Exceptions to the previous descriptions of the JTE are one-dimensional systems or when the degeneracy is due to a time-reversal symmetry (Kramers degeneracy). In all other cases, there is always a chance for a JTE. In some materials, properties can be explained by ignoring the JTE, which simply implies that the coupling is extremely weak. However, in other systems, a vibronic coupling can lead to structural deformations, specific heat anomalies, extra lines in optical spectra, or quenching of orbital magnetic components.

In any material, vibrations span wavelengths that range from their external dimensions to a couple of interatomic distances. Evidently, long wavelengths (elastic wave limit) do not change the relative positions of neighboring atoms, so these modes can be ignored as possible coupling modes. The best candidates for JT coupling are short wave vibrations, with large acoustic frequencies or optical modes. Thus, the JTE can be viewed as the coupling of phonons having an appropriate symmetry to which the electronic orbitals under concern are most sensitive. Due to such a variety of possibilities, it is not possible to give a general prescription to proceed with the JTE in any solid. It is necessary to examine each possible coupling to different electronic orbitals separately. Since symmetry is such an important issue in this problem, the group theory is used to designate the couplings. This is the reason why this tool is briefly described in this article; it is assumed that the reader is not a group theory expert. The particular case of a local environment with triangular symmetry is used to explain the essence of the JTE for one of the most common JT couplings ($E \times \varepsilon$), prior to which the symmetry elements for such an environment are quickly reviewed. Lastly, some examples of real manifestations of the JTE are given.

Electrons and Phonons in Triangular Environment

Two-dimensional systems are simple to understand and easy to represent on the paper. Consider a double-degenerate electronic system with states $|\theta\rangle$ and $|\varepsilon\rangle$ located at the center of a crystal with triangular symmetry in two dimensions as illustrated in **Figure 1**. There are six symmetry elements that leave this complex unaltered: E, the identity; off-plane rotations through angle π with respect to axes A, B, and C; in-plane rotations through angles $+2\pi/3$ (D) and $-2\pi/3$ (F). If the following column vector representations are used,

$$|\theta\rangle = \begin{vmatrix} 1 \\ 0 \end{vmatrix}, \qquad |\varepsilon\rangle = \begin{vmatrix} 0 \\ 1 \end{vmatrix}$$

the six symmetry elements can be represented by the following matrices:

$$E = \begin{vmatrix} 1 & 0 \\ 0 & 1 \end{vmatrix}, \qquad A = \begin{vmatrix} 1 & 0 \\ 0 & -1 \end{vmatrix}, \qquad B = \begin{vmatrix} \frac{1}{2} & \frac{\sqrt{3}}{2} \\ \frac{\sqrt{3}}{2} & -\frac{1}{2} \end{vmatrix}$$

$$C = \begin{vmatrix} +\frac{1}{2} & -\frac{\sqrt{3}}{2} \\ -\frac{\sqrt{3}}{2} & -\frac{1}{2} \end{vmatrix}, \qquad D = \begin{vmatrix} -\frac{1}{2} & -\frac{\sqrt{3}}{2} \\ +\frac{\sqrt{3}}{2} & -\frac{1}{2} \end{vmatrix}$$

$$F = \begin{vmatrix} -\frac{1}{2} & +\frac{\sqrt{3}}{2} \\ -\frac{\sqrt{3}}{2} & -\frac{1}{2} \end{vmatrix}$$

The cluster approximation is used, which assumes that only displacements of atoms that are close neighbors to the electronic cloud are included, which is similar to considering an isolated molecule. This is illustrated in **Figure 2** where nearest neighbors (numbered 1, 2, and 3) are considered. From the six degrees of freedom of these three atoms, two of them lead to the motion of the center of mass and they must be discarded for the present purposes. The remaining four degrees of freedom leave the center of mass fixed, allowing for interactions with the electronic orbitals at the center. With the aid of the axes x_i, y_i ($i = 1, 2, 3$) in **Figure 2**, the corresponding four normal modes can be expressed as

$$Q_B = \frac{1}{\sqrt{3}}(y_1 + y_2 + y_3)$$

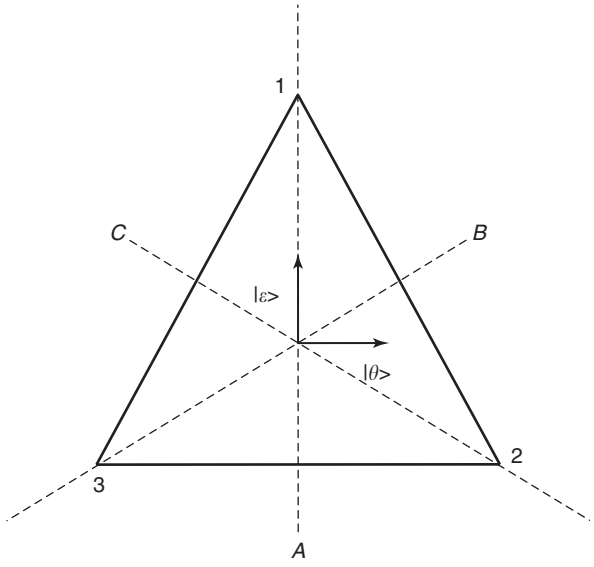

Figure 1 Symmetry elements for the triangular symmetry. Three off-plane rotations through angle π over axes A, B, and C. Additionally, operations D and F are in-plane rotations through angles $\pm 2\pi/3$.

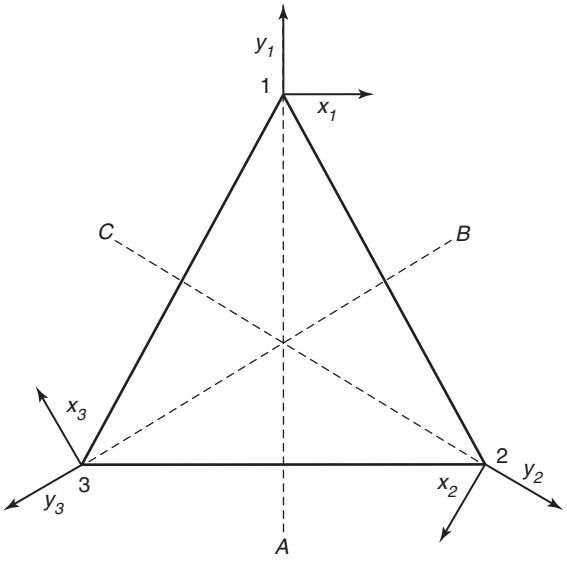

Figure 2 Basis coordinates for defining normal modes for the triangular cluster.

$$Q_R = \frac{1}{\sqrt{3}}(x_1 + x_2 + x_3)$$

$$Q_\theta = \frac{1}{\sqrt{3}}\left(x_1 - \frac{1}{2}x_2 + \frac{\sqrt{3}}{2}y_2 - \frac{1}{2}x_3 - \frac{\sqrt{3}}{2}y_3\right)$$

$$Q_\varepsilon = \frac{1}{\sqrt{3}}\left(y_1 - \frac{\sqrt{3}}{2}x_2 - \frac{1}{2}y_2 + \frac{\sqrt{3}}{2}x_3 - \frac{1}{2}y_3\right)$$

Table 1 Table of characters of group C_{3v}

Basis functions	*Irred. representation*	E	$3\sigma_v$	$2C_3$
Q_B	A_1	1	1	1
Q_R	A_2	1	−1	1
Q_θ, Q_ε	E	2	0	−1

First class E; second class $3\sigma_v$ (3 off-plane rotations A, B and C); third class $2C_3$ (2 in-plane rotations D and F).

The transformation properties of these modes can be obtained by applying symmetry operators to the basis axes x_i and y_i ($i = 1, 2, 3$). Thus, vertices (1, 2, 3) obey the following transformation laws under these operators: $E \rightarrow (1,2,3)$; $A \rightarrow (1,3,2)$; $B \rightarrow (2,1,3)$; $C \rightarrow (3,2,1)$; $D \rightarrow (2,3,1)$; and $F \rightarrow (3,1,2)$. This leads to transformation laws such as, $Ax_2 \rightarrow -x_3$, $Fy_3 \rightarrow y_1$, etc. When these transformation rules are applied to the four normal modes given by the equations above, the following properties are found:

1. E, the identity operator does not change anything (character of this operation is said to be $+1$).
2. A, B, and C leave Q_B unchanged (character $+1$), while it reverses the sense of Q_R (character -1).
3. D and F preserve both Q_B and Q_R (character $+1$) in both cases.
4. When the six operations are applied to Q_θ and Q_ε, the same transformation matrices given above for the transformation of electronic orbitals $|\theta\rangle$ and $|\varepsilon\rangle$ of **Figure 1** are obtained. The character here is the trace of the matrix (character $+2$ for E; 0 for A, B, and C; –1 for D and F).

With this information, one can build the table of characters corresponding to the triangular point group under consideration (usually designated by C_{3v}) (**Table 1**).

$E \times \varepsilon$ Coupling

Each electronic orbital couples differently to each set of vibrational modes. It is assumed here that the ground electronic level is a doublet whose wave functions transform as basis functions for the E irreducible representation of the C_{3v} point group (see **Table 1**). Such an electronic cloud sits at the center of a triangular crystal field. In the case of mode Q_R, the three atoms move simultaneously clockwise or counterclockwise, in what is a rotation or twist of the local surrounding. However, the electronic cloud at the center will not feel the atoms approaching it, so the coupling, if any, is expected to be very weak. In mode Q_B, the three neighboring atoms move outwards and inwards, in what is called the "breathing mode." This mode preserves the triangular symmetry.

The best candidates for coupling leading to a loss of symmetry are the other two modes, which involve a partial motion of atoms approaching the center. As already proved, these modes form the basis functions for the E irreducible representation of C_{3v}. However, it is customary to use Greek symbols for vibrations, so these are referred to as ε. In summary, this is the celebrated $E \times \varepsilon$ JT coupling, whose Hamiltonian can be written as

$$\boldsymbol{H} = \boldsymbol{H}_E + \boldsymbol{H}_{\mathrm{JT}} + \boldsymbol{H}_\varepsilon$$

where $\boldsymbol{H}_E$ is the component of the electronic Hamiltonian involving doublet E described by functions $|\theta\rangle$ and $|\varepsilon\rangle$; H_ε is the component of the vibrational Hamiltonian corresponding to coupling modes Q_θ and Q_ε, with vibrational quantum $\leqslant\omega$ and effective mass μ; H_{JT} is the coupling term which, in a first approximation, is given by a scalar product between a vector $\boldsymbol{G}$ of the electronic space and a vector $\boldsymbol{Q}$ of the vibrational space.

Static Case

The potential energy associated to the coupling modes is the static potential, namely

$$V = U + V_{\mathrm{JT}} = \tfrac{1}{2}\mu\omega^2\left(Q_\theta^2 + Q_\varepsilon^2\right) + K(G_\theta Q_\theta + G_\varepsilon Q_\varepsilon)$$

where the first term is the usual potential term in the harmonic approximation, while V_{JT} corresponds to the actual coupling whose strength is given by K. Normalized electronic operators G_θ and G_ε satisfy the following matrix representation on a basis formed by the vectors, $|\theta\rangle$ and $|\varepsilon\rangle$:

$$G_\theta = \begin{vmatrix} -1 & 0 \\ 0 & 1 \end{vmatrix}, \qquad G_\varepsilon = \begin{vmatrix} 0 & 1 \\ 1 & 0 \end{vmatrix}$$

(This can be found by studying the transformation properties of the matrix elements. For instance, under operator A, the element $\langle\theta|G_\theta|\varepsilon\rangle$ becomes $\langle+\theta|+G_\theta|-\varepsilon\rangle = -\langle\theta|G_\theta|\varepsilon\rangle = 0$.)

A general ground-state function can be written as

$$|f\rangle = \alpha|\theta\rangle + \beta|\varepsilon\rangle$$

which must be an eigenfunction of the static potential:

$$V|f\rangle = F|f\rangle, \qquad (F-U)|f\rangle = V_{\mathrm{JT}}|f\rangle$$

By letting operators G_θ and G_ε act on $|f\rangle$, it is obtained that

$$(F-U)(\alpha|\theta\rangle + \beta|\varepsilon\rangle) = K[(-Q_\theta\alpha + Q_\varepsilon\beta)|\theta\rangle + (Q_\theta\beta + Q_\varepsilon\alpha)|\varepsilon\rangle]$$

which leads to a secular equation giving the condition:

$$(F-U)^2 - K^2\left(Q_\theta^2 + Q_\varepsilon^2\right) = 0$$

A minimum energy is obtained by imposing the condition that the first derivative of the eigenvalue function F with respect to each coordinate is zero at the equilibrium position $(Q_{\theta 0},\ Q_{\varepsilon 0})$, yielding

$$F_0 = -U_0 = -\frac{\mu\omega^2}{2}\left(Q_{\theta 0}^2 + Q_{\varepsilon 0}^2\right) = -\frac{K^2}{2\mu\omega^2}$$

suggesting the parametrization,

$$Q_{\theta 0} = Q_0 \cos\varphi, \quad Q_{\varepsilon 0} = Q_0 \sin\varphi, \quad Q_0 = \frac{K}{\mu\omega^2}$$

as illustrated in the lower part of **Figure 3**.

The interpretation here is clear: new equilibrium conditions appear at a "distance" Q_0 away from the non-JT equilibrium position $(K=0)$. This is the JT distortion. The actual energy is now

$$F_0 = -\frac{\mu\omega^2}{2}\,Q_0^2 = -E_{\mathrm{JT}}$$

where E_{JT} is the so-called JT energy corresponding to the decrease from the non-JT situation. This is illustrated as the minimum energy reached by the lower curve in the upper part of **Figure 3**. Instead of the initial electronic doublet, the ground state corresponds to the singlet (lower state)

$$|f_{\mathrm{l}}\rangle = \cos\left(\frac{\varphi}{2}\right)|\theta\rangle - \sin\left(\frac{\varphi}{2}\right)|\varepsilon\rangle$$

Thus, JTE in this complex resulted in a ground level of lower energy and lower degeneracy.

The second static state is represented by the orthonormal function (upper state)

$$|f_{\mathrm{u}}\rangle = \sin\left(\frac{\varphi}{2}\right)|\theta\rangle + \cos\left(\frac{\varphi}{2}\right)|\varepsilon\rangle$$

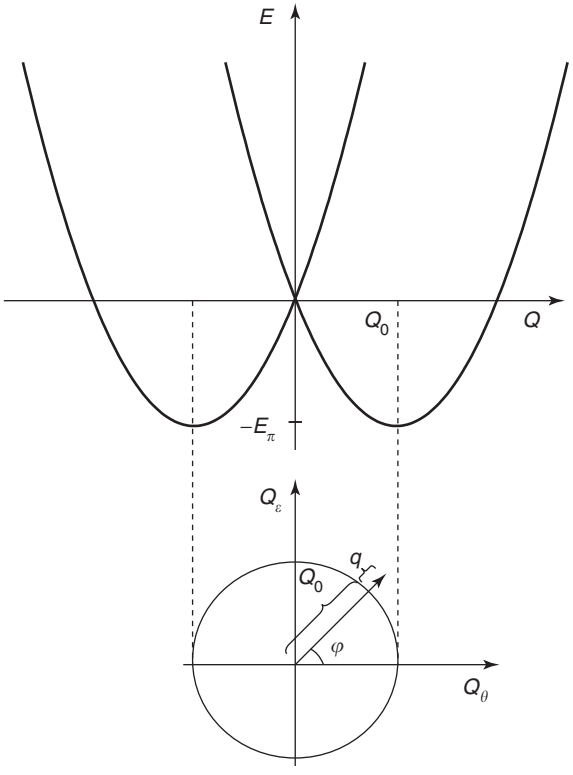

Figure 3 Parametrization of coordinates that result from solving the static problem for $E\times\varepsilon$ coupling. The coupling defines a new equilibrium condition at coordinates Q_0,φ.

Dynamic Picture

At $K=0$ (no JT), the potential can be represented by a paraboloid of revolution with its minimum at the origin of the $Q_\theta Q_\varepsilon$ plane. As K grows, the minimum energy is $-E_{\mathrm{JT}}$, occurring at $Q=Q_0$, for any φ (circle in **Figure 3**). A cut of the corresponding potential surface is illustrated in the upper part of **Figure 3**. The complete surface is obtained by revolving this curve about the E-axis; due to its shape, this potential is known as the Mexican hat.

Notice that the radial degree of freedom in the plane $Q_\theta Q_\varepsilon$ leads to oscillations, while excitations along the perpendicular direction do not find restoring forces leading to a circular motion associated to the coordinate φ. Since a transformation $\varphi\rightarrow(\varphi+2\pi)$ does not lead to the same function, a dynamic ground-state wave function must be written as

$$|f_{\mathrm{l}m}\rangle = \mathrm{e}^{\mathrm{i}m\varphi}\left(\cos\left(\frac{\varphi}{2}\right)|\theta\rangle - \sin\left(\frac{\varphi}{2}\right)|\varepsilon\rangle\right)$$

representing the family of low-energy wave functions, with m taking half-integer values. Higher energy states correspond to an admixture of oscillations $(Q\rightarrow Q_0+q)$ with occupation number n, rotational states with occupation number m and electronic basis function $|f_{\mathrm{l}}\rangle$. Such wave functions form the lower branch of vibronic levels. Similarly, states originating in static solution $|f_{\mathrm{u}}\rangle$ produce the upper branch of states.

Strength of JT Coupling

In the extremely weak coupling limit $(K=0)$, the system can be described as a doubly degenerate electronic system uncoupled to the vibrations of the surrounding, which can be represented here by a double-dimensional harmonic oscillator with occupancy quantum numbers n_θ and n_ε, energy $\hbar\omega(n_\theta+n_\varepsilon+1)$ and total vibronic degeneracy $2(n_\theta+n_\varepsilon+1)$ as represented on the left-hand side of **Figure 4**.

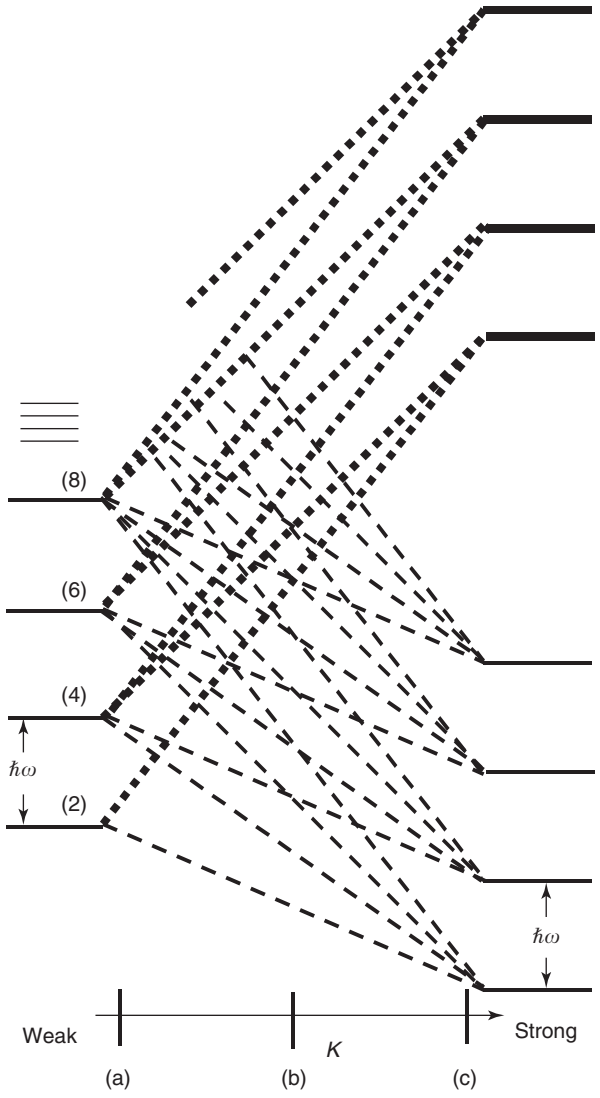

Figure 4 Schematic strength dependence of energy levels for $E \times \varepsilon$ coupling: (a) weak coupling limit, (b) intermediate coupling with admixture and crossing of levels, and (c) strong coupling limit.

On the other hand, in the extremely strong coupling limit, the system is better described by a coupled vibronic system, with states belonging to two branches. In each case, the wave function involves function $|f_l\rangle$ or $|f_u\rangle$ combined to quantum numbers n and m, producing a complex function whose actual form depends on the strength of the coupling. For large enough values of K, the energy for levels of the lower branch can be approximated by a series expansion, whose three leading terms are

$$E_{nm} = -K^2\hbar\omega + \left(n + \frac{1}{2}\right)\hbar\omega + \frac{m^2}{4k^2}\hbar\omega$$

The degeneracy of each vibronic level is infinite in the strong coupling limit ($K \to \infty$), due to the infinite possible values of m.

Figure 4 illustrates how the infinite energy levels of the weak coupling limit map onto the infinite levels of the strong coupling limit, for the $E \times \varepsilon$ coupling. All kinds of situations are possible according to the strength of the coupling. For the extremely weak coupling limit (case (a) in **Figure 4**), the JTE can be thought of as a perturbation to the adiabatic limit: no permanent distortion is to be found and physical properties show little difference with respect to the description coming from the plain crystal-field theory. On the contrary, in the strong coupling limit ((c) in **Figure 4**) large discrepancies in structure, optical and magnetic properties are possible. In such cases, the coupling is beyond perturbative methods and the system is better described by a set of displaced oscillators. Intermediate cases (such as (b) in **Figure 4**) can be extremely complicated as well as interesting, and the problem usually requires numerical methods to characterize it.

A way of measuring the strength of the coupling is the so-called Huang–Rhys factor S, defined as

$$S = \frac{E_{JT}}{\hbar\omega}$$

Normally, a weak coupling is understood for $S \leqslant 1.0$, while a strong coupling is found for $S \geqslant 10$, but this is a general guide only.

Ham Reduction Factors

The nature of the ground-wave function varies with K. In the extremely weak coupling limit, the ground-state function is a true zero-phonon wave function. However, as the strength of the coupling increases, the admixture with higher-order phonon components weakens the presence of the zero-phonon component. Thus, the contribution of purely electronic operators, such as those present in optical and magnetic properties, decreases with the strength of the vibronic coupling and it is said that the corresponding effect is quenched.

The expectation value corresponding to any given operator makes use of the vibronic functions at the appropriate K value. If JTE is ignored, expectation values make use of the purely electronic functions. When a comparison between these two results is done for the case of the ground states, reduction factors can be defined. Thus, the ratio of the first expectation value over the second one is called the Ham factor or a reduction factor for that operator. These factors give an idea of how much a physical magnitude is reduced by the JTE. For $E \times \varepsilon$ coupling,

the reduction factor $q_H(K)$ is defined as

$$q_H(K) = \frac{\langle f^K_{00\theta}|G_\theta||f^K_{00\theta}\rangle}{\langle\theta|G_\theta|\theta\rangle} = \frac{1}{2}\left(1 + \frac{1}{(2K)^4} + \cdots\right)$$

where the truncated asymptotic expression on the right-hand side is valid in the strong coupling limit only ($K \to \infty$). So, in this limit ($K \to \infty$), q tends to 0.5; then, as the coupling weakens, q grows to reach the value 1.0 in the case of no JTE ($K = 0$). Evaluation of other Ham factors can yield results in the range (0.0,1.0).

Quenching of Orbital Angular Momentum

One of the most frequently observed manifestations of the Ham effect (as it is sometimes called) is the quenching of the orbital angular momentum. The magnetic moment of ions is formed by both orbital and spin components. For free ions, both of them contribute fully to produce the final magnetic moment. In a molecule or solid, the orbital contribution depends on the zero-phonon component of the ground vibronic wave function. So, it is said that the angular momentum is quenched and the magnetic moment of the ion is different as compared with the value of the free ion. This phenomenon is directly measured by means of electron paramagnetic resonance and it is usually reported as a variation in the g factor or, more generally, as a change in the components of the g tensor.

Examples of Dynamical JT Couplings

Couplings

There is a large variety of couplings, in symmetry as well as in strength. For simplicity, the case of impurities in crystals is considered so that the previous analysis based on the point-group theory can be directly invoked. Transition metal impurities in semiconductors have been deeply investigated due to their optical properties and possible applications as sensors. One interesting system is the one defined by the presence of Fe impurities in II–VI compounds of strong ionic character such as CdTe; this case is used as an illustrative example. The crystal structure is that of zinc blende, where each cation is surrounded by four anions in a tetrahedral coordination and vice versa, leading to an overall cubic symmetry. Iron impurities substitute for the cation at a site with symmetry properties described by the operations that leave a regular tetrahedron invariant, namely point-group T_d (this is similar to the case of the operations that leave the equilateral triangle invariant in two dimensions, as discussed above).

The four anions at the vertices of the tetrahedron span 12 degrees of freedom: three translations, three rotations, and six vibrations. One of the vibrational modes is the breathing mode. There are two degenerate modes designated by ε and three degenerate modes designated by τ_2 (irreducible representations of T_d).

Iron appears in this system as a doubly ionized atom, Fe^{2+}, with a d^6 electronic configuration (within the approximation of the ionic picture). Each of the multiplets couples differently to each of the three vibrational sets of modes. Couplings to the ground multiplet ^5D are of the most importance. A crystalline field splits this level into a lower ^5E and an upper $^5T_2$ multiplet. A spin–orbit interaction further splits these multiplets as shown schematically on the left-hand side of **Figure 5**. Downward (upward) arrows on the left-hand side of this figure illustrate allowed electric-dipole emissions (absorptions) when the JTE is ignored. However, experiments show a completely different picture making it necessary to include JTE. In principle, any of the six vibrational modes can be

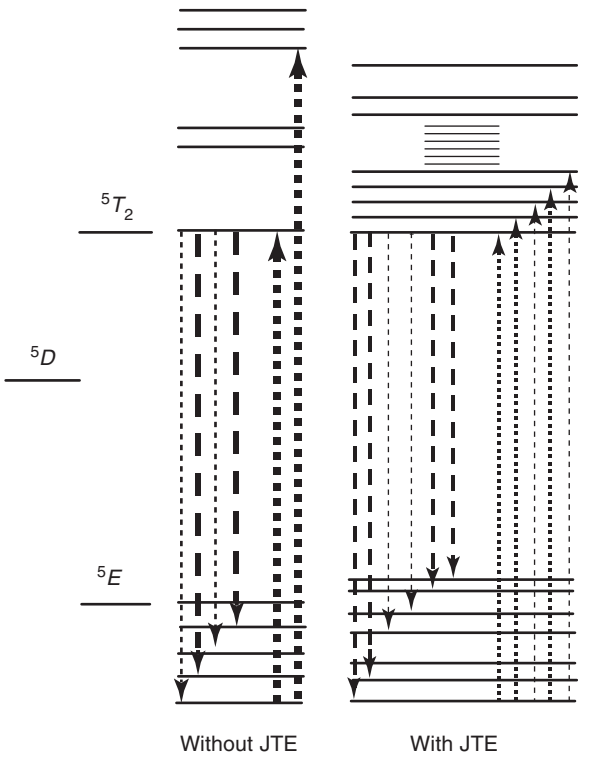

Figure 5 Consequences of the JTE on the emission and absorption spectra of Fe^{2+} in CdTe. The scheme on the left-hand side illustrates the case of no JTE, predicting few lines: four equally spaced lines in luminescence; two widely separated absorption lines. The scheme on the right-hand side shows actual emission and absorption lines after appropriate JTE is included: several unequally spaced lines in luminescence; several close lines near the absorption threshold.

responsible for this vibronic coupling. It turns out that ε modes give a good description of the main features of the emission and absorption spectra as schematically shown in the right-hand side of **Figure 5**, when appropriate values of the parameters are used. In the present case, the emphasis is on the rearrangement of energy levels corresponding to a dynamic JTE.

Emission Spectrum

Low-temperature emission lines originate in the lowest energy level of the T_2 multiplet ending in any compatible vibronic level of the E multiplet. Selection rules do not only take into account symmetry, but components must also have the same number of vibrational quanta, zero-phonon lines being the most important contributions. A good agreement with luminescent spectra is obtained after considering the vibronic coupling $E \times \varepsilon$ with the coupling phonon of $\leqslant \omega_E = 29\ \text{cm}^{-1}$ and $E_{\text{JTE}} = 3.2\ \text{cm}^{-1}$; this means a Huang–Rhys factor $S = 0.11$, evidencing a rather weak JTE. Then, this coupling can be treated as a minor perturbation, which is evident from the small deviation of vibronic levels as compared to purely electronic levels.

Absorption Spectrum

Low-temperature absorptions originate in the lowest level of the E multiplet ending in levels of the T_2 multiplet allowed by symmetry, matching components with the same vibrational quantum number. Vibronic couplings $T_2 \times \varepsilon$ and $T_2 \times \tau_2$ are possible, the former producing the energy level shown on the right-hand side of **Figure 5**, giving a good explanation of the positions and relative strengths of the absorption lines. Again, the main features of the experiment can be explained upon considering coupling to ε modes. Such modes have the same symmetry as the one considered for emission, but with a larger frequency. This mode is better suited to produce coupling to the more extended and differently oriented electronic orbitals of the upper multiplet. A good agreement with the absorption spectra is obtained for $\leqslant \omega_T = 35\ \text{cm}^{-1}$ and $E_{\text{JTT}} = 210\ \text{cm}^{-1}$; this means a Huang–Rhys factor $S = 6.0$ (~ 50 times larger than the previous one), is an important JTE, producing significant effects in the absorption spectrum. Calculations give many lines of similar intensity close to the absorption threshold (in perfect correspondence with experiments) instead of a single isolated line predicted by the plain crystal-field theory. This effect is shown in **Figure 5** by arrows pointing upward.

Cooperative JT Effect

This article so far has focused on isolated JT ions. When the crystal is formed by JT centers, local couplings can collectively combine in such a way that neighboring distortions cooperate to minimize the total energy. To visualize this effect, think of a local octahedron formed by the six anions surrounding the JT cation. If an octahedron elongates along one direction, the next octahedron along that same direction shrinks. The JT effect of each isolated ion does not need to be large, but the propagation of the phenomenon through the entire lattice makes such a cooperative JT effect (CJTE) a large effect, causing a long-range rearrangement of atoms.

One example of a system exhibiting CJTE is the perovskite $LaMnO_3$, whose ideal structure is cubic with the La at the center, one Mn at each of the eight corners and one O at the center of each of the 12 edges. The JT center (Mn ion) is surrounded by an octahedron of six O. However, the three axes of this octahedron are different due to the coupling of the Mn ions to crystal vibrations causing a JT distortion of the octahedron. The neighboring octahedra tilt in complementary ways and establish a CJTE that propagates through the crystal producing an orthorhombic lattice. This effective vibronic coupling reveals itself in other phenomena as well. Thus, the trivalent La can be substituted by bivalent ions (such as Ca), which turns some neighboring Mn ions magnetic. A vibronic coupling to these ions is important to explain the large increase of electrical resistivity of the system $La_{0.67}Ca_{0.33}MnO_3$ in the presence of a magnetic field in what is known as colossal magnetoresistance. Normally, the CJTE produces a low-symmetry structure, which appears below a certain temperature.

K

Kondo Effect (Theory)

B Coqblin, Université Paris-Sud, Orsay, France

Introduction to the Kondo Effect

The starting point of the long history of the "Kondo effect" is the first calculation performed by Kondo himself in 1964 to account for the observed experimental evidence of a resistivity minimum in magnetic dilute alloys such as CuMn, CuFe, YCe or LaCe. The first observed resistivity minimum in CuFe was dated from 1931.

Before discussing the Kondo effect itself in greater detail, it is important to note that the Kondo effect belongs to the wider field of the presently so-called "physics of strongly correlated electron systems," which originates primarily from the presence of an inner *d* or *f* shell in one of the atoms embedded in the considered system. The *d* electrons in transition elements and the 4*f* or 5*f* electrons in rare-earths or actinides are generally well localized and correlated. The correlations tend first to favor the existence of magnetism which is due to open inner *d* or *f* shells, as observed in pure iron, cobalt, or nickel in the 3*d* series, in rare-earth metals and in actinide metals after americium. Magnetism is also observed in many ionic, insulating, or metallic systems containing the preceding magnetic elements. But in fact, at present, the generic term of strongly correlated electron systems is mostly confined to metallic systems where there exists a strong interaction or hybridization between the inner *d* or *f* electrons and the conduction electrons. From a theoretical point of view, this type of physics started with the pioneering works of Mott for metal–insulator transition, of Friedel for the so-called "Friedel sum rule" and the theoretical concept of "virtual bound state" in 1956, of Anderson for the derivation of the hybridization "Anderson Hamiltonian" in 1961, and obviously of Kondo himself for the explanation of the resistivity minimum.

Thus, a summary of the main works on the Kondo effect is presented here, starting with the derivation of the calculation of the Kondo effect itself and the so-called "high-temperature" regime, that is, when the perturbation theory is valid; then, the "low-temperature" regime for one impurity and finally, the problems of the Kondo lattice and of the multichannel Kondo effect are described.

The "High-Temperature" Case

The first calculation of Kondo was performed in dilute alloys with magnetic transition impurities and the system is well described by the classical exchange Hamiltonian given by

$$H = -J\boldsymbol{s}_c\boldsymbol{S}_f \qquad [1]$$

In the expression [1], the localized spin $\boldsymbol{S}_f$ on the impurity interacts with the spins $\boldsymbol{s}_c$ of the conduction electrons coming from the host. The exchange constant J can be either positive (corresponding to a ferromagnetic coupling) or negative (antiferromagnetic coupling). It results that a localized spin $\boldsymbol{S}_f$ on site i interacts with another localized spin on site j by an indirect mechanism involving the conduction electrons through the exchange interaction given by [1]: this indirect interaction between two localized electron spins is called the "Rudermann–Kittel–Kasuya–Yosida" (or RKKY) interaction, which decreases as a function of the distance R between the two sites i and j as $\cos(k_F R)/(k_F R)^3$.

In 1964, Kondo computed the magnetic resistivity ρ_m up to the third order in J (or in the second-order perturbation) and found

$$\rho_m = A|J|^2 S(S+1)\left[1 + J\rho \log\frac{k_B T}{D}\right] \qquad [2]$$

where ρ is the density of states for the conduction band at the Fermi energy, A a constant value, and S the value of the spin for the localized electrons. It is immediately seen that for a negative J value, the magnetic resistivity decreases with increasing temperature. Thus, the total resistivity, which is the sum of the magnetic resistivity and the phonon one which increases with temperature, passes through a minimum. A negative J value corresponds to an antiparallel coupling between the localized and conduction electron spins, and the preceding treatment is valid

only at sufficiently high temperatures above the so-called "Kondo temperature" T_k given by

$$k_B T_k = D \exp\left(-\frac{1}{|J\rho|}\right) \quad [3]$$

where D is a cutoff corresponding roughly to the conduction bandwidth. The magnetic susceptibility decreases above T_k as $1/T$, as in a Curie law. The different transport, magnetic, and thermodynamic properties of a Kondo impurity have been extensively studied by perturbation in the so-called "high-temperature" regime (i.e., above T_k). On the other hand it is clear that, below T_k, the perturbative treatment is not valid and the low-temperature behavior was completely different from the previously described high-temperature one.

The exchange Hamiltonian [1] describes well the case of a magnetic impurity embedded in a normal matrix, when the inner d or f electrons are well localized corresponding to approximately integer values of $2S$. On the other hand, Anderson has introduced a Hamiltonian which can describe different situations, such as the nonmagnetic or the magnetic case, as well as the case of an intermediate valence or that of an almost integer valence. In the series of rare-earths, most of them have a valence of 3 and are well described by the Hamiltonian [1] with an integer $2S$ value, while systems containing anomalous rare-earths, like cerium or ytterbium, are better described by the Anderson Hamiltonian. Moreover, in the special case of a magnetic impurity with a valence close to an integer, Schrieffer and Wolff have shown that the Anderson Hamiltonian is equivalent to a Kondo Hamiltonian [1] with a negative J value given by

$$J = -\frac{|V_{kf}|^2}{|E_0 - E_F|} \quad [4]$$

where $E_0 - E_F$ is the distance between the $4f$ and the Fermi levels. Thus, this so-called Schrieffer–Wolff transformation allows one to show that the Anderson Hamiltonian in the almost ionic limit yields automatically a negative J value and, therefore, the Kondo effect.

The Anderson and the exchange Hamiltonians have been used first to describe the situation of magnetic systems with only a spin magnetic moment and a quenched orbital magnetic moment, as in the case of alloys with $3d$ transition elements. However, the physical situation of rare-earths is more complicated, because the magnetic moment has both spin and orbital components and the states are labeled according to the z-components of the total angular momentum $J = L + S$. For example, in magnetic cerium systems, the spin–orbit is sufficiently large to split the $4f^1$ configuration into a ground state $j = 5/2$ and an excited state $j = 7/2$. Then, the sixfold degenerate level $j = 5/2$ is split by the crystalline field effect which has a typical energy splitting $\sim 100\,\mathrm{K}$ and, therefore, of the same order as the usual temperature of experiment. Thus, both the orbital degeneracy and the crystalline field effect are important in the study of anomalous magnetic rare-earths such as cerium or ytterbium with $4f^1$ or $4f^{13}$ configurations. The Anderson Hamiltonian including the orbital degeneracy has been used first to explain the phase diagram of cerium metal, which provides a very fascinating example of many features of strong correlations. However, in the studied case of the so-called "Kondo limit," that is, when the number of $4f$ electrons (or holes) is close to 1, corresponding to the $4f^1$ configuration of cerium (or the $4f^{13}$ configuration of ytterbium), an effective Hamiltonian has been derived by use of the Schrieffer–Wolff transformation. Thus, the resulting so-called "Coqblin–Schrieffer" Hamiltonian including crystalline field effects has been extensively used to derive many transport and magnetic properties of cerium Kondo compounds. The magnetic resistivity, calculated by the perturbation theory at "high temperatures," that is, for $T > T_k$, presents a maximum at a temperature roughly equal to Δ, and two $\log T$ behaviors above and below Δ for the typical case of a cubic crystalline field of energy splitting Δ. The slopes of these $\log T$ behaviors are characteristic of the respective degeneracies of the levels, and these two $\log T$ behaviors separated by the maximum corresponding to the crystalline field were observed for the first time in the plot of the magnetic resistivity ρ_m of the $CeAl_2$ compound in 1972. A large effect of pressure has also been observed, because the absolute value of the $\log T$ slopes increases rapidly with pressure, which is directly accounted for by the theoretical model. These effects have been then observed in the other transport and magnetic properties and have been found in many cerium compounds.

Thus, the decrease of the magnetic resistivity in $\log T$ is now considered a clear "signature" of the Kondo effect in magnetic cerium compounds or in some related magnetic rare-earth systems, and has been in fact observed in more than a hundred compounds. The increase in the absolute value of the $\log T$ slope is also characteristic of the pressure effect in cerium Kondo compounds. Moreover, at present, the available highest pressures are much larger and there exist very nice new experiments on such cerium or ytterbium compounds.

The "Low-Temperature" Case

It has been seen that the perturbative calculation of Kondo is no more valid at low temperatures, that is, below the "Kondo temperature" given by eqn [3]. After several attempts, the theoretical problem of a single Kondo impurity was exactly solved in 1975 at $T = 0$ by Wilson using the renormalization group technique on the exchange Hamiltonian [1] with a negative J value. Wilson was the first to show numerically that the exact $T = 0$ solution is a completely compensated singlet formed by the antiparallel coupling between the conduction electron spin $s_c = 1/2$ and the localized electron spin $S_f = 1/2$. An analytical exact solution of the single Kondo impurity problem was then obtained by the Bethe–Ansatz method for both the classical exchange and the Coqblin–Schrieffer Hamiltonians. The exact solutions have given a clear description of the Kondo effect, but since it is difficult to use them for computing the different physical properties, sophisticated "mean field" methods have been introduced, such as the "slave boson" method or the method using correlators or more recently, the dynamical mean field theory. Many works may be mentioned to describe the dynamical effects or spectroscopic properties, and both the one-impurity Kondo and Anderson problems including dynamical properties have been solved by different theoretical techniques and, in particular, by the renormalization group technique.

The low-temperature (i.e., $T \ll T_k$) properties of a Kondo impurity are those of a "Fermi liquid" and can be summarized as follows:

1. The electronic specific heat constant γ and the magnetic susceptibility χ are much larger than those corresponding to a normal magnetic behavior. The first experimentally observed example for such a behavior corresponds to $CeAl_3$, where an extremely large electronic specific heat constant $\gamma = 1.62\,J\,mol^{-1}\,K^2$ was found in 1975 by Andres and co-workers. The term "Heavy fermions" originates from these high values of γ and χ.
2. The transport properties of cerium Kondo compounds are described by the Fermi liquid formalism at low temperatures. In particular, the electrical resistivity follows a T^2 law and the coefficient A of this term is particularly large in heavy fermion systems.
3. A direct evidence of the heavy fermion behavior has been obtained by de Haas–van Alphen effect experiments in many cerium compounds, such as $CeCu_6$, CeB_6, $CeRu_2Si_2$, and some uranium compounds. An effective mass up to $\sim 100\,m_e$ (where m_e is the electron mass) has been observed in cerium compounds.
4. It is finally important to notice that superconductivity was observed first in $CeCu_2Si_2$ compound by Steglich and co-workers in 1979, then in some cerium compounds at high pressure, and uranium compounds at normal pressure, which is clearly an outstanding experimental result and a fantastic theoretical challenge.

The Doniach Diagram and the Kondo Lattice Problem

Up to now, only the Kondo effect model for a single impurity has been studied and remains valid even for concentrated alloys or compounds at high temperatures above the Kondo temperature. However, when one deals with, for example, a lattice of cerium atoms, the situation becomes more difficult at very low temperatures. The competition between the Kondo effect on each atom which tends to suppress the magnetic moment with decreasing temperature and the RKKY interaction which, on the contrary, tends to give a magnetic ordering between different rare-earth atoms is well described by the well-known "Doniach diagram," where the Kondo temperature for a single impurity, and the Neel (or Curie in a few cases) temperature as a function of the exchange interaction term, $|J\rho|$ are plotted. It results in the real ordering temperature T_N increasing initially with increasing $|J\rho|$, then passes through a maximum and tends to zero at a critical value $|J\rho|_c$ corresponding to the so-called "quantum critical point" (QCP).

Such a behavior of T_N has been experimentally observed with increasing pressure in several cerium Kondo compounds, such as $CeAl_2$, CeAg, or $CeRh_2Si_2$. A maximum of the ordering temperature has been observed in some of them, for instance, CeAg, which is ferromagnetic, or $CePd_2Al_3$, but in all these compounds, the Neel temperature decreases and tends to zero at high pressures.

Above the QCP corresponding to the magnetic–nonmagnetic instability (or to the disappearance of the Neel temperature T_N), several different behaviors have been observed: a departure from the Fermi liquid (FL) behavior, called "non-Fermi liquid" (NFL), has been observed experimentally in many cerium compounds under high pressure, such as Ce_7Ni_3, which presents successively a magnetic ordering up to ~ 3 kbar, then an NFL behavior up to ~ 6–7 kbar, and finally an FL behavior above that pressure with a coefficient of the resistivity T^2 law decreasing rapidly with pressure and disappearing above 12 kbar. The NFL behavior of the Kondo lattice near the magnetic instability has been theoretically studied within the

scaling theory of critical phenomena and within the self-consistent renormalized theory of spin fluctuations. This last theory predicts a $\log T$ law for γ and a $T^{3/2}$ law for the magnetic resistivity ρ_m just at the QCP; when one goes farther from the QCP, the behavior tends back to an FL behavior, with a decrease of the $\log T$ slope of γ and a power law for ρ_m approaching the T^2 law.

In fact, the FL behavior exists above the QCP in some cerium compounds such as $CeRh_2Si_2$, and the real Kondo temperature has been found to remain roughly constant with $|J\rho|$ or with pressure in the nonmagnetic domain. A theoretical model, taking into account both the intra-site Kondo interaction and an additional inter-site Heisenberg-type interaction, can explain the observed decrease of the real Kondo temperature with respect to the one-impurity Kondo temperature, as a function of the increase of the intersite interaction and of the decrease of the number of conduction electrons; this last result corresponds to the idea of "exhaustion," which corresponds to a decrease of the Kondo effect when there are not enough conduction electrons to screen the localized electrons. The separation between the FL and the NFL behaviors above the QCP is not completely explained at present and is still an important subject of research.

There are, in fact, several different NFL behaviors, in contrast to the obviously unique FL behavior, and also several theoretical explanations for such experimentally observed NFL behaviors. In addition to the previously described NFL behavior directly connected to proximity to the QCP, a second observed NFL behavior is due to an effect of disorder. A simple model of a disordered Anderson lattice has been proposed and the disorder introduces a distribution of Kondo temperatures. This simple mechanism leads to logarithmic behaviors in thermodynamic properties and a linear temperature dependence of the resistivity, as experimentally observed in some cerium and uranium alloys. The third NFL behavior is due to the "multichannel Kondo effect," as explained in the next section.

The Multichannel Kondo Effect

An NFL behavior observed in cerium and uranium compounds arises also from the so-called "multichannel Kondo model." The regular Kondo effect corresponds to a complete screening of the localized electrons by the conduction electrons, while the multichannel Kondo effect corresponds to either an underscreening or an overscreening of the localized electrons by the conduction ones. The multichannel Kondo model for a single impurity has been completely solved analytically by the Bethe-ansatz method, and numerical solutions have been obtained to describe the different physical properties.

In the "underscreened" Kondo effect with $2S > n$ (where n is the number of channels for conduction electrons), a part $n/2$ of the impurity spin is compensated, while the part $S' = S - n/2$ is not compensated. The result is that the magnetic susceptibility is diverging in $1/T$ as for a Curie law, which is obviously different from the constant magnetic susceptibility obtained at low temperatures for the regular screened Kondo effect ($2S = n$). A ferromagnetic coupling between the resulting spin S' and the conduction electron spin is finally obtained in the underscreened Kondo model.

In the "overscreened" Kondo effect with $2S < n$, it remains $(n - 2S)$ uncoupled conduction electrons and the spin S' given by $S' = n/2 - S$ is antiparallel to S. For $S = 1/2$, $n = 2$, a logarithmic dependence of χ and γ is obtained, while for $S = 1/2$ and $n > 2$, the temperature dependence of χ and γ is given by a power law T^n. A particular model within this overcompensated case is the "quadrupolar Kondo effect," corresponding to the two-channel case: a logarithmic dependence for γ, a linear one for the magnetic resistivity, and an unusual value for the entropy (corresponding to half the value of the entropy for the regular Kondo effect) have been obtained and these theoretical results have been used to account for the NFL behavior observed in $Y_{1-x}U_xPd_3$ alloys.

Conclusions

As a present conclusion, it can be said that there have been, in the last decades, both a tremendous improvement of the experimental techniques used for the study of strongly correlated electron systems and a fantastic development of the theoretical ideas in the field of strongly correlated electron systems since the pioneering works of Mott, Friedel, Anderson, and Kondo. The Kondo effect has been understood for the case of a single impurity, while several features of the Kondo lattice problem are not clearly understood and remain interesting challenges. Several new subjects are being clearly studied at present: first, many cerium or uranium compounds become superconducting at low temperatures, generally close to the QCP and the occurrence of superconductivity in such systems, as well as the high-T_c superconductivity observed in cuprates or related compounds, remains a not-understood challenge; second, the Kondo effect has been observed for a small set of atoms in nanoscopic systems and this field is clearly a rapidly developing subject; third, a lot of new compounds have been obtained in recent years and many of these

systems present new and fascinating properties connected with magnetism and superconductivity.

Laser Radiation Sources

A Agnesi, G Reali, and A Tomaselli, Università degli Studi di Pavia, Pavia, Italy

Introduction

LASER is an acronym meaning light amplification by stimulated emission of radiation. Stimulated emission can be obtained from a medium prepared in a nonthermal distribution of its energy-level populations. In a solid-state material, for example, this is achieved through the absorption of light at an appropriate pumping wavelength. In the following, for simplicity, the laser medium will mean a solid-state matrix, contributing a background refractive index η, enclosing atoms which under pumping will be all set in the same final state, so that a homogeneous lineshape of their laser transition is also understood. For the same reason, level degeneracies will not be considered. Since Nd:YAG is a widely used solid-state laser material, numerical examples will refer to it in the following. A laser can be either an amplifier or a generator of coherent light, in which case an optical feedback is provided in order to allow the device to generate the laser beam from its own internally generated optical seed.

When a laser system is properly designed and operated, it is able to generate light of extraordinary quality, in terms of spectral purity, directionality, and power. The properties of the generated beam are precisely the reason of the importance of laser devices in scientific, biomedical, and industrial applications.

The basic interactions involved in laser operation proceed via the radiative processes of (induced) absorption, spontaneous emission, and stimulated (or induced) emission.

Spontaneous emission needs a quantum treatment. In addition to providing the seed into the right cavity mode that can start the laser action, it represents an incoherent and completely uncorrelated contribution with respect to the coherent stimulated terms. Ultimately, it is also responsible for the phase and amplitude fluctuations of laser systems.

For the induced processes instead, it is possible to resort to much simpler balance equations, first introduced by Einstein, that describe how light is transported through the system. The basic idea of transport or rate equations approach is to add or subtract the quasiresonant photon energies $\hbar\omega$ from the field as it travels through the atomic population, of densities N_2, N_1 that make transitions between levels separated by $\hbar\omega_0 = (E_2 - E_1)$. This is schematically shown in **Figure 1**.

Accordingly, the incident optical intensity S (energy per unit area per unit time), that sweeps across a volume of unit cross-sectional area and thickness dz, containing N_2 dz and N_1 dz atoms in upper and lower levels interested by the interaction, will be changed as

$$\frac{1}{c}\frac{\partial S}{\partial t} + \frac{\partial S}{\partial z} = \sigma(N_2 - N_1)S \qquad [1]$$

where σ (in units of length^2) is the transition cross section, equal for both the events. The overall change in [1] will be according to the sign of $(N_2 - N_1)$: for positive sign, the medium behaves as an amplifier of light, while in the opposite case of negative population inversion, under ordinary thermal equilibrium conditions, only absorption can be realized and the optical intensity decreases in going across the medium.

In recognition of the amplifier condition, it is usual to define the gain coefficient (in units of length^{-1}) as

$$g = \sigma(N_2 - N_1) \qquad [2]$$

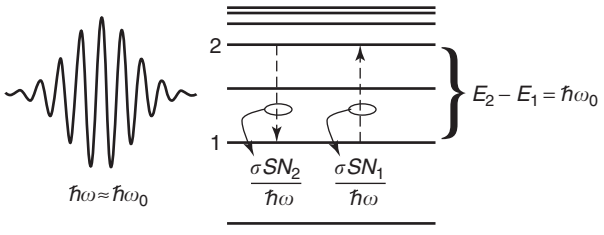

Figure 1 Schematic of the interaction of two atomic levels with a quasiresonant photon flux for an allowed transition.

so that, considering a steady-state ($\partial/\partial t = 0$) situation in [1],

$$\frac{dS}{dz} = gS \qquad [3]$$

In the case of constant gain coefficient, eqn [3] is easily solved, giving an exponential optical intensity growth

$$S(z) = e^{gz}S(0) \qquad [4]$$

An amplifier medium is used in laser oscillators, which are the most important devices. In their simplest configuration, they are set up enclosing the gain medium in a linear cavity formed by two (plane or curved) mirrors as shown in **Figure 2**, of which one, of partial reflectivity R, provides the useful output coupling.

The purpose is to trap only the almost axially emitted part of spontaneous emission and redirect it along the axis, so that it can be amplified and filtered through the combined action of the stimulated emission in the gain medium and the selective modal structure of the optical cavity. These iterated actions build up the self-sustained intense, highly monochromatic, and directional laser beam. A simple gain–loss balance analysis of the mode in the optical cavity (or resonator) immediately provides the threshold lasing condition. Following the history of gain and loss of the oscillating mode along a full round trip and requiring self-reproducibility at the end,

$$e^{2g\ell}R(1 - L_i) = 1 \qquad [5]$$

where ℓ is the gain medium length, R is the output coupling mirror reflectivity, and L_i are the double-pass passive cavity loss.

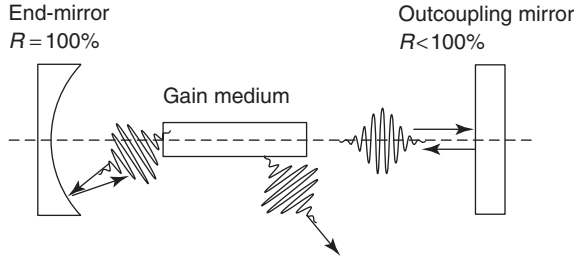

Figure 2 Optical laser cavity, with the pictorial description of its operation. Only almost axially emitted photons are trapped inside it.

This defines the threshold gain for the laser oscillator:

$$g_{th} = -\frac{\ln(R) + \ln(1 - L_i)}{2\ell} \qquad [6]$$

above which stimulated laser action initiates.

A second important condition constraints the change of phase of the oscillating mode after a round trip, and is presented later in this article.

Creating Population Inversion and Laser Beam Properties

In order to create a population inversion, the closed two-level system illustrated in **Figure 1** cannot work "as is," since the nature of up–down stimulated transitions and their relation (same cross section) prevents the possibility of using the same channel for both excitation and generation, in case of optical pumping.

The minimum number of required levels is thus three, and a more general four-level system may perform even better, depending on the relative magnitudes of the relaxation rates of the level populations and on the selective actions of the pumping system. **Figure 3** clarifies the kinematics of the level populations in a four-level system.

Typically, a four-level system is one in which upper laser level 2 is fed at a rate that almost coincides with the rate at which level 3 is fed, due to a very fast, nonradiative relaxation from level 3 to level 2; in addition, the lower laser level 1 is constantly drained off, keeping it essentially empty, by its fast decay to lower lying levels.

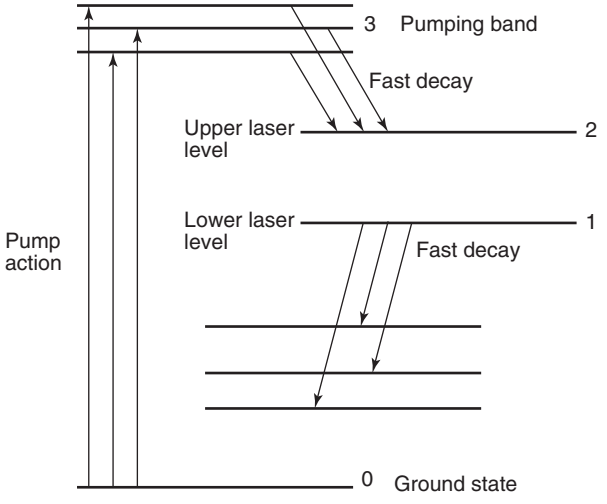

Figure 3 A "four-level" laser, with the indication of the most relevant energy exchanges: the pump, and the fast decays into the upper laser level and out of the lower laser level, which favor an efficient creation of the population inversion.

Pumping efficiency and resonator design are the most important problems in laser engineering, since the properties of the generated laser beam depend on their optimization.

Once the active medium has been chosen, and the application the laser is aimed at has suggested the operating regime (continuous wave, long pulses, short pulses, etc.), power, monochromaticity and spectral purity, coherence, and directionality are essentially controlled by pumping and by the optical resonator. An overall parameter, which can be used, for example, to compare laser light and standard generated light (sun, lamp, discharge, etc.), is the brightness which summarizes all the above properties.

As a rule, laser emission is not at a single frequency near the ω_0 of the laser transition. Because of natural lifetime and interactions of the active atoms with the surrounding environment, gain effects, and photon lifetime, there is a sizable spectral broadening of the emitted light. Still, laser light is far better than all other light sources. As an example, Nd:YAG, one of the most widely used solid-state laser materials, lases at 1064 nm, corresponding to $\omega_0 \approx 1.8 \times 10^{15}$ s^{-1}, and may have spectral purity $\Delta\omega/\omega_0 \approx 10^{-9}$, several order of magnitudes smaller than any unfiltered thermal light source, for which that figure approaches 1.

Since the stimulated emission forces all photons in exactly the same quantum state, coherence persists until the radiating atomic polarization remains temporally and spatially correlated, and is not disturbed by any spurious effects such as collisions with the environment. Collisions essentially determine the coherence time, which is connected to the degree of monochromaticity of the emitted light, $\tau_{coh} \sim 2\pi/\Delta\omega$.

To a large extent, spatial coherence is formed by the transverse modal structure of the resonator, from which the beam derives its directionality. Spatial coherence and directionality are the properties that allow the beam to be brought, with very low spill-out energy, to a tight focus, an essential requirement in most laser applications. Diffraction theory shows that the lowest order, Hermite–Gauss mode of a stable resonator diverges with an angle $\vartheta_{0x} = \lambda/(\pi w_{0x})$, where w_{0x} is the beam waist (its lowest radius) in an x-direction perpendicular to z-propagation direction; the same expression holds for the y-direction. This is the lowest divergence among beams with same beam waist. It can be shown that higher-order modes (and, more generally, a real beam made up of a mixture of these) with same waist diverge with an angle $\Theta_x = M_x^2 \vartheta_{0x}$, greater than the lowest-order mode by a factor of M_x^2, called the spatial beam quality factor; this expression can be used as an operative definition of the M_x^2 factor, which is always >1 for any real beam (a same expression holds for the y-direction).

High intensities and low divergence can be put together to define laser brightness, the power emitted per unit area per unit solid angle. The concept applies, in general, to any source of radiation; in case of lasers, a very simple form is assumed as

$$B \equiv \frac{P}{A \times \Omega} \approx \frac{P}{(w_{0x} w_{0y}) \times (\Theta_x \Theta_y)} \approx \frac{P}{\lambda^2 M_x^2 M_y^2} \qquad [7]$$

and can be used as an indicator of the laser quality.

The fact that laser brightness is directly proportional to power is one of the reasons for research in the area of short and ultrashort pulse generation; another reason is that very short pulses allow one to investigate very short phenomena, in the same way as very small spots allow one to see and work out very small details.

Interaction of Light with Matter

In order to understand the mechanisms that govern the generation of laser light, it is useful to analyze in some detail the results of the quantum treatment of light-matter interaction, using a simple two-level system as toy model.

An incident optical field $\boldsymbol{E}(\boldsymbol{r}, t)$ on a quantum system, possessing a set of stationary levels and eigenfunctions, $\{E_i, \phi_i(\boldsymbol{r})\}$, is assumed to be almost resonant with two levels 2 and 1 with energy separation $\hbar\omega_0 = (E_2 - E_1)$, so that all the other levels can be ignored. Levels 2 and 1 are also assumed to have a well-defined parity, and to be connected by a dipole-allowed transition. The time-dependent interaction is described by the second term of the Hamiltonian $H = H_0 + H_1$, where, in the dipole approximation, $H_1 = -\boldsymbol{p} \cdot \boldsymbol{E}$ and the optical field takes the form $\boldsymbol{E} = \hat{\varepsilon} E_0(t) \cos(\omega t)$, with a slowly time varying amplitude. With usual procedure, the solution is assembled in the form $\psi(\boldsymbol{r}, t) = c_1(t)\phi_1(\boldsymbol{r}) + c_2(t)\exp(-i\omega t)\phi_2(\boldsymbol{r})$. Defining the dipole matrix elements $\boldsymbol{p}_{ij} = \int_{\text{all space}} d^3 r \phi_i^*(\boldsymbol{r}) \boldsymbol{p} \phi_j(\boldsymbol{r})$, neglecting rapidly varying terms, introducing the detuning $\Delta = (\omega_0 - \omega)$, and the Rabi frequency $\Omega = (\boldsymbol{p}_{21} \cdot \hat{\varepsilon}) E_0/\hbar$, the amplitude equations result

$$\begin{aligned} i \frac{dc_1}{dt} &= -\frac{1}{2} \Omega^* c_2 \\ i \frac{dc_2}{dt} &= \Delta c_2 - \frac{1}{2} \Omega^* c_1 \end{aligned} \qquad [8]$$

These are used to form the set of equations obeyed by the density matrix

$$\rho = \begin{bmatrix} \rho_{11} & \rho_{12} \\ \rho_{21} & \rho_{22} \end{bmatrix} = \begin{bmatrix} c_1 c_1^* & c_1 c_2^* \\ c_2 c_1^* & c_2 c_2^* \end{bmatrix} \qquad [9]$$

with closure condition $\rho_{11} + \rho_{22} = |c_1|^2 + |c_2|^2 = 1$, which provides a most compact means to calculate quantum expectation values, $\langle A \rangle = \mathrm{tr}\{A\rho\}$. In their final form, the equations are

$$\begin{aligned} \frac{\mathrm{d}\rho_{11}}{\mathrm{d}t} &= -\frac{\mathrm{i}}{2}(\Omega\rho_{12} - \Omega^*\rho_{21}) \\ \frac{\mathrm{d}\rho_{22}}{\mathrm{d}t} &= -\frac{\mathrm{d}\rho_{11}}{\mathrm{d}t} \\ \frac{\mathrm{d}\rho_{12}}{\mathrm{d}t} &= \mathrm{i}\Delta\rho_{12} + \frac{\mathrm{i}}{2}\Omega(\rho_{22} - \rho_{11}) \end{aligned} \qquad [10]$$

These equations describe the evolution of the atomic densities and of the induced polarization of a material, introduced through the macroscopic variables:

$$\begin{aligned} N_1 &= N\rho_{11} \\ N_2 &= N\rho_{22} \\ \boldsymbol{P} &= N\int \mathrm{d}^3 r \psi^*(\boldsymbol{r},t)\boldsymbol{p}\psi(\boldsymbol{r},t) \\ &= N(\rho_{21}\boldsymbol{p}_{12}\exp(-\mathrm{i}\omega t) + \mathrm{c.c.}) \end{aligned} \qquad [11]$$

with N the total population density participating in the interaction, and where $\boldsymbol{p}_{ii} = 0$ has been used. Introducing the slowly varying macroscopic polarization, $\boldsymbol{P}(t) = 1/2[\hat{\varepsilon}P(t)\exp(-\mathrm{i}\omega t) + \mathrm{c.c.}]$, and comparing it with eqn [11],

$$P = 2N(\boldsymbol{p}_{12}\cdot\hat{\varepsilon})\rho_{21} \qquad [12]$$

is obtained. The macroscopic equations now result

$$\begin{aligned} \frac{\mathrm{d}N_1}{\mathrm{d}t} &= -\frac{1}{2\hbar}\Im m(E_0^* P) = -\frac{\mathrm{d}N_2}{\mathrm{d}t} \\ \frac{\mathrm{d}P}{\mathrm{d}t} &= -\mathrm{i}\Delta P - \frac{\mathrm{i}|\boldsymbol{p}_{12}\cdot\hat{\varepsilon}|^2}{\hbar}(N_2 - N_1)E_0 \end{aligned} \qquad [13]$$

These equations describe the dynamics of an ensemble of "closed" two-level systems. In this form, they do not yet reflect some very important features that extend the two-level system into a working model of laser, such as the existence of relaxation processes through collisions or radiative decays, and especially the possibility of pumping energy into the system to get population inversion, $(N_2 - N_1) > 0$. The inclusion of these physical effects is possible making a phenomenological fix of the eqn [13] based on physical considerations; this is illustrated in **Figure 4**.

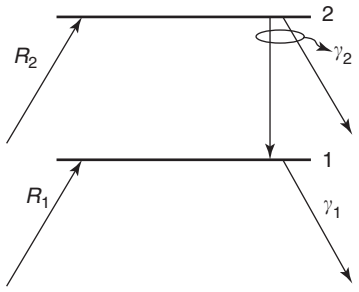

Figure 4 Pumping and decays that make the "two-level" model a "real" laser model.

The main effects to be included are: (1) pumping rates into levels 2 and 1, R_2 and R_1, respectively; (2) damping rates of levels 2 and 1 due to inelastic collisions and radiative decays, γ_2 and γ_1, respectively; and (3) elastic collisions, which only affect induced polarization, γ_{ph}. Taking all these effects into account leads to

$$\begin{aligned} \frac{\mathrm{d}N_1}{\mathrm{d}t} &= R_1 - \gamma_1 N_1 - \frac{1}{2\hbar}\Im m(E_0^* P) \\ \frac{\mathrm{d}N_2}{\mathrm{d}t} &= R_2 - \gamma_2 N_2 + \frac{1}{2\hbar}\Im m(E_0^* P) \\ \frac{\mathrm{d}P}{\mathrm{d}t} &= -(\gamma + \mathrm{i}\Delta)P - \frac{\mathrm{i}|\boldsymbol{p}_{12}\cdot\hat{\varepsilon}|^2}{\hbar}(N_2 - N_1)E_0 \end{aligned} \qquad [14]$$

where $\gamma = \gamma_{\mathrm{ph}} + (\gamma_1 + \gamma_2)/2$ is the damping rate for the induced polarization.

Rate-Equation Approximation and the Laser Amplifier

It happens quite often that in laser materials, γ is much larger than all the other rates, so that the induced polarization rapidly reaches a steady state and follows adiabatically the changes of the field and the atomic populations. In this "rate-equation approximation," $\mathrm{d}P/\mathrm{d}t = 0$ resulting in

$$P(t) = -\frac{\mathrm{i}|\boldsymbol{p}_{12}\cdot\hat{\varepsilon}|^2 E_0(t)}{\hbar(\gamma + \mathrm{i}\Delta)}(N_2 - N_1) \qquad [15]$$

This is substituted back into the population equations to give the rate equations:

$$\begin{aligned} \frac{\mathrm{d}N_1}{\mathrm{d}t} &= R_1 - \gamma_1 N_1 + W(N_2 - N_1) \\ \frac{\mathrm{d}N_2}{\mathrm{d}t} &= R_2 - \gamma_2 N_2 - W(N_2 - N_1) \\ W &= \frac{\pi|\boldsymbol{p}_{12}|^2|E_0(t)|^2}{6\hbar^2}\frac{\gamma/\pi}{\gamma^2 + \Delta^2} \end{aligned} \qquad [16]$$

A factor of 3, due to an orientational averaging performed over angles, has been included in W to

account for random local dipole disorientations with respect to the electric field:

$$\overline{|\boldsymbol{p}_{12}\cdot\hat{\varepsilon}|^2} = |\boldsymbol{p}_{12}|^2/3$$

It is recognized that the expression of W, which represents the rate at which the inversion is changed, can be written as

$$W = \frac{\sigma S}{\hbar\omega} \qquad [17]$$

using the photon flux

$$\frac{S}{\hbar\omega} = \frac{1}{\hbar\omega}\left(\frac{1}{2}\,\varepsilon_0\eta c|E_0(t)|^2\right)$$

where η is the average background refractive index of the material. From [17], the expression for the transition cross section is obtained:

$$\sigma = \frac{\pi|\boldsymbol{p}_{12}|^2\omega}{3\varepsilon_0\eta c\hbar}\,\frac{\gamma/\pi}{(\gamma^2+\Delta^2)} \qquad [18]$$

A quantum mechanical calculation of the spontaneous emission rate $A = 1/\tau_{sp}$ provides the explicit form

$$A = \frac{1}{\tau_{sp}} = \frac{\omega_0^3\eta|\boldsymbol{p}_{21}|^2}{3\pi\hbar\varepsilon_0 c^3} \qquad [19]$$

which, used in [18] to eliminate $|\boldsymbol{p}_{21}|^2$, with the consideration that $\gamma \ll \omega_0$, leads to the most popular form of the transition cross section

$$\begin{aligned}\sigma(\omega) &= \frac{\lambda_0^2}{4\eta^2\tau_{sp}}\,\frac{\gamma/\pi}{\gamma^2+(\omega-\omega_0)^2}\\ &= \frac{\lambda_0^2}{4\eta^2\tau_{sp}}L(\omega)\end{aligned} \qquad [20]$$

This expression can be used, for example, to get a numerical estimate of the cross section of Nd:YAG using available data $\tau_s = 230\ \mu s$, $\gamma = 2\pi \times 120$ GHz, $\eta = 1.82$. The computation gives $\sigma \approx 14 \times 10^{-19}$ cm^2, greater by a factor of ≈ 2 than its most quoted value, an acceptable result for this simple model.

$L(\omega)$ is the normalized Lorentzian lineshape, obtained in the hypothesis that all atoms behave in an identical manner in the interaction. Thus, the laser gain introduced in eqn [2] results

$$g(\omega) = \frac{\lambda_0^2}{4\eta^2\tau_{sp}}L(\omega)(N_2 - N_1) \qquad [21]$$

In more general situations, the lineshape has different widths and shapes, and can be largely inhomogeneous, if all the atoms do not have the same center transition frequency ω_0 (as, e.g., in Nd:glass).

From rate equations, it is immediately clear that the population inversion depends on optical intensity S, since W depends on it. In a strict four-level system, previously illustrated, in which pumping into lower laser level is suppressed, $R_1 = 0$, and the decay from the lower laser level is assumed to be very fast, these rate equations unveil this feature very clearly, when solved for the steady state. The result is

$$\begin{aligned}N_2 - N_1 &= \frac{(R_2/\gamma_2)}{1 + S/(\hbar\omega\gamma_2/\sigma)}\\ &= \frac{(N_2-N_1)_0}{1+S/S_{sat}}\end{aligned} \qquad [22]$$

where $(N_2 - N_1)_0 = R_2/\gamma_2$ is the inversion at low optical intensity, $S/S_{sat} \ll 1$, and $S_{sat} = (\hbar\omega\gamma_2/\sigma)$ is the saturation intensity. The gain thus becomes

$$\begin{aligned}g(\omega) &= \frac{\sigma(\omega)(N_2-N_1)_0}{1+S/S_{sat}}\\ &= \frac{g_0(\omega)}{1+S/S_{sat}}\end{aligned} \qquad [23]$$

where the small signal gain g_0 has been introduced with an obvious identification.

An immediate application of [23] is its use into [3] to obtain the general behavior of a single-mode amplifier. The equation

$$\frac{dS}{dz} = \frac{g_0}{1+S/S_{sat}}\,S \qquad [24]$$

has a general solution of the following form:

$$\frac{S(z)-S(0)}{S_{sat}} + \ln\left(\frac{S(z)}{S(0)}\right) = g_0 z \qquad [25]$$

where $S(0)$ is the input intensity. The exponential growth [4] is thus obtained only for small intensities compared with the saturation intensity. At the opposite limit, when the first term on the left-hand side of [25] dominates, the intensity difference grows linearly with the length as $g_0 S_{sat} z$. If multiplied by the effective area A_{eff} of the beam, and noting that $P_{ex} = g_0 S_{sat} = R_2\hbar\omega$ is the available power density from the gain medium, $g_0 S_{sat} A_{eff} z$ is seen to be the maximum extractable power from the amplifier, which is only attained working in saturation regime. In **Figure 5**, the plots of the "growth rate" $= (1/S)(dS/dz)$ and the "power extraction rate" $= dS/dz$ show that the growth rate is maximum for small S and drops to zero for large S, while an exactly specular behavior is followed by the power extraction.

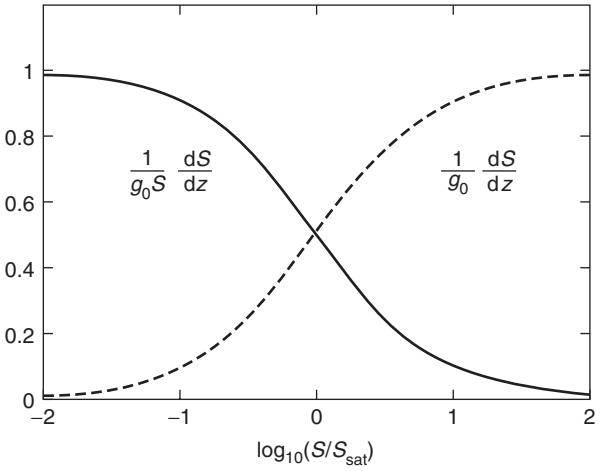

Figure 5 Growth rate and power extraction rate plots as a function of intensity normalized to the saturation intensity.

Finally, it is useful to summarize these considerations into the definition of a figure of merit for the amplifier; its internal efficiency

$$\eta_{\text{int}} = \frac{S(z) - S(0)}{R_2 \hbar\omega_{\text{p}} z} = \frac{S(z) - S(0)}{R_2 \hbar\omega z}\,\frac{\hbar\omega}{\hbar\omega_{\text{p}}} = \frac{S(z) - S(0)}{g_0 S_{\text{sat}} z}\,\eta_{\text{S}} \qquad [26]$$

where $P_{\text{p}} = R_2 \hbar\omega_{\text{p}}$ is the pump power density available in the amplifier, and $\eta_{\text{S}} = \omega/\omega_{\text{p}}$ is the Stokes efficiency.

Laser Resonators and Beam Modes

The importance and the advantages of making high-quality beams are so overwhelming that laser research has made enormous effort in studying optical resonators, which are the devices used to provide the oscillator feedback and to spatially shape the laser beams.

In a laser, the cavity is set up of (flat or curved) mirrors, surrounding the gain medium, which select only the light emitted approximately along the resonator axis, and reflect it back and forth several times, thus providing the necessary feedback that sustains the laser action. What characterizes a laser from other coherent devices at longer wavelengths (in the far-infrared and microwave ranges) is that an open resonator is needed to limit the number of possible oscillating modes that fit under the gain line width of the laser medium, and to get temporally coherent radiation.

In addition to the feedback action, the most important function of the resonator is the transverse spatial shaping of the radiated field, and the optical

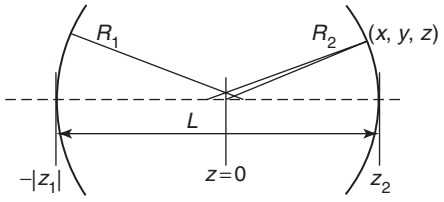

Figure 6 Empty laser resonator used to discuss the modes of a stable cavity laser. R_1 and R_2 are the curvature radii of the two confining mirrors, one of which eventually has a partial reflectivity to allow outcoupling of the laser field.

spatial quality of a beam is generated by using the modal structure of the resonator.

Optical resonators can be grouped into two classes: stable resonators are characterized by having closed ray paths, whereas unstable resonators have no closed path, and are mainly used in high gain laser systems. Only stable resonators are briefly described, while the book by Siegman provides a complete authoritative review on the subject of resonators.

The empty linear resonator shown in **Figure 6** is used to illustrate the sustained resonator modes. With this geometry, it is possible to select the fundamental TEM_{00} mode because the higher-order modes suffer significantly greater losses.

