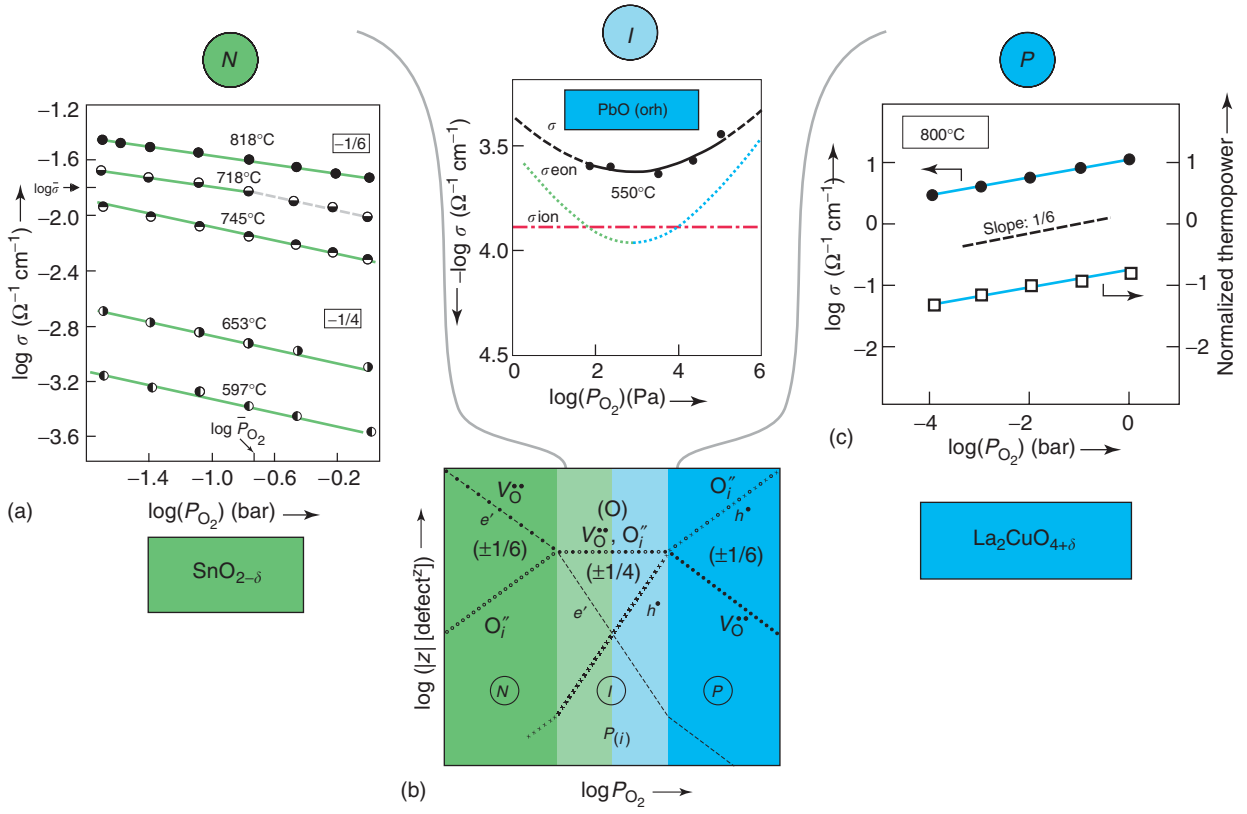

Figure 5 Three experimental examples of Kröger–Vink diagrams in a pure oxide MO with ideal defect chemistry. defect $Cd_{Ag}^{\bullet}$, do not significantly influence the mass action laws, but appear in the electroneutrality relation, here

$$[Ag_i^{\bullet}] + [Cd_{Ag}^{\bullet}] \simeq [V'_{Ag}] \quad [15]$$

Coupling the above relation with the Frenkel equation $[Ag_i^{\bullet}][V'_{Ag}] = K_F$ leads to

$$[V'_{Ag}] = \frac{C}{2} + \sqrt{\frac{C^2}{4} + K_F} \quad [16]$$

$$[Ag_i^{\bullet}] = -\frac{C}{2} + \sqrt{\frac{C^2}{4} + K_F} \quad [17]$$

where C stands for $[Cd_{Ag}^{\bullet}]$. Consider the Brouwer conditions again. For $C \ll \sqrt{K_F}$, the intrinsic result $[V_{Ag}^{\bullet}] = [Ag_i^{\bullet}] = \sqrt{K_F}$ is obtained. For $C \gg \sqrt{K_F}$, one arrives at

$$[V_{Ag}^{\bullet}] = C \quad [18]$$

$$[Ag_i^{\bullet}] = K_F C^{-1} \quad [19]$$

which are immediately obtained by neglecting $[Ag_i^{\bullet}]$ from the electroneutrality relation. Power-law equations are then also valid for the electronic minority carriers in AgCl.

Figure 6 displays the solutions for the ionic defect arrived at by the more accurate equations for both concentrations and conductivities. The different behaviors of defect concentrations and conductivities stem from the fact that the interstitials are more mobile than the vacancies. The introduction of the dopant increases the concentration of the oppositely charged defect and depresses the concentration of the counterdefect according to electroneutrality and mass action. This leads to a decreased ionic conductivity, before the counterdefect starts defining the overall conductivity. The conductivity minimum lies approximately at $\sqrt{K_F u_i / u_v}$.

Figures 7 and **8** display the dependence of conductivity on temperature in pure samples and on the doping concentration at given T with regard to positive and negative doping. While the response to Cd^{2+} doping ($Cd_{Ag}^{\bullet}$) follows exactly the predictions (see **Figures 7** and **8**), the effect of S^{2-} doping (S'_{Cl})

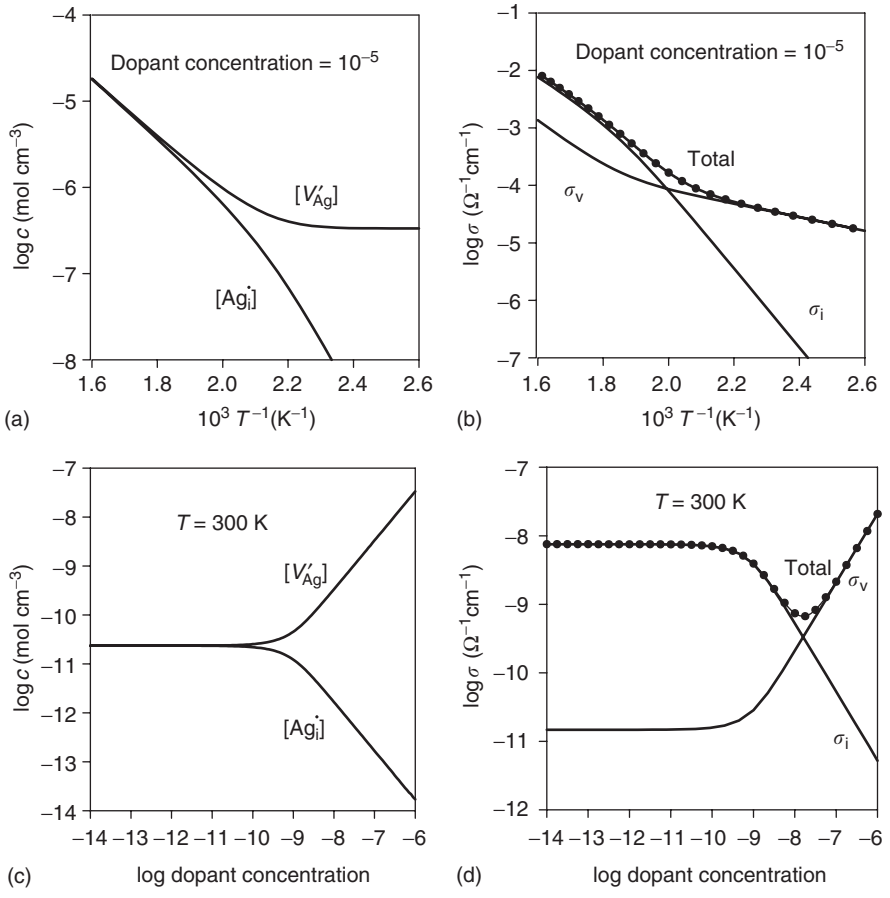

Figure 6 Defect concentrations and conductivities calculated as a function of temperature for a fixed Cd-content ((a) and (b)) and as a function of Cd-content for a fixed temperature ((c) and (d)).

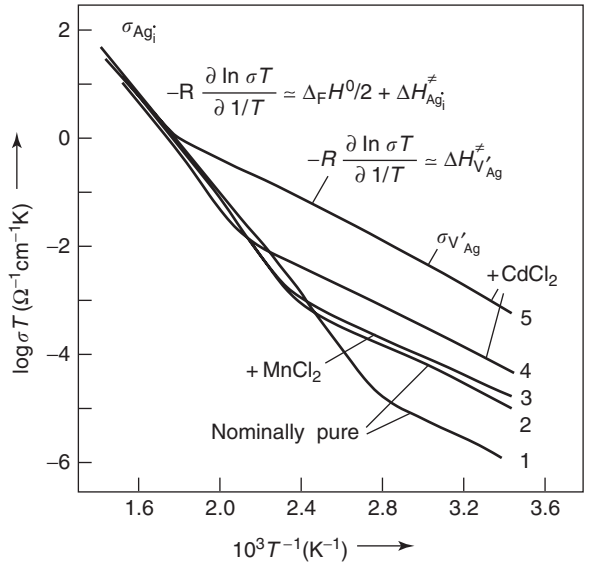

Figure 7 Experimental conductivity data for nominally pure and doped AgCl as a function of $1/T$. Here $\log(\sigma T)$ is plotted instead of $\log \sigma$ to take account of the slight T-dependence of the prefactor. However, this does not alter the slope noticeably ($\Delta_F H^0$: formation enthalpy of Frenkel defects; $\Delta H_j^{\neq}$: migration enthalpy). (Reproduced from Corish J and Jacobs PWM (1972) Ionic conductivity of silver-chloride single-crystals. *Journal of Physics and Chemistry of Solids* 33: 1799–1818, with permission from Elsevier.)

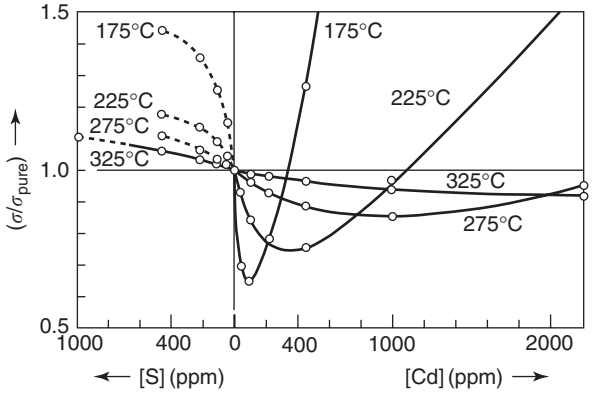

Figure 8 The dependence of the conductivity increase brought about by the impurities on the S and Cd content of AgBr. The RHS solid curves are calculated according to the ideal defect chemistry. (Reproduced with permission from Teltow J (1950) Zur Ionen-, Elektronenleitung und Fehlordnung von Silberbromid mit Zusätzen von Silber-, Cadmium- und Bleisulfid. *Zeitschrift für Physikalischs Chemie* 195: 213–224; © Oldenbourg Wissenschaftsverlag and Teltow J (1949) Zur Ionenleitung und Fehlordnung von Silberbromid mit Zusätzen zweiwertiger Kationen. I. Leitfähigkeitsmessungen und Zustandsdiagramme. *Annalen der Physik* 6: 63–70; © Wiley-VCH.)

suffers from interaction effects (see below, the absence of a minimum in **Figure 8**, LHS, is in qualitative agreement with the fact that $[Ag_i^\bullet]$ is increased).

It is clear that for doped samples under Brouwer and Boltzmann conditions, the concentration of any carrier is not only a function of P, T but also of C and reads

$$c_j(T,P,C) = \alpha_j^{\beta_j}\left(\prod_p P_p^{N_{pj}}\right) C^{M_j}\left(\prod_r K_r(T)^{\gamma_{rj}}\right) \qquad [20]$$

(P^{N_j} is replaced by $\prod_p P_p^{N_{pj}}$ in order to allow for multinary equilibria labeled by p). Since unlike (the *in situ* parameters) P and T, the variation of C requires a new high temperature preparation, C is designated as an *ex situ* parameter.

Now this also predicts sectionally constant slopes in diagrams of the type $\log C_j$ versus $\log C$ according to

$$\frac{\partial \ln c_j}{\partial \ln C} = M_j \qquad [21]$$

For a simple defect chemistry, the sign of M_j is determined by ("rule of heterogeneous doping")

$$\frac{z_j M_j}{z_d} < 0 \qquad [22]$$

which means that, for a positive (negative) doping, the concentration of all negative (positive) defects is increased and all positive (negative) defects are decreased (z_d: charge number of dopant defect). A negative doping is also the reason for change in the slope from the intrinsic value $-1/6$ to the extrinsic value $-1/4$, in **Figure 5a** for SnO_2, which directly results from the mass action law for oxygen incorporation, that is, $P_{O_2}^{1/2}[V_O^{\bullet\bullet}][e']^2 = \text{constant}$ (for $2[V_O^{\bullet\bullet}] \simeq C$, one obtains $\sigma \simeq \sigma_n \propto [e'] \propto P_{O_2}^{-1/4}$ whereas for $2[V_O^{\bullet\bullet}] = [e']$, the result is $\sigma \propto P_{O_2}^{-1/6}$).

High Charge Carrier Contributions — Interactions

The above solutions are valid for ionic and electronic carrier concentrations but require low concentrations. One way of correcting interactions is to introduce associates, that is, novel particles formed as the result of these interactions and responding differently to electrical fields or other driving forces. In this way, the scheme of defects is rescaled with the consequence of writing ideal chemical potentials (i.e., interaction free) for these to a better approximation. Examples are interactions of dopants with electronic or ionic carriers (these states appear as midgap states in **Figure 1**), associates between electronic carriers (excitons, Cooper-pairs), or between ionic carriers (such as vacancy pairs, interstitial pairs, and Frenkel associates). As an example, the association between $Cd^\bullet$ and V'_{Ag} is mentioned that leads to a thermally

activated process at low temperatures in the case of $CdCl_2$ doped AgCl (lower than those shown in **Figure 7**).

The more general approach is to include interactions via analytical corrections in the chemical potentials (μ^{ex}) of the charge carriers. (On the level of the concentration, this leads to the activity coefficient as a correction factor.) If the high carrier concentration is a consequence of the high temperatures, such a procedure is indispensable. If it is a consequence of a high doping content, it may be replaced by or better combined with the association procedure. Interactions lead to entropic corrections as well. One of them is obviously due to the exhaustibility of sites (Fermi–Dirac correction). The more detailed account of deviations from a random distribution owing to interactions leads to very complex expressions (e.g., by the Mayer theory for real gases). Fortunately in the case of weak interactions, the neglect of such entropic corrections is a tolerable approximation. Then, besides possible local vibrational entropies, only energetic nonideality corrections need to be considered. The Debye–Hückel theory (considering each central ion embedded into a diffusive cloud of counter ions, the size being characterized by λ) leads, in the first approximation, to an expression of the form

$$\mu_j^{ex} = RT \ln f_j = -\frac{z_j^2 F^2}{8\pi\varepsilon N_m \lambda} \propto c_j^{1/2} \qquad [23]$$

that reasonably corrects the chemical potential for low defect concentrations. The Debye–Hückel theory proved particularly helpful for electrolytic solutions.

At higher concentrations, the corrections become not only complicated but also individual. Here, an *ad hoc* model that is able to describe interactions in some simple binary crystals and estimate these interactions by assuming that the interaction energy (viz. the structure) can be assessed by a virtual Madelung-superlattice of defects of the mean lattice constant $\propto c^{1/3}$ is briefly discussed. The prefactor J in $\mu^{ex} = -Jc^{1/3}$ is determined by the Madelung energy of the ground lattice, the Madelung constants of lattice defect, and ground lattice as well as the dielectric constant.

The attractive interaction of oppositely charged carriers has the consequence that the formation becomes increasingly easier at high temperatures as soon as the carriers perceive each other in ionic crystals. The conductivity increases in an over-Boltzmann fashion (premelting) and eventually the avalanche effect leads to a phase transformation into the superionic (or molten) state. The order of the transition can be calculated by comparing the formation enthalpy, the formation entropy, and the interaction content.

Figure 9 shows the "thermal destiny" of a pure Frenkel disordered binary crystal from the perfect state at low T to the superionic state at high T.

Boundary Layers (Heterogeneous Doping)

At boundary layers, electroneutrality is no longer fulfilled and space charge regions (width $\sim$ Debye length) occur. The reason for this is the adjustment of structurally different regions. Not only are the electronic concentrations modified, but the mobile ionic charge carriers are also distributed according to the space charge field (both "Fermi levels" are positionally constant). Effects on the ionic conductivity can be immense.

Double layers formed by the contact of electrolyte solution to an electrode or charged membrane surfaces in electrophysiology are well-established examples.

Figure 10 depicts four prototype cases involving solid electrolytes: (1) the contact of an ionic conductor to an insulator, the surface of which is able to trap (internally absorb) ions, leading to the concept of heterogeneous doping (influence of conductivity by dispersing fine insulator particles characterized by a similar rule of heterogeneous doping as given above for homogeneous doping obtained by replacing the concentration and charge of the dopant defect by the surface charge density and its sign); (2) the contact of two ionic conductors leading to a charge transfer of ions from one conductor to the other (cf. ionic "*p–n* junctions"); (3) charge can also be stored within that core of the boundary, that is, in a grain boundary which joins two chemically identical grains and the effects can be tuned by chemical modification of the boundary or by varying the misfit; and (4) the contact to a fluid, for example, gas phase, is relevant in this context due to the fact that, acid–base active gases may cause attractive or repelling interactions with mobile ions.

Since in many mixed, even predominantly electronic conductors, ionic charge carriers may be in majority, the ionic redistribution effect may determine the overall electronic boundary concentrations (fellow-traveler effect).

Figure 11 shows the bending of ionic and electronic energy levels and their intercorrelation. The determination of the bending effect requires treatment of the chemical thermodynamics of the contact problem and hence a knowledge of energy levels in the interfacial core. In the case of a strong interfacial effect (c_o: carrier concentration in the first layer adjacent to the interface),

$$\Delta\sigma_m^{\parallel} = 2Fu\sqrt{\frac{2\varepsilon RTc_o}{L}} \qquad [24]$$

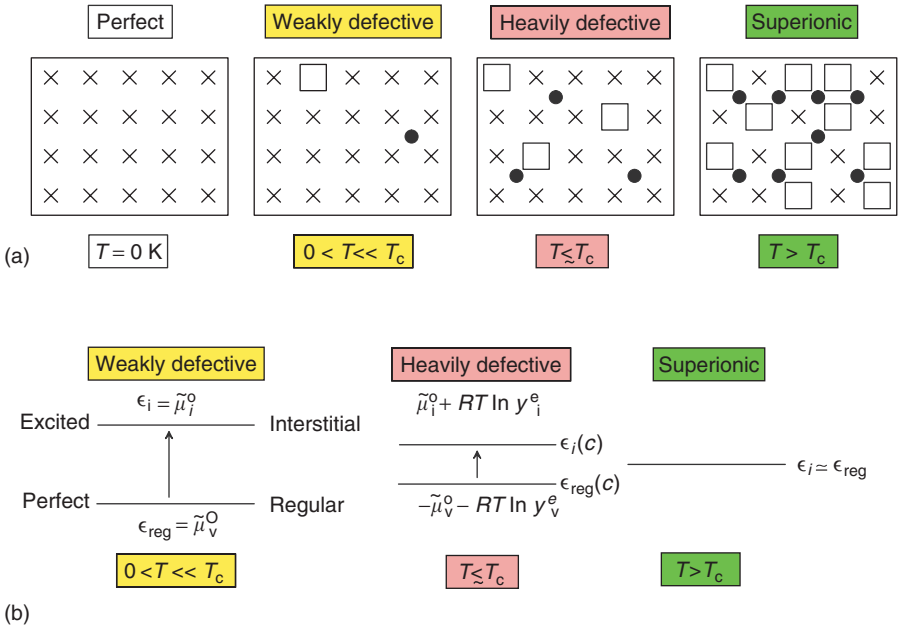

Figure 9 The "thermal destiny" of an ionic crystal above absolute zero: a progressive development from a perfect to a superionic phase via an ideally defective and a heavily defective state. (a) Crystallographic defect picture and (b) corresponding "energy level" schemes. The indices *v* and *i* refer to the vacant regular and interstitial sites. (Reproduced with permission from Maier J and Münch W (2000) Thermal destiny of an ionic crystal. *Zeitschrift für Anorganische and Allgemeine Chemie* 626: 264; © Wiley-VCH.)

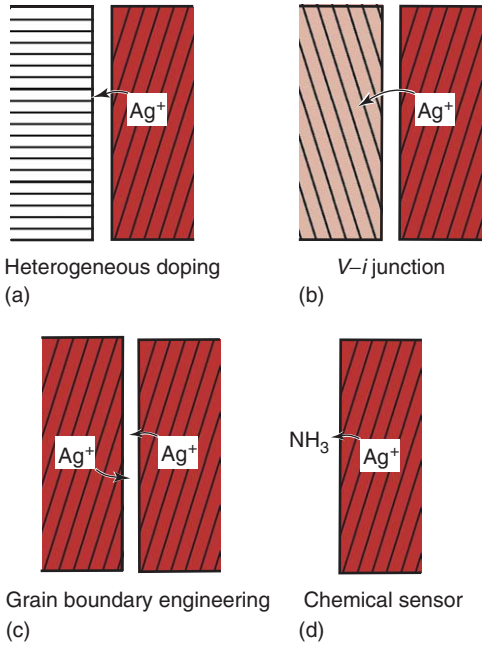

Figure 10 Four basic space charge situations involving ionic conductors (here silver ion conductor): (a) contact with an insulator, (b) contact with a second ion conductor, (c) grain boundary, and (d) contact with a fluid phase. (Reproduced with permission from Maier J (2002) Nanoionics and soft materials science. In: Knauth P and Schoonman J (eds.) *Nanocrystalline Metals and Oxides. Selected Properties and Applications,* Kluwer International Series in Electronic Materials: Science & Technology, vol. 7, pp. 81–110. Boston: Kluwer Academic; © Kluwer Academic/Plenum Publishers.)

describes the excess mean conductivity of the mobile majority defect in a Gouy–Chapman accumulation layer, and

$$\Delta\rho_{\mathrm{m}}^{\perp} = \frac{1}{L}\sqrt{\frac{\varepsilon RT}{2z_{\mathrm{d}}u^2z^3c_{\infty}F^4c_{\mathrm{o}}^2\ln(c_{\mathrm{o}}/c_{\infty})}} \qquad [25]$$

the excess mean resistivity of the mobile majority carriers across a single Mott–Schottky depletion layer situation (dopant with molar charge $z_{\mathrm{d}}F$ and concentration c_{∞}). L is the distance perpendicular to the interface over which the measurement averages.