The structure of these modes can be found by solving the wave equation, which governs the propagation of beams whose transverse (i.e., (x, y)) dependence is less rapid than their z-dependence. Recognizing these different spatial rates, the complex quasimonochromatic field is written as

$$E(x, y, z, t) = E_0(t) u(x, y, z) \mathrm{e}^{\mathrm{i}(kz - \omega t)} \qquad [27]$$

where the spatial shape $u(x, y, z)$ is a slowly varying function in its variables with respect to $\mathrm{e}^{-\mathrm{i}kz}$, and satisfies the following parabolic wave equation (also known in optics as paraxial wave equation):

$$\frac{\partial u}{\partial z} + \mathrm{i}2k\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right) = 0 \qquad [28]$$

It can be shown that, if a beam with Gaussian shape

$$u(x, y, 0) = \exp\left(-\frac{x^2 + y^2}{w_0^2}\right) \qquad [29]$$

is chosen as initial condition at its narrowest point in $z = 0$ (w_0 is correspondingly called the beam waist), then the solution for arbitrary z is given by

$$u(x, y, z) = \frac{1}{1 + \mathrm{i}(2z/kw_0^2)} \times \exp\left(-\frac{x^2 + y^2}{w_0^2 + 2z\mathrm{i}/k}\right) \qquad [30]$$

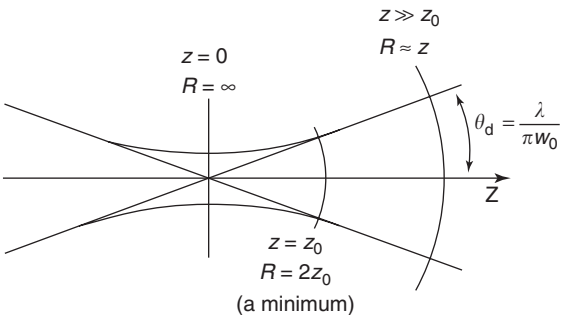

Figure 7 Geometrical meaning of the beam parameters defined in the text.

After defining new quantities (illustrated in **Figure 7**): $z_0 = kw_0^2/2$, the Rayleigh range or confocal parameter; $R(z) = z + z_0^2/z$, the beam radius of curvature; $w(z) = w_0[1 + (z/z_0)^2]^{1/2}$, the beam radius – eqn [39] can be put into the more convenient form

$$u(x,y,z) = \frac{w_0}{w(z)} \exp\left(-\frac{x^2+y^2}{w^2(z)} + \mathrm{i}\frac{k}{2}\frac{x^2+y^2}{R(z)} - \mathrm{i}\tan^{-1}\left(\frac{z}{z_0}\right)\right) \quad [31]$$

The fundamental TEM_{00} laser beam is thus

$$E_{00}(x,y,z,t) = E_0(t)\frac{w_0}{w(z)} \exp\left(-\frac{x^2+y^2}{w^2(z)} + \mathrm{i}\frac{k}{2}\frac{x^2+y^2}{R(z)} - \mathrm{i}\tan^{-1}\left(\frac{z}{z_0}\right) + \mathrm{i}(kz-\omega t)\right) \quad [32]$$

Higher-order transverse modes can also be found, and they are given in terms of the complete Hermite–Gauss set functions, so that

$$E_{mn}(x,y,z,t) = E_0(t)\frac{w_0}{w(z)} H_m \times \left(\frac{\sqrt{2}x}{w(z)}\right) H_n\left(\frac{\sqrt{2}y}{w(z)}\right) \times \exp\left(-\frac{x^2+y^2}{w^2(z)} + \mathrm{i}\frac{k}{2}\frac{x^2+y^2}{R(z)} - \mathrm{i}(m+n+1)\tan^{-1}\left(\frac{z}{z_0}\right) + \mathrm{i}(kz-\omega t)\right) \quad [33]$$

The first few transverse mode distributions are pictorially shown in **Figure 8**.

Now imagine that the resonator of **Figure 6** has mirrors at $z_1 < 0$ and $z_2 > 0$, with radii of curvature $R_1 = -R(z_1)$, $R_2 = R(z_2)$, respectively. A point (x, y, z) on mirror 2 satisfies the equation

$$R_2^2 = x^2 + y^2 + (R_2 - z_2 + z)^2 \quad [34]$$

which can be rewritten as

$$z_2 + \frac{(z-z_2)^2}{2R_2} = z + \frac{x^2+y^2}{2R_2} \quad [35]$$

The wave front of constant phase ϑ almost coincides (within lowest-order terms) with the mirror at z_2 when evaluated on the mirror surface:

$$\vartheta = k\left\{ z_2 - \frac{x^2+y^2}{2R_2} + \frac{(z-z_2)^2}{2R_2}\right\} + k\frac{x^2+y^2}{2R(z)} - (m+n+1) \times \tan^{-1}\left(\frac{z}{z_0}\right) - \omega t \quad [36]$$

and the rays strike the mirrors perpendicularly and propagate back and forth along the cavity. The losses due to phase mismatch can be eliminated by tuning the wave number $k = \omega/c$, so that the total phase change of the ray between the mirrors is an integer number l of π's:

$$l\pi = \frac{\omega L}{c} - (m+n+1) \times \left\{ \tan^{-1}\left(\frac{z_2}{z_0}\right) - \tan^{-1}\left(\frac{z_1}{z_0}\right)\right\} \quad [37]$$

where $L = (z_2 + |z_1|)$ is the cavity length.

The frequency satisfying [37] for given values of (l, m, n) is called ω_{lmn} and the corresponding field is called the TEM_{mn} transverse mode. The larger the transverse indices (m, n), the lesser the wave fronts coincide with the mirrors, which means that there is a tendency (if not otherwise managed) to have the suppression of higher-order transverse modes in favor of the lowest-order one. A change between two nearby longitudinal mode frequencies with same (m,n) is given by

$$\Delta\omega_{lmn} \equiv \omega_{l+1\,mn} - \omega_{lmn} \equiv \frac{c\pi}{L} \quad [38]$$

while varying the transverse mode indices at fixed l results

$$\delta\omega_{lmn} = \frac{c}{L}\delta(m+n) \times \left\{ \tan^{-1}\left(\frac{z_2}{z_0}\right) - \tan^{-1}\left(\frac{z_1}{z_0}\right)\right\} \quad [39]$$

where $\delta(m+n)$ is the change in $(m+n)$; it is not hard to see, for example, in the case when $z_0 \gg z_2, |z_1|$, that

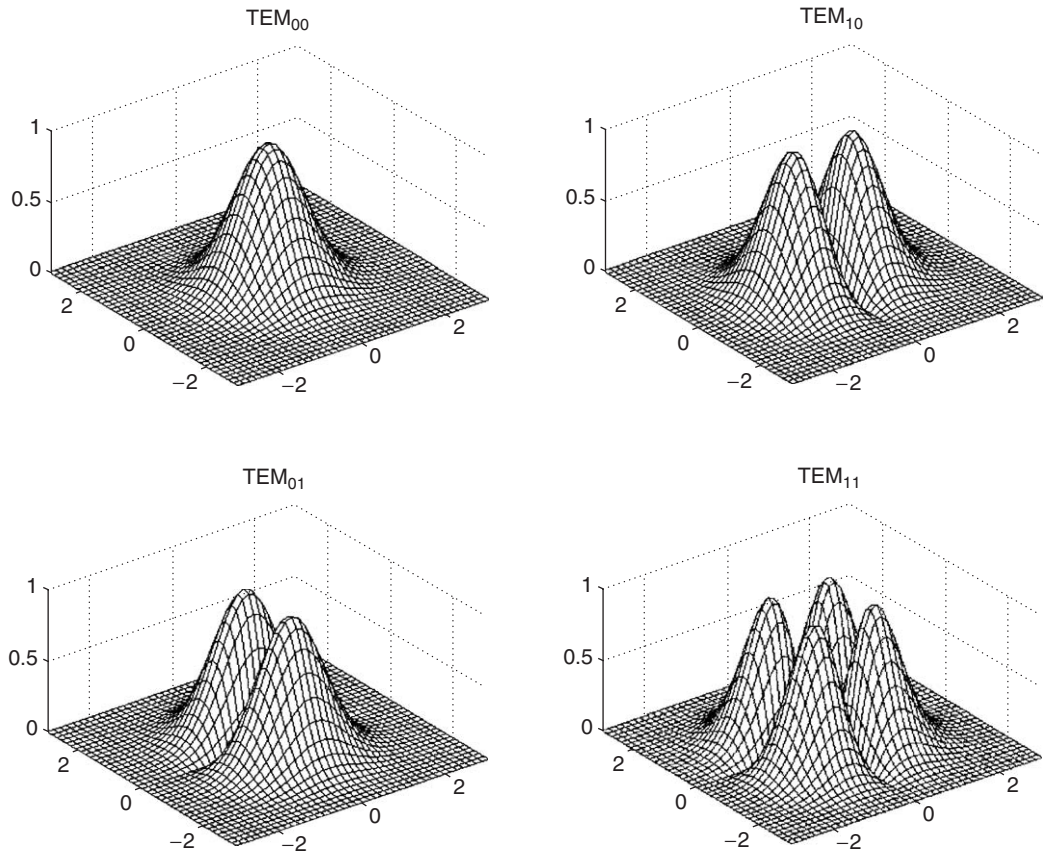

Figure 8 Patterns of first low-order Hermite–Gauss modes.

the transverse mode structure appears as a fine structure of the longitudinal mode spectrum.

It should be noted that, if the resonator is loaded with a gain medium of length ℓ, its length L must be replaced by the optical length $L' = L + (\eta - 1)\ell$, so that the phase condition [37] contains the refractive index of the gain medium $\eta(\omega,S)$, which depends on frequency as well as on laser beam intensity. This should alert that the exact longitudinal mode position is also a function of the working power of the laser.

Single Mode Continuous Laser Operation

Lasers can be operated in various regimes; some of them can be studied using the laser rate equations previously introduced:

$$\begin{aligned} \frac{dN_1}{dt} &= -\gamma_1 N_1 + \frac{\sigma S}{\hbar\omega}(N_2 - N_1) \\ \frac{dN_2}{dt} &= R_2 - \gamma_2 N_2 - \frac{\sigma S}{\hbar\omega}(N_2 - N_1) \\ \frac{1}{c}\frac{\partial S}{\partial t} + \frac{\partial S}{\partial z} &= \sigma S(N_2 - N_1) + \frac{R_{sp}}{c} - \frac{\gamma_c}{c} S \end{aligned} \qquad [40]$$

where the added spontaneous emission rate R_{sp} reminds one of the origin of the starting seed, and a loss term for the laser field has been inserted to account for both useful mirror output coupling and residual, undesirable losses due to intracavity absorption and scattering. According to [6], these are collectively given by

$$\begin{aligned} \frac{\gamma_c}{c} &= -\frac{\ln(R) + \ln(1 - L_i)}{2\ell} \\ &\approx \frac{(1 - R) + L_i}{2\ell} \end{aligned} \qquad [41]$$

where the approximation applies in the low loss limit.

In many common situations, the intensity $S(t)$ is approximately uniform along the cavity axis. Assuming this approximation, and taking into account the different lengths of the gain medium and the cavity, the final form of [40] becomes

$$\begin{aligned} \frac{dN_1}{dt} &= -\gamma_1 N_1 + \frac{\sigma S}{\hbar\omega}(N_2 - N_1) \\ \frac{dN_2}{dt} &= R_2 - \gamma_2 N_2 - \frac{\sigma S}{\hbar\omega}(N_2 - N_1) \\ \frac{dS}{dt} &= \frac{c\sigma\ell}{L} S(N_2 - N_1) + R_{sp} - \gamma_c S \end{aligned} \qquad [42]$$

which are the single-mode rate equations.

Under steady-state conditions, the rates of change of both population inversion and intensity are set to zero, and neglecting the small R_{sp} contribution, from [42] it follows

$$\begin{aligned} g(\omega, S) &= \frac{g_0(\omega)}{1 + S/S_{sat}} \\ 0 &= \left[\frac{c\ell}{L}\, g(\omega, S) - \gamma_c\right] S \end{aligned} \qquad [43]$$

where the first equation gives the saturated gain already derived in [23], with $S_{sat} = (\hbar\omega\gamma_2/\sigma)$, and $g_0 = \sigma(N_2 - N_1)_0 = \sigma R_2/\gamma_2$. Below threshold, the optical intensity remains zero until the pumping rate has grown high enough to bring the small signal gain at the threshold. Thus, g_0 grows linearly with the pump rate, and at threshold it results

$$\begin{aligned} &\frac{c\ell}{L}\, g_{th} = \frac{c\ell}{L}\, g_{0th} = \frac{c\ell}{L}\, \frac{\sigma R_{2th}}{\gamma_2} = \gamma_c \\ &R_{2th} = \frac{L}{c\ell}\, \frac{\gamma_2 \gamma_c}{\sigma} \end{aligned} \qquad [44]$$

Above threshold, $g(\omega,S)$ remains clamped to its threshold value, since $S \neq 0$ and it cannot be under the steady-state hypothesis:

$$\left[\frac{c\ell}{L}\, g(\omega, S) - \gamma_c\right] S > \left[\frac{c\ell}{L}\, g_{0th} - \gamma_c\right] S = 0 \qquad [45]$$

The result is

$$\frac{g_0}{1 + S/S_{sat}} = g_{0th} \qquad [46]$$

and for the internal intensity

$$S = S_{sat}\left(\frac{g_0}{g_{0th}} - 1\right) = S_{sat}\left(\frac{R_2}{R_{2th}} - 1\right) \qquad [47]$$

which, far above threshold, becomes $S \approx (\ell/L)(cR_2\hbar\omega/\gamma_c)$.

The resonator output intensity is, in the low loss limit of [41],

$$\begin{aligned} S_{out} &= (1 - R)S \\ &= \frac{\ell}{L}(1 - R) S_{sat}\left[\frac{2g_0\ell}{(1 - R) + L_i} - 1\right] \end{aligned} \qquad [48]$$

which is plotted in **Figure 9** as a function of the output coupling $T = (1 - R)$.

From the figure it is clear that there is an optimum working point, obtained maximizing S_{out} with respect to the output coupling at fixed small signal gain (i.e., at fixed pump rate):

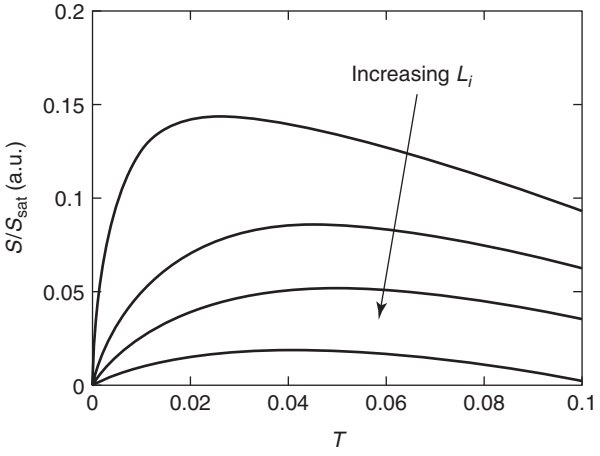

Figure 9 Output intensity as a function of outcoupling transmittance.

$$\begin{aligned} T_{opt} &= \sqrt{2g_0\ell L_i} - L_i \\ S_{out,opt} &= \frac{\ell}{L}\, S_{sat}(\sqrt{2g_0\ell} - \sqrt{L_i})^2 \end{aligned} \qquad [49]$$

which represents the working condition for well-engineered continuous wave-laser systems.

Laser Transients: Mode-Locking and Ultrashort Pulse Generation

In this section, time-dependent, transient effects are briefly discussed. There are distinctly two ways to generate powerful pulses, and which one is chosen depends on applications.

When high-power and high-energy are required, Q-switch operation is the preferred technique. This consists in keeping the Q of the resonator low at the beginning of the pump action, so that the population inversion can growth at a very high level; when this is achieved, the resonator Q is restored to its original value allowing an abrupt growth of the field to a high power concentrated in a short pulse. Q-switch can be discussed within the single-mode approximation of the previous section using eqn [44], even if fast transients always tend to bring many longitudinal modes into oscillation. Generally, this technique leads to nanosecond pulse durations, with single-pulse energies up to several hundreds of millijoules.

A different technique is used for the generation of ultrashort pulses, which find broad popularity in scientific, biomedical, and also, more recently, in industrial applications. This justifies a more in-depth description of how they are generated.

Short and ultrashort pulses generated by lasers have durations $< \sim 50$ and 1 ps, respectively. Laser media that allow such short pulses need to have wide spectral bandwidths to sustain their generation, since, according to Fourier relation, $\Delta\omega_g \tau_p \approx 2\pi$. The gain bandwidth $\Delta\omega_g$ is usually a fraction of the available spectral bandwidth. For example, the full bandwidth of the Nd:YAG allows pulses of ≈ 5 ps, while for many other laser materials this can be easily well below 1 ps.

If the number of longitudinal modes within the gain bandwidth is $N \approx \Delta\omega_g/(\pi c/L') = \Delta\omega_g T_R/2\pi$, where L' is the optical cavity length and T_R the round-trip time, an estimate from the Fourier relation gives $\tau_p \approx T_R/N$, so pulse duration depends on N. Nonetheless, this is not enough as the large number of longitudinal modes, that can be brought above threshold, tend to oscillate uncorrelated under free-running laser operation. In these conditions, the output intensity has a noisy pattern, and it is only when the modes are forced to maintain a fixed phase relationship to each other that the output as a function of time can vary in a well-defined manner. Under these conditions, the laser is said to operate in "mode-locking" regime.

Mode locking corresponds to correlating the spectral amplitudes and phases, so that the initial randomness is removed and a localized radiation pattern emerges that circulates in the laser cavity with a repetition rate of one per round trip, which appears at the output as a pulse train. The techniques that allow laser mode locking are modulation techniques implemented experimentally by placing inside the cavity either an externally driven loss or phase modulator, or a passive device which exhibits saturable absorption, which means (as for saturable gain) absorption diminishing at growing intensity. The shortest pulses, below 10 fs, have been obtained with passive techniques that are reviewed in full detail by Keller.

For the purpose of illustrating the principle, active mode locking is presented based on a time-domain model principally due to Haus, which is able to capture the main features of laser mode locking.

The model is not concerned with the starting mechanism itself, and assumes an already formed light pulse traveling inside the cavity. Looking for the conditions of self-reproducibility, let the field be

$$\boldsymbol{E} = \hat{\varepsilon} E(t) \qquad [50]$$

with

$$E(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} A(\omega)\, \mathrm{e}^{-\mathrm{i}\omega t}\, \mathrm{d}\omega \qquad [51]$$

$E(t)$ and $A(\omega)$ are Fourier transforms of each other, representing pulse envelopes in their domains at some position into the cavity.

Assuming a linear laser cavity of length L, containing a gain medium of length ℓ and gain coefficient with a frequency dependence $g(\omega) = g_0/[1+(\omega-\omega_0)^2/\Delta\omega_g^2]$, where g_0 is the saturated gain coefficient at the center frequency ω_0 of the gain medium, after one trip in the gain medium $A(\omega)$ becomes $\exp\{g_0\ell/[1+(\omega-\omega_0)^2/\Delta\omega_g^2]\}A(\omega)$.

The unavoidable cavity losses (either for output coupling or passive ones) can be modeled introducing a loss coefficient per unit length, so that the overall losses can be considered as $\alpha_i L_i$, with L_i an appropriate loss medium length. A passage through it produces the change $\exp(-\alpha_i L_i)A(\omega)$.

Finally, the essential element in the mode-locked laser is the modulator, for example, an active, externally driven acousto-optic device of loss coefficient α_m and length L_m, producing a time-dependent loss $\alpha_m L_m(1-\cos(\omega_m t))$ at the modulation frequency ω_m. This is best described in the time domain, affecting directly the field envelope after a passage through it, $\exp\{\alpha_m L_m(1-\cos(\omega_m t))\}E(t)$.

By taking the appropriate Fourier transforms to describe all the actions in the time domain, and assuming low net gain and low losses, so that only first-order terms in their expanded expressions are kept, after one round-trip time T_R, at the same space position,

$$E(t+T_R) = \left[1 + 2g_0\ell\left(1 + \frac{1}{\Delta\omega_g^2}\frac{\mathrm{d}^2}{\mathrm{d}t^2}\right) - 2\alpha_i L_i - 2\alpha_m L_m(1-\cos(\omega_m t)\right] E(t) \qquad [52]$$

Steady-state operation requires self-reproducibility, $E(t+T_R) = E(t)$, and for this to happen it needs

$$\omega_m = 2\pi/T_R$$

Since the pulse tends to adjust itself for minimum losses, the modulation function can be expanded up to its first nonzero contributed term, getting the final form of the mode-locking equation

$$\left[\frac{\mathrm{d}^2}{\mathrm{d}t^2} - \frac{\alpha_m L_m \omega_m^2 \Delta\omega_g^2}{2g_0\ell}\, t^2 + \Delta\omega_g^2\left(1 - \frac{\alpha_i L_i}{g_0\ell}\right)\right] E(t) = 0 \qquad [53]$$

This is written in a way that shows its similarity with the Schrödinger equation of one-dimensional harmonic oscillator:

$$\left[\frac{\mathrm{d}^2}{\mathrm{d}x^2} - \frac{m^2\omega^2}{\hbar^2}\, x^2 + \frac{2mE}{\hbar^2}\right]\psi(x) = 0 \qquad [54]$$

As for [54], eqn [53] has Hermite–Gauss solutions

$$E_n(t) = H_n(2\pi t/\tau_p)\exp\{-(2\pi t/\tau_p)^2/2\} \quad [55]$$

with

$$\frac{2\pi}{\tau_p} = \left(\frac{\alpha_m L_m \omega_m^2 \Delta\omega_g^2}{2g_0\ell}\right)^{1/4}$$
$$\left(1 - \frac{\alpha_i L_i}{g_0\ell}\right) = (2n+1)\left(\frac{2\pi}{\tau_p \Delta\omega_g}\right)^2 \quad [56]$$

Since as a rule the gain barely exceeds the loss, this last relation can be put into a more readable form as follows:

$$\frac{g_0\ell}{\alpha_i L_i}\left(1 - \frac{\alpha_i L_i}{g_0\ell}\right) = \left(\frac{g_0\ell - \alpha_i L}{\alpha_i L}\right)$$
$$= (2n+1)\left(\frac{2\pi}{\tau_p \Delta\omega_g}\right)^2 \frac{g_0\ell}{\alpha_i L_i}$$
$$\approx (2n+1)\left(\frac{2\pi}{\tau_p \Delta\omega_g}\right)^2 \quad [57]$$

which represents the excess gain over the threshold gain for continuous operation, needed to sustain a mode-locked Hermite–Gauss pulse of order n: higher orders need more gain.

It can be seen that gain saturation leads to the stability of lowest-order Gaussian pulse, and to the instability of higher-order solutions. If just the right net gain is supplied to excite the fundamental solution, higher-order ones do not have enough gain to start. If the supplied gain is in excess so that higher-order solutions can also start, the amplitude of the lowest order quickly grows to the point that it saturates the gain which settles it to its steady-state value, switching off the higher-order solutions.

It is thus seen from [55] that the pulse is Gaussian in shape; furthermore, from the first of [56] it is seen that the pulsewidth has a power dependence on both the modulation depth and the gain bandwidth.

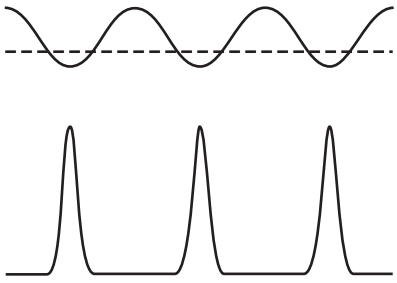

Figure 10 Gain and losses in an actively mode-locked laser, and its generated pulse train. The dotted line sets the net gain of the laser for continuous operation, and the extra, modulated loss are shown in full line above it. With periodicity of a round-trip time, a temporal window is opened in which the net gain is positive, and the pulses can go through, as shown in full line at the bottom. Pulse duration not to scale with round-trip time in the figure.

Figure 10 illustrates qualitatively the interplay of gain and losses in an actively mode-locked laser, and its Gaussian envelope pulses.

Introduction

Crystal lattice dynamics is based on the concept of phonons, that is, weakly interacting waves of atomic (or ionic) vibrations and corresponding quasiparticles (according to a corpuscular-wave dualism of the quantum physics, any excitation wave in a system can also be described as a particle). Due to the smallness of typical atomic displacements, $\bar{u}$ in crystals in comparison with interatomic distances d, one can pass rigorously from a problem of strongly interacting "particles" forming the crystal (atoms, ions, or molecules) to a problem of weakly

interacting "quasiparticles" (phonons). In the leading order in the smallness parameter $\eta = \bar{u}/d$, the crystal lattice dynamics and thermodynamics can be described in terms of an ideal phonon gas (harmonic approximation). For the ground state, the harmonic approximation can be justified rigorously on the basis of the adiabatic (Born–Oppenheimer) approximation of quantum mechanics due to the smallness of the ratio of the electron mass, m to the atomic (or ionic) mass M. With the increase in temperature T, the parameter η increases as well; however, due to a semi-empirical Lindemann criterion $\eta \simeq 0.1$ at the melting point $T = T_m$, higher-order contributions to thermodynamic properties are usually small up to the melting temperature. This statement is true for most of the average characteristics. At the same time, for some peculiar modes, the harmonic approximation can be completely inadequate, especially in the vicinity of some structural transformations, such as ferroelectric phase transitions or martensitic transformations in metals (soft modes). It is not sufficient also for quantum crystals, such as solid He^3 and He^4. Even in a generic case, some phenomena can be understood only beyond the picture of the ideal phonon gas, which means beyond the harmonic approximation. All these phenomena are called anharmonic. There are anharmonic effects in the crystal lattice thermodynamics (thermal expansion, temperature dependences of elastic moduli, etc.), kinetics (phononphonon scattering processes which are responsible for the thermal conductivity of insulators), and dynamics (phonon damping and temperature dependences of the phonon frequencies measured by the inelastic neutron scattering method).

Formulation of the Problem

In the adiabatic approximation, one can split the quantum-mechanical problem of the crystal into an electronic (a solution of the Schrödinger equation for fixed coordinates of nuclei $\{\boldsymbol{r}_j\}$) and a nuclear one which is the base of the theory of crystal lattice properties. Keeping in mind the smallness of the atomic displacements $\eta \ll 1$, one can expand the energy of the nuclei $V(\{\boldsymbol{r}_j\})$ into the displacement vectors $\boldsymbol{u}_j = \boldsymbol{r}_j - \boldsymbol{R}_j$, $\boldsymbol{R}_j$ being the equilibrium lattice positions:

$$V(\{\boldsymbol{r}_j\}) = V_0 + \frac{1}{2}\sum_{j_1 j_2 \alpha_1 \alpha_2} V^{\alpha_1\alpha_2}_{j_1 j_2}\, u^{\alpha_1}_{j_1} u^{\alpha_2}_{j_2} + \frac{1}{6}\sum_{j_1 j_2 \alpha_1 \alpha_2} V^{\alpha_1\alpha_2\alpha_3}_{j_1 j_2 j_3}\, u^{\alpha_1}_{j_1} u^{\alpha_2}_{j_2} u^{\alpha_3}_{j_3} + \cdots,$$

$$V^{\alpha_1 \ldots \alpha_n}_{j_1 \ldots j_n} = \left(\frac{\partial^n V}{\partial u^{\alpha_1}_{j_1} \ldots u^{\alpha_n}_{j_n}}\right)_{u=0} \qquad [1]$$

where α_j are Cartesian indices and the linear term is absent due to the equilibrium conditions. The harmonic approximation corresponds to taking into account only the quadratic term in the expansion [1]. Then the nuclear Hamiltonian, which is the sum of the potential energy V and the kinetic energy of nuclei, can be represented as a sum of the Hamiltonians of independent oscillators (phonons) by the transformation

$$\boldsymbol{u}_j = \sum_\lambda \sqrt{\frac{\hbar}{2M_j N_0 \omega_\lambda}}\, A_\lambda \boldsymbol{e}_\lambda \exp(\mathrm{i}\boldsymbol{q}\boldsymbol{R}_j),$$
$$A_\lambda = b_\lambda + b^\dagger_{-\lambda} \qquad [2]$$

where N_0 is the number of unit cells in the crystal, M_j is the mass of the jth nucleus, $\lambda \equiv \boldsymbol{q}\xi$ are the phonon quantum numbers ($\boldsymbol{q}$ is the wave vector running the Brillouin zone and ξ is the polarization index, $-\lambda \equiv -\boldsymbol{q}\xi$), $\boldsymbol{e}_\lambda$ is the polarization vector, b_λ and $b^\dagger_\lambda$ are the annihilation and creation phonon operators. In the phonon representation, the total Hamiltonian of the crystal lattice has the form

$$H = V_0 + H_0 + \sum_{k=3}^{\infty} H^{(k)},$$
$$H_0 = \sum_\lambda \hbar\omega_\lambda \left(b^\dagger_\lambda b_\lambda + \frac{1}{2}\right),$$
$$H^{(k)} = \sum_{\lambda_1 \ldots \lambda_k} \frac{\Phi^{(k)}_{\lambda_1 \ldots \lambda_k}}{k!} A_{\lambda_1} \ldots A_{\lambda_k} \qquad [3]$$

where H_0 is the Hamiltonian of the ideal phonon gas (the harmonic approximation) and the multiphonon scattering matrix elements $\Phi^{(k)}_{\lambda_1 \ldots \lambda_k}$ are proportional to the *kth* derivatives of the potential energy and the factors $\sqrt{\hbar/2M_j\omega_{\lambda_i}}$. These matrix elements describe the processes of phonon–phonon interaction, such as a merging of two phonons into one or, vice versa, a decay of a phonon into two ($k = 3$), scattering of two phonons into two new states ($k = 4$), etc. The anharmonic effects connected with these interactions are called self-anharmonic. There is also another kind of anharmonic effect which is connected to the dependence of the phonon frequencies ω_λ on the interatomic distances in the Hamiltonian H_0. These effects are called quasiharmonic. They are characterized by the microscopic Grüneisen parameters

$$\gamma_\lambda = -\frac{\partial \ln \omega_\lambda}{\partial \ln \Omega} \qquad [4]$$

where Ω is the crystal volume. For noncubic crystals, the dependence of ω_λ on shear deformations should also be considered. The point is that for harmonic oscillators described by the quadratic potential energy and, correspondingly, by linear interatomic forces, the frequencies are not dependent either on the

amplitudes of oscillations or on the equilibrium positions. Due to nonlinear (anharmonic) effects, there are renormalizations of the frequencies. Up to the lowest order η^2, one should take into account the quasiharmonic effects and the self-anharmonic effects with $k = 3$ and 4.

Thermodynamics

Thermal Expansion

Thermal expansion, characterized by the coefficient,

$$\alpha_p = \frac{1}{\Omega}\left(\frac{\partial\Omega}{\partial T}\right)_p \qquad [5]$$

(T is the temperature and p is the pressure) equals to zero in harmonic approximation. This can be easily proved from the Gibbs distribution for the potential energy V, which is quadratic in the atomic displacements $\boldsymbol{u}_j$ (and, moreover, if it is just an arbitrary even function of $\boldsymbol{u}_j$). It can be calculated by using the known thermodynamic identity

$$\left(\frac{\partial\Omega}{\partial T}\right)_p = -\left(\frac{\partial S}{\partial p}\right)_T \qquad [6]$$

where S is the entropy; as a consequence, due to the third law of thermodynamics, the thermal expansion coefficient should vanish at $T \to 0$. If one calculates the entropy in harmonic approximation but with the phonon frequencies dependent on the volume (quasiharmonic approximation), one can derive the Grüneisen law

$$\alpha_p = \frac{\gamma(T) C_V(T)}{\Omega B_T} \qquad [7]$$

where $B_T = -\Omega(\partial p/\partial\Omega)_T$ is the isothermal bulk modulus,

$$\gamma(T) = \frac{\sum_\lambda \gamma_\lambda C_\lambda}{\sum_\lambda C_\lambda},$$
$$C_\lambda = \left(\frac{\hbar\omega_\lambda}{k_B T}\right)^2 \frac{\exp(\hbar\omega_\lambda/k_B T)}{[\exp(\hbar\omega_\lambda/k_B T) - 1]^2} \qquad [8]$$

is the macroscopic Grüneisen parameter (which is temperature independent assuming that $\gamma_\lambda = \text{const}$) and $C_V(T) = k_B \sum_\lambda C_\lambda$ is the constant-volume lattice heat capacity. It follows from eqn [7] that the temperature dependence of the thermal expansion coefficient at low and high temperatures is the same as for the heat capacity: $\alpha_p \sim T^3$ at $T \ll \theta_D$ (θ_D is the Debye temperature) and $\alpha_p \simeq \text{const}$ at $T \geqslant \theta_D$.

For noncubic crystals, one should introduce parameters characterizing the anisotropy of the thermal expansion $\alpha_i = \partial u_i/\partial T$, where u_i are different deformations, for example, for uniaxial crystals with c-axis different from a- and b-axes, one can introduce $du_1 = d\ln\Omega$ and $du_2 = d\ln(c/a)$. As a generalization of eqn [6], one can prove from the equilibrium conditions at finite temperatures

$$\alpha_i = \sum_j (B^{-1})_{ij}\left(\frac{\partial S}{\partial u_j}\right)_T \qquad [9]$$

where $B_{ij} = (1/\Omega)(\partial^2 F/\partial u_i \partial u_j)$ is the matrix of isothermal elastic moduli and F is the free energy. In particular, for the uniaxial crystals

$$\left(\frac{\partial \ln c}{\partial T}\right) = \frac{1}{3BB_{22}}\left[(B_{22} - 2B_{12})\frac{\partial S}{\partial u_1} + (2B_{11} - B_{12})\frac{\partial S}{\partial u_2}\right]$$
$$\left(\frac{\partial \ln a}{\partial T}\right) = \frac{1}{3BB_{22}}\left[(B_{22} + B_{12})\frac{\partial S}{\partial u_1} - (B_{11} + B_{12})\frac{\partial S}{\partial u_2}\right] \qquad [10]$$

where $B = B_{11} - B_{12}^2/B_{22}$ is the bulk modulus of the uniaxial crystal.

Temperature Dependence of Elastic Moduli

Temperature dependence of the elastic moduli B_{ij} is another important anharmonic effect. This temperature dependence in quasiharmonic approximation results from the ideal phonon gas contribution to the free energy, $F_{ph} = -k_B T \sum_\lambda \ln[2\sinh(\hbar\omega_\lambda/2k_B T)]$, and from the volume dependence of the electronic contributions to the moduli. As a result, both terms behave as $\delta B_{ij} \propto -T^4$ at $T \ll \theta_D$ and $\delta B_{ij} \propto -T$ at $T \geqslant \theta_D$. Normally, this contribution is negative (elastic moduli decrease with the temperature increase), but for some shear moduli in peculiar cases an opposite behavior sometimes takes place (acoustic soft modes), usually near the structural phase transitions. Empirically, for many cubic crystals the trigonal shear modulus B_{44} at the melting point is 55% of its value at zero temperature (Varshni melting criterion).

Lattice Heat Capacity at High Temperatures

In harmonic approximation, the molar constant-volume heat capacity at $T \gtrsim \theta_D$ is independent of both the temperature and the chemical composition of the crystal: $C_V = 3R$ (Dulong–Petit law, $R \simeq 8.3144\ \text{J mol}^{-1}\ \text{K}^{-1}$ is the gas constant). Self-anharmonic effects lead to linear temperature dependence of the heat capacity, $\delta C_V \sim R\eta^2 \sim R(k_B T/E_{coh})$

where E_{coh} is a typical energy of the chemical bonding. These terms arise from both three-phonon and four-phonon processes (the second-order perturbation effect in $H^{(3)}$ and the first-order one in $H^{(4)}$, see eqn [3]):

$$C_V^{(3)} = \frac{4k_B^2 T}{3} \sum_{\boldsymbol{k}q\xi\eta\varsigma} \frac{|\Phi^{(3)}_{\xi\boldsymbol{k};\eta q;\varsigma,-\boldsymbol{k}-q}|^2}{\hbar^3 \omega_{\xi\boldsymbol{k}} \omega_{\eta q} \omega_{\varsigma,-\boldsymbol{k}-q}} \qquad [11]$$

$$C_V^{(4)} = -k_B^2 T \sum_{\boldsymbol{k}q\xi\eta\varsigma} \frac{\Phi^{(4)}_{\xi\boldsymbol{k};\xi,-\boldsymbol{k};\eta q;\eta,-q}}{\hbar^2 \omega_{\xi\boldsymbol{k}} \omega_{\eta q}} \qquad [12]$$

The three-phonon contribution [11] is always positive (the growth of C_V with the increase in the temperature), whereas the four-phonon one [12] can be, in principle, of arbitrary sign. Experimental separation of the self-anharmonic contribution to the lattice heat capacity is a difficult problem since it has, in general, the same order of magnitude and temperature dependence as the difference

$$C_P - C_V = T\Omega B_T \alpha_p^2 \qquad [13]$$

(C_P is the experimentally measurable heat capacity at a constant pressure) and, in metals, as the electron heat capacity.

Phonon Spectra and Damping

Temperature Dependences of Phonon Frequencies

According to classical mechanics, for a generic nonlinear system, the oscillation frequencies are dependent on the oscillation amplitudes. Therefore, one can expect that anharmonic effects lead to the temperature-dependent phonon spectra, due to growth of average oscillation amplitudes with the increase in temperature. In quantum terms, the same effect can be described as an appearance of the phonon self-energy due to the phonon–phonon interaction processes. Up to the second order in the smallness parameter η, the temperature shift of the phonon frequency ω_λ is determined by the following expression:

$$\Delta\omega_\lambda = \Delta_\lambda^{(\text{qh})} + \Delta_\lambda^{(3)} + \Delta_\lambda^{(4)} \qquad [14]$$

where $\Delta_\lambda^{(\text{qh})} = -\gamma_\lambda \Delta\Omega(T)/\Omega$ is the quasiharmonic contribution due to the temperature dependence of the crystal volume $\Omega(T)$, and $\Delta_\lambda^{(3)}$ and $\Delta_\lambda^{(4)}$ are the contributions of the three-phonon and four-phonon processes, correspondingly:

$$\begin{aligned}\Delta_{\xi\boldsymbol{k}}^{(3)} = &-\frac{1}{2\hbar^2}\mathscr{P}\sum_{q\eta\varsigma} |\Phi^{(3)}_{\xi\boldsymbol{k};\eta q;\varsigma,-\boldsymbol{k}-q}|^2 \\ &\times \left(\frac{1 + N_{\eta q} + N_{\varsigma,\boldsymbol{k}+q}}{\omega_{\eta q} + \omega_{\varsigma,\boldsymbol{k}+q} + \omega_{\xi\boldsymbol{k}}} + \frac{1 + N_{\eta q} + N_{\varsigma,\boldsymbol{k}+q}}{\omega_{\eta q} + \omega_{\varsigma,\boldsymbol{k}+q} - \omega_{\xi\boldsymbol{k}}} \right. \\ &+ \frac{N_{\eta q} - N_{\varsigma,\boldsymbol{k}+q}}{\omega_{\varsigma,\boldsymbol{k}+q} - \omega_{\eta q} - \omega_{\xi\boldsymbol{k}}} \\ &\left. - \frac{N_{\eta q} - N_{\varsigma,\boldsymbol{k}+q}}{\omega_{\eta q} - \omega_{\varsigma,\boldsymbol{k}+q} - \omega_{\xi\boldsymbol{k}}} \right) \end{aligned} \qquad [15]$$

$$\Delta_{\xi\boldsymbol{k}}^{(4)} = \frac{1}{2\hbar} \sum_{q\eta} \Phi^{(4)}_{\xi\boldsymbol{k};\xi,-\boldsymbol{k};\eta q;\eta,-q} (1 + 2N_{\eta q}) \qquad [16]$$

where $\mathscr{P}$ is the principal value symbol and $N_\lambda = (\exp \hbar\omega_\lambda / k_B T - 1)^{-1}$ is the Planck function. At high temperatures $T \gtrsim \theta_D$, one can use the classical asymptotic $N_\lambda \simeq k_B T/\hbar\omega_\lambda$ and see that all three contributions in eqn [14] are linear in temperature. Usually, the phonon frequencies decrease with the temperature increase; a typical behavior is shown in **Figure 1** (upper panel). However, for the soft modes, $d\omega_\lambda/dT > 0$, as it is illustrated by **Figure 2**. In the framework of the perturbation theory, this behavior is connected with the contribution $\Delta_\lambda^{(4)}$.

Phonon Damping

Beyond the harmonic approximation, the phonons cannot be considered as stable quasiparticles; for example, due to the three-phonon processes, they can decay into couples of other phonons. As a result, the phonon damping arises (which can be measured experimentally as a half-width of phonon peaks in inelastic neutron scattering spectra). In the lowest-order perturbation theory, the damping, or the inverse phonon lifetime, is equal to

$$\begin{aligned}\Gamma_{\xi\boldsymbol{k}} = &\frac{\pi}{2\hbar^2} \sum_{q\eta\varsigma} |\Phi^{(3)}_{\xi\boldsymbol{k};\eta q;\varsigma,-\boldsymbol{k}-q}|^2 \{(1 + N_{\eta q} + N_{\varsigma,\boldsymbol{k}+q}) \\ &\times \delta(\omega_{\eta q} + \omega_{\varsigma,\boldsymbol{k}+q} - \omega_{\xi\boldsymbol{k}}) + (N_{\eta q} - N_{\varsigma,\boldsymbol{k}+q}) \\ &\times [\delta(\omega_{\varsigma,\boldsymbol{k}+q} - \omega_{\eta q} - \omega_{\xi\boldsymbol{k}}) \\ &- \delta(\omega_{\eta q} - \omega_{\varsigma,\boldsymbol{k}+q} - \omega_{\xi\boldsymbol{k}})]\} \end{aligned} \qquad [17]$$

The delta functions in eqn [17] correspond to the energy and momentum conservation laws for the decay processes. At high temperatures $T \gtrsim \theta_D$, the damping is linear in T (see **Figure 1**, lower panel). Note that, both the damping and the frequency shift do not vanish at $T = 0$ where all $N_\lambda = 0$. These residual effects are due to quantum zero-point oscillations; they are of the order of $\sqrt{m/M}$ and small, in general (with the exception of the quantum crystals). For

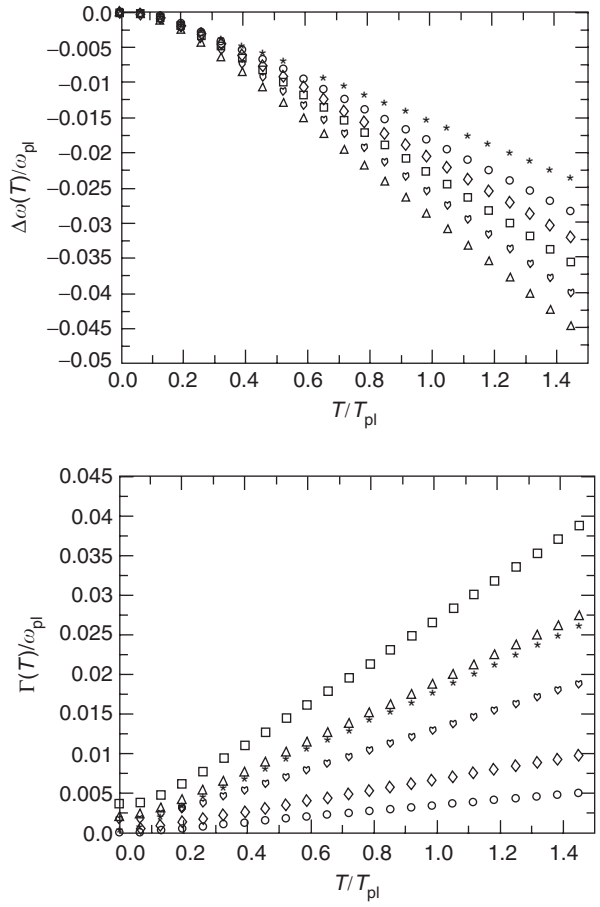

Figure 1 Temperature dependences of the frequency shifts (upper panel) and phonon damping (lower panel) for different phonon modes at the symmetric points of the Brillouin zone for face-centered cubic (f.c.c) phase of calcium. $\omega_{pl} = (4\pi Ze^2/M\Omega_0)^{1/2}$ is ionic plasma frequency, Z, M, and Ω_0 are the valency, ionic mass, and atomic volume, respectively, $T_{pl} = \hbar\omega_{pl}/k_B = 476$ K is the corresponding temperature. Asterisks and hearts label different phonon modes for L point, circles and triangles for W point, and squares and diamonds for X point. (From Katsnelson MI, Trefilov AV, Khlopkin MN, and Khromov KYu (2001) *Philosophical Magazine B* 81: 1893.)

acoustic phonons with $q \to 0$, the damping [17] is linear in q, as well as in the phonon frequency; however, this is not true for the case $ql \ll 1$, where l is the phonon mean free path. For this regime, according to general hydrodynamics consideration, the damping behaves like $q^2 l$.

For strongly anharmonic modes, the phonon damping can be comparable with the frequency; phonons are not well-defined in such a situation (high-temperature body-centered cubic (b.c.c) phases of Ti and Zr can be considered as examples). The perturbation theory reviewed here can also be insufficient under resonance conditions, where the frequency ratio for different phonons with the same wave vector is close to 1:2, 1:3, etc.

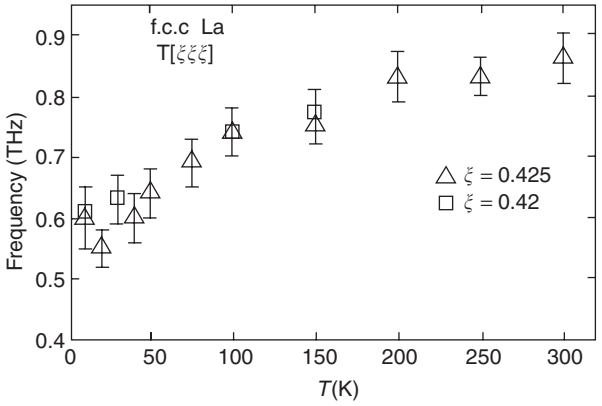

Figure 2 Temperature dependence of the phonon frequencies of the $T[\xi\xi\xi]$ phonon branch in (f.c.c) lanthanum in the soft mode region. (From Stassis C, Smith GS, Harmon BN, Ho KM, and Chen Y (1985) *Physical Review B* 31: 6298.)

Transport Properties

If one neglects phonon–phonon interactions as well as phonon scattering by any defects (impurities, different isotopes, crystal surface, etc.) and by other quasiparticles (conduction electrons in metals, spin waves in magnetic crystals, etc.), the mean free path $l = \infty$ which means, in particular, infinitely large thermal conductivity κ (any nonequilibrium distribution of the phonon momenta and energies conserves for an ideal phonon gas). This means that for the case of perfect, isotopically homogeneous, large enough insulating crystals, the anharmonic effects should determine the values and temperature dependences of both l and κ; they are connected by a simple relation:

$$\kappa = \frac{1}{3}\frac{C_V \bar{v} l}{\Omega} \qquad [18]$$

where $\bar{v}$ is a characteristic sound velocity. In principle, the same processes of phonon decay which are responsible for $\Gamma_{\xi k}$ contribute to the mean free path. However, for a continuum medium theory, any process of phonon–phonon interaction cannot lead to a finite thermal conductivity, since the momentum is conserved at any individual interaction act and any redistribution of the momenta among the phonons cannot change the energy current of the phonon gas as a whole. In crystals, Umklapp processes are possible when the momentum is conserved with the accuracy of some nonzero reciprocal lattice vector $\mathbf{g}$, and only these processes lead to the relaxation of the energy current and to finite κ. The energy conservation law for the Umklapp processes results in the appearance of some finite activation energy so that $l \propto \exp(\text{const} \times \theta_D/T)$ at $T \to 0$. For the very small temperatures, when the phonon mean free path is larger than the crystal size L, one should replace $l \to L$

in eqn [18] and thus $\kappa \propto C_V \propto T^3$. For high temperatures $T \geqslant \theta_D$, one has $\kappa \propto l \propto 1/T$.

Lattice Dynamics: Aperiodic Crystals

J-B Suck, Chemnitz University of Technology, Chemnitz, Germany

Introduction

Crystals with aperiodic structure are solids with long-range order (LRO) in the atomic positions but no translational invariance of a unit cell position. Their Fourier module consists of sharp diffraction spots, proving their LRO, which includes a long-range bond orientational order (BOO). The wave vectors Q of these diffraction spots can be represented by the sum over integer multiples of a number of rationally independent basis vectors, k, which span the Fourier module of the aperiodic crystal:

$$Q = \sum_{i=1}^{n} m_i k_i \qquad [1]$$

In contrast to periodic crystals, where the number of rationally independent basis vectors is equal to the dimension of the crystal (and of its periodic reciprocal lattice), for aperiodic crystals n exceeds the dimension of the space, in which the crystal is embedded. The minimal necessary number of independent basis vectors defines the "rank" of the Fourier module, which is finite in the quasiperiodic case. In a space of dimension n (the n-dim space), the crystal structure, aperiodic in three-dimensional (3D) Euclidean space, can be presented as a "periodic" structure with a unit cell, which usually has a relatively simple structure. Generally, the aperiodic structure can be obtained by an appropriate intersection of the n-dim periodic structure with the physical space, in which the aperiodic structure is observed. For quasicrystals (QCs), this intersection involves the intersection of the n-dim lattice with the physical space, which has an "irrational" slope relative to the orientation of the n-dim lattice. After a small change of this slope to a rational value, this intersection will lead to a crystal in physical space, which is periodic, but locally has a structure similar to the QCs. Such crystals are called "approximants" (to the corresponding QCs), the dynamics of which are discussed below as well.

Incommensurably modulated crystals, incommensurate composites, and QCs all belong to the aperiodic crystals. However, in some of their fundamental properties, they are different from each other. Therefore, the restriction to one or the other of them is mentioned explicitly as has just been done for QCs. Assuming that the physical (direct, external, or parallel) space, by which the n-dim space is intersected, is 3D, the remaining $(n-3)$-dimensional subspace is the "internal" or "perpendicular" (perp) space, which in the case of an incommensurably modulated crystal can be viewed as containing the information on the phase of the modulation function with respect to the original commensurate lattice, out of which the incommensurate phase developed. In view of the

atomic dynamics, it is important to realize that the additional dimensions belonging to the internal space can be interpreted as additional degrees of freedom not present in periodic crystals.

In n-dim space, the information about the atomic positions (density distribution) in the aperiodic structure in physical space is "stored" in $n-3$ dimensional hypersurfaces, for QCs called "atomic surfaces." The aperiodic structure is the intersection of the physical space with this periodic array of hypersurfaces. It depends on the shape of these atomic surfaces, and the consequences a shift of the physical space in the direction of the internal space will have on the aperiodic structure after the intersection: for continuous surfaces, it just results in a phase change of an incommensurate modulation. For disjunct atomic surfaces, as, for example, in the case of QCs, it leads to sudden changes of the atomic distribution, all of which, however, have the same energy. Thus, the ground state is infinitely degenerated. Likewise, a slow change of the modulation phase does not cost energy.

The Fourier module of the n-dim lattice is a periodic reciprocal n-dim lattice with sharp diffraction spots. This is the space in which inelastic scattering experiments are done to investigate the atomic dynamics. For incommensurate crystals, the 3D reciprocal space can be constructed on the basis of three reciprocal basis vectors. For QCs, which also contain rotation axes other than two-, three-, four-, and sixfold, one obtains the physical reciprocal space by a projection of the n-dim reciprocal space on the physical reciprocal space. Again, $n-3$ reciprocal lattice components belong to the reciprocal perpendicular space, and are usually called Q_{perp}. As the 3D projection plane in the n-dim reciprocal lattice has to have the same irrational slope with respect to the n-dim reciprocal lattice as the intersection in the n-dim real space had, all Bragg peaks of the n-dim reciprocal lattice will be projected into this hyperplane, as there is no mutual "shading" of different reflections because of the irrational slope. Thus, the Fourier module in this case consists of a dense set of Bragg reflections. In principle, this leads to infinitely many overlapping Brillouin zones and correspondingly to infinitely many gaps in the dispersion curves. Fortunately however, most of the Bragg peaks have an inmeasurably small intensity and can therefore be neglected, leading to a diffraction pattern with a finite number of intense Bragg (for single crystals) or Debye–Scherrer peaks (for polycrystals), the intensity of which is highest for peaks stemming from Bragg peaks in the n-dim Fourier module with smallest Q_{perp}. This fact enables the definition of pseudo-Brillouin zones (PBZs) next to reciprocal lattice points with highest Bragg peak intensity and dispersion relations for phonon and phase modes.

The dynamics of aperiodic phases has been studied most often by neutron inelastic scattering (NIS). Special questions such as the amplitudon mode and the central peak have been investigated by light scattering, and some experiments have also been done by X-ray inelastic scattering (XIS).

As aperiodic crystals usually contain more than one type of scatterer and different scatterers couple differently to the used probe, in all cases the total dynamic structure factor, $S(Q,\omega)$, was determined. For samples with n elements this is the weighted sum of the $n(n+1)/2$ partial dynamic structure factors, $S_{i,j}(Q,\omega)$, where the weights are given by the coupling strength to the probe (here NIS is used as an example in the following equation and consequently the scattering length b) and the atomic concentration c of each of the n elements:

$$\sigma S(Q,\omega) = 4\pi \sum \sum b_i b_j c_i c_j S_{i,j}(Q,\omega) + \sum \sigma_i^{\mathrm{inc}} c_i S_i^{\mathrm{s}}(Q,\omega) \quad (i,j=1,\ldots,n) \quad [2]$$

where σ are σ^{inc} are the total and the incoherent scattering cross sections and S_i^{s} is the self part of the dynamic structure factor of the element i. Alternatively, the single-particle motions can be investigated via the generalized vibrational density-of-states (GVDOS), which again is the weighted sum of the partial density-of-states of each element in the sample, weighted by the strength of the coupling of this element to the scattered probe (here for neutrons again):

$$G(\omega) = \frac{\sum w_i c_i g_i(\omega)}{\sum w_i c_i} \quad [3]$$

$$w_i = \frac{\mathrm{e}^{-2W_i}\sigma_{\mathrm{sc}}^i}{M_i} \quad [4]$$

Here, e^{-2W_i} is the Debye–Waller factor and M_i is the mass of the scatterer i. The density-of-states (DOS), as always, contains the information on the single-particle dynamics of the system, while the dynamic structure factor reflects also the collective atomic dynamics for coherent neutron scatterers, as is needed for measurements of dispersion relations.

In what follows, the vibrational modes (propagation and displacements in external space in the n-dim representation) and the phason modes (propagation in external space, displacements in internal space) of the three most often met aperiodic crystals, incommensurate modulated structures, incommensurate composites, and QCs are discussed separately.

Incommensurate Modulated Structures

Incommensurate modulated structures are crystal structures in which the atoms in the originally periodic lattice in the normal (N) phase have been displaced by a periodic (static) modulation function in the transition from the N to the incommensurate (I) phase, the period of this modulation being incommensurate with the periodicity of the original lattice. For a 3D crystal, eqn [1] can therefore be rewritten as

$$Q = ha^* + kb^* + lc^* + \sum_{i=4}^{n} m_i k_i \qquad [5]$$

where the first three terms describe the reciprocal lattice of the 3D basic (periodic) average structure, and a^*, b^*, c^*, and k_i are rationally independent. In reciprocal space, these structures (and with this also their dynamics) are characterized by a reciprocal lattice which contains the Bragg peaks of the original periodic lattice plus satellites from the incommensurate modulation. Due to the fact that incommensurate structures often form as a consequence of frustration caused by competing interactions, the incommensurate phase normally exists only within a certain temperature (and pressure) range, which is bounded by two transition temperatures, T_I and T_c. $\Delta T = T_I - T_c$ is, in some cases, only a few degrees wide, can, however, also extend down to $T_c = 0\,K$. If $T_c > 0\,K$, the wavelength of the modulation locks-in at T_c onto a rational fraction of the underlying (the main) lattice periodicity, either in a strongly discontinuous manner or by disappearance of phase defects. In contrast to this, the transition into the incommensurate phase at T_I is a second-order phase transition with a well-defined order parameter. From the viewpoint of the atomic dynamics, this transition from the periodic basis structure to the aperiodic modulation is normally associated with the softening of a phonon branch and the appearance of a Lorentzian shaped central peak at zero energy, part of which is most likely of dynamical origin also. The softening (additional (broad) minimum in the dispersion branches (see **Figure 2**)) of the dispersion occurs at a wave vector, which will become the modulation wave vector of the incommensurate phase as is shown in **Figure 1**.

For continuous modulation functions, theory (excluding the influence of defects) predicts a softening down to a zero frequency mode, with a finite phason gap for interruptions of the continuity of the modulation function by defects. Experimentally, the soft mode branch finishes at T_I with a finite frequency, which however, because of the strong overdamping

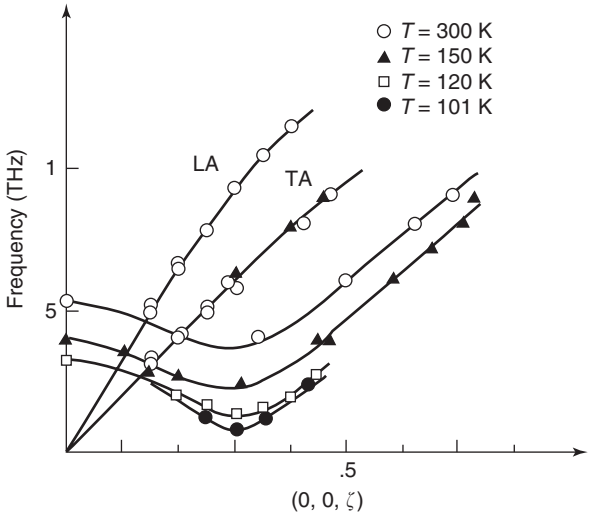

Figure 1 Mode softening in ThBr above the transition into the incommensurate modulated phase at T_I. Approaching T_I from higher T, the modes show a frequency decrease next to the modulation wave vector $q_s = 3.1\,nm^{-1}$, which arrives close to $\omega = 0$ in the I-phase.

of the soft mode, often cannot be resolved in NIS experiments. In the I-phase, this branch will then split up into two branches, the "amplitudon" (acoustic like) and the "phason" branches, the latter being related to a continuous shift of the modulation function with respect to the lattice. Near T_c, discommensurations (see below) develop which always lead to a finite gap for the phason mode, called "phason gap." The intensity of the acoustic modes is proportional to the intensity of the Bragg peak or satellite reflection at the Γ-point. This enables the identification of the phason mode, which is too intense for being an acoustic mode at the (weak) satellite reflection. In addition, the slope of the phason dispersion is lower than that of the lowest acoustic mode. The corresponding dispersion relations are shown in **Figure 2**.

While the amplitudon branch will increase with decreasing temperature (normal hardening of the acoustic phonons on temperature decrease), the phason energy may be temperature independent, as has been demonstrated for $(ClC_6D_4)_2SO_2$, for which the phason gap ($\sim 80\,GHz$) could be resolved. The temperature dependence of the width of the modes $\Gamma(T)$ is expected to be approximately the same for all three modes, which meet at the incommensurate modulation wave vector q_s.

The theoretical description of the atomic dynamics of the incommensurate phases often makes use of the periodicity of the corresponding crystals when lifted into n-dim space or applies models for the incommensurate structure in real space. Most of the

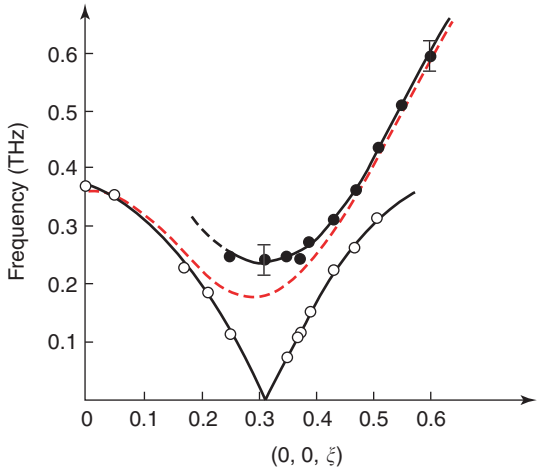

Figure 2 Phason and amplitudon branches next to the incommensurate modulation vector at 3.1 nm^{-1} in ThBr below T_I.

experimental results for incommensurate modulated crystals have been modeled very successfully using the discrete frustrated Φ^4 (DIFFOUR) model near the phase transition, where the modulation amplitude is still small. At temperatures well below T_I, the modulation amplitude may become rather large. As a consequence of this, a transition from a continuous to a discontinuous modulation function takes place, which means that the atomic surfaces are no longer continuous and smooth. This is always the case for QCs, where the atomic surfaces are generally discrete bounded objects. In the other two aperiodic crystals, modulated and composite, however, such a transition, a "discommensuration transition," may take place, resulting in domains with a structure close to a commensurate superstructure, separated by strongly incommensurate domain walls, sometimes called solitons. In this case, the description of the atomic dynamics has to also take into account an harmonic and nonlinear contributions. This situation was successfully described using the incommensurate version of the Frenkel–Kontorova model.

The transition occurs in metals and insulators for different reasons: in metals, an incommensurability of the Fermi wave vector with the basis lattice periodicity leads to a Peierls instability, which gives rise to the lattice dynamical precursor effects (local softening of the longitudinal acoustic branch) near the ordering vector, $2\boldsymbol{k}_F$. In insulators, the incommensurate structure either results from an intrinsic lattice instability, which corresponds to the "displacive" limit, or from a collective ordering mode in the "order–disorder limit." In these cases, the corresponding modulation wave vector is not predictable beforehand. Thus, the lattice dynamics is at the origin of these modulated phases.

Incommensurate Composites

Different from the crystals with incommensurate modulation, which is the only aperiodic structure, where a dominant "parent" periodic structure persists, incommensurate composites can be imagined to be made up of two (or more) interpenetrating periodic sublattices, the unit cell parameters of which are mutually incommensurate. Each of these sublattices, modeled by the incommensurate double chain model (DCM), pertain, to a large extent, to their dynamical characteristics as far as phonons are concerned. Thus, for example, two longitudinal acoustic branches have been found in $Bi_2Sr_2CaCu_2O_{8+\delta}$, which consists of two sublattices, one for each subsystem. However, as all aperiodic lattices, they also have phason degrees of freedom, which in this case concerns the phase between the two sublattices, which changes when one sublattice slides against the other, leading to "sliding modes," as predicted by the DCM. Whether or not these sliding modes have been observed experimentally is still under debate. As in the case of modulated crystals, these simplified descriptions are only valid as long as the interaction between the mutually incommensurate systems is not too strong. It is very likely that phasons are primarily "diffusive" in incommensurate composites, but considerably less experimental information exists on these systems than on the incommensurably modulated phases discussed above.

Quasicrystals

1D, 2D, and 3D QCs have been found, of which the 1D QCs consist of an aperiodic stacking (e.g., in a Fibonaci sequence) of periodic lattice planes. 2D QCs are made up of lattice planes with a quasiperiodic structure with pentagonal, octagonal, decagonal, or dodecagonal point symmetry, which are stacked periodically. Finally, 3D quasiperiodic structures have aperiodic lattices with icosahedral point symmetry.

The atomic structure of 2D and 3D QCs is based on "atomic clusters" of 1–2 nm diameter. In 2D QCs, these are cylindrical clusters made up of a stacking of the quasiperiodic lattice planes, neighboring planes often being rotated against one another, often with some "filling" atoms between the clusters. The atomic structure is dense. 3D QCs, the icosahedral ones, can be roughly divided into two classes on the basis of the dominant type of cluster characteristic of their structure: Mackay clusters and Bergman clusters, where the latter are also characteristic of the Frank–Kasper type of periodic crystals with many atoms per unit cell. As 2D QCs are often "relatives"

of the icosahedral phases, here these QCs are put in the same category as their icosahedral neighbors. Because the atomic dynamics is dominated by the type of atomic interaction (interaction potential) and the "local" structure, one expects that the type of cluster, which dominates the local environment of the vibrating atom, will influence the phonon dynamics.

Concerning the phasonic motions (displacements in internal space), one distinguishes two possible phasonic modes (apart from the static-phason strain): "phason flips," which only cause a local change in the phase of the aperiodic lattice by a (mostly collective) jump of a few neighboring atoms, leading to a "violation" of the matching rules of the perfect quasiperiodic lattice. These have to be distinguished from "phasons," which are collective diffusive modes. These are different from the incommensurate modulated phases due to the fact that QCs always have discontinuous aperiodic modulation because of the discrete bounded atomic surfaces, which cause jumps or discontinuities in the modulation function, when moving in internal space.

Of these structures, up to now, the atomic dynamics of mainly icosahedral (i-) and decagonal (d-) QCs has been investigated using NIS, XIS, and X-ray intensity correlation techniques. On single crystals, using crystal spectrometers, dispersion curves for acoustic phonons and some low-lying optic branches have been measured. On polycrystalline samples, bands at intermediate energies and the GVDOS have been determined by time-of-flight (TOF) spectroscopy for several metastable and nearly all stable quasicrystalline samples from the total dynamic structure factor, which one measures in all these cases. For i-AlCuFe also, the Fe partial density-of-state was measured using XIS and ^{57}Fe substitution. Quasielastic neutron scattering (QENS) was used on polycrystalline samples and an AlPdMn single crystal to measure phason flips and X-ray diffraction, and correlation techniques to investigate diffusing phasons in QCs. In the following, results from these four types of investigations will be discussed starting with the vibrational degrees of freedom in physical space.

Phonon Dispersions

Very characteristic for all phonon branches investigated so far is the important width of the phonon peaks in the measured spectra as soon as the modulus q of the wave vector $\boldsymbol{q}$ of the measured excitation exceeds a certain critical value, which essentially in all cases is ~ 3–$4\,\mathrm{nm}^{-1}$. The broadening of the peaks is of such an importance that the rapidly increasing width prevented measurements of excitations above energies of ~ 6–8 THz, even though the vibrational density-of-states (VDOS) often extends to twice that energy.

As an example, **Figure 3** shows some of the transverse acoustic branches measured with an AlPdMn single crystal along the twofold direction, the Γ point ($q = 0$, starting point of the dispersion) being one of the strongest Bragg peaks in this crystallographic direction. As the intensity of the inelastic structure factor is proportional to the intensity of the Bragg peak at the Γ point, and only next to a strong Bragg peak the PBZ is well defined, this choice is essential for the result of the experiment.

Figure 3 already demonstrates this very characteristic property of the lattice dynamics of QCs: the rapid damping of the lattice vibrations as soon as the wavelength of the excitation is smaller than ~ 2 nm, which in several cases is just the approximate diameter of the building unit. Corresponding results have also been obtained by computer simulations of icosahedral QCs, which show above the acoustic dispersion branches, rather dispersionless broadbands of optic modes, as they have also been found experimentally in some cases, and at even higher energies quasicontinuous spectra, which cannot be resolved in single excitations any more. This fact has limited so far the investigation of single excitations to energies below 8 THz, that is, to about half the upper energy limit of all vibrational excitations.

As is shown in **Figure 4**, for icosahedral QCs one finds "isotropic" dispersion branches for longitudinal and for transverse phonons, as these crystals, due to the high symmetry of the icosahedral structure, have – in the hydrodynamic limit – only two phonon elastic constants (plus two phason elastic constants and a phonon–phason one). This has also been proven experimentally for the sound velocity. In contrast, the sound "absorption" is anisotropic because of phonon–phason coupling.

For 2D QCs, computer simulations had predicted some anisotropies concerning lattice modes with polarization vectors in the aperiodic plane and in the periodic direction, respectively. However, experimentally the differences observed for d-AlCoNi (Mackay-type) single crystals using NIS are much less important and not far outside the error limits of the experimental results. Likewise, the gap structure of the dispersions, predicted for aperiodic lattices especially in low dimensions, has not clearly been confirmed experimentally up to now.

Above the acoustic branches, very few dispersionless branches of very broad excitations have been measured by NIS on single crystals by triple axis spectrometry (TAS) and extracted from $S(Q, \omega)$ measured on TOF spectrometers. Both results are

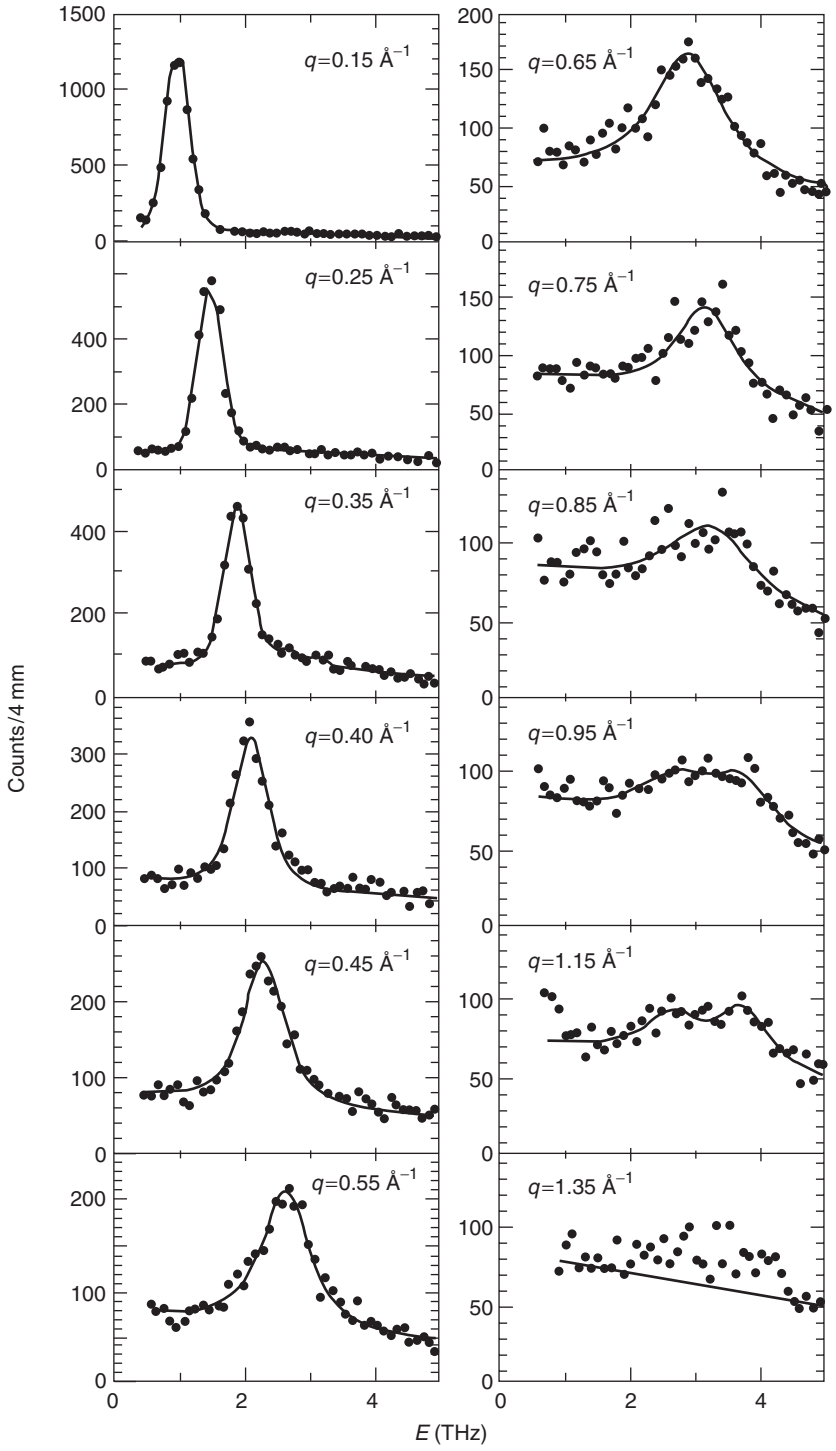

Figure 3 Spectra of transverse phonons measured by NIS at a strong Bragg peak in the twofold direction of an i-AlPdMn single crystal (Mackay type). The rapid increase of the phonon line width for $q > 4\,\mathrm{nm}^{-1}$ is obvious. The line width increases roughly proportional to q^2.

in good agreement. These excitations have been suggested to have the character of optic modes.

The phonon dispersions of QCs have been investigated in the accessible energy range (up to 4 THz in all cases, up to 6 THz for few examples, and up to 8 THz in one case) for most of the thermodynamically stable QCs using single crystals and mostly NIS and, in some cases, also XIS.

Generalized Vibrational Density-of-States

The energy range above 8 THz could be accessed by NIS up to now using only polycrystalline samples and

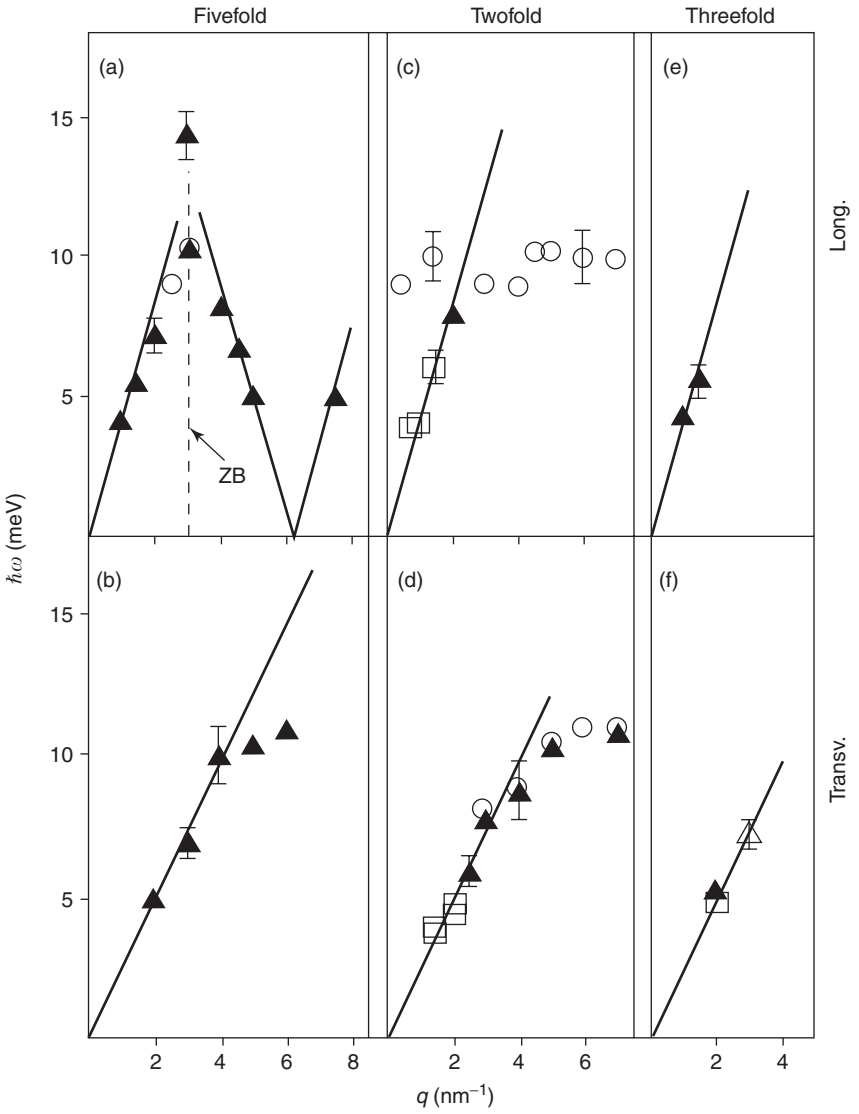

Figure 4 Dispersion of longitudinal and transverse phonons in i-AlLiCu (Frank–Kasper type) proving the isotropy of each of these excitations with respect to the three different crystallographic axes (twofold, threefold, and fivefold).