Figure 12 shows heterolayers of CaF_2 and BaF_2 and the effect of the concentration of interfaces on the overall parallel conductance.

In a polycrystalline material, bulk and boundary conductivities have to be superimposed according to the microstructural situation. An approximate relation that takes into account the conductivities across ($\perp$) and along ($\parallel$) grain boundaries ($\hat{\sigma}$: complex conductivity; $\hat{\sigma}^{\parallel}, \hat{\sigma}^{\perp}$ refer to the local mean values) is

$$\hat{\sigma}_{\mathrm{m}} = \frac{\hat{\sigma}_{\infty}\hat{\sigma}_{\mathrm{gb}}^{\perp} + \beta_{\mathrm{gb}}^{\parallel}\varphi_{\mathrm{gb}}\hat{\sigma}_{\mathrm{gb}}^{\parallel}\sigma_{\mathrm{gb}}^{\perp}}{\hat{\sigma}_{\mathrm{gb}}^{\perp} + \beta_{\mathrm{gb}}^{\perp}\varphi_{\mathrm{gb}}\hat{\sigma}_{\infty}} \qquad [26]$$

($\beta^{\parallel}$, $\beta^{\perp}$ refer to the portions of the volume fraction φ that contribute to the path; in the simplest approach, $\beta^{\parallel} = 2/3$, $\beta^{\perp} = 1/3$.)

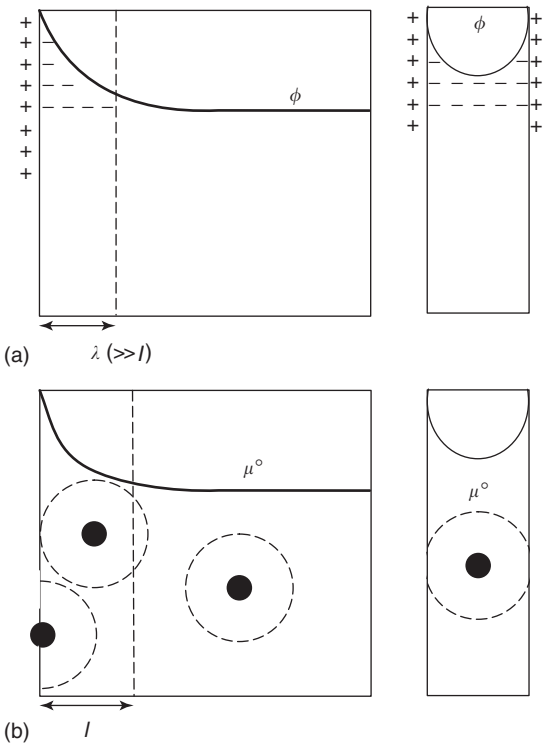
Nano-Ionics

Nano-sized conductors can provide large ionic conductivity anomalies owing to the high concentration of interfaces. Moreover, the spacing of interfaces may be so narrow that they perceive each other. **Figure 13a** shows the space charge overlap occurring in materials when the distance of neighboring interfaces becomes smaller than the Debye length, with the structure being invariant (cf. also **Figure 12**). If the distance is smaller than the effective thickness of the point defect (i.e., point defect including the sphere of influence in which the structure is perceptibly modified), then the local standard chemical potential changes (**Figure 13b**). In the case of delocalized electrons, this may happen at much larger distances. These are only two examples of the nano-size effects on ion conduction. Amongst others, the effects of particle geometry or curvature are mentioned, by which approximately a Gibbs–Kelvin term ($\propto \bar{\gamma}/\bar{r}$; $\bar{\gamma}$: mean surface tension, $\bar{r}$: mean radius) is introduced to the chemical potential.

Such effects do not only affect transport properties, they are also interesting as far as mass storage is concerned.

Partial Equilibrium – Bridge between High-Temperature and Low-Temperature Situation

Arbitrary deviations from equilibrium require a detailed kinetic treatment. The situations in which some carriers behave reversibly while others are completely frozen are briefly considered here. Such considerations are helpful when the bridge has to be spanned from high-temperature equilibrium (during preparation) to a low operational temperature. In fact, such a partial equilibrium situation was already tacitly assumed when doping effects were studied. At high enough temperatures, dopants become reversible and segregation equilibria become active. Generally speaking, freezing of carriers leads to a reshuffling of *in situ* to *ex situ* parameters (i.e., from the *P*-term to the *C*-term in the power-law equation [20]). The discrepancy between the equilibrium



+
+
+

that has made a jump from x to x' does not directly create its equilibrium environment and has a higher tendency to jump back again. It is, in particular, the rearrangement of the other defects that determines the finite relaxation time. This mismatch situation causes back-jumps to be more likely, making the rate constants of the hopping equation time dependent and hence the conductivity frequency dependent.

In liquids too, a relaxation effect occurs. Since the formation of the ion cloud does not immediately follow the mobile ion under regard, the charge cloud becomes asymmetrical and acts as a brake. The relaxation time is proportional to the viscosity. The occurrence of counter transport of differently charged ions which carry along these solvation spheres leads to friction, that is, to a second effect that diminishes the mobility, the so-called electrophoretic effect. These phenomena explain the Kohlrausch's $\sqrt{c}$ law, which is well established for strong electrolytes, and reads

$$\Lambda_c = \Lambda_o - \left[\frac{A}{(\varepsilon T)^{3/2}}\Lambda_o + \frac{B}{(\varepsilon T)^{1/2}}\right]\sqrt{c} \qquad [28]$$

(A and B are constants, $\Lambda_o \equiv \Lambda_c$ $(c = 0)$, ε the dielectric constant, and Λ_c the equivalent conductivity, that is, conductivity per equivalent salt concentration.) **Figure 15** gives some examples of the above phenomena.

Chemical Diffusion in Mixed Conductors

The simultaneous presence of ionic and electronic carriers in so-called mixed conductors leads to the phenomenon of chemical diffusion (coupled transport of ions and electrons) and the possibility of changing stoichiometry. Technologically important examples for which this phenomenon plays a decisive role are insertion electrodes, electrochemical windows, permeation membranes, and conductivity sensors; more generally, chemical diffusion is important for all electroceramics, the properties of which depend on the detailed stoichiometry (such as in dielectrics or high-temperature superconductors). Stoichiometry changes also occur, if the electrodes applied in the electrochemical measurements are not completely reversible for both ions and electrons; in this case, the partial current density is given by

$$i_j = \left(\frac{\sigma_j}{\sigma}\right) i + z_j F D^{\delta} \nabla c_j \qquad [29]$$

D^{δ} being the chemical diffusion coefficient that is determined by mobilities and concentrations of all charge carriers involved in the transport (i: total current density). If different internal reactions such as valence state changes occur for the conducting species, the equation has to be modified. The use of selectively blocking electrodes leads to the suppression of the current of one carrier type at the expense of a concentration polarization. This allows the separation of ionic and electronic conductivities and of the chemical diffusion coefficient.

A major application of ion conductors is their use as electrolytes which nullifies gradients in the electrochemical potential of ions but supports gradients in the electrochemical potential of electrons. This gives rise to a cell voltage (e.m.f.) which is consequently proportional to the integrated gradient of the neutral component (cf. distance in **Figure 2**) and corresponds to the Nernst equation. In other words, differences in the chemical component potentials can be transformed into an electrical voltage (such as exploited in batteries, fuel cells, and sensors). In mixed conductors, a partial internal short-circuit occurs, causing a nonzero gradient in the electrochemical potential of the ions, which is proportional to the gradient in the electronic Fermi level. Hence, the cell voltage is diminished by a factor that depends on the proportion of electronic conductivity and consequently allows for its determination.

Ionic Bonding and Crystals*

M W Finnis, Queen's University Belfast, Belfast, UK

Published by Elsevier Ltd.

Introduction

One can distinguish the models of ionic materials by their increasing degrees of sophistication, which are described briefly below. All contain parameters of one sort or another that have to be fitted either to experimental data or to the best available first-principles calculations. Following this introduction there is a more detailed discussion of how ionic models, in general, can all be related to the density-functional theory within the second-order perturbation theory.

The Born model, the shell model, and the compressible ion model are three well-known types of increasing complexity. More recently, they have been joined by models including ionic polarizability up to the quadrupole level. The simplest ionic models are typified by constant nominal ionic charges. These are usually integers, although fractional charges have been used as additional fitting parameters. Variable charge models have also been developed, which allow charge transfer within a simple classical description of the equilibration of an electronic chemical potential. Finally, a class of models has been developed that includes most of the aforementioned as subclasses and also treats covalency, namely, the self-consistent tight-binding models. The scope of ionic models, especially when charge transfer can be included, is potentially very wide. Although so far they have been less developed and applied, self-consistent tight-binding models have potentially the widest scope, which embrace traditional textbook ionic materials such as NaCl, KF and all the other alkali halides, the insulating oxides with wide bandgaps such as MgO and Al_2O_3, perovskites such as $SrTiO_3$, as well as oxides which are considered as less ionic, such as TiO_2 and ZrO_2.

The simplest ionic model is the rigid ion model. It is sometimes called the Born model after its pioneer Max Born and his co-workers in Edinburgh, who over 50 years ago developed most of the mathematical description of the ionic model that is still being used (see Further reading section for more details). Within the context of the density-functional perturbation theory, one can think of it as a first-order model, as seen in the following section. The ions interact by the Coulomb interaction, in addition to which there is a short-range pairwise repulsion.

Ions are not rigid, and the shell model was first developed by Dick and Overhauser in 1958 to include their polarizability. In its simplest version, a spherical shell of charge $-q^s$ surrounds an ion of reduced charge $\Delta Z + q^s$ and is attached to it by a harmonic spring. The nominal ionic charge is ΔZ. The repulsion between ions is now modeled as a repulsion between the centers of these shells.

The compressible ion model is an extension of the shell model in which the radius of the shells is a variable. The energy of a compressible ion is a function of this radius, which adjusts according to the environment of the ion. This model is most strongly motivated by the case of oxygen, as discussed further

*Adapted by permission of Oxford University Press.

below. The traditional models were mainly constructed by fitting their parameters to experimental data. This was a disincentive to make them too sophisticated, since the number of parameters would become so large that they could fit anything without any guarantee of being physically sound. The compressible ion model was held back for this reason, since in its early days, the parameters were determined by fitting them to experimental phonon dispersion curves. The work of Madden *et al*. attempted to reduce the empirical nature of the parameters by fitting them individually, rather than altogether. They were fitted to total energy data obtained by first-principles calculation on molecules and crystals at chosen interatomic distances. This approach also made it feasible to introduce independent parameters to describe quadrupolar polarization. Even so, the most sophisticated ionic models take no explicit account of covalent effects, and this may be a significant shortcoming.

None of the previous ionic models allow for the fact that the charge associated with an ion also depends on its environment. This has been treated in an empirical way by the model introduced by Streitz and Mintmire in 1994. A more recent approach is to use a self-consistent tight-binding model, which, in principle, can be regarded as an ionic model with a degree of covalency included, as described by Finnis *et al*. in 2003. Covalency is represented in the tight-binding model by the nonvanishing elements of a Hamiltonian matrix linking atomic-like orbitals. In fact, most other models can be derived from a tight-binding description, by making specific approximations, perhaps the most drastic being the complete neglect of interatomic Hamiltonian matrix elements as in the variable charge-transfer model, or the neglect of all covalent effects as in the rigid ion model.

The Rigid Ion Model Derived

In order to derive ionic models, like other models, one starts with an input charge density $\rho^{\text{in}}(\boldsymbol{r})$. It is constructed, at least notionally, by superimposing spherical "atomic" charge densities. The atomic charge density in the sense used here is not necessarily the same as the charge density of free atoms. A judicious choice of atomic charge density could make the input charge ρ^{in} closer to the exact, self-consistent charge density ρ^{ex}, improving the accuracy of a first-order model. The usual picture of the charge in an ionic crystal is, of course, a superposition of ions rather than of atoms, and one might expect that these would be a better starting point. In any case, the variational principle suggests that the error in the energy is second-order error in the charge density, provided that the energy is formulated as a function of the charge density.

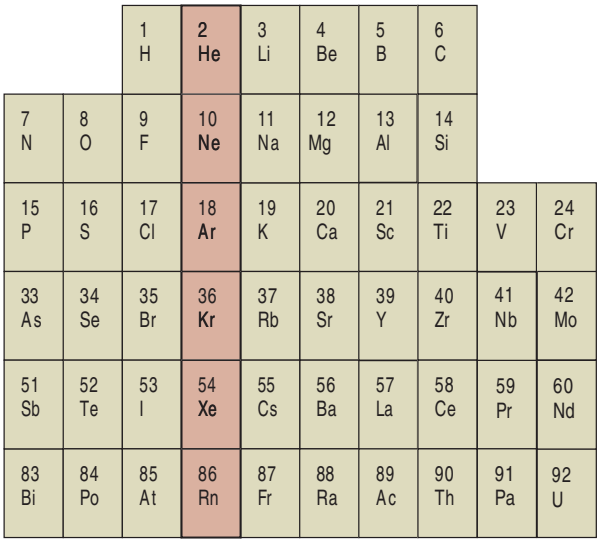

Figure 1 The periodic table centered on the noble gases.

A neat general recipe for the "atomic charge density" is to take the electron density of the nearest noble gas in the same row of the periodic table (see **Figure 1**). Thus, oxygen, fluorine, sodium, magnesium, and aluminum would all be represented by the charge density of neon atoms, chlorine and potassium by argon, and so forth.

This leads one to construct a first-order model for the total energy as follows. First, superimpose the noble gas atoms at the positions required in the material, keeping their charge densities rigid. The superimposed charge density is denoted by $\rho^{\text{in}}_{\text{ng}}$, where the individual noble gas atom on site I has a density ρ^{I}_{ng}. Thus

$$\rho^{\text{in}}_{\text{ng}}(\boldsymbol{r}) = \sum_{I} \rho^{I}_{\text{ng}}(\boldsymbol{r} - \boldsymbol{R}_I) \qquad [1]$$

The first-order energy of this system is denoted by $E^{\text{HKS}}[\rho^{\text{in}}_{\text{ng}},\ V_{\text{ext}}]$, where

$$E^{\text{HKS}}[\rho^{\text{in}}_{\text{ng}}, V_{\text{ext}}] = T_{\text{s}}[\rho^{\text{in}}_{\text{ng}}] + \int \rho^{\text{in}}_{\text{ng}}(\boldsymbol{r}) V_{\text{ext}}(\boldsymbol{r})\, \mathrm{d}\boldsymbol{r} + E_{\text{H}}[\rho^{\text{in}}_{\text{ng}}] + E_{\text{xc}}[\rho^{\text{in}}_{\text{ng}}] + E_{ZZ} \qquad [2]$$

The notation introduced here is as follows: E^{HKS} is a density functional that describes the total energy, $T_{\text{s}}[\rho]$ is the kinetic energy of noninteracting electrons with density ρ, V_{ext} is the potential felt by the electrons from the atomic nuclei, $E_{\text{xc}}[\rho]$ is the exchange and correlation energy of the electrons with density

ρ, E_H is the electrostatic self-energy (Hartree energy) and E_{ZZ} is the nucleus–nucleus Coulomb repulsion. The energy of this system is strongly repulsive, because the equilibrium spacing of noble gas atoms is considerably larger than that of the cations and anions in ionic materials. Indeed, because one is dealing with closed shell atoms, it is expected that the first-order charge density and energy are rather good approximations to the exact, self-consistent quantities denoted by ρ_{ng} and E_{ng}. The integer charge differences ΔZ_I on the nuclei, required to create the nuclei of the actual cations and anions, results in a perturbing external potential to the electrons, given by

$$\Delta V_{ext}(\boldsymbol{r}) = -\sum_I \frac{\Delta Z_I}{|\boldsymbol{r} - \boldsymbol{R}_I|} \qquad [3]$$

To first order, this does not disturb the charge density, but it introduces a strong electrostatic cohesive energy, due to the attraction between the unlike charges, which because of their alternating arrangement in space more than compensates for the repulsion of like charges. This works as follows: the total change in the electrostatic interactions of the nuclei introduced by "transmutation" is

$$\Delta E_{ZZ} = \sum_{I \neq J} \frac{Z_I \Delta Z_J}{|\boldsymbol{R}_I - \boldsymbol{R}_J|} + \frac{1}{2} \sum_{I \neq J} \frac{\Delta Z_I \Delta Z_J}{|\boldsymbol{R}_I - \boldsymbol{R}_J|} \qquad [4]$$

The second term is called the total Madelung energy of the particular structure, and is denoted as $N_a E_M$, where N_a is the total number of atoms and E_M is the Madelung energy per atom:

$$E_M = \frac{1}{2N_a} \sum_{I \neq J} \frac{\Delta Z_I \Delta Z_J}{|\boldsymbol{R}_I - \boldsymbol{R}_J|} \qquad [5]$$

Consider in more detail the example of a simple binary crystal structure, in which a formula unit consists of n^C cations and n^A anions of charges ΔZ^C and ΔZ^A, respectively. These charges derived according to the above definition are sometimes called formal charges, to distinguish them from actual electronic charge transfers. Generally, for any material, summing over all sites, charge neutrality requires that:

$$\sum_I \Delta Z_I = 0 \qquad [6]$$

For the binary crystal, the charge neutrality condition holds for each formula unit:

$$n^C \Delta Z^C + n^A \Delta Z^A = 0 \qquad [7]$$

Table 1 Madelung constants for ionic crystals

Structure	α_M
NaCl	1.75
CsCl	1.76
α-Al_2O_3	1.68
V_2O_5	1.49

Adapted from Johnson QC and Templeton DH (1961) Madelung constants for several structures. *Journal of Chemical Physics* 34: 2004–2007.

In this case, the Madelung energy per atom can be written as

$$E_M = \alpha_M \frac{\Delta Z^C \Delta Z^A}{2R_{CA}} \qquad [8]$$

where R_{CA} is the nearest-neighbor cation–anion distance and α_M is the Madelung constant, which is tabulated in the literature for a number of crystal structures. Examples are given in **Table 1**. For an arbitrary arrangement of ions, for example, within a supercell which may comprise thousands of atoms, or without periodic boundary conditions, there are special strategies for calculating $N_a E_M$, such as the Ewald method for periodic systems, which are well described. The first-order model for the total energy omits the second-order effects due to the deviation of both ρ_{ng} and of the final exact charge density, ρ^{ex} from ρ^{in}_{ng}:

$$\begin{aligned} E^{(1)} &= E^{HKS}[\rho^{in}_{ng}, V_{ext}] + \int \rho^{in}_{ng}(\boldsymbol{r}) \Delta V_{ext}(\boldsymbol{r})\, d\boldsymbol{r} + \Delta E_{ZZ} \\ &= E^{HKS}[\rho^{in}_{ng}, V_{ext}] + N_a E_M \\ &\quad - \sum_{I \neq J} \int \rho^I_{ng}(\boldsymbol{r} - \boldsymbol{R}_I) \frac{\Delta Z_J}{|\boldsymbol{r} - \boldsymbol{R}_J|}\, d\boldsymbol{r} + \sum_{I \neq J} \frac{Z_I \Delta Z_J}{|\boldsymbol{R}_I - \boldsymbol{R}_J|} \\ &\quad - \sum_I \int \rho^I_{ng}(\boldsymbol{r} - \boldsymbol{R}_I) \frac{\Delta Z_I}{|\boldsymbol{r} - \boldsymbol{R}_I|}\, d\boldsymbol{r} \end{aligned} \qquad [9]$$

The interaction of the atomic charge density with the perturbation on its own site has been separated out as the final term. This expression is dominated by the first two terms, namely $E^{HKS}[\rho^{in}_{ng}, V_{ext}]$ and the Madelung energy. It is a reasonable approximation to write $E^{HKS}[\rho^{in}_{ng}, V_{ext}]$ as a sum of pairwise interactions V_{IJ}, since closed-shell atoms are being dealt with. With this assumption one obtains the simplest form of the rigid ion model:

$$E_{rim} = \frac{1}{2} \sum_{I \neq J} V_{IJ} + N_a E_M \qquad [10]$$

The remaining first-order terms will be much smaller, as discussed below. If all the atoms happen

to be represented by the same noble gas, the final sum must vanish identically by the condition of charge neutrality. But in any case, it is a structure-independent term that is not relevant to interatomic forces. The third and fourth terms taken together represent the electrostatic interaction between the noble gas atomic densities, which are neutral objects, and the perturbations ΔZ_I, excluding the self-interactions. These are pairwise interactions, that are short-ranged and weak compared to the electrostatic interactions contained in $E^{\mathrm{HKS}}[\rho_{\mathrm{ng}}^{\mathrm{in}}, V_{\mathrm{ext}}]$. They fall to zero by Gauss's theorem when the neighbor J is entirely outside the charge density ρ_{ng}^{I}, which must be a good approximation beyond the nearest neighbors. Furthermore, the nearest neighbors will usually have opposite signs of ΔZ_I and ΔZ_J, so the two contributions $\rho_{\mathrm{ng}}^{I}\Delta Z_J$ and $\rho_{\mathrm{ng}}^{J}\Delta Z_I$ tend to cancel. Indeed, the cancellation is obviously exact if the noble gas is the same for I and J and if $\Delta Z_I = -\Delta Z_J$, such as in binary compounds, for example, MgO or NaF. Now comparing these terms with the pairwise electrostatic contributions to $E^{\mathrm{HKS}}[\rho_{\mathrm{ng}}^{\mathrm{in}}, V_{\mathrm{ext}}]$, one gets

$$\int\int \frac{\rho_{\mathrm{ng}}^{I}(\boldsymbol{r})\rho_{\mathrm{ng}}^{J}(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}\,\mathrm{d}\boldsymbol{r}\,\mathrm{d}\boldsymbol{r}' + \frac{Z_I Z_J}{R_{IJ}} - \int\left\{\frac{\rho_{\mathrm{ng}}^{I}(\boldsymbol{r})Z_J}{|\boldsymbol{r}-\boldsymbol{R}_J|} + \frac{\rho_{\mathrm{ng}}^{J}(\boldsymbol{r})Z_I}{|\boldsymbol{r}-\boldsymbol{R}_I|}\right\}\mathrm{d}\boldsymbol{r} \qquad [11]$$

This interaction will generally be much bigger. Notice that, first, it involves the full nuclear charges Z rather than ΔZ, second, it is always repulsive, because it comprises the direct Coulomb interaction between nuclei, partially screened by the electron distributions, and third, it is of longer range, being nonzero when ρ_{ng}^{I} overlaps ρ_{ng}^{J}, not merely Z_J. The terms being considered are all strictly pairwise, and so can be exactly accounted for by a relatively small correction to the V_{IJ} introduced to represent $E^{\mathrm{HKS}}[\rho_{\mathrm{ng}}^{\mathrm{in}}, V_{\mathrm{ext}}]$. Since the form of V_{IJ} in practical applications has been parametrized, the extra terms could be absorbed without explicitly evaluating them.