TOF spectroscopy. In this case, one obtains angular-averaged (in reciprocal space) dispersion relations from the shape of the total dynamic structure factor and the GVDOS from its intensity averaged in a reasonably large region of reciprocal space. In order to cover the full energy range, in what follows, the discussion will therefore concentrate more on the GVDOS, which have been determined for most of the thermodynamically stable and several metastable QCs. The GVDOS normally contains several energy bands, the position (energy of the center of gravity of the band) and intensity of which are usually different for different samples. Thus, it is mainly the shape (and the energy range and the slope at lowest energy (if resolved)) of the GVDOS, which can be used to characterize the atomic dynamics of a sample via the GVDOS.

One obtains considerably more detailed information, if the experimental results are combined with results from computer simulations (CSs). These simulations are based on interactions, which are either calculated directly during the simulation, as is done in the method due to Car and Parrinello, or they are modeled in a more or less realistic manner. The second basic input is a model for the atomic structure, which in the case of QCs is always a structural model for a rational approximant, because of the finite size of the computer model, and it is of similar uncertainty as is the complicated interaction. Because of these inherent uncertainties, the comparison of the results of CSs with those of experiments is "essential" for a judgment on the quality of the simulation results, that is, how realistic these results are. If they

are in fairly good agreement, nothing is proved; however, it seems reasonable to use them for the interpretation of the measured results, as they provide very detailed information, which otherwise is possible only with great effort and extensive cost of experiments. In what follows, therefore, the experimental results will be confronted with those from realistic CSs as far as they exist.

Atomic dynamics and cluster structure As mentioned above, QCs are built from different types of clusters, the structure of which should influence the dynamics as it is the local structure which has the strongest influence on the dynamics. In fact, one finds a difference in the shape of the corresponding GVDOS for the two types of QCs. QCs dominated by more or less complete Mackay icosahedra, such as i-AlPdMn, i-AlCuFe, and d-AlCoNi, seem to have very smooth, nearly structureless one- or two-band spectra, whereas QCs of the Frank–Kasper type, such as i-AlLiCu, i-ZnMGRE (RE = Ho, Er,…, and also Y), and d-ZnMgY have more structured spectra with several energy subbands. This is easily seen in a comparison of **Figure 5** with **Figure 7**.

CSs suggest that this stronger band structure is due to a stronger grouping of the local vibrational density-of-states (LVDOS), that is, the vibrational spectra of all atoms on different Wyckoff positions in this computer-approximant to the Frank–Kasper type of QCs. This is different in the case of the Mackay type of QCs, where the LVDOS are more different from one another and result in a broad smooth spectrum after summation.

Quasicrystals and their rational approximants Because one of the basic input parameters for CSs, the structural model, is based on considerable approximations in the case of QCs, quite a few simulations have also been done on periodic crystals with similar chemical compositions as the QCs have, but with a well-known structure. Compared to the atomic dynamics of QCs, the dynamics of these periodic crystals is rather similar to that of the corresponding aperiodic phase if the periodic crystal is an approximant to the QCs. For example, the GVDOS of AlLiCu in the i- (Fank–Kasper type) and the periodic R-phase (built up of the same kind of clusters) are very similar to each other, having energy bands at essentially the same energies, but with slightly different intensities. The same results have been obtained in the measurement of the phonon dispersions of the same alloy system, where also hardly any difference could be detected except for a dispersionless branch at the upper energy limit of this investigation in the case of the i-phase seen in the center of **Figure 4**. Likewise, CSs of this alloy system, providing the information on the partial (element specific) dynamical properties, showed a small difference in peak intensity but not in peak position in the calculated GVDOS of the i- and R-phase, respectively. Even more identical results have been obtained for the Mackay type of QCs d–$Al_{71.5}Co_{13.5}Ni_{15}$ and its modulated approximant $Al_{71.5}Co_{15.5}Ni_{13}$. In fact, phonon dispersion measurements done on both types of QCs suggest slightly narrower phonon groups for the rational approximant compared with the QCs in the case of the Frank–Kasper type but not in the case of QCs of the Mackay type. These nearly identical results can be understood from the fact that the atomic dynamics is most strongly determined by the local (cluster) structure and potential, which seem to be sufficiently similar for the QCs and their approximants, while their structure differs on the long-range scale. For the 2D QCs just mentioned, this striking similarity of the atomic dynamics was even found at 1000 K, which also means that the thermal expansion (see below) of the QC and its rational approximant are nearly identical. All these conclusions do not apply to periodic crystals of similar chemical composition as the QCs have, but to those which are (structurally) not approximants.

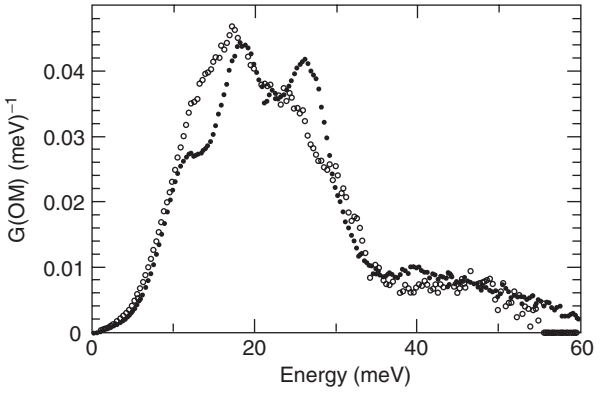

Figure 5 GVDOS of i-$Zn_{63}Mg_{26}.3gY_{10.7}$ and d-$Zn_{58}Mg_{40}Y_2$ (both Frank–Kasper type) showing the highly structured distributions with several energy bands and subbands.

Low-energy modes in quasicrystals Within the harmonic approximation, which should also apply to QCs at not too high temperatures, at low energies, one expects to find the linear dispersions $\omega = vq$, of transverse (TA) and longitudinal (LA) acoustic phonons, which join the linear dispersions of transverse and longitudinal ultrasound near $q = 0$. Here v is the sound velocity of the mode under consideration ($v = v_T$ *or* v_L) and q is the corresponding wave vector of the mode. On the basis of the Debye approximation, one therefore expects the phonon

density-of-states (PDOS) to start at the lowest energies proportional to $\omega^{(d-1)}$, where d is the dimension of the sample under consideration. For a 3D system with particle density n and a weighted mean value of the sound velocity v, one therefore expects the PDOS to start at the lowest energies proportional to the Debye DOS:

$$G_{\mathrm{Deb}}(\omega) = \frac{\omega^2}{2\pi n v^3} \qquad [6]$$

$$\frac{3}{v^3} = \frac{1}{v_{\mathrm{L}}^3} + \frac{2}{v_{\mathrm{T}}^3} \qquad [7]$$

For several – but not all – QCs (and some of their rational approximants), this general rule does not apply either for the measured GVDOS or for the CSs calculated PDOS. One finds a considerably higher intensity in the low-energy region compared to the intensity calculated by using the known sound velocities. Corresponding higher values for these QCs have also been found for the low-temperature specific heat by different groups. Likewise, the temperature dependence of the sound velocity of these QCs shows an unexpected behavior. Investigations of this kind are only possible with thermodynamically stable QCs as normal production defects have to be annealed out before.

Metastable QCs obtained by annealing of a metallic glass show additional low-energy modes stemming from the large grain boundary volume in these samples, as annealing here leads to nanocrystalline samples as has been shown for i-PdSiU and AlCuV. In this case, the intensity of the low-energy modes reaches nearly the level of a well-relaxed metallic glass.

Temperature dependence of the atomic dynamics The temperature dependence of the dynamics outside the quasielastic region has been investigated most extensively for i- and d-QCs of the Macky type. In all cases, one finds a considerable shift of the GVDOS to lower energies, that is, an anharmonic behavior of the DOS. However, on quantifying this shift with temperature, for example, with the "integrated" amount of modes shifted (e.g., integration from 0 to 16 or 25 meV) into the low-energy region, one finds a linear dependence of this transfer of modes with temperature up to 1000 K in all investigations, for d-AlCoNi even in the full range of temperatures investigated (up to 1100 K). This linear increase of the shifted intensity is parallel to the shift of the Debye–Scherrer lines in the diffraction diagrams to lower momentum transfers with increasing temperature, caused by the expansion of the lattice. Investigating the shift of lines having contributions only from the periodic axis or only from the aperiodic lattice planes, one observes, for example, in the case of d–$Al_{71.5}Co_{13.5}Ni_{15}$ that at temperatures above 750 K, the thermal expansion of the QCs in the periodic direction is stronger with increasing T than in the aperiodic plane.

Investigations of the energy dependence of the shifted intensity (by how much has one to shift the intensity of the calculated PDOS to arrive at the experimentally determined GVDOS) show a nearly constant energy shift of $\delta\omega/\omega$ of $\sim$6–10% at all temperatures analyzed from the upper limit of the GVDOS down to $\sim$12 meV. After this, one finds a strong increase of the shifted intensity, becoming more important with increasing temperature and reaching a relative shift of 20% and more. The participation ratio P ($P(\omega) = 1$ if all atoms of the model take part in the mode at frequency ω) shows, in the case of a QC or its approximant, that the smallest participation, that is, the strongest localization of the vibrations takes place at the smallest and highest frequencies. This is shown in **Figure 6**. Correlating this relative frequency shift $\delta\omega/\omega$ with the participation ratio P for the modes at these energies, CSs show that the strongest shifts correlate with the lowest participation ratio. Thus, one has to conclude that a large part of the shifted modes are most likely localized modes. The same CSs clearly demonstrate that the Al atoms contribute more strongly to these shifts than do the TM atoms, as one would expect from the structure, where the TM atoms form a rigid network in the clusters.

For i-AlPdMn, a new phenomenon comes in at temperatures above 1000 K. While one finds essentially the same linear behavior for the integrated intensity and shift of the Debye–Scherrer peaks, as for d-AlCoNi up to 1000 K, the integrated intensity suddenly increases well above this linear continuation (see **Figure 7**).

A careful investigation of the total dynamic structure factor of i-AlPdMn in the low-energy region shows that this additional intensity is due to quasielastic scattering being caused most likely by phason flips (see below), that is, a new degree of freedom in addition to the phonon degrees of freedom. As this quasielastic intensity gets considerably broader with increasing wave vector transfers Q, it overlaps with the inelastic region of the spectra and thus contributes to the intensity used to determine the GVDOS.

Phason flips As the n-dim space corresponding to the structure of the QCs is a "periodic lattice" decorated by disconnected atomic surfaces, any movement of the

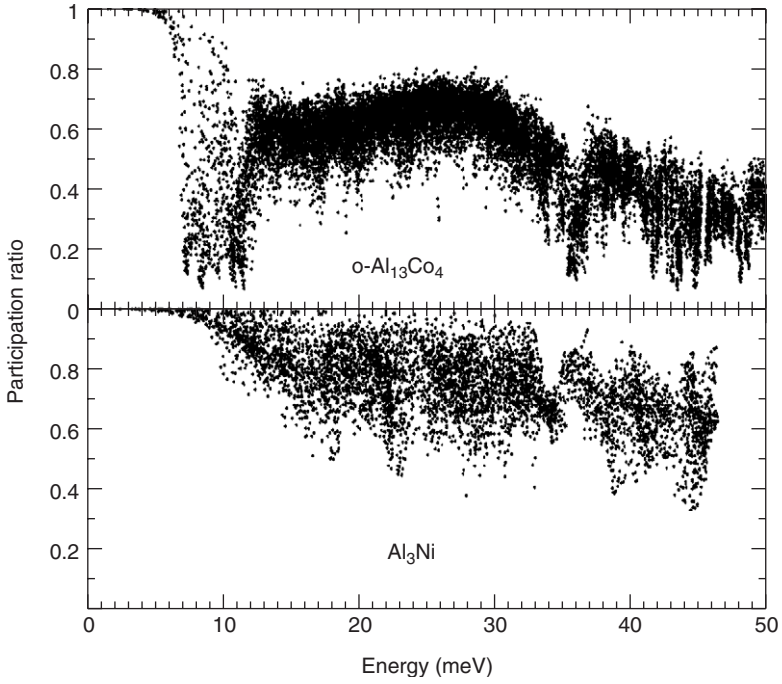

Figure 6 Participation ratio as a function of the energy of the vibrations for the orthorhombic approximant o-$Al_{13}Co_4$ to quasicrystalline d-$Al_{71.5}Co_{13.5}Ni_{15}$ in comparison with the chemically comparable but nonapproximant Al_3Ni. The strong decrease of the participation (= localization) of the modes with $\omega < 12$ meV in the case of the approximant is clearly seen.

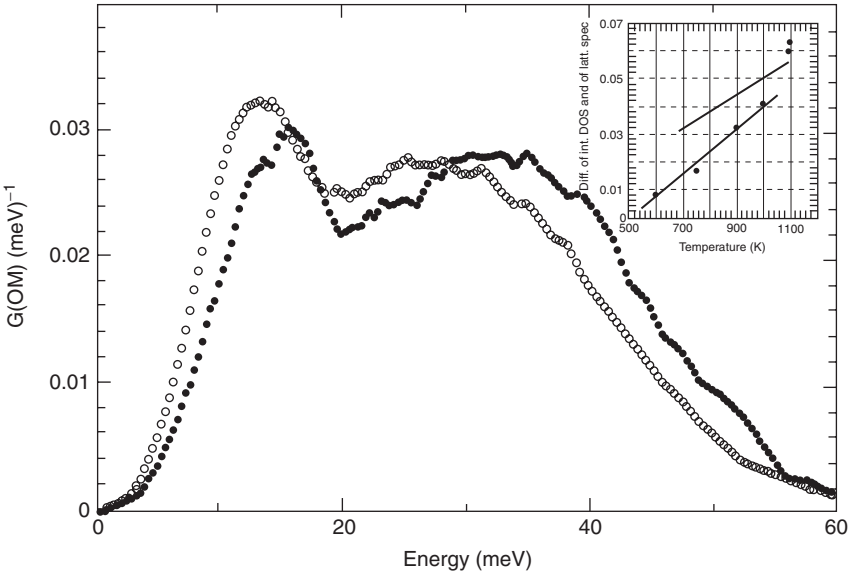

Figure 7 GVDOS of i-$Al_{63}Pd_{26.3}Mn_{10}$ (Mackay type) showing the important shift of the GVDOS to lower energies with increasing temperature. The insert demonstrates that the integrated shifted intensity has a linear behavior nearly parallel to the linear shift of the Debye–Scherrer lines in the diffraction diagrams (expansion of the alloy), except for temperatures higher than 1000 K.

physical space, with which the *n*-dim space is intersected, orthogonal to itself will lead to sudden jumps in the atomic positions instead of a continuous change as in the case of a continuous modulation function such as in perfect incommensurably modulated systems. Phason degrees of freedom will, therefore, always concern either flips of atoms in the aperiodic structure, corresponding to a local deviation of the intersection or by a diffusion kind of motion on a much longer timescale.

On the basis of calculations, one expects the phason dynamics to be frozen-in at lower temperatures even in random tilings, where phasons are principally in an unlocked state – in contrast to the locked state in energetically stabilized QCs below the unlocking transition. Only at temperatures well above room temperature, one could expect unlocking and with this, any sign from phason dynamics. Starting from a perfect (decorated) tiling at lower temperatures, phason flips will violate the matching rules and lead to a random tiling, which will be stabilized by its configurational entropy. The reverse mechanism will most likely be incomplete due to kinematic constraints. This process has been studied in several CSs, and at least in one of these investigations, correlated flips of several atoms have been observed.

Experimentally, quasielastic scattering has been found for most of the thermodynamically stable QCs by different groups at temperatures near the upper limit of the existence region of the QCs using polycrystalline samples and TOF spectroscopy. In the case of i-AlCuFe, for example, one obtains a nearly Q-independent width Γ of the Lorentzian fitted to the quasielastic spectrum, Γ being ~ 0.1 meV. This width of the spectrum would then correspond to jumps in the region of $\hbar/\Gamma \approx 7$ ps. The Q-dependence of the integrated intensity of this quasielastic signal with a maximum at $10\,\mathrm{nm}^{-1}$ suggests a process localized within a jump distance of 0.4 nm. The most detailed investigation was done at 1073 K using a single crystal of i-AlPdMn on a cold neutron TAS. While the Q-dependence of the quasielastic scattering from polycrystalline samples only allows one to determine the jump distances of the scattering atoms, experiments on single crystals allow, in addition, one to determine the orientation of the jumps. The variation of the measured intensity with the rotational angle in reciprocal space can be best fitted by a model for quasielastic scattering from simultaneous correlated jumps of several atoms in the phason flips. The quasielastic spectra can be fitted with one broad Lorentzian with $\Gamma = 0.7$ meV or (better) with two Lorentzians with $\Gamma = 0.2$ and 0.7 meV. Measurements on the twofold axis now show a maximum of the intensity near $27\,\mathrm{nm}^{-1}$, which corresponds to considerably shorter jump distances than found in the less detailed investigation of i-AlCuFe.

Phason fluctuation in quasicrystals For reasons mentioned in the previous section, one does not expect to find propagating phason modes as in the case of modulated phases. However, phasons do play a role in the elastic and dynamic properties of QCs. The elastic-free energy of a QC is given by three different terms:

$$F = F_{\mathrm{phon}}(\lambda, \mu) + F_{\mathrm{phas}}(K_1, K_2) + F_{\mathrm{cross}}(K_3) \quad [8]$$

Here λ and μ are the Lame coefficients, K_1 and K_2 the phason elastic constants, and K_3 the phonon–phason coupling term. From investigations of the diffuse scattering, assuming $K_3 = 0$, one can obtain the ratio of K_2/K_1, which at 300 K was found to be near -0.5 for i-AlPdMn. At temperatures in the range of 1000 K, a diffusive relaxation of phason strain or "phason walls" (left behind a moving dislocation in a QC) can lead to a collective diffusive phasonic excitation or long wavelength phason fluctuations. According to different theoretical investigations performed by several authors, these fluctuations will contribute to the Debye–Waller factor and to the diffuse scattering in a similar way as do phonons and defects, with the exception that the timescales of phonon and phason fluctuations differ by many orders of magnitude, lattice vibrations being in the picosecond range, while the characteristic times for long wavelength phason fluctuations is more between 0.1 and 100 s. Correspondingly, phonons can follow a lowering of the temperature instantaneously, whereas phason fluctuations fall out of equilibrium as a consequence of fast T-changes.

Experimentally, phason diffusion has been investigated in reciprocal space using high-resolution X-ray diffraction to study the phonon and the phason contribution to the Debye–Waller factor in a single crystal of i-AlCuFe in the temperature range between 300 and 1023 K, and to study diffuse scattering from a single crystal of i-AlPdMn as a function of temperature between 300 and 1043 K. Finally, X-ray intensity fluctuation spectroscopy (XIFS) has been used to investigate the time and temperature dependence of the diffuse scattering from a single crystal of i-AlPdMn at 923 K. In real space, *in situ* HRTEM was used to investigate the time-dependent structural changes in d-AlCoCu at 1123 K.

The X-ray diffraction experiment demonstrates a very strong temperature dependence of the phason contribution to the Debye–Waller factor (change by a factor of 9 between 750 and 650 K) and to the diffuse scattering, which decreases with increasing T while the intensity of large Q_{perp} reflections increases. Freezing of the phason dynamics was observed just below 900 K already. The most detailed results were obtained using highly coherent synchrotron radiation in the XIFS experiment. Here, the time evolution of the speckle pattern from diffuse scattering could be directly resolved and a time-dependent intensity correlation $g(Q, t)$ could be determined from the time dependence of the

measured intensity:

$$F_{cor}(Q,t) = [1 - \beta g(Q,t)] \quad [9]$$

where β corrects for the partial coherence of the beam. Above 923 K, the expected exponential decay $g(Q,t) = \exp(-t/\tau(Q))$ was found with $\tau(Q)$ proportional to $1/Q^2$, that is, D_{phas} proportional to λ^2, which proves the diffusive character of the long wavelength phason fluctuation observed, as the width Γ of the spectrum should be $\Gamma = DQ^2 = D4\pi^2/\tau$ for diffusive dynamics. D_{phas} was found to be $1.5 \times 10^{-16}\,m^2\,s^{-1}$ with the phason excitation wavelength λ between 50 and 100 nm. Again, a very strong temperature dependence was found, τ varying between 60 and 300 s when lowering the temperature from 923 to 873 K.

A comparable slow phason dynamics was found in the *in situ* HRTEM investigations of single crystals of d-AlCoCu at 1123 K. The duration for a change of the position of one of the columnar clusters of the decagonal structure was smaller than 10 s, the time between jumps was between 0.1 s and 10 min.

Lattice Dynamics: Structural Instability and Soft Modes

R A Cowley, University of Oxford, Oxford, UK

Introduction

The description of structural instabilities of crystals is both topical and goes back to the early days of lattice dynamics and the ideas of Born and Raman. The subject became of importance after 1960 when Cochran developed the concept of a soft mode and made specific predictions that could be experimentally verified. Born had shown that a crystal was harmonically stable if all the frequencies squared of the normal modes were positive, $\omega(qj)^2 > 0$, where q is the wave vector of the normal mode within the first Brillouin zone and j is the branch index. Clearly, if the crystal has long-range order then this result must be satisfied. Cochran discussed the case when the frequency squared was temperature dependent and made the simplest possible assumption that:

$$\omega(qj)^2 = A(T - T_c)$$

At temperatures above T_c, the frequency squared is positive and the crystal is stable, whereas below T_c, it is negative and the crystal distorts to a new crystal structure so that the frequency is no longer negative. This is the basis behind the concept of a soft mode, as a mechanical instability of the crystal against a particular normal mode.

The Classical Era

Above T_c, neutron scattering is usually the best way of studying the soft modes particularly if the wave vector of the soft mode is not at the center of the Brillouin zone. In the special case of ferrodistortive modes, the wave vector transfer is zero and studies with infrared or Raman spectroscopy may also be possible. The most studied material is $SrTiO_3$ and its structural phase transition at 105 K is illustrated in **Figure 1**. The crystal structure in the high temperature phase is cubic and in the low-temperature phase is distorted, as shown in **Figure 1**, by a rotation of the oxygen octahedra by the angle, ϕ. There are three degenerate soft modes corresponding to rotations about the three (1 0 0) axes. **Figure 2** shows the results of measurements of the soft mode frequencies. Above T_c the triply degenerate soft mode frequency squared decreases to zero in a linear fashion with all three degenerate modes. Then at T_c the degeneracy is broken and one mode increases rapidly with

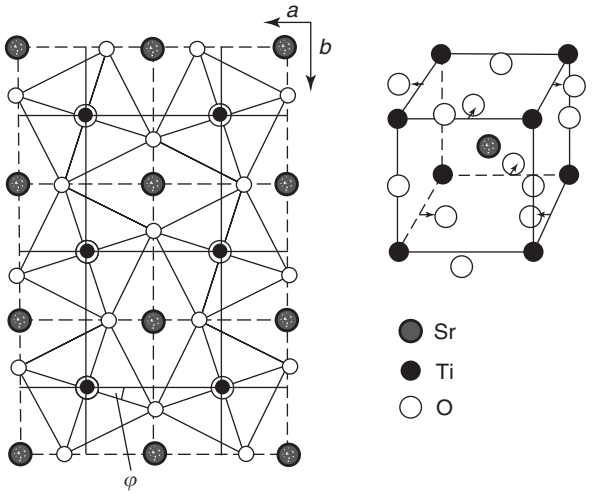

Figure 1 A projection down the cube axis of the distorted phase of $SrTiO_3$. (Reproduced from Unoki H and Sakudo T (1967) Electron spin resonance of Fe^{3+} in $SrTiO_3$ with special reference to the 110 K phase transition. *Journal of the Physical Society of Japan* 23: 546.)

decreasing temperature while the other two also increase in frequency but less rapidly.

This type of behavior above T_c has now been observed in many materials such as $BaTiO_3$, KDP, $Pb_5Ge_3O_{11}$, and others. Unfortunately, if T_c becomes comparable to typical phonon energies then the soft modes are often overdamped and it may be difficult to observe them directly.

Below T_c, the situation is more complex and depends on the degeneracy of the soft mode, j. For example consider $SrTiO_3$, there are three soft modes corresponding to the rotations of the octahedra about the x, y, or z axes and the free energy can be written as a power series in the amplitudes of the modes Q_x etc. The result is

$$F = F_0 + a(T - T_c)(Q_x^2 + Q_y^2 + Q_z^2) + d_1(Q_x^2 + Q_y^2 + Q_z^2)^2 + d_2(Q_x^4 + Q_y^4 + Q_z^4)$$

where the constants a, d_1, and d_2 are temperature-independent constants. This is a Landau expansion for the free energy of the soft mode and for $T < T_c$, the structure depends on the sign of d_2. If $d_2 > 0$ then the distorted structure has equal contributions of the x, y, and z components, as in $LaAlO_3$, whereas if $d_2 < 0$ then the structure is distorted along one of the principal axes (1, 0, 0), as in $SrTiO_3$.

Raman scattering is always a suitable tool to investigate the soft modes below T_c because at least one soft mode must have the full symmetry of the crystal and this is necessarily a Raman active mode. Nevertheless in most cases the intensity also drops to zero at T_c and that makes a precise determination of the temperature dependence difficult. Well away from T_c the higher order terms in the expansion can also play an important role so that it is difficult to test the Landau theory exactly using Raman scattering.

For some soft modes the wave vector is within the Brillouin zone and incommensurate. The theory then proceeds as discussed above, except that in the low-temperature phase the equivalent term in the free energy to d_2 is zero by symmetry. In this case one of the modes below T_c has zero frequency and it is an excellent example of a Goldstone boson that arises from the broken continuous symmetry in the direction of the order parameter. Phason is the name given to the dispersion curve of this mode and its frequency is proportional to the difference in $\boldsymbol{q}$ between the soft mode and the mode being observed. Unfortunately, there are relatively few examples of well-defined phasons that have been observed experimentally but one example is $ThBr_4$.

In some cases the phase transitions are somewhat different when the soft mode is an acoustic mode of the crystal. The acoustic modes are described by the elastic constants and their energies are proportional to the wave vector. The soft mode behavior then occurs if the slope of the acoustic modes goes to zero. Very often the symmetry of the acoustic mode is such that the soft mode undergoes a first-order transition because the free energy has a cubic invariant. An example of this is the behavior of Ce metal that undergoes a volume change when it changes from one valence state to another. In other cases, the phase

transition may be of first order as found, for example, in KDP where the ferroelectric fluctuations couple linearly with the C_{66} acoustic mode giving rise to a continuous phase transition.

Despite the undoubted success of the soft mode concept there have been relatively few examples where there is any understanding of the parameters in the Landau theory. In the case of order–disorder transitions in materials like NH_4Br, the ordering of the NH_4 molecules between the two different states is analogous to a spin vector and some progress has been made in calculating the transition temperature and determining whether the transition is ferrodistortive or antiferrodistortive. It has been suggested that the transition in KDP can be explained by the transverse-Ising model because there is a substantial difference between the transition temperatures of the hydrogenated and deuterated materials (**Figure 3**). This has however been questioned because all the atoms are involved in the ferroelectric fluctuations and the difference in the transition temperature probably arises from the change in the force constants. The most carefully studied material is $SrTiO_3$ where the temperature dependence of the soft mode arises from the anharmonicity of the lattice dynamics. Anharmonic lattice dynamics predicts that the self-energy of the normal modes depends on the frequency with which the modes are studied. Nevertheless for most materials the self-energy is only slowly varying with the applied frequency and the corrections to be applied to a temperature-dependent mode are small. In the case of $SrTiO_3$ calculations were made of the terms in the Landau expansion and other anharmonic properties and reasonable agreement was obtained with fairly realistic interatomic forces. The question then remains as to why the anharmonic effects have a much larger effect on the properties of $SrTiO_3$ than they do on, say, KBr, for example. In the high-temperature phase there is one formula unit in each cubic unit cell so that there are three ionic radii and only one lattice parameter that can be adjusted. It is therefore only good fortune if the three different ionic radii exactly fit into the available space and, in practice, the Sr and Ti ions are somewhat too large for the O ion. As a result the O ions tend to displace away from the center of the bond and the crystal structure becomes distorted. At high temperatures the motion of the atoms increases their size and there is no distortion but at low temperatures the crystal distorts to a noncubic phase. The anharmonic effects are basically no bigger than is normally the case. The unusual aspect of $SrTiO_3$ is that the harmonic frequencies are unusually low (indeed the squares of the harmonic frequencies are negative) whereas the anharmonic effects are much the same size as in other materials.

Critical Era

The theory that is outlined here has been a Landau theory that does not take account of the critical fluctuations that occur close to T_c, while the experiments have not looked carefully at the behavior close to T_c. The mean field theory neglects the interactions between the soft mode and those modes with the same branch index but with slightly different wave vectors. When these interactions are included the susceptibility and order parameter have the following forms:

$$\chi_{\pm}(T - T_c) = C|T - T_c|^{-\gamma}$$

while the order parameter is

$$\langle Q \rangle = B(T_c - T)^{\beta}$$

The exponents, β and γ, are then often very different from those predicted by mean field theory with typically γ about 1.35 and β about 0.33 for systems in three dimensions and having conventional behavior. It is generally expected that measurements of these nonclassical exponents require the reduced temperature $t = |T - T_c|/T_c$ to be less than 0.1 and to cover 2 or 3 decades of temperature. In practice it has proved surprisingly difficult to satisfy these requirements.

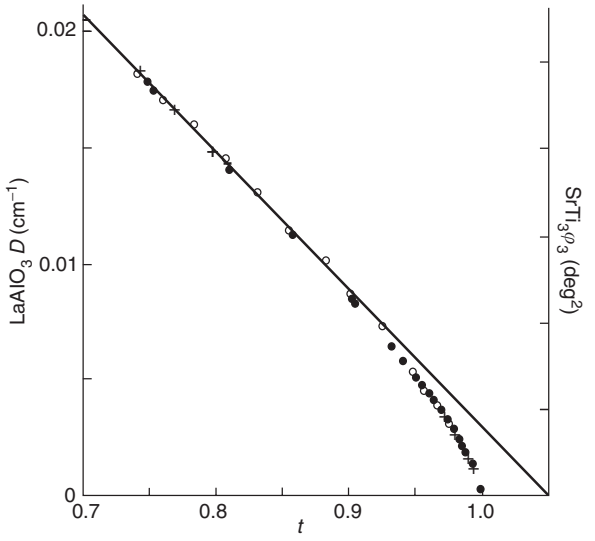

Figure 4 The temperature dependence of the order parameter of $SrTiO_3$ and $LaAlO_3$ as measured by EPR techniques. (Reproduced from Muller KA and Berlinger W (1971) Static critical exponents at structural phase transitions. *Physical Review Letters* 26: 13.)

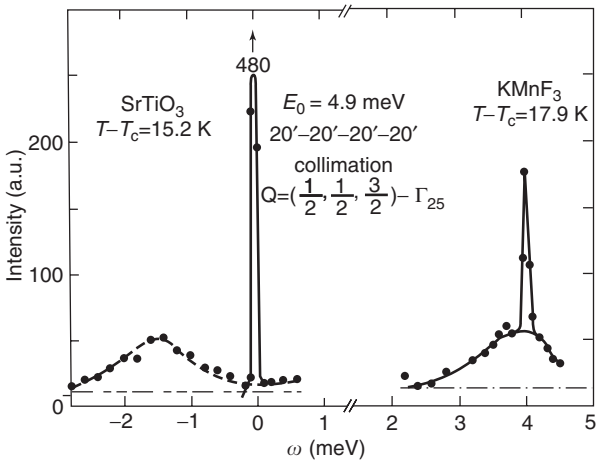

Figure 5 The scattering from the soft mode in $SrTiO_3$ and $KMnF_3$ showing the quasi-elastic scattering and the soft mode. (Reproduced from Shapiros S, *et al.* (1972) Critical neutron scattering in $SrTiO_3$ and $KMnF_3$. *Physical Review B* 6: 4332.)

The first clear evidence for nonclassical exponents came from measurements of the critical exponents of the order parameter in lightly doped Fe in $SrTiO_3$ by Muller and Berlinger, as shown in **Figure 4**. The results clearly show that the temperature dependence of the order parameter is different from classical theory and that $\beta = 0.33 \pm 0.02$. Other types of measurements have been much less successful. Raman scattering has been used below T_c but does not give reliable measurements close to the phase transition because it follows an energy singularity and is difficult to measure. Diffraction methods have been used for T above T_c but for reasons to be explained later satisfactory results have not been obtained. Many experiments have now followed the first X-ray measurements by Andrews. They have given very conflicting results that are dependent on the X-ray energy, and precise conditions for the experiment. Only one experiment has studied the incommensurate phase transition in Rb_2ZnCl_4 and that gives good agreement with the expected critical exponents.

The basic assumption of the critical theories is that close to the phase transition, the behavior is described by a single length-scale and a single timescale and that both diverge as the phase transition is approached. Experiments by Riste and co-workers in 1971 and later work by others showed that the behavior was not described by a single timescale. **Figure 5** shows the scattering observed just above T_c in $SrTiO_3$ and this has an inelastic peak and a sharp quasi-elastic peak. When the temperature is well above T_c the frequency of the mode decreases and there is little quasi-elastic scattering. Closer to the phase transition, the intensity of the quasi-elastic scattering rapidly increases while the soft mode part becomes almost independent of temperature. The scattering can be described by a response function of the form:

$$\chi^{-1}(qj) = \omega(qj)^2 - \omega^2 - 2i\omega\gamma_0 + \frac{i\omega\tau\delta_0^2}{1 - i\omega\tau}$$

in which the response is a damped harmonic oscillator plus an additional term to produce the quasi-elastic scattering and δ and τ are constants that need to be adjusted. The experiment showed that the additional relaxation was very slow and could not be easily resolved in the experiments. Similar results have now been observed at many phase transitions and indeed at most order–order phase transitions. Comparison with the results of X-ray scattering measurements has shown that the central peak needs to be included in the scattering if both X-ray and neutron scattering methods are to agree with one another and the measurements are not too close to the phase transition.

The first evidence for two length scales came from the observations of Andrews. He performed X-ray scattering measurements with Cu radiation and found that close to T_c, $|t| < 0.03$, there was additional scattering with a new and longer length scale. Subsequently, most materials that have been studied with high-resolution techniques have shown a very similar behavior, with a new long length scale that diverges at the phase transition with an exponent that is larger than that expected for the susceptibility. In summary the experimental results

for the second timescale and second length scale are as follows:

1. Two energy scales
   (a) At phase transitions between two ordered phases there is both soft mode and quasi-elastic scattering with very different energy scales for $t<1$,
   (b) The quasi-elastic energy scale is very slow, <0.01 meV,
   (c) The quasi-elastic neutron scattering is well described by a low-frequency Debye relaxation,
   (d) Both inelastic and quasi-elastic components of the neutron scattering experiments are measured by X-ray scattering techniques, and
   (e) The quasi-elastic peak is enhanced by the introducing defects but much more slowly than linearly with the defect concentration.
2. Two length scales
   (a) Two length scale components have been observed in measurements made with adequate resolution, 0.001 Å,
   (b) The narrow scattering corresponds to a length scale that is 10 times longer than the short length scale,
   (c) The critical exponents for the two length scales are different from one another with the shorter scale being broadly consistent with that expected from nonclassical fluctuations,
   (d) The long length scale scattering is broadly consistent with an isotropic Lorentzian squared, and
   (e) The scattering seems to arise from the "near," within 50 μm, surface and its intensity depends on the surface preparation.

Much effort has been put into finding the origin of the additional second timescale. It is well established that the theory of anharmonic lattice dynamics can give rise to the required behavior below T_c and also above if the mode is a special type of ferrodistortive mode. This theory cannot however explain the scattering observed from most quasi-elastic peaks and in particular cannot explain the effects observed in $SrTiO_3$. Considerable effort has been made to try to account for the results in terms of a critical theory but it is very difficult to make a clear distinction between the quasi-elastic peak and the inelastic peak.

Halperin and Varma suggested that the slow quasi-elastic peak could be accounted for by introducing defects. There is no doubt either theoretically or experimentally that defects can produce a central peak. Nevertheless, Halperin and Varma were unable to make any specific theoretical predictions that could be tested experimentally. The defects were of unknown strength and unknown concentration and it is surprising that the effects are so similar for different types of crystals containing very different

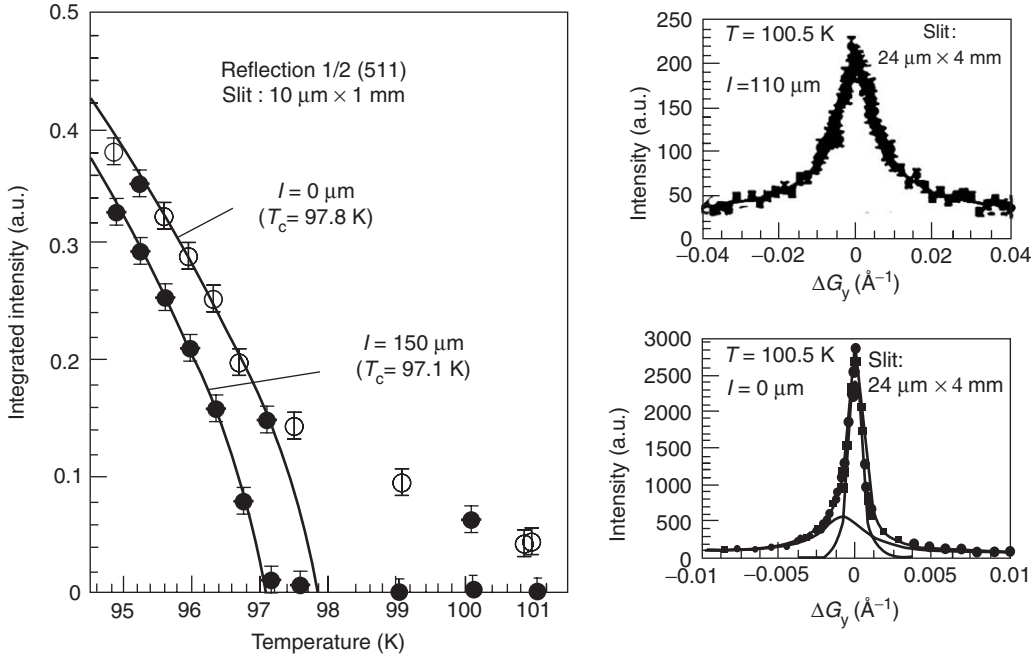

Figure 6 Critical scattering at the surface and at a depth of 110 μm from $SrTiO_3$ as well as the order parameter temperature dependence. (Reproduced permission from Rutt U, *et al.* (1997) Depth dependence of strain, mosaicity and sharp component in the critical scattering of $SrTiO_3$. *Europhysics Letters* 39: 395.)

defects. The authors conclude that the dynamic central peaks are not yet understood and that more experiments and an improved theory are needed to explain the results.

In the case of the two length scales, high-energy X-ray measurements do not show the effect because the scattering is then not dominated by the surface region. Two possible explanations have been put forward. First, Altarelli *et al*. have suggested that dislocations at the surface could alter the response in the near surface region while Harris *et al*. have suggested that random fields at the surface would be dependent on the surface preparation. There is no doubt that the preparation of the surface does make a difference to the results, but nevertheless it is difficult to understand why the defects have very similar results for very different materials and indeed for both magnetic and structural phase transitions. An alternative explanation is that the surface waves propagating at the surface are free in the sense that the surface of the crystal can respond to these strains while it cannot respond to bulk elastic strains. This can raise the temperature of the phase transition so that the distorted region steadily grows in from the surface. The new narrow component of the scattering is then a measure of the extent to which the surface distortion has grown into the crystal due to the coupling of the strain to the degree of order.

Summary

The concept of a soft mode has been reviewed as a mechanical instability of a crystal against one of the normal modes of vibration. The basic concept is correct and has been shown to very satisfactorily account for the experimental behavior in very different systems. Despite this undoubted success detailed measurements close to the phase transition are not well understood. Structural phase transitions are usually characterized by quasi-elastic scattering as well as the inelastic soft mode scattering and currently there is no satisfactory account of that scattering although it is now over 30 years since the phenomenon was discovered. The basic theory depends on the second energy scale coming from defects even though no defects have been introduced into the crystals and it is unlikely that very similar results would be obtained from mechanically very different crystals. Experiments have also been performed that have shown a second length scale in a "near" surface region. These are now understood as arising either from defects or from a part of the critical scattering that arises from the order parameter strain coupling that is dependent on the scattering from the free surface. Further experiments and theory are needed before these effects are understood (**Figure 6**).

Lattice Dynamics: Vibrational Modes

K Parlinski, Institute of Nuclear Physics, Kraków, Poland

Introduction

Atoms vibrate in any material. The vibrational modes describe a number of properties, like temperature dependence of crystal lattice parameters and elastic constants; they determine thermal expansion properties, heat and electric conductivity, thermo dynamic functions, and location of the critical temperature in the phase diagram. Vibrational modes enhance the diffusion processes, and play a crucial role in superconductivity, ferroelectricity, shape-memory alloys, etc. Neutron and synchrotron radiation scattering, Raman scattering, and infrared absorption methods are used to study atomic vibrations in detail. Of course, atoms vibrate in pure crystals, in crystals with substitutional and interstitial defects, atomic clusters, dislocations, or grain boundaries. Atomic vibrations on surfaces and interfaces are different compared to those in the bulk, due to differences in neighboring atoms at these locations.

Lattice Dynamics Theory

The basic theory of the lattice dynamics has been given by Born and Huang, who developed the theory

for crystal lattices with translational symmetry. The theory uses the Born–Oppenheimer adiabatic approximation, which means that the electrons, moving fast due to their lighter masses, follow the much slower motion of nuclei. This approximation allows one to write the potential energy V of the system as a function of the instantaneous position of atomic nuclei $\boldsymbol{R}(\boldsymbol{n},\mu)$:

$$V = V(\ldots, \boldsymbol{R}(\boldsymbol{n},\mu),\ \ldots)$$

where $\boldsymbol{R}(\boldsymbol{n},\mu)$ is the position of an atom vibrating close to the lattice site μ of the primitive unit cell $\boldsymbol{n}$. One defines the site position $\boldsymbol{R}^0(\boldsymbol{n},\mu)$ at the minimum of the potential energy. Crystal symmetry may fix the location $\boldsymbol{R}^0(\boldsymbol{n},\mu)$. Indeed, some intersections of two or more symmetry elements at a single point define a site symmetry, and, consequently, any crystal function, including the potential energy, may have an extremum at this point. The atomic vibrations are usually small and amount to a small percentage of the closest interatomic distances. The potential energy can formally be expanded in terms of such displacements, $\boldsymbol{u}(\boldsymbol{n},\mu) = \boldsymbol{R}(\boldsymbol{n},\mu) - \boldsymbol{R}^0(\boldsymbol{n},\mu)$:

$$\begin{aligned} V = {} & V(\ldots \boldsymbol{R}^0(\boldsymbol{n},\mu), \ldots) \\ & + \frac{1}{2} \sum_{\boldsymbol{n},\mu,\boldsymbol{m},\nu} \Phi(\boldsymbol{n},\mu;\boldsymbol{m},\nu)\boldsymbol{u}(\boldsymbol{n},\mu)\boldsymbol{u}(\boldsymbol{m},\nu) \\ & + \text{higher-order terms} \end{aligned}$$

The term $V(\ldots \boldsymbol{R}^0(\boldsymbol{n},\mu), \ldots)$ stands for the athermal crystal ground-state energy. Linear expansion terms vanish because they are the first derivatives of a continuous function at the extrema (usually minima). The second expansion term is called harmonic. The expansion coefficient

$$\Phi(\boldsymbol{n},\mu;\boldsymbol{m},\nu) = \left.\frac{\partial^2 V}{\partial \boldsymbol{R}(\boldsymbol{n},\mu)\partial \boldsymbol{R}(\boldsymbol{m},\nu)}\right|_{\mathrm{o}}$$

defines the 3×3 matrix of force constant connecting atoms $(\boldsymbol{n},\mu)$ and $(\boldsymbol{m},\nu)$. In crystals, the force constant matrices remain invariant with respect to these crystal symmetry elements, which do not alter the vector joining the two connected atoms $(\boldsymbol{n},\mu)$ and $(\boldsymbol{m},\nu)$. Third-, fourth-, and higher-order terms of the potential energy expansion are called anharmonic contributions and are neglected in the harmonic approach.

In the harmonic approximation, the equations of motion of vibrating atoms are exactly solvable. The solutions of the equations of motion for the atomic displacements are usually chosen as

$$\begin{aligned} \boldsymbol{u}(\boldsymbol{n},\mu) = {} & \frac{Q(\boldsymbol{k},j)}{\sqrt{M_\mu}}\boldsymbol{e}(\boldsymbol{k},j;\mu) \\ & \times \exp[2\pi \mathrm{i}(\boldsymbol{k}\times\boldsymbol{R}(\boldsymbol{n},\mu) - \omega(\boldsymbol{k},j)t)] \end{aligned}$$

where M_μ denotes atomic mass, $\boldsymbol{k}$ is the wave vector defining a point in the reciprocal space of the crystal lattice. The $Q(\boldsymbol{k}, j)$ is the normal-mode amplitude. The equations of motion then leads to the eigenvalue problem

$$\omega^2(\boldsymbol{k},j)\boldsymbol{E}(\boldsymbol{k},j) = \boldsymbol{D}(\boldsymbol{k})\boldsymbol{E}(\boldsymbol{k},j)$$

where $j = 1, 2, \ldots, 3r$ labels the phonon branches. The number of phonon branches can be less than $3r$, if some of them become degenerate due to crystal symmetry.

The eigenvector $\boldsymbol{E}(\boldsymbol{k}, j)$ is a column vector and the dynamical matrix forms a square matrix:

$$\boldsymbol{E}(\boldsymbol{k},j) = \begin{pmatrix} \boldsymbol{e}(\boldsymbol{k},j;1) \\ \vdots \\ \boldsymbol{e}(\boldsymbol{k},j;\mu) \\ \vdots \\ \boldsymbol{e}(\boldsymbol{k},j;3r) \end{pmatrix}$$

and

$$\boldsymbol{D}(\boldsymbol{k}) = \begin{pmatrix} \boldsymbol{D}(\boldsymbol{k};1,1), & \ldots, & \boldsymbol{D}(\boldsymbol{k};1,3r) \\ & \vdots & \\ \ldots, & \boldsymbol{D}(\boldsymbol{k};\mu,\nu), & \ldots \\ & \vdots & \\ \boldsymbol{D}(\boldsymbol{k};3r,1), & \ldots, & \boldsymbol{D}(\boldsymbol{k};3r,3r) \end{pmatrix}$$

and

$$\begin{aligned} \boldsymbol{D}(\boldsymbol{k};\mu,\nu) = {} & \frac{1}{\sqrt{M_\mu M_\nu}} \sum_{m} \Phi(0,\mu;\boldsymbol{m},\nu) \\ & \times \exp\{-2\pi \mathrm{i}\boldsymbol{k}\cdot[\boldsymbol{R}(0,\mu) - \boldsymbol{R}(\boldsymbol{m},\nu)]\} \end{aligned}$$

$\boldsymbol{D}(\boldsymbol{k})$ is an Hermitian matrix of dimension $3r \times 3r$. Here, r is the number of atoms in the primitive unit cell. The summation $\boldsymbol{m}$ runs over unit cells of the crystal. The eigenvalue equation provides the values of squares of the eigenfrequencies, $\omega^2(\boldsymbol{k}, j)$. The eigenvectors $\boldsymbol{E}(\boldsymbol{k},j)$, also called the polarization vectors, satisfy the orthonormality conditions.

For a given wave vector $\boldsymbol{k}$, there exist $3r$ values of $\omega^2(\boldsymbol{k}, j)$ frequencies, each of which describes a normal mode vibration. In a stable crystal, all $\omega^2(\boldsymbol{k}, j)$ are real and positive. To each $\omega^2(\boldsymbol{k}, j)$ is associated an eigenvector $\boldsymbol{E}(\boldsymbol{k}, j)$ having $3r$ components, as many as

the number of degrees of freedom in the primitive unit cell. The eigenvector controls the participation and displacements of atoms in the vibrational mode. The eigenvector components are complex numbers.

Quantum Treatment

In quantum mechanics, the crystal harmonic vibrations are treated as a set of independent harmonic oscillators. The states of each quantum oscillator form equidistant energy levels, which are labeled by the quantum number n. In the classical treatment, the amplitude of oscillations can increase continuously. In the quantum approach, the amplitude of vibrations is specified by the probability of the oscillator wave functions, which spread wider for higher quantum numbers. The energy of the quantum oscillator at state n is then

$$E_n(\boldsymbol{k},j) = \hbar\omega(\boldsymbol{k},j)\left(n+\tfrac{1}{2}\right)$$

In contrast to a classical oscillator, for which the lowest energy is zero, the ground-state energy of the quantum oscillator is nonzero, $E_0(\boldsymbol{k},j) = (1/2)\,\hbar\omega(\boldsymbol{k},j)$.

The quantum of an energy difference $\Delta n = 1$ is called a phonon. Thus, to specify a crystal state, one should give the number of phonons occupying each normal mode. The amplitude of atomic vibrations, or the number of phonons, depends on the crystal temperature. In a canonical ensemble, in which the external variables are temperature T and volume V, the mean number of phonons in the vibrational normal mode $(\boldsymbol{k},j)$ is given by the Bose–Einstein statistics,

$$n(\boldsymbol{k},j) = \frac{1}{\exp[\hbar\omega(\boldsymbol{k},j)/k_{\mathrm{B}}T]-1}$$

where k_{B} is a Boltzmann constant. Any number of phonons can be inserted into the crystal. Harmonic phonons do not interact, hence a thermal equilibrium between them can be achieved only with a contribution of anharmonicity.

In the harmonic approximation, the energy E of the atomic vibrations is a sum of kinetic and potential energies, and could be represented as

$$E = \sum_{\boldsymbol{k},j} \omega^2(\boldsymbol{k},j)\langle|Q(\boldsymbol{k},j)|^2\rangle$$

where the mean square amplitude of the quantum harmonic oscillator depends on the crystal temperature, and is given by

$$\langle|Q(\boldsymbol{k},j)|^2\rangle = \frac{\hbar}{2\omega(\boldsymbol{k},j)}\,\mathrm{cth}\,\frac{\hbar\omega(\boldsymbol{k},j)}{2k_{\mathrm{B}}T}$$

Phonon Dispersion Relations

The phonon dispersion relations are defined as the $\boldsymbol{k}$ dependence of the frequencies, $\omega(\boldsymbol{k},j)$, of the normal modes for all branches j and selected directions in the crystal (**Figure 1**). The number of phonon branches, $j = 1, 2, \ldots, 3r$, is equal to the number of degrees of freedom in the primitive unit cell. Each point on the phonon dispersion curve $\omega(\boldsymbol{k},j)$ gives the frequency of a phonon, which can be visualized as a dynamical wave of length $\lambda = 1/|\boldsymbol{k}|$, propagating along the $\boldsymbol{k}/|\boldsymbol{k}|$ direction. In this wave, the atoms vibrate with frequency $\omega(\boldsymbol{k},j)$, and displace from the equilibrium positions as indicated by the polarization vectors $\boldsymbol{E}(\boldsymbol{k},j)$. Typical maximal phonon frequencies range from 10 to 30 THz, where $1\,\mathrm{THz} = 10^{12}\,\mathrm{s}^{-1}$. Other units are also used: $1\,\mathrm{THz} = 4.1357\,\mathrm{meV} = 33.356\,\mathrm{cm}^{-1}$. The amplitudes of vibrations are ~ 0.03–$0.08\,\text{Å}$.

Conventionally, the phonon dispersion relations are drawn along crystal high-symmetry axis, but other directions might also be shown. At the Γ point, which corresponds to $\boldsymbol{k} = 0$, or to a reciprocal lattice vector $\boldsymbol{k} = \boldsymbol{b}^*$, there are always three phonons with zero frequency, $\omega(\boldsymbol{k} = \Gamma, j) = 0$. The phonon

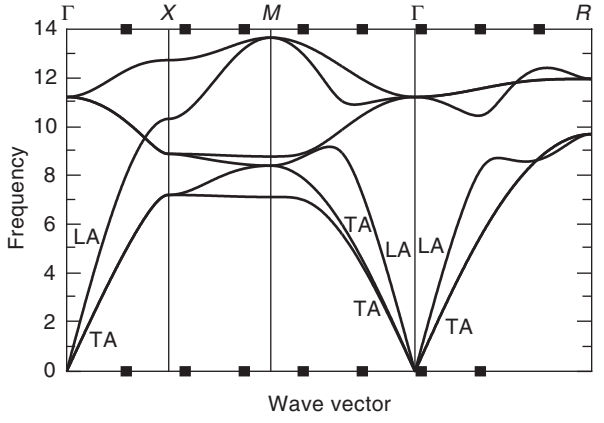

Figure 1 Schematic representation of phonon dispersion relations of a primitive cubic crystal *AB*, with atoms *A* and *B* at positions (0,0,0) and $(1/2, 1/2, 1/2)$. The high-symmetry directions Γ–*X*, *X*–*M*, *M*–Γ and Γ–*R* connect the high-symmetry points $\Gamma = (0,0,0)$, $X = (1/2,0,0)$, $M = (1/2,1/2,0)$, $R = (1/2,1/2,1/2)$ of the primitive cubic Brillouin zone. In this example the force constants for *A* and *B* atoms are assumed to be the same, while the masses are different, $M_A = 1.5\,M_{\mathrm{B}}$. Animations of normal-mode vibrations of selected phonons can be viewed at http://wolf.ifj.edu.pl. Vibrational amplitudes are much larger than in real crystals.

branches starting at $\omega(\boldsymbol{k}=\Gamma,j)=0$ are called acoustic phonon dispersion curves. Close to $\boldsymbol{k}=\Gamma$, the acoustic branches show a linear dependence, that is, $\omega\sim|\boldsymbol{k}|$, and the slope is described by a combination of the elastic constants of a crystal. The exact relationship between the slope and elastic constants depends on the crystal point group. In some high-symmetry crystals, and along high-symmetry directions, the atomic vibrations are either polarized along the propagation wave vector $\boldsymbol{k}$ (longitudinal acoustic modes, LA), or perpendicular to $\boldsymbol{k}$ (transverse acoustic modes, TA). Other phonon dispersion relations, being of nonzero frequency at Γ point $\omega(\boldsymbol{k}=\Gamma,j)\neq 0$, are called optic. Optic modes could have similar longitudinal and transverse characters. Local atomic vibrations lead usually to flat phonon dispersion relations. A strong coupling of displacements between neighboring atoms causes a large phonon dispersion, that is, a large $\boldsymbol{k}$ dependence of $\omega(\boldsymbol{k},j)$.

The frequencies of phonon modes are periodic with the reciprocal lattice vector $\boldsymbol{b}^*$,

$$\omega(\boldsymbol{k}+\boldsymbol{b}^*,j)=\omega(\boldsymbol{k},j)$$

in other words, the phonon dispersion relations in every Brillouin zone of the crystal are the same. In contrast, the polarization vectors may differ by a phase factor in going from one Brillouin zone to another zone.

In principle, the complete phonon dispersion relations can be measured by coherent inelastic neutron scattering, or by inelastic X-ray scattering, provided the phonon peaks are well resolved, and their intensities are sufficient. Some phonon frequencies $\omega(\boldsymbol{k}=\Gamma,j)$ at wave vector $\boldsymbol{k}=\Gamma$ can be measured by infrared absorption and/or Raman scattering methods. In nonmetallic crystals, the phonon modes, having symmetry which allows one to observe them by an infrared absorption method, are split into longitudinal optic (LO) and transverse optic (TO) components having different frequencies. The difference between LO and TO frequencies depends on the magnitude of the Born effective charges and the electronic part of the dielectric constant. In metals, the LO/TO splitting does not occur. In molecular crystals, the internal vibrations of molecular constituents usually present local vibrations; therefore, the phonon dispersion curves remain flat, while the intermolecular coupling provides acoustic and low-frequency lattice optic phonons of appreciable dispersion.

Realistic phonon dispersion relations for the athermal regime ($T=0$, no phonon displacements) can be calculated from first principles either by a direct method, or by a linear response perturbation method. In the direct method, the Hellmann–Feynman forces, being the first derivatives of the crystal potential energy and arising due to the atomic displacements, are calculated from first principles, and then used to derive the force constants. In the linear response method, the force constants are calculated directly as the second derivatives of the ground-state energy of the crystal.

Phonon Density of States

The phonon density of states $g(\omega)$ describes the number of phonon modes of a specific frequency $\omega(\boldsymbol{k},j)$ in a given frequency interval $(\omega-1/2(\Delta\omega),\omega+1/2(\Delta\omega))$, if the density of wave vectors $\boldsymbol{k}$ in the Brillouin zone is homogeneously distributed (**Figure 2**). Formally, $g(\omega)$ is obtained from the relation

$$g(\omega)=\frac{1}{3r\,N\,\Delta\omega}\sum_{\boldsymbol{k},j}\delta_{\Delta\omega}(\omega-\omega(\boldsymbol{k},j))$$

where the new δ function is defined as $\delta_{\Delta\omega}(x)=1$ if $\Delta\omega/2<x\leqslant\Delta\omega/2$, and $\delta_{\Delta\omega}(x)=0$ otherwise. The summation runs over wave vectors $\boldsymbol{k}$ of the first Brillouin zone, and all phonon branches. Here, N is the number of wave vectors $\boldsymbol{k}$. The phonon density of states is normalized $\int_0^\infty \mathrm{d}\omega\, g(\omega)=1$.

The phonon density of states $g(\omega)$ spreads from zero to the maximal phonon frequency existing in a given crystal. For acoustic phonons, behaving linearly close to $\boldsymbol{k}=\Gamma$, $g(\omega)$ is proportional to ω^2 close to $\omega=0$. In simple crystals, the ω^2 dependence may

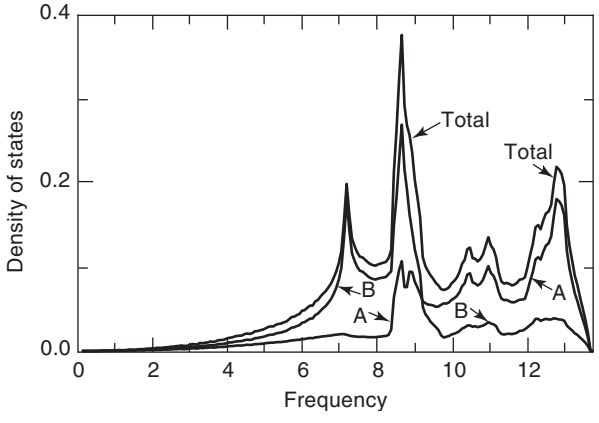

Figure 2 Schematic representation of phonon density of states of a primitive cubic crystal *AB*, with atoms *A* and *B* at positions (0,0,0) and $(1/2,1/2,1/2)$ the same as in **Figure 1**. In this example the force constants *A* and *B* atoms are assumed to be the same, while the masses are different, $M_A=1.5\,M_B$. The partial phonon density of states for *A* and *B* atoms are also shown.

cover a substantial part of the ω interval; however, in complex crystals, the quadratic dependence is limited to the close vicinity of the point $\omega = 0$. Flat phonon dispersion relations may lead to sharp peaks in $g(\omega)$. In simple crystals with a large mass difference of the constituents the vibrations could separate to a low-frequency phonon band, caused mainly by oscillations of heavy atoms, and to a high-frequency band, occupied by light atoms. The bands could be separated by a frequency gap. It should, however, be stressed that, without measurements or precise calculations, the prediction of phonon spectra is impossible.

To describe the vibrations of a specific atom μ moving along the i-direction a partial phonon density of states is introduced

$$g_{i,\mu}(\omega) = \frac{1}{3r\,N\,\Delta\omega} \sum_{k,j} |e_i(\boldsymbol{k}, j; \mu)|^2 \times \delta_{\Delta\omega}(\omega - \omega(\boldsymbol{k}, j))$$

The factor $|e_i(\boldsymbol{k}, j; \mu)|^2$ represents the abundance of a given mode. It is normalized to $\int_0^\infty \mathrm{d}\omega\, g_{i,\mu}(\omega) = 1/3r$. This density of states defines a participation of an atom μ in harmonic vibrations occurring along the selected direction i. It suggests which atom is taking part in a given peak of $g(\omega)$.

Remarks

Crystal symmetries are specified by the space groups. Possible transformations of atomic displacements are then classified by the irreducible representations of the crystal space group. An irreducible representation can be assigned to each normal mode or phonon. The classification of normal modes by irreducible representations can be done without diagonalization of the dynamical matrix, that is, without the knowledge of the phonon frequencies. These irreducible representations also describe the activity of phonon peaks in Raman scattering and infrared absorption, the possibility of LO/TO splitting, the low-symmetry space group arising at a phase transition caused by a soft mode, and the interaction of phonon branches. In particular, phonon branches labeled by the same irreducible representation cannot cross.

The energy E of the harmonic crystal shows that any phonon-like fluctuation always increases the system energy, since $\omega^2(\boldsymbol{k}, j) > 0$ and $\langle |Q(\boldsymbol{k}, j)|^2 \rangle > 0$. Thus, phonons do not destroy the crystal stability. If, however, due to external conditions, $\omega^2(\boldsymbol{k}_c, j_c)$ becomes negative, the crystal ceases to be stable. It induces a phase transition with a change of space group. The increasing vibrational amplitude is confined by anharmonic terms. The phonon with critical frequency $\omega^2(\boldsymbol{k}_c, j_c)$ is called a soft mode.

Light Emitting Diodes

E F Schubert and T Gessmann, Rensselaer Polytechnic Institute, Troy, NY, USA

Introduction

Electrons and holes in semiconductors recombine either radiatively, that is, accompanied by the emission of a photon, or nonradiatively. In light emitting devices, the former is the preferred process. Although nonradiative recombination can be minimized, it can, under practical conditions, never be reduced to zero. Thus, there is competition between radiative and nonradiative recombination. Maximization of the radiative process can be attained in a number of ways that is discussed below.

In light emitting diodes (LEDs), radiative recombination is spontaneous in nature and the recombination rate depends on the concentration of carriers.

The situation is different for laser diodes, in which stimulated recombination dominates. This process depends on the concentration of photons as well as the concentration of carriers.

The energy of emitted photons is near the bandgap energy of the active (light-emitting) material. To date, LEDs are available that cover the IR and entire visible wavelength range from 390 nm (violet) to 720 nm (red). In addition, LEDs emitting in the UV wavelength range have recently become available. For visible-spectrum LEDs, III–V compound semiconductors such as AlGaInP, GaInN, and AlGaAs are used. Their bandgap energy can be adjusted by the chemical composition, for example, the mole fraction x in $Ga_{1-x}In_xN$. III–V phosphides are used for emitters in the IR, and in the red to green wavelength range, whereas III–V nitrides are used for emitters in the green to violet range and the UV wavelength range. The emission of III–V arsenides extends from the IR to the red part of the spectrum.

Optical Properties

The probability that electrons and holes recombine radiatively is proportional to the product of electron and hole concentration, that is, $R \propto np$. The recombination rate per unit time per unit volume can be written as

$$R = -\frac{dn}{dt} = -\frac{dp}{dt} = Bnp \qquad [1]$$

where B is a proportionality constant, the bimolecular recombination coefficient, with a typical value of $10^{-10}\,cm^3\,s^{-1}$ for direct-gap III–V semiconductors.

Fundamental types of band structures and associated recombination processes are shown in **Figure 1**. During the recombination process, the electron momentum ($p = (2m^*E)^{1/2}$) cannot change significantly because momentum must be conserved and the photon momentum ($p = h/\lambda$) is negligibly small. Thus optical transitions must be "vertical" in nature, that is, electrons recombine only with holes that have the same k value as shown in **Figure 1**.

Efficient recombination occurs in direct-gap semiconductors shown in **Figure 1a**. However, the recombination probability is much lower in indirect-gap semiconductors because a phonon is required to satisfy momentum conservation, as shown in **Figure 1b**. The radiative efficiency of indirect-gap semiconductors can be increased by isoelectronic impurities, for example, N in GaP. Isoelectronic impurities can form an optically active deep level that is localized in real space (small Δx) but, according to the uncertainty relation, delocalized in k space (large Δk), so that the impurity can satisfy the momentum conservation, as indicated in **Figure 1c**.

During nonradiative recombination, the electron energy is converted to vibrational energy of lattice atoms, that is, phonons. There are several physical mechanisms by which nonradiative recombination can occur with the most common ones being point defects (impurities, vacancies, interstitials, antisite defects, and impurity complexes) and spatially extended defects (screw and edge dislocations, cluster defects). It is quite common for such defects to form one or several energy levels within the forbidden gap. The defects act as efficient recombination centers (Shockley–Read recombination centers) in particular, if the energy level is close to the middle of the gap.

The emission spectra of an AlGaInP red, a GaInN green, and a GaInN blue LED are shown in **Figure 2**. The spectral line width of spontaneous emission can be calculated to be $1.8\,kT$ and is caused by the thermal energy of carriers. However, the LEDs shown in **Figure 2** have an active region comprised of a ternary

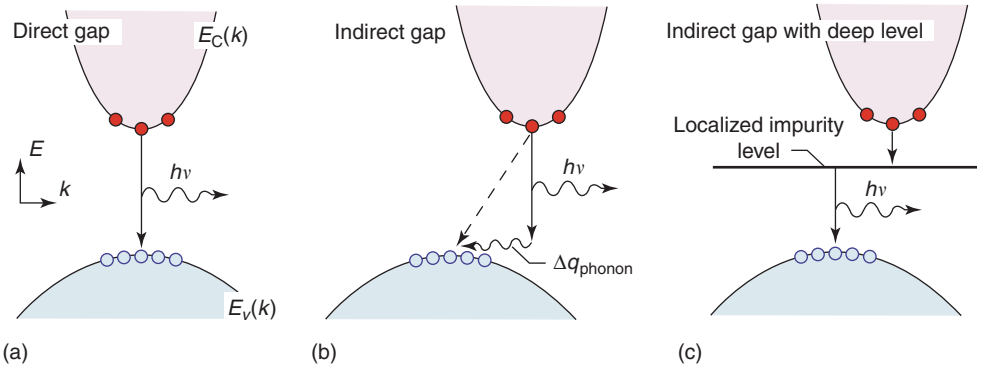

Figure 1 Semiconductor band structure for (a) direct-gap, (b) indirect-gap, and (c) indirect-gap semiconductors with deep isoelectronic impurity level. Indirect transitions have a much smaller probability due to the requirement of a phonon.

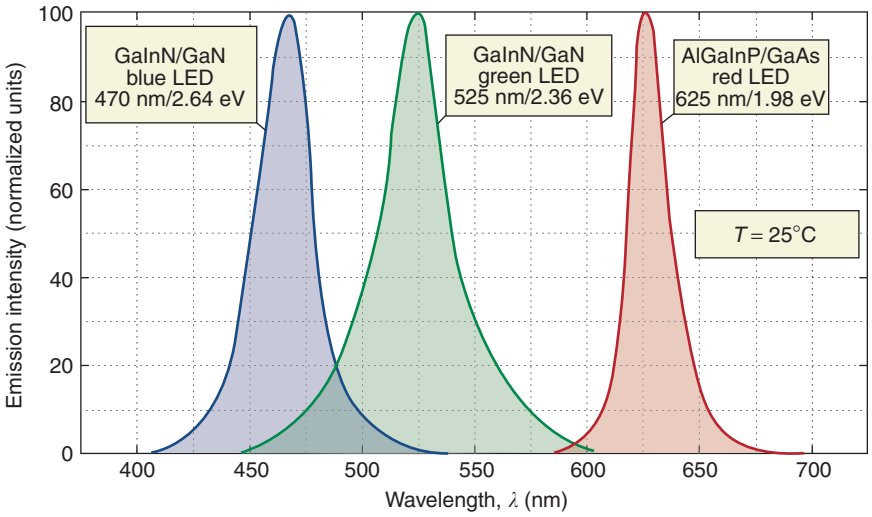

Figure 2 Typical emission spectrum of GaInN/GaN blue, GaInN/GaN green, and AlGaInP/GaAs red LEDs.

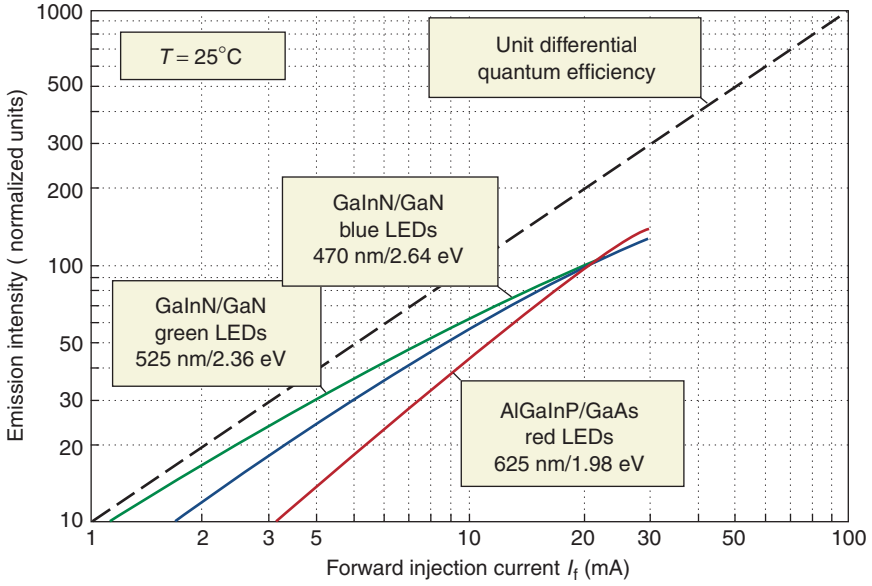

Figure 3 Typical light output power vs. injection current of GaInN/GaN blue, GaInN/GaN green, and AlGaInP/GaAs red LEDs.

or quaternary alloy, for example, $Ga_{1-x}In_xN$. Alloy broadening, caused by fluctuations of the active region chemical composition, leads to spectral broadening that goes beyond $1.8\,kT$. Alloy broadening is particularly strong in the green $Ga_{1-x}In_xN$ LEDs with line widths as wide as $10\,kT$ at room temperature.

The light-output-power versus injection-current is shown in **Figure 3** for three types of visible-spectrum LEDs. A linear dependence with unit slope (dashed line), that is, unit differential quantum efficiency, is expected for the light-versus-current curves. The mature AlGaInP LED closely follows the unit-slope line. However, the slope of the green and blue LEDs decreases with increasing current level indicating a decreasing efficiency (efficiency droop).

Electrical Properties

In the vicinity of the unbiased *p–n* junction plane shown in **Figure 4a**, electrons originating from donors on the *n*-type side diffuse to the *p*-type side where they recombine. A corresponding process occurs with holes. As a result, a region near the *p–n* junction, the depletion region, is depleted of

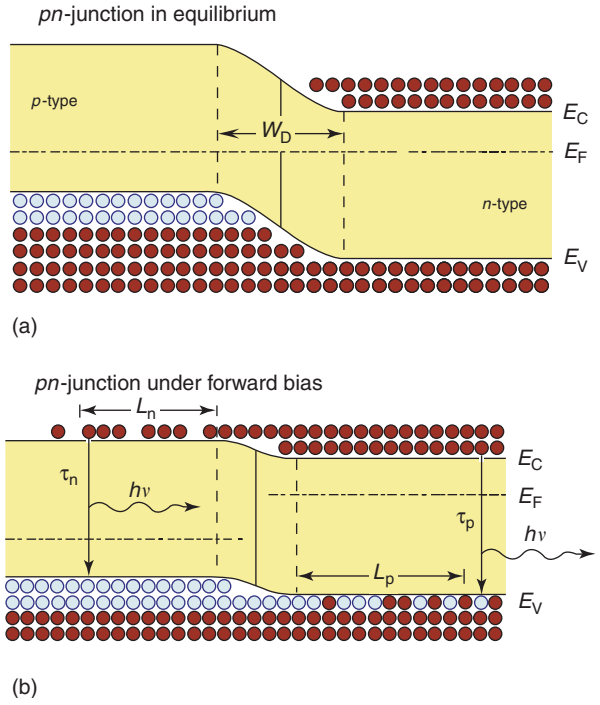

Figure 4 Band diagram and carrier distribution of a *p–n* homojunction (a) without and (b) with applied forward bias. $L_{n/p}$ and $\tau_{n/p}$ are the minority carrier diffusion lengths and lifetimes, respectively. W_D is the width of the depleted region.

free carriers. In the absence of free carriers in the depletion region, the only type of charge is ionized donor and acceptor charges. This depletion region produces a potential, the diffusion voltage, V_D, given by

$$V_D = \frac{kT}{e} \ln \frac{N_A N_D}{n_i^2} \quad [2]$$

where N_A and N_D are the acceptor and donor concentrations, respectively, and n_i is the intrinsic carrier concentration of the semiconductor. The diffusion voltage represents a barrier that free carriers must overcome in order to reach the neutral region of the opposite conductivity type.

The width of the depletion region is given by

$$W_D = \sqrt{\frac{2\varepsilon}{e}(V_D - V)\left(\frac{1}{N_A} + \frac{1}{N_D}\right)} \quad [3]$$

where $\varepsilon = \varepsilon_r \varepsilon_0$ is the dielectric permittivity of the semiconductor and V is the diode bias voltage.

An external bias applied to a *p–n* junction will drop across the depletion region, which is resistive due to the lack of free carriers. A forward bias decreases the *p–n* junction barrier causing electrons and holes to be injected into the neutral regions with opposite conductivity type. As the current increases, carriers diffuse into the regions of opposite conductivity type and recombine, thereby emitting photons.

The theory of current transport in *p–n* junctions was first developed by William Shockley in the early 1950s and the equation describing the *I–V* characteristic is known as the Shockley equation

$$I = eA\left(\sqrt{\frac{D_p}{\tau_p}}\frac{n_i^2}{N_D} + \sqrt{\frac{D_n}{\tau_n}}\frac{n_i^2}{N_A}\right)(e^{eV/kT} - 1) \quad [4]$$

where A is the junction area and $D_{n,p}$ and $\tau_{n,p}$ are the electron and hole diffusion constants and minority carrier lifetimes, respectively.

Under typical forward bias conditions, the diode voltage is $V \gg kT/e$, and thus $[\exp(eV/kT) - 1] \approx \exp(eV/kT)$. For forward bias conditions, the Shockley equation can be rewritten as

$$I = eA\left(\sqrt{\frac{D_p}{\tau_p}}N_A + \sqrt{\frac{D_n}{\tau_n}}N_D\right)e^{e(V-V_D)/kT} \quad [5]$$

The exponent in eqn [5] illustrates that the current strongly increases as the diode voltage approaches a threshold, which is about equal to the diffusion voltage, that is, $V_{th} \approx V_D$.

In an ideal diode, every electron injected into the active region will generate a photon. Thus, conservation of energy requires that the electron energy eV equals the photon energy $h\nu$, that is,

$$eV = h\nu \quad [6]$$

Beyond turn-on, the diode becomes highly conductive and the diode voltage V is about the same as the threshold voltage V_{th}. The energy of photons emitted from a semiconductor with energy gap E_g is given by

$$h\nu = E_g + (1/2)kT \approx E_g \quad [7]$$

Thus eqn [6] can be rewritten as

$$V_{th} \approx V_D \approx E_g/e \quad [8]$$

Diode I–V characteristics of AlGaInP red and GaInN green and blue LEDs are shown in **Figure 5**. The experimental threshold voltages shown in the figure and the comparison with the bandgap energy of these materials indicate that the energy gap and the threshold voltage indeed agree reasonably well.

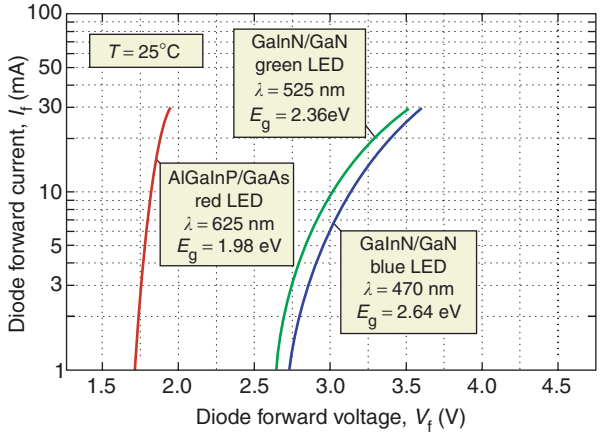

Figure 5 Forward current–voltage characteristic of GaInN/GaN blue, GaInN/GaN green, and AlGaInP/GaAs red LEDs.

Definitions of LED Efficiencies

The internal quantum efficiency of a current-injected semiconductor device is given by

$$\eta_{\text{int}} = \frac{\text{Number of photons emitted from active region per second}}{\text{Number of electrons injected into LED per second}} = \frac{P_{\text{int}}/(h\nu)}{I/e} \quad [9]$$

where P_{int} is the optical power emitted from the active region and I is the injection current. Not all photons emitted by the active region will escape from the LED semiconductor chip. The light extraction efficiency is defined as

$$\eta_{\text{extraction}} = \frac{\text{Number of photons emitted into free space per second}}{\text{Number of photons emitted from active region per second}} = \frac{P/(h\nu)}{P_{\text{int}}/(h\nu)} \quad [10]$$

where P is the optical power emitted into free space.

The external quantum efficiency is defined as

$$\eta_{\text{ext}} = \frac{\text{Number of photons emitted into free space per second}}{\text{Number of electrons injected into LED per second}} = \frac{P/(h\nu)}{I/e} = \eta_{\text{int}}\eta_{\text{extraction}} \quad [11]$$

The external quantum efficiency gives the ratio of the number of useful light particles to the number of injected charge particles.

The power efficiency is defined as

$$\eta_{\text{power}} = P/IV \quad [12]$$

where IV is the electrical power provided to the LED. Informally, the power efficiency is also called "wall-plug efficiency."

The luminous flux measures the light power of a source as perceived by the human eye in units of lumen (lm). One lumen is defined as the luminous flux of a light source emitting an optical power of (1/683) watt at 555 nm. For visible-spectrum LEDs, the luminous efficacy of radiation is defined as the luminous flux emitted by the source divided by the optical power, that is,

$$\eta_{\text{lum radiation}} = 683\,\frac{\text{lm}}{\text{W}}\int_{\lambda} V(\lambda)P(\lambda)\,d\lambda \Big/ \int_{\lambda} P(\lambda)\,d\lambda \quad [13]$$

where 683 lm/W is a normalization factor and $V(\lambda)$ is the eye sensitivity function. The luminous efficiency of the source is defined as the luminous flux emitted by the source divided by the input electrical power, that is,

$$\eta_{\text{lum source}} = 683\,\frac{\text{lm}}{\text{W}}\int_{\lambda} V(\lambda)P(\lambda)\,d\lambda/IV \quad [14]$$

where IV is the LED input power.

High Internal-Efficiency Structures

The radiative recombination rate R given in eqn [1] is proportional to the product of the carrier concentrations n and p. Therefore, a high concentration of carriers in the active region decreases the radiative carrier lifetime and the probability of nonradiative recombination.

The distribution of carriers in a p–n homojunction was shown in **Figure 4**. The minority carrier concentration decreases exponentially with distance from the p–n junction. The mean distance that a minority carrier diffuses before recombination is the diffusion length $L_{n/p}$ which is given by

$$L_n = \sqrt{D_n\tau_n} \quad \text{and} \quad L_p = \sqrt{D_p\tau_p} \quad [15]$$

where τ_n and τ_p are the electron and hole minority carrier lifetimes, respectively. In typical semiconductors, the diffusion length is of the order of micrometers. For example, the diffusion length of electrons in p-type GaAs is $L_n = (220\ \text{cm}^2\ \text{s}^{-1} \times 10^{-8}\ \text{s})^{1/2} = 15\ \mu\text{m}$. Thus, minority carriers are distributed over a region several microns thick and recombination occurs within a relatively large volume.

All high-brightness LEDs employ heterojunctions or quantum wells. A structure consisting of two barriers, that is, two large-bandgap semiconductors, is a

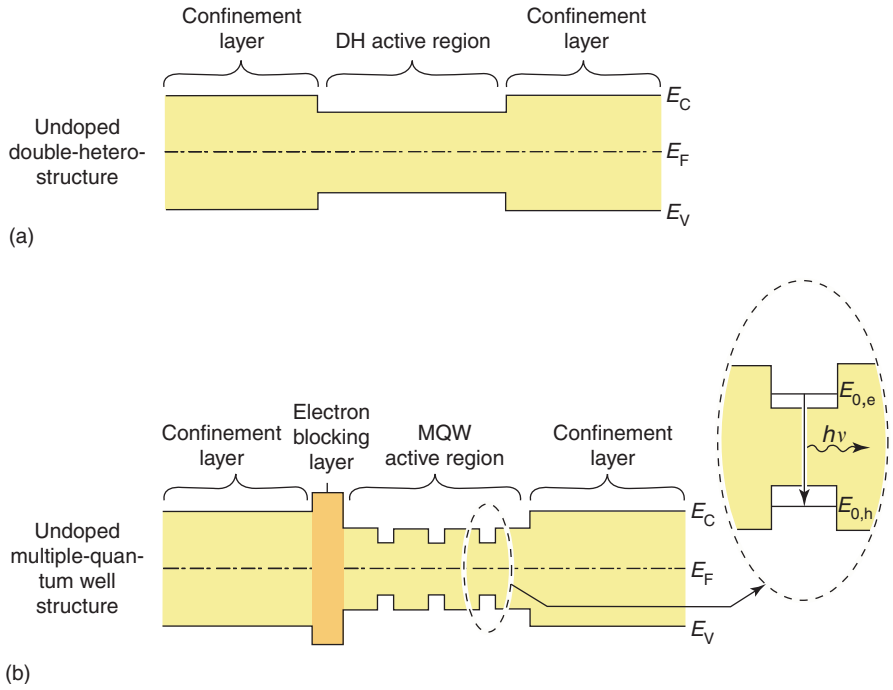

Figure 6 Band diagrams of undoped (a) double hetero (DH) and (b) multiple-quantum well (MQW) structures. The MQW structure employs an electron-blocking layer to avoid electron leakage out of the MQW active region. The inset shows the quantum well region and optical transition between quantized states.

double heterostructure (DH). A multiple quantum well structure (MQW) consists of wells made of a small-bandgap material embedded in the active region of a DH. Band diagrams of a DH and MQW structure are schematically shown in **Figure 6**. Carriers injected into the active regions of the DH or the MQW are confined to the well regions by the barriers. As a result, the thickness of the region in which carriers recombine is given by the thickness of the well rather than the diffusion length.

The consequences of this change are significant. It is assumed that the thickness of the active region is much smaller than the typical diffusion length. Whereas diffusion lengths are several micrometers, the well region of a DH ranges from 0.1 to 1.0 μm. An MQW structure can have well regions as thin as 2 nm. Thus, carriers in a DH or MQW structure have higher carrier concentrations than carriers in homojunctions and a resulting higher radiative efficiency. To further prevent leakage of carriers out of the active region, blocking layers are used, as shown in **Figure 6**. Because electrons are more mobile than holes, electron-blocking layers (rather than hole-blocking layers) are commonly used.

Although DHs and MQWs allow for impro ved LED designs, there are also problems associated with such structures. One of the problems introduced by heterostructures is the resistance caused by the formation of a barrier at the heterointerface. Carriers transferring from one semiconductor to another must overcome this barrier by either tunneling or by thermal emission. The resistance caused by heterojunctions can have a strong deleterious effect on device performance, especially in high-power devices. Fortunately, it has been shown that heterostructure band discontinuities can be completely eliminated by grading of the chemical composition of the semiconductor in the vicinity of the heterostructure.

The overflow of carriers from the active region into the confinement regions is another loss mechanism. Carrier overflow occurs at high injection current densities. As the injection current increases, the carrier concentration in the active region increases. For sufficiently high current densities, the active region is flooded with carriers and the Fermi level may rise to the top of the barrier. As a result, the optical intensity saturates. Carrier overflow of the active region is a potential problem in DH and MQW structures. In order to avoid this problem, high-current LEDs must employ thick DH active regions, or many QWs for MQW active regions.

High Extraction-Efficiency Structures

Owing to the high refractive index of semiconductors, light incident on a planar semiconductor–air interface is totally internally reflected, if the angle of

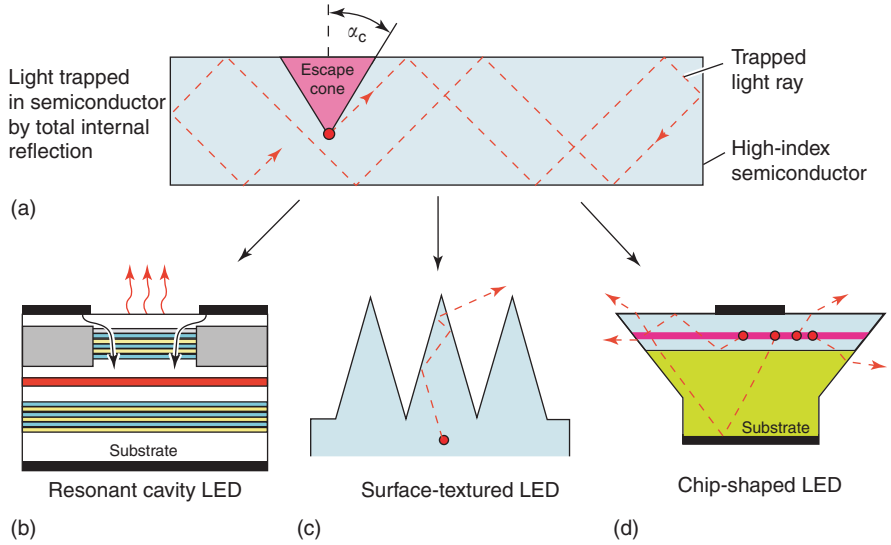

Figure 7 (a) Light rays emanating from a point-like emitter are trapped inside the semiconductor due to total internal reflection. Only light rays with propagation directions falling within the escape cone can leave the semiconductor. Strategies increasing the extraction efficiency include (b) resonant-cavity, (c) textured, and (d) chip-shaped LEDs.

incidence is sufficiently large. Snell's law gives the critical angle of total internal reflection. As a result of total internal reflection, light can be "trapped" inside the semiconductor. The occurrence of trapped light is illustrated in **Figure 7a**. In the high-index approximation, the angle of total internal reflection is given by $\alpha_c = n_s^{-1}$, where n_s is the semiconductor refractive index.

For high-index semiconductors, the critical angle is quite small. For example, for the GaAs refractive index of 3.3, the critical angle for total internal reflection is only 17°. Thus most of the light emitted by the active region is trapped inside the semiconductor. The trapped light eventually will be reabsorbed. Once absorbed, the electron–hole pair may re-emit a photon ("recycling" of a photon) or recombine nonradiatively. If re-emitted as a photon, the photon propagation direction may fall into the escape cone. Thus the exact magnitude of the active region internal quantum efficiency and the probability of a photon to be emitted into the escape cone will determine the overall quantum efficiency of a device. The magnitudes will also determine which strategy (direct light extraction or light extraction by photon recycling) will result in the most efficient device. In the limit of low and high internal efficiency, photon recycling is an ineffective and effective strategy to maximize power efficiency, respectively. Absorption of light in substrates and metallic contacts are other mechanisms lowering the extraction efficiency.

It has been known since the infancy of LED technology that the light-escape problem is strongly correlated to the geometrical shape of the LED chip. Common LED chips have the shape of a rectangular parallelepiped. Such LED chips are fabricated by cleaving the wafer along its natural cleaving planes. In a parallelepiped-shaped chip, light rays propagating within a total of six different cones (corresponding to the six surfaces of a parallelepiped) can escape from the chip. Although rectangular-parallelepiped LEDs have low extraction efficiency, a substantial advantage of such LEDs is low manufacturing cost.

There are different strategies to increase light extraction from LEDs including the resonant-cavity, surface-roughened, and chip-shaped LED shown in **Figures 7b–7d** respectively. The resonant-cavity light-emitting diode (RCLED) has a light emitting region inside an optical cavity. The optical cavity has a thickness of typically one-half or one times the wavelength of light, that is, a fraction of a micrometer for devices emitting in the visible or in the infrared. The resonance wavelength of the cavity coincides with the emission wavelength of the active region. The spontaneous emission properties from a light emitting region located inside the resonant cavity are enhanced by the change in optical mode density occurring in optical cavities. The RCLED was the first practical device making use of a spontaneous emission enhancement occurring in resonant cavities.

The placement of an active region inside a resonant cavity results in multiple improvements of the device characteristics. First, the light intensity emitted from the RCLED along the axis of the cavity, that

is, normal to the semiconductor surface, is enhanced by a typical factor of 2–10. Second, the emission spectrum of the RCLED has a higher spectral purity compared with conventional LEDs. In conventional LEDs, the spectral emission line width is determined by the thermal energy kT. However, in RCLEDs, the emission line width is determined by the quality factor (Q factor) of the optical cavity. As a result, the spectral emission width of the RCLED is a factor of about 2–10 narrower compared with conventional LEDs. Third, the emission far-field pattern of the RCLED is more directed compared with conventional LEDs. In conventional LEDs, the emission pattern is lambertian (i.e., cosine-function-like). In an RCLED, the emission pattern is directed along the optical axis of the cavity.

Other efficient ways to increase the light extraction efficiency include the use of roughened or textured semiconductor surfaces. A cone-shaped surface-roughening is shown in **Figure 7c**. Light rays emanating from the active region below the base of the cone undergo multiple reflections until they eventually have near-normal incidence at the semiconductor–air interface and then escape from the chip. For infrared GaAs-based devices, external quantum efficiencies of 40% have been demonstrated with surface-textured LEDs.

Several chip-shaped LEDs have been commercialized including the pedestal-shaped chip shown in **Figure 7d** and the truncated inverted pyramid (TIP) chip. The ray traces indicated in the figure show that light rays at the base of the pyramid can escape from the semiconductor after undergoing one or multiple internal reflections. The TIP geometry reduces the mean photon path-length within the crystal, and thus reduces internal losses. Ray tracing computer models are employed to optimize the sidewall angle thereby maximizing light extraction.

Packaging

Virtually all LED chips are encapsulated with optically transparent materials such as polymers, epoxies, or silicone. The most common encapsulant is epoxy resin, or briefly epoxy. Encapsulation is accomplished when the epoxy resin mixture is in its liquid state. The mixture is subsequently cured at high temperature to solidify the encapsulant.

The refractive index contrast between the semiconductor and air is reduced by epoxy. Epoxies have typical refractive indices of 1.5 to 1.8. A lower index contrast at the semiconductor surface increases the angle of total internal reflection thereby enlarging the LED escape cone and extraction efficiency.

Furthermore, the epoxy encapsulant commonly has the shape of a hemisphere, as shown in **Figures 8a** and **8b**, so that the angle of incidence at the epoxy–air interface is always perpendicular to the epoxy surface. As a result, total internal reflection does not occur at the epoxy–air interface.

Epoxy domes provide protection against unwanted mechanical shock, chemicals, and moisture (hermeticity). Epoxy also stabilizes the LED chip and bonding wire. Finally, epoxy provides mechanical stability to the two metal leads of the LED chip and holds them in place.

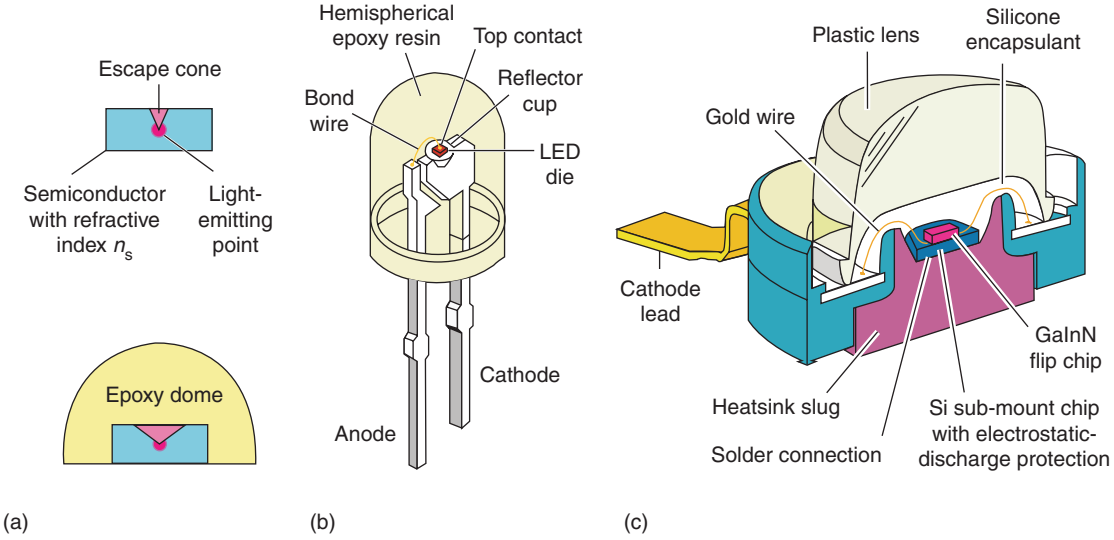

Figure 8 (a) Influence of an encapsulant on the escape cone. (b) Conventional LED in 5 mm package with hemispherical epoxy dome. (c) Package of high-power LED. (After Krames (2003) Overview of current status and recent progress of LED technology. *US Department of Energy Workshop* "*Solid State Lighting – Illuminating the Challenges*," Crystal City, VA.)

Epoxy remains transparent and does not show signs of degradation over a period of many years for long-wavelength visible-spectrum and IR LEDs. However, epoxies lose transparency in LEDs emitting at shorter wavelengths, namely in the violet and UV range. Furthermore, when exposed to temperatures exceeding 120°C for a sustained period of time, epoxies lose transparency and become yellowish.

In epi-side up GaInN LEDs grown on sapphire substrates with two side-by-side contacts, a large-area *p*-type top contact that covers the entire *p*-type mesa results in a uniform current distribution in the active region. However, such a large top contact will hinder the extraction of light. This fundamental trade-off can be avoided by flip-chip packaging where the LED is mounted with its topside facing a holder with good thermal and electrical conductivity. Flip-chip packaging is particularly advantageous for high-power devices.

A high-power LED package is shown in **Figure 8c**. The package has several advanced features including an Al or Cu heatsink slug that provides a low thermal resistivity of the package, a highly transparent silicone encapsulant that is chemically more stable than epoxy resin, and an electrostatic discharge protection (ESD) circuit integrated into a silicon submount.

The thermal resistance of LED packages together with the maximum temperature of operation determines the maximum thermal power that can be dissipated in the package. The maximum temperature of operation may be determined by reliability considerations, by the degradation of the encapsulant, and by internal-quantum-efficiency considerations. The 5 mm packages used for low-power LEDs (see **Figure 8b**) have a high thermal resistance of about $250\,\mathrm{K\,W^{-1}}$. Packages using heatsink slugs that transfer heat from the chip directly to a printed circuit board (PCB) which in turn spreads the heat, have thermal resistances of $6–12\,\mathrm{K\,W^{-1}}$.

Organic Light Emitting Diodes

Besides light emitting diodes based on inorganic materials, organic materials such as polymers and single crystals composed of organic molecules have been used as light emitters. Organic materials can display strong photo- and electroluminescence with quantum efficiencies of several percent. Organic light emitting diodes (OLEDs) have been used in active-matrix displays. With increasing efficiency, OLEDs could also become candidates for solid-state lighting applications. A schematic OLED structure consisting of a substrate, a transparent anode, organic electron and hole transport layers (ETL and HTL, respectively), and a low-workfunction metal cathode is shown in **Figure 9a**.

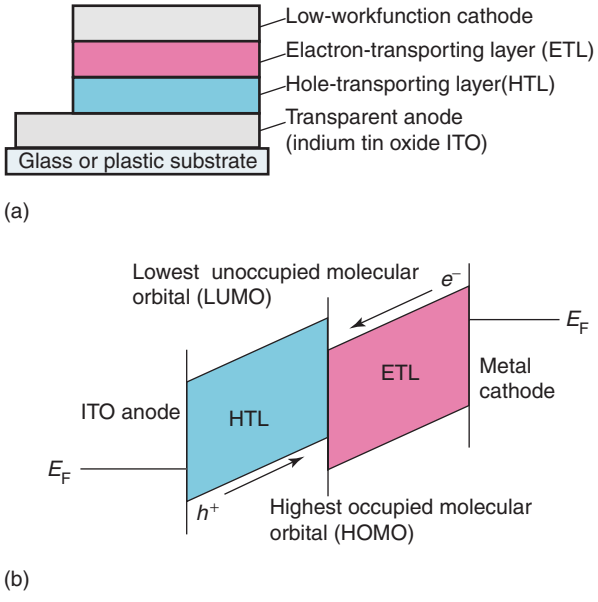

Figure 9 (a) Schematic structure of an OLED and (b) band diagram of an OLED in operation. (After Shinar (ed.) (2002) *Organic Light-Emitting Devices*, pp. 1–41. New York: Springer.)

Several organic materials are strongly luminescent such as the molecule tris-(8-hydroxy quinoline), Al (Alq_3), or the polymer poly(*p*-phenylene vinylene) (PPV). Many of the luminescent organic materials are π-conjugated compounds, in which p_z and p_y orbitals of neighboring C-atoms overlap and form π-orbitals and π-bonds. Due to the overlap, electrons in π-orbitals are delocalized along the bond axis between the two C-atoms. In organic polymers, the delocalized π-electron cloud extends along the entire length of the chain. The energy of electrons in π-orbitals is usually higher than the energies of electrons in σ orbitals. The gap between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) is usually between 1.5 and 3 eV (see **Figure 9b**). Both HOMO and LUMO are π orbitals.

Light-emission in OLEDs is caused by radiative transitions between a singlet-exciton excited state and the singlet-exciton ground state or by a radiative decay of the triplet excitons into the singlet ground state (phosphorescence). However, competing processes such as the decay of singlet states into polarons (charge transfer) or the photooxidative formation of carbonyl groups acting as singlet-quenching centers may drastically reduce the luminescence yield.

Under the influence of an electric field, holes and electrodes are injected into the organic material from

the anode and cathode, respectively (see **Figure 9b**). In most cases, the injection of electrons from the metal contact is less efficient than hole injection through the ITO anode resulting in vastly different carrier concentrations and in reduced device efficiencies.

Transport of carriers inside the OLED structure occurs through inter-site hopping between localized states forming narrow bands around the HOMO and LUMO levels. Electrons and holes crossing the organic HTL/ETL interface into the HTL and ETL, respectively, experience a significant reduction of their mobility. This carrier deceleration results in a charge accumulation near the interface and light generation in the near-interface region. However, strong carrier-concentration gradients at the interface can also lead to local electric fields strong enough to dissociate singlet excitons and decrease the emission efficiency.

OLEDs emitting in the red-to-green wavelength region with lifetimes exceeding 10^4 h (at low current densities) and external quantum efficiencies $>4\%$ have been demonstrated. White and blue OLEDs with lifetimes around 10^3 hours and similar efficiencies have been demonstrated as well. The external quantum efficiency is expected to increase so that organic light emitters may become attractive for an increasing number of applications.

Liquid Crystals

S Kumar and S-W Kang, Kent State University, Kent, OH, USA

Introduction

Liquid crystals (LCs) represent a state of matter intermediate between crystalline solids, which are characterized by a regular periodic arrangement of atoms or molecules, and isotropic liquids, which lack any type of order. They exhibit varying degree of orientational and/or translational order in specific spatial directions. For example, in the LC phase known as the smectic-A (SmA), with molecules arranged in stacked layers, one-dimensional translational order similar to a crystal exists in the stacking direction. However, within the layers, the molecular arrangement is liquid-like. Such a phase that is "liquid" in the two in-plane directions and "crystal" in the third, is one example of a large number of LC phases.

LC phases are formed by materials made of anisotropic molecules or other entities, such as aggregates of molecules in surfactant solutions known as micelles. LC phases formed by surfactant solutions are known as lyotropic liquid crystals and their discussion is beyond the scope of this article. The simplest of the LC phases, the nematic (N) phase, is formed when the molecules are oriented, on average, parallel to a common direction represented by an apolar unit vector, $\boldsymbol{n}$, referred to as the "director." The structure of the phases with degrees of order higher than the N phase is different for different molecular shapes. Different nomenclatures are introduced here to describe them. For the purpose of this article, the N phases are described first, followed by other phases exhibited by rod-like, disk-like, and then bent-core (banana) shaped molecules. Although

more than 50 LC phases are known, the focus here is only on those that are of fundamental scientific interest, commonly encountered, and/or have potential for technological applications. Classification of various phases is usually based on the concepts of symmetry relevant for liquid crystals such as orientational order, translational order, bond-orientational order, chirality, and dipolar ordering. The bond orientational order (BOO) refers to the degree to which crystal axes are parallel to each other over large distance. BOO can exist even when the lattice periodicity does not extend over large distances.

Nematic Phases

In the simplest nematic phase, rod-like molecules are oriented with their long axis on average parallel to the director, $\boldsymbol{n}$. The degree of order is described by a symmetric, diagonal, traceless, and real tensor order parameter $\boldsymbol{Q}$:

$$\boldsymbol{Q} = \begin{bmatrix} -\frac{S+\eta}{2} & 0 & 0 \\ 0 & -\frac{S-\eta}{2} & 0 \\ 0 & 0 & S \end{bmatrix}$$

When η is zero, it describes the uniaxial N phase, **Figure 1**, which may comprise of rod-like, disk-like, or bent-core molecules. In the uniaxial N phase, orientational order exists only along $\boldsymbol{n}$. The two directions orthogonal to $\boldsymbol{n}$ are degenerate. The order parameter S then measures how well the symmetry axes of the molecules are aligned. If the long axes of individual molecules are assumed to make an angle θ with respect to $\boldsymbol{n}$, then S reduces to

$$S = 1/2\langle 3\cos^2\theta - 1\rangle$$

where $\langle \cdots \rangle$ specifies thermal average. Optically, such phases are described by two indices of extraordinary and ordinary refraction, n_e and n_o in the directions parallel and perpendicular to $\boldsymbol{n}$, respectively.

Almost all LC displays used in commercial products such as laptop computers, hand-held devices, and flat-panel televisions employ the N phase. The ability to control the optic axis of this phase with the application of an electric field permits measured changes in the optical path length and the state of polarization of the transmitted light beam, and forms the basis of their operation.

If η is not zero, then $\boldsymbol{Q}$ represents a phase which has additional orientational order along a secondary director, $\boldsymbol{m}$, in the plane orthogonal to the primary director, $\boldsymbol{n}$. Such a phase, shown in **Figure 2**, is known as the biaxial nematic phase, N_{bx}, and it has three different indices of refraction along the three spatial directions. The parameter η measures the degree of biaxial order along the secondary director, $\boldsymbol{m}$.

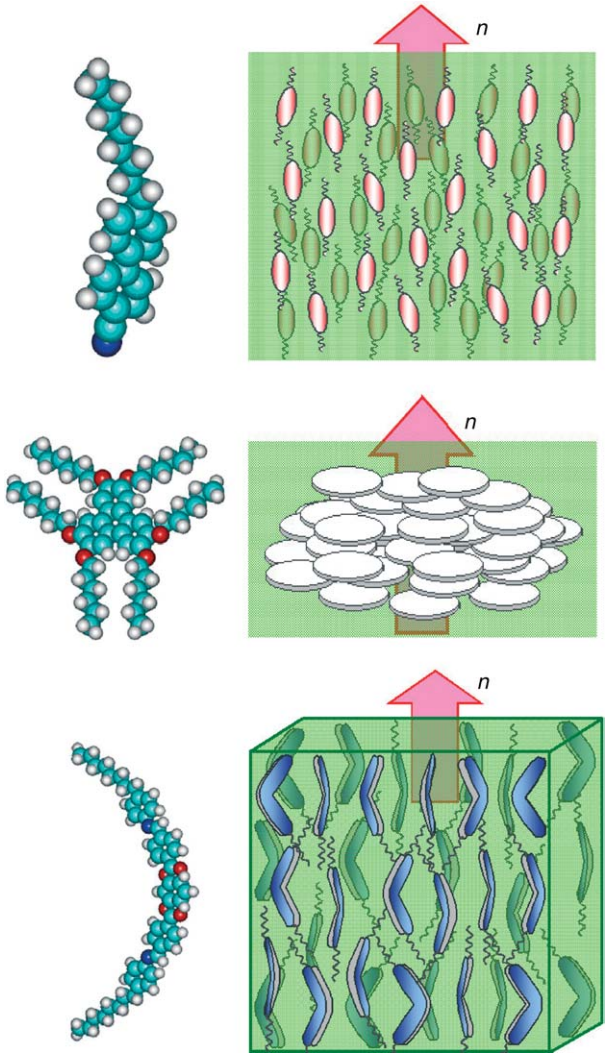

Figure 1 Schematic representation of molecular arrangement of (top to bottom) rod-like, discotic, and bent-core molecules in the uniaxial N phase.

The biaxial nematic phase was predicted on the basis of symmetry arguments in 1970 followed by a flurry of activity in theoretical and experimental areas. It was discovered in 1980 in lyotropic liquid crystals that, for a long time, have remained the only type of system to exhibit this phase. However, in monomeric (or molecular) systems, there were only false reports of its discovery. According to a group of experts who analyzed all prior reports of the existence of the N_{bx} phase in molecular LCs in 1998, the existence of this phase had not been substantiated. It is only very recently that its existence has been confirmed in the bent-core mesogens with X-ray

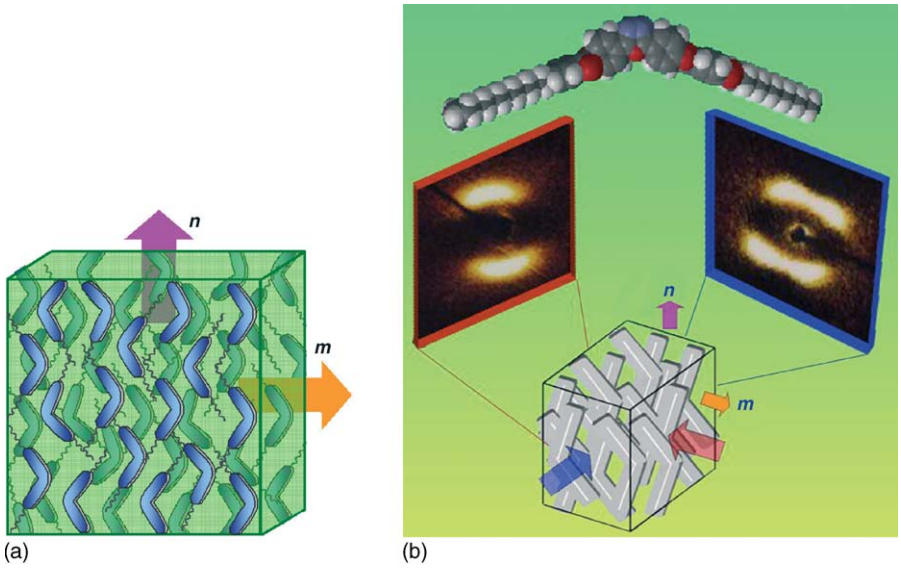

Figure 2 (a) Arrangement of bent-core molecules in the N_{bx} phase. (b) X-Ray diffraction patterns for the incidence directions (red and blue arrows) of X-rays with respect to the unit directions ***n*** and ***m***. Rubbed substrates were used to define ***n*** while an applied electric field controlled the orientation of ***m***.

diffraction on samples in which surface treatment and electric field were used to align the primary and secondary directors, respectively. The structure of this phase and experimental situations that confirmed the biaxiality is schematically shown in **Figure 2**. Subsequent to this discovery, a more careful study of the N phases formed by new bent-core materials has revealed the existence of both uniaxial and biaxial nematic phases at different temperatures in several single-component systems.

A special case of the uniaxial N phase arises when it is constituted of chiral (lacking mirror symmetry) molecules or when a small amount of chiral additive is dissolved in the N phase. This phase is known as the cholesteric phase as it was first observed in the derivatives of cholesterol. In the cholesteric phase, the unit vector ***n*** describes a helical trajectory of a well-defined pitch (**Figure 3**). Since there is no directionality to the vector ***n***, the molecular orientation repeats for every 1/2 pitch length or π-rotation. The pitch is, in general, strongly temperature dependent and often comparable to the wavelength of visible light. Cholesteric phases exhibit brilliant colors due to Bragg diffraction of light at the corresponding pitch. Thus, they show different colors of light at different temperatures. This property forms the basis of the "mood rings." (Mood rings are sold in gift shops. They change color as the wearer's body temperature (or, mood) changes.) The director for the cholesteric phase, in its component form, is written as $\boldsymbol{n} = [\cos(q_o z + \phi), \sin(q_o z + \phi), 0]$.

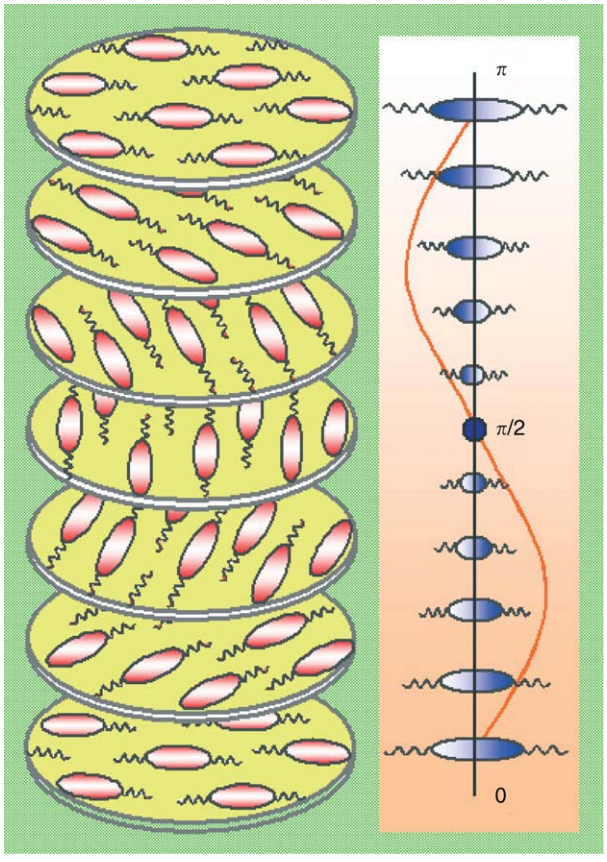

Figure 3 The orientation of molecules describes a helical trajectory in a cholesteric phase. Bragg reflections in optical regime occur for wavelengths equal to 1/2 of the pitch length.

Calamitic Mesophases

Molecules with cylindrical shape can form, in addition to the N and cholesteric phases, a class of phases that are known as the calamitic mesophases. These are layered structures referred to as the "smectic" phases. They all possess translational order in the direction perpendicular to the layers. In the two in-layer directions, the molecules can possess varying degrees of translational and bond orientational orders to form a large number of smectic phases. These phases are denoted with a different letter in the order of their discovery.

The SmA phase is characterized by a liquid-like order of molecules within the layers. As illustrated in **Figure 4**, the centers of mass of molecules are arranged in a periodic manner. The SmA phase is described by a two-component order parameter,

$$\Psi(\boldsymbol{r}) = \Psi_0 \exp(qz + \phi)$$

where Ψ_0 is the amplitude, ϕ is a phase factor, and the wave vector $\boldsymbol{q}$ is taken to be parallel to the z-direction. Within the layers, the molecules are oriented approximately parallel to each other defining the director $\boldsymbol{n}$ that is coincident with the layer normal, z.

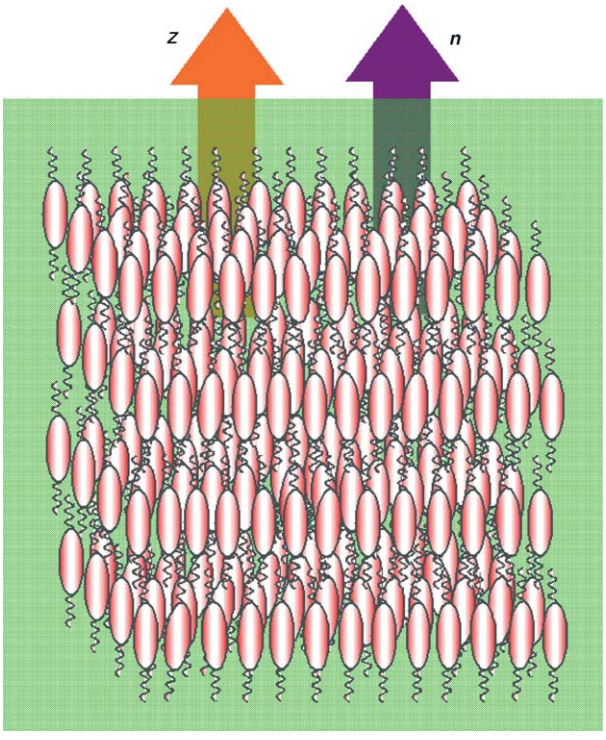

Figure 4 In the SmA phase, molecules are almost perfectly parallel to each other, $\boldsymbol{n}$, and the layer normal z. Within a smectic layer, they have no positional or bond-orientational order.

The smectic-C (SmC) phase, **Figure 5**, is very similar to the SmA phase and has layers with liquid-like molecular order. The major difference is that the molecules are tilted with respect to the layer normal. The molecular tilt in the SmC phase, or the angle between $\boldsymbol{n}$ and layer normal z, is a strong function of temperature as shown for the compound terephthal-bis-butylaniline (TBBA) in **Figure 6**.

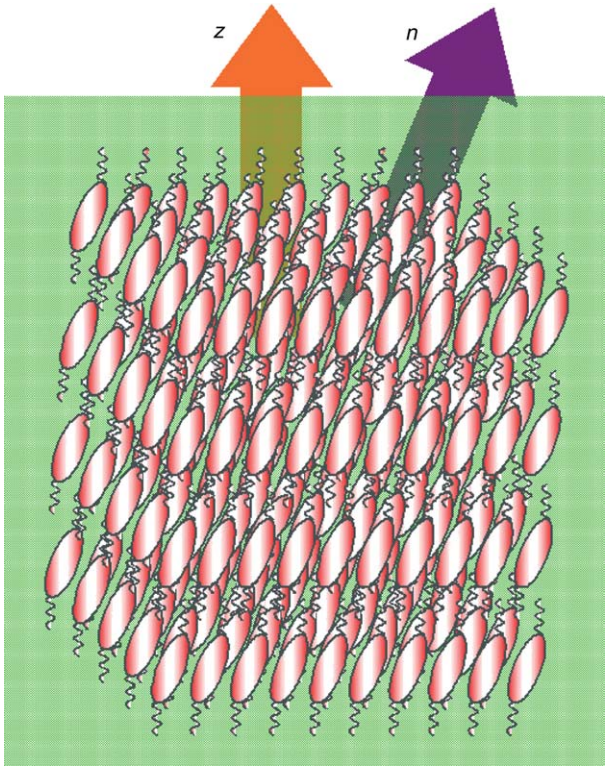

Figure 5 In the smectic-C phase, the director $\boldsymbol{n}$ along which the molecules are oriented, is oblique with respect to the layer normal z. Within a layer, the arrangement of molecules is liquid-like.

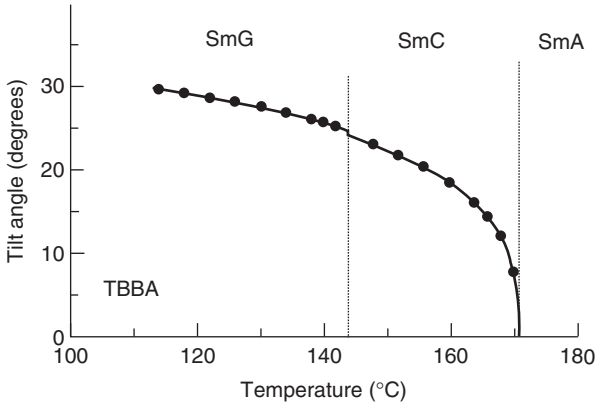

Figure 6 Temperature dependence of molecular tilt angle in the SmC and SmG phases of TBBA. The tilt continuously goes to zero as the SmA phase is approached.

Other more ordered smectic phases possess different degrees of bond-orientational and positional order within the smectic layers. Exotic calamitic, hexatic, and crystalline smectic phases with long-range bond-orientational and/or positional order are known to exist with and without molecular tilt with respect to the layers. These are not discussed in this article.

Ferroelectric and antiferroelectric smectic phases are formed by molecules lacking reflection symmetry and having a permanent molecular dipole moment directed nearly perpendicularly to the molecular long axis. These phases are very similar to the SmC phase with added chirality along the direction parallel to the layer normal. Molecular dipoles within a smectic layer are all oriented in the same direction, that is, in a ferroelectric manner. This chiral ferroelectric smectic phase is denoted as the SmC^* phase (**Figure 7a**), here "*" implies the chiral nature. The SmC^* phase possesses macroscopic spontaneous polarization density ***P***, the orientation of which can be manipulated with the help of a torque exerted on molecular dipoles by an applied electric field. Electrooptical devices based on the SmC^* phase have been shown to respond with a time constant of a few microseconds, about a thousand times faster than nematic devices.

When the dipole ordering in adjacent smectic layers is antiparallel, as shown in **Figure 7b**, the phase is known as the antiferroelectric SmC^* phase or SmC^*_A phase. The structure is still helical, but here azimuthal orientation of molecules in two layers with oppositely directed ***P*** describes the helical trajectory. Other versions of such phases are also known and can be found in the literature.

The twist-grain boundary (TGB) phase is an analog of the Abrikosov phase in a type-II superconductor, and is made of blocks of smectic layers, with no in-plane order, permeated by regions of twist deformation, **Figure 8**. Depending on the absence (SmA) or presence (SmC) of molecular tilt with respect to the layer normal, one obtains the TGB_A or

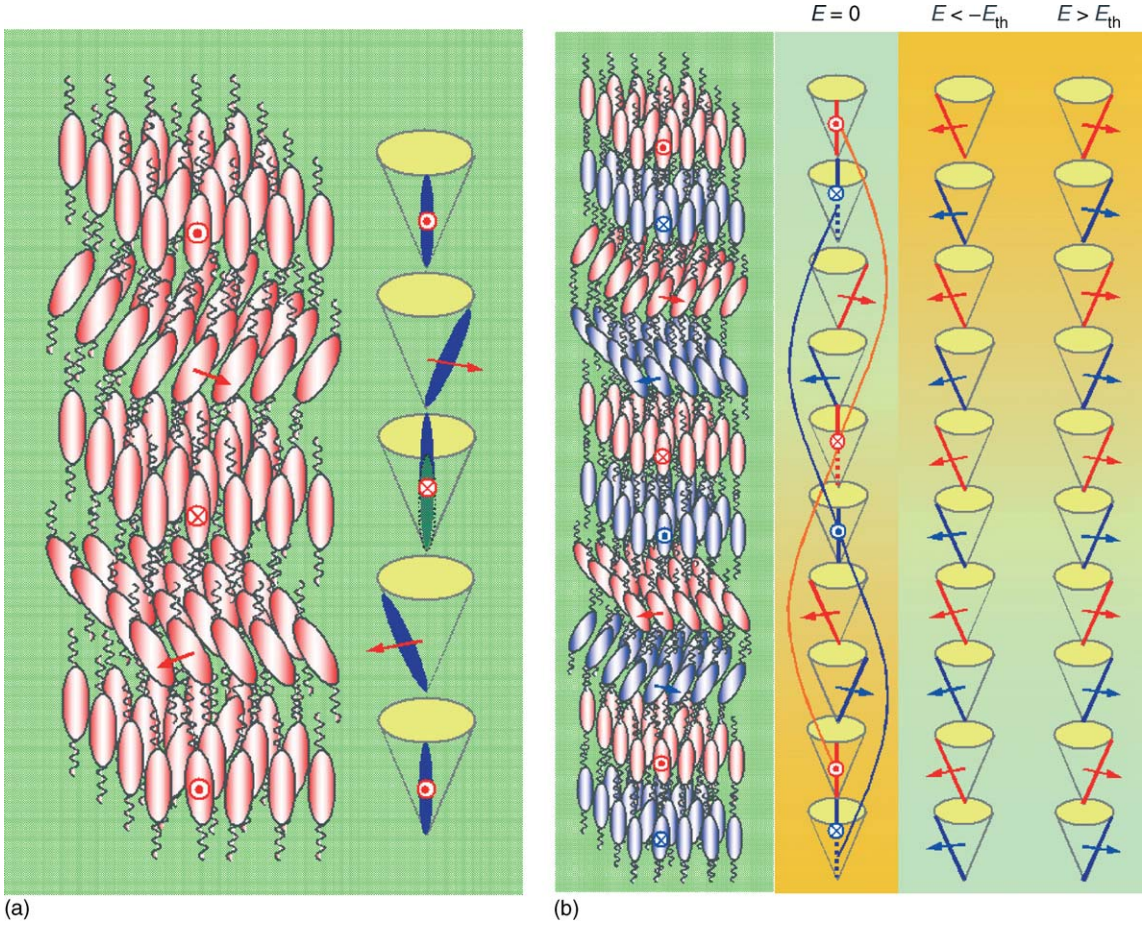

Figure 7 (a) Ferroelectric SmC^* phase. (b) Antiferroelectric SmC^*_A phase in which oppositely tilted molecules describe double helical trajectory. Red and blue arrows represent molecular dipoles. The antiferroelectric phase reverts to ferroelectric phase when a field higher than a threshold is applied. The orientation of the molecular dipoles depends on the direction of the field.

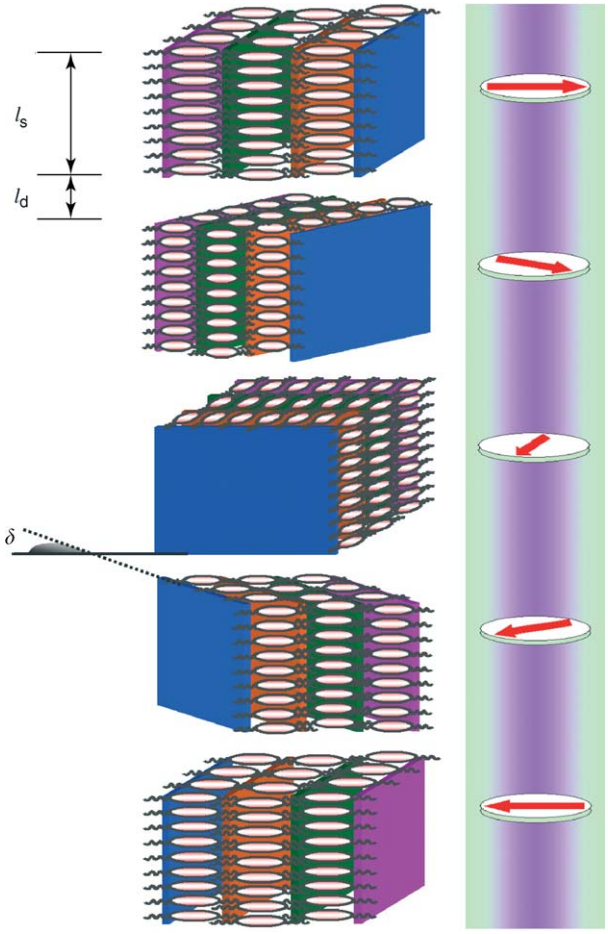

Figure 8 Schematic drawing of TGB_A phase with pitch axis vertical. The red arrows mark the direction of layer normal.

TGB_C phases. In these phases, a twist axis exists in the direction of smectic planes. Consequently, the phase appears to be a string of smectic-like slabs of a fixed dimension l_s, and arranged adjacent to each other with a narrow (of length l_d) region of twist defect. When the angle of twist, δ, between neighboring slabs is such that $2\pi/\delta$ is an integer (or, a rational number), it is referred to as the "commensurate" TGB phase and X-ray diffraction pattern of an oriented sample features a discrete set of reflections at the same magnitude of momentum transfer vector. However, if $2\pi/\delta$ is an irrational number, then the X-ray pattern consists of a continuous diffraction ring and it is referred to as the "incommensurate" TGB phase.

Discotic or Columnar Mesophases

Discotic mesophases are exhibited by somewhat larger molecules that have nearly flat disk-like cores. These molecules naturally like to pack by forming stacks (or, columns) of cores as illustrated in

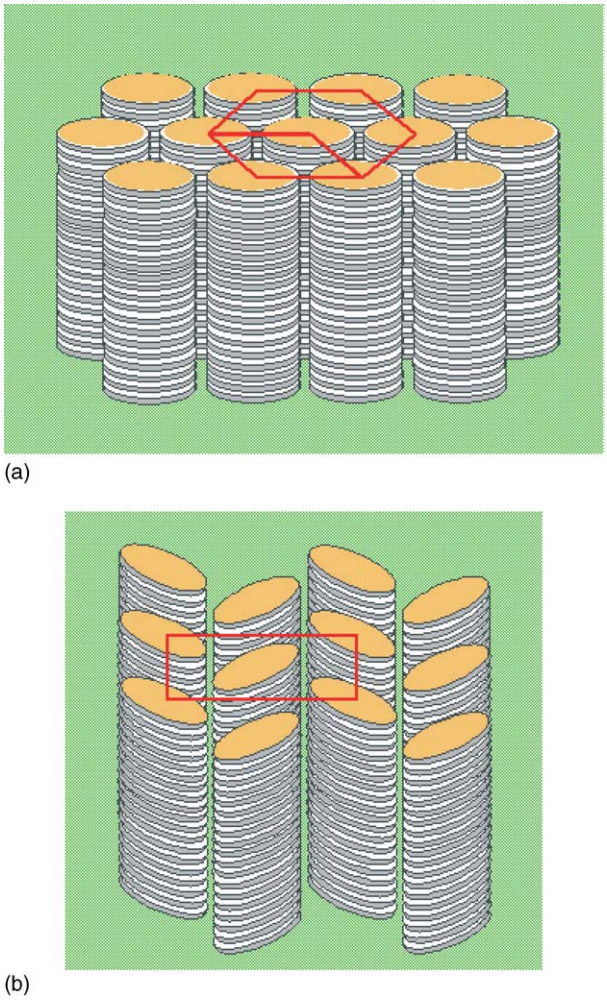

Figure 9 (a) Hexagonal D_h and (b) rectangular D_r columnar mesophases. Discotic mesophases lack positional order in the direction of column axis.

Figure 9. The alkyl chains are not shown for clarity. The columns of molecules form two-dimensional lattices depending on the details of molecular shape and intermolecular interactions. There is no long-range positional order in the direction of the column axis. They are crystal in two dimensions and liquid in one, in contrast to the calamitic mesophases.

Depending on the 2D space group corresponding to the arrangement of columns, these are given different names. In the hexagonal (D_h) phase, the disks are arranged in hexagonal close-packed manner and the plane of the molecular cores is perpendicular to the column axis. The cores can also be tilted with respect to the column axis and permit rectangular (D_r) or rectangular face-centered phase molecular arrangement. In the D_r phase, the core in a column is tilted with respect to the cores in neighboring columns, forming a herringbone arrangement. The tilted cores are shown as ellipses in **Figure 9b**.

Bent-Core Mesophases

Bent-core (or, banana) mesophases, as the name suggests, are formed by molecules resembling a boomerang (see **Figures 1** and **10**). In recent years, the discovery of novel mesophases formed by the bent-core molecules has engendered much scientific interest in them. The phases exhibited by bent-core molecules are denoted as B_i, where $i = 1,2,\ldots,8$, etc. The progression of the index i does not in any way imply a systematic evolution of the structure of the various phases. The structure of some of the phases has been determined while it remains uncertain for others. In the following, what is known at this point in time is summarized. The structure of different phases is discussed in an order to minimize confusion. This is an active and rapidly growing area of research and it is likely that the current understanding of some of these phases will undergo revision/refinements. Their names and notations are very likely to change in the near future as one learns more about them and streamlines the nomenclature on the basis of the symmetry.

Owing to their unique geometrical shape, the phases have revealed surprising structures and properties. For example, the formation of polar and chiral structures by achiral molecules is unexpected. Bent-core materials show the largest electronic second-order susceptibility $\chi^{(2)}$ of all known LCs. Until now, the formation of ferroelectric phases with macroscopic electric polarization was limited to chiral molecules. Some of the bent-core mesophases exhibit interesting ferro- and anti-ferroelectric properties.

In the B_1 phase, the molecules partially overlap along their overall long axis and they are arranged in smectic layers. Additionally, in a plane perpendicular to the smectic layers, molecules are organized in a 2D centered rectangular lattice, **Figure 10**. From studies of single domain samples, there are no indications of positional correlations in the direction perpendicular to the plane containing the 2D lattice. From a symmetry point of view, this phase resembles the columnar D_r phase. Unit cell dimensions, as expected, are related to molecular size. For example, in case of a series of bent-core azo compounds (i.e., those containing the divalent radical N:N), the rectangular cell dimensions are $a = 36.4 \pm 0.2$ Å and $c = 30.4 \pm 0.2$ Å. Two forms of the B_1 phase have been reported; in one, the molecules are orthogonal to the smectic layers while in the second form, they are tilted in a manner similar to the SmC phase. These have been assigned the names B_{1o} and B_{1t} for the orthogonal and tilted phases, respectively.

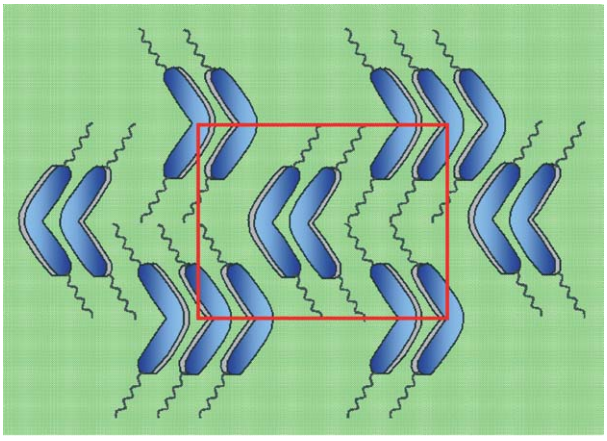

Figure 10 Molecules in the B_1 phase occupy a rectangular lattice in a plane perpendicular to smectic layers. No long-range positional correlations exist in the direction perpendicular to the rectangle.

A group of four phases which are stacked layers (or smectic) is known as the B_2 phase(s). Here, the molecules are tilted and they resemble the tilted chiral phases (SmC^*, SmC^*_A) of calamitic mesogens. The molecules forming these phases may possess a dipole p directed along their apex. Furthermore, the tilt in adjacent layers may be in the same azimuthal direction (synclinic, S) or in opposite directions (anticlinic, A). The direction of the molecular dipoles in one smectic layer may be the same as in the adjacent layers (ferroelectric, F) or antiparallel (antiferroelectric, A). These four possibilities are schematically shown in **Figure 11** and denoted as SmC_AP_F, $SmC_SP^*_F$, SmC_SP_A, and $SmC_AP^*_A$. It should be noted that the $SmC_SP^*_F$ and $SmC_AP^*_A$ phases essentially possess the same symmetry as the calamitic ferroelectric SmC^* and antiferroelectric SmC^*_A phases, respectively, and they may exist in both left- and right-handed chiral states. The other two phases, SmC_SP_A and SmC_AP_F, are antiferroelectric and ferroelectric racemates, respectively.

The B_3 and B_4 phases are actually crystalline phases. In the literature, the B_4 phase is also referred to as the blue crystal phase. This phase is chiral and exhibits circular dichroism. Only preliminary details about the structure of the B_3 and B_4 phases are available at this time. These phases are not discussed here.

The B_6 and B_8 mesophases possess smectic stacked-layer organization with no in-plane order. The B_6 and B_8 phases differ from the regular smectic phases in an important way. The smectic layer spacing is different from molecular length because in the B_6 phase, the molecules have partial lengthwise overlap at the smectic layer interface. However, unlike the B_1 phase, in the B_6 and B_8 phases, **Figure 12**, there is no other order present apart from the smectic layering. The primary layer thickness is less than the

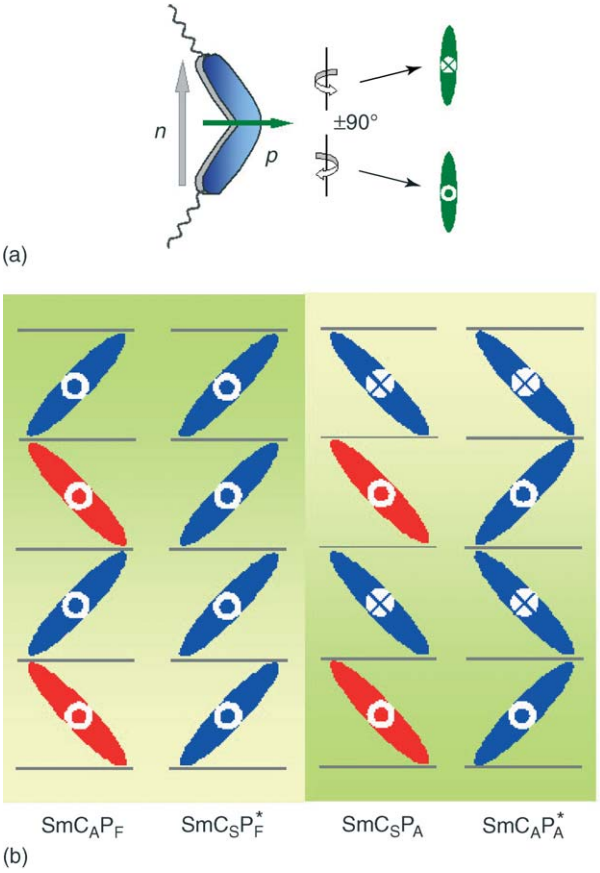

Figure 11 (a) Different views of bent-core molecules and (b) the four structures formed in the B_2 phase. In some materials, more than one structure may be simultaneously present.

molecular length. Such phases exhibit additional peaks in the X-ray diffraction pattern, corresponding to a length that is less than twice the molecular length. A tilted analog phase of the B_6 phase has also been reported. In the B_8 phase, the molecules form a weak antiparallel association with molecules in the adjacent layers and act as dimers with no overlap of the cores. The smectic layer spacing in this phase is close to twice the molecular length. The B_6 and B_8 phases can be considered as analogs of the SmA_d and SmA_2 phases in the frustrated (or polar) smectics. The B_8 phase presents an antiferroelectric arrangement of molecular dipoles. Tilted and chiral variants of the B_6 and B_8 phases are also likely to exist.

The B_7 phase exhibits chiral textures of both right and left handedness under a polarizing microscope. There are some reports of this phase responding to an applied electric field in both ferro- and antiferroelectric manner. The B_7 phase has a layered structure with either the same or different tilts in adjacent layers, which are either ferroelectric or antiferroelectric. They exhibit twisted helical filaments, high- and low-birefringence focal conics striped patterns

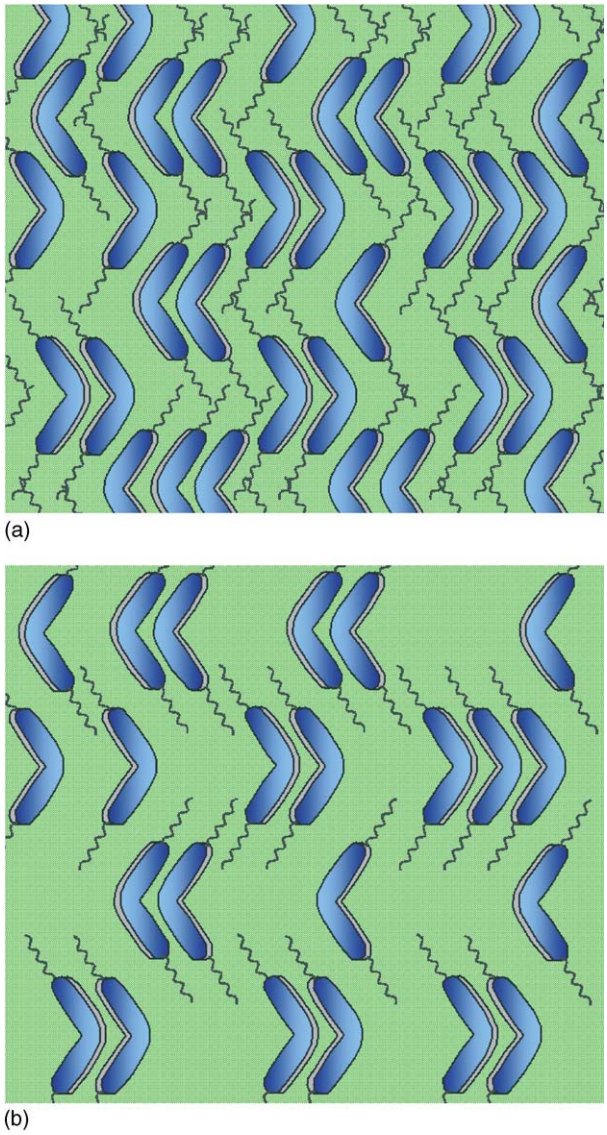

Figure 12 (a) Partial bilayer structure of the B_6 and (b) B_8 phase.

parallel or normal to the smectic layers. Unraveling the structure of this phase has been the most challenging of all bent-core mesophases. Optical, freeze fracture, and high-quality synchrotron X-ray diffraction studies of thin and bulk samples are beginning to reveal a complex 3D structure. In the B_7 phase, SmC^*-type layers are subdivided into stripes with splay deformation and defect lines shown as red and blue vertical lines in **Figure 13**. Splay deformations naturally cause smectic layer (thickness) undulations because the disorder of ***P*** and molecular tilt produces a smaller molecular tilt and thus higher layer spacing. For a specific sign of splay, there are four possible combinations of handedness and orientations of ***P*** across smectic layers. These four

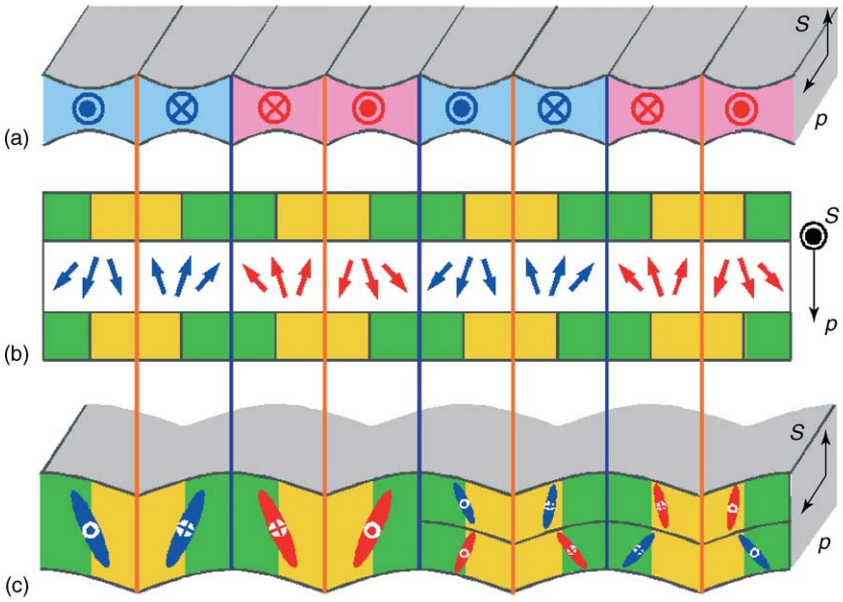

Figure 13 (a) Variation of the layer spacing due to polarization modulation induced by the formation of splay stripes shown in (b). (c) Different regions separated by defect lines possess local structures similar to the SmCSPF and SmCAPF structures of the B_2 phase. Vectors ***P*** and ***S*** represent the polarization and average layer normal directions, respectively. Arrows in (b) and vector directions in (a) and (c) represent the molecular dipoles and their splay organization.

combinations are exactly the same as already discussed for the B_2 phase (**Figure 11**). A general depiction of the essential feature of layer undulations and molecular arrangement is illustrated in **Figure 13**. The uniformity of the pitch in the layer-normal direction on a macroscopic scale requires the thinner layer regions between the defect (vertical blue and red) lines to tilt and become thicker. This results in a polarization-modulated structure with a pitch much larger than the smectic layer spacing. X-ray studies reveal that the period of modulations of the smectic layers is very well defined, giving rise to sharp Bragg peaks in the transverse direction. The undulations have a temperature- and material-dependent period ranging from $\sim$15 to 35 nm. The length over which the undulations are correlated is found to be the same as the dimension over which the smectic layers prevail, that is, undulations are long-range deformations and an integral feature of the B_7 phase.

The possibility of helical polarization-modulated filaments and twisted grain-boundary (TGB) structures with polarization modulation open the possibility of the formation of a number of unique defect structures which may be responsible for the basis of formation of a large variety of textures by the B_7 phase.

The B_5 phase is normally obtained upon cooling from the B_2 phase. The molecular arrangement in the B_5 phase is similar to the B_2 phase. The liquid-like X-ray diffraction peaks at large angles arising from the in-plane structure of the smectic layers are quite sharp. However, they remain reasonably wide to suggest that the in-plane structural order is not long range. This phase is very likely to be an analog of the orthogonal hexatic smectic (SmB_{hex}) phase of calamitic liquid crystals. The B_5 phase responds, albeit sluggishly, to an applied field confirming increased order and viscosity.

Many soft condensed matter systems and biological materials possess liquid crystalline structures. For example, rod-like objects such as tobacco mosaic virus on one hand and carbon nanotubes on the other, are known to form LC phases. With the ever expanding knowledge of naturally occurring phenomena and efforts to synthesize new molecular shapes, the list of liquid crystalline materials is bound to keep growing, revealing new structures and novel scientific phenomena.

Liquids, Electronic Structure of

M P Tosi, Scuola Normale Superiore, Pisa, Italy

Introduction and Overview

Everyday experience testifies to the existence of three states of matter: solid, liquid, and gas. Solids are rigid, while liquids and gases flow under a shear stress however small. Crystals when studied by X-ray diffraction give rise to sharp Bragg reflections, while there are no sharp spots in the diffraction pattern when X-rays are scattered from a fluid or from a glass. This shows that long-range order among atoms or molecules is no longer present. However, the qualitative distinction drawn from the diffraction pattern does not carry through to distinguish between liquid and gas. Below a critical temperature and pressure these two phases can coexist at equilibrium with different densities, while above the critical point there is a single fluid phase. The difference between the two fluid phases lies in their density and this implies that the interatomic forces play a much greater role in the dense liquid than in the dilute gas.

A useful way to open an overview on the electronic structure of liquids is to recall the five types of crystal binding: covalent, hydrogen, ionic, metallic, and van der Waals bonding. Rare gas atoms such as argon are spherical and chemically saturated, so that the binding is due to van der Waals forces and the electronic structure is essentially unchanged on melting (here and in the following, liquids near the melting curve at standard pressure, except where explicitly noted, are considered). The only disorder that is possible in these fluids is related to translational motions – but when the building blocks are molecular units, the possibility of rotational disorder arises. Rotational order may disappear before melting as in plastic crystals such as N_2, or persist beyond the loss of translational order as in liquid crystals. Transitions may also occur in some molecular liquids on heating, such as a breakage of chains in Se or of eightfold rings in S.

It stands to reason that the electronic structure of a metal is essentially unchanged on melting. There are, however, a number of properties of liquid metals that intrinsically depend on the sea of conduction electrons, and these are the first item in this article. The article also describes how electrons may enter to determine the approach of a metal to the critical point, the transport properties of metals, the structure of some liquid alloys, and the phase diagram of elemental hydrogen in its various phases and of hydrogen–helium mixtures inside the giant planets.

In contrast to metals, dramatic changes in the electronic structure occur on melting in some covalent systems such as B, Si, Ge, and III–V compounds: the covalent bonds collapse into a metallic state, though with some peculiarities of its own. These elemental melts can be brought into an amorphous state by rapid quenching, just as those of other covalent compounds such as SiO_2 or $GeSe_2$ whose liquid structure is best described as a disordered covalent network.

Turning to ionic materials, their electronic structure is again quite stable across melting, although in some cases the state of aggregation of the ions may drastically change: for example, $AlCl_3$ melts from a layer structure where the Al ions are sixfold coordinated into a liquid of Al_2Cl_6 molecular dimers showing fourfold coordination of Al. The presence of chemical order in these melts can favor the acceptance of foreign electrons inside the liquid structure, as in

mixtures with metals that may be stable over a wide range of concentration.

The article ends with a brief reminder of how hydrogen bonding is formed in water and leads to the unique properties of this life-sustaining liquid.

Electron Theory of Liquid Metals

Interatomic Forces and Liquid Structure

Here, some properties of simple liquid metals with *s* and *p*-type conduction electrons, which reflect their nature as two-component liquids of ions and electrons, are reviewed. First of all, the effective interactions between pairs of ions in the metal involve screening of their bare Coulomb repulsions by the conduction electrons. For simplicity, an ion inside a fluid of interacting electrons as a static point charge Z_1e is considered. A second ion with charge Z_2e sees the potential of the first as well as the potential due to the polarization induced in the electron gas, so that the effective interaction potential of the two ions (in Fourier transform at wave number q) is

$$\phi_{12}(q) = \frac{4\pi Z_1 Z_2 e^2}{q^2 \varepsilon(q)}$$

with $\varepsilon(q)$ the dielectric function of the electron gas. The Thomas–Fermi theory affords a simple model for this function, yielding $\varepsilon(q) = 1 + (q\lambda_{TF})^{-2}$ where $\lambda_{TF}\sqrt{(\pi\hbar^2/4mk_Fe^2)}$ is the Thomas–Fermi screening length. Here $\hbar$ is Planck's constant, $k_F = (3\pi^2 n)^{1/3}$ the Fermi wave number of the electron gas, and n, m, and e the density, mass, and charge of the electrons.

As a simple example, the sound waves propagating in the metal are considered. In the absence of screening, the collective ionic motions at long wavelengths would be oscillations occurring at the ionic plasma frequency $\Omega_p = (4\pi NZ^2e^2/M)^{1/2}$. The effect of screening is to replace Z^2e^2 by $Z^2e^2/\varepsilon(q) \to Z^2e^2(q\lambda_{TF})^2$ at long wavelengths: screening thus yields an acoustic mode at frequency $\omega = c_s q$ with a value $c_s = v_F(Zm/3M)^{1/2}$ for the speed of sound. Here Z is the ionic valence, $N = n/Z$ the ionic density, M the ionic mass, and $v_F = k_F/m$ the Fermi velocity.

Classical theories of liquid structure aim to calculate the ion-pair distribution function and hence the diffraction pattern of the liquid from a given interatomic force law. Conversely, one may invoke the use of experimental diffraction data to extract an interionic pair potential by a careful analysis. **Figure 1** shows a comparison between such a "diffraction potential" from data on liquid Na and that calculated from electron theory. All major features of the diffraction potential are reproduced by the theory, though some quantitative discrepancies remain.