The rigid ion model in the form [10] is now considered again. It was first derived on the basis of overlapping noble gas atomic charge densities by Gordon and Kim in 1972 and Kim and Gordon in 1974. A completely local density-functional theory (DFT) (including the local kinetic energy functional) was used to evaluate the pair potential between noble gas atoms, with atomic charge densities overlapped but unrelaxed, and it was discovered that this could account fairly well for the lattice parameters and bulk moduli of ionic crystals. The $E^{\mathrm{HKS}}[\rho_{\mathrm{ng}}^{\mathrm{in}}, V_{\mathrm{ext}}]$ could also be fairly well fitted by the Lennard-Jones potential, the parameters of which have been used, together with the appropriate Madelung energy, to calculate bond lengths in a number of compounds, as illustrated in **Figure 2**, where the results are compared with experimental bond lengths. Because some of the crystal structures are a bit complicated, convenient simplifications have been made, so that the bond length can be predicted by minimizing the energy analytically with respect to R_{CA}. For example, only the nearest-neighbor interactions in the Lennard-Jones potential were included. Then for Al_2O_3, the sum of ionic radii for Al^{3+} and O^{2-} was taken as the "experimental" bond length, namely 0.191 nm, which is also the mean of the two close neighbor bond lengths observed in the actual corundum structure. Such ionic radii incidentally reproduce the experimental bond lengths of the other common oxides to an accuracy of 0.002 nm. Notice that in some cases, a mixture of rare gases is involved, for example, Nb_2O_5 has to be built out of Kr and Ne, because Nb in the 5+ state of ionization resembles Kr. Since a value for the Madelung constant was not listed in this case by Johnson and Templeton, it is assumed that their V_2O_5 value would do for Nb_2O_5. The agreement of calculated and observed bond lengths in such diverse materials as ZrO_2 and KCl, with no fitting of parameters to any experimental data, is quite striking. Not surprisingly, the worst candidate tested here is SiC, which is a classic covalent compound, but even in this case the crude ionic model does better than one might have expected, since the perturbations ΔZ_I are by no means small. Such is the power of the variational principle. It should be added that the

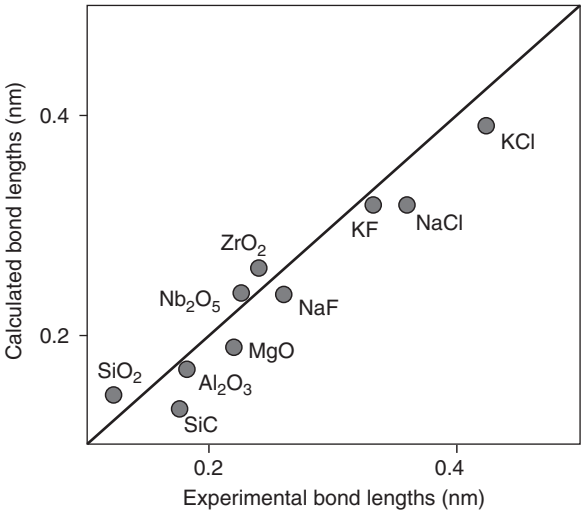

Figure 2 Bond lengths calculated from Lennard-Jones and Madelung energies.

relatively good agreement of this model breaks down when it comes to calculating the second derivative of the energy, the bulk modulus. Superficially, that is easily repaired if one allows the pair potential to be empirically fitted. Predictions of phonon frequencies and the properties of defects nevertheless generally require a higher-quality model than rigid ions can provide, even when some degree of empirical fitting is allowed.

Beyond the Rigid Ion Model

The Basic Second-Order Model

Several other models can be derived within the broad framework of a second-order functional, which can be written in terms of the reference density from the noble gas atoms as

$$\begin{aligned} E^{(2)}[\rho] = {} & E^{\mathrm{HKS}}[\rho_{\mathrm{ng}}^{\mathrm{in}}, V_{\mathrm{ext}}] + \int \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r})\Delta V_{\mathrm{ext}}(\boldsymbol{r})\,\mathrm{d}\boldsymbol{r} \\ & + \Delta E_{ZZ} + \int [\rho(\boldsymbol{r}) - \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r})]\Delta V_{\mathrm{ext}}(\boldsymbol{r})\,\mathrm{d}\boldsymbol{r} \\ & - \frac{1}{2}\int\int [\rho(\boldsymbol{r}) - \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r})]\chi_{e1}^{-1}(\boldsymbol{r},\boldsymbol{r}')[\rho(\boldsymbol{r}') \\ & - \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r}')]\,\mathrm{d}\boldsymbol{r}\,\mathrm{d}\boldsymbol{r}' \end{aligned} \quad [12]$$

The linear response function $\chi_{e1}(\boldsymbol{r},\boldsymbol{r}')$, of which the inverse operator $\chi_{e1}^{-1}(\boldsymbol{r},\boldsymbol{r}')$ appears here, measures the density induced at $\boldsymbol{r}$ by a delta function of the external potential at $\boldsymbol{r}'$. Recall that the first term represents the energy of the noble gas solid to first order, and the idea is that the above rigid ion model has taken care of this and the next two terms, that is, all terms of first order in ΔV_{ext}. The task is then to approximate the two remaining terms that depend on $[\rho - \rho_{\mathrm{ng}}^{\mathrm{in}}]$ and that are both of second order in ΔV_{ext}. The second-order energy functional in this picture is therefore

$$\begin{aligned} E^{(2)}[\rho] = {} & \frac{1}{2}\sum_{I\neq J} V_{IJ} + N_{\mathrm{a}}E_{\mathrm{M}} \\ & + \int [\rho(\boldsymbol{r}) - \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r})]\Delta V_{\mathrm{ext}}(\boldsymbol{r})\,\mathrm{d}\boldsymbol{r} \\ & - \frac{1}{2}\int\int [\rho(\boldsymbol{r}) - \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r})]\chi_{e1}^{-1}(\boldsymbol{r},\boldsymbol{r}')[\rho(\boldsymbol{r}') \\ & - \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r}')]\,\mathrm{d}\boldsymbol{r}\,\mathrm{d}\boldsymbol{r}' \end{aligned} \quad [13]$$

The difference between this functional and the usual second-order functional is that the one-electron energies are here subsumed into the classical pairwise potential, an approximation that is only justifiable for the closed-shell electronic structure of noble gas atoms. By this manoeuvre, the entire responsibility has been shifted for the description of any covalent bonding effects, which are of second order in $[\rho - \rho_{\mathrm{ng}}^{\mathrm{in}}]$, onto χ_{e1}. The response function χ_{e1} refers to an electron density distribution $\rho_{\mathrm{ng}}^{\mathrm{in}}$, and it can only be modeled in rather crude ways. Whatever way this is done (an example is given below), the model so generated is entirely classical in form, and requires $E^{(2)}[\rho]$ to be minimized directly with respect to ρ, without the solution of any Schrödinger equation. The resulting density will then satisfy

$$\rho(\boldsymbol{r}) - \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r}) = \int \chi_{e1}(\boldsymbol{r},\boldsymbol{r}')\Delta V_{\mathrm{ext}}(\boldsymbol{r}')\,\mathrm{d}\boldsymbol{r}' \quad [14]$$

Deformable Ions

The above formalism is a way to derive the shell model, which is the simplest extension of the rigid ion model to introduce deformable ions. Originally, this model was entirely empirical, providing sufficient disposable parameters to fit phonon spectra much better than previous models did. Now from the previous analysis, one is in a better position to see how its parameters can be related to real physical quantities. The shell model is, in effect, a representation of the terms in $\rho - \rho_{\mathrm{ng}}^{\mathrm{in}}$:

$$\begin{aligned} \Delta E^{(2)}[\rho] = {} & \int [\rho(\boldsymbol{r}) - \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r})]\Delta V_{\mathrm{ext}}(\boldsymbol{r})\,\mathrm{d}\boldsymbol{r} \\ & - \frac{1}{2}\int\int [\rho(\boldsymbol{r}) - \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r})]\chi_{e1}^{-1}(\boldsymbol{r},\boldsymbol{r}')[\rho(\boldsymbol{r}') \\ & - \rho_{\mathrm{ng}}^{\mathrm{in}}(\boldsymbol{r}')]\,\mathrm{d}\boldsymbol{r}\,\mathrm{d}\boldsymbol{r}' \end{aligned} \quad [15]$$

In this case, the density $\rho - \rho_{\mathrm{ng}}^{\mathrm{in}}$ of eqn [13] is modeled by the sum of displacements by $\boldsymbol{u}_I^{\mathrm{s}}$ of rigid, spherical shells of negative charge, $-\Delta q_I^{\mathrm{s}}$ originally centered about each atom. Each shell is tethered to its nucleus by a spring. At equilibrium in a perfect crystal, an undisturbed shell can be thought of as representing part of the density $\rho_{\mathrm{ng}}^{\mathrm{in}}$. The shells are assumed to be massless, since the inertia of electrons does not enter the dynamics of the system in the Born–Oppenheimer approximation, which is the framework for all the models. When the atoms are not in their equilibrium positions, the shells are subject to three kinds of forces, corresponding to three terms in the total energy. First, they are pulled toward their nuclei by the tethering spring, second, they are pulled toward other nuclei by the Coulomb attraction, and third, the shells repel each other. The first two kinds of forces are a representation of the term $\int(\rho - \rho_{\mathrm{ng}}^{\mathrm{in}})\Delta V_{\mathrm{ext}}$ in eqn [13]. In the harmonic approximation, the change in energy when the shells

are displaced by $\boldsymbol{u}_I^s$ from their nuclei has the form

$$\Delta E^{(2)} = \frac{1}{2}k u_I^{s2} + \sum_{J\neq I}\left\{-q_I^s \Delta Z_J\left[\frac{1}{|\boldsymbol{R}_I + \boldsymbol{u}_I^s - \boldsymbol{R}_J|} - \frac{1}{|\boldsymbol{R}_I - \boldsymbol{R}_J|}\right] + \frac{1}{2}q_I^s q_j^s\left[\frac{1}{|\boldsymbol{R}_I + \boldsymbol{u}_I^s - \boldsymbol{R}_J - \boldsymbol{u}_J^s|} - \frac{1}{|\boldsymbol{R}_I - \boldsymbol{R}_J|}\right]\right\} \quad [16]$$

A number of points can be made about this model. First, it captures the long-ranged Coulomb interactions between induced dipoles. The on-site elements of χ_{e1}^{-1} are represented within the first term $\frac{1}{2}ku_I^{s2}$, while the last term in the braces represents its intersite elements. The Coulomb interactions in [16] could be expanded to first order in $\boldsymbol{u}_I^s$ to display the dipole–dipole interactions explicitly, and indeed the model could be formulated in terms of variable dipoles on the sites instead of explicit shell charges and displacements. These Coulomb interactions are an important part of the inverse response function, trying to be modeled. However, they are certainly not the whole story, since the true inverse response function contains terms in the kinetic energy and the exchange and correlation energy. A short-ranged empirical potential between the shells can be introduced to model these contributions.

In a more realistic model, the shells are allowed to change their radius in response to their environment. Such an effect can be accomplished by including a kind of compressibility of the ion as a further parameter, which adds a functional dependence on $(r^s - r_0^s)$ to the potential energy, where r^s and r_0^s are the current and relaxed values of the shell radius. This is the idea behind the "breathing shell" model, or more recently the "compressible ion" model. For recent developments in the compressible ion model, the reader is referred to the "Further reading" section. The compressibility of an ion has a significant effect on properties, and is most noticeable in the case of oxygen, because the size of the O^{2-} ion is particularly sensitive to its environment. Indeed, in free space the O^{2-} ion is unstable, which can be thought of as the limiting case of the radius of the ion going to infinity as its coordination is reduced to zero. A noteworthy example of the importance of compressible oxygen is MgO. Within the rigid ion model the Cauchy relation between elastic constants, $C_{12} = C_{44}$, holds, since the potential energy is purely pairwise, yet experimentally C_{12} and C_{44} differ by $>50\%$. The shell model does not help here, because by symmetry the elastic strains do not displace the shells from their lattice sites; therefore, the Cauchy relation should still hold. The difference between C_{12} and C_{44} is only obtained when compressible oxygen ions are introduced. This is because the elastic constant C_{12} is associated with a change in volume, which induces compression or expansion of the ions if the model allows them this degree of freedom. It may help to appreciate this if C_{12} is considered as a linear combination of the bulk modulus, $B = \frac{1}{3}(C_{11} + 2C_{12})$ and the shear modulus, $C' = \frac{1}{2}(C_{11} - C_{12})$, that is, $C_{12} = \frac{1}{3}(3B - 2C')$.

There are now more sophisticated models with polarizable ions, going beyond the notion of spherical shells and harmonic springs. Closer in spirit to the density-functional framework is the approach of Ivanov and Maksimov in 1996. These authors represent $(\rho - \rho_{\mathrm{ng}}^{\mathrm{in}})$ as a superposition of atomic charge densities ρ_{ng}^I, each of which is allowed to shift rigidly with respect to its nucleus, thereby modeling the dipole moments. The associated changes in energy are calculated with a completely local density functional along the lines of Gordon and Kim. A natural extension, considered by Ivanov and Maksimov, is to include parameters that describe distortions of the atomic charge densities, such as expansion and contraction or quadrupolar distortion. Besides the local density approximations for kinetic, exchange, and correlation energies, the only limitation of this approach is the number of free parameters one is prepared to include to characterize the charge density.

Another line of attack starts as before with the assumption that the ions are polarizable as dipoles and quadrupoles, and are compressible. The strategy is then, as far as possible, to obtain the many parameters such a model requires as independently as possible, by fitting functions to an extensive set of first-principles calculations on ions in specially chosen potential wells or in clusters. It is a great improvement on the simple shell model, and can reproduce a range of strain energy data and phonon spectra. However, in spite of the extensive use of first-principles calculations, it is impossible to eliminate some arbitrary choices regarding the functional forms used, and some pairwise approximations. A detailed example of this approach was given by Marks *et al*. in 2001.

Variable Charge Transfer Models

In the models described so far in this article, a fixed charge transfer between ions is defined. The net charges on ions are fixed at the formal charges, which are specified by the electronic structure of noble gases. In reality, the occupancy of atomic orbitals varies with the local atomic environment, so it is worth thinking about how this effect can be

modeled. In fact, a model of ionic crystals that includes covalency, polarizable ions (dipoles and quadrupoles), and variable charge transfer was introduced by Finnis *et al*. under the heading of self-consistent tight binding. Self-consistent tight binding offers a way of treating pure metal atoms as well as their oxides, since, at least for *sd*-bonded metals, it models the nature of chemical bonding from the metallic to the ionic state.

Conceptually, the application of self-consistent tight binding to an ionic material is no different from its application to metals. However, an alternative input charge density might be considered. In the tight-binding models discussed previously, atomic charge densities were superimposed to create the notional input charge density, so that all the long-ranged electrostatic interactions appeared in the second-order term. However, one could also formulate the tight-binding model starting from the superimposed atomic charge densities of noble gases, in which case the Coulomb interactions would appear in the pair potential, exactly as they do in the rigid ion model. A systematic study of the consequences of one or the other starting point has not yet been made.

In spite of advantages of self-consistent tight binding in comparison to the models introduced earlier in this article, it has certain disadvantages that should be mentioned. These include the obvious one of greater computation time, but there may be others. For example, in current implementations the second-order term is represented by Coulomb interactions between point multipoles. This appears to take no account of the effect that the compressible ion model is trying to capture. The logical way to describe a compressible oxygen ion within tight binding would be, to include more orbitals of *s* and *p* character in the basis set, so that the spread of the charge density on an anion could vary by transfer of electrons between the orbitals on a site. The price to pay would be more parameters to determine and more computation time. The benefits over a first-principles tight-binding method would be diminished or eliminated.

On the other hand, notions of compressible ions and charge transfer are not absolute; a transfer of electrons from cations to anions might be rather well described in terms of the charge density by a contraction of anion densities accompanied by an expansion of cation charge densities, and vice versa. The tight-binding model predicts a violation of the Cauchy relations because of its noncentral forces and covalency, and possibly charge transfer, whereas the compressible ion model predicts the Cauchy violation from the form of its classical nonpairwise potential energy. A one-to-one mapping of these properties such as charge transfer between the compressible ion model and the tight-binding model is not unique, so, at least at the time of writing, it would be unfair to dismiss one or the other description as wrong; they may both be grasping at the same physics from different points of view.

It may be noted that the classical variable charge model is also the basis of a popular empirical model that includes charge transfers. The determination of ρ is considered as a variational problem for which the solution equalizes a classical chemical potential of the electrons everywhere. The result is a model that has some similarities to that proposed by Ivanov and Maksimov in 1996. One can think of it as a second-order ionic model with charge transfer, or as a tight-binding model in which the effect of covalency (intersite matrix elements of the Hamiltonian) is neglected. This is a model that enables large-scale molecular dynamics simulations to be carried out, giving a broad-brush description that may be adequate, if details such as the relative energies of different structures are not of interest.

Ionizing Radiation Effects in Biological Materials

A Ottolenghi and F Ballarini, Università degli Studi di Pavia, Pavia, Italy

Introduction

The action of ionizing radiation in biological targets is a stochastic, multistep process involving several orders of magnitude, both in the space scale and in the time scale. A schematic representation of the main steps is reported in **Figure 1**. The main effects at the subcellular/cellular level and tissue/organ level are discussed in detail in the following sections; an overview is provided herein.

Primary energy deposition, which can be considered completed at 10^{-15} s after irradiation ("physical stage"), produces a spatial distribution of ionized and excited molecules. Although the DNA occupies only $\approx 2\%$ of the cell nucleus volume, it is the most important target for ionizing radiation. However, energy deposition in the surrounding water also plays a significant role, since during the so-called "pre-chemical stage" (from 10^{-15} to 10^{-12} s after irradiation) the dissociation of ionized and excited H_2O molecules gives rise to free radicals (e.g., the OH radical) that can attack the double helix constituents and produce DNA damage, mainly during the "chemical stage" (from 10^{-12} to 10^{-6} s after irradiation, when an intra-track chemical equilibrium can be assumed).

DNA damage, either produced by direct energy deposition in the double-helix atoms ("direct damage"), or produced by free-radical attack ("indirect damage"), is processed by specific repair enzymes. The oxygen level in the environment is an important parameter, because O_2 can also link damaged sites

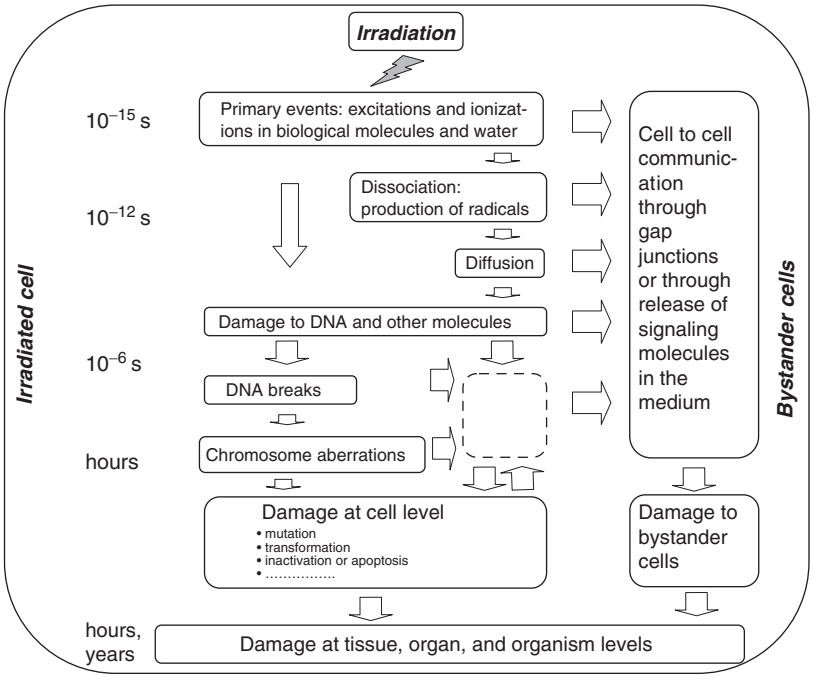

Figure 1 Schematic representation of the main steps characterizing the induction of biological damage by ionizing radiation, from initial energy deposition to different endpoints.

preventing repair and thus acting as a damage fixer. This has implications for radiation therapy, since hypoxic tumors are particularly radioresistant. In the case of incorrect DNA repair, the initial damage can evolve within a few hours into endpoints such as gene mutations and chromosome aberrations, which in turn may lead to cell death, or conversion to malignancy and possibly cancer. While cell death and conversion to malignancy can be detected *in vitro* after a few days or weeks, cancer is characterized by long latency times of the order of several years. To have a quantitative idea of the yields of the various damage types, one may consider that, for example, a cell nucleus irradiated with 1 Gy of gamma rays will be affected, on average, by about 100 000 ionizations (2000 in the DNA), 1000 DNA single-strand breaks (ssb), 40 double-strand breaks (dsb), 1 chromosome aberration, and 10^{-5} specific gene mutations. The probability of cancer development is far less than 10^{-5}.

Since the double-helix diameter is ~ 2 nm, a knowledge of the radiation track structure at the nanometer level is an essential prerequisite for understanding the mechanisms underlying the processes of interest. The expression "track structure" refers to a set of information including, for each energy deposition event (typically, an ionization or excitation), spatial coordinates of the event, event type, and amount of deposited energy. As an example, **Figure 2** shows the inelastic-scattering mean free path in water for electrons of different energies, as implemented in the track-structure code PARTRAC. The minimum value is ≈ 2 nm (that is the DNA diameter), at electron energies between 100 and 200 eV; this explains the high effectiveness of ultrasoft X-rays.