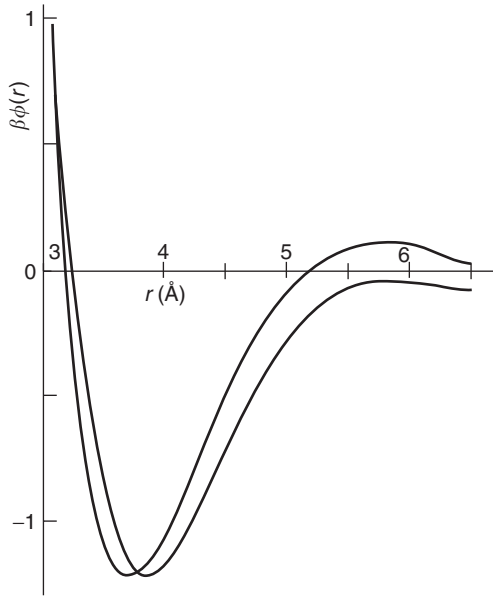

Figure 1 Effective pair potentials (multiplied by $\beta = (k_B T)^{-1}$) in liquid Na: from diffraction data (lower curve at large distance r) and from electron theory (upper curve at large r).

Expanded Fluid Cesium

Through its dependence on electron screening, the effective interionic pair potential in a liquid metal depends on the electron density in an important way. The detailed extensive work carried out in the 1980s and 1990s by Hensel and co-workers on expanded liquid alkali metals, and especially on liquid Cs, along the liquid–gas coexistence curve toward the critical point and has shown that, as the liquid density is reduced, the coordination number of each ion rapidly decreases whereas the near-neighbor distance stays remarkably constant. The coordination number of a Cs atom that is obtained from the data by extrapolation to the critical density approaches the value 2. This suggests that, as the metallic fluid is driven toward a metal–insulator transition, chain-like structures are stabilized by chemical bonding and probably coexist with small clusters such as ionized dimers. On the gas side of the critical point, one finds a large number of diamagnetic units such as Cs_2 molecules and probably larger clusters.

Transport Coefficients

The electrical resistivity ρ_e of a liquid metal in an ideally pure state is determined by the quasielastic scattering of conduction electrons on the Fermi surface against screened fluctuations in the ionic density.

The spectrum of these fluctuations as a function of wave number q and frequency ω is expressed in terms of the nucleus–nucleus dynamic structure factor $S(q,\omega)$ and, on exploiting the vast difference in the frequency scales for ionic and electronic motions, one obtains the result

$$\rho_e = \frac{3\pi m^2}{4Ne^2\hbar^3 k_F^6}\int_0^{2k_F} dq|\phi_{ie}(q)|^2 q^3 S(q)$$

Here, $\phi_{ie}(q)$ is the screened electron–ion potential and $S(q)$ is the structure factor which describes the measured diffraction pattern of the liquid metal. A comparison with the data on the electrical resistivity of liquid alkali metals as a function of temperature is shown in **Figure 2**.

The electronic contribution is also dominant in the thermal conductivity κ of metals. Indeed, the Wiedemann–Franz law asserts that the quantity $\rho_e\kappa/T$ is a universal constant, the Lorenz number $L = \pi^2 k_B^2/3e^2$ where k_B is the Boltzmann constant.

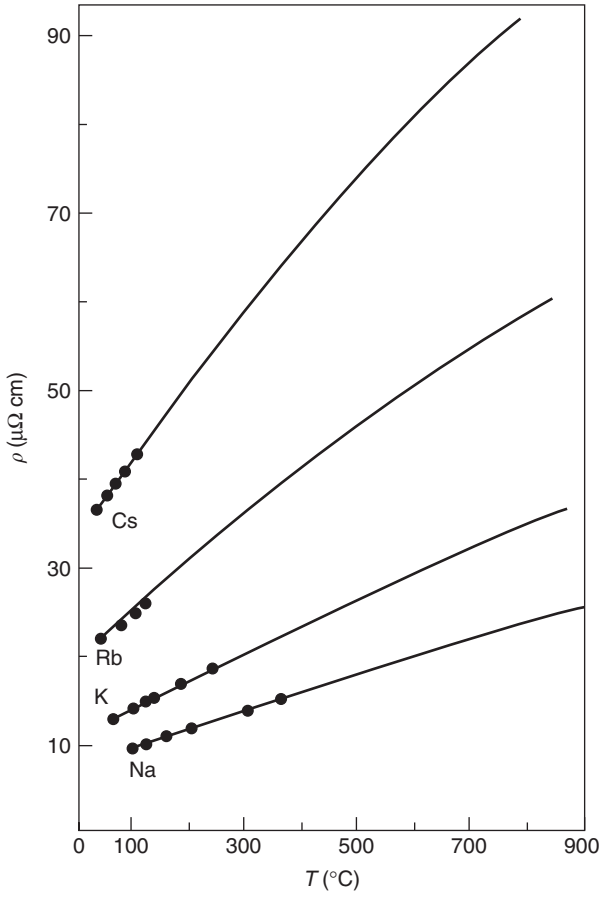

Figure 2 Electrical resistivity of liquid alkali metals as a function of temperature from electron theory (solid lines), compared with experimental data (dots).

Empirically, this law is satisfied by many liquid metals near freezing within a scatter of about $\pm 10\%$.

The electronic contribution is instead minor in the shear and bulk viscosities of simple liquid metals; The shear viscosity η is directly related to the properties of the ionic system, $\eta \propto T^{1/2}M^{1/2}N^{1/3}$, where all quantities refer to the melting point.

Chemical Short-Range Order in Some Metallic Alloys

In diffraction experiments, the melts of some alloys of metallic elements, such as Cs–Au or Li–Pb and other alloys of alkali metals with Pb or Sn, show a marked preference for unlike first neighbors near certain compositions. This behavior arises from electron transfer between the two elements, which is especially marked at such "stoichiometric" compositions. Minima in the electrical conductivity and spin susceptibility at these compositions reflect a minimum in the density of states at the Fermi level if not the opening of a gap due to full charge transfer.

The elements Cs and Au form a solid compound CsAu which is a strongly polar semiconductor with an optical bandgap of 2.6 eV. Its electrical conductivity drops on melting to a value of a few $(\Omega\,\mathrm{cm})^{-1}$, which is comparable to that of a molten salt. Electromigration experiments give evidence that in the melt, one Cs^+ ion is transported to the cathode and one Au^- ion to the anode per elementary charge to the electrodes. From X-ray diffraction, the Cs–Au first-neighbor distance at 0.36 nm can be followed away from stoichiometry up to 80% Cs, while the Cs–Cs distance of pure Cs at 0.53 nm starts emerging at 70% Cs. The electronic structure in the Cs-rich side of the phase diagram resembles that of metal–molten salt solutions (see below).

With regard to the melts of alloys of alkalis with group-IV metals, compound formation has been reported at the electronic octet composition for Li_4Pb and Li_4Sn, with chemical order extending over a range of 2 nm. Chemical order at equimolar composition in liquid alloys such as KPb and NaSn has been interpreted as due to the formation of tetrahedral Pb_4 or Sn_4 polyanions. In such a tetrahedral cluster, which is known in the solid state as a "Zintl ion," the p-type electron states of Pb, say, would be split into bonding and antibonding and the former could be filled by electron transfer from the alkali atoms.

Phase Diagram of Hydrogen and Hydrogen–Helium Mixtures in the Giant Planets

Hydrogen is the most abundant element in the Universe and has a very rich phase diagram, notwithstanding the simplest structure of the atom. In

standard laboratory conditions, cooling the gas of diatomic molecules brings it into a liquid of weakly coupled molecules and then into a crystal, in which the molecules are rotating with weak hindrance from each other. Compression at low temperature brings the crystal into a new phase, in which the molecular rotations are hindered and ultimately into a further crystal phase whose strong infrared activity indicates a mainly dipolar distortion of the electronic distribution. Molecular dissociation can occur as hydrogen is brought into the regions of high temperature and density which are relevant to astrophysics. A continuous transition from a semiconducting to a metallic state has been observed to occur at 3000 K and 140 GPa in dynamic compression experiments.

Theoretical studies of the phases of fluid hydrogen take account of several species (diatomic molecules, atoms, protons, and electrons) and examine their chemical equilibria. The results are in broad agreement with path-integral Monte Carlo studies by Ceperley and co-workers. A molecular gas is found to form spontaneously from a neutral system of protons and electrons as the temperature is lowered from 10^5 to 5000 K, with a molecular bond length which contracts with increasing density because of the stiff intermolecular repulsions. Molecular dissociation is then reported to occur as the temperature is raised or under isothermal compression. Thermally activated dissociation at high density is accompanied by decreasing pressure, signaling the presence of a first-order transition and a critical point. A proposed reason for the transition is the increase of electronic kinetic energy which is associated with bond formation: in essence, this increase derives from angular localization as the electrons leave spherical atomic-like orbitals to go into molecular bonding orbitals.

The dissociation transformation revealed by these studies, in which molecular hydrogen transforms not directly into a fully ionized plasma but first into a partially ionized atomic fluid, is also relevant to modeling the interior of giant planets such as Jupiter or Saturn. However, the situation there is more complex because hydrogen and helium coexist as main components. It is estimated that these two elements are at pressures of up to 4500 GPa and temperatures up to 24 000 K in Jupiter, and about 1000 GPa and 10 000 K in Saturn. The planet is thought to consist of three main layers: an outer layer of molecular hydrogen and atomic helium, a middle layer of metalized atomic hydrogen and helium, and a rocky core compressed to as high as 10^4 GPa at the center of Jupiter. In Saturn, an internal energy source has been proposed, from demixing and gravitational separation of the hydrogen–helium fluid at pressures below 1000 GPa.

Covalently Bonded Elements and Compounds

Molten and Amorphous Semiconductors

Semiconducting group-IV elements and polar III–V compounds crystallize in tetrahedrally coordinated open structures and melt with an increase in density into liquids, showing metallic conductivity. The first-neighbor coordination number rises on melting from four to about seven, though it remains well below that of common liquid metals which is about twelve. The elements Si and Ge can be quenched from the melt into a network-like amorphous state, in which an essentially fourfold coordination of first neighbors is restored and the semiconducting properties are regained. Melting of these solids is thus effected by a partial release of valence electrons from interatomic bonds into conducting states, and the chemical bonds are reconstructed in crystallization and in the transition to the amorphous state.

Figure 3 compares the structure factors of liquid and amorphous Ge as measured in diffraction experiments and also shows their correspondence with the location of the crystalline Bragg reflections. The shoulder to the right of the main peak in the structure factor of the liquid corresponds to the main peak of the amorphous structure factor and to the (2 2 0) and (3 1 1) Bragg spots. The interpretation of these structural features is that a remnant of the interatomic bonds is present in the melt, with some residue of the

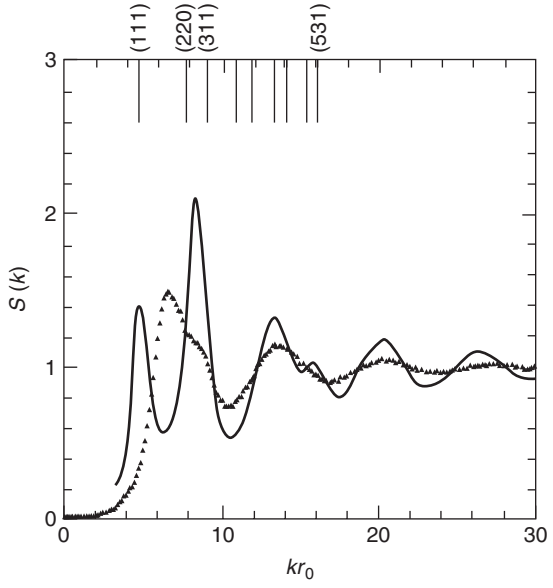

Figure 3 Structure factor of liquid Ge at 1000°C (triangles) and of amorphous Ge at room temperature (solid line). The vertical bars at the top give the location of the Bragg diffraction spots of crystalline Ge. The wave number k is scaled by the appropriate value of the first-neighbor distance r_o.

distribution of valence electrons still residing among the ionic cores, so that the transition to the crystal or to the amorphous state can be viewed as associated with "freezing of the bonds."

It is also seen in **Figure 3** that the diffraction pattern of the amorphous material shows a secondary peak to the left of the main peak. This is the "first sharp diffraction peak" (FSDP), which is a very general feature of the glassy state of matter. In Ge, its position corresponds to that of the (1 1 1) Bragg reflection from the crystal, while there is no corresponding feature in the diffraction pattern of the liquid. The FSDP comes from the reconstruction of the covalent bonds and reflects the connectivity that exists between the local tetrahedral units. The reconstruction would be frustrated if the system did not open up by lowering its density on freezing.

The presence of an FSDP is a signal of intermediate range order (IRO) in glasses. In strong glasses and liquids of the IV–VI compounds, IRO originates from the connectivity of chemically unsaturated tetrahedral units: these may join together either by pure corner sharing as in SiO_2, or by mixed corner and edge sharing as in $GeSe_2$, or by pure edge sharing as in $SiSe_2$. These connectivities give rise to networks having dimensionality $d = 3$, 2, and 1, respectively. The FSDP also behaves anomalously when compared with other diffraction peaks from disordered materials: its intensity increases with an increase in temperature and a decrease in pressure, since in both cases the available volume increases and the frustration of the network is reduced.

Crystalline, Liquid, and Amorphous Silicon Studied by the Car–Parrinello Method

The coexistence in Si and Ge of crystalline and amorphous covalent structures with a liquid metallic structure cannot receive a unified description by the standard methods of molecular dynamics (MD), which studies condensed matter systems by means of empirically fixed pair-potential models for the interatomic forces. On the other hand, density-functional theory provides a basic approach to the determination of electronic structure, but its direct use in the study of disordered systems is precluded, as it would require a full evaluation of electronic states for each of a very large number of configurations of the ionic system. The Car–Parrinello method successfully combines these two techniques in a way that allows MD calculations during which one follows the simultaneous evolution of the electronic and ionic structures and determines the interatomic forces from a parameter-free quantum mechanical approach.

In brief, the Car–Parrinello method treats variationally the total energy of a system such as liquid or amorphous Si as a function of both the electronic orbitals and the ionic positions. It uses a novel and efficient procedure of simulated annealing to carry out the minimization of the energy functional under evolving external constraints such as the volume and the strain of the sample. This is achieved by constructing a Lagrangian which determines the dynamics of orbitals, atomic positions, and constraints so as to guide the evolution of the simulation sample into a real physical system whose representative point in configuration space lies on the correct Born–Oppenheimer surface.

The three condensed states of Si indeed provided the first testing ground for the new MD approach. A number of static and dynamic properties of crystalline, amorphous, and liquid Si were calculated and successfully compared with experimental data whenever possible. The calculations yield contours of the valence charge density in correspondence to the atomic positions and allow one to visually follow its evolution in time during the atomic motions. In particular, in the case of liquid Si the persistence of some covalent chemical bonds was demonstrated from the analysis of the electronic charge density.

Solutions of Metals in Molten Salts

The liquid structure of an ionic compound such as CsI is characterized by strong short-range chemical order: each Cs^+ ion is surrounded by about five I^- ions and vice versa. A true solution is formed on a microscopic scale by adding Cs metal to molten CsI, and a continuous increase in electrical conductivity σ from the ionic to a metallic regime is observed as the concentration c of dissolved metal is increased at high-enough temperature. **Figure 4** reports the phase diagram of the CsI system together with the data showing the dependence of σ on composition. It is seen from the figure that addition of I to CsI is also possible: various intermediate compounds are formed and the system ultimately evolves into a fluid of I_2 molecules.

In the salt-rich region the added metal atoms are ionized and their valence electrons can be accommodated inside the structure of the host ionic melt. In analogy with the formation of F centers by localization of added electrons into negative-ion vacancies in the CsI crystal, optical absorption and magnetic resonance experiments show that at low c a solvated-electron state is formed in the liquid, with a residence time $\sim 10^{-12}$ s. The optical spectrum evolves from aggregation processes which start at very low metal content (< 0.01 M) and progressively reduce the

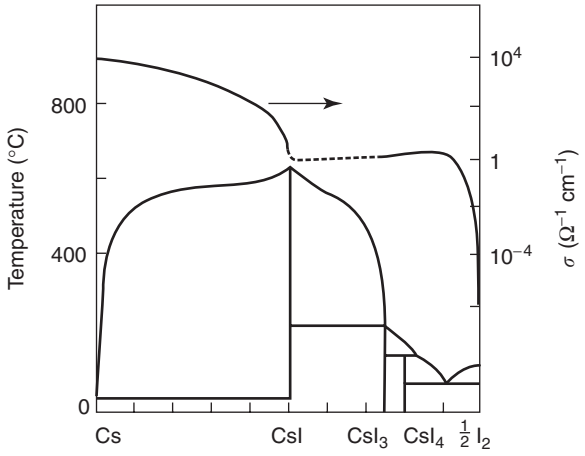

Figure 4 Phase diagram of the cesium–iodine system. The upper curve, with the scale on the right-hand side of the figure, shows the electrical conductivity σ.

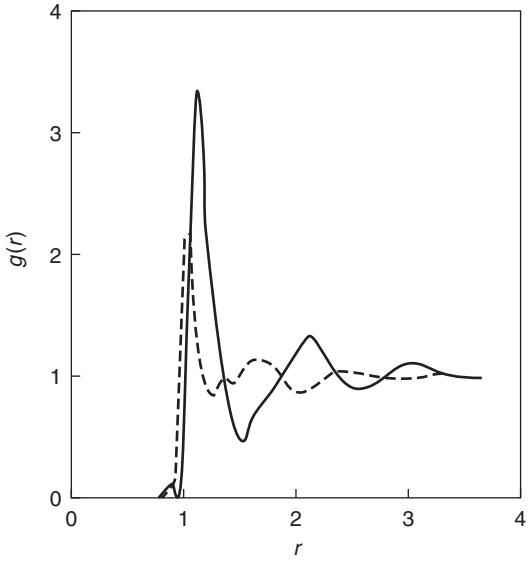

Figure 5 Pair distribution function $g(r)$ for oxygen atoms in water (dashed line) and for liquid argon (solid line). Both liquids are near freezing and the distance r is scaled by the van der Waals diameter.

fraction of electrons that are localized in F-center-like states. Electron spin resonance experiments show that spin-paired species are being formed. Finally, the transition to a metallic state is most strikingly signaled by a dielectric anomaly: according to a criterion proposed by Herzfeld in 1927, the low-frequency dielectric constant should indeed diverge at the transition as the reflectivity acquires metallic character.

Different scenarios are met on adding polyvalent metal to polyvalent metal halides. Subhalide compounds can be formed either from cationic species of intermediate valence (such as HgCl in Hg–Hg_2Cl melts) or from polyatomic cationic species (such as Bi clusters in Bi–BiI_3 at the concentration corresponding to the BiI compound). In all cases, one observes thermally activated electron transport at low c and a transition to a metallic regime shifted to the high-c region of the phase diagram by the stability of the intermediate subhalide compounds.

Hydrogen Bonding in Water and Ice

The specific nonspherical shape of the H_2O molecule and the interactions that it gives rise to have a number of important consequences. In the molecule the oxygen atom binds two hydrogen atoms by electron pairing, thereby creating a permanent electric dipole moment, and arranges its further four valence electrons in two "lone-pair" bonds. The four bonds point toward the corners of an almost perfect tetrahedron and each lone pair can interact with an electron-deficient hydrogen atom belonging to a neighboring molecule. By virtue of this hydrogen bond, each H_2O molecule in water or ice is tetrahedrally coordinated by four H_2O molecules. **Figure 5** contrasts the pair distribution function $g(r)$ of water with that of liquid argon from X-ray diffraction experiments, showing how different structural correlations build up in space for essentially tetrahedral molecules and for spherical atoms. The average number of first-neighbor oxygens is estimated from these data to be about 4.4 in water and about 10 in liquid argon. Water can be brought into a supercooled liquid state and also into a supercritical regime which is of great importance in extraction and reaction process technology.

As water crystallizes into ice at standard pressure, the local tetrahedral arrangement of the oxygens is frozen into a periodic lattice made of layers of rippled hexagons. This microscopic arrangement of the H_2O molecules in the crystalline phase is beautifully revealed by the sixfold symmetry of snowflakes. The structure of this form of ice is very open and this has two main consequences: melting is accompanied by some structural collapse leading to an increase in density, and the crystalline structure is very sensitive to pressure (some ten crystalline polymorphs of ice are known, all of them showing fourfold coordination of the oxygens).

Liquid and solid H_2O have been widely studied by diffraction techniques. X-rays are almost blind to hydrogen atoms, so that the water structure shown in **Figure 5** is in fact that taken by pairs of oxygens. Special techniques in neutron diffraction have allowed a detailed mapping of the distribution of the two atomic species in pure water and also in water around foreign cations and anions.

$\phi_{ie}(q)$	effective electron–ion potential
Ω_p	ionic plasma frequency

Liquids, Theory of: Fermi Liquids

J Spalek, Jagiellonian University, Kraków, Poland

Introduction: Quantum Liquids

Basic Characteristics

By Fermi liquid (FL), one means a quantum many-particle system of interacting fermions (i.e., particles with half-integer spin, such as electron, neutron, proton, ^{3}He atom, and also quarks), which is related to the (almost) ideal gas of fermions when the same system becomes sufficiently diluted. The FL has the same type of overall phase diagram as a classical liquid except for two specific features clearly observable for the canonical FL – condensed phase of ^{3}He atoms. First, due to the quantum nature of the particles involved, the zero-point motion prevents the solidification at temperature $T = 0$ and low pressure. Second, the FL transformations can take place to the superconducting or/and magnetic states. This feature is not touched upon here. In **Figure 1**, a schematic phase diagram for the condensed ^{3}He is provided.

First, some useful formulas for the ideal gas are provided. Namely, as the fermions obey the Pauli exclusion principle, they fill at $T = 0$ the single momentum $\boldsymbol{p} = \hbar\boldsymbol{k}$ states up to the highest occupied level – the Fermi energy ε_F. In the case of an ideal gas with spin $s = 1/2$, the value is

$$\varepsilon_F = \frac{\hbar^2 k_F^2}{2m}, \quad \text{with } k_F = \left(3\pi^2 \frac{N}{V}\right)^{1/3} \qquad [1]$$

where $\hbar k_F$ is the Fermi momentum and N is the number of particles in volume V. For gaseous ^{3}He at pressure $p = 0$, one has the velocity of particles at the

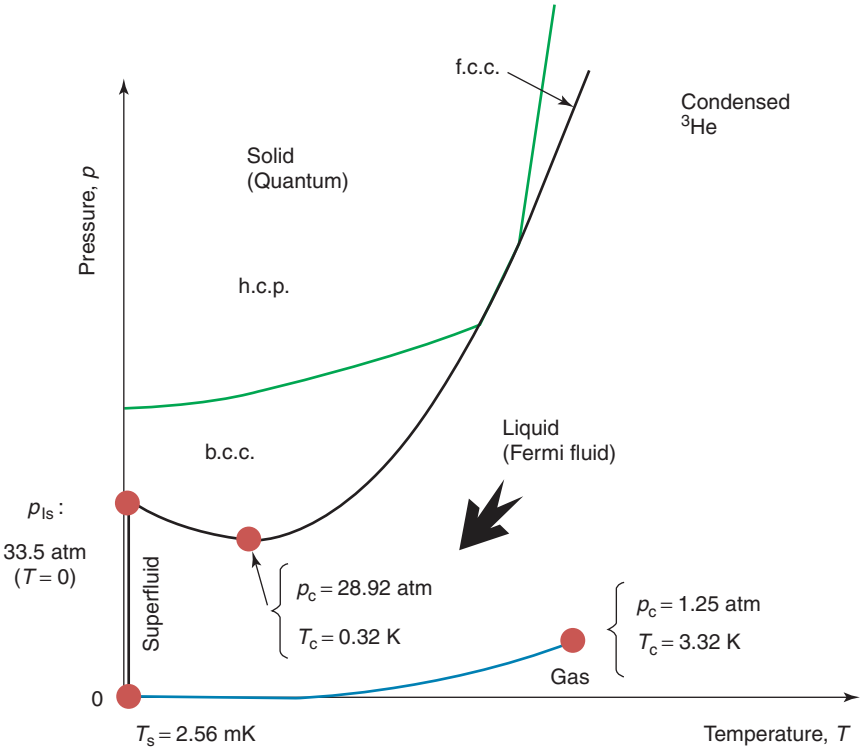

Figure 1 Schematic phase diagram of condensed ^{3}He including the critical points (solid curve).

Fermi energy $v_F = \hbar k_F/m \approx 10^4$ cm s^{-1} and the Fermi temperature $T_F = \varepsilon_F/k_B \approx 6.2$ K. The additional characteristic is the density of bare states at the Fermi level, $N_0(\varepsilon_F)$. When counted per atom per spin, it has the value

$$N_0(\varepsilon_F) = \frac{1}{8\pi^2}\frac{V}{N}\frac{2m}{\hbar^2}\left(3\pi^2\frac{N}{V}\right)^{1/3} \qquad [2]$$

In the case of electrons in a solid, one has: $\varepsilon_F \sim$ 1–10 eV, $k_F \sim (1\text{–}2)$ Å^{-1}, and $N_0(\varepsilon_F) \sim 10^{22}$ states eV^{-1}. This is the reason why the particle–energy distribution is regarded as quasicontinuous. However, the topology of the Fermi surface for electrons in metals is not spherical and the particle momentum is conserved with accuracy of the order of the inverse-lattice vector $\boldsymbol{G}$. On the contrary, the liquid ^{3}He can be regarded as a model Fermi liquid on both counts, since it is a truly translationally invariant FL system.

Basic Definitions

The Fermi liquid theory bears its name from the phenomenological approach proposed by L D Landau which aims to describe the quantum properties of liquid ^{3}He in the normal (nonsuperfluid) state at low temperatures: $k_B T \ll \varepsilon_F$. The spin $s = 1/2$ is that of ^{3}He nucleus, since the $1s^2$ filled electronic shell is spinless. The electronic liquid composed of valence electrons in metals such as Li, Na, or Cs represents a charged anisotropic FL state coupled to periodically arranged (much heavier) ions via the electron–phonon coupling. Separate classes of the FL represent the neutron stars (their external layers) and the quark–gluon plasma. The FL state is a viable concept for three-dimensional systems, whereas one-dimensional systems (fermionic chains, ladders, and nanotubes) are described as Tomonaga–Luttinger liquids (TLL). The exact nature of the two-dimensional electronic liquids (e.g., the high-temperature superconductors in the normal state or the quantum Hall liquids) is not yet clear. Also, the three-dimensional systems close to the magnetic quantum critical point represent non-Landau (non-Fermi) liquids, NFL. Therefore, by normal FL (or Landau FL), one understands that it is a three-dimensional quantum liquid composed of interacting fermions with delocalized states and without phase transition in this state.

A separate class is formed by the FLs close to the localization; these are called the almost localized Fermi liquids (ALFLs) (in the case of ^{3}He, this transition corresponds to the solidification, also included in **Figure 1**). The schematic division of the liquids of fermions, together with the corresponding examples, are listed in **Figure 2**.

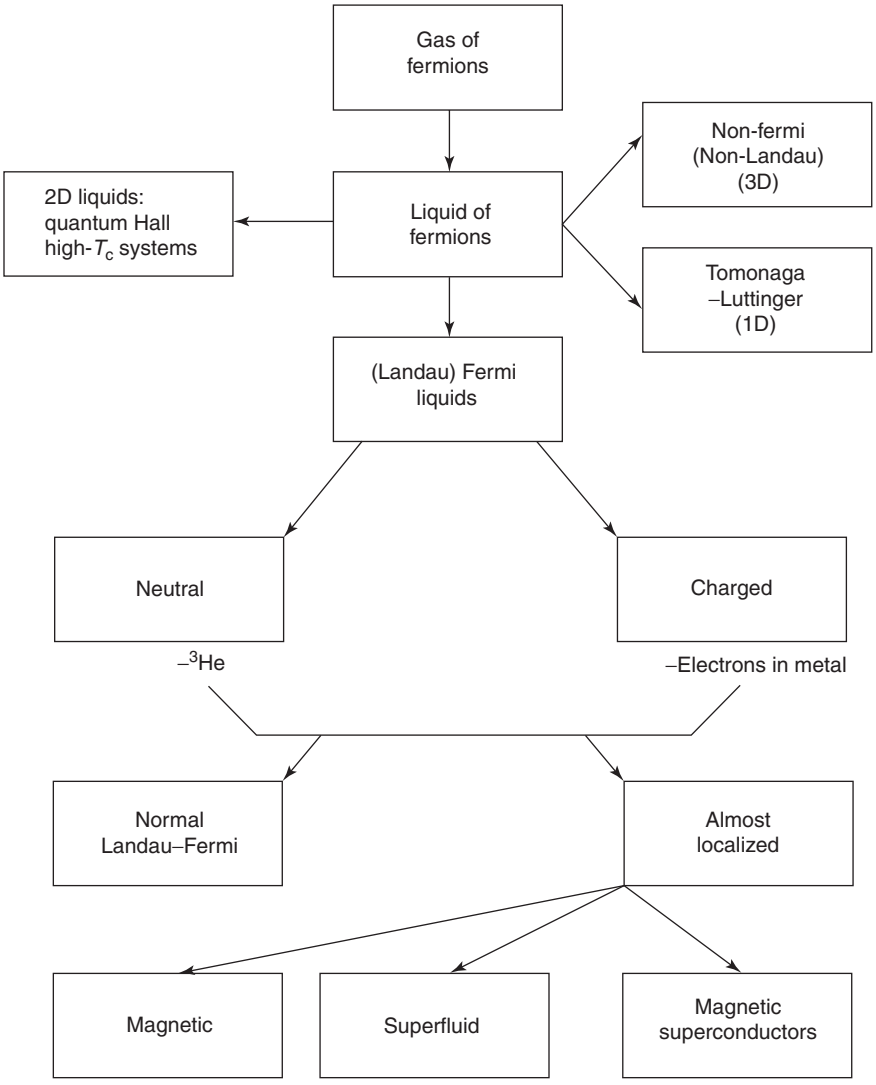

Figure 2 Division of various liquids of fermions and the subdivision of the FLs into various classes.

Signatures of the Normal FL State

The fundamental property of the FL state is the existence of a well-defined reference (gas) of single-particle states $|\boldsymbol{k}\sigma\rangle$ in the ground and first excited configurations with the energy $\varepsilon_{\boldsymbol{k}\sigma}$, where their (quasi) momentum is $\boldsymbol{p} = \hbar\boldsymbol{k}$ and the spin quantum number is $\sigma = \pm 1$ (note that $S = \sigma/2$). These reference states occupy their energy levels $\varepsilon_{\boldsymbol{k}\sigma}$ according to the Fermi distribution

$$n^0_{\boldsymbol{k}\sigma} = \frac{1}{\exp\left[\beta(\varepsilon_{\boldsymbol{k}\sigma} - \mu)\right] + 1} \qquad [3]$$

where $\beta = (k_B T)^{-1}$ is the inverse temperature in energy units and μ is the chemical potential determined from the fact that the total number of particles is conserved, that is, $N = \sum_{\boldsymbol{k}\sigma} n^0_{\boldsymbol{k}\sigma}$. In the ground state, this distribution reduces to the step function $n_{\boldsymbol{k}\sigma} = \Theta(\mu - \varepsilon_{\boldsymbol{k}\sigma})$ expressing the Pauli exclusion principle, and μ expresses the Fermi energy ε_F. The equation $\varepsilon_{\boldsymbol{k}\sigma} = \varepsilon_F$ determines the shape of two (spin-dependent Fermi) surfaces in the $\boldsymbol{k}$ space. In the normal state and in the absence of an applied magnetic field, $\varepsilon_{\boldsymbol{k}\sigma} = \varepsilon_{\boldsymbol{k}}$, and in this circumstance, a single Fermi surface and k_F represent (angle-dependent in the general case) the Fermi wave vector.

Interaction among Particles

The FL concept is particularly useful in the low-temperature regime $T \ll T_F = \varepsilon_F/k_B$, where the interest lies only in the thermal (and dynamic) properties of weakly excited states. In this limit, one is interested in determining the system energy change δE induced by the small change $\delta n_{\boldsymbol{k}\sigma} \equiv n_{\boldsymbol{k}\sigma} - n^0_{\boldsymbol{k}\sigma} \ll 1$

(on average) and due to interaction among them, and/or by the thermal excitations (the exact knowledge of the total state energy, is difficult to calculate and even not necessary). In this situation, in the energy δE the interaction in the diluted gas of excited states can be included in the following manner:

$$\delta E = \sum_{k\sigma} (\varepsilon_k - \mu)\delta n_{k\sigma} + \frac{1}{2}\sum_{kk'\sigma\sigma'} f_{kk'}^{\sigma\sigma'} \delta n_{k\sigma}\delta n_{k'\sigma} + \cdots \quad [4]$$

where $f_{kk'}^{\sigma\sigma'}$ expresses the (spin-dependent) density–density interaction between the particles, that leads foremostly to the elastic scattering processes at the Fermi surface, since inside it the scattering processes are practically blocked out by the Pauli principle. It is also to be noted that the bare (without interaction included) energy ε_k is counted from ε_F. In this formulation, the ground state is regarded as a vacuum state.

In such an approach, there are two subtleties apart from the unknown structure of the scattering function $f_{kk'}^{\sigma\sigma'}$. The first is connected with the conservation of particles, which now takes the form $\sum_{k\sigma} \delta n_{k\sigma} = \delta N = 0$. In other words, if the single-particle excitations with $\varepsilon_k > \mu$ are regarded as particles ($\delta n_k = +1$), then those with $\varepsilon_k < \mu$ should be regarded as having $\delta n_k = -1$. In other words, the excitation from the vacuum state requires that if the charge e is associated with the state $\varepsilon_k > \mu$ and $\delta n_{k\sigma} = +1$, then the charge $-e$ has to be associated with the excitation $\varepsilon_k < \mu$ and $\delta n_{k\sigma} = -1$, so that the total charge of the system is zero. This concept bears its origin from the Dirac concept of electrons and holes, which in the present (nonrelativistic) situation does not lead to any peculiarities.

The Entropy of Interacting Particles ($T \ll T_F$)

The second feature is associated with the inclusion of the determination of δn_k at $T > 0$ or equivalently, with the determination of the system entropy. Here, the phenomenology appears in its earnest namely, one assumes that it is taken in the usual form for non-interacting fermions for the number of particles $\{\delta n_{k\sigma}\}$, that is,

$$\delta S = -k_B \sum_{k\sigma} \{\delta n_{k\sigma} \ln \delta n_{k\sigma} + (1 - \delta n_{k\sigma}) \ln(1 - \delta n_{k\sigma})\} \quad [5]$$

This assumption is justified by adopting the adiabatic principle: the single-particle (quasiparticle) states in the presence of the interparticle interaction are in a one-to-one correspondence with those for the ideal gas. In other words, the number of microconfigurations in the interacting system does not change, nor does the entropy. This theorem finds its microscopic justification through the Luttinger theorem: the volume (i.e., the number of states encompassed by k_F at $T = 0$) does not depend on the interaction magnitude as long as the system does not undergo either magnetic or superconducting or delocalization–localization transition. This theorem implies that the occupation number ($\delta n_{k\sigma}$) can change, but the Fermi ridge (discontinuity) position in $\boldsymbol{k}$ space does not.

Quasiparticles

By writing down the total energy in the form

$$\delta E = \sum_{k\sigma} \left\{ \varepsilon_{k\sigma} - \mu + \frac{1}{2}\sum_{k'\sigma'} f_{kk'}^{\sigma\sigma'} \delta n_{k'\sigma} \right\} \delta n_{k\sigma} \equiv \sum_{k\sigma} E_{k\sigma} \delta n_{k\sigma} \quad [6]$$

the energy $E_{k\sigma}$ of the quasiparticle can be defined. In effect, the distribution [3] for quasiparticles can be defined (by minimizing the free energy $\delta F = \delta E - T\delta S$), that is, with respect to $\{\delta n_{k\sigma}\}$, with the replacement $\varepsilon_{k\sigma} - \mu \to E_{k\sigma}$. **Figure 3** provides the statistical distribution function n_p for liquid ^{3}He obtained from the neutron scattering experiment of Mook. It can be seen that the Fermi distribution function describes the quasiparticle states well, but with the Fermi temperature $T_F = 1.8\,\mathrm{K}$ and the energy given by $E_k = p^2/2m^\star$, where $m^\star \approx 3m_0$ is the effective mass of ^{3}He atoms in the FL state. The Fermi temperature is also renormalized by the factor $T_F = (m_0/m^\star)T_{F0}$, where T_{F0} is the corresponding quantity for ^{3}He gas of the same density. So, the interaction changes both the mass and the Fermi energy to the same extent for all particles (i.e., not only those close to k_F).

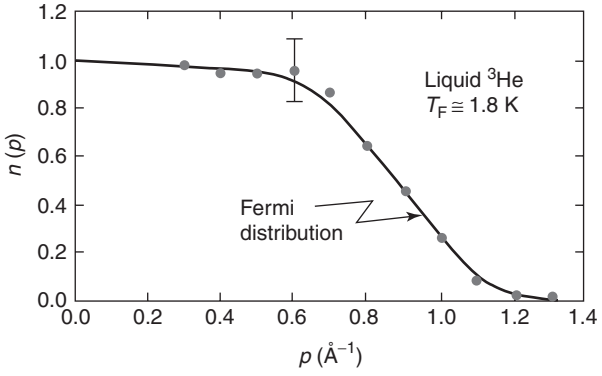

Figure 3 The Fermi distribution for liquid ^{3}He at $T = 0.37\,\mathrm{K}$ and ambient pressure. (After Mook HA (1985) Momentum distribution of ^{3}He. *Physical Review Letters* 55: 2452.)

Electrons in a Metal as Quasiparticles

The states of electrons in a metal are probed by exciting them with photons in the photoelectron emission from the solid. To describe such a process, one has to know the spectral density function $A_{k\sigma}(\omega)$ describing microscopically the form of the system energy spectrum when extracting (or adding) one electron with momentum $\hbar\boldsymbol{k}$ and the energy ω. $A_{k\sigma}(\omega)$ is, in turn, defined as

$$A_{k\sigma}(\omega) = -\frac{1}{\pi}\,\mathrm{Im}\; G_{k\sigma}(\omega) \equiv -\frac{1}{\pi}\,\mathrm{Im}\,\frac{1}{\omega - E_{k\sigma} + \mathrm{i}\Sigma''_{\sigma}(\omega)} \qquad [7]$$

where $G_{k\sigma}(\omega)$ is the (retarded) single-particle Green function for the electron. The quantity $\Sigma''_{\sigma}(\omega)$ represents the imaginary part of the self-energy and for a three-dimensional FL is given by

$$\Sigma''_{\sigma}(\omega) = \beta\omega^2, \quad \beta = \text{const.} \qquad [8]$$

The real part of the self-energy is included in $E_{\boldsymbol{k}}$ (replacing in microscopic theory the phenomenological part $\sim f_{\boldsymbol{k}\boldsymbol{k}'}$).

The function $A_{k\sigma}(\omega)$ is of fundamental importance for the many-particle system. This is because the density of states $N(\omega)$ and the statistical distribution function $n_{k\sigma}$ are derived from it, namely,

$$N_{\sigma}(\omega) = \sum_{k} A_{k\sigma}(\omega); \quad n_{k\sigma} = \int \mathrm{d}\omega\; A_{k\sigma}(\omega) \qquad [9]$$

where the integration is over allowed values of energy of the system (e.g., the band width or the cutoff energy). In the paramagnetic systems, the spin subscript is dropped; sometimes $A_{\boldsymbol{k}}(\omega)$ is defined by summing up over $\sigma = \pm 1$. The photoemission intensity, that is, the number of electrons emitted in the direction $\boldsymbol{k}$ with the energy ω is given by

$$I_{\boldsymbol{k}}(\omega) = I_0 \int \mathrm{d}\omega' A_{\boldsymbol{k}}(\omega') n(\omega') R(\omega - \omega') \qquad [10]$$

where $R(\omega - \omega')$ is the so-called resolution (instrument) function (usually taken in the Gaussian form), $n(\omega)$ is the Fermi factor: $n(\omega) = [\exp(\beta\omega) + 1]^{-1}$, with $\omega = 0$ representing the Fermi energy (I_0 is the normalization constant). **Figure 4** provides an exemplary angle-resolved photoemission spectrum (ARPES) with the quasiparticle peak dispersing as the regime of energies is probed with $E_{\boldsymbol{k}} < \mu(= 0)$; the angle θ describes the angle at which the photoelectron is emitted, and determines the wave vector $\boldsymbol{k}_{\parallel}$ in this quasi-two-dimensional metal, the Fermi energy.

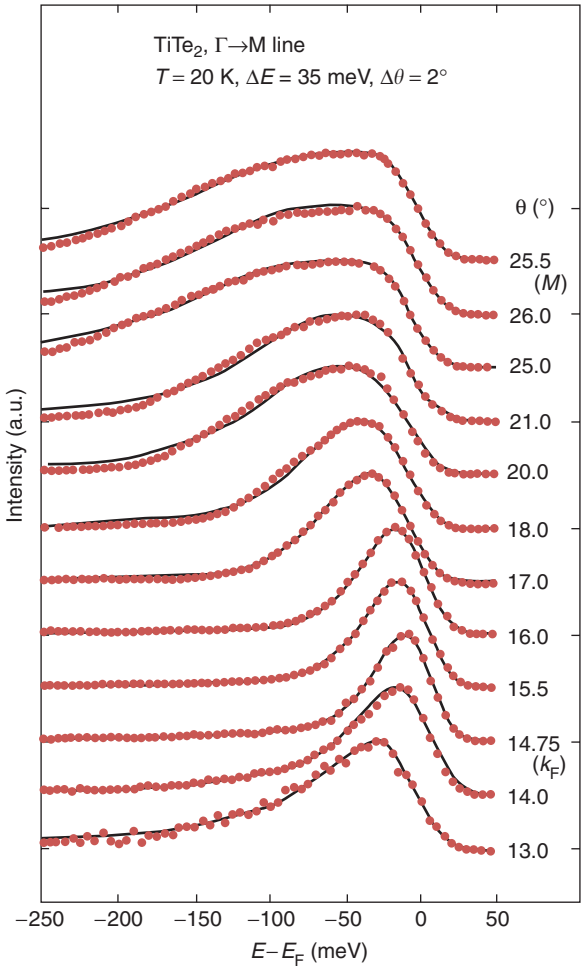

Figure 4 Photoemission spectra $TiTe_2$ along the $\Gamma \rightarrow M$ line (from bottom to top). The solid line represents the Fermi-liquid fit [9]. The spectra are normalized to the same maximum height. (After Allen JW, Gweon G-H, Claessen R, and Matho K (1995) Fermi liquids and non-Fermi liquids – the view from photoemission. *Journal of the Physics and Chemistry of Solids* 56: 1849.)

The dispersion relation for quasiparticles is linear when $E_{\boldsymbol{k}} \rightarrow \varepsilon_{\mathrm{F}}$.

Properties at Low Temperatures

A brief description of the properties at low T follows. However, for that, first the function $f^{\sigma\sigma'}_{\boldsymbol{k}\boldsymbol{k}'}$ has to be specified. Namely, if processes at the Fermi surface only are included, then one can write that $f^{\sigma\sigma'}_{\boldsymbol{k}\boldsymbol{k}'} = f^{\sigma\sigma'}_{\boldsymbol{k}\boldsymbol{k}'}(\boldsymbol{k}\cdot\boldsymbol{k}'/k_{\mathrm{F}}^2)$, that is, the elastic scattering processes depend only on the angle between the particles. Additionally, one can write

$$f^{\sigma\sigma'}_{\boldsymbol{k}\boldsymbol{k}'} = f^{s}(\boldsymbol{k}\cdot\boldsymbol{k}'/k_{\mathrm{F}}^2) + \sigma\cdot\sigma' f^{a}(\boldsymbol{k}\cdot\boldsymbol{k}'/k_{\mathrm{F}}^2) \qquad [11]$$

where $\sigma = (\sigma_x, \sigma_y, \sigma_z)$ denotes the Pauli matrices. The form [11] defines the spin-symmetric

($f^{\mathrm{s}} = \frac{1}{2}(f^{\uparrow\uparrow} + f^{\uparrow\downarrow})$) and the antisymmetric ($f^{\mathrm{a}} = \frac{1}{2}(f^{\uparrow\uparrow} - f^{\uparrow\downarrow})$) functions in the situation when the spin–spin interactions are rotationally invariant (e.g., neglect the spin–orbit interaction). Additionally, introducing $\cos\theta \equiv \boldsymbol{k}\cdot\boldsymbol{k}'/k_{\mathrm{F}}^2$, the functions can be expanded in terms of the Legendre polynomials $P_l(\cos\theta)$, that is,

$$f_{\boldsymbol{k}\boldsymbol{k}'}^{\mathrm{s,a}} = \sum_{l=0}^{\infty} f_l^{\mathrm{s,a}} P_l(\cos\theta) \qquad [12]$$

where

$$f_l^{\mathrm{s,a}} = (2l+1)\int_{-1}^{+1} \mathrm{d}x P_l(x) f^{\mathrm{s,a}}(x) \qquad [13]$$

are the partial spherical-wave amplitudes. The ingenuity of this approach is rooted in the circumstance, realized only *a posteriori*, that all the principal properties are expressed in terms of a few parameters ($f_0^{\mathrm{s}}, f_1^{\mathrm{s}}$, and f_1^{a}). These properties can be expressed in terms of the dimensionless parameters $F_l^{\mathrm{s,a}} \equiv N(0)F_l^{\mathrm{s,a}}$, where $N(0)$ is the density of states at the Fermi level including both spin directions and is defined by

$$\begin{aligned} N(\mu \equiv 0) &= \sum_{k\sigma} \delta(E_{\boldsymbol{k}} - \mu) \\ &= -2(2\pi)^{-3}\int \mathrm{d}^3k(\partial/\partial E_{\boldsymbol{k}})\theta(\mu - E_{\boldsymbol{k}}) \\ &= Vp_{\mathrm{F}}(m^{\bigstar}/\hbar^3\pi^2) \end{aligned} \qquad [14]$$

Summary of Properties

1. Effective mass enhancement at $T = 0$,

$$m^{\bigstar} = m_0\left(1 + \tfrac{1}{3}F_1^{\mathrm{s}}\right) \qquad [15]$$

   where m_0 is the bare mass (band-theory mass for the case of electrons).
2. Bulk compressibility of the FL system at $T = 0$,

$$\kappa \equiv -\frac{1}{V}\frac{\partial V}{\partial p} = \frac{\rho^2}{V}\frac{\partial \mu}{\partial N} = \frac{\rho^2}{V}\frac{1+F_0^{\mathrm{s}}}{N(0)} \qquad [16]$$

   where $\rho \equiv \mathrm{d}N/\mathrm{d}V$ is the particle density at a given volume; associated with this quantity is the sound velocity V_{s}, which is $\boldsymbol{p}_{\mathrm{F}}^2/(3m_0m^{\bigstar})(1+F^{\mathrm{s}})$.
3. Paramagnetic susceptibility at $T = 0$ is enhanced in the following manner:

$$\chi(0) \equiv \left(\frac{\partial M}{\partial H_{\mathrm{a}}}\right)_0 = \frac{1}{4}(g\mu_{\mathrm{B}})^2 N(0)\frac{1}{1+F_0^{\mathrm{a}}} \qquad [17]$$

   where g is the Lande factor and $(\partial M/\partial H_{\mathrm{a}})_0$ expresses the ratio of magnetization to the magnitude of the (small) field creating it. At $T > 0$, the susceptibility takes the form $\chi(T) = \chi(0)(1 + aT^2)$, where a is a constant.
4. Electrical resistivity of the electron fluid can be represented by the formula $\rho = m^{\bigstar}/(n_{\mathrm{c}}e^2\tau)$, where n_{c} is the carrier concentration and τ is the inverse lifetime for scattering due to the particle interactions (Baber–Landau–Pomeranchuk)

$$1/\tau \sim (m^{\bigstar})T^2 \qquad [18]$$

   So the resistivity can be described by $\rho(T) = AT^2$, with $A \sim \gamma(0)^2$, where $\gamma(0)$ is the linear specific-heat coefficient $\gamma(0) = (\pi^2/3)k_{\mathrm{B}}^2 N(0)$. In the case of neutral FL, this relaxation time determines the viscosity.
5. Specific heat has both the contributions due to single-particle excitations, $\sim(\gamma(0)T)$ and that due to the collective spin fluctuations; the latter are reflected in the simplest case as a maximum in the dynamic susceptibility $\chi(\boldsymbol{q},\omega)$ at $\boldsymbol{q} = \omega = 0$. In effect,

$$C(T) = \gamma(0)T + \delta T^3 \ln(T/T_{\mathrm{sf}}) \qquad [19]$$

   where $\gamma(0) = m^{\bigstar}p_{\mathrm{F}}/(3\hbar^3)$, and δ and T_{sf} are characteristics of the spin fluctuation spectrum.
6. The Wilson ratio of the extrapolated values, $R_{\mathrm{w}} \equiv \chi(0)/\gamma(0)$, describes the relative strength of magnetic and charge excitations.

Collective Excitations

Apart from the paramagnetic spin fluctuations, there is a specific collective excitation of the FL – the zero sound. It appears for frequencies, for which $\omega \gg \tau^{-1}$, that is, in the collisionless regime for quasiparticles. The role of the restoring force during the propagation of such density fluctuations is provided by the averaged self-consistent field of the remaining particles in the system. In such a nomenclature, the hydrodynamic (collision-dominated) regime corresponds to the sound propagation for $\omega \ll \tau^{-1}$. The density oscillations in this regime correspond to first-sound propagation, which can be identified with damped oscillation, the ordinary sound. Apart from those excitations, there are electron–hole and plasmon excitations, for elaboration on which the reader is advised to consult more specialized texts (see "Further reading" section). The same remark applies to the discussion of other nonequilibrium and transport properties of Fermi liquids.

Unconventional Fermi Liquids

A nonstandard behavior is to be expected when a normal FL undergoes a phase transition. As liquids which undergo the superconducting or superfluid transitions are discussed elsewhere in this encyclopedia, the focus here is on the solidification of ^{3}He and the Mott–Hubbard localization of an almost localized electron liquid. **Figure 5** provides the molar pressure dependence of $\gamma(0) = (\pi^2/3)k_B^2 N(0)$, as well as the mass enhancement $m^\star/m_0$ for ^{3}He calculated from the relation $\gamma(0) = \gamma_0(m^\star/m_0)$, where $\gamma_0 = (\pi^2/3)k_B^2 N_0(0)$, and $N_0(0)$ represents the corresponding density of states for an ideal ^{3}He gas (of the same density). As the liquid approaches the solidification threshold, that is, the localization of atoms into a lattice, the quasiparticle mass doubles. At the highest pressure, the system undergoes a discontinuous Mott–Hubbard transition.

Heavy-Electron Systems

A spectacular effective mass enhancement is observed in the heavy-electron systems, which compose intermetallic compounds involving itinerant $4f$ or $5f$ electrons, for example, $CeAl_3$, UPt_3, UBe_{13}, and many others. The effective masses encountered there are $\sim 10^2 m_0$. In **Figure 6**, the (molar) specific heat data for the moderately heavy-fermion compound $CeCu_2Si_2$ is presented. The extrapolated value of $\gamma(0) = 355\,\mathrm{mJ\,K^{-2}\,mol^{-1}}$ has been subtracted from the C/T data. The heavy mass of these quasielectrons is characterized by the effective Kondo (coherence) temperature $T_K = \pi^2 R/3\gamma$, which characterizes the bandwidth of these quasiparticle states. The solid curve represents the second term of the expression [19] divided by T. The heavy masses are associated, in this case, with the hybridization of $4f^1$ states of Ce^{3+} with the conduction states, and the intra-atomic Coulomb interaction for the $4f^2$ configuration is large, so the f-states can become itinerant only when the valency is slightly larger than Ce^{3+} ($4f^{1-\varepsilon}$ configuration). In other words, a small number of holes in the $4f^1$ configuration cause the almost-localized behavior when these electrons additionally hybridize with the extended valence states.

The Fermi liquid nature of the compounds for $T < T_K$ is evidenced further in the behavior of the resistivity $\rho(T) = \rho_0 + AT^2$, as well as by the Wilson ratio $R_w \sim 1$. The two observations are displayed in **Figures 7** and **8**, respectively. The straight line in **Figure 7** illustrates the relation $A \sim \gamma(0)^2$, whereas that in **Figure 8** corresponds to a Fermi gas. So, indeed, the concept of very heavy quasiparticles is applicable even in these extreme conditions.

Almost Localized Systems

The Mott–Hubbard localization takes place when the magnitude U of the short-range (intra-atomic) Coulomb repulsive interaction exceeds the average band energy per particle $(1/N)\sum_{k\sigma}\varepsilon_k \equiv \bar{\varepsilon}$. This is because the band energy represents the binding energy gained by forming an extended (Bloch) state of electron in solid, whereas the Coulomb repulsion competes with such a process as it tries to keep them as far apart as possible, that is, on their parent atoms.

To put such an argument on a quantitative basis, the renormalized band energy is represented as $q\bar{\varepsilon}$, where the band narrowing factor is $q \leqslant 1$ and vanishes at the localization threshold. The Coulomb

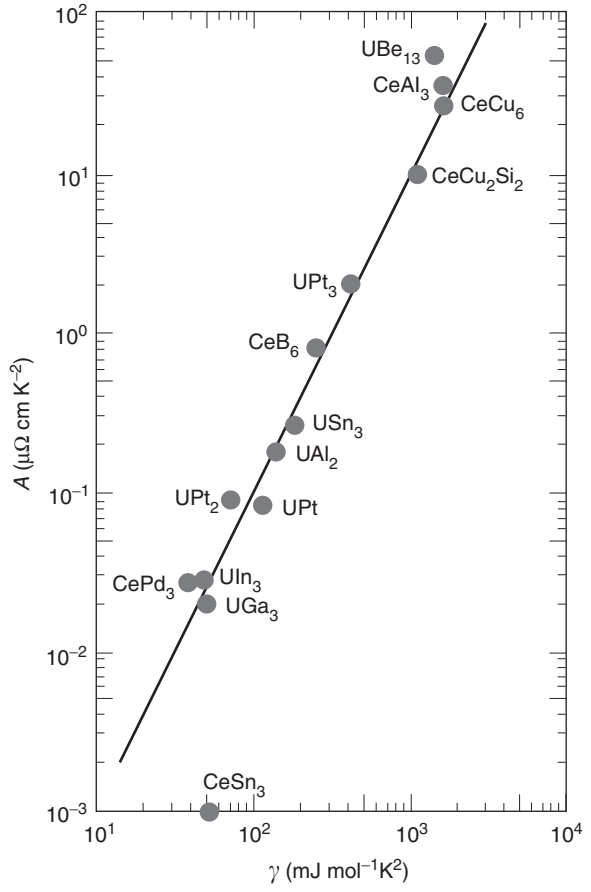

Figure 7 Universal scaling to the A coefficient in resistivity ($\rho(T) = \rho_0 + AT^2$) of various heavy fermion systems vs. the coefficient γ_0. The straight line represents the Kadowaki–Woods scaling law $A \sim \gamma(0)^2$.

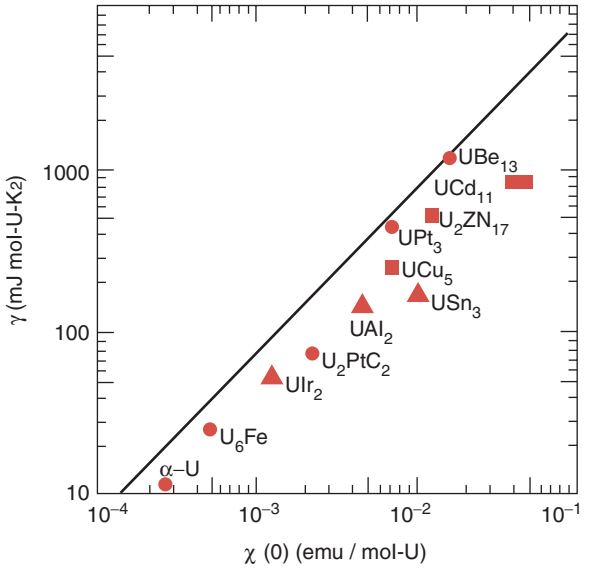

Figure 8 Universal scaling of the coefficient $\gamma(0)$ vs. the susceptibility $\chi(0)$ for various heavy fermion systems. The straight line is for the ideal electron gas.

energy (per atom) is written as $U\eta$, where $\eta = \langle n_{i\uparrow} n_{i\downarrow} \rangle$ represents the probability that the atom "i" is doubly occupied (a single state per atom is taken, so that the spins are opposite). When $\eta > 0$, the double occupancies are formed and the electrons (originally one per atom) can hop from one atom onto a neighboring one and thus conduct charge. To close the argument, one specifies $q \equiv q(\eta)$, which in the simplest formulation (the Gutzwiller ansatz) is of the form $q(\eta) = 8\eta(1 - 2\eta)$. Thus, the total energy is

$$E_G/N = q(\eta)\bar{\varepsilon} + U\eta \qquad [20]$$

In the equilibrium state, $\partial E_G/\partial\eta = 0$, $\partial^2 E_G/\partial\eta^2 > 0$. One then obtains

$$\eta \equiv \eta_0 = \tfrac{1}{4}(1 - U/U_c) \qquad [21]$$

$$q \equiv q_0 = 1 - (U/U_c)^2 \qquad [22]$$

$$E_G/N = \bar{\varepsilon}(1 - U/U_c)^2 \qquad [23]$$

where $U_c = 8|\bar{\varepsilon}|$ is the critical value of the interaction, at which $E_G = \eta_0 = 0$, that is, the energies totally compensate each other (the metallic state for $U > U_c$ is unstable). One can also calculate the magnitude of spin on the representative atom "i" and obtain

$$\langle S_i^2 \rangle = \frac{3}{4}(1 - 2\eta_0) = \frac{3}{8}\left(1 + \frac{U}{U_c}\right) \qquad [24]$$

At $U = U_c$, the spin of the particle reduces to the Pauli spin, with $\langle S_i^2 \rangle = \frac{1}{2}(\frac{1}{2} + 1)$.

Mott–Hubbard Transition as a Phase Transition

The factor $q(\eta_0)$ describes the mass enhancement also. Namely,

$$\frac{m^\star}{m_0} = \frac{\gamma(0)}{\gamma_0} = q^{-1} = [1 - (U/U_c)^2]^{-1} \qquad [25]$$

So, $m^\star$ diverges (and so does the linear specific heat) as $U \to U_c$. Additionally, one can also calculate the magnetic susceptibility $\chi(0)$, which reads

$$\chi(0) = \chi_0/q(\eta_0)\left\{1 - \frac{U}{U_c}\frac{1 + U/(2U_c)}{(1 + U/U_c)^2}\right\} \qquad [26]$$

where χ_0 is the Pauli susceptibility. Note that χ is divergent as $U \to U_c$, since $q \to 0$ in this case (the other divergence represents the renormalized Stoner criterion for the onset of ferromagnetism). Hence, the point $U \to U_c$ represents, at least within this simple approach, a quantum critical point (the Brinkman–Rice point). One can also define the parameters

F_1^s and F_0^a by comparing [25] and [26] with [15] and [17].

Localization of Electrons at Nonzero Temperature

One can generalize the meaning of the factor $q(\eta)$ by defining statistical quasiparticles with energies $E_k = q(\eta)\varepsilon_k$. Hence, the statistical distribution of quasiparticles is, as in the Landau–Fermi liquid, $f(E_k) = \{\exp[\beta(E_k - \mu)] + 1\}^{-1}$. The free energy of the metallic ALFL written for all electrons is then

$$\frac{F}{N} = \frac{1}{N}\sum_{k\sigma} E_k f(E_k) + U\eta + \frac{k_B T}{N}\sum_{k\sigma}\{f(E_k)\ln f(E_k) + [1 - f(E_k)]\ln[1 - f(E_k)]\} \quad [27]$$

In the low-T limit, the expansion to the first nontrivial order leads to

$$\frac{F}{N} = -q(\eta)\bar{\varepsilon} + U\eta - \frac{\gamma_0 T^2}{2q(\eta)} + o(T^4) \quad [28]$$

The next step is to introduce the discontinuous phase transition in the context of ALFL instability. The localized electrons (atomic $s = 1/2$ spins) are represented in the paramagnetic phase by their entropic part only, that is, their free energy is

$$\frac{F_l}{N} = -k_B T \ln 2 \quad [29]$$

where the exchange interactions between the electrons have been neglected as only paramagnetic states have been described here. Equating $F = F_l$, the coexistence of the phases is obtained.

The phase diagram for this system on the plane $T - U/U_c$ is shown in **Figure 9**, together with the "mean-field" critical points. The main feature is the reentrant (PM) metallic behavior in the high-temperature regime. Such a reentrant behavior is observed for the condensed ^{3}He (on the $p - T$ plane, cf. **Figure 1**). For the canonical Mott–Hubbard system, pure and doped V_2O_3, the upper line $T_+(U)$ represents a crossover behavior accounted for in a more refined approach.

Spin-Dependent Quasiparticle Masses

There are two specific properties of almost-localized electrons in the presence of a magnetic field. The first of them is the metamagnetism, that is, the transition in an applied magnetic field to a saturated ferromagnetic phase via a first-order transformation. The second is the appearance of a spectacular spin dependence of the quasiparticle masses, with $m^\star/m_0 \equiv m_\sigma/m_0 = 1/q_\sigma$, which appears only for a non-half-filled narrow-band situation. In the limit of strongly correlated electrons ($U \gg U_c$), the

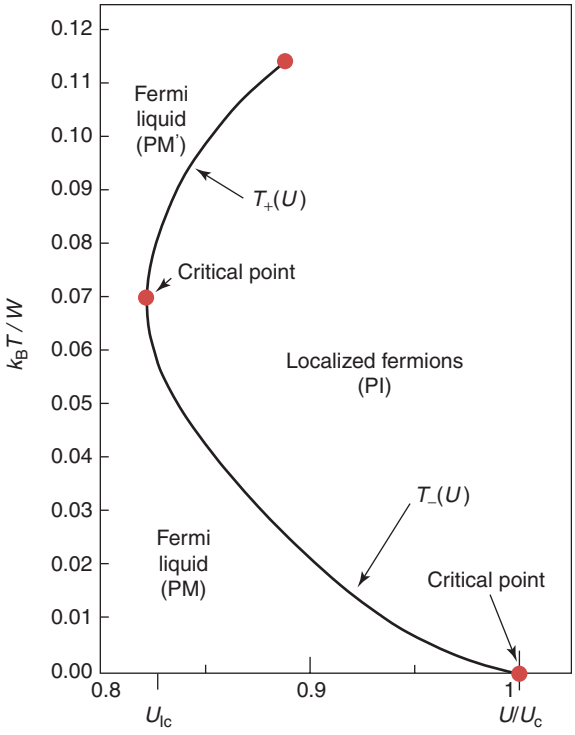

Figure 9 Schematic phase diagram for the almost localized electrons in a narrow band in the paramagnetic state.

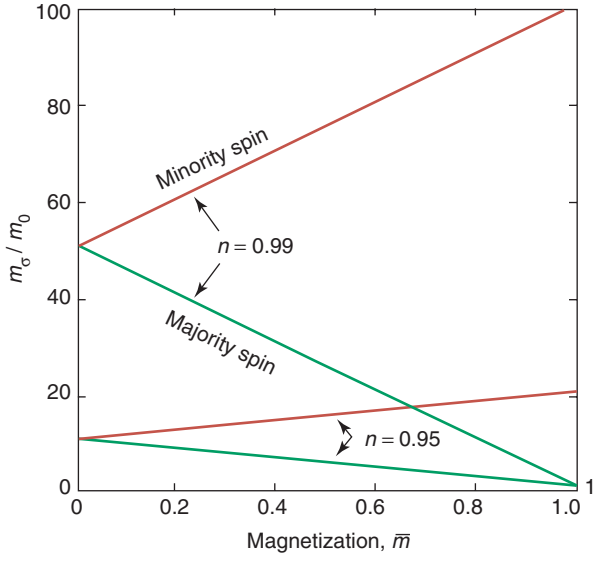

Figure 10 Spin-split effective masses for almost localized electrons as a function of magnetic polarization $\bar{m} = (n_\uparrow - n_\downarrow)/(n_\uparrow + n_\downarrow)$ for the number n of electrons per atom specified. (cf. Spalek J and Gopalan P (1990) Almost localized electrons in a magnetic field. *Physical Review Letters* 64: 2823.)

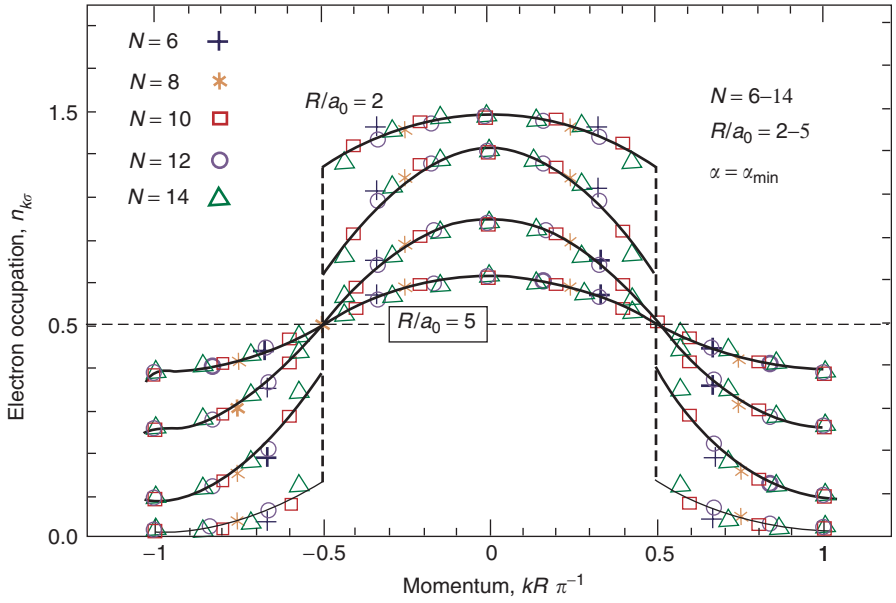

Figure 11 Momentum distribution for a nanochain of N atoms specified and for different interatomic distances R (in units of 1s Bohr orbit). (cf. Spalek J and Rycerz A (2001) Electron localization in a one-dimensional nanoscopic system: a combined exact diagonalization – an *ab initio* approach. *Physical Review B* 64: 161105.)

enhancement factor takes the form

$$1/q_\sigma = (1 - n_\sigma)/(1 - n) \qquad [30]$$

where n is the number of electrons per atom in the correlated band, with the energies of particles $E_k \equiv E_{k\sigma} = q_\sigma \varepsilon_k - \sigma \mu_B H_a$, and n_σ is the number of electrons (per atom) of spin σ (the quantity $\bar{m} \equiv (n_\uparrow - n_\downarrow)/(n_\uparrow + n_\downarrow)$ is the spin polarization). **Figure 10** presents the spin-split masses as a function of $\bar{m}$ for both the majority and the majority-spin subbands for two-band fillings close to the half-filling, where the Mott–Hubbard transition localized phase would be already stable. The spin-split masses were predicted theoretically but have not been detected as yet.

Marginal Fermi Liquid

In the case of a normal FL, one has $\mathrm{Re}\,\Sigma(\omega) \sim \omega$, whereas $\Sigma''(\omega) \sim \omega^2$, whereas in the phenomenological approach to high-temperature superconductors, Varma and co-workers assume that

$$\Sigma(\omega) \sim \lambda \left(\omega \ln \frac{\omega_c}{|\omega|} + i|\omega| \right)$$

and hence the imaginary part is comparable to the quasiparticle energies with energies $\omega \sim \varepsilon_k$ (λ is the effective coupling constant and ω_c is the so-called cutoff frequency, beyond which the marginal FL (MFL) concept does not hold). The real part of the self-energy is weakly singular and this, in conjunction with the fact that $\Sigma'' \sim |\omega|$, specifies the two-dimensional nature of those systems.

Nanosystems as Quantum Liquids

In the era of nanotechnology, a legitimate question is: how short can a quantum (monoatomic) wire be? The answer to this question can be provided by solving exactly the system of $N \sim 10$ atoms with one valence electron (e.g., a chain of N hydrogen atoms in the simplest situation). **Figure 11** shows the statistical distribution function $n_{k\sigma}$ drawn for different interatomic distances R in units of Bohr radius a_0. For $R = 2a_0$, the distribution is close to the Fermi distribution, with quasi-discontinuity (the vertical dashed line) near the Fermi point for the infinite system. The distribution is continuous $n_{k\sigma} \approx 1/2$ when the particles become localized on atoms.

Summarizing this article in one sentence, the concept of FLs introduced in 1956 is valid even today, often in a completely different context.

Lithography Masks and Pattern Transfer

C Romeo and P Cantù, STMicroelectronics, Agrate Brianza, Italy

Introduction

Integrated circuits (ICs) are commonly manufactured using "planar technology." The different layers of an electronic device are fabricated with a sequence of technological processes (deposition, lithography, etching, and implantation) opportunely integrated.

Electronic performances and financial costs are essential goals in the semiconductor business and both are dependent on the ability of printing small feature sizes (transistors, connections, etc.) or more precisely small critical dimensions (CDs).

Lithography is the technique used to print these features; therefore, its role in the semiconductor industry is of paramount importance.

In a very schematic way, the process can be described as follows:

The electrical design of each layer is drawn on a lithographic photomask or reticle (both terms are used interchangeably) in a way that the circuit features are made of an absorbent material, while the remaining background is transparent to light; the reticle (which is partially transparent) is exposed to a source of light (see **Figure 1**) and its image is projected through a lens (4–5× reducing power) onto a silicon wafer previously covered with a photosensitive polymer (resist).

The light modifies the chemical nature of the exposed resist making it soluble to a specific solution. A development treatment then, with a basic solution, (0.26 N), removes the exposed resist (positive process), transferring the mask design onto the resist

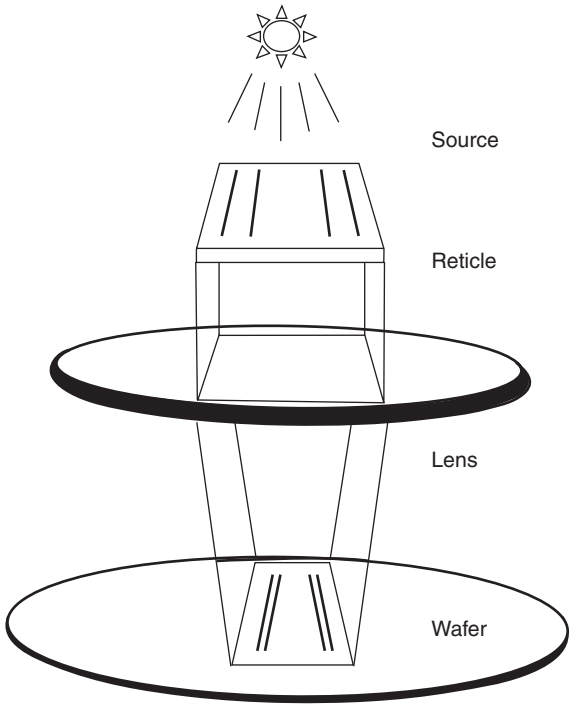

Figure 1 Schematic representation of the photomask exposure onto a silicon wafer in a lithographic process for IC fabrication.

layer that will be used to protect areas of the wafer from metal-oxide etching, implantation, etc. After the resist is removed, these process steps are repeated a number of times according to the complexity of the IC.

Currently, the semiconductor industry is mass-manufacturing ICs with a minimum CD of 130 nm (130 nm node), and the production of 90 nm electronic devices (90 nm node) has begun. Lithographic exposure tools use wavelengths of 248 and 193 nm with chemical-amplified photo-resists and phase-shifting reticles for the most critical layers.

There is a general consensus among IC makers that future developments will be the 65 nm node in 2005, the 45 nm node in 2007, and the 32 nm node in 2010.

Lithographically, this can be achieved using smaller wavelengths (13.5 nm for extreme ultraviolet lithography), a new technique called immersion lithography, lenses with higher numerical aperture, phase-shift masks (PSMs), and more advanced photo-resist processes.

The following paragraphs first describe how the reticle image is formed at the wafer level and then, a more detailed description of photomask characteristics and their manufacturing process is given.

Aerial Image Formation

Photomask or Reticle Diffraction

The interaction of electromagnetic waves with a reticle produces an image intensity profile in accordance with the diffraction theory of light. In order to describe this phenomenon, consider for simplicity, a binary reticle with equal lines and spaces; $l = s = d$ and with periodicity $P = 2d$.

For simplicity, this reticle is considered to be illuminated uniformly (Köhler's illumination) by a plane monochromatic wave λ, normally incident.

The diffracted light produces a Fraunhofer diffraction pattern with a maxima of intensity in the directions given by the angle θ:

$$\sin\theta - \sin\theta_0 = \frac{m\lambda}{nP}, \quad m = 0, \pm 1, \pm 2, \ldots \qquad [1]$$

where θ_0 is the angle of incidence, m is an integer, and n is the refraction index of the medium surrounding the mask and the lens.

If z is the distance between the reticle and the image plane (see **Figure 2**), it is known from the optical theory that in the far field approximation

$$z \gg \frac{\pi}{\lambda}(x^2 + y^2)$$

the Fraunhofer diffraction pattern in the plane (x_0, y_0) is given by the Fourier transform of the reticle transmission function calculated at the special frequencies $p = x_0/(\lambda z), q = y_0/(\lambda z)$, where z is the distance between the reticle and the image plane.

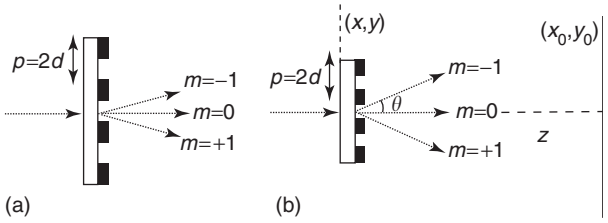

Figure 2 (a) A ray of coherent light normally incident ($\theta_0 = 0$) onto a reticle is diffracted in different directions. (b) For a smaller pitch P or larger λ, the diffraction angle θ becomes larger.

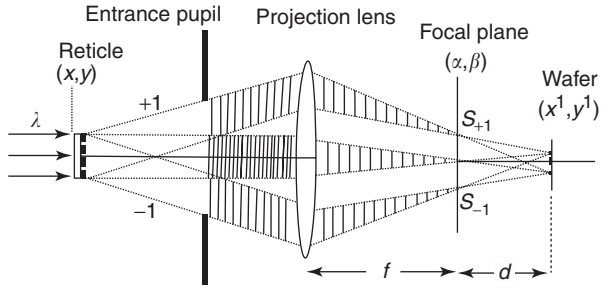

Figure 3 Reticle image formation at the wafer plane.