The higher-order organization characterizing mammalian DNA has to be taken into account as well. Each DNA molecule winds around globular proteins ("histones") to form structures called nucleosomes, which in turn are packed to form a 30 nm diameter chromatin fiber. The fiber is organized as a succession of loops that, for most of the cell cycle duration, are localized within distinct domains called chromosome territories, with linear dimensions $\approx 1\,\mu$m. During the 1990s, when the advances in confocal microscopy allowed more detailed investigation of nuclear architecture, it became clear that DNA damage processing mainly occurs in small channels separating neighboring domains. Therefore, the spatial distribution of the initial energy depositions needs to be considered not only at the nanometer scale (i.e., the double helix level), but also at the micrometer scale (i.e., the chromosome level).

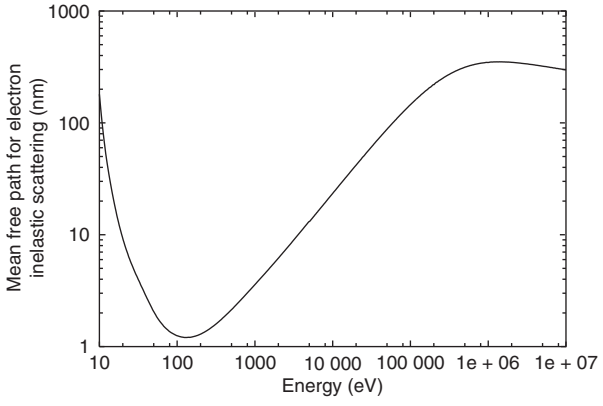

Figure 2 Mean free path for electron inelastic scattering in liquid water as a function of the initial electron energy, as implemented in track-structure code PARTRAC.

Initial DNA Damage

Ionizing radiation can induce DNA damage either by direct energy deposition, or by free-radical attack. Breaks of the DNA strands, especially dsb, are widely recognized for playing a fundamental role in the evolution of the initial damage. The sugar–phosphate moiety is the main target for the formation of strand breaks, although recent studies showed that base damage can also play a role. Energy depositions ≈ 10 eV in the sugar–phosphate can induce an ssb, either via direct dissociation, or via hydrogen loss and subsequent breakage of the sugar–phosphate bond. The sugar–phosphate is the most important target for indirect damage also, which mainly arises following an attack by OH radicals created during water radiolysis. Of the OH radicals reacting with the DNA, 80% react with a nucleobase, whereas the remaining 20% react with the sugar–phosphate. The probability that a reaction OH-DNA leads to an ssb has been estimated as 0.13.

While ssb are generally repaired efficiently, thanks to the complementarity of the two DNA strands, dsb repair is more error-prone and thus dsb are generally considered as critical initial lesions. Conventionally, a dsb is given by two ssb on opposite strands within a few base pairs (bp). A maximum separation of 10 bp is generally assumed, corresponding to a distance of 3.4 nm. Although it has been suggested that a dsb may arise also from a single energy deposition or OH attack due to charge or radical transfer, the most reliable theory on dsb formation requires two radiation-induced ssb, each of them produced either by direct energy deposition or by OH attack. The dsb yields increase linearly with dose, and 40 dsb $\mathrm{Gy}^{-1}\,\mathrm{cell}^{-1}$ is the value generally accepted for mammalian cells. The sensitivity with respect to dsb induction depends both on the target structure

and on the environment scavenging capacity. For example, plasmids are more sensitive than intact mammalian cells due to the lack of protection provided by histones and chromatin folding against OH attack. Furthermore, high concentrations of OH scavengers, which have a high probability of reacting with free radicals, lead to lower yields of ssb and dsb. Due to the clustering properties of high-LET tracks, the role of DNA structure and environment scavenging capacity becomes less important at high-LET, where indirect damage is much less important with respect to low-LET radiation. Many available experimental studies do not show significant dependence of dsb induction on the radiation LET. However, these results may be biased by the impossibility of detecting fragments smaller than a few tens kbp, and by the randomness assumption adopted in fragment analysis. Models based on track-structure simulations, which are not affected by fragment-size limitations, generally suggest a slight dsb increase with LET up to $\approx 100\,\mathrm{keV\,\mu m^{-1}}$. Recent experimental data obtained with the fragment counting technique are consistent with these expectations.

Effects at Subcellular Level

Gene Mutations

Gene mutations consist of alteration or loss of the genetic material within relatively small regions of the DNA base sequence. Generally, mutations are not lethal and result in the expression of an altered protein or in the increase/decrease in the level of a normal protein. This can lead to modifications of cellular functions including loss of proliferation/differentiation control and possibly cell conversion to malignancy. Mutations can occur either by loss of a DNA fragment ("deletion") or by change of the base sequence; changes involving only a few base pairs are called "point mutations." The simplest example of mutation is given by the alteration of a single nucleobase, which may arise from changes in the chemical structure of the base itself.

Although radiation-induced mutations are not qualitatively different from those produced by other agents (e.g., chemicals), ionizing radiation is a particularly effective mutagenic agent. Furthermore, radiation tends to produce a higher proportion of deletions relative to point mutations. While the mutation background level for a given gene is $\sim 10^{-7}$–10^{-6} per surviving cell, *in vitro* radiation-induced mutations are of the order of at least 10^{-5} per survivor. The order of magnitude of the "doubling dose," that is, the dose able to induce a doubling of the spontaneous mutation rate, has been estimated to be $\sim 1\,\mathrm{Sv}$. However, it has to be taken into account that different genes are characterized by different radiosensitivities.

Generally *in vitro* dose–response curves for mutations increase linearly up to a maximum, which is followed by a saturation region due to increased cell killing. Since mutation induction does not show significant variations with the dose rate, mutations are considered as one-hit events. Mutation yields generally increase with LET up to $\approx 100\,\mathrm{keV\,\mu m^{-1}}$, and subsequently tend to decrease. While RBE–LET relationships for mutations are qualitatively similar to those for clonogenic inactivation (see below), the relative biological effectiveness (RBE) values for mutations are higher (~ 10 at $100\,\mathrm{keV\,\mu m^{-1}}$).

Following *in vivo* exposure, mutations can affect both somatic cells and germ cells. In the former case, the consequence is generally the formation of a clone of mutated cells in the exposed individual, whereas germ cell mutations can lead to mutations in the offspring.

Chromosome Aberrations

Cells irradiated before DNA replication can show chromosome aberrations (CA), which arise from large-scale chromatin rearrangements and appear in metaphase as juxtaposition of chromatin fragments originally belonging to different chromosomes, or to different regions of the same chromosome. The product of a single unrejoined chromosome break is called "terminal deletion." Two breaks on the same chromosome can result in a "ring," whereas two breaks on distinct chromosomes can produce either a "dicentric" or a "translocation." All aberrations involving at least three breaks and two chromosomes are called "complex exchanges."

With conventional solid staining (Giemsa), all chromosomes have the same color and scoring is based on the chromosome shape and number of centromeres. Therefore, only dicentrics, rings, and a few complex exchanges, as well as excess acentric fragments, can be scored. The introduction of fluorescence *in situ* hybridization (FISH) in the early 1980s represented a fundamental turn, since it allows selective painting of specific homolog pairs. Besides dicentrics, rings, and excess acentrics, FISH allows scoring of translocations and most complex exchanges. **Figure 3** shows a translocation involving chromosomes 10 and 13 scored with multi-FISH, where each homolog pair is painted with a specific probe.

Translocations are of particular interest since they are specifically correlated with various cancer types and thus they can be used to estimate cancer risk. A typical example is the translocation involving the

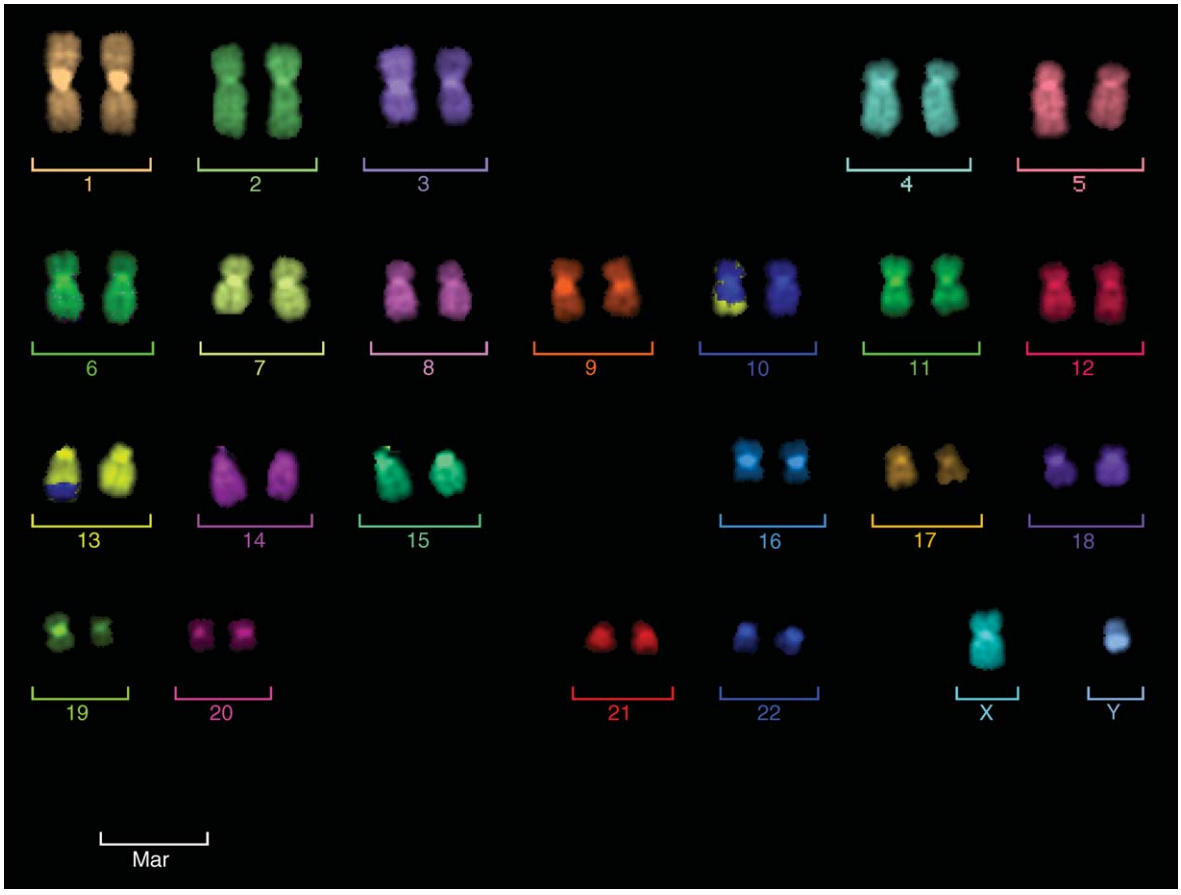

Figure 3 Translocation between one copy of chromosome 10 (painted blue) and one copy of chromosome 13 (painted yellow) following irradiation of human lymphocytes and application of the multi-FISH painting technique. (Image kindly provided by Prof. Marco Durante.)

ABL and BCR genes (on chromosomes 9 and 22, respectively), which is observed in most chronic myeloid leukemia (CML) cells. CML is one of the best-known radiation-induced cancer types and has been observed in A-bomb survivors. The interest in complex exchanges mainly relies on that they can be regarded as biomarkers of the radiation quality that can have applications in radiation protection problems such as radon exposure.

In vitro dose–response for exchange-type CA can be approximated by a linear-quadratic relationship. Low-LET dose responses show a pronounced curvature, whereas at high LET the quadratic component is generally not significant. Back in 1946, before the DNA structure was discovered, Lea hypothesized that chromosome exchanges are due to pairwise misrejoining of independent chromosome free-ends close in space and time, each free end being originated by a chromosome break ("breakage-and-reunion theory," B&R). By contrast, according to Revell's "exchange theory," all aberrations are produced by pairwise interaction of chromosome "discontinuities" arising from "unstable lesions," which can either decay or become reactive. While both these theories require two radiation-induced chromosome lesions, it has also been hypothesized that an exchange may arise from a single radiation-induced lesion, the second lesion being produced by enzymes involved in DNA repair ("one-hit hypothesis"). Although none of these theories can be disregarded at the moment, the B&R model seems to better agree with the available data with the only exception of ultrasoft X-ray data, for which the one-hit mechanism may play a non-negligible role.

The mechanisms underlying CA formation have not been fully elucidated yet. One of the key points is the nature of the initial DNA lesions that can evolve into aberrations: while many research groups think that any dsb can participate in CA formation, others assume that only clustered – and thus severe – dsb can be involved. This assumption mainly relies on those clustered dsb which show a strong dependence on the radiation quality, consistent with the dependence shown by gene mutation and cell inactivation.

Understanding the relationship of CA with other endpoints, such as cell death and conversion to malignancy, is one of the most challenging tasks in this field.

Effects at Cellular Level: Cell Death

Radiation-induced cell death occurs via two main pathways, that is interphase death and clonogenic inactivation. While the former does not allow the cell to reach the first post-irradiation mitosis, the latter consists of a loss of proliferative ability. *In vitro* clonogenic survival is generally assumed when the cell can divide at least six times. The damage produced in the case of interphase death can manifest as swelling of the nucleus and nucleoli, as well as DNA depolymerization. Different cell types can show very different radiosensitivity; lymphocytes seem to be particularly sensitive. Interphase death is closely related to apoptosis, a form of programmed cell death characterized by a specific sequence of morphologic events (detaching from neighboring cells, chromatin condensation, nucleus fragmentation, cell shrinking, and eventually separation into a number of fragments called apoptotic bodies). Apoptosis is highly cell-type dependent and is controlled by different genes including p53. Several aspects of the mechanisms underlying interphase death and apoptosis are still unclear.

Clonogenic inactivation has been studied much more extensively. A large number of *in vitro* data is available, especially on HeLa cells (human cervical carcinoma), CHO cells (hamster ovary cells), and V79 cells (hamster lung fibroblasts). These studies represent a fundamental basic knowledge for applications in radiation therapy, where the main aim consists of achieving tumor control by inactivating the cells constituting the tumoral tissue; the mean lethal dose for loss of proliferative capacity is generally lower than 2 Gy. The results of *in vitro* survival studies are usually graphed as the logarithm of the surviving fraction against the radiation dose. While survival curves obtained by irradiating viruses and bacteria are represented by straight lines, the curves relative to most mammalian cells tend to show a shoulder at low doses. Dose–response for mammalian cell survival is generally well described by a relationship of the form $S(D) = \exp(-\alpha D - \beta D^2)$. Although during the last few years deviations from this behavior have been observed, both as low-dose hypersensitivity and as increased radioresistance, the linear quadratic relationship is still considered a good description for survival fractions not smaller than $\approx 10^{-3}$.

The shoulder is modulated not only by the cell type, but also by the radiation quality. For instance, mammalian cells irradiated with high-LET radiation are generally characterized by straight survival curves. The shoulder is considered to be indicative of repair of "sublethal damage," that is, there must be an accumulation of damage before the cell loses its reproductive ability. Clonogenic inactivation correlates very well with specific chromosome aberrations (e.g., dicentrics and centric rings, see above), suggesting that the major cause of radiation-induced inactivation of mammalian cells is aberrant mitosis leading to uneven distribution of chromosomes or loss of chromosome fragments.

Most cell survival data come from *in vitro* studies. However, when techniques became available to perform *in vivo* experiments, the parameters characterizing the dose–response were similar to those found *in vitro*. In clinical radiotherapy, the radiation dose is usually delivered in a series of equal fractions separated by an interval time allowing for repair of sublethal damage. The resulting effective dose survival curve becomes an exponential function of dose, since repetition of the shoulder leads to a straight line in the lin-log scale.

Effects at the Level of Tissues and Organs

In vivo exposure, which can lead to damage at the tissue/organ and organism level, can be either acute (e.g., in accidents) or chronic, which is often the case for exposed workers and populations. The exposure can affect either the whole organism ("panirradiation") or only parts of it ("partial irradiation"). Two main types of effects are generally introduced: deterministic effects, which occur following exposure above a certain threshold dose and increase in severity by increasing the radiation dose, and stochastic effects, for which there is no threshold and the induction probability (*not* the severity) increases with dose.

Skin erythema is an example of deterministic effect, whereas cancer is the most important stochastic effect. Cataracts are generally classified as deterministic effects. However, recent studies on astronauts suggest that they are more likely to be stochastic processes. Acute total body exposure to 1.5–2 Gy causes nausea and vomiting in 50% of individuals within a few hours ("prodromal radiation sickness"), as well as depletion of granulocytes and platelets within a few weeks ("acute radiation syndrome"). With only minimal supportive care, mortality may occur following acute total body exposure of a few Gy. The acute skin dose necessary to produce erythema is ~ 6 Gy, whereas that for desquamation is in the range 15–20 Gy. In case of gonadal irradiation,

sterility can occur, either transient (following 0.5 Gy for males and ~1 Gy for females) or permanent (following doses in the range 2.5–4 Gy for males and 6–20 Gy for females).

The A-bomb survivors of Hiroshima and Nagasaki represent the most important group studied for radiation-induced cancer, since about 120 000 persons have been followed. By 1990, 6000 cancer deaths had occurred, of which about 400 were ascribed to radiation. Other examples of radiation-induced cancer in humans include leukemia in ankylosing spondylitis patients treated with spine radiotherapy, thyroid cancer in children irradiated for enlarged thymus, and breast cancer in fluoroscoped tuberculosis patients. The time interval between exposure and cancer appearance is called the latent period. While leukemia is characterized by the shortest latent period (7–12 years), solid tumors show longer latency (10–50 years).

Ionizing radiation can induce different cancer types. Acute and chronic myeloid (not lymphocytic) leukemia are the types mainly responsible for the excess cancer incidence observed in irradiated adults, for which the main data come from A-bomb survivors and ankylosing spondylitis patients. A-bomb survivors, together with Chernobyl victims, also provide the main data for thyroid cancer. Breast cancer can be induced by radiation with relatively high frequency; the corresponding data, mainly derived from female A-bomb survivors and tuberculosis patients, are generally well fitted by a straight line. Radiation-induced lung cancer has been observed following both external exposure (A-bomb survivors and ankylosing spondylitis patients) and radon inhalation (mainly underground miners; there is also some evidence from domestic exposure). The largest body of data relative to bone cancer comes from young persons employed as dial painters, who ingested radium, and from tuberculosis or ankylosing spondylitis patients injected with Ra-224. Interestingly, the dial-painter data imply that a linear extrapolation to low doses would overestimate the low-dose risk.

Current risk estimates are mainly based on A-bomb survivor data, which refer to acute exposure to relatively high doses (from 0.2 to 4 Gy) of mainly low-LET radiation. The excess incidence of cancer was assumed to be a function of dose, age at exposure, and time since exposure. For some tumors, such as breast cancer, sex dependence was considered as well. On this basis, the relationship between excess relative risk for solid tumors and equivalent dose is linear up to 3 Sv and flattens out at higher doses due to increased cell killing. The same relationship for leukemia at low doses is best fitted by a linear-quadratic relationship. However, a linear no-threshold (LNT) extrapolation to low doses has been recommended for radiation protection purposes. A "dose rate effectiveness factor" (DREF) reducing the estimated risk by a factor of 2 under conditions of low dose rate or protracted exposure has also been introduced.

According to the International Commission on Radiological Protection, the fatal cancer lifetime risk for a working population has been estimated as $0.08\,\mathrm{Sv}^{-1}$ for high doses and dose rates, and $0.04\,\mathrm{Sv}^{-1}$ for low doses and dose rates. The corresponding values for the whole population are slightly higher ($0.10\,\mathrm{Sv}^{-1}$ for high doses and dose rates, and $0.05\,\mathrm{Sv}^{-1}$ for low doses and dose rates) due to the higher sensitivity of young people. Since epidemiological studies on human exposure to high-LET radiation are not available, high-LET risk estimates are based on low-LET estimates multiplied by radiation weighting factors. The only available systematic study of the relationship between LET and tumor RBE, performed for mouse Harderian gland tumors, shows an increase in RBE with LET, with a peak of RBE ≈ 30 in the range $100–200\,\mathrm{keV\,\mu m}^{-1}$.

During the 1990s, the LNT assumption has been challenged by observations of low-dose phenomena such as bystander effect and genomic instability (see below), which suggest a supralinear low-dose response for different endpoints including mutations and cell conversion to malignancy. The question whether this may imply higher cancer risk levels than those estimated with the LNT model is still open. While a supralinear response for conversion to malignancy and nonlethal mutations might imply a supralinear response for cancer risk, death of bystander cells – especially via apoptosis – may represent a systemic response aimed to protect the tissue/organ by eliminating the most damaged cells, which would be substituted by new, undamaged cells.

"Nontargeted" Effects: Bystander Effect and Genomic Instability

That energy from radiation must be deposited in the cell nucleus to induce an effect in that cell is a long-standing dogma. However, in the 1990s, this dogma was challenged by a number of studies including bystander effects and genomic instability. "Bystander effect" refers to the induction of damage in unirradiated cells ("bystander cells"), mainly due to cellular communication. In *in vitro* studies, bystander cells are often in the proximity of hit cells, that is the case of broadbeam irradiation with low doses of light ions or irradiation with microbeams, which can deliver an exact number of particles specifically targeting selected cell nuclei. However, the term "bystander

effect" also refers to the observation of damage in unexposed cells cultured into a medium taken from irradiated cultures.

Whatever the experimental procedure, bystander effects have been observed for different endpoints, both lethal (e.g., clonogenic inactivation and apoptosis) and nonlethal (e.g., gene mutations and oncogenic transformation). Such effects start being observed at doses of the order of ≈ 0.01 Gy and tend to saturate around ≈ 0.5 Gy, where direct effects dominate. The effect is strongly dependent on factors such as cell type and degree of cell-to-cell contact, which is a key parameter. In fact, although the underlying mechanisms have not been elucidated yet, it is widely accepted that a major role is played by two main cellular communication pathways, involving either the release of signaling molecules into the medium or the transfer of small molecules and ions (e.g., Ca^{++}) through gap junctions, which are channels directly connecting the cytoplasms of adjacent cells.

"Genomic instability" refers to an increased rate of acquisition of alterations in the genome. Radiation-induced instability generally manifests in the progeny of irradiated cells as gross chromosomal rearrangements, micronuclei, and gene mutations. Similar to bystander effect, genomic instability is efficiently induced by low doses and depends both on the cell type and on the radiation quality. The prevailing hypothesis on the mechanisms is that radiation destabilizes the genome and initiates a cascade of events that increase the rate of mutations, chromosomal changes, and possibly other effects in the progeny of irradiated cells. The molecular and cellular events that initiate and perpetuate instability are still unknown. Whereas deficiencies in DNA damage response, alterations in gene expression, and perturbations in cellular homeostasis (i.e., control of activities such as proliferation and differentiation) are likely to be involved, directly induced DNA damage (e.g., dsb) probably does not play a significant role. Interestingly, instability can be induced not only following direct irradiation, but also by a bystander-type mechanism. It is, therefore, likely that both bystander effects and genomic instability are manifestations of the same processes.

Most evidence on these phenomena comes from *in vitro* experiments, and the extrapolation to *in vivo* scenarios is still an open question. However, while waiting for further *in vivo* studies, it would be prudent to take into account the possible implications of nontargeted effects when considering models of radiation-induced carcinogenesis, particularly at low doses where the LNT model might not necessarily hold.

Irreversible Thermodynamics and Basic Transport Theory in Solids

J M Honig, Purdue University, West Lafayette, IN, USA

Introductory Comments

An overview of basic ideas in irreversible thermodynamics as they apply to electron transport phenomena in solids is provided; the theory is thus not presented in its full generality. The discussion is limited to systems that are at rest, remain at constant volume, undergo no chemical changes, are isotropic, and for which steady-state conditions hold. In these circumstances, the ordinary time differential operator d/dt and its partial counterpart, $\partial/\partial t$, are equivalent, and the tensorial notation can be dispensed with. Readers who desire a full introduction to irreversible phenomena should consult the listings under "Further reading" section. The discussion is also limited to the linearized regime, in which departures from equilibrium are small, such that intensive variables such as temperature, pressure, concentration, chemical potential, and the like retain their significance locally.

However, these variables are presumed to vary with position in such a manner that their gradients are small compared to their values averaged over the system.

Elementary Description of Heat and Mass Transport

Transfer of Heat between Two Different Systems

To begin with, a heuristic introduction of basic concepts characterizing relaxation processes that lead toward establishment of equilibrium conditions is given. Consider two isolated regions in space, designated by (and at) temperatures T' and T''; when brought into contact (see **Figure 1**), and on allowing the intervening partition to become slightly diathermic, heat is slowly transferred between the compartments. If the enlarged unit remains isolated, and the interfacial phenomena are ignored, the energies, E' and E'', of the two subsystems are additive, as are the entropies $S'(E',V')$ and $S''(E'',V'')$. Assume further that the volumes V' and V'' remain fixed. Then the first and second laws of thermodynamics lead to the relations

$$\mathrm{d}E' + \mathrm{d}E'' = 0 \qquad [1a]$$

$$\mathrm{d}S = (\partial S'/\partial E')_{V'}\,\mathrm{d}E' + (\partial S''/\partial E'')_{V''}\,\mathrm{d}E'' \geqslant 0 \qquad [1b]$$

On account of [1a] and with $(\partial E/\partial S)_V = T$, where T is the temperature of the bulk of the system, eqn [1b] becomes

$$\mathrm{d}S = (1/T'' - 1/T')\,\mathrm{d}E'' \geqslant 0 \qquad [2]$$

which immediately establishes the requirement $T' = T''$ as a necessary condition for thermal equilibrium. Moreover, according to the second law, as equilibrium is established, the total entropy of the isolated compound system increases toward a maximum, consistent with the remaining constraints. Hence, the time derivative of the total entropy, $\dot{S} \equiv (\mathrm{d}S/\mathrm{d}t)$, may be written as

$$\dot{S} = (1/T'' - 1/T')\,(\mathrm{d}E''/\mathrm{d}t) \geqslant 0 \qquad [3]$$

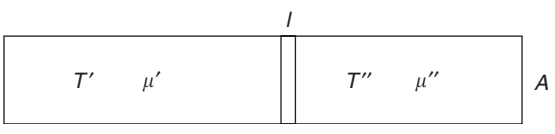

Figure 1 Two bodies of cross section A at temperatures T' and T'' and at chemical potentials μ' and μ'' are in tenuous contact. Changes in T and μ occur over a small distance l straddling the boundary. When no mass transfer occurs, the chemical potentials are irrelevant.

In the present case, no work has been performed and no material has been transferred; therefore, all energy changes involve solely a transfer of heat between the two subsystems. It is then appropriate to identify $\mathrm{d}E''/\mathrm{d}t$ with the rate of heat transfer $\dot{Q}$ across the boundary. Hence, eqn [3] is rewritten as $\dot{S} = \Delta(1/T)\dot{Q}$. Next, a heat flux is defined by $J_Q \equiv \dot{Q}/A$, where A is the cross section of the partition. In the experiment, the temperatures T' and T'' remain nearly constant within both compartments, except near the common boundary, where the change from T' to T'' occurs over a small distance l perpendicular to the partition (see **Figure 1**). The product Al roughly defines a volume V in the boundary region over which the temperature changes. One can then write $\dot{S} = \Delta(1/T)VJ_Q/l$. In the limit of small l, the ratio $\Delta(1/T)/l$ becomes the gradient of inverse temperature, $\nabla(1/T)$. The ratio $\dot{S}/V$ is the rate of entropy production per unit volume, $\dot{\theta}$, in the heat transfer region. This gives, finally,

$$\dot{\theta} = \nabla(1/T)J_Q \geqslant 0 \qquad [4]$$

Heat Transfer Equations

The above discussion is very suggestive. The rate of entropy generation is seen to be a product of two conjugate variables, namely, a heat flux, J_Q, and a generalized force, $F_T \equiv \nabla(1/T)$; hence, schematically $\dot{\theta} = F_T J_Q \geqslant 0$. Note that in eqns [3] and [4], and with the directions indicated in **Figure 1**, $\dot{\theta} > 0$ means either that $F_T > 0$, $J_Q > 0$, with $T'' < T'$, or that $F_T < 0$, $J_Q < 0$, with $T'' > T'$. In either case, heat flows from the hotter to the cooler side. When $\dot{\theta} = 0$, equilibrium prevails; J_Q and F_T both vanish. It is then plausible to claim that the heat flux is "driven" by the existence of a temperature gradient (actually, a gradient in inverse temperature).

Next, a relation between J_Q and F_T is established, which requires extrathermodynamic information, such as a microscopic transport theory or experimental considerations. Close to the equilibrium, a linear relation $J_Q = L_T F_T$ is assumed to prevail between force and flux, where L_T is a parametric function independent of J_Q or F_T. The proportionality factor is known as a phenomenological or macroscopic coefficient. The essential correctness of this very primitive approach may be checked by noting that

$$J_Q = L_T \nabla(1/T) = -(L_T/T^2)\nabla T \equiv -\kappa \nabla T \qquad [5]$$

where $\kappa \equiv L_T/T^2$ is the thermal conductivity, and one recovers the Fourier law of heat conduction.

Transfer of Energy and Mass between Two Different Regions

The above approach will now be generalized. Consider two compartments at different temperatures that contain the same material at two different mole numbers n' and n''. The two units are joined and the intervening partition is rendered slightly porous, allowing the very gradual transfer of energy and of mole numbers (**Figure 1**). As long as the compartmental volumes are unchanged, one can invoke the fundamental relation

$$\begin{aligned} \mathrm{d}S = &(\partial S'/\partial E')_{V',\,n'}\,\mathrm{d}E' + (\partial S''/\partial E'')_{V'',\,n''}\,\mathrm{d}E'' \\ &+ (\partial S/\partial n')_{V',\,E'}\,\mathrm{d}n' + (\partial S/\partial n'')_{V'',\,E''}\,\mathrm{d}n'' \end{aligned} \qquad [6]$$

Since $\mathrm{d}S = \mathrm{d}E/T - (\mu/T)\mathrm{d}n$, where μ is the chemical potential, and with $\mathrm{d}E'' = -\mathrm{d}E'$, $\mathrm{d}n'' = -\mathrm{d}n'$, the above may be recast as

$$\begin{aligned} \mathrm{d}S = &(1/T'' - 1/T')\mathrm{d}E'' \\ &- (\mu''/T'' - \mu'/T')\mathrm{d}n'' \geqslant 0 \end{aligned} \qquad [7a]$$

from which it follows that at equilibrium, $T' = T''$ and $\mu' = \mu''$, consistent with well-established thermodynamic principles. The earlier procedure can be extended by introducing two fluxes, namely $J_E \equiv \mathrm{d}E''/A\mathrm{d}t$ and $J_n \equiv \mathrm{d}n''/A\mathrm{d}t$, as well as two generalized forces, $F_T \equiv \Delta(1/T)/l \equiv \nabla(1/T)$ and $F_n \equiv \Delta(\mu/T)/l \equiv \nabla(\mu/T)$, appropriate for small distances, l, across the junction. Equation [7a] thus becomes

$$\dot{\theta} = J_E\nabla(1/T) - J_n\nabla(\mu/T) \qquad [7b]$$

The minus sign in this equation can also be rationalized via a sufficiency argument. To ensure that $\dot{\theta} > 0$, both terms in the expression need to be positive. Referring to **Figure 1**, assume that $J_E > 0$ (i.e., energy flows left to right); to keep the first term positive it is necessary that $T'' < T'$, as before. In order to render the second term positive, one requires that $(\mu''/T'' - \mu'/T')J_n < 0$. Assume that $J_n > 0$ (particles flow from left to right), which then requires the multiplier to be negative, so that $\mu'/T' > \mu''/T''$, or $\mu'/\mu'' > T'/T'' > 1$, implying that the particle flux occurs from the region of higher chemical potential to one of lower chemical potential.

Phenomenological Equations

The relation $T\mathrm{d}S = \mathrm{d}E - \mu\mathrm{d}n$ is now introduced, reformulated after time differentiation as $TJ_S = J_E - \mu J_n$, valid in the absence of any mechanical pressure–volume work (V' and V'' remain fixed). Using eqn [7b], the rate of entropy production per unit volume may be written as

$$\dot{\theta} = -\frac{1}{T}\{J_S\nabla T + J_n\nabla\mu\} \geqslant 0 \qquad [8]$$

Such a relation is of fundamental importance, in that it specifies $\dot{\theta}$ as a sum of products that involve conjugate flux–force pairs, namely, $(J_S, -T^{-1}\nabla T)$ and $(J_n, -T^{-1}\nabla\mu)$. These quantities are of great importance in the formulation of the so-called linear phenomenological equations (PEs), valid for small departures from equilibrium. These are constructed so as to relate the two fluxes J_S and J_n to the two forces $(1/T)\nabla T$ and $(1/T)\nabla\mu$ in the following linear form:

$$J_S = (L_{11}/T)\nabla T + (L_{12}/T)\nabla\mu \qquad [9a]$$

$$J_S = (L_{21}/T)\nabla T + (L_{22}/T)\nabla\mu \qquad [9b]$$

The minus signs have been absorbed in the L coefficients. One should note the implied superposition principle: both forces contribute to both fluxes. The L_{ij} are known as phenomenological or macroscopic coefficients; L_{11} and L_{22} connect the fluxes to their principal driving forces, while L_{12} and L_{21} give rise to interference effects that are studied in detail below.

Basic Principles of Mass, Energy, and Entropy Balances

Mass Balance Equation

The very heuristic approach presented so far, while leading to correct results, ought really to be supplanted by a more rigorous (though simplified) derivation of eqn [9]. One can begin with the conservation law

$$\mathrm{d}\rho_k/\mathrm{d}t = -\boldsymbol{\nabla}\cdot\boldsymbol{J}_k \qquad [10]$$

wherein the total rate change in concentration ρ_k of species k within the system (**Figure 2**) is given by the imbalance between the influx and outflow of species k across the boundaries; the minus sign arises because the normal unit vector in **Figure 2** faces outward.

Energy Balance Equations

In order to introduce relations for energy balance, one can follow the convention by changing from energy or mass per unit volume to energy per unit mass and mass fraction. This is indicated by overbars such as $\bar{u}, \bar{e}, \bar{\psi}, \bar{n}_k$, as introduced below. Further, let species k interact with a stationary external potential $\bar{\psi}_k$ (e.g., electrons in an electrostatic potential); then operating on both sides of eqn [10] with $\sum_{(k)}\bar{\psi}_k$ and

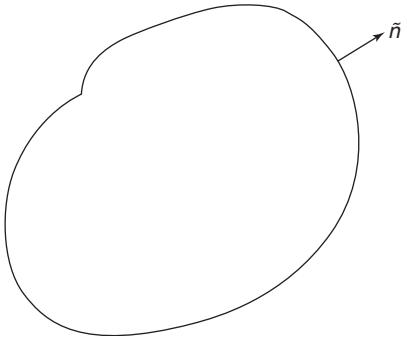

Figure 2 Boundary of a system, with the unit vector pointing opposite to the inward flow of energy, entropy, or mass.

setting $\sum_{(k)} \bar{\psi}_k \rho_k \equiv \bar{\psi}\rho$, and using the vector calculus involving a scalar function a and a vector function $\boldsymbol{v}$, $\boldsymbol{\nabla} \cdot a\boldsymbol{v} = a\boldsymbol{\nabla} \cdot \boldsymbol{v} + \boldsymbol{v} \cdot \boldsymbol{\nabla} a$, one obtains

$$\mathrm{d}(\rho\bar{\psi})/\mathrm{d}t = -\boldsymbol{\nabla} \cdot \sum_k \bar{\psi}_k \boldsymbol{J}_k + \sum_k \boldsymbol{J} \cdot \boldsymbol{\nabla}\bar{\psi}_k \quad [11]$$

As a third step, one introduces the conservation law for total energy density $\rho\bar{u}$ (energy cannot be generated or destroyed locally):

$$\mathrm{d}(\rho\bar{u})/\mathrm{d}t = -\boldsymbol{\nabla} \cdot \boldsymbol{J}_U \quad [12]$$

The total energy density can be separated into $\bar{u} = \bar{e} + \bar{\psi}$, where $\bar{e}$ is the internal energy per unit mass. Correspondingly,

$$\boldsymbol{J}_U = \boldsymbol{J}_Q + \sum_k \bar{\psi}_k \boldsymbol{J}_k \quad [13]$$

This nomenclature is appropriate; the net total energy flux density $\boldsymbol{\nabla} \cdot \boldsymbol{J}_U$ consistently reflects the performance of work, potential energy changes, and heat flows. The first two effects are subsumed in the term $\boldsymbol{\nabla} \cdot \sum_k \bar{\psi}_k \boldsymbol{J}_k$; the rest is contained in the net heat flux, $-\boldsymbol{\nabla} \cdot \boldsymbol{J}_Q$. Next, subtracting [11] from [12] and introducing eqn [13], this yields an expression for the overall rate of change of internal energy

$$\mathrm{d}(\rho\bar{e})/\mathrm{d}t = -\boldsymbol{\nabla} \cdot \boldsymbol{J}_Q - \sum_k \boldsymbol{J}_k \cdot \boldsymbol{\nabla}\bar{\psi}_k \quad [14]$$

This involves not only the customary divergence term but also the last term, which represents a source term that arises from the interaction of species k with the external potential $\bar{\psi}_k$.

Entropy Balance Relations

The entropy balance equations can be introduced by using the expression (for $\mathrm{d}V = 0$) $T\mathrm{d}S = \mathrm{d}E - \sum_k \mu_k \mathrm{d}n_k$ to write

$$T(\mathrm{d}(\rho\bar{s})/\mathrm{d}t) = (\mathrm{d}(\rho\bar{e})/\mathrm{d}t) - \sum_k \bar{\mu}_k(\mathrm{d}\rho_k/\mathrm{d}t) \quad [15a]$$

On insertion of eqns [14] and [10], one obtains

$$\frac{\mathrm{d}(\rho\bar{s})}{\mathrm{d}t} = \frac{1}{T}\left\{-\boldsymbol{\nabla} \cdot \boldsymbol{J}_Q - \sum_k \boldsymbol{J}_k \cdot \boldsymbol{\nabla}\bar{\psi}_k + \sum_k \bar{\mu}_k \boldsymbol{\nabla} \cdot \boldsymbol{J}_k\right\} \quad [15b]$$

The above may be rearranged by repeated application of the vector identity cited earlier; standard manipulations lead to the final result

$$\begin{aligned}\frac{\mathrm{d}(\rho\bar{s})}{\mathrm{d}t} = &-\boldsymbol{\nabla} \cdot \left\{\left(\boldsymbol{J}_Q - \sum_k \bar{\mu}_k \boldsymbol{J}_k\right)/T\right\} \\ &- (1/T^2)\boldsymbol{J}_Q \cdot \boldsymbol{\nabla}T + (1/T^2)\sum_k \bar{\mu}_k \boldsymbol{J}_k \cdot \boldsymbol{\nabla}T \\ &- (1/T)\sum_k \boldsymbol{J}_k \cdot \boldsymbol{\nabla}(\bar{\mu}_k + \bar{\psi}_k) \end{aligned} \quad [16]$$

Although this looks complicated, it is amenable to a simple interpretation which is based on the entropy balance equation in the form $\mathrm{d}(\rho\bar{s})/\mathrm{d}t = -\boldsymbol{\nabla} \cdot \boldsymbol{J}_S + \dot{\theta}$. Comparison with eqn [16] shows that it is appropriate to consider the quantity in curly brackets as a flux vector, so that

$$\boldsymbol{J}_S = \frac{1}{T}\left(\boldsymbol{J}_Q - \sum_k \bar{\mu}_k \boldsymbol{J}_k\right) \quad [17]$$

is an entropy flux vector. The remaining terms are then to be identified as source terms $\dot{\theta}$ in the entropy balance equation. This allows one to express the contribution of local events to the entropy generation rate as

$$\dot{\theta} = -(1/T)\boldsymbol{J}_S \cdot \boldsymbol{\nabla}T - (1/T)\sum_k \boldsymbol{J}_k \cdot \boldsymbol{\nabla}\bar{\zeta}_k \geqslant 0 \quad [18]$$

where the generalized chemical potential has been introduced as $\bar{\zeta} \equiv \bar{\mu} + \bar{\psi}$. For isotropic materials in the absence of external potentials, eqn [18] reduces to eqn [8]. This establishes the proper background for constructing the PEs, eqn [9], precisely in the same manner as was done earlier.

Phenomenological Equations for Thermoelectric Effects; Onsager's Reciprocity Conditions

A very important characteristic of eqns [9] is the fact that the Onsager reciprocity relations, $L_{ij} = L_{ji}$ apply

to such equations, so long as conjugate flux–force pairs are employed in formulating eqns [9]. For proofs, the reader is referred to the literature; a simpler version, applicable to processes under steady-state conditions, was provided by Tykody.

Thermoelectric Phenomena

Equations [9] can be specialized to characterize interactions between heat flow and electric currents in a conductor, known as thermoelectric effects; this topic has been treated elsewhere in great detail (see the "Further reading" section). Consider a rectangular bar clamped between two thermal reservoirs at different temperatures (**Figure 3**). The electron flow in the conductor is established by charging external condenser plates; this cumbersome method is used here (though not in actual practice) to avoid distracting complications from leads that normally connect the sample to the current source. Using the dissipation function, eqn [18] with $k = n$, substituting $\bar{\zeta} = \bar{\mu} - e\bar{\varphi}$ in place of $\bar{\mu}$, and then replacing the electron flux vector $\boldsymbol{J}_n$ by the current density $\boldsymbol{J} = (-e)\boldsymbol{J}_n$, where $-e$ is the charge on the electron and $\bar{\varphi}$ is the electrostatic potential per electron mass, the dissipation relation can be written as $\dot{\theta} = \boldsymbol{J}_S \cdot (-T^{-1}\boldsymbol{\nabla} T) + \boldsymbol{J} \cdot (-T^{-1}\boldsymbol{\nabla}(\bar{\zeta}/e))$. One can identify, from this relation, the proper fluxes and forces, so as to construct the phenomenological relations for an isotropic material (the vector notation can then be dropped):

$$J_S = -(L_{SS}/T)\nabla T + (L_{Sn}/T)\nabla(\zeta/e) \qquad [19a]$$

$$J = -(L_{nS}/T)\nabla T + (L_{nn}/T)\nabla(\zeta/e) \qquad [19b]$$

with $L_{nS} = L_{Sn}$. In doing so, one has also switched from $\bar{\zeta}$ to ζ, absorbing the mass factor and the minus sign in L_{Sn} and L_{nn}.

Thermoelectric Transport Coefficients

By imposing a variety of constraints, the above expressions can be attributed to physical significance:

(1) Set $\nabla T = 0$ and eliminate $\nabla(\zeta/e)$ between [19a] and [19b] to obtain $J_S/J = L_{Sn}/L_{nn} = -J_S/eJ_n$; since $J_S/J_n \equiv S^*$ is the total entropy carried per electron, one obtains

$$L_{Sn}/L_{nn} = -S^*/e \qquad [20]$$

Next, consider eqn [19b] with $\nabla T = 0$. For a homogeneous sample $\nabla\mu = 0$; eqn [19b] then reduces to $J = (L_{nn}/T)\nabla(-\phi) = (L_{nn}/T)E$, where E is the electrostatic field. Thus, one recovers Ohm's law $J = \sigma E$, where σ is the electrical conductivity. This leads to the identification

$$L_{nn}/T = \sigma, \quad J = \sigma\nabla(\zeta/e) \qquad (\nabla T = 0) \quad [21]$$

(2) If current flow is suppressed, set $J = 0$, solve eqn [19b] for $\nabla(\zeta/e)$, and substitute the result in eqn [19a]; this yields

$$J_S = -(1/T)[L_{SS} - L_{nS}^2/L_{nn}]\nabla T \quad (J = 0) \quad [22]$$

Now, as shown in eqn [17], in the absence of current flow the entropy flux may be replaced by J_Q/T; thus, one recovers Fourier's law of heat conduction, $J_Q = -\kappa\nabla T$, with the thermal conductivity given by

$$\kappa = L_{SS} - L_{nS}^2/L_{nn} \qquad [23]$$

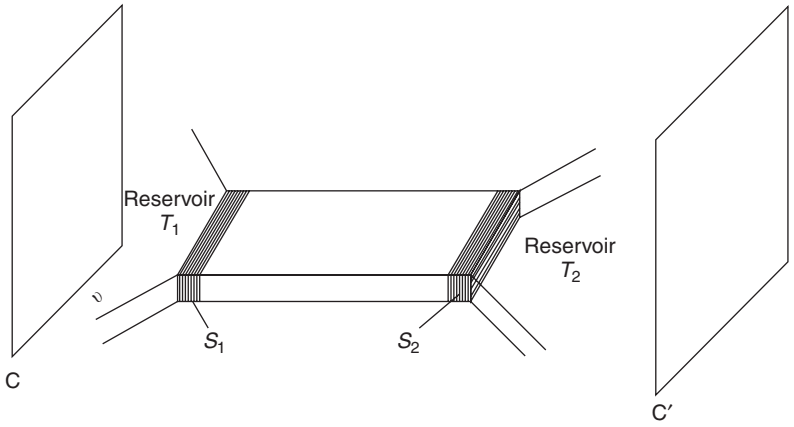

Figure 3 Idealized setup for detection of thermoelectric effects. The solid is clamped between two thermal reservoirs at temperatures T_1 and T_2; S_1 and S_2 are removable strips for thermal insulation. Current flow is activated through charging of the condenser plates C and C′.