According to [1], the diffraction angle θ of each Fourier component is larger for a smaller pitch or for a larger λ (**Figure 2**). In other words, a lens facing a reticle with the scope of collecting the diffraction orders transmitted must have a larger diameter when the feature sizes are smaller. A diffraction-limited lens will faithfully reconstruct the image recombining all the Fourier components. However, in a real situation where the lens dimension is finite, only a few orders are collected and the image is partially reconstructed.

Image Formation

The image formation of the reticle in the image plane (wafer level) can be explained with the Abbe's theory of image formation. According to this theory, the image arises from a double diffraction process: the wave plane is diffracted first by the reticle and then by the lens (**Figure 3**).

The wave front transmitted through the reticle becomes a set of plane waves or spatial frequencies traveling in different directions (m_0, $m_{\pm 1}$, $m_{\pm 2}$, etc.). The Fraunhofer diffraction pattern obtained in the focal plane (α, β) at a distance f from the lens is proportional to the Fourier transform of the reticle

transmission function $G(x, y)$:

$$H(\alpha, \beta) = A_0 \int \int_C G(x, y) \times \exp - ik\left[\frac{\alpha}{f}x + \frac{\beta}{f}y\right] dx\ dy \qquad [2]$$

where A_0 is a constant and the integration is done over the reticle area C.

The maxima of intensity in the focal plane, S_0, $S_{\pm 1}$, $S_{\pm 2}$, etc., can be envisioned as emitters of Huygens waves that interfere in the reproducing of the image of the reticle in the image plane (x^1, y^1) of the lens.

The perfect reconstruction of the reticle image can be obtained considering that all the spatial frequencies are collected by the lens. In a real situation, the lens has a finite aperture, therefore, the highest frequencies are cut off. Only low special frequency components, corresponding to small θ in [1], passing close to the center of the lens, contribute to the image formation.

The reticle image can be reconstructed if there are at least two interfering plane waves; therefore, the lens must be large enough to capture the order $m = 0$ and $m \geqslant 1$. The minimum resolved feature is then

$$\sin\theta = \frac{\lambda}{nP} \qquad [3]$$

or

$$d = \frac{1}{2}\frac{\lambda}{n\sin\theta} = \frac{1}{2}\frac{\lambda}{NA} \qquad [4]$$

The above equation is known as Rayleigh's resolution limit for lines and spaces, for coherent illumination, where $n\sin\theta = NA$ is the numerical aperture of the lens.

It can be demonstrated that in the case of incoherent illumination, the expression can be rewritten as

$$d = \frac{1}{1+\sigma}\left(\frac{1}{2}\frac{\lambda}{n\sin\theta}\right) = \frac{1}{2}\frac{\lambda}{NA}\frac{1}{(1+\sigma)} \qquad [5]$$

where σ represents the partial coherence factor which is a measure of the physical extent of the light source. The larger the light source, the larger the σ. For a point source, $\sigma = 0$ and one has coherent illumination , for $\sigma = 1$ one has a large source and incoherent illumination.

As already said, the image of the reticle on the plane (x^1, y^1) is given by the Fraunhofer diffraction of the waves emitted by S_0, $S_{\pm 1}$, $S_{\pm 2}$, etc., and the total field distribution is

$$E(x^1, y^1) = A_1 \int \int_B H(\alpha, \beta) \times \exp - ik\left[\frac{x^1}{d}\alpha + \frac{y^1}{d}\beta\right] d\alpha\, d\beta \qquad [6]$$

where d is the distance between the focal plane and the image plane, $k = 2\pi/\lambda$, and B is the area of the aperture on the focal plane assuming that its dimension is smaller than d.

Using [2], the expression [6] can be rewritten as

$$E(x^1, y^1) = A_0 A_1 \int_{+\infty}^{-\infty} \int_{+\infty}^{-\infty} \int_{+\infty}^{-\infty} \int_{+\infty}^{-\infty} P(\alpha, \beta) \times G(x, y) \exp - i\frac{k}{f}\left[\left(x - \frac{x^1}{M}\right)\alpha + \left(y - \frac{y^1}{M}\right)\beta\right] dx\ dy\ d\alpha\ d\beta \qquad [7]$$

$G(x, y)$ is assumed as zero for all points that are outside C; the pupil function $P(\alpha, \beta)$ is the transmission function in the pupil plane (equal to 1 for transmitted frequencies $\leqslant NA/\lambda$, and zero for blocked components); $f/d = -1/M$ where M is the magnification factor of the lens that for leading edges lithography equipment is 4 or 5 (reticle 4–5 times larger than its image on the wafer).

Generally, the intensity at the wafer level can be obtained by [7]:

$$I(x^1, y^1) = |E(x^1, y^1)|^2 = \left| A_0 A_1 \int_{+\infty}^{-\infty} \int_{+\infty}^{-\infty} \int_{+\infty}^{-\infty} \int_{+\infty}^{-\infty} P(\alpha, \beta) \times G(x, y) \exp - i\frac{k}{f}\left[\left(x - \frac{x^1}{M}\right)\alpha + \left(y - \frac{y^1}{M}\right)\beta\right] dx\ dy\ d\alpha\ d\beta \right|^2 \qquad [8]$$

In the case of a photomask with N equidistant spaces (N large) of width s and with pitch P, and if the aperture in the focal plane is such that $-a \leqslant \alpha \leqslant a$, eqn [7] can be written in x^1-direction:

$$E(x^1) = E_0\left[1 + 2\sum_{1<m<m_0} \frac{\sin(m\pi s/P)}{m\pi s/P} \cos\frac{2\pi m x^1}{-dP/f}\right]$$

where $m_0 = aP/\lambda f$. In the case of $m_0 = \infty$, the summation can be changed with an integration and the image collected in the image plane (or wafer level) becomes similar to the object.

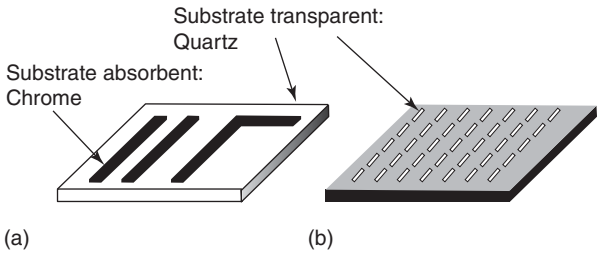

Figure 4 Schematic view of two binary masks for two different electronic layers: (a) lines and spaces (active area, poly, metal, etc) and (b) contact level.

Definition of Photomask

A mask is a transparent substrate selectively covered with a thin opaque layer, intended for the reproduction of patterns on wafers. In the case of optical photomasks, the pattern, which represents one level of an IC, is formed in a chromium layer sputtered over a fused silica substrate. Typically 20 to 30 masks, defined as a mask set, are required for imaging all layers necessary for the manufacturing of an IC. The terms mask and reticle are used interchangeably although historically, the first one was used for defining 1X patterned substrates used for exposing the whole wafer with contact printing technology, while the term reticle is used to define 2X, 4X or 5X patterned substrates used in optical projection systems. **Figure 4** represents a schematic of photomasks for two different layers: (a) lines and spaces, and (b) contact holes.

Types of Photomask

One may distinguish optical photomasks in two main categories: binary masks and PSMs. Masks for EUV applications, stencil masks or membrane masks for X-ray or electron projection lithography are not specifically discussed.

Binary Mask

A binary mask is a close replication of the circuit design pattern, with the possible addition of biases (i.e., the CD can be modified compared to the original design) in order to take into account lithography for optical proximity corrections (OPCs) or etch loading effects; its patterned area can be only clear or opaque, hence the term binary.

Phase-Shift Masks

PSMs were introduced in 1982 to improve the ultimate resolution achievable with wafer scanner exposure tools. The principle of this method consists in taking advantage of phase differences caused by different areas on the mask to obtain destructive interference and achieve better image contrast. PSMs can be separated in two categories: "weak PSMs," that include half-tone and embedded attenuated phase shift masks (EAPSMs), and "strong PSMs" that include alternating phase shift masks (APSMs). In the case of EAPSMs, the opaque region of the binary mask is substituted by a partially transmitting material that induces a 180° phase variation with respect to the bright regions. The destructive interference between clear areas and a partially transmitting background enhances the image contrast of the bright region. The improved image quality allows one to achieve a larger process latitude and depth of focus leading to a robust lithographic process. Usually 6% transmittance is used for leading edge masks; a higher transmittance allows one to achieve better contrast, due to a greater phase interaction, but is practically unusable due to the risk of unwanted side-lobe printing. Specifications related to half-tone and EAPSMs can be found in *SEMI P29-0997: Guideline for description of characteristics specific to Halftone Attenuated Phase Shift Masks and Mask Blanks*.

In strong APSMs, chrome structures are bordered with clear areas of 180° phase difference that leads to a destructive interference and thus to an enhanced image contrast. While in EAPSMs, the phase and transmission variation is obtained using appropriate materials, the most common being moly-silicide (MoSi), in strong PSMs the phase variation is generally obtained directly by etching the quartz substrate. **Figure 5** summarizes the binary mask and the PSM imaging principle.

Photomask Manufacturing Process

The manufacturing process of a photomask is quite similar to the one used for producing silicon wafers: the mask blank, which consists in a very flat piece of glass covered by a thin layer of chrome, is spun with a thin film of resist. The resist is exposed to light or to electrons in order to define the circuit geometries, and is then developed so as to form the required pattern. After development, the chrome material is etched and, finally the residual resist is removed.

In order to provide more details, the steps of photomask manufacturing can be summarized as follows (**Figure 6**): (1) mask blank preparation; (2) pattern writing; (3) processing; (4) critical dimension metrology; (5) position accuracy metrology; (6) defect inspection; (7) cleaning; (8) defect repair; (9) pellicle attachment; and (10) final inspection.

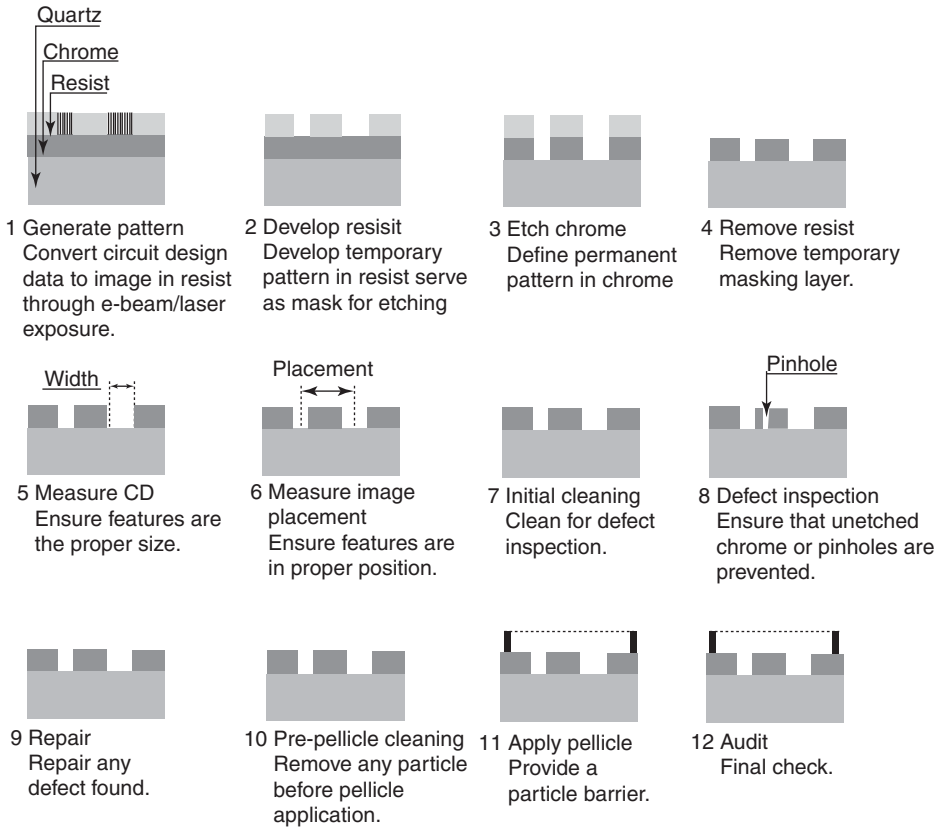

Figure 6 Photomask fabrication process.

Mask Blanks

Substrate Sizes

Photomask substrates requirements are defined in SEMI standard reticle format document (*SEMI P1-92 Re-approved P01-0299: Specification for Hard Surface Photomask Substrate*).

Actually, the standard size for leading edge masks is 15.24 cm square by 0.635 cm thick. The substrate size has been progressively increased in order to

Table 1 Optical characteristics of chrome film at different wavelengths

Wavelength (nm)	*Complex refraction index*	*Reflection from chrome glass interface*	*Transmission through* 60 nm *thick film of chromium*	*Effective transmitted light* (%)
436	1.79 *i*4.05	0.60	0.0009	0.036
365	1.39 *i*3.24	0.56	0.0012	0.055
248	0.85 *i*2.01	0.47	0.0022	0.119
193	0.84 *i*1.65	0.38	0.0016	0.098
157	0.68 *i*1.11	0.32	0.0048	0.310

accommodate larger and larger die sizes, while mask thickness has been increased from 0.09″ up to 0.25″ to minimize edge placement errors induced by the gravitational lag of the substrate as well as plate distortions caused by the clamping system of tools used for mask patterning and wafers exposure.

Substrate Materials

Mask substrate materials are chosen to comply with some mechanical and physical properties that can be summarized as follows: transparency at the exposure wavelength, thermal expansion, flatness, birefringency (only for 157 nm).

Low thermal expansion materials are required mainly for two reasons:

1. To minimize mask pattern placement errors induced by temperature variations that may happen during the mask patterning process, and
2. To minimize wafer pattern placement errors induced by mask heating that may happen when the mask is exposed to laser radiation in exposure tools.

A substantial portion of the placement error induced by temperature variations during mask patterning consists in magnification errors, which can be adequately compensated by wafer exposure tools, but residual errors caused by thermally instable material cannot be compensated.

A consideration of the depth of focus is the main driver for the tight control of reticle flatness which, for leading edge masks can be specified down to minor-equal 0.5 μm, depending on focus budget considerations.

Photomasks for leading technology use fused silica (SiO_2) substrates; this material has been chosen mainly for its low thermal expansion coefficient and for its transmission at current exposure wavelengths. For 157 nm exposure wavelength, fluorine-doped fused silica is introduced to maintain transparency at a sufficient level.

Opaque Film

The typical opaque film deposited on photomask blanks is chrome whose top surface is usually covered with a thin antireflective layer in order to minimize reflection of light reflected back by the wafer surface. The film characteristics are specified in *SEMI P2-86 Re-approved P2-0298: Specification For Chrome Thin Films For Hard surface Photomasks*. Chrome is normally deposited using a sputtering process with a thickness that may range from 50 to 110 nm. **Table 1** reports the optical characteristics of the chrome film at different wavelengths.

Several alternative materials have been tested over time; among others, a molybdenum-silicon layer has been proved to be a good alternative and is actually used for embedded phase-shift masks (EPSMs).

Mask Lithography

Mask writing tools are used to define the latent image of circuit patterns in the resist film spun over the mask substrate. Commercially available mask writing tools may be divided into two big categories:

1. electron-beam tools:
   (a) raster based (Gaussian beam);
   (b) vector based (beam shaped); and
2. laser tools.

Electron Beam Tools

Electron beam tools used for mask patterning are based on the same technology initially developed for electron microscopy. Energetic electrons induce chemical reaction in the resist, in the same way as photons do when using laser tools. One of the main advantages related to this kind of equipment, when compared to laser-based ones, is its very high resolution because electron diffraction occurs in the atomic range. Ultimate resolution is mainly limited by scattering of the electrons with the resist. To reduce this undesired effect, new tools adopt higher and higher beam energy together with complex electron proximity effect correction methodologies which are used to avoid dose variations induced by back-scattered electrons.

Electron beam tools may be divided into two subcategories: raster scan tools, which use a Gaussian beam, and vector shaped tools, where the beam shape is changed while patterning the mask.

Electron beam raster scan tools In raster scan tools, the design is divided into pixels, whose dimension, in the simplest implementation, is the one of the electron beam itself. The mask is scanned by deflecting the e-beam electromagnetically, while a high-precision stage, controlled by an interferometric system, moves the substrate. The beam is blanked or unblanked in synchronism with the deflection to form the desired circuit latent image in the resist. One should observe that the mask is progressively scanned for its whole area: even areas that should not be exposed must be scanned, leading to increased overall exposure time.

Electron shaped beam vector tools In vector tools, an electron beam is addressed just over the areas to be exposed: this approach dramatically reduces the exposure time. Additionally, these tools usually adopt a shaped beam, obtained by passing the electron beam through appropriate apertures. The pattern is obtained by exposing these elementary shapes that are butted or stitched together. Shaped beam tools have been introduced only recently, mainly due to the complexity required by their engineering, but are actually used for writing most of the leading edge masks as they allow one to achieve sharper corners and better resolution when compared to raster tools.

Laser Tool

Laser tools use an array of focused laser beam, with a roughly Gaussian profile, that is individually blanked or unblanked while scanning the mask. The light, generated by a laser, is split in a certain number of independent beams, the intensity of each beam being individually modulated using an acoustic–optic modulator. Laser beams are then scanned over the mask surface using a multifaced polygonal mirror rotating at high speed. During the exposure, the mask is clamped on a reticle stage that is moved under laser interferometric control.

Resist and Processing

Resists are radiation sensitive materials, typically composed of organic polymers and small molecules, used for enhancing lithographic performance. The exposure of resists to laser or e-beam radiation induces a change in solubility of the exposed regions compared to nonexposed ones: this property is used during the development step in order to define the pattern into the resist. The choice of the resist material is mainly related to the exposure tool environment, together with other lithographic properties such as sensitivity, contrast, and ultimate resolution achievable. Sensitivity is particularly important as it is directly related to the throughput of the tool. No material can meet sensitivity requirements for both laser and e-beam radiation, so two completely different processes are used by mask manufacturers depending on the writing tools used for patterning.

e-Beam Resists

Historically, the most common e-beam resist has been PBS poly (butane-1-sulfone), an alternating copolymer of 1-butene and sulfur dioxide, developed by Bell Laboratories. PBS is a positive resist usually developed using pentanone and other solvents such as methyl iso-amyl ketone. The need for better and better lithographic performances and the introduction of plasma etch of chrome brought about the development of alternative materials such as ZEP7000, a polymer of methylstyrene and chloromethyl acrylate from Nippon Zeon.

i-Line and DUV Resists

In general with optical ($\lambda = 365$ nm) resists, the process control can be reduced by the standing waves phenomena. A post-exposure bake (PEB) step is then usually applied in order to reduce the standing waves and improve the process control, as it happens in wafer lithography. New tools, operating at DUV wavelengths (248 nm), allowed the introduction of chemical amplified resists that obliged mask makers to start coating mask blanks themselves; historically mask blanks were pre-coated with appropriate resists by blank suppliers. PEB temperature control is quite critical and much more difficult than the one achievable with silicon wafers due to the mass of the substrate: that is the main reason why resist materials are selected with low sensitivity toward post-exposure bake temperature.

Chrome Etching

After resist development, the chrome opaque film is removed from the mask surface, using a wet-or-dry-etch process. Wet etch has been used for many years and it is based on a solution containing ceric ammonium nitrate mixed with nitric, perchloric, or acetic acid. Wet-etch processes are characterized by a non-negligible undercut that may contribute to line width variations, especially when the chrome thickness is not uniform. Additionally, patterns cannot be well defined if the undercut becomes comparable

with the dimension of the structures to be defined. For these reasons, the need for better and better pattern fidelity, together with the continuous shrinkage of CDs, pushed mask makers to move from wet-etch processes toward dry-etch processes. Typically, chrome is dry etched using a mixture of Cl and O_2 together with other gases added for reducing etch-loading effects that may bring iso-dense critical dimension variations.

Metrology

Three main parameters are measured once the mask is finished: feature dimension, pattern placement, and defect density.

Feature Dimension Control

The feature dimension control is performed to assure that geometry dimensions on the mask match the expected one. Three parameters related to CDs are usually reported: the average CD with respect to its nominal value, the CD uniformity across the reticle, generally reported as a three-sigma deviation of mask feature sizes for a single dimension, the feature size linearity down to a given dimension.

The average of a given CD with respect to its nominal value is specified as mask mean to target: which, for a given nominal CD value N (or target), is the difference between the mean of all measured CD values (CD_i) and their nominal N:

$$\text{Mask mean to target} = \frac{\sum_i (CD_i)}{n} - N$$

where n is the number of measurements.

More commonly, the CD accuracy is specified using the Max CD deviation, which, for a given nominal CD value N, is the greatest absolute value of the difference among the all measured CD values (CD_i) and their nominal N:

$$\text{Max CD deviation} = \text{MAX}|CD_i - N|$$

If more than one nominal CD is required, the Max CD deviation is the greatest among all the Max CD deviations for each nominal.

The CD uniformity across the mask is specified by the CD range which, for a given nominal CD value N (taking into account all measured CD values at that nominal) is the difference between the maximum and the minimum measured value:

$$CD_{\text{range}} = \text{MAX}(CD_i) - \text{MIN}(CD_i)$$

Finally, the linearity is specified as the difference between MAX and MIN "mask mean to target" for a range of features of the same nature, same tone, and different design sizes.

Mask CD control becomes significantly important when considering feature sizes near the diffraction limit. In such a condition, there is a change in magnitude by which feature sizes on the mask are reduced by lens reduction onto the wafer. This effect is described by the mask error factor (MEF):

$$\text{MEF} = \frac{\partial(CD_{\text{wafer}})}{\partial(CD_{\text{mask}}/M)}$$

where M is the imaging system reduction ratio, typically $M = 4$ for DUV lithography systems. For larger features, $\text{MEF} = 1$ but becomes bigger as lithography is pushed to the diffraction limit (i.e., for CDs close to the Rayleigh's resolution limit).

CD measurements have been performed for many years using optical microscopes coupled with software image analysis. Actually, CD measurements for leading edge masks are mainly performed using scanning electron microscope (SEMs) while several alternative methodologies are being explored for future technologies; these include scatterometry, Atomic force microscope (AFM), and optical immersion microscope.

Pattern placement

The pattern placement accuracy, or registration accuracy, refers to the deviation of pattern centerlines relatively to a defined reference grid. Registration is a vector quantity defined, at every point on the mask, as the difference between the vectorial position of the mask geometry and the vectorial position of the corresponding point on a reference grid. Pattern placement is measured on registration control tools that consists in a microscope, used for locating the feature to be measured, coupled with a high precision stage whose position is controlled by a laser interferometer.

Mask Defects and Inspection

A key requirement to mask makers is to produce "zero defect" reticles. A mask defect can be defined as any imperfection on the photomask pattern liable to be reproduced on a photoresist film, thus preventing the proper functioning of the microelectronic device being manufactured. One may distinguish defects in different categories:

- Macro defects: defects on mask that are visible to the naked eye, with or without the aid of a collimated spot light, for example, fingerprint left either by bare fingers or gloves;

- Micro defects: defects not visible to the naked eye, whose detection requires the use of automatic defect inspection systems or of any magnification tool.

One could also distinguish defects by their nature:

1. Soft defects, defined as defects that can be removed by a cleaning process:
   (a) particles
   (b) contaminations
   (c) process residuals
2. Hard defects, defined as defects that cannot be removed by a cleaning process
   (a) chrome protrusions
   (b) chrome intrusions
   (c) splintering: damaging of the substrate along its perimeter, glass missing
   (d) pinholes
   (e) scratches: an incision having regular or irregular shape and three dimensions: length, width, and depth where the length is much bigger than the width and the width itself is almost equal to the depth.
3. At each technological node (generation of semiconductor devices), the minimum CD is usually related to the minimum defect size allowable. In order to guarantee defect-free masks, automatic defect inspection tools have been developed. Inspection tools may work in two modes:
   - Die-to-die mode: automatic inspection of mask defectivity based on the comparison of at least two identical patterns, structured into regular arrays;
   - Die-to-database mode: automatic inspection of mask defectivity based on the comparison of the mask pattern against its original database.

The ability of an inspection tool to detect accurately all the defects present on a plate determines its defect capture efficiency that is related to many factors: inspection light wavelength, pixel size, sensors efficiency, real-time signal analysis, stage resolution, and many others. It is to be taken into account that high sensitivity requires small pixel sizes, and so higher inspection time and a higher chance to detect false defects: differences detected, even if below the defect specification requirement.

Once mask inspection is terminated, defects are normally manually reviewed by an operator who classifies all captured defects transferring coordinates of hard defects to be repaired to appropriate tools. Inspection equipment are certified by performing a mask inspection with pre-programmed defects of certified dimensions.

Repair

Mask defects may be repaired by proper tools, and several techniques have been developed over the years: laser tools are the most diffused together with focused ion beam. More recently, a mechanical method that utilizes the positional control of an AFM coupled with RAVE LLCs nanomachining head to perform material removal with nanometer level precision has been proposed.

Cleaning

The scope of cleaning is to remove resist residuals, particles, and all other possible contaminations without damaging the mask itself. Traditionally, the cleaning step has not been a major concern for the mask industry. Mask cleaning is usually performed by the use of wet methods developed by the wafer industry. In the past, immersion processes were most diffused for the cost of ownership reasons, while recently the tightening of cleaning specifications pushed mask manufacturers to introduce spin/spray processes. Several cleaning chemistries have been developed over the years: among the others, the most used are based on H_2SO_4 and H_2O_2 to remove heavy organic materials such as resist and hydrocarbons, or H_2O, H_2O_2, and NH_4OH to remove light organic residues and particles.

Pellicle

The requirement to produce "zero defect" masks has already been discussed. To avoid contamination of mask surface during its usage, pellicles are attached to the photomasks. Pellicles consist in a thin ($<1\,\mu m$) polymer film, usually made of nitrocellulose or a form of teflon, stretched on an anodized aluminum frame, that is attached to the photomask using special adhesives characterized by low outgassing and stability to exposure at actinic light. **Table 2** reports

Table 2 Pellicle materials commonly used

Materials	*Thickness* (μm)	*Transmission* (%)	*Wavelength* (nm)
Nitrocellulose	1.4	99	436 (g-line), 365 (I-line)
Cellulose	1.4	99	436 (g-line), 365 (I-line)
Fluorocarbon	1.2	99	365 (I-line), 248 (DUV)
Teflon	0.6	99	248 (DUV), 193 (EDUV)

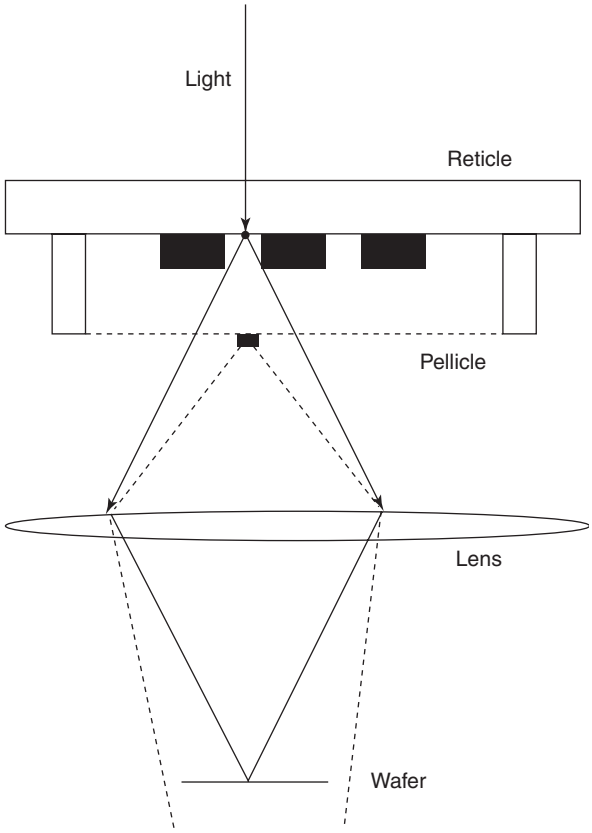

Figure 7 Cross-sectional view of a mask with pellicle. The particle accidentally deposited on the pellicle will produce an image severely blurred onto the wafer.

the most commonly used materials used for mask pellicles and their characteristics:

Characteristics of various pellicle materials are illustrated more in detail in the document *SEMI P5-94: Specification For Pellicles*. Pellicles keep contaminations far away from the chrome features that are to be printed; in that way, with a typical depth of focus $<1\,\mu m$, particles are not in the focus plane of the wafer and then are not printed on the wafer (**Figure 7**).

The typical frame height is in the range of 6 mm, small holes in the frame allow one to maintain air pressure of the space between the mask surface and the pellicle equal to the ambient pressure. The frame surface has to be quite flat so as to avoid the distortion of the mask that may induce registration and focus errors.

Local Field Effects

W Schattke, Christian-Albrechts-Universität zu Kiel, Kiel, Germany

Introduction

If a dielectric material is exposed to an electric field, a dipole moment is established which is detected by the force the field exerts on it. It is a common experience to have felt the attraction acted by a charged external body as by a comb on one's hair. Such materials show induced polarization in an external electric field usually observed as surface charges disregarding the microscopic details of the interior. However, the field acts in the interior of the whole dielectric body and induces the polarization therein through the polarizability of the atomic constituents of the body. The well-known textbook Lorentz–Lorenz construction of the so-called "local field" is applied, which explicitly takes into account the presence of an induced field adding to the external field and being self-consistently determined at every point. In course of time, the Lorentz–Lorenz construction has been set on an *ab initio* fundament by considering the total many-body system, which also led to the quantitative determination by well-accepted definite rules though the whole problem cannot be solved in a closed manner.

From a macroscopic point of view, say, considering length dimensions in centimeters, the polarization is continuously spread over space, discontinuities arising at the edges of bounded bodies only. The total dipole moment causes a resulting induced field which adds to the external field usually screening it, that is, reducing it within the material. Of course, the sources for the induced fields may be inhomogeneously distributed and arbitrarily macroscopically shaped. For example, a spherical solid dielectric body introduced between the plates of a condenser expels the initially homogeneous field from the interior created by dipole charges on the surface of the sphere and situated opposite to the condenser plates. This general macroscopic situation has its origin on an atomic scale that finally gives rise to what is called "local field effects."

From a microscopic point of view, atomic polarization constitutes the source of macroscopic polarization. The atomic polarization is localized being attached to the electronic cloud around the nuclei and showing a global distribution of the dipole moments reflecting the positions of the nuclei. The local variability from granularity on an atomic scale relates to the notion of local fields. Thus, the local field considered here arises from the electric response of atomically structured material to an external field. It can be viewed as an induced granular field, which in the special case of a crystalline solid is structured by the details of the potential within the unit cell being periodically repeated. Such a local field occurs in insulators, as well as in semiconductors and metals. Crystallinity is a widely understood origin for the existence of local structure in the response fields, though the general atomic consistence of matter gives rise to local response fields also. However, the former are much easier to be dealt with than classifying or calculating, for example, amorphous or gaseous material.

The above interpretation is not to be confused with the notion of local field as applied to a theoretical extension of the random phase approximation (RPA), which is a very common and basic approximation in the calculation of dielectric properties of general condensed matter. This also traces back to the roots of the Lorentz local field, though the emphasis does not lie on the granularity and geometric structure but on the many-body influences which affect even homogeneous systems.

The first achievement along both lines may be seen in the Lorentz–Lorenz formula

$$\varepsilon_{\mathrm{M}} = 1 + \frac{\alpha/\varepsilon_0}{1 - \alpha/3\varepsilon_0} \qquad [1]$$

for the macroscopic dielectric constant ε_{M} in terms of atomic polarizability per unit volume α with vacuum permittivity ε_0 (SI units used).

Induced Field

For the theory of dielectrics, Maxwell's equations of electrostatics constitute the framework

$$\mathrm{div}\, \boldsymbol{D} = \rho, \;\; \mathrm{rot}\, \boldsymbol{E} = 0 \qquad [2]$$

to be supplemented by the appropriate material's equation, specifically

$$\boldsymbol{D} = \varepsilon\varepsilon_0 \boldsymbol{E} \qquad [3]$$

for a linear relation between the so-called dielectric displacement $\boldsymbol{D}$ and the electric field $\boldsymbol{E}$ with dielectric constant or relative permittivity ε of the medium. The charge density ρ refers only to the sources of the external field $\boldsymbol{E}_{\mathrm{ext}}$ which can be written as $\mathrm{div}\, \varepsilon_0 \boldsymbol{E}_{\mathrm{ext}} = \rho$. One usually splits off the electric field from $\boldsymbol{D}$ by defining the polarization $\boldsymbol{P}$, that is, the dipole moment per unit volume, and the external field from the microscopic field by defining the induced field $\boldsymbol{E}_{\mathrm{ind}}$

$$\boldsymbol{D} = \varepsilon_0 \boldsymbol{E} + \boldsymbol{P}, \;\; \boldsymbol{E} = \boldsymbol{E}_{\mathrm{ext}} + \boldsymbol{E}_{\mathrm{ind}} \qquad [4]$$

Inserting eqn [4] in [2] yields

$$\mathrm{div}\, \varepsilon_0 \boldsymbol{E}_{\mathrm{ind}} = -\mathrm{div}\, \boldsymbol{P} = \rho_{\mathrm{ind}} \qquad [5]$$

This identifies $-\mathrm{div}\, \boldsymbol{P}$ as the source of the induced field associating with the induced polarization charge ρ_{ind}, an analogous to the external charge, which is a rather trivial statement from the atomic point of view.

In principle, the electrostatic relations have to be complemented in order to deal with optics. The topic of local field effects, however, allows a limitation to the discussion of the longitudinal case, that is, to the above equations of electrostatics, decoupling it from the transverse fields introduced by the time-dependent electromagnetic field. The approximation is valid as long as the length scale of the induced field is small compared to the optical wavelength. Transverse components are of course nonzero and need the full dielectric tensor which may be anisotropic. But the simplification occurs because the self-consistent generation of the total electric field from the applied external field (see the section "Macroscopic fields") derives this approximation solely from the longitudinal field, for which Maxwell's electrostatic equations are already sufficient.

The above simple relationship [3] is, however, a compact abbreviation of the most general linear relation which should be written as

$$D_i(\boldsymbol{r},t) = \sum_j \int_{-\infty}^{+\infty} \mathrm{d}t' \int \mathrm{d}^3\boldsymbol{r}' \varepsilon_{ij}(\boldsymbol{r},t;\boldsymbol{r}',t')\varepsilon_0 E_j(\boldsymbol{r}',t') \quad [6]$$

where the indices refer to the Cartesian axes of a tensor relation through ε_{ij}, the time integration sums up contributions of the electric field at various times to the dielectric displacement, and the space integration does similarly with respect to position. In physical terms, the tensor character relates an electric field in a certain direction to the displacement in any other direction with a specific weight, for example, as an anisotropic material would imply. The time integration takes into account a delay in the effect of the electric field on, for example, the polarization, which for a causal relation obviously implies zero ε for $t' > t$. Switching on a field or, in terms of Fourier transforms, of an incident optical wave which as an oscillating process, excites an oscillating polarization with a weight depending on the frequency, this is the standard case of optical spectroscopy. The dependence on position in space, is the interesting quantity in view of the effects considered here. An electric field at a specific position in principle can excite polarizations everywhere and all contributions are summed up by the integral. The above quantity ε is usually called the microscopic dielectric constant, and "constant" is often replaced by "function" to stress the functional dependence on its variables.

Macroscopic Fields

Measurements as, for example, in classical optical spectroscopy with wavelengths orders of magnitude larger than atomic distances may not resolve the atomic structure of matter, and therefore deal with spatially averaged quantities instead of the microscopic fields considered above. The averaging follows from space integration or from the zeroth Fourier component when expressing the field equations by Fourier transforms as conveniently done. Dealing with the example of a crystalline solid, the periodic repetition of the unit cell imposes this symmetry also on all observable quantities as fields, densities, coefficients of linear relations in position, space, etc., as long as the external fields are homogeneous. Then, the periodicity allows for a representation of the total field by a Fourier series

$$\boldsymbol{E}(\boldsymbol{r}) = \sum_{\boldsymbol{G}} \mathrm{e}^{\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{r}} \boldsymbol{E}_{\boldsymbol{G}} \quad [7]$$

omitting the time or respective frequency dependence in the notation. The vectors $\boldsymbol{G}$ constitute the reciprocal lattice of the crystal. A nonhomogeneous external field may vary on a macroscopic scale, then $\boldsymbol{E}_{\boldsymbol{G}}$ will also depend on $\boldsymbol{r}$. However, the length scales of this field as well as those of the additional variations of the induced fields are large. In which case, all considerations still apply locally within ranges limited by that length scale. The linear relation [3] reads, under the Fourier transformation, as

$$\boldsymbol{D}_{\boldsymbol{G}} = \sum_{\boldsymbol{G}'} \hat{\varepsilon}_{\boldsymbol{G}\boldsymbol{G}'} \boldsymbol{E}_{\boldsymbol{G}'} \quad [8]$$

where the hat is used to indicate a tensor instead of writing the Cartesian indices explicitly. If a homogeneous electric field is applied to an infinitely extended crystal, then the displacement field is constant everywhere and thus possesses only a zeroth Fourier component which is given by a suitable distribution (e.g., charged condenser plates) of its sources, the external charges. Inversion of eqn [8] then yields

$$\boldsymbol{E}_{\boldsymbol{G}} = (\varepsilon^{-1})_{\boldsymbol{G}0} \boldsymbol{D}_0 \quad [9]$$

the Fourier components of the microscopic field, that is, local field which, in principle may spatially fluctuate on each length scale within the periodicity cell. Taking only the zeroth component of eqn [9], one obtains the observable averaged electric field $\boldsymbol{E}_0$ and can write the material's equation as

$$\boldsymbol{D}_0 = \frac{1}{(\varepsilon^{-1})_{00}} \boldsymbol{E}_0 \quad [10]$$

This linear relation between averaged quantities constitutes what is called the local field effect, specifically a macroscopic permittivity ε_{M} which is the reciprocal of the (0,0) element of the inverse microscopic dielectric function matrix $\varepsilon_{\boldsymbol{G}\boldsymbol{G}'}$

$$\varepsilon_{\mathrm{M}} = \frac{1}{(\varepsilon^{-1})_{00}} \quad [11]$$

and applies to homogeneous external fields.

Furthermore, it also covers the case that the field additionally depends on $\boldsymbol{q}$ within the Brillouin zone describing larger length scales than the lattice length. Then also ε carries this additional dependence, (see the section "Dielectric response"). As indicated before, the derivation of eqn [11] is valid for the longitudinal response to longitudinal fields, so the hat was omitted because it is a scalar quantity. The transverse average fields are related through a similar reasoning. The general tensor can be written as $\hat{\varepsilon}_{\mathrm{M}}$ consisting of the bare ε and an added longitudinal correction

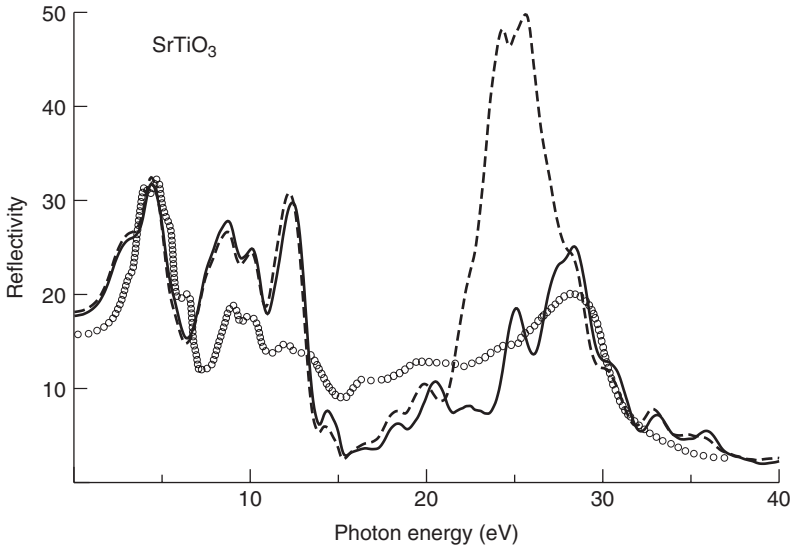

Figure 1 Calculated reflectivity of $SrTiO_3$, with local field effects included (—) and neglected (- - - -) compared to experiment (○).

which originates from the polarization by the Coulomb interaction.

$$\hat{\varepsilon}_{\mathrm{M}} = \hat{\varepsilon}_{00} - \sum_{\mathrm{GG}'(\neq 0)} \hat{\varepsilon}_{0\mathrm{G}} \, (\hat{\varepsilon}_{\mathrm{r}}^{\mathrm{LL}})^{-1}_{\mathrm{GG}'} \, \hat{\varepsilon}_{\mathrm{G}'0} \qquad [12]$$

The quantity $\hat{\varepsilon}_{\mathrm{r}}^{\mathrm{LL}}$ is the microscopic dielectric constant matrix in reciprocal space restricted (subscript r) to the subspace of nonzero reciprocal lattice vectors. Only the longitudinal component of the tensor is involved which is denoted by the upper index, that is, the tensor can be written as the product of the dyad $(\boldsymbol{q}+\boldsymbol{G})/|\boldsymbol{q}+\boldsymbol{G}| \cdot (\boldsymbol{q}+\boldsymbol{G}')/|\boldsymbol{q}+\boldsymbol{G}'|$ with a scalar $\varepsilon^{\mathrm{LL}}_{GG'}$. Taking the longitudinal component of eqn [12], algebraic manipulations lead back to eqn [11], $\varepsilon_{\mathrm{M}}^{\mathrm{LL}} = 1/(\varepsilon^{\mathrm{LL}})^{-1})_{00}$, with inversion of the whole unrestricted matrix. This generalization refers to the local field effect of optical and related spectra valid as long as the wavelength $\lambda = 2\pi/q$ is much larger than the length scale of the atomic structure. In **Figures 1** and **3**, calculated optical spectra, up to the vacuum ultraviolet, of $SrTiO_3$ and Nb with or without the local field effect are compared with experiment. The importance of the local field effect in describing the experimental result is striking. As a matrix inversion is involved, a lucid picture is absent to discuss these effects in simple terms, for example, the disappearance of the huge peak at 25 eV. The comparison of theory with experiment shows agreement with respect to the relative positions of maxima and minima, whereas the strength of the variation is smoothed by experimental broadening not considered in the theoretical calculation. It should be noted that the theoretical curves are obtained *ab initio* with the density-functional theory,

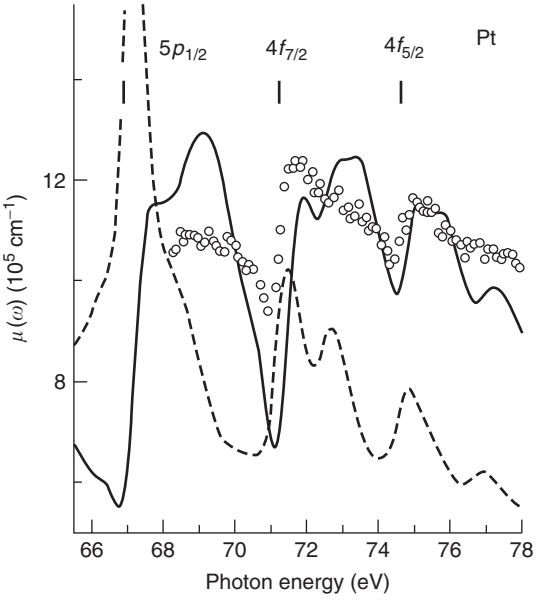

Figure 2 Theoretical absorption coefficient of Pt including local field effects (—) compared with experiment (absorption: ○, XPS energy levels: (‖)), and neglecting local field effects (- - - -).

and broadening from additional many-body corrections might also occur.

Occasionally the connection with the local polarization is obvious in the spectra as shown in **Figure 2**. A steep slope marks the onset of absorption from the localized semicore levels, $5p_{1/2}$, $4f_{7/2}$, $4f_{5/2}$, in both experiment and theory. Specifically, the $5p_{1/2}$ peak and also the relative intensities need local field effects to be included for explanation. Both 4*f* peaks are considerably enhanced by the accompanying high atomic polarization of the medium proving this to be

the origin of local field effects, even though the overall shape of a spectrum may often hide this connection, for instance, at low-energy excitations of valence states.

Dielectric Response

Maxwell's theory describes the field from its source, that is, the total charge. Conversely, the total field forces the positional adjustment of the charges through the laws of quantum mechanics, which is condensed into the dielectric constant ε. Once the bare response to a small test field is known through ε, the numerical evaluation of charge and field from eqns [2] and [10] is straightforward by using a suitable mathematical solution. Thus, one has to determine quantitatively the dielectric function. As already stated, the RPA is the basic approximation for calculating these properties *ab initio* with generally sufficient accuracy. The quantum mechanical change of the density $\delta\rho$ induced as a response to a change of the field $\delta\boldsymbol{E}$ is obtained from first-order perturbation expansion with respect to the latter. The total field must be treated here as a perturbation. Equation [2] is used in Fourier space, $i(\boldsymbol{q}+\boldsymbol{G})\delta\boldsymbol{D}(\boldsymbol{q}+\boldsymbol{G})=\delta\rho(\boldsymbol{q}+\boldsymbol{G})$, and the field in eqn [3] is replaced by its associated potential, $\delta\boldsymbol{E}(\boldsymbol{q}+\boldsymbol{G})=-i(\boldsymbol{q}+\boldsymbol{G})\delta\phi(\boldsymbol{q}+\boldsymbol{G})$. Then, the induced charge is given by the difference between total charge $\delta\rho_{\text{tot}}=\varepsilon_0|\boldsymbol{q}+\boldsymbol{G}|^2\delta\phi$ and external charge $\delta\rho$ with the result

$$\sum_{G'}(\boldsymbol{q}+\boldsymbol{G})\cdot(\hat{1}\delta_{G,G'}-\hat{\varepsilon}_{GG'}(\boldsymbol{q},\omega))\cdot(\boldsymbol{q}+\boldsymbol{G}') \times\delta\phi(\boldsymbol{q}+\boldsymbol{G}')=\delta\rho_{\text{ind}}(\boldsymbol{q}+\boldsymbol{G})/\varepsilon_0 \qquad [13]$$

This has to be compared with the expression obtained for the induced charge from the perturbation expansion, which finally leads to

$$\varepsilon^{\text{LL}}_{GG'}(\boldsymbol{q},\omega) =\delta_{GG'}+\frac{e^2}{2\pi^2\varepsilon_0|\boldsymbol{q}+\boldsymbol{G}|\,|\boldsymbol{q}+\boldsymbol{G}'|}\sum_{\lambda\lambda'}\int_{\text{BZ}}\mathrm{d}^3\mathbf{k} \times\frac{\langle\boldsymbol{k}+\boldsymbol{q}\lambda'|\mathrm{e}^{\mathrm{i}(\mathbf{q}+\mathbf{G}')\mathbf{r}}|\mathbf{k}\lambda\rangle\langle\mathbf{k}\lambda|\mathrm{e}^{-\mathrm{i}(\mathbf{q}+\mathbf{G})\mathbf{r}}|\mathbf{k}+\boldsymbol{q}\lambda'\rangle}{E_{\lambda'}(\boldsymbol{k}+\boldsymbol{q})-E_{\lambda}(\boldsymbol{k})-\hbar\omega-i\hbar\eta} \qquad [14]$$

Here, a single matrix element of the dielectric function for reciprocal lattice vectors $\boldsymbol{G}$ and $\boldsymbol{G}'$ is represented by a sum of occupied (λ) and unoccupied (λ') states and an integral over an elementary cell (Brillouin zone) of the reciprocal lattice in an expression which, of course, reminds of the quantum mechanical perturbation theory. It contains the denominator for the energy difference between the ground and the excited states of the system including the photon energy $\hbar\omega$, and the numerator with the matrix elements for a transition between both states caused by the wave part of the Fourier decomposition of the perturbing potential. The wave vector $\boldsymbol{q}$ which is confined to the first Brillouin zone appears only once as an independent variable of ε which is diagonal with respect to it. Owing to translational symmetry, charge and field can differ in total momentum only by reciprocal lattice vectors.

One observes again that only longitudinal fields are involved in this electrostatic treatment and consequently only longitudinal components ε^{LL} of the dielectric tensor

$$\varepsilon^{\text{LL}}_{GG'}(\boldsymbol{q},\omega)=\frac{(\boldsymbol{q}+\boldsymbol{G})}{|\boldsymbol{q}+\boldsymbol{G}|}\cdot\hat{\varepsilon}_{GG'}(\boldsymbol{q},\omega)\cdot\frac{(\boldsymbol{q}+\boldsymbol{G}')}{|\boldsymbol{q}+\boldsymbol{G}'|} \qquad [15]$$

are accessed. They constitute, nevertheless, the most important contributions in the domain of optics and related fields.

Exchange and Correlation

As mentioned before, the notion of local field effects can also be applied to the many-body extensions of RPA. Because of complexity, their investigation cannot claim a success similar to the above-discussed standard effects. For simplicity, the main work is usually directed towards homogeneous systems though a few quantitative calculations also exist for solids. In **Figure 3**, such corrections for considering exchange and correlation (XC) which go beyond RPA are shown. The observed influence is rather small compared to the usual local field effects. Since the comparison of *ab initio* calculations with experimental spectra still leaves many questions open and the importance of many-body corrections is generally unknown, this is an active field of present research.

Nonlocal Dielectric Response

The term nonlocal response can be taken literally as a far reaching effect of a local perturbation. The local field effects above have been considered under the restriction of smoothly varying external fields on a macroscopic scale, that is, long wavelengths ($q=2\pi/\lambda\approx 0$). This condition is relaxed here. However, both effects interfere in the experiment and one has to be discerning in its interpretation. A change of the field at one site can result in changes of the dielectric displacement at very distant sites which, of course, is also contained in the general dependence of eqn [6]. As this dependence of the field on the charges is provided by a nonlocal long range relation,

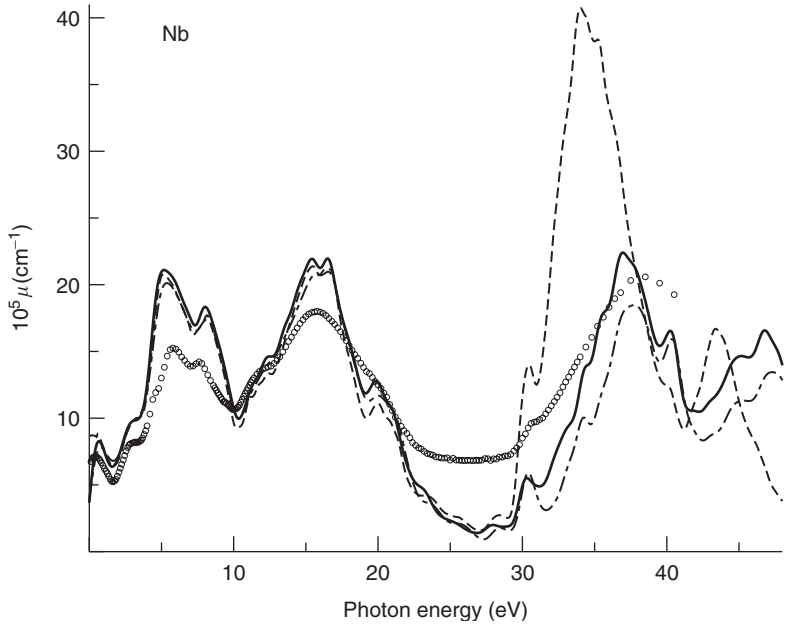

Figure 3 Calculated absorption coefficient of Nb, with local field effects included (–· –·–·–) and neglected (- - - -) compared to experiment (○); solid line includes XC corrections neglected otherwise.

Coulomb's law, each local internal polarization by the field causes induced fields and hence, dielectric displacement everywhere. This holds in the static as well as in the dynamic case where the plasmon excitation is a very prominent long-range feature.

This rather general theoretical effect will not be easily detected in measurements on homogeneous systems, it becomes visible by local perturbations as, for example, a surface imposes. There the surface may be the source for plasmon waves which travel into the bulk and modulate the field. In addition, even below the plasmon frequency multipole surface, plasmons enhance the frequency-dependent nonlocal response. The theoretical treatment, essentially governed by eqn [6], can be based on eqn [13] with the potential representing the full self-consistent field in time-dependent local density approximation (LDA)

$$\delta\phi = \phi_{\text{ext}} + \delta\phi + \delta V_{\text{XC}} \qquad [16]$$

Self-consistency is imposed by coupling to the charge density as before in RPA, in fact with Poisson's equation through $-\Delta\delta\phi = \delta\rho/\varepsilon_0$, and by using the exchange–correlation potential in LDA through $\delta V_{\text{XC}} = V'_{\text{XC}}(\rho_0)\delta\rho$. Because of the surface, translational symmetry is broken in one direction and calculation is restricted to real space in that direction utilizing an iterative process based on self-consistency. The centroid $d_\perp(\omega)$ of the charge density is suitable to characterize the surface response, that is, it yields the position of the electromagnetically effective surface by its real part and the absorbed power by its imaginary part. For a jellium model, it shows a resonance at ~ 0.8 of the plasma frequency.

The combined effect of local fields and nonlocal response shows a rather complex behavior as seen in **Figure 4**. The excitation from an external field localized just below the surface extends into the bulk with a penetration depth increasing with frequency and attains long-range behavior at the surface plasma frequency ($\hbar\omega = 6.7\,\text{eV}$) and above the bulk ($\hbar\omega = 9.2\,\text{eV}$) plasma frequency. Closely around the surface, a dipole charge distribution establishes which is replaced by a complex multipole behavior above the bulk plasma frequency. The granularity in the depth dependence reflects local field effects.

Further Application

In addition to traditional optical spectroscopy, the reflection anisotropy/difference spectroscopy (RAS/RDS) offers newer surface-sensitive optical tools for access to details of the electromagnetic response.

Local field effects are of importance not only in optical and related spectroscopy but they strongly affect electron spectroscopy as, for example, electron losses (EELS) or O photoexcited electrons of angle resolved ultraviolet photremission spectroscopy (ARUPS), too. The loss function of EELS

$$S(\boldsymbol{q},\omega) = -\text{Im}\frac{1}{\varepsilon_{\text{M}}(\boldsymbol{q},\omega)} \qquad [17]$$

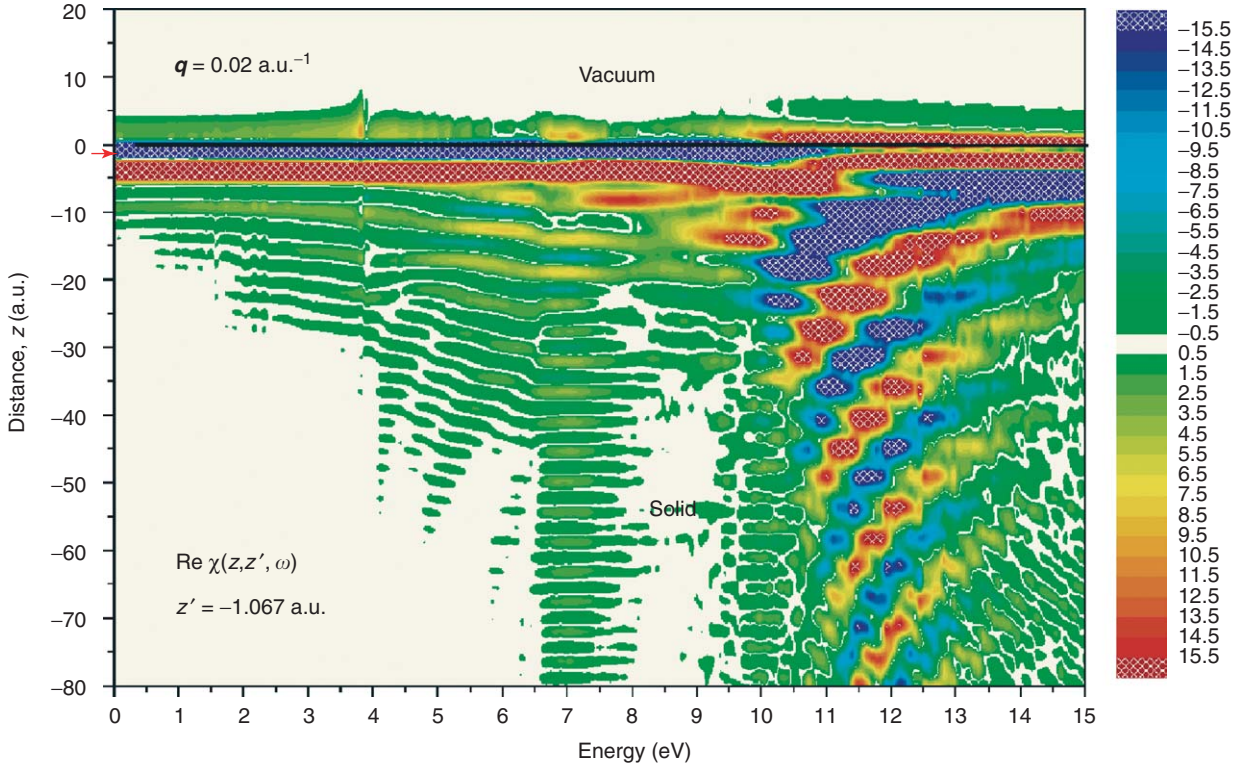

Figure 4 Susceptibility of Ag (1 1 1) slab, i.e., charge density at varying depth z from the surface at $z=0$ as response to a local excitation potential at z' with lateral wave vector $\boldsymbol{q}$, plotted vs. excitation frequency, model potential used for bulk (Courtesy of Silkin VM and Chulkov EV, Donostia International Physics Center (DIPC).)

measures the macroscopic ε_M. ARUPS reflects the local fields themselves as they cause specific photoexcitations, and also depend sensitively on the nonlocal multipole plasmon generation. Their main effects are observed near the plasmon frequency and can attain an order of magnitude change.

Recent development of photonics towards the nanoscale regime opens the door to the details of the position dependence of electromagnetic response. For example, small metallic particles close to a molecule on a surface may produce surface enhanced Raman scattering (SERS) of that molecule by many orders of magnitude, because the field considerably increases in this geometrical configuration. At sufficiently small scales, nonlocal effects will become important such that the full dielectric function will be needed for theoretical considerations there also.

Localized and Itinerant Magnetism

H Yamada, Shinshu University, Matsumoto, Japan
T Goto, University of Tokyo, Kashiwa, Japan

Introduction

The quantum theory of magnetism has been developed from two opposite starting points. One is the localized-electron model, where the electrons remain on the atoms in the crystal and contribute to magnetism. The intra-atomic interaction between these electrons is so strong that the magnetic moment is determined on each individual atom by Hund's rules. The interatomic exchange interaction is, on the other hand, much smaller than the intra-atomic one, and competes with thermal disorder to determine the long-range magnetic ordering. This model is applied to insulating crystals and rare-earth metals. The other model of magnetism is based on the band structure of electrons. These electrons move around in the crystal and contribute to the electric conduction. The ferromagnetic state may be stabilized for materials with a strong exchange interaction and a high density of states at the Fermi level. This is the band model or itinerant-electron model, which is commonly applied to 3d transition metals, alloys, and compounds.

In this section, magnetic properties as well as magnetic ordering are discussed for both localized-electron and itinerant-electron models. A molecular field theory is extremely useful in describing the ground state and finite temperature properties. In this approximation, the focus is on how various magnetic properties can be explained, and then, how spin wave excitations and spin fluctuations at finite temperature can be studied. SI units are used in this article. The magnetic induction, $\boldsymbol{B}$, is given by $\mu_0(\boldsymbol{H}+\boldsymbol{M})$, where $\boldsymbol{H}$, $\boldsymbol{M}$, and μ_0 are the magnetic field, magnetization, and permeability in vacuum, respectively. The Bohr magneton is denoted by $\mu_B = e\hbar/2m$ in this unit system, where e and m are the charge and mass of an electron, respectively, and where $\hbar$ is the Planck constant divided by 2π. To avoid confusion, μ_B is taken to be positive, so that the direction of magnetization is the same as that of the spin.

Localized-Electron Model

The concept of exchange coupling between the spins of two or more nonsinglet atoms arose with the Heitler–London theory of chemical bonding and was applied in 1928 to the theory of ferromagnetism by Heisenberg. The spin Hamiltonian is given by $\mathscr{H} = -\sum_{i\neq j} J_{ij}\boldsymbol{S}_i \cdot \boldsymbol{S}_j$, where J_{ij} is the interatomic exchange integral between the electrons on atoms at $\boldsymbol{R}_i$ and $\boldsymbol{R}_j$. $\boldsymbol{S}_i$ and $\boldsymbol{S}_j$ are spin operators on these atoms. The exchange integral J_{ij} comes from the antisymmetric nature of wave functions with respect to the spatial and spin coordinates, and is given by

$$J_{ij} = \frac{e^2}{4\pi\varepsilon_0}\int\int \frac{\psi_j^*(\boldsymbol{r})\psi_i^*(\boldsymbol{r}')\psi_i(\boldsymbol{r})\psi_j(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'-\boldsymbol{R}_i+\boldsymbol{R}_j|}\,\mathrm{d}\boldsymbol{r}\,\mathrm{d}\boldsymbol{r}'$$

where $\psi_i(\boldsymbol{r})$ is the wave function on the atomic site $\boldsymbol{R}_i$. The value of J_{ij} becomes small obviously when $|\boldsymbol{R}_i - \boldsymbol{R}_j|$ is large, as $\psi_i(\boldsymbol{r})$ is localized on the atom at $\boldsymbol{R}_i$ in this model. Here, J_{ij} is assumed to take a constant value, J for the nearest neighbor atomic pair at $\boldsymbol{R}_i$ and $\boldsymbol{R}_j$, and to be zero for other pairs. In this case, the Hamiltonian is written by $\mathscr{H} = -2J\sum_{\langle i,j\rangle}\boldsymbol{S}_i\cdot\boldsymbol{S}_j$, where $\langle i,j\rangle$ on the summation denotes the sum over nearest neighbor pairs at $\boldsymbol{R}_i$ and $\boldsymbol{R}_j$.

Ferromagnetism

Before the concept of quantum mechanics had been established, Weiss proposed in 1907 a very successful description of ferromagnetism by introducing a molecular field acting on atomic magnetic moments, which is assumed to be proportional to the net magnetization. The origin of the molecular field is nowadays known to be a quantum mechanical exchange interaction. A material, which consists of the same type of atoms, is considered. When the magnetic field is applied to the z direction (quantized axis of spin), the average value (or expectation value) of the spin operator $\boldsymbol{S}_i$ has a z component $\langle S_z\rangle$ only. The magnetization is now written as $M = Ng\mu_B\langle S_z\rangle$, where N is the number of atoms in the material, $g = 2$ (g-factor for spin system), and μ_B is the Bohr magneton. The term $\boldsymbol{S}_i\cdot\boldsymbol{S}_j$ in the Hamiltonian is approximately written by $\boldsymbol{S}_i\cdot\boldsymbol{S}_j \simeq \langle S_z\rangle S_{j,z} + S_{i,z}\langle S_z\rangle - \langle S_z\rangle^2$. One gets, together with the Zeeman energy by the magnetic induction B, $\mathscr{H} \simeq -2zJ\langle S_z\rangle\sum_i S_{i,z} - g\mu_B B\sum_i S_{i,z} + \mathrm{NzJ}\langle S_z\rangle^2 = -g\mu_B B_{\mathrm{eff}}\sum_i S_{i,z} + NzJ\langle S_z\rangle^2$, where z is the number of the nearest neighbor atoms in the crystal. Here, J is taken to be positive as the ferromagnetic state is discussed. The effective magnetic field is given by $B_{\mathrm{eff}} = 2zJ\langle S_z\rangle/g\mu_B + B$. The first term $2zJ\langle S_z\rangle/g\mu_B$ corresponds to the molecular field proposed by Weiss. The molecular field coefficient ω, defined by $B_{\mathrm{eff}} = \omega M + B$, is given by $\omega = 2zJ/N(g\mu_B)^2$.

The magnetic quantum number m_S on an atom may take $S, S-1, \ldots, -S$. The average value $\langle S_z \rangle$ is evaluated by the standard statistics as $\langle S_z \rangle = SB_S(g\mu_B SB_{eff}/k_B T)$ at finite temperature T, where $B_S(x)$ is the Brillouin function defined by

$$B_S(x) = \frac{2S+1}{2S}\coth\left(\frac{2S+1}{2S}x\right) - \frac{1}{2S}\coth\left(\frac{x}{2S}\right)$$

where $x = g\mu_B SB_{eff}/k_B T$ and k_B is the Boltzmann constant. (In the limiting case of $S = \infty$, $B_S(x)$ becomes the Langevin function, which appears when $S_{i,z}$ is treated as a classical spin vector.) The average value $\langle S_z \rangle$ is obtained as a function of T and B by solving the equation for $\langle S_z \rangle$ self-consistently, as the argument in the Brillouin function contains $\langle S_z \rangle$ itself. **Figure 1** shows the calculated result of the magnetization for $S = 5/2$ as a function of T and B. T_C is the Curie temperature where $\langle S_z \rangle$ becomes zero at $B = 0$. The T-dependence of M at $B = 0$ is very weak at low T in this theory, being different from the observed results. At low T, M decreases with increasing T as $T^{3/2}$ by the thermal excitations of spin waves. This is discussed in the subsection, "Spin waves."

The susceptibility χ_p $(= \mu_0 M/B)$ above T_C is written at high T as $\chi_p = \mu_0 C/(T - T_C)$. This is called the Curie–Weiss law. Here, T_C and C are the Curie temperature and the Curie constant respectively, given by $T_C = 2zJS(S+1)/3k_B$ and $C = N(g\mu_B)^2 S(S+1)/3k_B$. This is derived by using the approximation $B_S(x) \sim x(S+1)/3S$ at small x. At $T = T_C$, M is proportional to $B^{1/3}$. Then, the susceptibility χ_p diverges as $B^{-2/3}$ when B tends to zero. The critical index δ, defined by $M \propto B^{1/\delta}$, is 3 in the molecular field theory. However, the observed result of δ for conventional ferromagnets is ~ 4. The molecular field theory breaks down at $T \simeq T_C$.

Antiferromagnetism

The crystal, which consists of two equivalent sublattices A and B, may have an antiferromagnetic spin structure when the exchange integral J_{AB} between the nearest neighbor spins on the different sublattices is negative. Sublattice moments are given by $M_A = Ng\mu_B\langle S_z^A \rangle/2$ and $M_B = Ng\mu_B\langle S_z^B \rangle/2$, where the number of atoms on each sublattice is $N/2$. Here, S_z^A and S_z^B are the z components of S on these sublattices. Magnitudes of M_A and M_B without magnetic fields are equal to M, that is, $M_A = -M_B = M$.

Effective fields acting on the A and B sublattice spins are written by $B_{eff}^A = \omega' M_A - \omega M_B + B$ and $B_{eff}^B = -\omega M_A + \omega' M_B + B$, where ω and ω' are the molecular field coefficients of inter- and intra-sublattice moments given by $\omega = 4z_{AB}|J_{AB}|/N(g\mu_B)^2$ and $\omega' = 4z_{AA}J_{AA}/N(g\mu_B)^2$. Here, J_{AA} $(= J_{BB})$ is the intra-sublattice exchange integral and z_{AB} and z_{AA} $(= z_{BB})$ are the numbers of the nearest neighbor atoms on the different sublattices and on the same sublattice. By the same procedure as used in the ferromagnetic case, the thermal averages $\langle S_z^A \rangle$ and $\langle S_z^B \rangle$ are obtained by the Brillouin function as $\langle S_z^A \rangle = SB_S(x_A)$ and $\langle S_z^B \rangle = SB_S(x_B)$, where $x_A = g\mu_B SB_{eff}^A/k_B T$ and $x_B = g\mu_B SB_{eff}^B/k_B T$. The Néel temperature T_N, where the sublattice moment at $B = 0$ vanishes, is given by $T_N = 2S(S+1)(z_{AB}|J_{AB}| + z_{AA}J_{AA})/3k_B$. Solving the simultaneous equations

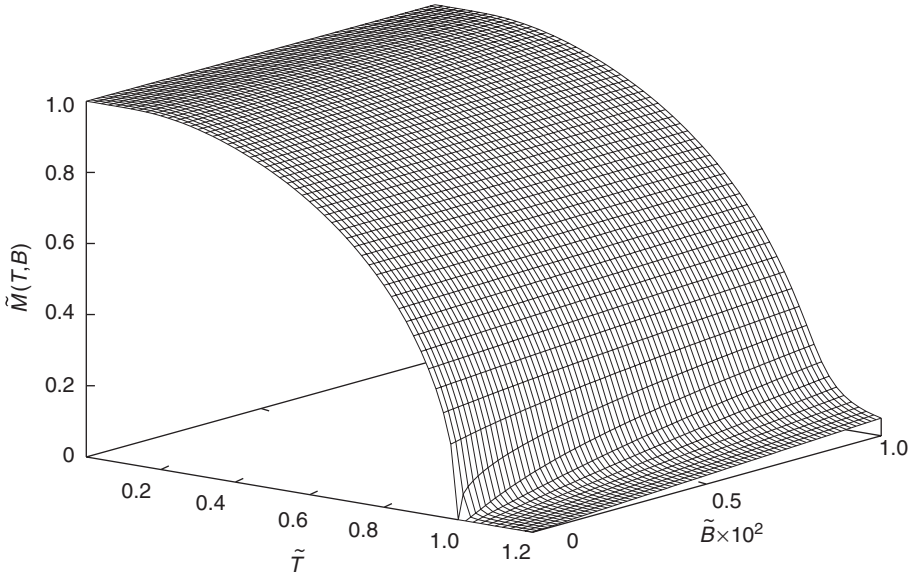

Figure 1 Temperature and field dependences of the magnetization M for $S = 5/2$. $\tilde{M} = M/Ng\mu_B S$, $\tilde{T} = T/T_C$ and $\tilde{B} = g\mu_B B/2zJS$.

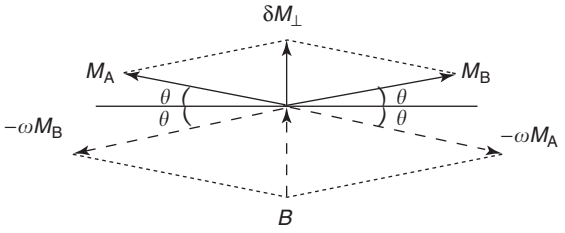

Figure 2 Magnetic induction B of the applied field and molecular fields $-\omega M_A$ and $-\omega M_B$ on the sublattice moments M_A and M_B, respectively. $\delta M_\perp$ is the induced moment.

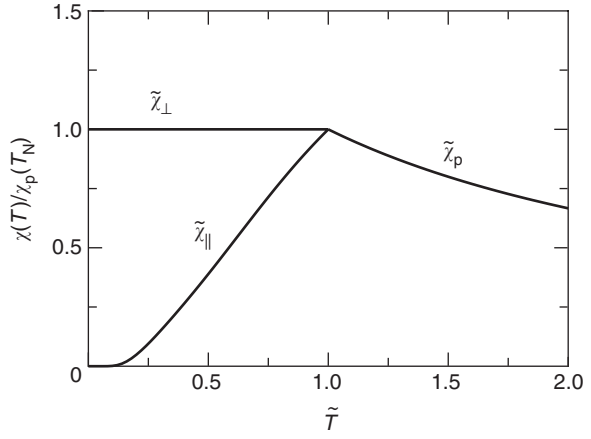

Figure 3 Parallel and perpendicular susceptibilities $\tilde{\chi}_\parallel(T)$ and $\tilde{\chi}_\perp(T)$ below T_N, and of $\tilde{\chi}_p(T)$ above T_N for $S = 5/2$ and $\omega' = 0$. $\tilde{\chi}_\parallel(T) = \chi_\parallel(T)/\chi_p(T_N)$, $\tilde{\chi}_\perp(T) = \chi_\perp(T)/\chi_p(T_N)$, $\tilde{\chi}_p(T) = \chi_p(T)/\chi_p(T_N)$, and $\tilde{T} = T/T_N$.

for M_A and M_B, the susceptibility $\chi_p(T)$ above T_N is obtained as $\chi_p(T) = \mu_0 C/(T + \Theta_p)$, where $\Theta_p = 2S(S+1)(z_{AB}|J_{AB}| - z_{AA}J_{AA})/3k_B$ and $C = N(g\mu_B)^2 S(S+1)/3k_B$. At $T = T_N$, $\chi_p(T_N)$ is given by $\chi_p(T_N) = \mu_0/\omega$. When $J_{AA} = 0$, T_N is equal to Θ_p. The observed value of T_N for conventional antiferromagnets is smaller than that of Θ_p.

Below T_N, there are two kinds of susceptibility. One is the susceptibility when the magnetic field is applied along the direction of M_A. In this case, M_A increases by $\delta M_\parallel/2$, and M_B shrinks by $\delta M_\parallel/2$. $\delta M_\parallel$ is obtained by solving simultaneous equations of M_A and M_B given by the Brillouin functions with B^A_{eff} and B^B_{eff}. Noting that $M_A = -M_B = M$ at $B = 0$, one gets the susceptibility $\chi_\parallel(T)(= \mu_0 \delta M_\parallel/B)$ parallel to the sublattice moment as $\chi_\parallel(T) = \mu_0 C/\{\Theta_p + (S+1)T/\ 3SB'_S(x)\}$, where $x = 6MT_N/Ng\mu_B(S+1)T$ and $B'_S(x)$ is the derivative of $B_S(x)$ with respect to x. At $T = 0$, $\chi_\parallel(0) = 0$ as $\lim_{T\to 0} T/B'_S(x) = \infty$. At $T = T_N$, $\chi_\parallel(T_N) = \chi_p(T_N) = \mu_0/\omega$ as $B'_S(0) = (S+1)\ /3S$. The other is the susceptibility when the magnetic field is applied in the perpendicular direction to M_A and M_B. In this case, the induced moment $\delta M_\perp/2$ appears on each sublattice in the field direction. The susceptibility $\chi_\perp(= \mu_0 \delta M_\perp/B)$ perpendicular to the sublattice moment is obtained by the balance of effective fields shown in **Figure 2**. The sublattice moments rotate by an angle θ so that $\boldsymbol{B} - \omega(\boldsymbol{M}_A + \boldsymbol{M}_B) = 0$. One gets $\chi_\perp = \mu_0/\omega$, which does not depend on T and also on the value of ω'. In **Figure 3**, $\chi_\parallel(T)$ and $\chi_\perp(T)$ below T_N, and $\chi_p(T)$ above T_N are shown as a function of T for $S = 5/2$ and $\omega' = 0$. For polycrystalline or powder samples, the antiferromagnetic moments in domains or particles will orientate in random directions, so that $\chi(T) = \chi_\parallel(T)/3 + 2\chi_\perp(T)/3$ below T_N.