An additional contribution to κ arises from the lattice thermal conductivity that is not included here.

(3) In the more general case when $J>0$, one may still eliminate $\nabla(\zeta/e)$ between eqns [19a] and [19b] to obtain

$$J_S = -(S^*/e)J - (\kappa/T)\nabla T = S^* J_n - (\kappa/T)\nabla T \qquad [24]$$

This shows that the total electronic entropy flux involves the entropy transport $S^* J_n$ as well as heat transport through the motion of the electrons.

(4) A second result arises by imposing the condition $J=0$ and solving eqn [19b] for

$$\nabla(\zeta/e) = (L_{nS}/L_{nn})\nabla T \equiv \alpha \nabla T \qquad [25]$$

Here, one encounters a new prediction: the imposition of a temperature gradient necessarily establishes a gradient in the electrochemical potential. The proportionality factor, here designated as α, is called the Seebeck coefficient, or less desirably, the thermoelectric power. It is measured by connecting the ends of the sample in a temperature gradient to a voltmeter under open circuit conditions, and by determining the resulting temperature difference with, for example, a thermocouple. Comparison with eqn [20] shows that $\alpha = -S^*/e = \nabla(\zeta/e)/\nabla T \approx \Delta(\zeta/e)/\Delta T$. Equation [19a] may thus be rewritten as

$$J_S = \alpha J - (\kappa/T)\nabla T \qquad [26]$$

The three phenomenological coefficients may now be solved in terms of the three experimental parameters α, κ, and σ, so as to express the PEs in their final form

$$J_S = -(\sigma\alpha^2 + \kappa/T)\nabla T + \alpha\sigma\nabla(\zeta/e) \qquad [27a]$$

$$J = -\sigma\alpha\nabla T + \sigma\nabla(\zeta/e) \qquad [27b]$$

Equation [27b] represents a further generalization of Ohm's law, showing how the current density is affected by the presence of a temperature gradient. The apparent differences in sign involving $\alpha\sigma$ arise because there is a corresponding sign difference in eqns [19a] and [19b]. Thus, Onsager's relations are indeed satisfied.

A physical explanation of the thermoelectric effect is based on the fact that electrons at the hot end have a larger thermal velocity along the downstream direction than that associated with electrons at the cold end along the upstream direction. Consequently, a net accumulation of electrons takes place at the cold end, leaving an effective positive charge at the hot end.

Hole conductors may be treated by the same approach: a rather lengthy analysis shows that one may simply replace $-e$ by $+e$; for n-type carriers $\alpha<0$, whereas for p-type materials $\alpha>0$. The results otherwise carry over without change. Thermoelectric effects thus provide a means for distinguishing between n- and p-type charge transport.

Peltier and Thomson Effects

Two other thermoelectric effects encountered in the literature are only briefly mentioned. The so-called Peltier effects arise when current is passed through an isothermal junction of two dissimilar materials (1 and 2), resulting in the production of heat. The explanation is based on eqn [13], with $k=1$, and ψ and $\mu \to \zeta$. An electrochemical potential is continuous across the junction; also, the current density is conserved. Hence, in passing from region 1 to region 2,

$$J_{U2} - J_{U1} = J_{Q2} - J_{Q1} = T(J_{S2} - J_{S1}) = T(\alpha_2 - \alpha_1)J$$

where eqns [17] and [26] and $\nabla T = 0$ have been used. The Peltier coefficient is defined as

$$\Pi \equiv (J_{Q2} - J_{Q1})/J = T(\alpha_2 - \alpha_1) \qquad [27c]$$

showing the relation between Π and α. On the other hand, if current flows through a conductor with an established temperature gradient, the heat generated in line element dx (in excess of the Joule heating effect) is proportional to the current and to the temperature gradient, as expected: $\dot{Q}/dx \propto I\nabla_x T$. On introducing a proportionality factor, τ, the so-called Thomson coefficient, one obtains

$$J_{Qx} = \tau J_x \nabla_x T \qquad [27d]$$

For an extended derivation and discussion of these effects see the "Further reading" section.

Transport Effects in Magnetic Fields

Now consider the effects that operate in the presence of a magnetic field, H, aligned with the z-axis. Provision is made in the sample for current and heat flow in the x and y directions (**Figure 4**).

Phenomenological Equations for Thermomagnetic Phenomena

A study of the thermoelectric and thermomagnetic interactions resulting in the presence of magnetic fields is useful. The effects introduced by the electric leads will be ignored. For this purpose the choice of $(J_S, \nabla T)$ and $(J, \nabla(\zeta/e))$ as conjugate variables is extended; the $1/T$ factors and minus signs are absorbed

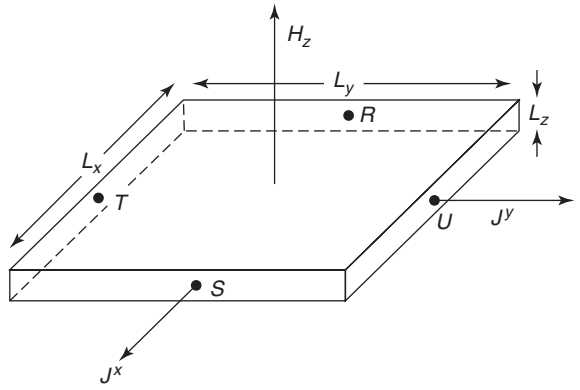

Figure 4 Sample cut in a rectangular parallelepiped geometry and placed in a magnetic field H aligned with the z-axis. Current and heat pass into the solid through leads connected to R and S along x, and to T and U along y.

into the phenomenological coefficients. Three new points must be taken into account: (1) since the observed effects occur along two dimensions, $(J_S^x, \nabla_x T)$, $(J_S^y, \nabla_y T)$, $(\nabla_x(\zeta/e), J^x)$, $(\nabla_y(\zeta/e), J^y)$ are introduced as conjugate flux–force pairs. (2) For later convenience, $J_S^x, J_S^y, \nabla_x(\zeta/e), \nabla_y(\zeta/e)$ are considered as dependent variables, so that the PEs cited below appear in partially inverted form. Such a partial interchange of dependent and independent variables is a perfectly permissible mathematical step and greatly simplifies the subsequent analysis. (3) The Onsager reciprocity conditions must now be generalized to read (Casimir–Onsager relations) $L_{ij}(H) = \pm L_{ji}(-H)$, the adopted sign depending on whether or not the forces on the charged particles change sign when the magnetic field is reversed. Without loss of generality, the sequence of signs in eqn [28a] is selected arbitrarily; the signs in the other equations are then determined by the augmented reciprocity relations. The above considerations lead to macroscopic PEs of the form

$$J_S^x = -L_{11}\nabla_x T - L_{12}\nabla_y T + L_{13}J^x + L_{14}J^y \quad [28a]$$

$$J_S^y = L_{12}\nabla_x T - L_{11}\nabla_y T - L_{14}J^x + L_{13}J^y \quad [28b]$$

$$\nabla_x(\zeta/e) = L_{13}\nabla_x T + L_{14}\nabla_y T + L_{33}J^x + L_{34}J^y \quad [28c]$$

$$\nabla_y(\zeta/e) = -L_{14}\nabla_x T + L_{13}\nabla_y T - L_{34}J^x + L_{33}J^y \quad [28d]$$

The above formulation permits a systematic investigation of the 560 possible thermoelectric and thermomagnetic effects. A selection of these is presented under a variety of headings.

Transport Coefficients for Thermomagnetic Phenomena

(1) $J^y = \nabla_x T = \nabla_y T = 0$: isothermal conditions are maintained along x and y and no current is allowed to flow along y. The PEs then reduce to

$$\begin{aligned} J_S^x &= L_{13}J^x \quad \text{(a)} \\ J_S^y &= -L_{14}J^x \quad \text{(b)} \\ \nabla_x(\zeta/e) &= L_{33}J^x \quad \text{(c)} \\ \nabla_y(\zeta/e) &= -L_{34}J^x \quad \text{(d)} \end{aligned} \quad [29]$$

Expression [29c] is simply a reformulation of Ohm's law, $J^x = \sigma_I \nabla_x(\zeta/e)$, wherein $L_{33} \equiv \rho_I$ is the isothermal resistivity of the sample. Equation [29d] describes the isothermal Hall effect: a current in the longitudinal direction induces a transverse gradient in the electrochemical potential; for convenience, the magnitude of the magnetic field is explicitly introduced: it can be seen that

$$\nabla_y(\zeta/e) = -(L_{34}/H)J^x H \equiv \Re_I J^x H \quad [30]$$

where the magnitude of the effect is characterized by the Hall coefficient $\Re \equiv -L_{34}/H$. Equations [29a] and [29b] simply relate the entropy transport along x and y to current flux along x; L_{13} and L_{14} are determined below.

(2) $J^y = \nabla_x T = J_S^y = 0$: open-circuit conditions are imposed and no heat flow is allowed along y; isothermal conditions prevail along x. The PEs now reduce to

$$\begin{aligned} J_S^x &= -L_{12}\nabla_y T + L_{13}J^x \quad \text{(e)} \\ 0 &= -L_{11}\nabla_y T - L_{14}J^x \quad \text{(f)} \\ \nabla_x(\zeta/e) &= L_{14}\nabla_y T + L_{33}J^x \quad \text{(g)} \\ \nabla_y(\zeta/e) &= L_{13}\nabla_y T - L_{34}J^x \quad \text{(h)} \end{aligned} \quad [31]$$

Equation [31f] shows that under these conditions, a longitudinal current flow produces a transverse temperature gradient; this is the so-called Ettingshausen effect $\nabla_y T = -(L_{14}/L_{11}H)J^x H$, with a coefficient specified by $\Im \equiv \nabla_y T/J^x H = -L_{14}/L_{11}H$. Insertion of [31f] into [31g] yields the expression $\nabla_x(\zeta/e) = (L_{33} - L_{14}^2/L_{11})J^x$, which is Ohm's law under "adiabatic" conditions, with a resistivity $\rho_A = (L_{33} - L_{14}^2/L_{11})$. When [31f] is used in [31h], one obtains $\nabla_y(\zeta/e) = -[(L_{13}L_{14}/L_{11} + L_{34})/H]J^x H$, which represents the "adiabatic" Hall effect, with a corresponding coefficient $\Re_A \equiv -(1/H)[L_{13}L_{14}/L_{11} + L_{34}]$.

(3) Next, set $J^x = J^y = \nabla_y T = 0$: no current flows and the temperature is uniform along y. The

PEs reduce to

$$\begin{aligned} J_S^x &= -L_{11}\nabla_x T \quad \text{(i)} \\ J_S^y &= L_{12}\nabla_x T \quad \text{(j)} \\ \nabla_x(\zeta/e) &= L_{13}\nabla_x T \quad \text{(k)} \\ \nabla_y(\zeta/e) &= -(L_{14}/H)H\nabla_x T \quad \text{(l)} \end{aligned} \qquad [32]$$

Under these conditions, TJ_S^x and TJ_S^y represent heat fluxes. Equation [32i] then specifies an "isothermal" heat flux (a contradiction in terms!) $TJ_S^x = -L_{11}T\nabla_x T$ that identifies the thermal conductivity $\kappa_I = TL_{11}$ in the absence of a transverse thermal gradient. Moreover, [32k] represents nothing other than the "isothermal" Seebeck effect, along x, for which the coefficient is given by $\alpha = L_{13}$. Furthermore, according to [32l], a T gradient along x produces a gradient in ζ along y. This is the so-called transverse Nernst effect, with a corresponding coefficient $N_I \equiv -L_{14}/H$.

(4) Another set of constraints of interest is given by $J^x = J^y = J_S^y = 0$. These reduce the PEs to

$$\begin{aligned} J_S^x &= -L_{11}\nabla_x T - L_{12}\nabla_y T \quad \text{(m)} \\ 0 &= L_{12}\nabla_x T - L_{11}\nabla_y T \quad \text{(n)} \\ \nabla_x(\zeta/e) &= L_{13}\nabla_x T + L_{14}\nabla_y T \quad \text{(o)} \\ \nabla_y(\zeta/e) &= -L_{14}\nabla_x T + L_{13}\nabla_y T \quad \text{(p)} \end{aligned} \qquad [33]$$

Equation [33n] shows that, in this case, the temperature gradient in the longitudinal direction induces one in the transverse direction; this is known as the Righi–Leduc effect, rewritten as

$$\nabla_y T = (L_{12}/L_{11}H)H\nabla_x T \equiv MH\nabla_x T \qquad [34]$$

with a corresponding coefficient $M \equiv L_{12}/L_{11}H$. A second relation of interest is found by inserting eqn [34] into [33m] and multiplying through by T; this yields $TJ_S^x = -T[L_{11} + L_{12}^2/L_{11}]\nabla_x T$, leading to the "adiabatic" thermal conductivity $\kappa = T(L_{11} + L_{12}^2/L_{11})$. Also, use of [34] in [33o] leads to $\nabla_x(\zeta/e) = (L_{13} + L_{14}L_{12}/L_{11})\nabla_x T$, which represents the adiabatic Seebeck effect, with a corresponding coefficient $\alpha_A = L_{13} + L_{14}L_{12}/L_{11}$. Lastly, combining [34] with [33p] yields $\nabla_y(\zeta/e) = (1/H)[-L_{14} + L_{13}L_{12}/L_{11}]H\nabla_x T$, which represents the adiabatic transverse Nernst effect, with a coefficient $N_A = (1/H)[-L_{14} + L_{13}L_{12}/L_{11}]$.

The above procedure may be applied repeatedly to obtain other galvano-thermomagnetic effects; these are left to the reader to explore.

Identification of Phenomenological Coefficients

The principal inference of the discussion so far is that the various parameters L_{ij} of the PEs in eqn [28] can be rewritten in terms of experimentally determined parameters. These are:

$$\begin{aligned} L_{33} &= \rho_I \quad \text{(q)}, & L_{34} &= -\Re_I H \quad \text{(r)} \\ L_{11} &= \kappa_I/T \quad \text{(s)}, & L_{13} &= \alpha_I \quad \text{(t)} \\ L_{14} &= -N_I H \quad \text{(u)}, & L_{12} &= \kappa_I M_I H/T \quad \text{(v)} \end{aligned} \qquad [35]$$

The subscript I has been introduced to indicate isothermal conditions, that is, $\nabla_y T = 0$. By inserting [35] into the PEs, a complete description of the galvano-thermomagnetic effects that are observable in the rectangular parallelepiped geometry of **Figure 4** has been obtained.

Transport in Two-Band (Electron–Hole) Conductors

In conclusion, a limited set of galvano-thermomagnetic phenomena for a material in which both holes and electrons contribute to the conduction process can be considered. For this purpose, it is necessary to use the PEs in uninverted form, so that the partial currents can be summed to form the total current. Specializing to the case $J^y = \nabla_x T = \nabla_y T = 0$, the expressions involving J_S^x and J_S^y are not needed. In an obvious notation, the PEs for electron and hole conduction become, with due regard to the Casimir–Onsager conditions,

$$J_-^x = \Gamma_1\nabla_x(\zeta/e) + \Gamma_2\nabla_y(\zeta/e) \qquad [36a]$$

$$J_-^y = -\Gamma_2\nabla_x(\zeta/e) + \Gamma_1\nabla_y(\zeta/e) \qquad [36b]$$

$$J_+^x = \Gamma_3\nabla_x(\zeta/e) + \Gamma_4\nabla_y(\zeta/e) \qquad [36c]$$

$$J_+^y = -\Gamma_4\nabla_x(\zeta/e) + \Gamma_3\nabla_y(\zeta/e) \qquad [36d]$$

Use of Constraints to Identify Transport Coefficients

Consider first the one-band, n-type semiconductor, by setting $\Gamma_3 = \Gamma_4 = 0$. If $J_-^y = 0$ as well, [36a] and [36b] can be solved for:

$$J_-^x = [(\Gamma_1^2 + \Gamma_2^2)/\Gamma_1]\nabla_x(\zeta/e) \equiv \sigma_n\nabla_x(\zeta/e) \qquad [37a]$$

which immediately identifies the n-type conductivity σ_n. One can also write

$$J_-^x = [(\Gamma_1^2 + \Gamma_2^2)/\Gamma_2]\nabla_y(\zeta/e) \qquad [37b]$$

Table 1 Galvano-thermomagnetic effects for a two-band *n–p* conductor in a magnetic field

Electric resistivity:	$\rho = [(\sigma_n + \sigma_p) + H^2\sigma_n\sigma_p(\sigma_n\Re_n^2 + \sigma_p\Re_p^2)]/D$
Hall coefficient:	$\Re = [\Re_n\sigma_n^2 + \Re_p\sigma_p^2 + (H\sigma_n\sigma_p)^2(\Re_n\Re_p)(\Re_n + \Re_p)]/D$
Seebeck coefficient:	$\alpha = [(\sigma_n + \sigma_p)(\sigma_n\alpha_n + \sigma_p\alpha_p) + (H\sigma_n\sigma_p)^2(\Re_n + \Re_p)(\Re_n\alpha_p + \Re_p\alpha_n) + H^2\sigma_n\sigma_p(N_n - N_p)(\Re_n\sigma_n - \Re_p\sigma_p)]/D$
Thermal conductivity:	$\kappa = \kappa_n + \kappa_p + (T/D)\{[\sigma_n\sigma_p(\sigma_n + \sigma_p)(\alpha_n - \alpha_p)^2 - (N_n - N_p)(\sigma_n\sigma_p H^2)] \times [(\sigma_n + \sigma_p)(N_n - N_p) - 2\sigma_n\sigma_p(\Re_n + \Re_p)(\alpha_n - \alpha_p)]\}$

$D \equiv [(\sigma_n + \sigma_p)^2 + (H\sigma_n\sigma_p)^2(\Re_n + \Re_p)^2]$ σ_n, σ_p are electrical conductivity of electrons and holes, respectively; $\Re_n$, $\Re_p$ are Hall coefficients of electrons and holes; ρ is the electrical resistivity; α_n, α_p are the Seebeck coefficient of electrons and holes, respectively; κ_n, κ_p are the thermal conductivity of electrons and holes, respectively; N_n, N_p are the transverse Nernst coefficients of electrons and holes, respectively; and H is the applied magnetic field. Note that $\alpha_n = -|\alpha_n|$, $\Re_n = -|\Re_n|$ are negative, while σ_n, σ_p, N_n, N_p are positive; hence $\Re$ and α tend to be small except in large applied magnetic fields.

which introduces the Hall coefficient for electrons as

$$\Re_n H = \Gamma_2/(\Gamma_1^2 + \Gamma_2^2) \qquad [38]$$

Equations [37a] and [38] yield the result $\Gamma_2/\Gamma_1 = \sigma_n H\Re_n \equiv X_n$.

On elimination of Γ_2 using [38], $\Gamma_1 = \sigma_n/(1 + X_n^2)$. Similarly, $\Gamma_2 = \sigma_n X_n/(1 + X_n^2)$. Analogous operations for a hole conductor yield the results $\Gamma_4/\Gamma_3 = \sigma_p H\Re_p \equiv X_p$, $\Gamma_3 = \sigma_p/(1 + X_p^2)$, $\Gamma_4 = X_p/(1 + X_p^2)$. The total current density is then given by

$$J^x = J_-^x + J_+^x = \Gamma_a\nabla_x(\zeta/e) + \Gamma_b\nabla_y(\zeta/e) \qquad [39a]$$

$$J^y = J_-^y + J_+^y = -\Gamma_b\nabla_x(\zeta/e) + \Gamma_a\nabla_y(\zeta/e) \qquad [39b]$$

with $\Gamma_a \equiv \Gamma_1 + \Gamma_3$, $\Gamma_b \equiv \Gamma_2 + \Gamma_4$. Setting $J^x = 0$ and eliminating either $\nabla_y(\zeta/e)$ or $\nabla_x(\zeta/e)$ from eqns [39]. One finds

$$J^x = \frac{\Gamma_a^2 + \Gamma_b^2}{\Gamma_a}\nabla_x(\zeta/e) \quad \text{or} \quad \sigma = \frac{\Gamma_a^2 + \Gamma_b^2}{\Gamma_a} \qquad [40a]$$

$$J^x = \frac{\Gamma_a^2 + \Gamma_b^2}{\Gamma_b}\nabla_y(\zeta/e) \quad \text{or} \quad \frac{1}{H\Re} = \frac{\Gamma_a^2 + \Gamma_b^2}{\Gamma_b} \qquad [40b]$$

The last step consists in replacing Γ_a, Γ_b by $\Gamma_1, \ldots, \Gamma_4$, and introducing X_n, X_p, σ_n, $\Re_n H$, σ_p, $\Re_p H$. The steps are elementary but tedious. The results are listed in **Tables 1** and **2**.

A similar procedure may be used to determine the Seebeck coefficient and thermal conductivity of a two-band conductor. For detailed derivations, the reader is referred to the literature. The results are again displayed in **Tables 1** and **2**.

Table 2 Galvano-thermomagnetic effects to the limit of small applied magnetic fields: $H \to 0$

$\sigma = \sigma_n + \sigma_p$,	$\alpha = \dfrac{\alpha_n\sigma_n + \alpha_p\sigma_p}{\sigma_n + \sigma_p}$
$\Re = \dfrac{\Re_n\sigma_n^2 + \Re_p\sigma_p^2}{(\sigma_n + \sigma_p)^2}$,	$\kappa = \kappa_n + \kappa_p + \dfrac{T\sigma_n\sigma_p(\alpha_n - \alpha_p)^2}{\sigma_n + \sigma_p}$

See notes in **Table 1**.

The principal points to be noted are (1) that the results are model-independent, and (2) that the contribution from electrons and holes in general are not simply additive.

Concluding Comments

This article has focused on the thermodynamic representation of irreversible effects as applied to electron transport phenomena in conductors. The advantage of this approach is its generality (aside from specific restrictions mentioned earlier); it does not depend on the adoption of a specific model for electron transport. The disadvantage is that the phenomenological parameters and transport coefficients remain unspecified. One may now invoke the microscopic transport theory to evaluate these quantities from first principles, at least in certain degrees of approximation, but this is a rather lengthy procedure beyond the scope of the present article.

Isotopic Effects in Solids

E E Haller, University of California at Berkeley, Berkeley, CA, USA

Published by Elsevier Ltd.

Introduction

Close to 80% of the elements in the periodic table are multi-isotopic. Most semiconductors contain at least one element that consists of more than one stable isotope (Al, As, and P are important mono-isotopic exceptions). For example, silicon is composed of the three isotopes $^{28}_{14}$Si, $^{29}_{14}$Si, and $^{30}_{14}$Si with abundances of 92.23%, 4.67%, and 3.10%, respectively. Gallium arsenide consists of mono-isotopic As and two Ga isotopes $^{69}_{31}$Ga (60.11%) and $^{70}_{31}$Ga (39.89%). Recent advances in isotope separation technology have led to the availability of semiconductors with controlled the isotopic composition. Many physical properties of semiconductors depend on the isotopic composition. Some of these are affected relatively weakly while others, thermal conductivity for example, can be influenced strongly. Here, the isotope-related effects are divided into three groups: (1) those that are due to atomic mass differences between the isotopes; (2) those that are due to nuclear spin differences between isotopes; and (3) those that are due to differences in thermal neutron capture cross sections.

Atomic Mass-Related Properties

Structure

The lattice constants a_0 of large, chemically pure and crystallographically highly perfect crystals can be measured with high-precision X-ray diffraction techniques. As a consequence of the zero-point motion, the atomic volumes are expected to change with isotopic composition. The resulting effect on a_0 has been carefully studied for a number of elemental semiconductors including C, Si, and Ge. A theoretical analysis of the dependence of the lattice constant on isotopic composition at low temperatures compared to the Debye temperature of the material yields the following relationship:

$$\frac{\Delta a}{a} = -\frac{C}{a^3}\frac{\Delta M}{M}\left(\gamma_0\hbar\omega_0 + \frac{3}{4}\gamma_0 k\theta\right)$$

where C is the isothermal compressibility, M is the atomic mass, γ_o and γ_a are the Grüneisen parameters for optical and acoustic phonons, respectively, ω_o is the optical phonon frequency, k is Boltzmann's constant, and θ is the Debye temperature

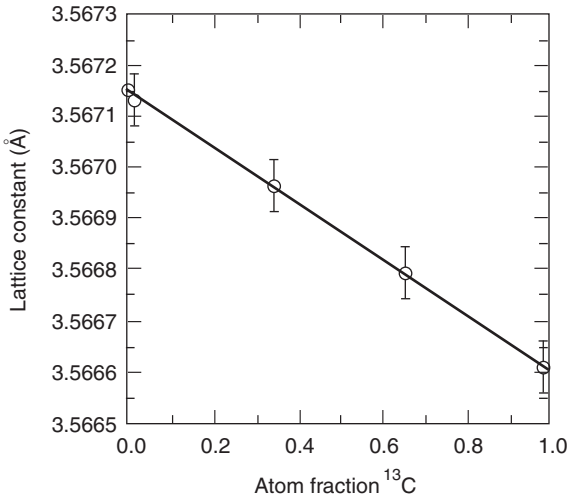

Figure 1 Lattice constant of diamond as a function of isotopic composition. (Adapted from Holloway *et al.* (1991) *Physical Review* B 44: 7123.)

(constant-mode Grüneisen parameters and a Debye frequency spectrum for the phonon modes are assumed). Evidently, the effect will be the largest for semiconductors with light atomic masses, large compressibilities, and high Debye temperatures. Experimental data for diamond are shown in **Figure 1**. The reduction of the lattice constant for ^{13}C diamond compared to ^{12}C diamond is 150 ppm, which is in qualitative agreement with the simple theory illustrated above.

Phonon Dispersion

A number of isotope effects in semiconductors are related to changes in the properties of phonons with atomic mass. A very simple harmonic analysis within the virtual crystal approximation predicts that the frequency ω of a given phonon should vary with the average mass M:

$$\omega \propto M^{-1/2}$$

As shown in **Figure 2**, this dependence is indeed observed for the zone-center optical phonon for a series of isotopically enriched single crystals of germanium with average masses between 70 and 76 amu (M of natural Ge is 72.59 amu).

Modern thin-film growth techniques have made isotopically engineered structures available to the experimentalist. Very interesting phonon effects can be observed in isotope superlattices (SLs), which consist of alternating layers with different isotopic composition. In contrast to SLs consisting of different materials such as GaAs and AlGaAs, the electronic band

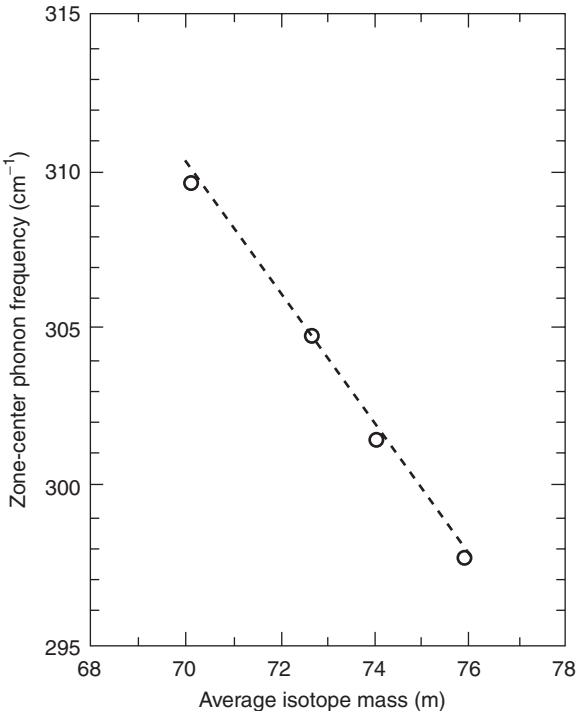

Figure 2 Zone-center phonon observed by Raman spectroscopy at 90 K for single-crystal germanium of varying isotopic composition. Dotted line shows the predicted $M^{-1/2}$ dependence. (After Fuchs HD *et al.* (1992) *Solid State Communications* 82: 225.)

structure in isotope SLs is not significantly affected by the mass differences and the material looks bulk-like for electrons throughout the crystal layers. However, the changes in the phonon properties are sufficiently large to observe confinement effects. A number of detailed experimental studies have been performed with Ge isotopes in structures consisting of a series of alternating sets of atomic planes of ^{A}Ge and ^{B}Ge where A and B are different atomic masses. Experimentally observed and theoretically calculated Raman spectra are compared in **Figure 3** for zone-center optical phonons for $^{70}\mathrm{Ge}_n/^{74}\mathrm{Ge}_n$ [0 0 1] oriented structures with n, the number of atomic layers, varying from 2 to 32. The Raman frequencies and mode mixing calculated by a simple bond-charge model, and the force constants of natural Ge and the relative peak intensities determined by a bond polarizability approach are in good agreement with the experimental data. The shortest periods studied consisted of two atomic layers each and produce a single Raman line corresponding to the zone-center optical phonon in a Ge crystal with $M = 72$ amu, the linear average of the two masses. That is, the phonon behavior is the same as in a bulk crystal with $M = 72$ amu. Confinement effects are observed at higher values of n as folded optical modes become

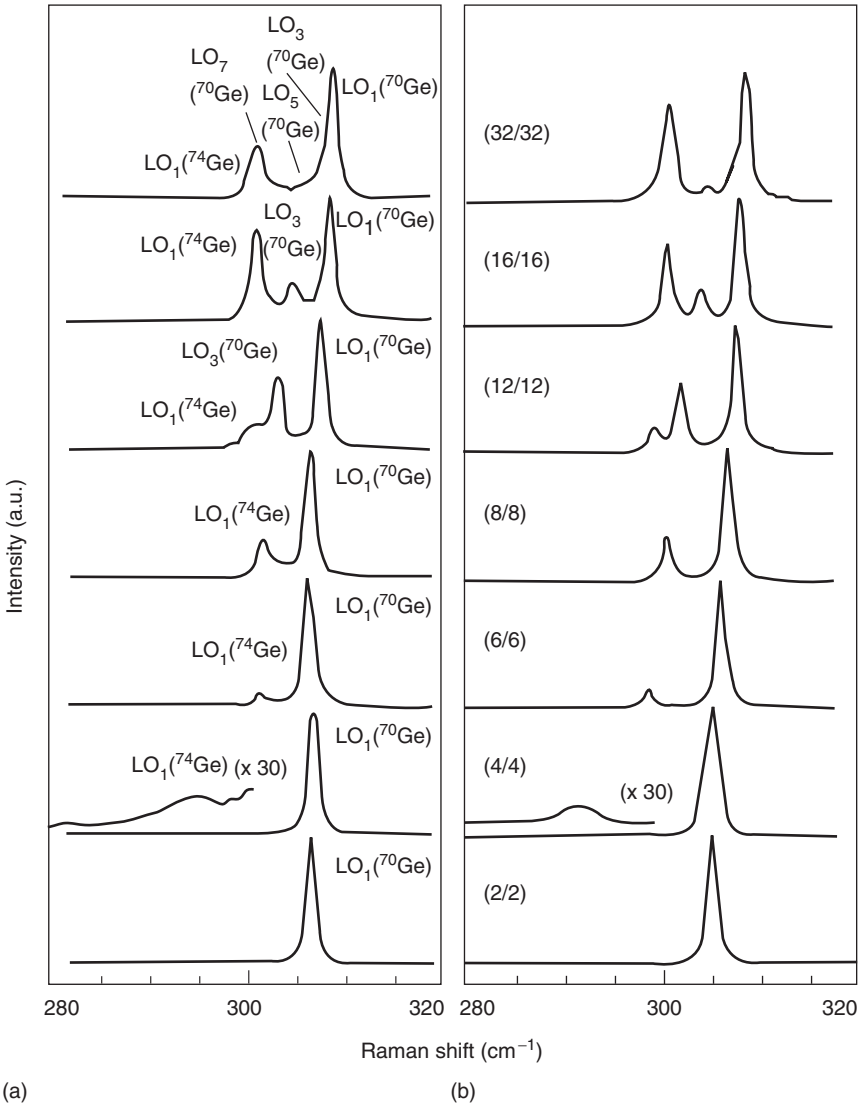

Figure 3 (a) Measured at $T = 10\,K$ and (b) calculated Raman spectra for a series of isotope superlattices $^{70}Ge_n/^{74}Ge_n$ grown along [0 0 1] with $n = 2$, 4, 6, 8, 12, 16, and 32. A number of modes confined to the ^{70}Ge and ^{74}Ge layers are evident. (Adapted from Spitzer *et al.* (1994) *Physical Review Letters* 72: 1565.)

Raman active at the zone center. For example, in the $n = 12$ superlattice at least three strong Raman lines are observed. For $n = 32$, the Raman spectra begin to approach the structure expected for two isotopically pure bulk crystals, one made up of ^{70}Ge, the other of ^{74}Ge.

Thermal Conductivity

The most dramatic phonon-related isotope effect is found for the thermal conductivity. Pomeranchuck was the first to point out in 1942 that in a multi-isotopic material, minority isotopes must be treated as mass defects and that they lead to scattering of acoustic phonons, reducing thermal conductivity with respect to a mono-isotopic material. The first experimental measurements of what can be a very strong dependence of the thermal conductivity (which depends on acoustic phonons) on small degrees of isotopic disorder were performed in the late 1950s in germanium. The most dramatic effect is found, however, in diamond. **Figure 4** illustrates the fivefold increase in thermal conductivity found near 100 K in isotopically enriched ^{12}C. (It should be pointed out that measurements of such extremely high thermal conductivities for millimeter-size samples are very difficult to perform because the samples act like close to perfect thermal short circuits.) The measured value, $410\,W\,cm^{-1}\,K^{-1}$, is the highest measured for any material above liquid nitrogen temperature (77 K). The most successful modeling of the effect of isotopic disorder on thermal con-

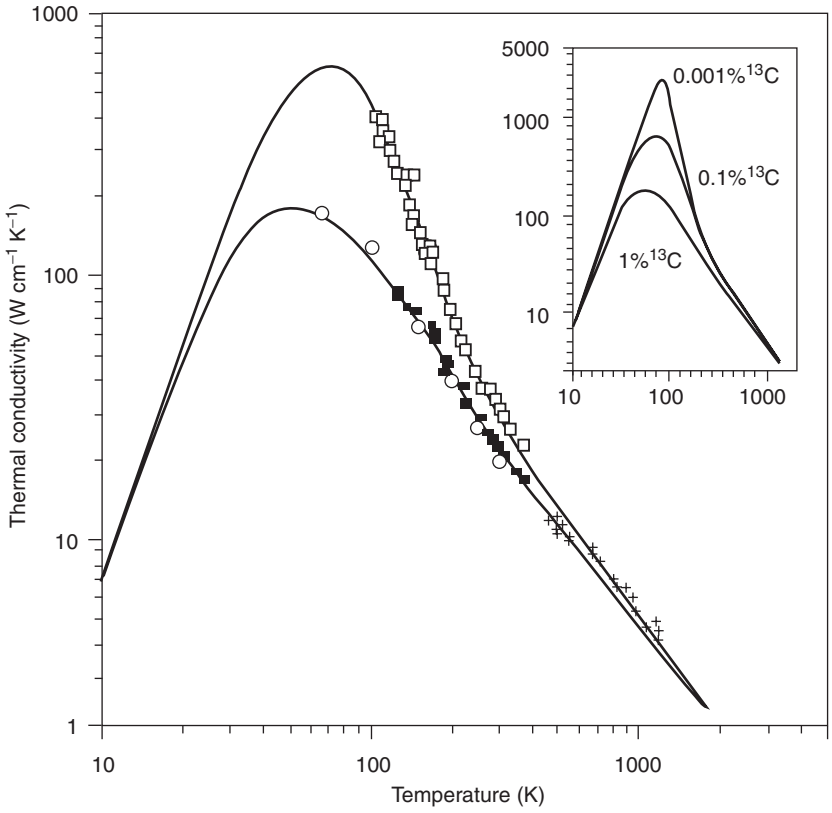

Figure 4 Thermal conductivity of natural abundance (1.1% ^{13}C) diamond (■), isotopically enriched (0.1% ^{13}C) diamond (□), together with the low-temperature data of Slack (1973), (○) and the high-temperature data of Olson *et al.* (1993) (×). The solid curves are the result of fitting the Callaway theory illustrated in the text. The inset shows the calculated thermal conductivity corresponding to 1%, 0.1%, and 0.001% ^{13}C concentrations according to the Callaway theory. (Adapted from Wei *et al.*(1993) *Physical Review Letters* 70: 3764.)

ductivity splits the thermal conductivity into four terms – normal, Umklapp, boundary, and isotope processes – which are inversely proportional to the phonon lifetime τ associated with the specific effect:

$$\tau^{-1}_{\text{Normal}} = AvT^3\lambda^{-1}$$

$$\tau^{-1}_{\text{Umklapp}} = BvT^3\lambda^{-1}\exp(-C/T)$$

$$\tau^{-1}_{\text{Boundary}} = v/D$$

$$\tau^{-1}_{\text{Isotope}} = 4\pi^3 v\lambda^{-4}V_0 x(1-x)(12+x)^{-2}$$

where v and λ are the average phonon velocity and wavelength, x is the isotope fraction of ^{13}C, V_0 is the atomic volume, and A, B, C, and D are adjustable parameters. These relations can be used not only to reproduce the observed temperature dependence but also to predict the limits of thermal conductivity for samples with very high isotopic purity. The inset in the figure shows the prediction of a thermal conductivity above 2000 W cm^{-1} K^{-1} for very highly enriched ^{12}C at 80 K.

Similar increases of the thermal conductivity at low temperature of the enriched semiconductors Ge and Si have been measured. It is important to note that at temperatures well above the thermal conductivity maximum, the isotope enrichment-related increases vanish rapidly. For example, the increase in thermal conductivity for highly enriched ^{28}Si compared to natural Si is in the range of 10–15%.

Electronic Structure

Isotope composition affects the electronic structure through the electron–phonon coupling and through the change of volume with the isotopic mass (see above section on lattice constants). The effect most often studied experimentally is the influence of the isotopic mass on the bandgap of the semiconductor. For example, using optical modulation techniques the isotope dependence of the direct and indirect bandgaps of germanium and of the indirect gap of silicon have been determined. The effect is small but satisfactorily predicted by theory. Another sensitive way to measure this dependence uses the very narrow no-phonon exciton photoluminescence (PL)

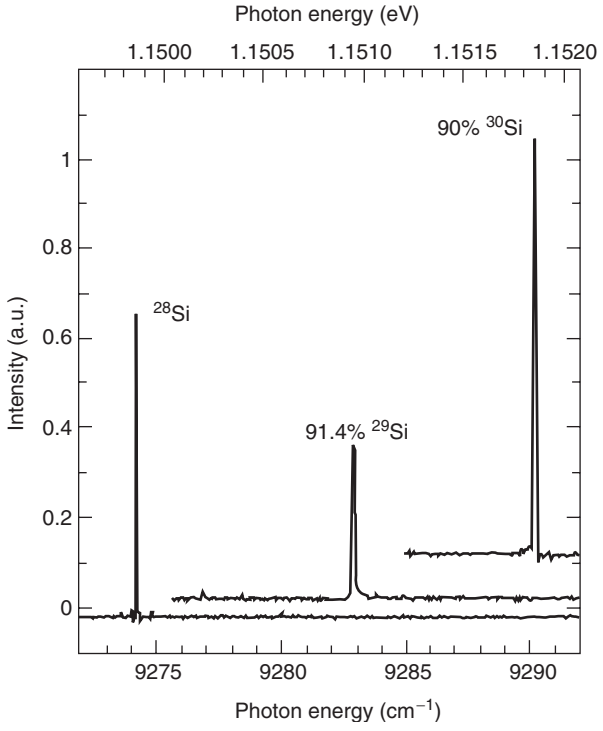

Figure 5 Effect of Si isotopic composition on the Si bandgap as observed by the shift of the P_{NP} PL line observed at 4 K as a function of isotopic enrichment. The three curves are offset for clarity.

lines found in Si and Ge. Measurements of the energies of these impurity-bound excitons allow direct determination of bandgap shifts because their radiative recombination does not require phonon participation. Furthermore, due to their large Bohr orbits, their energy depends only on the average isotopic mass and not on the isotopic disorder. **Figure 5** shows the change in the Si bandgap measured using the phosphorus no-phonon line P_{NP} for a series of samples enriched in ^{28}Si, ^{29}Si, and ^{30}Si.

In general, the contribution to the bandgap shift from the isotopically induced volume change is the smaller of the two effects and can be addressed with the methods described above for the lattice constant effects. The analysis of the electron–phonon coupling effect is similar to that used to understand the change of bandgap with temperature. The change is described by structure factors, which include electron–phonon interaction terms (Debye–Waller factors) and self-energy terms. These terms are then expanded in powers of the atomic displacements u. The leading terms are proportional to the mean-square displacements $\langle u^2 \rangle$. These, in turn, can be modeled as harmonic oscillators:

$$\langle u^2 \rangle = \hbar\left(\tfrac{1}{2} + n\right)/M\omega$$

As temperature increases, n and thus $\langle u^2 \rangle$ increase, and the bandgap is reduced. At low temperature, $n = 0$. Substituting the dependence of ω on M,

$$\langle u^2 \rangle \propto M^{-1/2}$$

For increasing M, this analysis predicts decreasing $\langle u^2 \rangle$ and a bandgap increase, in agreement with the observation.

Self- and Dopant Diffusion

The study of self- and dopant diffusion in semiconductors has been advanced significantly through the use of isotopically controlled multilayer structures. Diffusion measurements performed with radiotracer methods are limited by the half-lives of radioactive isotopes, by the damage produced during their introduction and by near-surface effects.

In contrast, the use of Secondary Ion Mass Spectrometry (SIMS) in isotope superlattice structures provides quantitative concentration profiles of the masses of the matrix as well as the dopant atoms. In the simplest case, two layers with different isotopes of a semiconductor are grown on a substrate of natural composition. The results of annealing such a structure are illustrated in **Figure 6** for a ^{nat}Ge/^{74}Ge/^{70}Ge/^{nat}Ge-substrate configuration. The ^{70}Ge concentration profile in the ^{74}Ge layer can be fitted with a simple complimentary error function (the solution to the 1D simple Fick's law diffusion equation) over a range of four and one half orders of magnitude in concentration, yielding very precise self-diffusion data. Similar structures of silicon isotopes have been used to obtain precise measurements of the Si self-diffusion coefficient shown as a function of the absolute inverse temperature (**Figure 7**).

The influence of the Fermi level (and hence of specific native defects) on self- and dopant diffusion has been studied with the aid of silicon isotope multilayers capped with an amorphous layer of natural silicon. Ion implantation into the amorphous layer was used as a source of the desired dopant and to affect Fermi level control inside the structure. Such a dopant source has been found to produce only the expected electronic effects that are due to dopant-related shifts in the Fermi level position. A representative SIMS result of silicon self- and As dopant diffusion is shown in **Figure 8**. The modeling of the silicon isotope and the arsenic concentration profiles yields the unambiguous result that the negatively charged vacancy is the major native defect involved in the diffusion process.

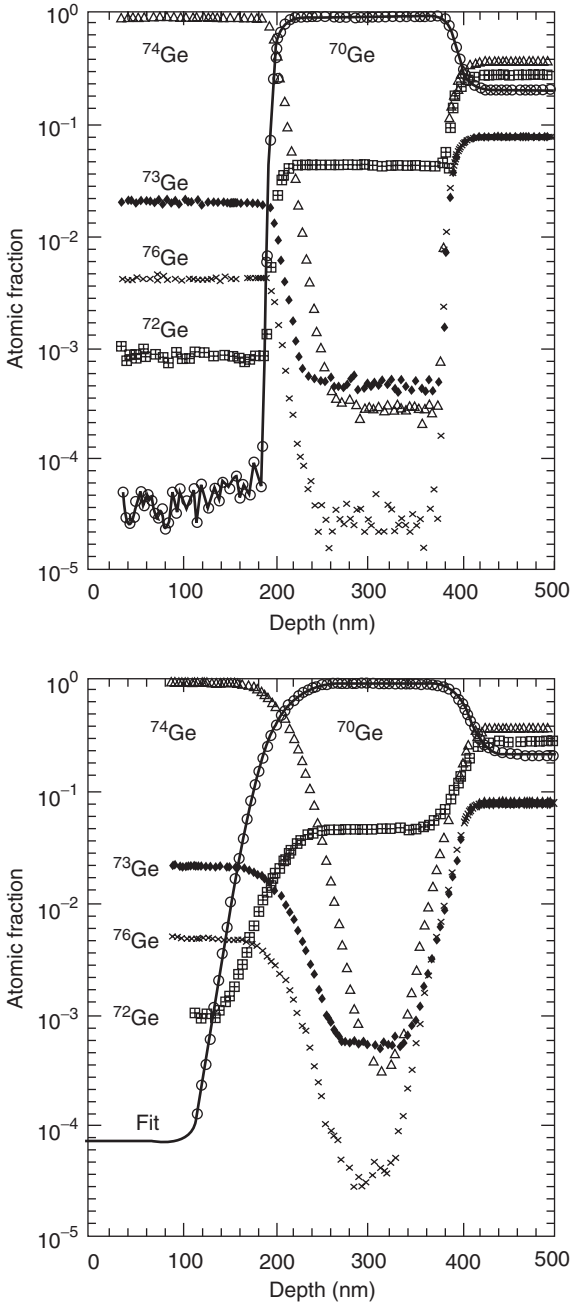

Figure 6 (a) SIMS profile of a ^{nat}Ge/^{74}Ge/^{70}Ge/^{nat}Ge-substrate structure before and (b) after annealing for 55.55 h at a temperature of 586°C . The self-diffusion of the ^{70}Ge into the ^{74}Ge layer can be modeled with a simple complimentary error function to a very high level of precision. (Adapted from Fuchs HD *et al.* (1995) *Physical Review* B 51: 16817-21.)