Magnetizing Process of Antiferromagnets

For the magnetizing process of antiferromagnets, magnetic anisotropy plays an important role. The magnetic moment prefers to align in a certain crystallographic direction without a magnetic field. For the sake of simplicity, consider the case of uniaxial anisotropy. Taking the easy axis of magnetization along the z-axis, the sublattice moment $\boldsymbol{M}_A$ prefers to align in the positive (negative) z direction and $\boldsymbol{M}_B$ in the negative (positive) z direction. The anisotropy energy is phenomenologically given by $E_{ani} = -(K_u/2)(\cos^2\theta_A + \cos^2\theta_B)$, where θ_A and θ_B are angles between the sublattice moments and the easy axis. The coefficient K_u is called the uniaxial anisotropy constant. The anisotropy fields, B^A_{ani} and B^B_{ani} acting on the A and B sublattice moments, are defined by $B^A_{ani} = K_u M^z_A/M^2$ and $B^B_{ani} = K_u M^z_B/M^2$.

The induced moment $\delta M_\perp$ by the field applied perpendicular to the z-axis (hard axis of magnetization) is suppressed by the anisotropy field. The susceptibility $\chi_\perp$ is given by $\chi_\perp = \mu_0/(\omega + K_u/2M^2)$. This is derived in the following way. E_{ani} is rewritten as $(K_u/2)(\sin^2\theta_A + \sin^2\theta_B) - K_u$. The anisotropy field to the hard axis of magnetization is written by $-K_u \delta M_\perp/2M^2$ (negative field), and then one can get the above expression of $\chi_\perp$. On the other hand, when the magnetic field is applied along the easy axis of magnetization and when the sublattice moments align in the hard axis, the induced moment $\delta M_\perp$ in the field direction is enhanced by the anisotropy field. The susceptibility, in this case, is written by $\chi'_\perp = \mu_0/(\omega - K_u/2M^2)$.

When the magnetic field is applied along the easy axis of magnetization, the magnetic energy together with E_{ani} is approximately given by $\Delta E_\parallel = -\chi_\parallel(T)B^2/2\mu_0 - K_u$ at low fields. On the other hand, when the magnetic field is applied along the easy axis of magnetization and when the sublattice

moments align in the hard axis, the magnetic energy is given by $\Delta E_\perp = -\chi'_\perp(T)B^2/2\mu_0$. At weak magnetic fields applied along the direction of the easy axis, the sublattice moments keep to align in the easy axis by the gain of the anisotropy energy. However, under strong magnetic fields they may align in the direction perpendicular to the magnetic field, as $\chi'_\perp$ is larger than $\chi_\parallel$, and then, $\Delta E_\perp$ becomes lower than $\Delta E_\parallel$. That is, a spin flipping takes place from the parallel direction to B to the perpendicular one at a certain magnetic field. The critical value B_{sf} of the spin flipping is given by the equation $\Delta E_\parallel = \Delta E_\perp$, and one obtains $B_{sf}(T) = [2\mu_0 K_u/\{\chi'_\perp(T) - \chi_\parallel(T)\}]^{1/2}$. At $T = 0$, B_{sf} is written by $B_{sf} = \{B_{ani}(2B_{ex} - B_{ani})\}^{1/2}$, where $B_{ex} = \omega M$ and $B_{ani} = K_u/M$. When $B > 2B_{ex} - B_{ani}$, the sublattice moments become parallel to each other. The critical value is denoted by B_c $(= 2B_{ex} - B_{ani})$. The spin structures are the antiferromagnetic one at $B < B_{sf}$, the canted one at $B_{sf} < B < B_c$, and the ferromagnetic one at $B > B_c$. When T increases, B_c decreases, while B_{sf} increases slightly, as shown in **Figure 4**.

When B_{ani} is larger than B_{ex}, the canted spin state does not appear. The magnetization curve at $T = 0$ shows a jump from the antiferromagnetic state to the ferromagnetic one at $B = B_{ex}$. This is a field-induced metamagnetic transition. However, the transition at finite T becomes gradual at B_{ex}, as shown in **Figure 5**. When the magnetic field is applied to the hard axis of magnetization, the induced moment $\delta M_\perp$ increases as $\chi_\perp B/\mu_0$ up to $B'_C = 2B_{ex} + B_{ani}$ and saturates to $2M$.

Spin Waves

The low-lying energy states of spin systems coupled by exchange interactions are wave-like, as originally discussed by Bloch. This is called a spin wave or a magnon. Spin waves have been studied for all types of ordered spin arrays. In this subsection, the ferromagnetic spin wave is studied.

The energy associated with nonuniform distributions of the spin direction is given by the Heisenberg exchange energy $W = -J\sum_i \sum_\delta \boldsymbol{S}_i \cdot \boldsymbol{S}_{i+\delta}$, where $\boldsymbol{\delta}$ is the nearest neighbor vector of $\boldsymbol{R}_i$. Here, the $\boldsymbol{S}$s are quantum mechanical spin operators. They are treated as if they were classical vectors. $\boldsymbol{S}_{i+\delta}$ is expanded in a Taylor series as $\boldsymbol{S}_i + (\boldsymbol{\delta}\cdot\nabla)\boldsymbol{S}_i + (1/2)(\boldsymbol{\delta}\cdot\nabla)^2\boldsymbol{S}_i$. For lattices with inversion symmetry, the first-order term in $\boldsymbol{\delta}$ is cancelled out by the summation over δ, and one gets $W = -J\sum_i |\boldsymbol{S}_i|^2 - (J/2)\sum_i\sum_\delta \boldsymbol{S}_i \cdot \{(\boldsymbol{\delta}\cdot\nabla)^2\boldsymbol{S}_i\}$. It is noted here that $\nabla^2(\boldsymbol{S}_i\cdot\boldsymbol{S}_i) = 0$, as $|\boldsymbol{S}_i|^2$ is a constant. Then, one can get the exchange energy for the local magnetization $\boldsymbol{M}(\boldsymbol{r}) = g\mu_B\sum_i \boldsymbol{S}_i\delta(\boldsymbol{r} - \boldsymbol{R}_i)$ as $E_{ex} = (1/2V)D\int |\nabla \boldsymbol{M}(\boldsymbol{r})|^2 \,d\boldsymbol{r}$, where $|\nabla \boldsymbol{M}(\boldsymbol{r})|^2 = \sum_\alpha\{(\partial M_\alpha/\partial x)^2 + (\partial M_\alpha/\partial y)^2 + (\partial M_\alpha/\partial z)^2\}$, $\alpha = x, y, z$, and V the volume of the sample. The coefficient D in E_{ex} is called the Landau–Lifshitz constant. The exchange field is defined by $\boldsymbol{B}_{ex}(\boldsymbol{r}) = \partial E_{ex}/\partial \boldsymbol{M}(\boldsymbol{r})$. Neglecting the boundary effects, one gets $\boldsymbol{B}_{ex}(\boldsymbol{r}) = D\nabla^2\boldsymbol{M}(\boldsymbol{r})$. Then, the torque equation is given by $\partial \boldsymbol{M}(\boldsymbol{r},t)/\partial t = \gamma D\boldsymbol{M}(\boldsymbol{r},t)\times\nabla^2\boldsymbol{M}(\boldsymbol{r},t)$, where γ is the gyromagnetic ratio $g\mu_B/\hbar$. One looks for travelling wave solutions of the form $M_x(\boldsymbol{r},t) = \delta m_x \exp\{i(\boldsymbol{q}\cdot\boldsymbol{r} - \omega t\}$, $M_y(\boldsymbol{r},t) = \delta m_y \exp\{i(\boldsymbol{q}\cdot\boldsymbol{r} - \omega t\}$

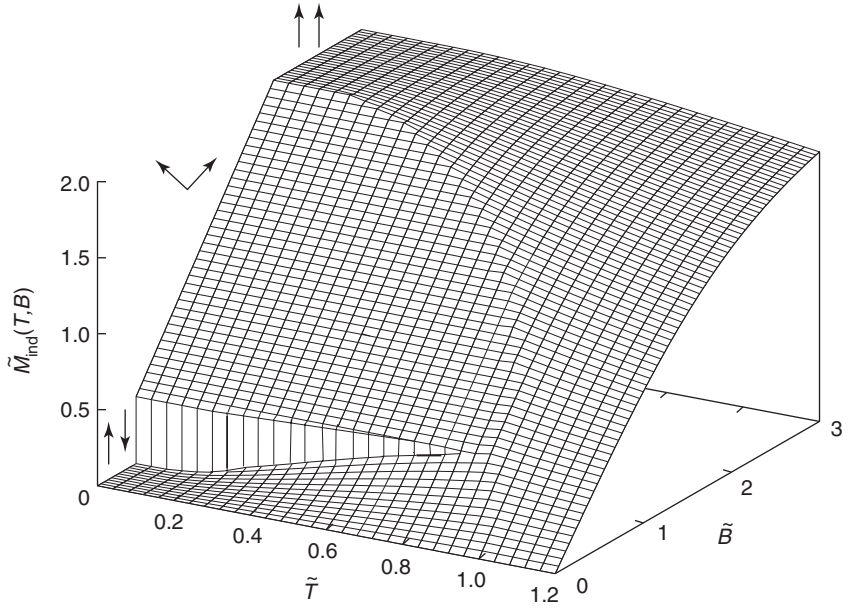

Figure 4 Temperature and field dependences of the induced moment M_{ind} for $S = 5/2$, $\omega' = 0$, and $2K_u/Nz_{AB}|J_{AB}|S^2 = 0.2$. $\tilde{M}_{ind} = 2M_{ind}/Ng\mu_B S$, $\tilde{T} = T/T_N$, and $\tilde{B} = g\mu_B B/2z_{AB}|J_{AB}|S$.

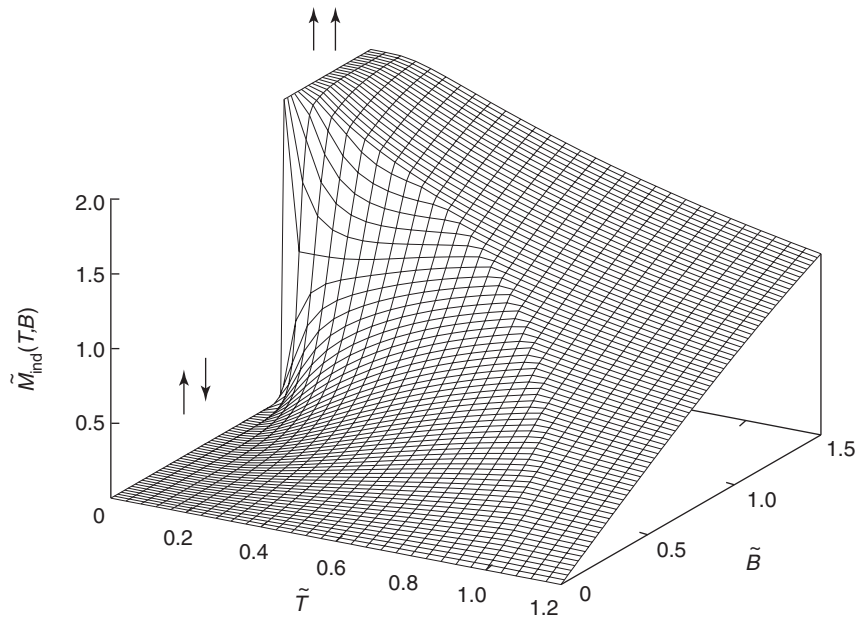

Figure 5 Temperature and field dependences of the induced moment M_{ind} for $S = 5/2$ and $\omega' = 0$ for the case of the strong anisotropic field ($B_{ani} > B_{ex}$). $\tilde{M}_{ind} = 2M_{ind}/Ng\mu_B S$, $\tilde{T} = T/T_N$, and $\tilde{B} = g\mu_B B/2z_{AB}|J_{AB}|S$.

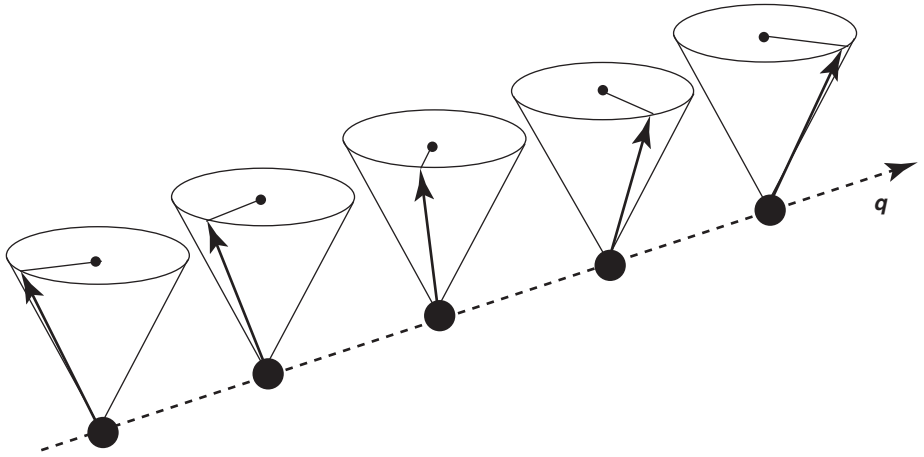

Figure 6 Schematic representation of the spin wave with wave-number vector $\boldsymbol{q}$.

and $M_z \simeq M_s$. One gets $\hbar\omega_q = g\mu_B D M_s q^2$ for small q. The coefficient of q^2 is called the exchange stiffness constant, which is observed by neutron scattering and spin wave resonance measurements. A schematic representation of $\boldsymbol{M}(\boldsymbol{r}, t)$ at a fixed time t is shown in **Figure 6**.

The wave of local magnetization, that is, the spin wave is quantized. By the analogy with phonons, the Hamiltonian for the quantized spin wave (magnon) is written by $\mathcal{H} = \sum_q (n_q + 1/2)\hbar\omega_q$, where n_q is the occupation quantum number of magnons with the wave-number vector $\boldsymbol{q}$. The temperature dependence of the magnetization is given by $M(T) = M_s - 2\mu_B \sum_q \langle n_q \rangle$, where M_s is the spontaneous magnetization and the thermal average $\langle n_q \rangle$ is a Bose distribution function $\{\exp(\hbar\omega_q/k_B T) - 1\}^{-1}$. One obtains $\Delta M(T) = M_s - M(T) \propto T^{3/2}$ at low temperature where $\hbar\omega_q$ is proportional to q^2. The theory of spin waves is also established in the itinerant-electron model of magnetism.

Itinerant-Electron Model

A quantum theory of ferromagnetism of conduction electrons in metals began with Bloch's paper in 1929. A free-electron gas with sufficiently low density was shown to be ferromagnetic. This means that

the carriers of the magnetic moment in metals also participate in electric conductions. In 1933, Stoner pointed out that nonintegral values of the observed magnetic moment per atom in 3*d* transition metals is explained if 3*d* electrons are itinerant, having a suitable density of states (DOS) and an exchange interaction parameter. Slater discussed ferromagnetism of Ni metal, using calculated results of the electronic structure and estimating the exchange couplings between electrons from spectroscopic data.

The subsequent development of itinerant-electron magnetism has proceeded mainly along two lines. One is the study on refinements of the electronic structure. The other is the study on the interaction between electrons. For both studies, electron correlations make the problem difficult. In the former, the electron correlations are taken into account in the potential of the electrons. A local spin-density functional formalism for the band calculation is established. Ferromagnetic, antiferromagnetic, and spin-density wave states are discussed for real materials by this formalism. In the latter, the interaction between electrons is treated as a many-body problem. To discuss the electron correlations, the Hubbard Hamiltonian is often made use of.

Band Theory of Ferromagnetism

The band theory (or Stoner theory) is widely used in the study of magnetism for transition metals, alloys, and compounds. In the original paper of Stoner, the DOS of electrons is assumed to be a parabolic one with respect to the energy. However, the DOS for actual transition metals is not so simple, but has a lot of peaks, as many energy levels overlap with one another. **Figure 7** denotes the calculated DOS curve for a b.c.c. Fe metal in the nonmagnetic state at the lattice constant 28.5 nm. E_F denotes the Fermi level. Electrons occupy energy levels up to E_F.

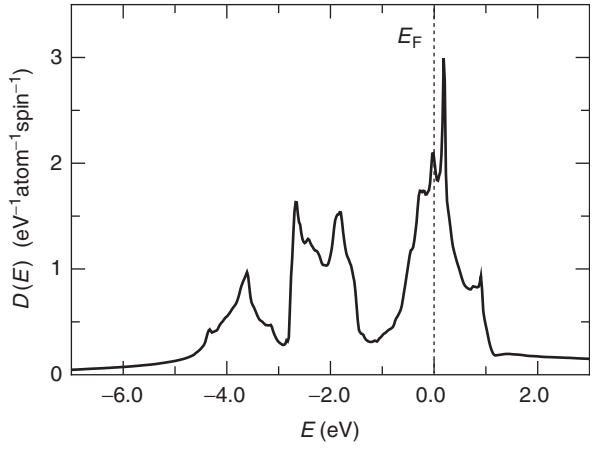

Figure 7 DOS curve for a b.c.c. Fe metal in the nonmagnetic state. E_F denotes the Fermi level. The value of D_0 is 2.05 eV^{-1} atom^{-1} spin^{-1}. The unit of energy 1 eV is 1.602×10^{-19} J.

The Pauli spin susceptibility is written in terms of the DOS curve, $D(E)$, as $\chi_0(T) = 2\mu_0\mu_B^2[D_0 - (\pi^2 k_B^2 T^2/6)\{D_0'^2/D_0 - D_0''\}]$ at low T, where D_0, D_0' and D_0'' are the values of $D(E)$ at E_F and the first and second derivatives of $D(E)$ with respect to E at E_F, respectively. The T-dependence comes from the low temperature expansion of the integrals connected with the Fermi distribution function. One takes into account the exchange interaction by the molecular field approximation. The induced magnetic moment, M, by the external field is given by $M = \chi_0(T)(B + IM)/\mu_0$, where I is the molecular field coefficient. Then, the susceptibility $\chi(T)$ $(= \mu_0 M/B)$ is obtained as $\chi(T) = \chi_0(T)/\{1 - I\chi_0(T)/\mu_0\}$. The factor $1/\{1 - I\chi_0(T)/\mu_0\}$ is the exchange-enhancement factor of the susceptibility. When the value of I is so large that the denominator in the enhancement factor becomes zero, the susceptibility $\chi(T)$ diverges. This is the magnetic instability in the paramagnetic state, which is called the Stoner condition for the appearance of ferromagnetism.

When $I\chi_0(0)/\mu_0 > 1$, the ferromagnetic state is stable at $T = 0$. In this case, the Curie temperature T_C is obtained by $I\chi_0(T_C)/\mu_0 = 1$. In the native Stoner theory, the value of I is an adjustable parameter to fit the Curie temperature. However, the value of I is nowadays obtained by the local spin-density functional formalism of the band calculation. The value of T_C estimated with the calculated value of I is much larger than the observed one, although reasonable values of the magnetic moment for 3*d* transition metals are obtained. This is because the effect of spin fluctuations at finite temperature is not taken into account in the theory.

Description of Ferromagnetism by the Landau Theory

By the fixed-spin-moment method developed recently, the magnetic energy $\Delta E(M)$ can be calculated numerically as a function of the magnetic moment M. The open circles in **Figure 8** denote the calculated results of $\Delta E(M)$ for a b.c.c. Fe metal at the lattice constant 28.5 nm. The equilibrium state is achieved at $M \sim 2.2\,\mu_B$ per Fe atom, being very close to the observed one. The calculated $\Delta E(M)$ can be fitted in the form of $\Delta E(M) = (a_0/2)M^2 + (b_0/4)M^4$, as shown by the dotted curve in the figure. This is just the Landau expansion of the magnetic energy. For some materials, the calculated $\Delta E(M)$ is expanded up to much higher order terms of M.

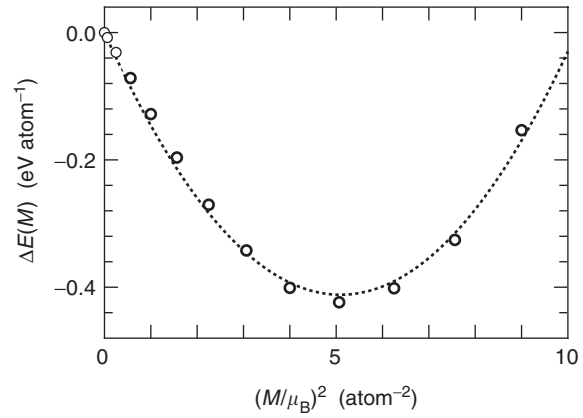

Figure 8 Magnetic energy $\Delta E(M)$ as a function of M^2 for a b.c.c. Fe metal. The unit of energy 1 eV is 1.602×10^{-19} J. The dotted curve denotes the form of $\Delta E(M) = (a_0/2)M^2 + (b_0/4)M^4$ with $a_0 = -5.59 \times 10^3$ T atom μ_B^{-1} and $b_0 = 1.10 \times 10^3$ T *atom*^{3} μ_B^{-3}.

The Landau coefficients a_0 and b_0 are also obtained by the Stoner theory. At $T = 0$, they are written by $a_0 = [1/2D_0 - I]/\mu_0\mu_B^2$, and $b_0 = [\{3D_0'^2/D_0^2 - D_0''/D_0\}/48D_0^3]/\mu_0\mu_B^4$. These expressions of a_0 and b_0 are derived by a rather crude approximation of the rigid band model, where DOS curves in the up and down spin bands are assumed not to change their shapes from those in the paramagnetic state. Nevertheless, those expressions of a_0 and b_0 are still relevant. When E_F lies near a peak of the DOS, $D_0' \sim 0$, and $D_0'' < 0$, the value of b_0 is positive at 0 K. On the other hand, when E_F lies near a minimum of the DOS, $D_0' \sim 0$, and $D_0'' > 0$, b_0 is negative. Even if D_0 is so small that the Stoner condition is not satisfied, the ferromagnetic state would be stabilized when the value of b_0 is negative and large. In the case of $a_0 > 0$ and $b_0 < 0$, a magnetic field-induced metamagnetic transition from the paramagnetic state to the ferromagnetic one may take place. This is the itinerant-electron metamagnetism. Moreover, the value of I can be estimated from the calculated values of a_0 and D_0. The evaluated value of I is 0.57 eV atom for a b.c.c. Fe metal at the lattice constant 28.5 nm.

The magnetic equation of state is given by $B = a_0M + b_0M^3$, as $B = \partial\Delta E(M)/\partial M$. The spontaneous magnetic moment M_s at $B = 0$ is given by $M_s = (|a_0|/|b_0|)^{1/2}$ if $a_0 < 0$ and $b_0 > 0$. It is noted that the magnetic moment in this theory increases with increasing B even at $T = 0$. The differential susceptibility χ_{hf} $(= \mu_0 dM/dB)$ is finite $(2\mu_0|a_0|)$ at $T = 0$. This is the high-field susceptibility in the ferromagnetic state. In the localized electron model, χ_{hf} vanishes at $T = 0$. The finite value of χ_{hf} at $T = 0$ is one of the characteristics of the itinerant-electron model.

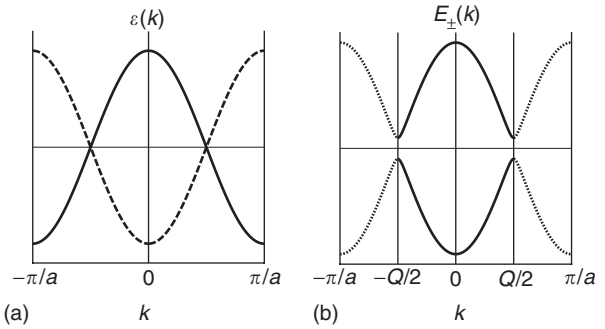

Figure 9 (a): One-electron energy $\varepsilon(k)$ in the nonmagnetic state, and (b): $E_\pm(k)$ in the antiferromagnetic state. A thin horizontal line denotes the Fermi energy.

Band Theory of Antiferromagnetism

An antiferromagnetic state in the itinerant-electron model can also be described by the electronic structure. For the sake of simplicity, consider a 1D lattice, where atoms are arranged along the x direction with a lattice constant a. The wave function $\phi_k(x)$ in the nonmagnetic state is given by a Bloch function in the periodic potential by the ions. The one-electron energy $\varepsilon(k)$ is expressed with the wave number k. The wave numbers are restricted to the first Brillouin zone $(-\pi/a < k \leqslant \pi/a)$. A schematic representation of $\varepsilon(k)$ is shown by the solid curve in **Figure 9a**.

When the antiferromagnetic moment is given by $M_Q(x) = M_0 \exp(iQx)$, where $Q = \pi/a$, the potential of electrons includes a term with the modulation of the wavelength $2a$. This modulated potential is treated by the perturbation theory of quantum mechanics. The wave function $\psi_k(x)$ in the antiferromagnetic state is given by a linear combination of the unperturbed wave functions $\phi_k(x)$ and $\phi_{k+Q}(x)$, as $\psi_k(x) = \alpha_k\phi_k(x) + \beta_k\phi_{k+Q}(x)$ with $|\alpha_k|^2 + |\beta_k|^2 = 1$. One gets two energy curves $E_\pm(k) = (1/2)[\varepsilon(k) + \varepsilon(k+Q) \pm \{(\varepsilon(k) - \varepsilon(k+Q))^2 + \Delta^2\}^{1/2}]$, where Δ is the off-diagonal matrix element of the perturbed potential. The broken curve in **Figure 9a** denotes $\varepsilon(k+Q)$. The two energy curves cross each other at $k = \pm Q/2$. A bandgap Δ appears at the crossing point, as shown in **Figure 9b**. The lower energy band $E_-(k)$ is that for electrons with up spin at the up-spin sites, or for electrons with down spin at the down-spin sites. The higher energy band $E_+(k)$ is that for electrons with opposite spin at the up and down spin sites. This is a simple mechanism for the appearance of the antiferromagnetic state in the band theory. It is called the split band model of antiferromagnetism.

In actual materials, the situation becomes more complicated. In **Figure 10**, the calculated Fermi surfaces of Cr metal in the nonmagnetic state are shown.

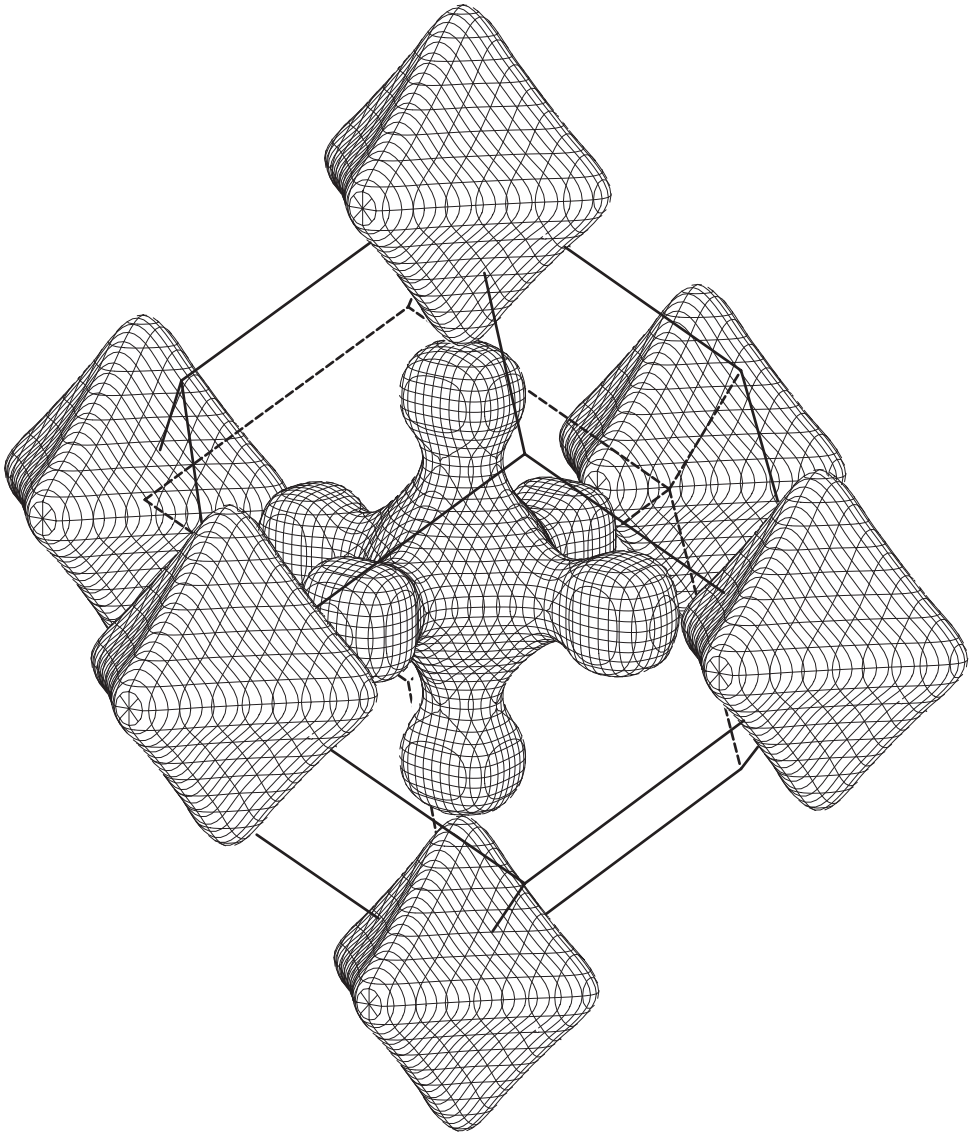

Figure 10 Main parts of the Fermi surfaces of Cr metal. The hole surface (octahedron-like) is located around H in the Brillouin zone. The surface centered at Γ (center of the Brillouin zone) is for electrons (K Nakada, unpublished work).

A Fermi surface denotes the equal energy surface in the reciprocal lattice space at the Fermi level. A hole surface has the octahedron-like shape centered at the H-point in the Brillouin zone and the electron surface is centered at the Γ-point (center of the Brillouin zone). Here, H and Γ are conventional symbols labeled to the symmetry points in the Brillouin zone. When the electron surface centered at Γ is shifted toward H, some portions of the electron and hole surfaces may overlap with one another. On these overlapping surfaces, the bandgap appears and the antiferromagnetic state is stabilized. Strictly speaking, the shift of the electron surface is not exactly the same as the length between the Γ- and H-points in this case. The antiferromagnetic wave-number vector $\boldsymbol{Q}$ is slightly different from that at the H-point. Then, the spin-density wave state is stabilized in the Cr metal. This is the nesting model of the Fermi surfaces.

Spin Fluctuations

As mentioned in the section, "Band theory of ferromagnetism," the value of T_C, estimated by the calculated value of I, becomes rather higher than the observed one. This is because the excitations of the collective modes of spins are not taken into account in the theory. The excitations of collective modes play an important role in the magnetic properties at finite temperature. In this subsection, it

is studied within the phenomenological Ginzburg–Landau theory.

The magnetic free energy ΔF_m is written by $\Delta F_m = (1/V)\int d\boldsymbol{r}\Delta f_m(\boldsymbol{r})$, where the free energy density $\Delta f_m(\boldsymbol{r})$ is given by $\Delta f_m(\boldsymbol{r}) = (a_0/2)|\boldsymbol{m}(\boldsymbol{r})|^2 + (b_0/4)|\boldsymbol{m}(\boldsymbol{r})|^4 + (D/2)|\nabla\cdot\boldsymbol{m}(\boldsymbol{r})|^2$. D is the Landau–Lifshitz constant given in the section "Spin waves." ΔF_m is rewritten by using the Fourier transformation for the ith component of the magnetization density, $m_i(\boldsymbol{r}) = M\delta_{i,z} + (1/V)\sum'_q m_i(\boldsymbol{q})\exp(i\boldsymbol{q}\cdot\boldsymbol{r})$, where M is the bulk moment in the z direction. The prime on the summation denotes the sum over q except $q = 0$. The expression of ΔF_m contains terms up to the fourth power of $m_i(\boldsymbol{q})$. Among them, only the terms with even power of $m_i(\boldsymbol{q})$ are considered. In this case, ΔF_m is given by a functional of only M and $|m_i(\boldsymbol{q})|^2$.

The equation of state, defined by $B = \langle \partial\Delta F_m/\partial M\rangle$, is written as $B = a(T)M + b(T)M^3$, where $\langle\cdots\rangle$ denotes a thermal average. The Landau coefficients $a(T)$ and $b(T)$ are given by $a(T) = a_0 + b_0\{3\langle(\delta m_\parallel)^2\rangle + 2\langle(\delta m_\perp)^2\rangle\}$ and $b(T) = b_0$. $\langle(\delta m_\parallel)^2\rangle$ and $\langle(\delta m_\perp)^2\rangle$ are mean square amplitudes of the longitudinal and transverse magnetization densities given by $\langle(\delta m_i)^2\rangle = (1/V)\sum_q \langle|m_i(\boldsymbol{q})|^2\rangle$. The T-dependence of the Landau coefficients comes from that of the mean square amplitudes of spin fluctuations $\xi(T)^2 = \langle(\delta m_\parallel)^2\rangle + 2\langle(\delta m_\perp)^2\rangle$. Isotropic spin fluctuations are assumed, that is, $\langle(\delta m_\parallel)^2\rangle = \langle(\delta m_\perp)^2\rangle$. In this case, the Landau coefficients are given by $a(T) = a_0 + (5/3)b_0\xi(T)^2$ and $b(T) = b_0$. The present T-dependence of the Landau coefficients is very different from that in the Stoner theory where it comes only from the Fermi distribution function. The degeneracy temperature for electrons estimated from the Fermi level is very high, and then the T-dependence in the Stoner theory is very weak in the conventional ferromagnets. Thus, the spin fluctuations are found to play a dominant role at finite T.

In the case of $a_0 < 0$ and $b_0 > 0$, the Curie temperature is given by $\xi(T_C)^2 = 3|a_0|/5b_0$ as the inverse of the susceptibility should be zero at T_C, that is, $a(T_C) = 0$. By classical thermodynamics, the mean square amplitude of thermal fluctuations is known to increase monotonically as T increases. The susceptibility (at $\xi(T)^2 = pT$) above T_C is written in the form of the Curie–Weiss law as $\chi(T) = \mu_0 C/(T - T_C)$, where $C = 3/5b_0p$, $T_C = 3|a_0|/5b_0p$, and p a positive constant. Such a Curie–Weiss law cannot be obtained in the Stoner model. By analogy with the localized-electron model, the square of the effective magnetic moment M_p^2 in the paramagnetic state, estimated from the susceptibility, is proportional to the Curie constant C. On the other hand, the square of the spontaneous magnetization is given by $M_s^2 = |a_0|/b_0$ at $T = 0$. Then, the value of $(M_p/M_s)^2$ is shown to be proportional to $|a_0|^{-1}$, and subsequently to T_C^{-1}. This type of behavior of M_p/M_s is observed for $3d$ transition metals, alloys, and compounds (Rhodes–Wohlfarth plot). Spin fluctuations in itinerant-electron antiferromagnets have also been studied.

Low-Energy Electron Microscopy

E Bauer, Arizona State University, Tempe, AZ, USA

Introduction

Modern surface science, thin film science, and in particular, nanoscience needs characterization methods with high lateral resolution. The most prominent of these methods are scanning probe methods such as scanning tunneling microscopy and atomic force microscopy that probe the topmost layer of a surface with atomic resolution. In many cases, however, a somewhat larger and somewhat tunable probing depth is required. This is provided by elastic reflection of slow electrons that has been used for many years in low-energy electron diffraction (LEED) in the structure analysis of the top several layers of crystals. Similar to the diffracted fast electrons in conventional transmission electron microscopy (TEM), diffracted low-energy electrons can also be used for imaging in low-energy electron microscopy (LEEM) though not with the high lateral resolution that scanning probe microscopy and transmission electron microscopy provide. Essential features of LEEM are not so much the tunable sampling depth but the well-defined wavelength, the high sensitivity to surface topography, and the spin-dependent interaction of slow electrons with magnetic materials that allows imaging of the magnetization distribution on surfaces and in thin films in spin-polarized LEEM (SPLEEM).

Understanding the image formation in LEEM and SPLEEM requires an understanding of the electron–specimen interaction and of the electron optics needed to form an image with the reflected electrons. The discussion begins with the electron–specimen interaction, then the electron optics, and finally illustrates the application of LEEM and SPLEEM with a number of examples.

Electron–Specimen Interaction

Electrons are scattered in matter elastically and inelastically. Elastic scattering in the backward direction determines the number of electrons available for imaging. Contrary to the fast electrons used in TEM, which are nearly completely scattered in the forward direction, low-energy electrons are also strongly scattered in the backward direction. This is illustrated in **Figure 1** for two surfaces of a W single crystal. In single crystals, the backscattered electrons are focused by diffraction into narrow beams whose

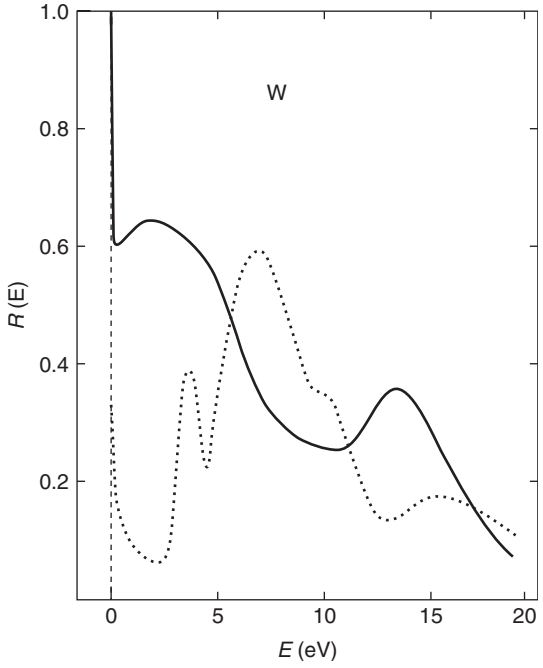

Figure 1 Specular reflectivity of two W surfaces for slow electrons. Solid line (110), dotted line (100) surface. (Reproduced with permission from Bauer E (1994) Low-energy electron microscopy. *Reports on Progress in Physics* 57: 895–938; © IOP Publishing Limited.)

intensity is determined by diffraction, that is, by the periodicity of the crystal, and by the scattering potential of its constituents. The different periodicity normal to the two surfaces shown in **Figure 1** causes the strong difference in reflected intensity and is one of the major contrast mechanisms in LEEM, called diffraction contrast. **Figure 1** shows the intensity of the specularly reflected beam ("(00)-beam"). Other (nonspecularly reflected) diffracted beams may also be used for imaging which gives contrast caused by differences of the lateral periodicity of the surface.

For imaging with the (00)-beam, the specimen does not have to be a single crystal but may consist of many crystals that have the same orientation with respect to the incident beam but otherwise random orientation. However, when the crystals are completely randomly oriented or when the specimen is amorphous, the backscattered electrons are distributed over a wide angular range. In this case, it is necessary to limit the angular acceptance of the instrument to a narrow cone around its optical axis because of the aberrations of the electron-optical system used for imaging that will be discussed below. This reduces the number of electrons available for imaging considerably which requires a considerable increase of the image acquisition time. For this

reason, LEEM and SPLEEM are mainly used for the study of specimens with strong preferred crystal orientation which allows image acquisition at video rates and thus allows the study of the dynamics of processes.

The wave nature of the electron, which is a basic requirement for diffraction, can also be used in other ways to produce image contrast. Optical path differences of the electrons reflected from the terraces adjoining a surface step produce phase contrast that can be made visible by lens aberrations and/or defocusing. This so-called step contrast is used, for example, in **Figure 2** to make the monoatomic steps on a Mo(110) surface clearly visible.

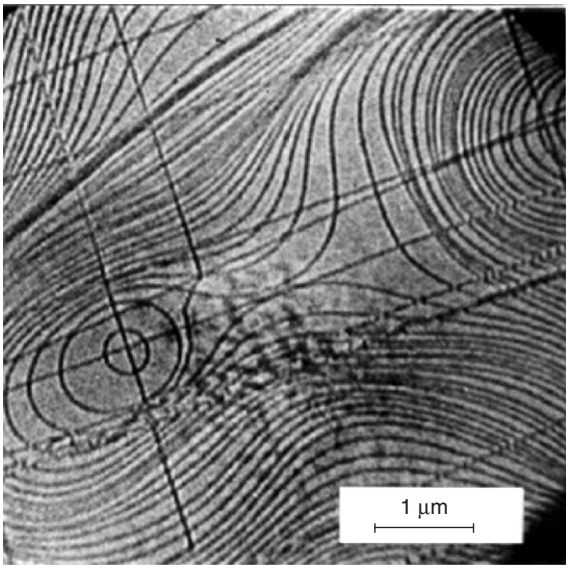

Figure 2 Monatomic steps on a Mo(110) surface. Sublimation and glide steps are visible (electron energy – 14 eV). (Reproduced from Telieps W and Bauer E (1985) An analytical reflection and emission UHV electron microscope. *Ultramicroscopy* 17: 57, with permission from Elsevier.)

Another contrast mechanism that rests on the wave nature of the electron is the so-called quantum size contrast. In a thin film with parallel boundaries and thickness t, standing electron waves can form whenever $n\lambda/2 + \varphi = t$, where λ is the wavelength and φ represents the phase shifts at the boundaries. This causes reflectivity differences between regions with different thicknesses as illustrated in **Figure 3**, similar to the interference phenomena in thin films in light optics. Finally, one contrast mechanism, which is due to the electrical field at the surface in an LEEM instrument, has to be mentioned: topographic contrast caused by the field distortion around surface asperities and pits. It is most evident when the electrons are reflected immediately in front of the surface, that is, when the instrument is operated in the mirror mode (mirror electron microscopy (MEM)), but is also noticeable in LEEM under proper focusing conditions. MEM does not require crystalline surfaces and, thus, is widely applicable, also to flat surfaces with locally varying surface potentials.

Before turning to the influence of inelastic scattering on LEEM, one important difference between the scattering of fast and slow electrons has to be mentioned. While the scattering of fast electrons by atoms can be described to a good approximation by the first Born approximation which predicts increasing scattering strength with increasing nuclear charge Z, this is not true any longer for the backscattering of slow electrons. The backscattering cross section does not vary monotonically with increasing Z or energy E. Atoms with small Z may backscatter in certain energy ranges much more than atoms with large Z. For example, ~ 50 eV Al and Si backscatter much stronger than W. Therefore, the analog to the Z contrast in TEM does not exist in LEEM.

Inelastic scattering of the electrons determines the sampling depth of LEEM unless elastic backscattering

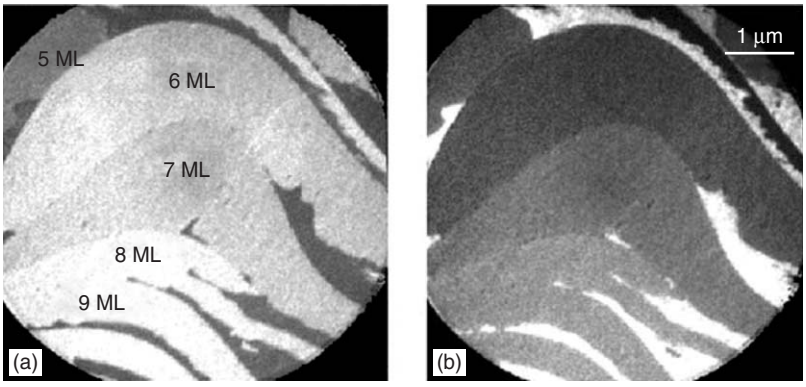

Figure 3 Quantum size contrast in an Fe layer on a W(110) surface. The film thickness varies from terrace to terrace as indicated in the image taken with 11.0 eV electrons (a). A comparison with image (b), taken with 16.4 eV electrons, illustrates the dependence of the contrast upon the wavelength $\lambda = \sqrt{1.5/E}$ (λ in nm, E in eV). (Reproduced with permission from Zdyb R and Bauer E (2002) Spin dependent quantum size effects in the electron reflectivity of ultrathin ferromagnetic crystals. *Surface Review Letters* 9: 1485.)

is very strong and inelastic scattering weak. Inelastic scattering involving small energy losses, such as excitation of lattice vibrations or spin waves in magnetic specimens, is not eliminated from the image by the energy-dispersive elements of present LEEM/SPLEEM instruments and thus does not limit the sampling depth. The sampling depth is limited by energy losses of say more than 0.5–1 eV, to give a rough limit. These electrons do not contribute to the image formation. In electron spectroscopy, the sampling depth is normally defined by the inelastic mean free path Λ that takes into account all losses ranging from single electron excitation to collective electron (plasmon) excitation to inner shell ionization. Its energy dependence is usually described by a universal curve which is a good approximation for many materials at energies above ~ 50 eV but breaks down in the energy range mainly used in LEEM ($\leqslant 20$ eV). Here, the energy loss mechanisms are strongly material-dependent. For example, in noble metals such as Au, Λ may be as large as several nanometers whereas in 3*d* metals such as Fe, it is only a few tenths of a nanometer. Surface and depth sensitivities are thus strongly material-dependent.

Instrumentation

Because of the high surface sensitivity of low-energy electrons, the instruments using them require ultrahigh vacuum (UHV) and surface cleaning facilities. For electron-optical reasons, the electrons are decelerated from the high energy as they approach the specimen. This is done in a so-called cathode lens whose light-optical analog is the immersion lens. In order to be able to observe the image of the surface, the illumination beam has to be separated from the imaging beam by a beam separator. This leads to a system configuration as schematically shown in **Figure 4a**. Lens 1 produces a demagnified image of the electron source (cathode C) – or more precisely of the "crossover" in front of C – which is imaged by lens 2 into the back focal plane of the objective lens O. In the objective lens – which also includes the specimen S – the electrons are decelerated from the high initial energy, typically 5–20 keV, to the desired low energy which is determined by the potential difference between cathode and specimen. After reflection from the surface, the electrons are accelerated again to high energy. The objective lens produces the diffraction pattern of the specimen in its back focal plane and a first intermediate image in the middle of the beam separator B. The subsequent lenses produce further intermediate images and lens 4 allows switching between imaging the specimen and its diffraction pattern, which are imaged by lens 5 into the image plane I. The brightness of the image is enhanced by a pair of channel plate multipliers so that it is high enough on the final fluorescent screen to be recorded with a CCD camera with short image acquisition times. The electron lenses are, in general, magnetic lenses but electrostatic lenses are used too. The magnetic beam separator B is designed so as to minimize the unidirectional focusing of magnetic fields. Not shown in **Figure 4a** are the deflection elements needed for beam alignment, the stigmators for correction of the astigmatism of the electron-optical components, and the apertures needed for confining the angular acceptance of the system and for selecting the specimen area contributing to the LEED pattern. The first aperture, the so-called contrast aperture, is placed in the intermediate image of the diffraction pattern produced by lens 3, the second one either in the first intermediate image of the specimen in the beam separator or into the symmetric position in the illumination beam. Various beam separators are used with deflection angles ranging from 16° to 90°.

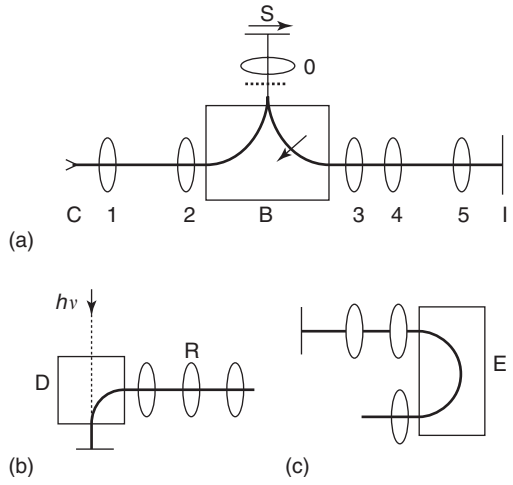

Figure 4 Schematic of an LEEM instrument. (a) Basic instrument setup, (b) illumination system of a SPLEEM instrument, and (c) imaging system for a spectroscopic instrument. The locations of the first image and diffraction planes are indicated by an arrow and dotted line, respectively.

The heart of the microscope is the objective (cathode) lens because it determines the resolution and transmission of the microscope. Cathode lenses have much larger chromatic and spherical aberrations than the lenses used in TEM. Therefore, the acceptance angle α has to be strongly limited by the "contrast aperture" in the diffraction pattern. While in TEM, the contrast aperture may accept many diffracted beams which allows one to reach resolutions in the 0.1 nm range, in LEEM only one diffracted beam, usually the (00)-beam, and its immediate environment can be used for optimum resolution.

The best resolution achieved to date is about 5 nm, using a field emission cathode that has a narrow energy distribution and, thus, minimizes the chromatic aberration, which is dominant at low energies. Most instruments use magnetic cathode lenses because of their somewhat lower aberrations and higher transmission. Resolution improvement requires aberration correction, which is possible with an electron mirror, by monochromatizing the illumination beam and energy-filtering the imaging beam. Calculations for mirror correctors predict resolutions of $\sim$1 nm and somewhat less which still have to be demonstrated with instruments presently in construction. The present routine resolutions of 10–20 nm are largely determined by the stability of the specimen and by local charging, not by the electron optics.

Extensions of the basic LEEM instrument shown schematically in **Figure 4a** are the SPLEEM instrument and the LEEM instrument equipped with an imaging energy filter, called spectroscopic photoemission and low-energy electron microscope (SPELEEM) because its main application is in spectroscopic photoemission microscopy.

SPLEEM requires a different illumination system which is schematically shown in **Figure 4b**. The electron source is now not a field emitter or a LaB_6 cathode as used in LEEM but a GaAs(100) single crystal surface which has been exposed to Cs and an electronegative gas, usually O_2, so that the lowest point of the conduction band of GaAs is slightly above the vacuum level. This surface is illuminated with circular polarized light from a laser with an energy hv corresponding to the direct bandgap of GaAs so that electrons excited from the top of the valence band into the bottom of the conduction band can be emitted. Due to optical selection rules, up to 50% of the photoemitted electrons are spin-polarized with their spin perpendicular to the surface. Changing the helicity of the light from right to left circular polarization inverts the spin direction, characterized by the polarization vector $\boldsymbol{P}$. When a magnetic surface with local magnetization $\boldsymbol{M}$ is illuminated with these electrons, then the reflected intensity not only depends upon the topography and crystal structure, but also upon $\boldsymbol{P} \cdot \boldsymbol{M}$. The difference image between two images taken with opposite directions of $\boldsymbol{P}$ eliminates all nonmagnetic contrast and shows only the distribution of $\boldsymbol{M}$.

In order to determine the direction of $\boldsymbol{M}$ completely, $\boldsymbol{P}$ must not only be inverted but adjustable in any direction. This is achieved with the 90° electrostatic/magnetic deflector D and the spin rotator lens R. Pure electrostatic deflection leaves $\boldsymbol{P}$ unchanged; in pure magnetic deflection, $\boldsymbol{P}$ rotates along with the direction of the beam, and mixed deflection allows one to cover all $\boldsymbol{P}$ directions between these two directions, that is within the plane of the drawing of **Figure 4b**. The rotator lens allows $\boldsymbol{P}$ rotation around the beam direction, that is out of this plane so that all directions are accessible. Usually the direction normal to the specimen surface and two preferred directions in it are selected. **Figure 5** illustrates the application of these possibilities.

In the SPLEEM, the imaging column is modified by inserting an energy filter and adding additional lenses at its output. In the example shown in **Figure 4c**, the energy filter is a 180° electrostatic analyzer in which the electrons are retarded to a fraction of the input energy and reaccelerated at its output to the input energy again. Energy selection is made by a slit in the dispersive plane at the exit of the energy filter. By choosing the excitation of the pre-filter lenses 4 and 5 and of a lens in the filter, either the energy-filtered image or the diffraction pattern can be obtained with the lenses behind the filter. These can also be used to image the dispersive plane and thus to do electron spectroscopy from small specimen regions selected by the field-limiting aperture. An energy resolution of $\sim$0.3 eV can be obtained without much loss of intensity in LEEM and LEED. The advantage of the energy filtering in LEEM and LEED is the elimination of secondary electrons, which can cause a strong background in specimens with large electronic band gaps. The main application of the energy filter is however in X-ray photon-excited secondary electron emission microscopy, usually called XPEEM, in which the filter allows selection of a small energy window in the wide secondary electron energy distribution and thus improves the resolution. A second application is in PEEM with photoelectrons from inner shells characteristic for the specimen composition. **Figure 6** shows the presently most widespread SPLEEM.

Applications

Clean Surfaces

Because of its importance in microelectronics, Si is the material that has been studied most extensively. The demonstration in 1985 that the "reconstruction" of the Si(111) surface with bulk periodicity into one with sevenfold periodicity at $\sim$1100 K, the Si(111)-$(1 \times 1) \rightarrow$Si(111)-(7×7) transition, is a first-order phase transition which demonstrated the power of LEEM. It also clearly showed the limitations of laterally averaging studies because surfaces with the same LEED pattern produced completely different LEEM images as shown in **Figure 7**.

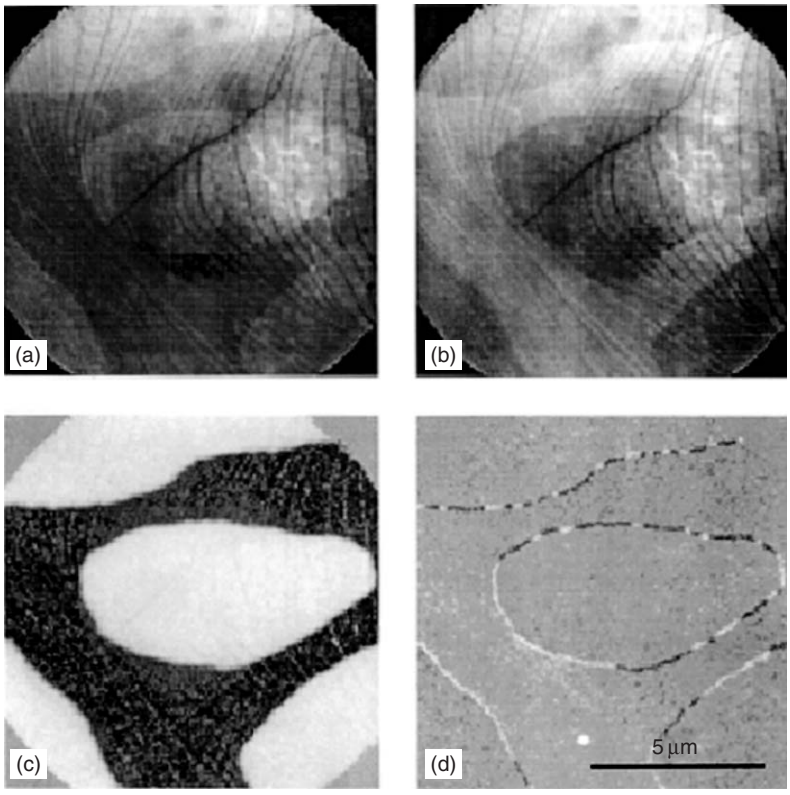

Figure 5 Imaging of the magnetization distribution in a thin Co layer on a W(110) surface with SPLEEM. Images (a) and (b) are taken with opposite direction of the polarization $\boldsymbol{P}$ parallel to $\pm\boldsymbol{M}$. Their difference image (c) shows the magnetic domains while the difference image taken with $\boldsymbol{P} \perp \pm \boldsymbol{M}$ (d) shows the domain walls (electron energy – 2 eV). In: *Precision Science and Technology for Perfect Surfaces*, p. 753. Tokyo: The Japan Society for Precision Engineering.)

Extensive subsequent work on Si(111) and Si(100) surfaces has not only brought a detailed understanding of these surfaces but has contributed immensely to the understanding of processes on clean surfaces such as surface diffusion, adatom density, two-dimensional nucleation, step dynamics, and stability. An example is the step proliferation by B segregation of highly B-doped Si(100) upon cooling, illustrated in **Figure 8**, which is due to a strong increase of the anisotropy of the step energy and of the surface stress. Exchange processes between the volume and the surface also occur in clean crystals as seen, for example, in changes of the step dynamics and reconstruction on the $TiO_2(110)$ surface. Such

processes play an important role in heterogeneous catalysis, in particular, in the so-called three-way catalysts used in automotive exhaust remediation. Other frequently studied surfaces are the W(110) and Mo(110) surfaces that have become popular in the study of the growth of thin films because they can be reused nearly indefinitely as they have a high melting point and low vapor pressure. An example is shown in **Figure 2**.

Chemisorption and Chemical Reactions

The diffraction contrast in LEEM allows detailed studies of chemical processes on surfaces whenever they are connected with specific diffraction patterns. In general, chemisorption modifies the (00) intensity sufficiently so that regions covered with a specific chemisorbed species produce clear contrast. Frequently, chemisorbed phases form domains with different azimuthal orientations. These can be identified by imaging with beams in the LEED pattern (**Figure 9a**) that are characteristic for these domains as illustrated in **Figures 9c** and **9d**. The bright region in **Figure 9b** produces the hexagonal pattern in **Figure 9a**.

Another application of imaging with diffracted beams is the study of the dynamics of chemical surface reactions in which different regions of the surface have different composition and different diffraction patterns. This allows the study of reaction front propagation in oscillatory reactions as found, for example, in the reaction of NO and H_2 on Rh(110). **Figure 10** shows four images of a spiral wave taken about 1 min apart with diffracted beams from the four phases that occur in this reaction, ranging from a pure N phase (a) to a pure O phase (c). Two-dimensional alloying, domain formation, and domain dynamics in systems such as Pb on Cu(111) are other surface processes that have been elucidated by LEEM.

Thin Film Growth

LEEM is a valuable method for the study of the growth of thin films, in particular, of epitaxial growth. Si again has been one of the materials studied most extensively, ranging from homoepitaxial growth on Si(100) via the growth of Ge and Ge–Si alloy layers on Si(100) to the growth of pentacene films on Si(100). These studies have made important contributions to the development of the SiGe technology for wireless telecommunication and to the optimization of organic thin film transistors. Another example

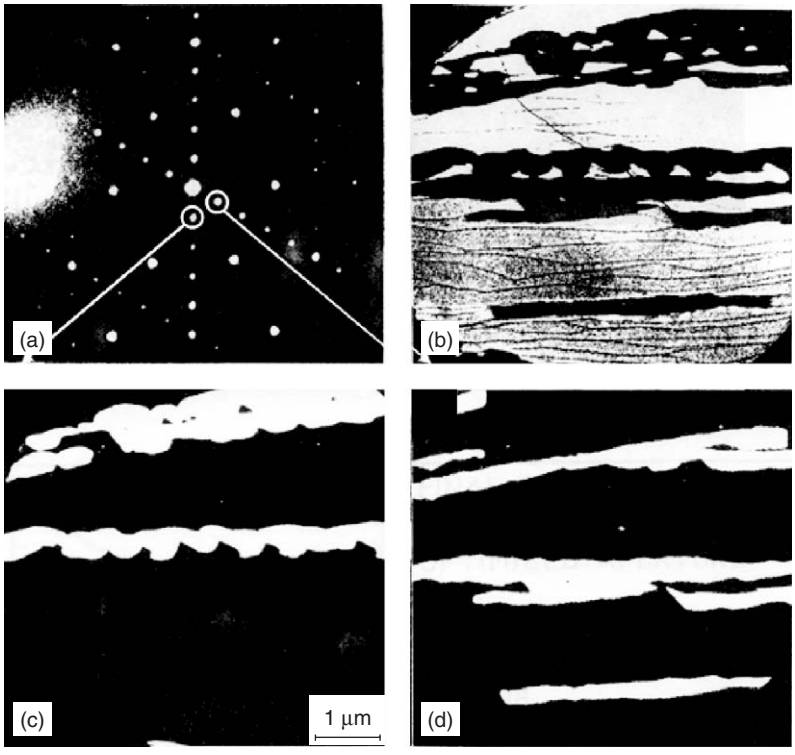

Figure 9 LEED pattern (a), taken at 30 eV, brightfield (b) and darkfield (c,d) LEEM images of an Si(111) surface covered with an Au submonolayer. Image (b) was taken with the (00) beam, images (c,d) with the diffracted beams marked by circles (electron energy – 6 eV). Figure 10 LEEM images of the oscillatory reaction of adsorbed NO and H_2 on an Rh(110) surface taken with diffracted beams from different ordered phases that form locally during reaction. (Reproduced from Schmidt Th *et al.* (2000) *In situ* imaging of structural changes in a chemical wave with low-energy electron microscopy: The system Rh(110)/NO + H_2. *Chemical Physics Letters* 318: 549, with permission from Elsevier.)

is the reactive growth of Si nitride on Si(111) by reaction with NH_3 whose initial stages are illustrated in **Figure 11**.

Heteroepitaxial films develop considerable roughness with increasing thickness in order to relieve misfit strain. Methods to counteract this tendency have been developed in LEEM studies, by either using so-called surfactants that tend to accumulate on top of the film or interfactants that remain at the interface between film and substrate. These methods are of increasing importance as the dimensions of many electronic and magnetic devices shrink into the nanometer range. The second method is illustrated in **Figure 12** by the influence of Au as an interfactant on the growth of Pb on Si(111). On the clean surface, the nucleation rate of Pb is small so that isolated three-dimensional islands are formed that grow individually, monolayer by monolayer, while on the Au-covered surface the two-dimensional nucleation rate is high so that, initially, a continuous monolayer is formed followed by further monolayer growth. Another result of LEEM studies of the growth of epitaxial films is that a quasiliquid Ga double layer is needed to grow smooth GaN film with the polar basal plane parallel to the substrate. Although the layer is liquid at the growth temperature, single and double layer differ sufficiently in the backscattered intensity to allow distinction between them. This result is important for the growth of GaN-based blue UV diode lasers and light emitting diodes.

Metal layer growth on W(110) and Mo(110) surfaces has been studied extensively, mainly in connection with the study of the electronic and magnetic properties of single crystal films. Two examples are shown in **Figures 3** and **5**, more can be found in the general references and below. Many metals grow below $\sim 500\,K$, quasi-monolayer by monolayer, but there are also many which form three-dimensional crystals as illustrated in **Figure 13** for the growth of Co on the W(100) surface. After initial two-dimensional pseudomorphic growth, that is with W lateral periodicity, long ribbon-shaped three-dimensional crystals develop due to the strong anisotropic misfit between the film and the substrate.

Magnetic Properties

Because of the very short inelastic mean free path of electrons, in particular of the minority spin electrons, in ferromagnetic materials which is mainly due to excitations into the unoccupied minority spin states, SPLEEM is only sampling the topmost few layers. Together with their well-defined wavelength, this makes them uniquely suited for the study of very thin films. For example, the spin-dependence of the quantum size effect illustrated in **Figure 3** allows the determination of the spin-resolved electronic band structure above the vacuum level. For this, it is necessary to select, in the SPLEEM image, regions with well-defined thickness and measure the reflected intensity as a function of thickness and energy. The energy dependence in a six-monolayer thick film is illustrated in **Figure 14** for $\boldsymbol{P}$ parallel to the spins $\uparrow$ and $\downarrow$ of the majority and minority electrons, respectively.

The shift of the $\downarrow$ curve, caused by the exchange splitting, and its stronger damping, caused by the shorter inelastic mean free path are clearly seen. A second example is the study of the so-called spin reorientation transition in which the magnetization rotates from out-of-plane to in-plane with increasing thickness. SPLEEM showed that this transition proceeds differently in different materials. In Co films on the Au(111) surface, it starts with the broadening of domain walls; in Fe–Co alloys with Co contents up to 30%, the magnetization tilts initially somewhat into the plane of the film and abruptly switches into the plane when the initially pseudomorphic film transforms into the b.c.c. structure. SPLEEM has also contributed to the understanding of the evolution of the magnetization with thickness of the much discussed system, Fe/Cu(100).

A problem of more practical interest is the exchange interaction between two ferromagnetic layers through a nonferromagnetic spacer layer. It is the basis of the giant magnetoresistance effect that is used in the reading/writing heads of hard disk drives in computers. This interaction oscillates between ferromagnetic and antiferromagnetic coupling with increasing spacer thickness. However, biquadratic coupling, in which the magnetizations in neighboring

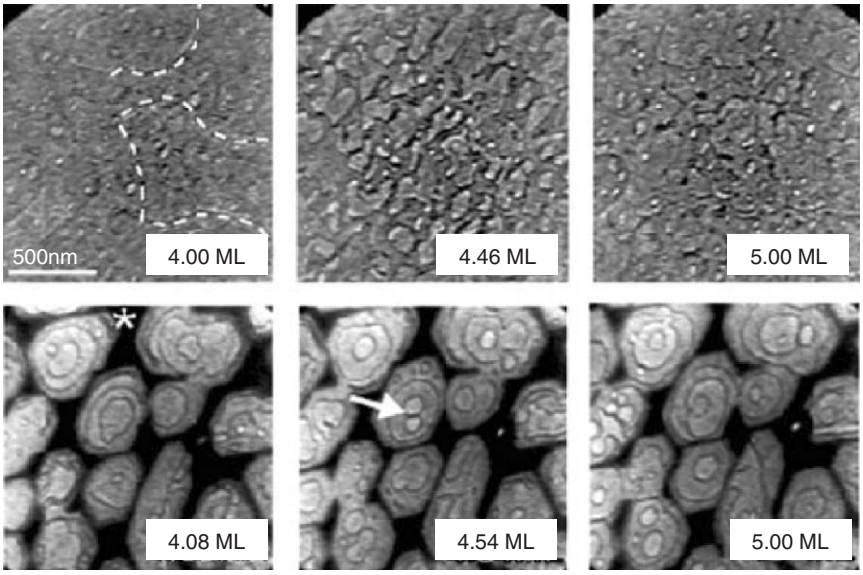

Figure 12 LEEM video frames taken during the growth of Pb from 4 to 5 monolayers on an Si(111) surface at 280 K with (top) and without (bottom) Au interfactant (electron energy – 8 eV). Dots and crosses for majority and minority spins, respectively. (Reproduced with permission from Zdyb R and Bauer E (2002) Spin-resolved unoccupied electronic band structure from quantum size oscillations in the reflectivity of slow electrons from ultrathin ferromagnetic crystals. *Physical Review Letters* 88: 166403; © American Physical Society.)

layers are perpendicular to each other, is also encountered frequently. This coupling is usually attributed to interface roughness. A SPLEEM study of the system Co/Au(111)/Co, however, has shown that it can occur also with rather smooth interfaces. **Figure 15** illustrates this phenomenon for a six-monolayer thick Au spacer. The top two images are from the bottom Co layer with $\boldsymbol{P}$ along the easy ($\parallel \pm \boldsymbol{M}$) and hard ($\perp \pm \boldsymbol{M}$) magnetization axis, respectively, and the bottom-row images correspond to the seven-monolayer thick top Co layer. Ferromagnetic coupling is indicated in the left image but there is also

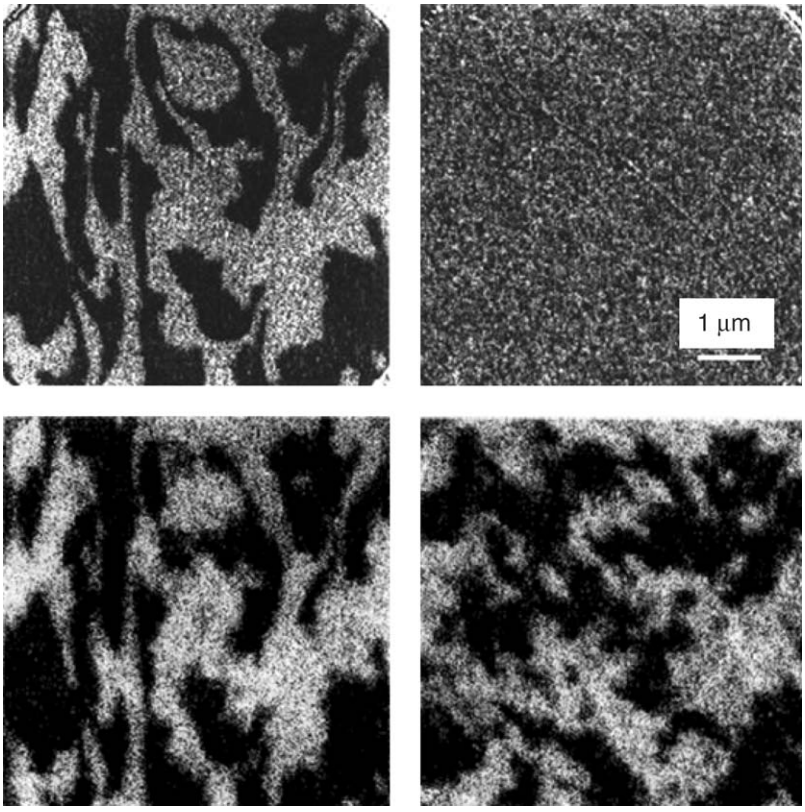

Figure 15 SPLEEM images from a Co/Au(111)/Co sandwich study. The top images are from the bottom layer, the bottom images from the top layer. For explanation see text (electron energy – 2 eV). strong magnetization in the right image, which is a biquadratic coupling to the bottom layer.

Concluding Remarks

This article covers only LEEM and SPLEEM. The instruments used in these techniques are equally well suited for all kinds of photoelectron emission microscopies (PEEM), secondary electron microscopy (SEEM), and Auger electron emission microscopy (AEEM), provided that they are equipped with the necessary accessories. Combining these methods allows a comprehensive surface analysis with high lateral resolution. Scanning low-energy electron microscopy, in which the electron beam is focused onto the specimen and scanned across it, has also not been discussed. This technique also uses a cathode lens in front of the specimen. When operated under ultrahigh vacuum conditions, diffraction contrast is possible too but, in general, secondary electrons are used for imaging. In this case, work function contrast or topography contrast are dominating, or – in the presence of specimen contamination – contact potential difference contrast between regions with different doping in semiconductors.

As mentioned at the beginning, LEEM and SPLEEM are microscopies for the study of surfaces and thin films. These can, of course, also be studied with many other methods. The one closely related to LEEM is reflection electron microscopy (REM) in which the surface sensitivity of fast electrons is achieved with a small grazing angle of incidence. This causes a strong foreshortening in the beam direction but has better resolution perpendicular to it. Conventional scanning electron microscopy (SEM) has the advantage that it can be used with much rougher surfaces than LEEM but lacks the surface structure contrast of LEEM. This is true both in the secondary electron emission mode, which is sensitive to the work function, and in the backscattering mode. Spin-polarized SEM, also called SEM with polarization analysis (SEMPA), is comparable in surface sensitivity to SPLEEM but like all SEM methods, is slower because of the sequential image acquisition compared to the parallel image acquisition in SPLEEM. Conventional dark field transmission electron microscopy (TEM) can also image

surface structures in very thin samples, in particular, when diffracted beams resulting from surface reconstructions are used. The resolution is much better than in LEEM but its application rather limited. Finally, there are many other surface imaging methods, foremost being the various scanning probe techniques. In general, they have better resolution than LEEM but are slower and cover smaller fields of view than LEEM. Although several of these methods have a wide overlap with LEEM/SPLEEM, they are largely complementary in their application range.

Low-Temperature Properties of Materials

T Dietl, Polish Academy of Sciences, Warsaw, Poland

Introduction

Heat and charge transport phenomena in solid-state devices are usually satisfactorily described by the semiclassical Drude–Boltzmann theory. Within this theory, the influence of quantum effects and of electron correlation are taken into account in the Born approximation for the momentum relaxation time τ and by the Fermi liquid renormalization of the effective masses m^*, respectively. However, in a number of cases such a theory fails to describe transport properties even in a qualitative way. These nonclassical aspects of electron transport show up particularly clearly at low temperatures, and exhibit a strong dependence on the system dimensionality d. The celebrated example in the two-dimensional (2D) case ($d=2$) is the integer and fractional → quantum Hall effects, but the list of important novel phenomena is much longer. Here, the Coulomb blockade in 0D quantum dots, the quantization of conductance in 1D wires, mesoscopic phenomena in small conductors, quantum localization in macroscopic systems as well as hopping conductivity in the strongly localized regime are discussed. Somewhat related, but not discussed here, is the issue of thermodynamic phenomena in small samples, such as persistent currents in nanorings and nanocylinders.

Through this article, the notion of metal refers to materials whose conductance G, the ratio of the current to the applied voltage, is nonzero in the limit of zero temperature, $G>0$ as $T\to 0$, in contrast to insulators for which $G\to 0$ as $T\to 0$.