Isotopically controlled compound semiconductor structures offer the possibility of observing self-diffusion of each of the constituent atoms. Using this method, a very spectacular result of self-diffusion has been reported for the III–V semiconductor GaSb. Both host elements, Ga and Sb, have two isotopes occurring at comparable concentrations; a double-labeled ^{69}Ga^{121}Sb/^{71}Ga^{123}Sb heterostructure was used for the study. **Figure 9** shows the concentration profiles of the four isotopes ^{69}Ga, ^{71}Ga, ^{121}Sb, and ^{123}Sb for the as-grown structure and after thermal annealing at different times and temperatures. The Ga host atoms diffuse by a factor of $\sim$1000 faster than the Sb atoms. Even after four days at a temperature just under the bulk melting point of GaSb and long after the labeled Ga atoms have diffused into the bulk, the Sb atoms have barely moved. The large difference can be explained with the formation of Ga_{Sb} antisites that suppress the formation of Sb vacancies required for the diffusion of this constituent.

Local Vibrational Modes

The vibrations of light impurity atoms in a semiconductor can occur at much higher frequencies than the maximum single-phonon frequencies of the host lattice. In this case, the coupling to the host lattice is weak, such that this local vibrational mode (LVM) can have a long lifetime and a very narrow spectral line width as observed by infrared absorption, Raman scattering, or other techniques. Depending on the details of the lattice location of the impurity, particularly on symmetry and on how many bonds are formed with host lattice atoms, a number of normal vibrational modes are observed. Because of the simple dependence of vibrational frequencies on the inverse square root of the vibrating mass, isotope substitution of the impurity is used to obtain unambiguous proof for the association of an LVM feature with a certain impurity. The largest isotope shift caused by such a substitution of stable isotopes is close to 40% and is obtained for hydrogen substituted by deuterium.

In order to obtain a crude understanding of an LVM spectrum, it usually suffices to model the impurity and the nearest-bound neighbors as a quasimolecule embedded in the host crystal. The model can be improved substantially by taking into account next-nearest neighbor atoms in the form of an additional mass correction, the "host interaction mass" and by extending the linear force dependence on impurity displacement with higher terms (anharmonicity). When the host lattice consists of several stable isotopes with some of these present at significant atomic fractions (Ge is an example), LVM spectra can contain many closely spaced or overlapping lines because the impurity and its host lattice neighbors form quasimolecules with a number of different reduced masses. Isotope enrichment of the host material can lead to drastic simplification of the LVM spectra in such cases. This is illustrated in **Figure 10**

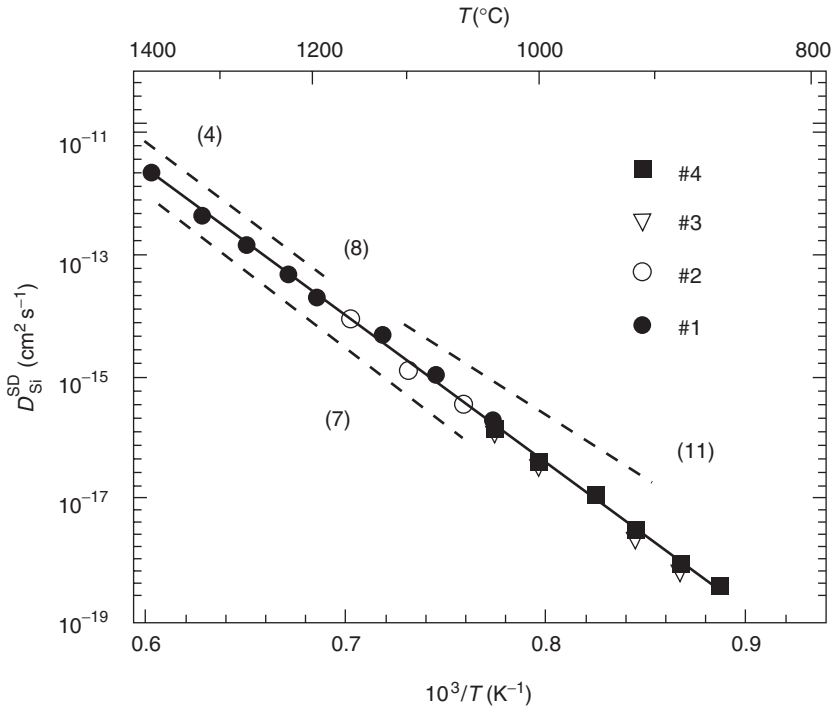

Figure 7 Self-diffusion coefficient of Si measured using multilayer structures of the stable isotopes. (The numbers in the figure refer to references in the original article.) (Adapted from Bracht H, Haller EE, and Clark-Phelps R (1998) *Physical Review Letters* 81(2): 393.)

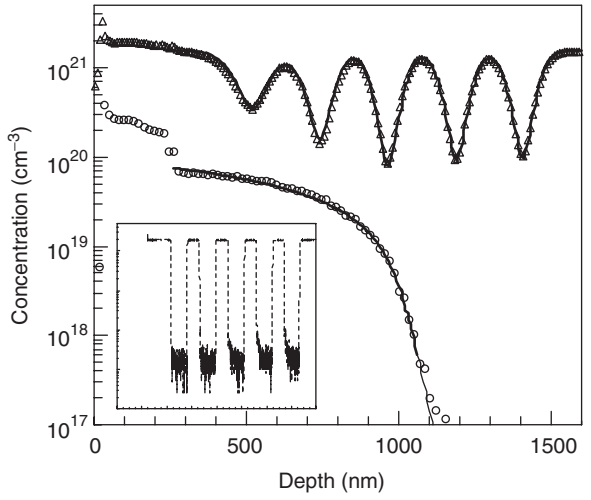

Figure 8 Depth profiles of ^{30}Si (△) and As (○) in an a-Si/(^{30}Si/$^{nat.}$Si)/$^{nat.}$Si structure with five ^{30}Si/$^{nat.}$Si periods, measured with secondary ion mass spectrometry (SIMS). Consistent modeling of both the dopant, As, and self-diffusion profiles (——) shows that the singly negatively charged self-interstitial is the mediating native defect responsible for the diffusion of both species. Inset figure shows the SIMS depth profile of the as-grown isotope structure, with the same axis limits. (Adapted from Silvestri HH, Ph.D. thesis, UC Berkeley 2004, unpublished.)

for the LVM of oxygen in Ge. Taking into account two nearest neighbors, the ^{x}Ge–O–^{y}Ge molecule has three fundamental modes. The "wag" mode (v_3) has the highest frequency. It leads to 11 lines resulting from the different mass combinations of ^{x}Ge and ^{y}Ge, each one split into several components whose intensities depend on temperature. Isotopic enrichment not only greatly simplifies the spectrum (one split line is observed instead of 11), it also allows a quantitative study of the line width and of the coupling between v_3 and the other modes as a function of temperature. In this way, it was shown that the observed splitting is a result of the nonlinear superposition of the v_2 and v_3 modes and that the temperature dependence is due to the thermal population of low-frequency v_2 mode, which can be significant, even at near liquid helium temperature.

Spin-Related Properties

A number of elements found in typical semiconductors have half-odd nuclear spins I and hence magnetic moments. Examples are ^{73}Ge ($I = 9/2$), ^{29}Si ($I = 1/2$), ^{31}P ($I = 1/2$), and both stable isotopes of Ga: ^{69}Ga ($I = 5/2$) and ^{71}Ga ($I = 5/2$). The magnitude of the magnetic moment and the spin-lattice (T_1), and transverse (decoherence, T_2) lifetimes of nonequilibrium nuclear spin populations are measured with nuclear magnetic resonance (NMR). In high-quality single-crystal material, lifetimes can be long. For example, the spin lattice relaxation time of the ^{29}Si (4.67% natural abundance) nuclear spin can be as long as several hours at room temperature in high-

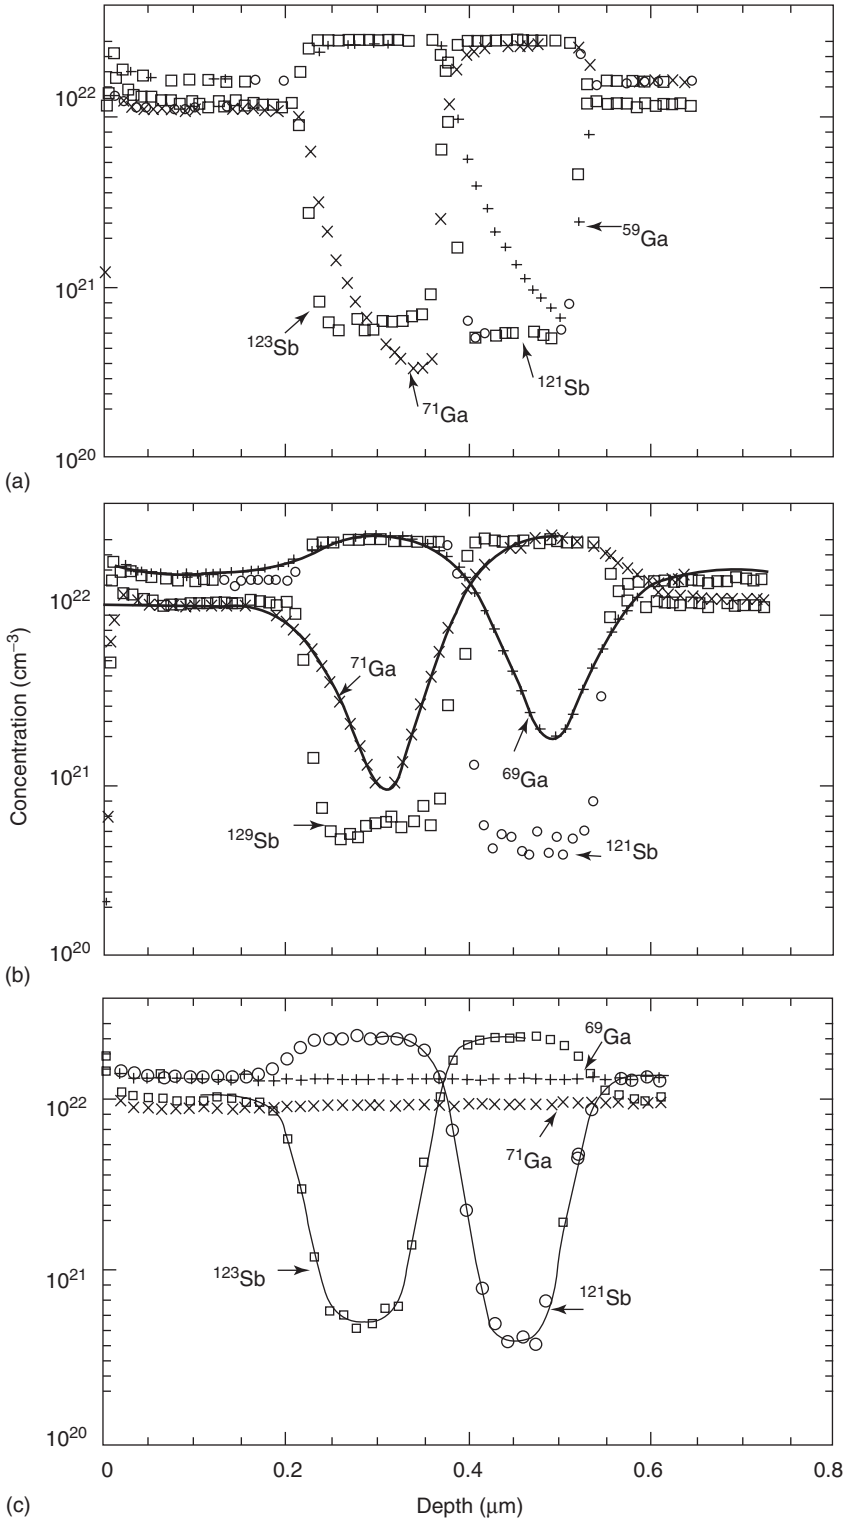

Figure 9 Concentration–depth profiles of Ga and Sb isotopes in GaSb isotope heterostructures measured with SIMS. Data are shown for ^{69}Ga (+), ^{71}Ga (×), ^{121}Sb (○) and ^{123}Sb (□). (a) Ga and Sb profiles of the as-grown ^{69}Ga^{121}Sb/^{71}Ga^{123}Sb heterostructure. Profiles after annealing the isotope structure under Sb-rich conditions at 700°C for 105 min (b) and 18 days (c). The Ga and Sb diffusion coefficients were determined by fitting the solution of Fick's law for self-diffusion across an interface to the Ga and Sb profiles measured after annealing. Solid lines in (b) and (c) show best fits. (Adapted from Bracht H, Nicols SP, Walukiewicz W, Silvera JP, and Briones F (2000) *Nature* 408(6808): 69–72.)

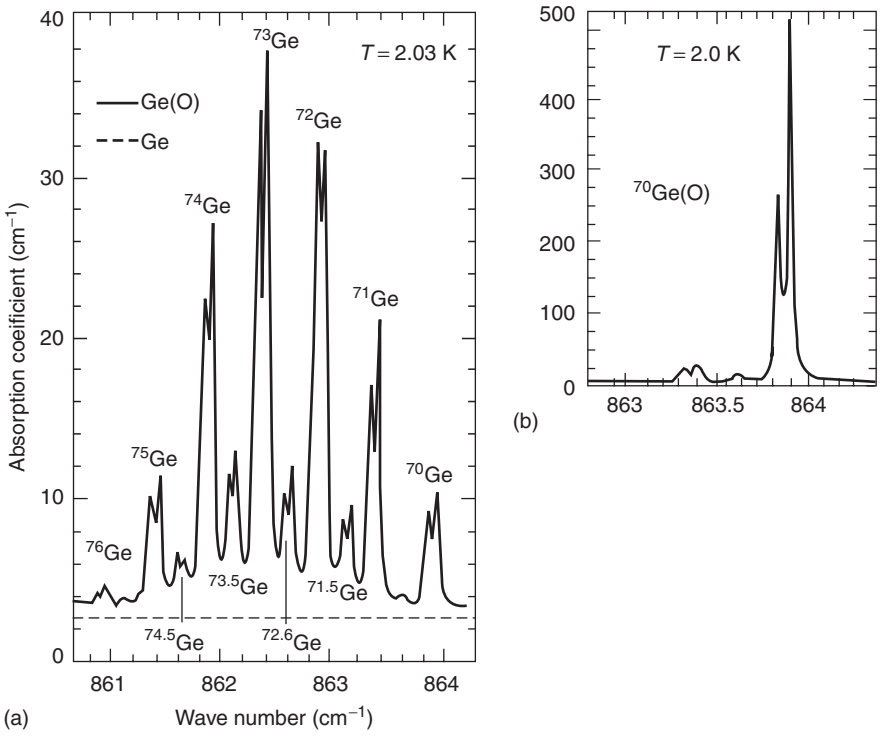

Figure 10 (a) Spectrum of the Ge_2O quasimolecules in natural Ge at 2.05 K. Eleven lines split by $\nu_2 + \nu_3$ coupling excitations correspond to the distinct isotopic mass combinations of the two Ge atoms in the quasimolecule. An oxygen-free sample produced the dashed line. (b) The spectrum of an oxygen-doped, highly enriched sample of ^{70}Ge. The lines labeled ^{71}Ge are caused by traces of ^{72}Ge in ^{70}Ge. purity single crystals; decoherence times are of the order of milliseconds (ms) at cryogenic temperatures. In the case of electron spin resonance (ESR), soon after the demonstration of the effect in the late 1950s, the effects of isotopic enrichment on the spin dynamics of donor electrons bound to ^{31}P were investigated. At that time, a doubling of T_2 from 0.2 to 0.5 ms was observed by removing the hyperfine spin–orbit coupling interaction between the electron spin and the nuclear spin of the ^{29}Si. Modern measurements on higher purity $>99\%$ ^{28}Si-enriched material have demonstrated $T_2 > 60$ ms. These and related effects are expected to be important in developing solid-state quantum computing schemes based on electron and/or nuclear spin as "qu-bits." Two references to this rapidly evolving field are given in the "Further reading" section.

Neutron Transmutation Doping

The extreme versatility of semiconductors in their wide range of applications is based on our ability to dope these solids with donors and acceptors. For device fabrication, dopants are introduced at or near the surface either by diffusion or by ion implantation. Bulk crystal doping is typically achieved by adding the appropriate minute quantities of dopant elements to the melt from which the crystal is pulled. An alternative doping technique is neutron transmutation doping (NTD).

The radioactive decay of an isotope of one element into an isotope of a different element forms the foundation of NTD of semiconductors. The NTD of Si is illustrated here. The NTD process is typically performed in a nuclear reactor. During exposure of natural silicon to thermal neutrons, all three isotopes capture neutrons with well-known capture cross sections, σ_n, and the following reactions occur:

$$^{28}_{14}\mathrm{Si} + \mathrm{n}_{th} \rightarrow {}^{29}_{14}\mathrm{Si}$$

$$^{29}_{14}\mathrm{Si} + \mathrm{n}_{th} \rightarrow {}^{30}_{14}\mathrm{Si}$$

$$^{30}_{14}\mathrm{Si} + \mathrm{n}_{th} \rightarrow {}^{31}_{14}\mathrm{Si} \overset{T_{1/2}=2.62\,h}{\longrightarrow} {}^{31}_{14}\mathrm{P} + \beta^- + \upsilon_e^-$$

The third reaction leads to the formation of the donor P. NTD differs from other dopant technologies in that very high doping uniformity can be obtained. The unmatched doping uniformity achieved by NTD is based on three factors. First, the stable isotopes are truly randomly distributed in a semiconductor of

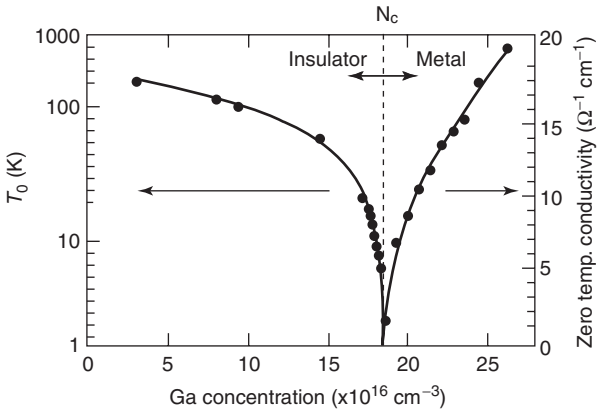

Figure 11 Extrapolated zero-temperature electrical conductivity (right axis) and characteristic temperature T_0 (left axis) for variable range hopping for 14 samples with carefully controlled concentrations of ^{71}Ga-doped ^{70}Ge made with neutron transmutation doping. The MIT is found to occur at an acceptor concentration of $1.86 \times 10^{17}\,\text{cm}^{-3}$. (Adapted from Itoh KM *et al.* (1996) *Physical Review Letters* 77: 4058.)

natural composition. Second, the source of thermal neutrons is typically larger than the semiconductor crystal to be doped. This, in turn, leads to a large homogeneous thermal neutron field guaranteeing identical exposure of all parts of the crystal. Third, the capture cross section for thermal neutrons is typically of the order of a few barns ($1\,\text{barn} = 10^{-24}\,\text{cm}^2$), which means that a few centimeters of material absorb the thermal neutron flux by significantly less than 1%, maintaining the nearly uniform neutron flux throughout the depth of the sample.

For this reason, semiconductors that are used in high-power, high-voltage applications, such as Si rectifiers (SCRs) are manufactured using NTD Si. Scientifically, NTD enables researchers to control doping levels more precisely. For example, it is possible to precisely dope Ge with Ga very close to the metal–insulator transition (MIT). As shown in **Figure 11**, it was found that the critical concentration was $1.86 \times 10^{17}\,\text{cm}^{-3}$ when the MIT was approached from both above and below. In addition, instrumentation for far infrared and submillimeter wave astronomy and astrophysics have profited from NTD. Small temperature-sensing elements of crystalline NTD germanium are assembled into large arrays in the focal planes of all modern far IR telescopes.

J

Jahn–Teller Effect

E E Vogel, Universidad de La Frontera, Temuco, Chile

Introduction

All the phenomena that can be explained by the coupling between vibrational modes of the material and electronic orbitals are said to be due to the Jahn–Teller effect (JTE). In its initial proposal (previous to experimental confirmation), the JTE anticipated a decrease in energy and degeneracy for nonlinear molecules with degenerate ground levels. This concept was later extended to localized electronic orbitals in crystals, ions, and vacancies. In another manifestation of the vibronic coupling, states of the same symmetry mix among themselves, changing energy intervals with respect to the states of different symmetry; such a phenomenon (which affects even singlets) is called the dynamic JTE. When the interaction is mediated by higher-energy states, it is referred to as pseudo-JTE. When the JTE effect extends through the lattice, neighboring centers cooperate causing a decrease in the ground-state energy. Thus, for instance, if one cell elongates along one direction due to JTE, a neighboring cell contracts along that direction. Such long-range ordering is reached below a critical temperature producing what is called the "cooperative JTE," which can modify several properties of the solid. Nevertheless, the basic phenomenon is always the same and can be described by means of coupling of the vibrational degrees of freedom to the electronic degrees of freedom of the system, in what generically can be called a "vibronic coupling."

The crystalline field theory can be thought of as a static electric multipole expansion of ionic and bond charges, defined by the equilibrium positions of constituent atoms. Such a symmetric field usually gives rise to a degenerate ground level or multiplet. Atoms interact due to bonding forces, which allow the propagation of vibrations through the crystal. Vibrational modes (phonons in quantum mechanical language) may raise the energy of some of the components of the electronic multiplet, while lowering the energy of other electronic states of the same multiplet. Thus, the JTE is usually associated with a splitting of the ground multiplet, which decreases the effective ground-state energy and reduces the ground-level degeneracy. In the real lattice, this can manifest itself as a local distortion (static JTE). In configuration space, this means complex functions describing observables and electronic properties (dynamic JTE).