Coulomb Blockade

In the case of standard field effect transistors, the equilibrium charge Q accumulated in the channel is determined by a competition between a positive energy of the Coulomb repulsion between the charges and a negative energy of the charge in the

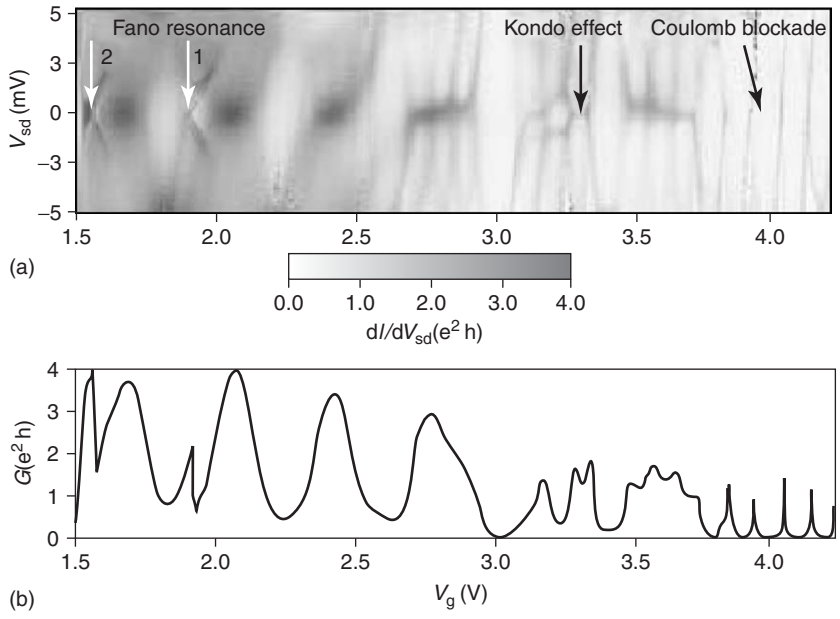

Figure 1 Two-terminal conductance at 0.3 K of a carbon nanotube as a function of the source-drain voltage V_{sd} (a) of gate voltage V_g (b) that increases both carrier density and transmittance of contacts between the sample and the current leads. Regimes corresponding to the Coulomb blockade (low V_g), Kondo effect, and Fano resonance superimposed on Fabry–Perot-like oscillations (high V_g) are visible. At high V_g, the conductance maximums attain the value expected for a metallic carbon nanotube, $G = 4e^2/h$. (Reprinted figure with permission from Babić B and Schönenberger C (2004) *Physical Review B* 70: 195408; © American Physical Society.)

gate potential V_g, $E(Q) = Q^2/2C - QV_g$. By minimizing $E(Q)$, one arrives at the standard linear dependence between Q and V_g, $Q = CV_g$. Since the channel conductance is proportional to the accumulated charge, $G \sim V_g$. If, however, channel dimensions decrease, effects of charge quantization may show up, particularly if the channel is separated from the current leads by tunneling barriers. The charging of such a quantum dot is only possible if $E[(N+1)e] = E(Ne)$. Therefore, as shown in **Figure 1**, except for $V_g, = (N + 1/2)e/C$, the current flow through the dot is blocked and $G = 0$.

The Coulomb blockade is effective as long as the corresponding maximum value of the barrier height e^2/C is greater than the thermal spread of electron energies; for example, $e^2/C = k_B T$ at 1 K for a plate capacitor with the surface $S = 1\,\mu m^2$ and the air gap $b = 4.76$ nm. The Coulomb blockade is also removed if the channel assumes the character of a quantum wire, that is, the contact transmittance is so high that the broadening Γ of the electron states, associated with a finite time the electron spends in the dot, is greater than the barrier height, $\Gamma > e^2/C$, though Fabry–Perot-like interference may lead to conductance oscillations as a function of V_g, if the contacts are not totally transparent. In the intermediate region, the Coulomb blockade is partly removed by the appearance of the Abrikosov–Suhl resonance at the Fermi level. This many-body enhancement of the density-of-states develops below the Kondo temperature whose magnitude increases with the contact transmittance. Furthermore, interference between nonresonant and resonant tunneling via dot-quantum states may lead to additional features in $G(V_g)$ dependence (**Figure 1**), known as "Fano resonances."

Several applications have been proposed for these artificial atoms–quantum dots with a controlled number of electrons. A single electron transistor (SET), electrometer, and primary thermometer constitute a few examples.

Landauer–Büttiker Formalism

A convenient approach to determine conductance of quantum structures is offered by the Landauer–Büttiker formalism, according to which the process of electron transport can be viewed as a scattering problem of fluxes of the Fermi-level electrons entering and leaving the medium through ideal leads. Within this formalism, the conductance can be expressed by eigenvalues of the familiar quantum-mechanical transmission and reflection matrices for the corresponding electron fluxes. These matrices contain information on the potential distribution in a given sample and are subject to symmetry constraints imposed, for instance, by spin degeneracy occurring if no spin-dependent perturbations are present.

Ballistic Transport

Progress in nanofabrication makes it possible to investigate samples, whose dimensions L are smaller than the mean free path of the electrons at the Fermi level, $l = v_F\tau$, so that electron motion is ballistic and G is determined by a sample geometry rather than by a random scattering potential. In a simple two-terminal wire geometry with transparent contacts, the electron spectrum consists of 1D subbands for which electron transmission probability is 1. Hence, the current I generated by the difference in the chemical potentials of the two leads, $-eV$, reads

$$I = \sum_i e^2 v_F^{(i)} N_F^{(i)} V \qquad [1]$$

where k_BT is assumed to be much smaller than the inter-subband distance, and $N_F^{(i)} = 1/hv_F^{(i)}$ is the density of states at the Fermi level of the ith occupied 1D subband. This leads to $G = se^2/h$, where s is the number of the 1D subbands (waveguide modes) crossing the Fermi level and h is the Planck constant. Hence, despite the absence of scattering, G is finite but its value is independent of the wire length and quantized in the units of e^2/h.

As shown in **Figure 2**, characteristic conductance plateau are observed as a function of the gate voltage that changes s. Similar conductance quantization is observed for junctions containing a small number of atoms or molecules. If $s \gg 1$, G can be determined rather accurately from classical "billiard ball"-type models that are particularly useful for complex sample geometries.

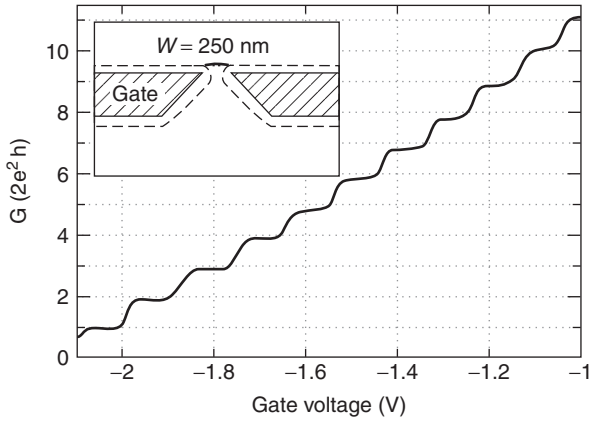

Figure 2 Quantized conductance as a function of gate voltage V_g in a split-gate modulation-doped GaAs/(Al,Ga)As:Si heterostructure. A submicrometer channel is defined in 2D electron gas by negatively biased top metallic gates that deplete carriers in the regions underneath and affect the channel width as shown in the inset. Mesoscopic Transport Phenomena

Without too much simplification, all novel quantum phenomena to be discussed in this section are caused by two effects, which to a large extent determine the spectrum of the eigenvalues of the transmission matrices in the diffusive regime, $L > l$. The first is quantum interference of transition amplitudes corresponding to different electron paths through the disordered medium. The second is a certain spectral rigidity of the eigenvalues, which has been widely discussed in the context of quantum chaos, but can be traced back to the celebrated Mott observation that in disordered system, states close in energy are far apart in real space.

Similarly, in the case of images of fringes produced by interference of light, a change of the conductance occurs over a scale corresponding to the length of the interfering waves. Such an effect was observed as irregular but reproducible conductance fluctuations as a function of the gate voltage, that is, the de Broglie wavelength of the electrons at the Fermi level. Since the magnetic field (vector potential) affects the phase of the wave function also, similar aperiodic fluctuations occur when the magnetic field is ramped, the correlation field corresponding to one quantum flux through the sample surface S, $B_c \approx h/eS$. Of course, in multiconnected geometries, a substantial number of electron trajectories encompass the same magnetic flux and the fluctuations, as a function of the magnetic field acquires a periodic component. This expectation has been confirmed in a series of beautiful experiments with nanorings, in which the Aharonov–Bohm (AB) oscillations with the period $B_{AB} = h/(e\pi r^2) \approx 4.136\,\mathrm{mT}\,\mu\mathrm{m}^2/(\pi r^2)$, where r, the ring radius has been put into evidence, as shown in **Figure 3**.

An interesting aspect of the conductance fluctuations is the universality of their amplitude, closely related to the spectral rigidity mentioned above. According to diagrammatic calculations and numerical simulations as well as numerous experimental studies, the root-mean square (RMS) value of the fluctuation amplitude of two-terminal conductance G of any metallic sample at zero temperature is given by $\mathrm{RMS}(\Delta G) = ae^2/h$. Here, the numerical value of a depends on the universality class, that is, on whether spin and/or time reversal symmetries are conserved, a typical value being $a = 1/2$. Since, however, $\mathrm{RMS}(\Delta G)$ is independent of scattering details and the system size L, the effect is known as "universal conductance fluctuations (UCF)."

As already mentioned, zero-temperature conductance contains information on the actual impurity distribution in a given sample. Actually, conductance is nonlocal and its value G depends on the impurity

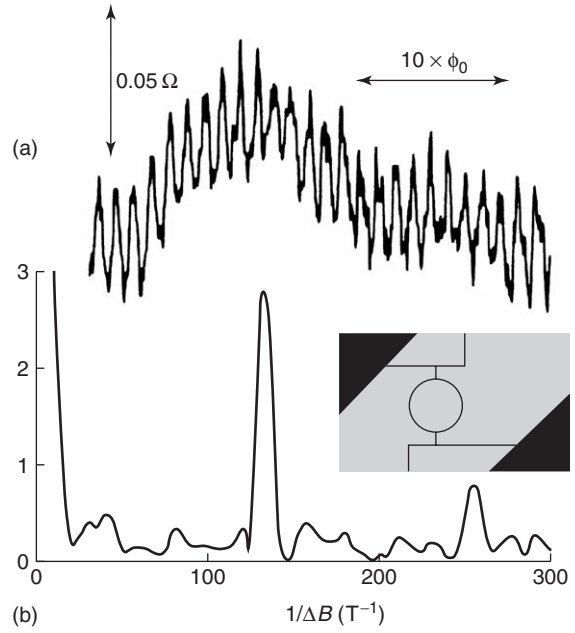

Figure 3 Oscillations of conductance at 10 mK in a gold ring of diameter 784 nm (a), which according to the Fourier transform (b), contain components corresponding to the Aharonov–Bohm period *h*/*e* and *h*/2*e*. (Reprinted figure with permission from Washburn S, Umbach CP, Laibowitz RB, Webb RA *et al.* (1985) *Physical Review Letters* 54: 2696; © American Physical Society.)

distribution even outside the region embedded by the voltage probes. Furthermore, statistical fluctuations of G for various impurity distributions are again characterized by $\mathrm{RMS}(\Delta G) = ae^2/h$. This means that conductance loses a self-averaging property at zero-temperature.

An important question then arises, why these quantum effects are not observed in the case of standard resistors or, in other words, how to model a cross-over between quantum and classical behaviors. Obviously, the coupling to the reservoir at $T > 0$ leads to various random processes such as atom diffusion, flipping of localized spins, lattice and Fermi liquid excitations. Each of these processes leads to changes in the potential landscape, and thus in G, on timescales faster than the time constant of a standard resistance meter. Hence, these processes can wash out quantum signatures in electron transport such as AB oscillations and UCF.

As an example, the effect of impurity tunneling and diffusion is considered. A mean change of G upon displacing a single scattering center by ΔR is evaluated by diagrammatic technique to be $\mathrm{RMS}(G_1) \approx \mathrm{RMS}(\Delta G)[\mathrm{C}(\Delta R k_\mathrm{F})\sigma_\mathrm{imp}/lL^{d-2}]^{1/2}$. Here $C(x \to 0) = x^2/12$, and $C(x \to \infty) = 1$; $\sigma_\mathrm{imp} = 1/ln_\mathrm{imp}$ is the cross section of the relevant scattering centers of concentration n_imp. In the case of, for example, neutral impurities in semiconductors, σ_imp is substantially smaller than that corresponding to the unitary limit $\sigma_\mathrm{imp} \approx 1/k_\mathrm{F}^{d-1}$. Hence, in general, $\mathrm{RMS}(G_1)/\mathrm{RMS}(\Delta G) \ll 1$, which means that the motion of a single impurity perturbs UCF only weakly.

However, the intensity of time-dependent processes grow with the temperature. In particular, if the fraction p of all impurities in the sample undergoes uncorrelated displacement, then the corresponding L dependent conductance variance $\mathrm{RMS}(G_p) = [p(T)L^d n_\mathrm{imp}]^{1/2}\mathrm{RMS}(G_1)$ can attain the universal value $\mathrm{RMS}(\Delta G)$. At this point, the amplitude of AB oscillations and UCF start getting reduced by random impurity motion. This means that the phase coherence length L_φ controlled by time-dependent processes has diminished to the size of the sample L. At still higher temperatures, the sample can be considered as consisting of $[L/L_\varphi(T)]^d$ uncorrelated "coherence boxes." In this regime, the classical self-averaging property of G is recovered as the sensitivity of G to, say, a magnetic field decreases with L and increases with L_φ. Here $L_\varphi = (D\tau_\varphi)^{1/2}$, where $D = k_\mathrm{F} l/dm^*$ is the diffusion coefficient and τ_φ is the phase coherence time. Usually, L_φ is controlled by Fermi liquid thermal excitations and is ~ 0.1–$1\,\mu\mathrm{m}$ at 1 K, so that $L_\varphi \gg l$, that is, a diffusing electron experiences many elastic collisions before its phase coherence is lost.

In addition to $L_\varphi(T)$, there exists one more relevant length scale at nonzero temperatures, which is associated with an averaging of the interference effects by thermal spread $\Delta\lambda$ of the de Broglie wavelengths of electrons contributing to G. This spread is of significance once $\Delta\lambda/\lambda^2$ becomes greater than the inverse of a mean length of the electron path through the sample, that is, if $L > L_\mathrm{T} = (hD/k_\mathrm{B}T)^{1/2}$. Actually, $L_\varphi(T)$ and L_T control the dimensionality also – if one of the sample dimensions, say the film width, becomes smaller than either of them, a dimensional crossover takes place.

A strong sensitivity of G to the motion of impurities has led to the suggestion that the quantum effects in question account for a surprisingly large magnitude of $1/f$ noise observed in any conductor. This is a conjecture corroborated by a change in the noise magnitude once the magnetic field lifts the spin degeneracy. **Figure 4** depicts the appearance of strong low-frequency noise and recovery of UCF in a quantum wire of n-$Cd_{0.93}Mn_{0.07}Te$:I below 300 mK, where spin-glass freezing slows down the dynamics of the Mn spins.

Quantum Localization and Hopping Conduction

The above discussion might suggest that the quantum effects are only important in mesoscopic samples L_φ,

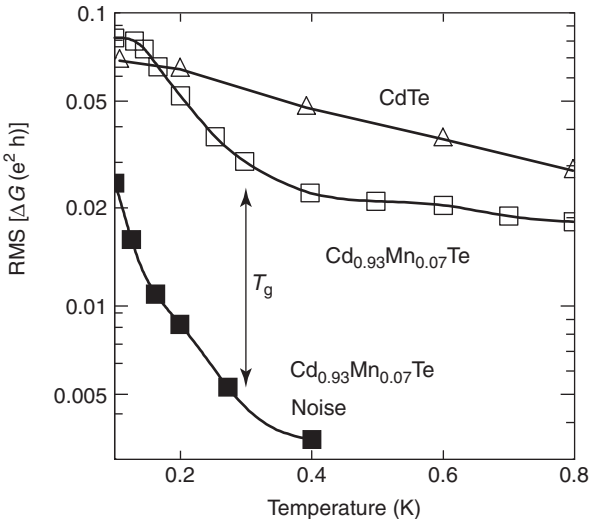

Figure 4 RMS of aperiodic conductance fluctuations as a function of the magnetic field in the vicinity of 2 kOe and RMS of conductance noise measured for a submicron wire of *n*-$Cd_{0.93}Mn_{0.07}Te$ with low-pass filters rejecting frequencies above 0.3 and 3 Hz, respectively. Slowdown of Mn spin dynamics below spin freezing temperature T_g leads to appearance of low-frequency noise and to reentrance of conductance fluctuations with the amplitude comparable to that observed in a similar wire of nonmagnetic *n*-CdTe. (Reprinted figure with permission from Jaroszyński, Wróbel J, Karczewski G, Wojtowicz T, Dietl T, *et al.* (1998) *Physical Review Letters* 80: 5635; © American Physical Society.)

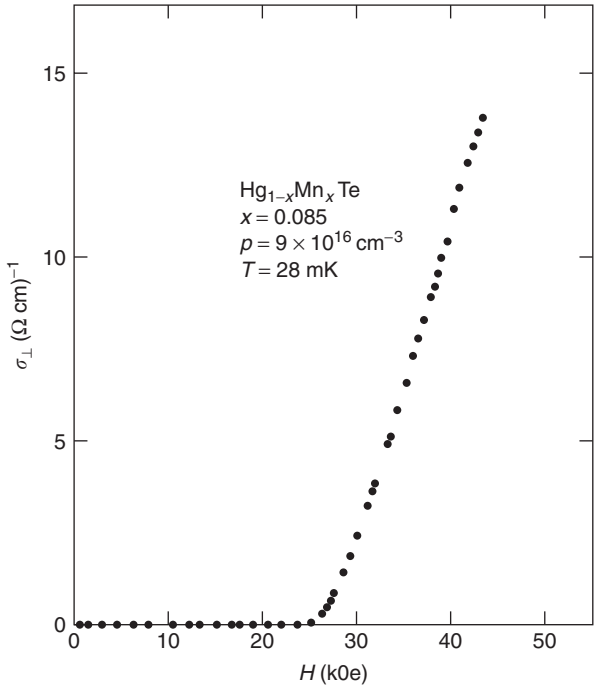

Figure 5 Low-temperature conductivity of a bulk *p*-(Hg, Mn)Te sample as a function of the magnetic field showing an insulator-to-metal transition. The transition results from the field-induced ordering of Mn spins and the corresponding increase in the hole mean free path. (After Wojtowicz T, Dietl T, Sawicki M, Plesiewicz W, Jaroszyński J, *et al.* (1986) *Physical Review Letters* 56: 2419.)

$L_T > L \gg l$, while they become totally insignificant at $L \gg L_\varphi$, L_T. Actually, there are two quantum phenomena that survive the averaging procedure and control low-temperature conductance and magnetoconductance of disordered macroscopic samples.

The first is quantum interference corresponding to the clockwise and counterclockwise electron trajectories along the same self-intersecting electron paths. Since such interference is constructive, it increases the probability of return to the starting point, and thus diminishes the conductivity. The presence of such interference is best seen in cylinders of radius $r < L_\varphi$ and length $L \gg L_\varphi$. In this and related geometries, magnetoconductance exhibits Altshuler–Aronov–Spivak oscillations characterized by the period $B_{AAS} = h/2e\pi r^2$.

The second effect stems from the earlier mentioned disorder-induced correlation between electron energies and their position in real space. Such an additional correlation introduces modifications to the standard Landau theory of Fermi liquids – electron–electron interactions cannot be longer taken into account by a qualitatively unimportant renormalization of the effective mass m^*.

These two quantum effects turn out to be controlled by diffusion poles in the particle–particle and particle–hole correlation functions of the Fermi liquid in the random potential. In the limit of weak disorder, $k_F l \gg 1$, and at low temperatures, $k_B T \ll h/\tau$, they lead to characteristic terms in conductance proportional to $T^{1/2}$ and $B^{1/2}$ in the 3D case, and to $\ln T$ and $\ln B$ in the 2D films, whose sign depends on the universality class as well as on the relative magnitude of the cyclotron and spin splittings.

Interestingly enough, these effects account for Anderson–Mott localization in disordered conductors. This localization results from scattering by many centers, so that the localization radius ξ is usually much greater than the inter-impurity distance. According to the scaling theory, a continuous disorder-driven metal-to-insulator transition occurs when $k_F l \approx 1$ in the 3D case, as shown in **Figure 5**. In doped semiconductors, this takes place when the average distance between electrons becomes 2.5 times larger than the effective Bohr radius of the relevant impurity. In contrast, in any 1D- and 2D-disordered system all states are localized, ξ growing exponentially with $k_F l$ in the 2D case. However, transport signatures of carrier localization can only be seen if $L_\varphi(T)$, L_T, and L are greater than ξ; otherwise, one is in the weakly localized regime discussed above.

In the strongly localized regime, conductance proceeds owing to phonon-assisted tunneling between occupied and empty localized states. In this case, the Mott variable range hopping sets in at low temperatures, where $G(T) \sim \exp[-(T_o/T)^{\gamma}]$, with $\gamma = (\Theta + 1)/(\Theta + 1 + d)$. Here T_o is a material constant, while Θ describes the character of the Efros–Shklovskii Coulomb gap, that is the decay of the density of localized states at the Fermi level, $N(\varepsilon) \sim |\varepsilon - \varepsilon_F|^{\Theta}$, in the energy interval important for the hopping conductivity at given temperature T.

To what extent charge and spin thermal excitations, in addition to lattice excitations, can promote hopping conductance is under active debate.

Nomenclature

a	numerical coefficient between the magnitude of universal conductance fluctuations and the unit of conductance e^2/h
b	air gap between capacitor electrodes
B	magnetic field
B_c	correlation field in universal conductance fluctuations
C	capacitance
$C(x)$	a function describing effect of the defect displacement on the universal conductance fluctuations
d	space dimensionality; $d=1$ for one-dimensional (1D) case, $d=2$ for 2D, $d=3$ for 3D cases, respectively
D	charge carrier diffusion coefficient
e	absolute value of the magnitude of the electron charge
E	total energy of charges in a capacitor
f	noise frequency
G	electrical conductance, $G = I/V$
G_1	change of conductance for a displacement of a single scattering center
h	Planck constant
i	index of 1D electric subbands
k_B	Boltzmann constant
k_F	wave vector of the carriers at the Fermi level
l	mean free path for elastic collisions
L	sample linear dimensions
L_φ	carrier coherence length
L_T	carrier thermal length
m^*	effective mass of carriers
n_{imp}	concentration of scattering centers
p	fraction of all impurities in the sample undergoing uncorrelated displacement
Q	charge
r	radius of a ring or cylinder
S	surface
T	temperature
T_o	a temperature characterizing thermal activation of hopping conductance
V	voltage
V_g	gate voltage
v_F	Fermi velocity
γ	exponent describing character of temperature dependence of hopping conductivity
ε	carrier energy
ΔG	amplitude of conductance fluctuations
ε_F	Fermi energy
λ	de Broglie electron wavelength
σ_{imp}	cross section of electron scattering by a single impurity
Θ	exponent describing the character of the Coulomb gap in the density of localized states
ξ	localization length
τ	momentum relaxation time
τ_φ	phase coherence time

Luminescence

R Capelletti, University of Parma, Parma, Italy

Introduction

As a consequence of energy absorption at moderate temperature, a luminescent material re-emits part of it as light (IR, visible, and UV). Such a light emission was called luminescence by E Wiedemann in 1888 and it must not be confused with the "blackbody" one, which occurs at high temperatures. The energy absorption or excitation of a luminescent material can be accomplished in different ways and these are expressed in a prefix accompanying the word luminescence.

For example, the excitation energy may be supplied by sound or light waves (sonoluminescence or photoluminescence, see **Figure 1**), by moderate heating (thermoluminescence (TL)), by electric field (electroluminescence (EL)), by particles, as electrons (cathodoluminescence (CL)), by rubbing (triboluminescence), and by high-energy radiation, as X- or γ-rays, (radioluminescence). The light emission may result from chemical reactions (chemiluminescence) or physical processes, as crystallization (crystalloluminescence) or solution (lyoluminescence). The prefix may also originate from specific features of the luminescent materials, for example, bioluminescence is a form of chemiluminescence produced in living organisms and pyroluminescence is related to the radiative emission from atoms or molecules in a gas, previously excited by heating. **Table 1** provides a more detailed list of different luminescence phenomena. A further distinction comes from the time elapsed between the excitation and the light emission, that is, if the emission stops as the excitation ceases, one is dealing with fluorescence, while if it lasts for a more or less long time after the excitation, one is dealing with phosphorescence (or afterglow). Independent of this definition, a luminescent material is conventionally defined as a phosphor; on the basis of its etymology, that is, in Greek it means "to bear light," and should not be confused with the chemical element phosphorus P ($Z = 15$). Luminescence can be regarded as an ability of matter to convert various forms of energy into light; therefore, luminescent materials can be exploited and tailored for a variety of applications. In fact, the color of the emitted light depends on the intrinsic characteristics of the material, on the impurity and defect content, on the temperature, on the external applied fields (stress, magnetic, and electric), and on the particle size (quantum dots). The number of applications in science and everyday life is extremely large and continuously growing. A few examples are mentioned in the following and in **Table 1**. The solid-state laser operation (e.g., ruby, Nd:YAG) is based on photoluminescence (stimulated emission). In the common fluorescent tubes, a phosphor coating absorbs the invisible UV radiation (emitted by the de-excitation of Hg atoms) and re-emits visible light. Phosphors added to laundry detergents and paper make white textiles and paper brighter, because the sunlight UV tail excites a pale blue luminescence which adds to

Table 1 Different types of luminescence, their origin, examples and applications, based on E N Harvey

Type	*Origin*	*Examples/applications*
Candoluminescence	Emission from incandescent solids at shorter wavelengths than those expected from their blackbody emission	Rare-earth oxides in Auer lamps (outside lighting); Mg/MgO in flash-light photography
Pyroluminescence	Emission from excited atoms, ions, and molecules in flames	He, Na, Fe, Ca, etc.; Sun line emission spectrum; lamps, fireworks; I_2, NO_2 in flames
Thermoluminescence	Emission from solids previously irradiated and then moderately heated	Heavy spar; fluorite; zircon; personal and environmental dosimeters; archeological pottery dating; rock dating (e.g., stalagmites); irradiated food identification
Photoluminescence	Irradiation by UV or visible light	Impurities and defects (e.g., color centers) in crystals and minerals, phosphors: laser, counterfaction detection
Radioluminescence	Irradiation by high-energy photons (X-, γ-rays) or particles (e.g., neutrons)	Scintillators (e.g., NaI: Tl, CsI, BGO, $PbWO_4$), AgBr grains for X-ray film radiography; scintillator-based calorimeters to detect high-energy particles; Cherenkov effect
Cathodoluminescence	Excitation by electron impact on solids or gases	Color TV screen; impurity mapping, microinclusions in minerals by using electron microscopy; discharge lamps, aurora borealis in air
Anodoluminescence	Irradiation by anions	ZnS phosphors
Ionoluminescence	Excitation produced by particles (e.g., alpha particles emitted by radioactive elements)	Early clock dials; sapphire
Sonoluminescence	Ultrasonic irradiation of liquids	Small gas bubbles emit very short light flashes (a few ps long)
Galvanoluminescence	Luminescence emitted during electrolysis	Electrolysis of NaBr
Electroluminescence	Excitation by an electric field	LED; injection lasers; alpha-numeric displays; lighting, medical applications; backlight in electric clocks; flexible EL lamps; laser pointers
Crystalloluminescence	Excitation induced by rapid crystallization of certain salts from liquid solution or from molten phase	Growth of crystallites from solutions: NaCl, As_2O_3, K_2SO_4, organic compounds
Lyoluminescence	Light emitted on dissolution (e.g., in water) of pre-irradiated solids	Alkali halides; organic materials (dosimetry); irradiated food identification
Chemiluminescence	Excitation produced by chemical reactions	Luminol; lightsticks; reactions between gaseous species at high temperature; chemical species trace (e.g., iron in hemoglobin) determination
Bioluminescence	Chemiluminescence in biological matter (e.g., accompanying the oxidation of luciferin)	Bacteria, fungi, algae, glow worms, fishes, mollusks, jellyfishes, fireflies, etc.
Triboluminescence	Excitation brought about by the crushing of crystals	Uranyl nitrate, sugar, quartz, rock salt, Wint-O-Green candies

the white reflected light. Simple apparatuses exploit the UV-induced fluorescence in stamps, money (e.g., euro bills), credit cards, and traveler's checks to detect counterfeiting. Many traffic safety products utilize photoluminescence. Different color light emitting diodes (LEDs), used in a variety of displays, are based on EL. The color-TV screen phosphor operation exploits CL. The chemiluminescence of luminol reacting with hemoglobin is used in crime scene investigations to detect even tiny traces of blood, which might last for years at the scene. Scintillator applications originate from radioluminescence and are addressed to astrophysics, high-energy physics (e.g., the calorimeter on the KTeV beamline at FermiLab, see **Figure 2**), medical diagnostics, and security controls. TL is exploited in the dating of buried materials and dosimetry. Phosphorescence provides nighttime visibility to the dials of alarm clocks and watches, by using long-persistence phosphorescent materials, activated by daylight. In the earlier watches, the same purpose was accomplished by a mildly radioactive paint. In newer electric clocks, the backlight behind the dial is based on electroluminescence.

In this article, after brief hints about the historical development of luminescent phenomena, some fundamental mechanisms of emission of luminescence are described. The basic concepts and the spectroscopic tools required to enlighten such microscopic

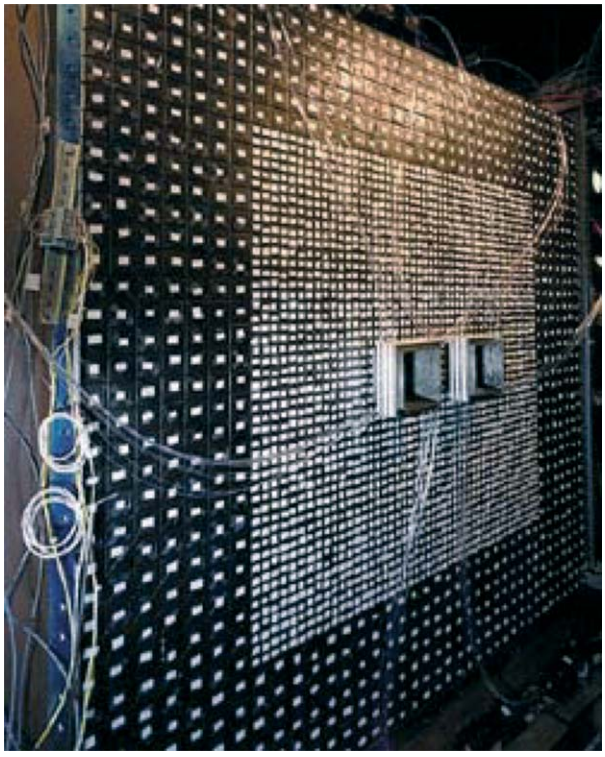

Figure 2 Scintillator-based calorimeter on the KTeV beam line at the FermiLab (Batavia, Illinois, USA). It is a 1.9 m × 1.9 m array of 3100 pure scintillating CsI crystals. The calorimeter measures with high precision energy of particles emanating from kaon decays by recording the light emitted (radioluminescence) as the particles pass through the scintillating material. mechanisms are illustrated mainly for photoluminescence. A few examples of thermoluminescence, electroluminescence, and cathodoluminescence are also supplied. Phenomena related to inorganic condensed matter are considered.

Historical

Luminescence-related phenomena have been observed for thousands of years, but only in the last century were they systematically studied, understood, and exploited. The bioluminescence of fireflies was reported in Chinese literature as early as three millennia ago, while Pliny, the Elder in Naturalis Historia, mentions the "cold fire" emitted in the dark by glow worms, jellyfishes, and mollusks and describes various gems, such as ruby, which shine after being exposed to the sun. In 1602, Vincenzo Casciarolo, an Italian cobbler and amateur alchemist, discovered the Bolognian Phosphorus or Litheophosphorus. This natural stone (heavy spar) became the first object for the scientific study of luminescent phenomena and raised the interest of many scientists, such as Galileo Galilei. Robert Boyle reported to the London Royal Society the glimmering light emitted by a diamond when placed on the warmest part of his body and the effects produced by the luminous bacteria which feed on decaying flesh (1672). In the same period, Francis Bacon and Lorenzo Magalotti described the light emitted in the dark by sugar, as a consequence of friction. In 1824, Friedrich Mohs observed that fluorite shone in the dark on being heated and called this property "fluorescence" after the mineral (nowadays it is named thermoluminescence). Sir David Brewster (1833) noted that a beam of sunlight, condensed by a lens into a chlorophyll solution, was marked by a bright red emission. Probably the first to explain it was Sir George Stokes, who also named the phenomenon fluorescence again after fluorite, which exhibits a strong photoluminescence under UV light, in addition to phosphorescence and thermoluminescence, already reported by Mohs. Stokes is credited with the discovery (1852) that fluorescence can be induced in certain substances by their stimulation with UV light. Wiedemann, in 1888, proposed the name luminescence (Latin, lumen – light) for this wide class of phenomena. He distinguished six types – photo-, electro-, thermo-, tribo-, crystallo-, and chemi-luminescence. An extensive study of these phenomena and of phosphorescence induced by insolation (i.e., exposure to sunlight) was also performed by Edmond Becquerel, who defined them as phosphorescence (1882–97).

Microscopic Interpretation of Some Luminescence Phenomena

Luminescence may occur in pure and perfect crystals (intrinsic luminescence), may be related to intrinsic defects (e.g., F centers in ionic crystals), or to impurity-induced defects (extrinsic luminescence). Impurities and defects are either intentionally introduced for scientific and application purposes or are already present in the material under study. The energy delivered to the crystal to excite luminescence (e.g., X-rays, high-energy particles, see **Table 1**) may also produce defects. In **Figure 3**, a few mechanisms responsible for luminescence are exemplified in the case of electronic transitions, although transitions between the vibrational levels of some molecular groups (e.g., CN in alkali halides) may also give rise to luminescence (in the IR range). An electron is raised from the valence band (VB) to the conduction band (CB) as a consequence of a transition induced by the energy absorption, that is, the excited electron, which is free in the CB, subsequently recombines with a free hole left in the VB, by emitting a photon (band to band radiative recombination, **Figure 3a**). The emission occurs in the UV, visible,

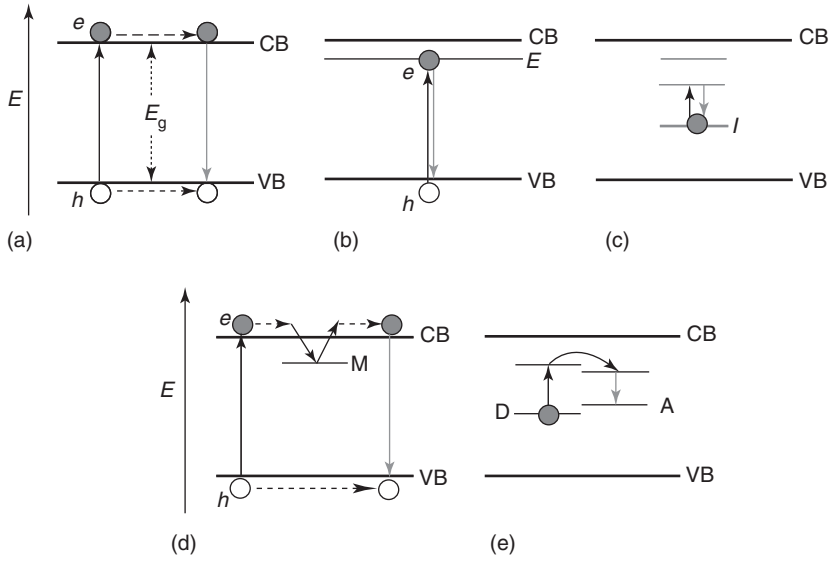

Figure 3 Examples of electronic processes responsible for luminescence: (a) Band-to-band emission; (b) excitonic emission; (c) impurity luminescence; (d) band-to-band emission, delayed by trapping and de-trapping processes; (e) energy transfer between a donor (D) and an acceptor (A). CB indicates the bottom of the conduction band, VB the top of the valence band. The gray circles indicate the electron and the open circles the hole. The vertical black arrows indicate the energy absorption, the gray ones the radiative emission. The dashed arrows indicate the electron (or hole) migration in the conduction (or valence) band. Nonvertical arrows indicate nonradiative processes.

or near IR range according to the amplitude of the energy gap E_g. The excitation can also produce an exciton, that is, an electron, which being still more or less bound to the hole left in the VB, occupies a level just below the bottom of the CB. The radiative recombination of the electron–hole pair gives rise to the excitonic luminescence (**Figure 3b**). Both processes are intrinsic. An impurity (or a defect) can introduce in the energy gap a set of localized levels: an electron, by absorbing energy, jumps from the ground to an excited level of the impurity and subsequently decays by emitting radiation (**Figure 3c**). An impurity or defect can introduce metastable or trap levels in the energy gap: an electron, raised to the CB as in **Figure 3a**, may be trapped in the metastable level M (**Figure 3d**), instead of recombining immediately with a hole in the VB. The band-to-band radiative recombination is delayed until the trapped electron gains enough energy, for example, from the lattice vibrations, to become free again in the CB. The time necessary to empty the trap may be rather long at ordinary temperatures; the delayed light emission is named phosphorescence (or afterglow). By a moderate temperature increase, the time to empty the trap can be significantly shortened, thus giving rise to thermoluminescence. The distribution of impurities (either of the same or of different kind) within the sample plays an important role. The energy acquired by an impurity (D, the donor) from the excitation source may be transferred to a neighboring impurity (A, the acceptor) which may decay radiatively. This means that D is excited and A emits its own luminescence (**Figure 3e**). The process, defined as energy transfer, occurs, for example, if the two impurities are rather close to each other (see sections "Time dependence and lifetimes" and "Concentration effects and energy transfer" and **Figures 6–8**).

Photoluminescence

The Franck–Condon Scheme

In gases, the emission from excited atoms is characterized by a narrow line lying at the same wavelength as that of the excitation (pyroluminescence). In condensed matter, due to the interaction of the emitting center with neighboring atoms, the emission is broader giving rise rather to an emission band than to an emission line. Moreover, the emission occurs, as a rule, at lower energy (longer wavelength) with respect to the excitation one. The energy shift, named Stokes shift, is explained in terms of the Franck–Condon scheme (**Figure 4**). The electron energy levels in a luminescent center depend on the average distance of the center from the neighboring atoms (that is, on the so-called configurational coordinate), which is at variance with the simplified description given in **Figure 3c**. The electron is excited from A (in the ground state) to B (in the excited state) by absorbing a photon. The transition is vertical on the basis of the adiabatic approximation. The electron gives up part of the absorbed energy to the lattice vibrations as it goes to

the relaxed excited state C. After living in C for the lifetime typical of the excited state (10^{-9}–10^{-7} s), it decays into the ground state, again by a vertical transition C–D, with a photon emission. The electron returns into the initial state A, by giving up energy to the lattice. The typical times for the vertical transitions are $\sim 10^{-15}$–10^{-16} s, only the electrons being involved. Those related to the energy transfer to the lattice are roughly three orders of magnitude longer, the more inert nuclei being involved. The excitation energy, represented by AB, is larger than the emission one CD, because part of the absorbed energy (AB) is transferred to the lattice vibrations (along BC and DA), accounting for the Stokes shift, that is, the absorption (excitation) band lies at energy higher than that of the emission band, see **Figures 4** and **5**.

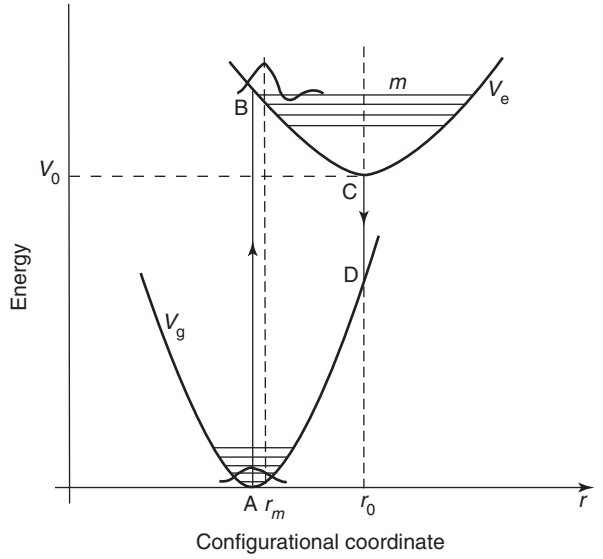

Figure 4 The Franck–Condon scheme.

Excitation and Emission Spectra

The emission intensity is related to the number $N_e(\lambda_{em})$ of emitted photons per unit time at a given wavelength λ_{em}. This depends on the number $N_a(\lambda_{exc})$ of absorbed photons per unit time at a given excitation wavelength λ_{exc} and on the luminescence quantum yield η, that is,

$$N_e(\lambda_{em}) = \eta N_a(\lambda_{exc}) = \eta N_i(\lambda_{exc})\{1 - \exp[-\mu(\lambda_{exc})x]\} \quad [1]$$

where $N_i(\lambda_{exc})$ is the number of incident photons per unit time at a given λ_{exc}, $\mu(\lambda_{exc})$ the corresponding absorption coefficient, and x the sample thickness.

For low $\mu(\lambda_{exc})x$ values, that is, for thin and/or weakly absorbing samples, eqn [1] becomes

$$N_e(\lambda_{em}) \approx \eta N_i(\lambda_{exc})\mu(\lambda_{exc})x \quad [2]$$

or

$$N_e(\lambda_{em}) \propto \eta N_i(\lambda_{exc})N_L \quad [3]$$

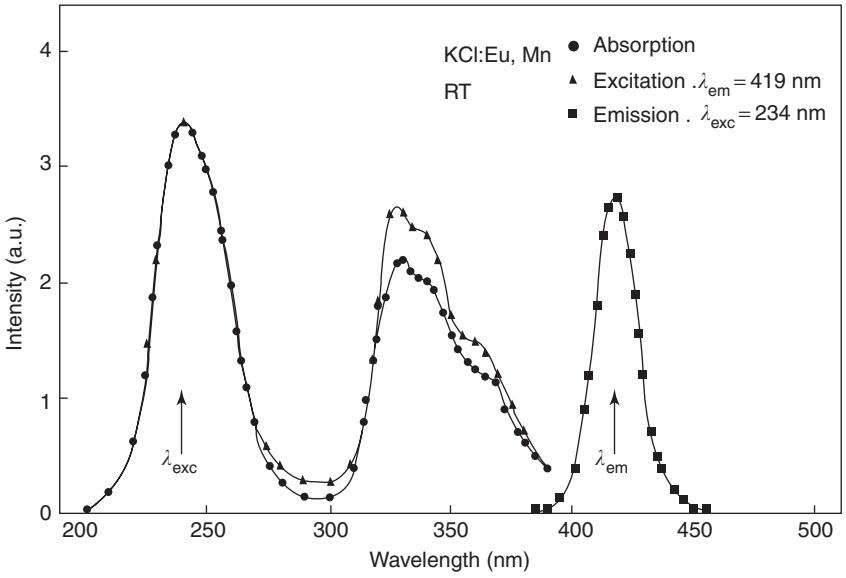

Figure 5 Example of absorption (solid circles), excitation (triangles), and emission (squares) spectra measured at room temperature on a single crystal of KCl: Eu (54 ppm), Mn (3 ppm). The sample was quenched from 500°C: in this way the impurities (Eu and Mn) are dispersed and well separated. The absorption, excitation, and emission spectra are related only to the presence of Eu. The excitation spectrum is measured by keeping constant the emission wavelength $\lambda_{em} = 419$ nm (in the blue) and its intensity is normalized to the absorption spectrum at 234 nm for the sake of comparison. The emission spectrum is measured by keeping constant the excitation wavelength $\lambda_{exc} = 234$ nm (in the UV). For the luminescence color, see **Figure 1**. (Reproduced with permission from Capelletti R, Manfredi M, Cywiński R, Damm JZ, Mugeński M, and Solzi M (1987) Energy-transfer mechanism in the KCl: Eu^{2+}, Mn^{2+} system. *Physical Review B* 36: 5124–5130.)

because μ is proportional to the number of luminescent centers N_L.

In real solids the photoluminescence, excited in a broad wavelength (energy) range, may consist of more than one emission band, due to the presence of more than one luminescent center. The analysis of the emission, excitation, and absorption spectra is a powerful tool to identify the centers. By keeping the excitation wavelength λ_{exc} fixed, an emission spectrum is obtained by measuring the emitted light intensity (or $N_e(\lambda_{em})$) as a function of the emitted wavelength λ_{em} (see **Figure 5**). On the other hand, by keeping λ_{em} fixed, an excitation spectrum is obtained by measuring the emitted light intensity as a function of λ_{exc}, see **Figure 5**. In this way it is possible to identify the λ_{exc} range which excites a given emission. The excitation band should fit to an absorption band (see eqns [1] and [2]): for example, the emission can be attributed to a band-to-band recombination or to an impurity, if the corresponding excitation spectrum coincides with the fundamental absorption or with the impurity absorption band, respectively, see **Figure 5**. The photoluminescence of a phosphor can be described comprehensively by a 3D plot in which the emission intensity is plotted versus λ_{em} and λ_{exc}. Furthermore, the analysis of the emitted light polarization supplies useful information on the symmetry of the luminescent centers.

Interaction with the Lattice Vibrations

The interaction with the lattice vibrations (phonons) is responsible for the Stokes shift and broadening of the emission (or absorption/excitation) lines related to a luminescent center in a solid, see **Figure 5**. By increasing the temperature, the lines broaden (homogeneous broadening) and weaken as a rule. The lattice disorder due to defects (e.g., dislocations, impurities) is responsible for broadening even at low temperatures (inhomogeneous broadening). This is particularly severe in glasses and amorphous solids, characterized by a disordered network. Such effects are practically absent for some color centers (e.g., R′ and M′ in LiF) and impurities (e.g., rare earths, see **Figure 10**) in some insulating crystals: very narrow lines, or zero-phonon (ZP) lines, are observed in emission spectra measured at low temperatures. This occurs when the minima of the electronic excited and ground states fall at the same configurational coordinate in **Figure 4**. A very narrow ZP line may be accompanied by a weaker, more or less structured spectrum on the lower energy side, which corresponds to electron transitions to vibrational excited states of the electronic ground state (vibronic spectrum). In other words, the electron de-excitation occurs by emitting a photon and subsequently a phonon. A similar process may take place with the emission of a photon and of a localized vibrational quantum that is related to the luminescent center itself.

Time Dependence and Lifetimes

The radiative emission from a single excited level decays as soon as the excitation is turned off, that is, the time evolution of N_e is given by

$$N_e(t) = N_e^0 \exp(-t/\tau) \qquad [4]$$

where N_e^0 is the number of emitted photons per unit time at $t = 0$ and τ is a time constant or the excited state lifetime. It does not necessarily coincide with the radiative lifetime τ_r, that is, the time the electron spends in C for an isolated center (see **Figure 4**) before decaying, but may be shortened by a number of processes. In terms of a simple model, τ may be written as

$$\frac{1}{\tau} = \frac{1}{\tau_r} + \frac{1}{\tau_0} \exp \frac{-\Delta E}{kT} + \frac{1}{\tau_Q} \qquad [5]$$

where $(1/\tau_0)\exp(-\Delta E/kT)$ is the probability, at temperature T, that the electron in the excited state (e.g., C in **Figure 4**) is brought by thermal activation into a higher level from which the decay is nonradiative, ΔE is the activation energy, and $1/\tau_Q$ is the probability of any other process. Shortening of τ with respect to τ_r causes also a decrease of the luminescence quantum yield η. This is defined either as the ratio of the number $N_{L,r}$ of centers which decay by a radiative pathway to the total number N_L or as the ratio of τ and τ_r, that is,

$$\eta = \frac{N_{L,r}}{N_L} = \frac{N_{L,r}}{N_{L,r} + N_{L,nr}} = \frac{\tau}{\tau_r} \qquad [6]$$

$N_{L,nr}$ accounts for the number of centers which decay through nonradiative pathways, for example, as a consequence of heat emission or absorption, intersystem crossing, capture in metastable levels, quenching caused by other centers, and energy transfer, see **Figures 6** and **7**. Therefore, the lifetime τ measurement supplies valuable information on a variety of processes occurring in the excited state, see **Figure 8**. Since the pioneering study performed by A E Becquerel with his phosphoroscope at the end of the nineteenth century, the time analysis has been extended nowadays to times as short as 10^{-12}–10^{-15} s. The availability of femtosecond excitation pulses allows one to also watch the fast processes by which the excited electron gives up part of its energy

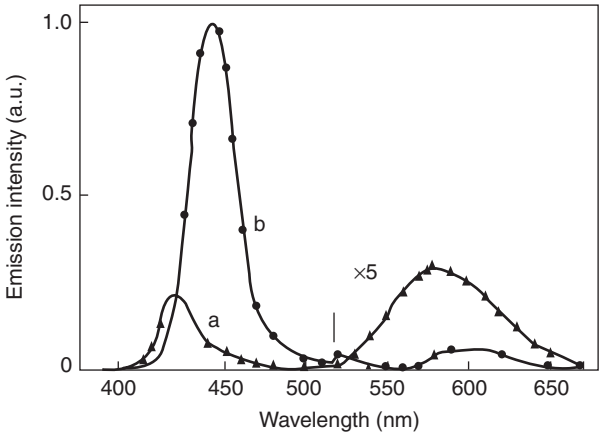

Figure 6 Example of energy transfer between Eu^{2+} (the donor) and Mn^{2+} (the acceptor) in a single crystal of KCl: Eu (54 ppm), Mn (3 ppm). The sample (the same as in **Figure 5**) was submitted to annealing at 225°C for 360 h. The treatment causes the formation of mixed Eu–Mn clusters, strongly reducing the separation between Eu^{2+} and Mn^{2+}. The emission spectra were measured at room temperature (curve a) and at 78 K (curve b). As a consequence of the excitation at 275 nm, i.e., in the Eu absorption band (see **Figure 5**), two emission bands are observed. The former in the 420–450 nm range (in blue, as in **Figure 5**) is related to the Eu emission, while the latter in the 550–620 nm range (in red, absent in **Figure 5**) is related to Mn emission, proving the energy transfer from Eu to Mn. The energy transfer is more efficient at room temperature than at 78 K, in fact the red Mn emission is stronger than the blue Eu emission. For the luminescence color, see **Figure 7**. (Reproduced with permission from Capelletti R, Manfredi M, Cywiński R, Damm JZ, Mugeński M, and Solzi M (1987) Energy-transfer mechanism in the KCl: Eu^{2+}, Mn^{2+} system. *Physical Review B* 36: 5124–5130.)

to the lattice (i.e., from B to C and from D to A in **Figure 4**). Emission spectra (see above) can be collected for different time windows along the decay and displayed as time-resolved emission spectra (TRES) in a 3D plot, which quickly reveals complexities in a sample. For example, a mixture of two luminescent centers with different lifetimes will exhibit a distinct difference in the TRES as the time window is varied.

Concentration Effects and Energy Transfer

For application purposes, one would increase the emission intensity by increasing the number N_L (or the concentration c_N) of the luminescent centers, according to eqn [3]. However, by increasing c_N the average distance among centers decreases, enhancing the energy transfer probability, and, as a consequence, $1/\tau_Q$ in eqn [5]. This causes a lifetime shortening, and, according to eqn [6], an η decrease, which might make the c_N increase ineffective, if not detrimental (concentration luminescence quenching). $1/\tau_Q$ may also increase as a result of clustering processes: the energy transfer between neighboring luminescent centers (e.g., Eu and Mn) in a cluster allows the tuning of the luminescence color, see **Figures 3e**, and **6–8**. The energy transfer to molecular groups (e.g., OH, H_2O, O_2), which decay without emitting light may cause the decrease or even the total suppression of the luminescence (impurity luminescence quenching).

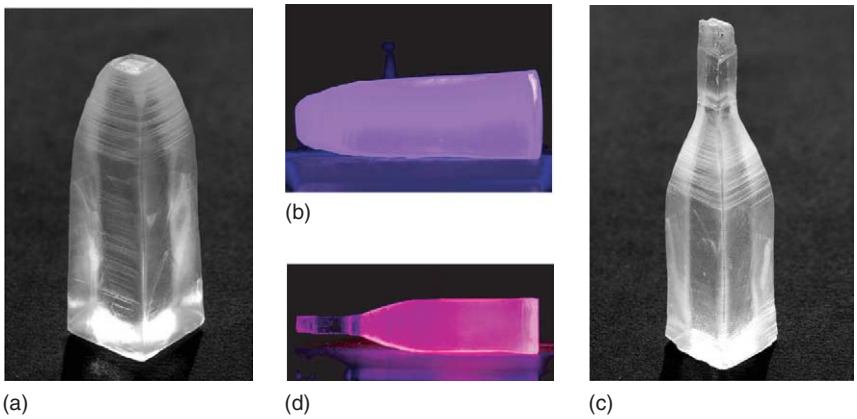

Figure 7 Photoluminescence excited by 253 nm UV light in Eu and Mn double-doped alkali halide single crystals grown by the Czochralski method and energy transfer between Eu and Mn. (a) and (b) are related to KCl: Eu (500 ppm), Mn (4000 ppm) (size: $2.2 \times 2.2 \times 6.4\,cm^3$); (c) and (d) to NaCl: Eu (100 ppm), Mn (2000 ppm) (size: $1.9 \times 1.9 \times 6.4\,cm^3$); (a) and (c) daylight illumination; (b) and (d) the samples are illuminated only by UV light. In agreement with the emission spectrum shown in **Figure 6**, the Eu→Mn energy transfer is proven by the presence of the Mn red emission which adds to the Eu blue one displayed in **Figure 1** for a KCl: Eu sample. The Eu→Mn energy transfer is more efficient (higher red emission contribution) in NaCl than in KCl due to its smaller lattice constant, which makes possible shorter distance between Eu and Mn. In (d) the luminescence is emitted from the body of the crystal which is Eu and Mn doped, but not by the seed (left end) which is undoped NaCl. The crystals were grown at Physics Department, University of Parma, Italy. (Photographs by Carlo Gardini, Parma (carlgard@inwind.it).)

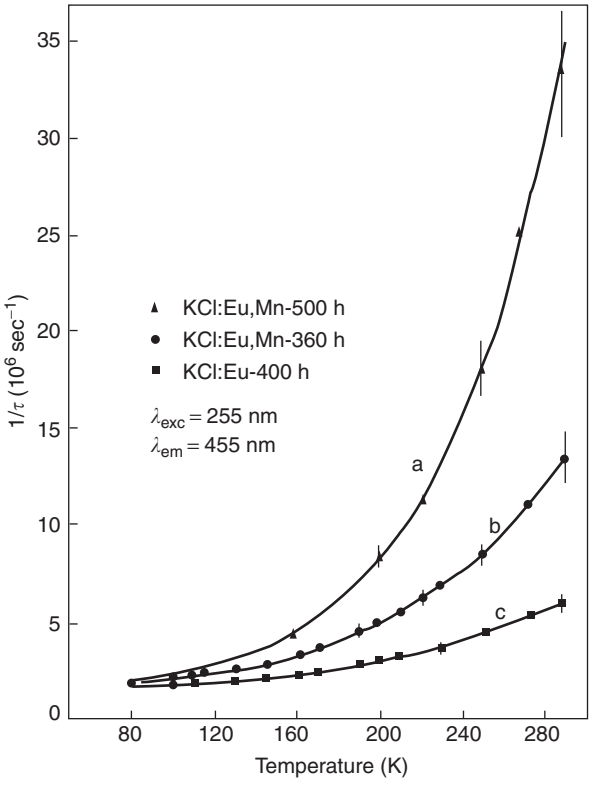

Figure 8 Eu luminescence time decay rates $1/\tau$ as a function of the temperature in a single crystal of KCl: Eu (54 ppm), Mn (3 ppm) at different steps of the clustering process. Curve (b) is related to a 360 h annealing (as in **Figure 6**) while curve (a) to a 500 h one (more advanced Eu–Mn clustering process). Curve (c) is related to a KCl:Eu (90 ppm) annealed for 400 h. For all the samples the annealing temperature is 225°C, the excitation and emission wavelengths are $\lambda_{exc} = 255$ nm and $\lambda_{em} = 419$ nm, respectively. According to eqn [6], the decay rate increases by increasing the temperature (for all the samples) and as the energy transfer from Eu to Mn takes place (compare curves (a) and (b) with curve (c)). The effect is more pronounced at a more advanced clustering step (compare curve (a) with curve (b)). (Reproduced with permission from Capelletti R, Manfredi M, Cywiński R, Damm JZ, Mugeński M, and Solzi M (1987) Energy-transfer mechanism in the KCl: Eu^{2+}, Mn^{2+} system. *Physical Review B* 36: 5124–5130.)

Size Effects

Thanks to modern technology, nanoparticles, either free standing or embedded in a host matrix, are available on a nanometer scale. Their size plays a key role in the excitation and emission spectra; an example is provided by the excitonic luminescence (see **Figure 3b**) in a semiconductor (e.g., CdSe). The particle size may be smaller than the orbit radius R ($\sim$10 nm) of the bulk exciton, regarded as a hydrogen-like system composed of a bound electron–hole pair. The exciton confinement within the nanoparticle increases the excitation and emission energies, as for a particle in a box. The exciton emission shifts from the deep red, to orange, yellow, green, and blue by gradually decreasing the nanoparticle size to $\sim$2 nm, see **Figure 9**. The effect can be exploited to tailor-tunable lasers.

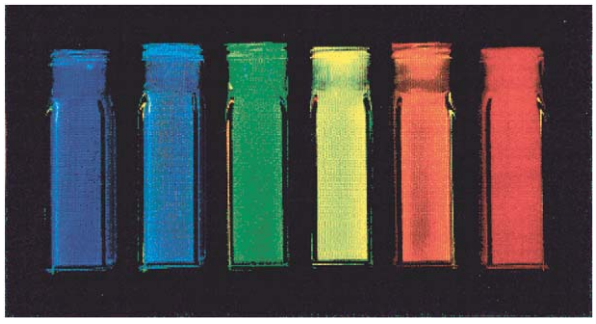

Figure 9 Color photograph demonstrating the wide spectral range of bright photoluminescence (PL) from different size samples of ZnS overcoated CdSe quantum dots, dispersed in dilute hexane solutions placed in identical quartz cuvettes and irradiated with 365 nm UV light. The sizes of the CdSe core increases from the left to the right. Their PL peaks occur at (going from left to right) 470, 480, 520, 560, 594, and 620 nm. (Photograph by F. Frankel) (From Dabbousi BO, Rodriguez-Viejo J, Mikulec FV, Heine JR, Mattoussi H, Ober R, Jensen KF, and Bawendi MG (1997) (CdSe)ZnS core-shell quantum dots: synthesis and characterization of a size series of highly luminescent nanocrystallites. *Journal of Physical Chemistry B* 101(46): 9463–9475.)

Two-Photon Processes and Anti-Stokes Emission

As a rule, the light emission from a center is excited by a single photon. With the availability of high-power light sources, two photons can be absorbed simultaneously and excite the luminescence. In the energy scheme, there is no intermediate level which can be reached by one of the two photons. The probability of such an event is very low and scales with the square of the exciting light intensity, at variance with the one-photon (OP) excited emission, which scales linearly with the incident light intensity, see eqn [3]. The information obtained from the two-photon (TP) excited luminescence spectroscopy is complementary to that obtained from the conventional OP one, because it allows one to study transitions which are forbidden if induced by an OP process, see **Figure 10**.

Generally, there is a large interest in the up-conversion processes, where more than one photon of lower energy is absorbed to cause the emission of a higher-energy photon, for example, to convert IR photons into visible ones. Two simple mechanisms are exemplified for centers with suitable level schemes. (1) In a single center the electron is enhanced by a photon to an excited state, while being there, it absorbs a second photon (excited state absorption, or ESA), reaching a still higher level, then it decays to the ground state by emitting a high-energy photon. (2) Two centers, at rather close distance, are simultaneously excited, then

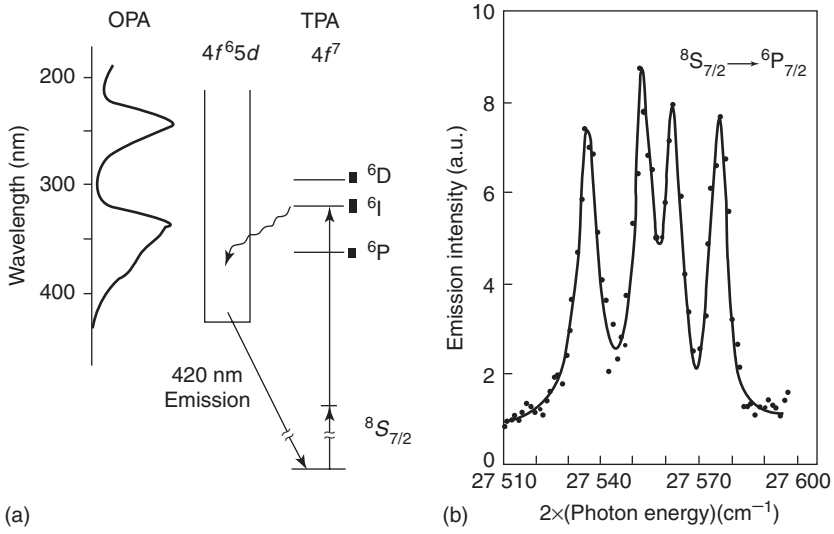

Figure 10 TP excited luminescence in a KCl: Eu single crystal. (a) Comparison between the OP and TP excitation. By the OP excitation the photon induces the allowed electron transition from the ground $4f^7$ to the excited $4f^6$ $5d$ state of Eu^{2+}. The decay to the ground state is accompanied by the blue luminescence (see **Figure 1**) at 420 nm, the emission spectrum of which is portrayed in **Figure 5**. The related excitation spectrum coincides with the OP absorption (OPA) displayed on the left side and in **Figure 5**. By the TP excitation, transitions within the $4f^7$ configuration are allowed, e.g., between the ground $^8S_{7/2}$ and excited ^{6}I manifold: on the left, the two consecutive vertical arrows indicate the TP absorption (TPA). The excited electron relaxes to the $4f^6$ $5d$ state, then decays to the ground state, by emitting the luminescence at 420 nm as above, but the excitation spectrum is different, as shown in (b). (b) TP excitation spectrum ($\lambda_{em} = 420$ nm) excited by the $^8S_{7/2} \rightarrow {}^6P_{7/2}$ transition. At variance with the broad OP excitation spectrum of **Figure 5**, it is characterized by very narrow lines, covering only 1 nm (from 363.5 to 362.5 nm). The four lines are meaningful of $^6P_{7/2}$ manifold splitting induced by cubic crystal field probed by Eu^{2+} in KCl. (From Casalboni M, Francini R, Grassano UM, and Pizzoferrato R (1986) Two-photon spectroscopy in KCl: Eu^{2+}. *Physical Review B* 34: 2936–2938.)

the former de-excites transferring its excitation to the latter, which is raised to a higher level and subsequently decays to the ground state by emitting a high-energy photon: this process is an energy transfer up-conversion. The two processes can be distinguished by analyzing the luminescence decay times (see section on "Time dependence and lifetimes").

The anti-Stokes emission occurs when a substance is excited by a photon of a given energy and emits one of slightly higher energy: seemingly, the Stokes' law is contradicted and more energy is radiated than is absorbed. After absorbing a photon, the center returns to equilibrium by absorbing phonons (heat) from the environment and then it decays to the ground state by emitting a photon, whose additional energy is subtracted from the lattice vibrations. The consequent cooling may be exploited for prospective interesting applications.

Down-conversion processes (or quantum cutting) should also be considered. A UV photon (with an energy higher than twice the energy of a visible photon) excites a center and the subsequent de-excitation takes place, for example, through a cascade emission of two visible photons. In this way, a quantum yield η, in terms of the ratio of the emitted visible photon number to that of the absorbed ones, may be >1, see eqn [6]. The process may be exploited to tailor UV-excited phosphors with enhanced emission in the visible range, for lighting applications.

Thermoluminescence

Thermoluminescence (TL) is light emission caused by moderate heating of a solid, previously exposed to ionizing radiation. It is displayed at temperatures at which the blackbody light emission is negligible. The exposure to the ionizing radiation (X- or γ-rays, high-energy particles) takes place at rather low temperatures, creates traps, and fills them (or those already present) with electrons and/or holes. The subsequent heating makes the electrons and/or holes free to migrate in the lattice, until they fall into other traps (or recombine) with a consequent photon emission (**Figure 3d**). A comprehensive description of TL is provided by 3D spectra, in which the emitted light intensity is plotted versus temperature T and emitted wavelength λ_{em}, the heating rate being, as a rule, constant, see **Figure 11**. From the analysis of such plots, the energy depth of traps can be evaluated. For many purposes, the simpler plot of the total emitted light intensity I_{TL} (regardless of the wavelength) as a function of T supplies valuable information. Materials which display one or more TL peaks which are linear functions of the absorbed radiation dose can

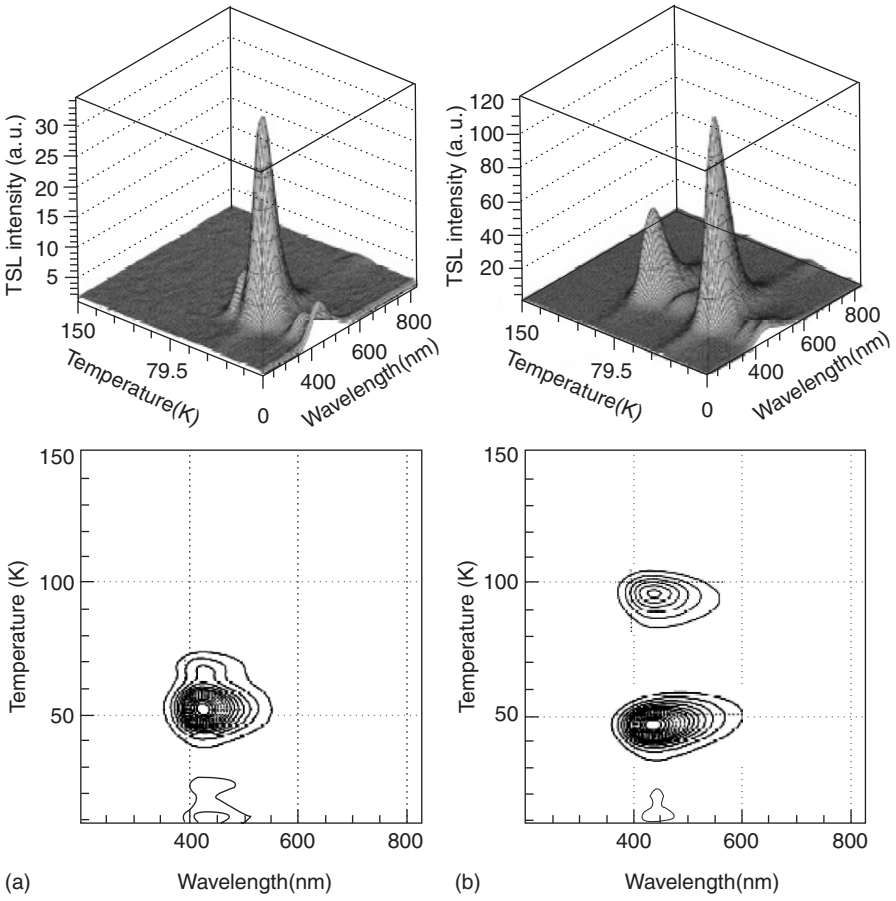

Figure 11 Example of wavelength-resolved TL of a scintillator. 3D TL measurement and contour plot of the TL in the 10–150 K range, following X-ray irradiation at 10 K of undoped (a) and La^{3+} doped $PbWO_4$ single crystal. The high density and fast radioluminescent (scintillation) response make it interesting for application in high-energy physics experiments. The comparison between (a) and (b) plots shows that the La^{3+} doping increases the emitted light intensity and introduces at least an additional TL peak. (From Martini M, Meinardi F, Spinolo G, Vedda A, Nikl M, Usuki Y (1999) Shallow traps in PWO_4 studied by means of wavelength-resolved thermally stimulated luminescence. *Physical Review B* 60: 4653–4658.)

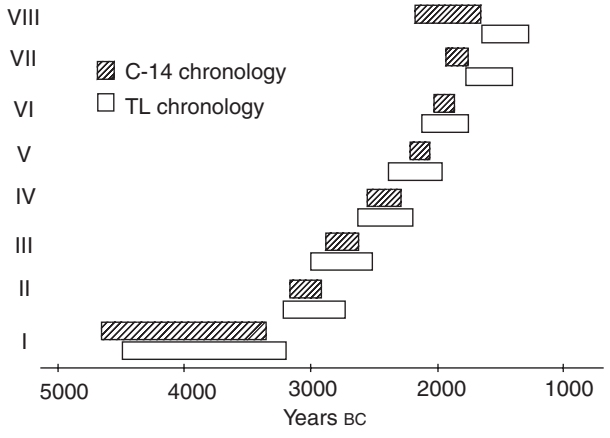

Figure 12 Example of TL application for dating. Comparison between independent absolute TL and radiocarbon (^{14}C) chronologies for dating ceramics of Valdivia culture (Ecuador). (From Martini M and Sibilia E (2001) Radiation in archeometry: archeological dating. *Radiation Physics and Chemistry* 61: 241–246.)

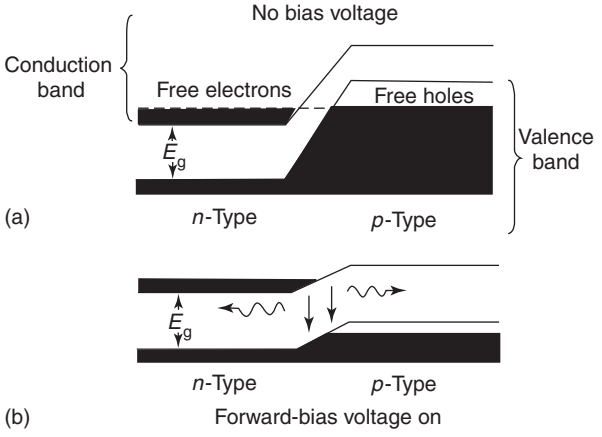

Figure 13 The EL process in an LED. A *p*–*n* junction is shown. (a) The junction is not voltage biased; (b) the junction is forward biased: the energy levels bend and, as a consequence, in the junction some free electrons in the CB recombine with free holes in the VB giving up the energy as light (EL). The mechanism is the same as in **Figure 3a**.

be exploited as dosimeters. If a calibration curve of I_{TL} versus dose is known, it is easy to evaluate the dose absorbed by a dosimeter that is, for example, worn by an individual exposed to radiation, by reading the TL emission spectrum. TL also provides a tool to date buried materials of archeological (e.g., pottery) or geological interest (e.g., stalagmites). In this case, the radiation dose is supplied by the decay of radioactive isotopes (e.g., ^{40}K, Th, and U) present in the soil. By estimating the dose/year supplied by the surrounding soil (paleodose), it is possible to evaluate the time elapsed from the last firing of a pottery item and detect possible counterfeiting. With very few exceptions, the consistency of the TL results with other absolute dating methods is found to be good, see **Figure 12**.

Electroluminescence

The application of an electric field to an insulator or semiconductor can cause the injection of electrons and/or holes. The recombination between electrons

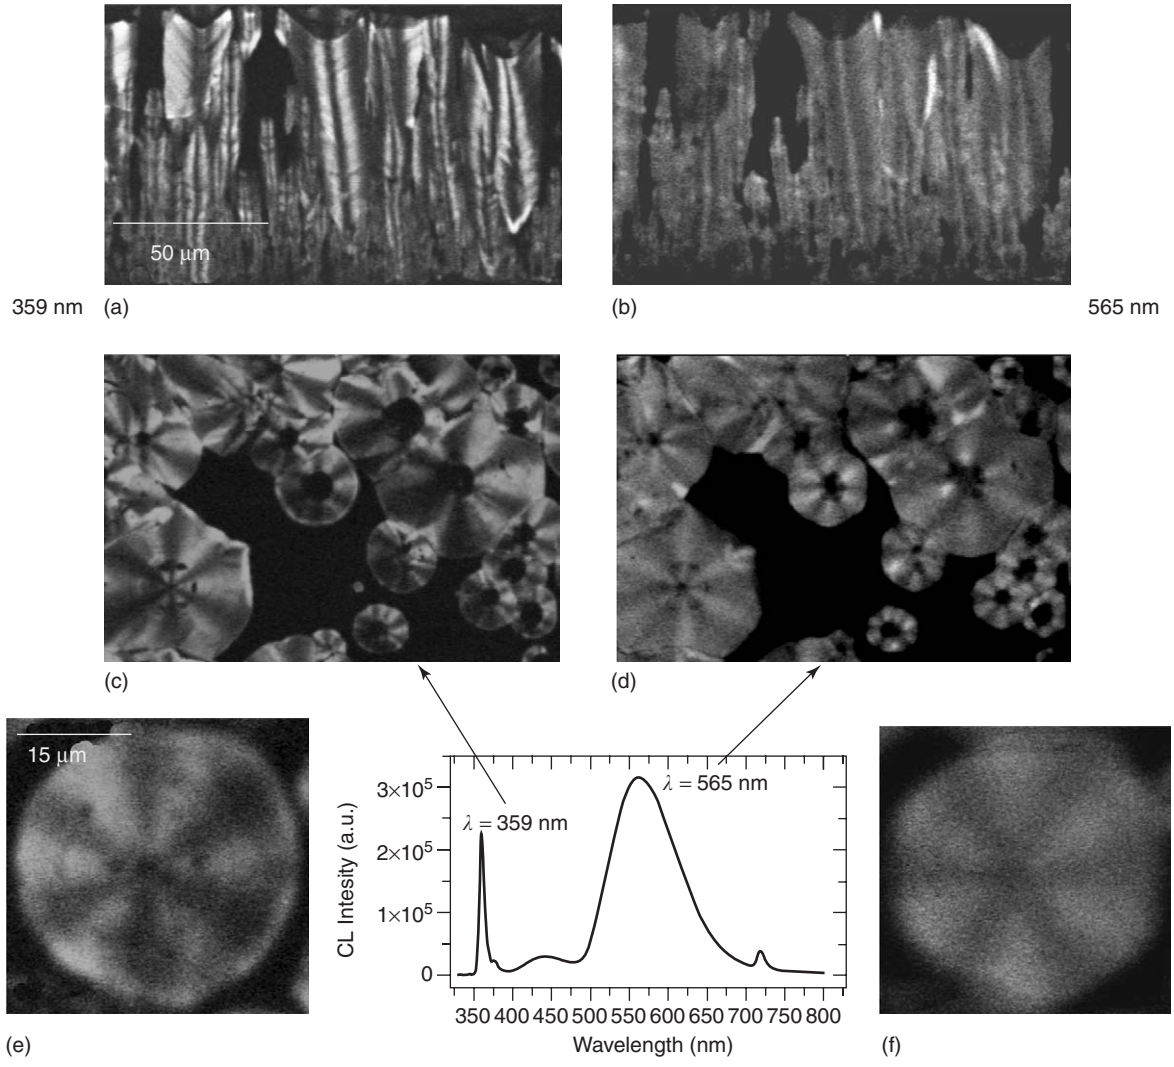

Figure 14 Example of CL excited by an SEM electron beam at 5 K in a bulk GaN sample. The emission is monitored at 359 nm (near UV) in (a), (c), and (e) images and at 565 nm (yellow) in (b), (d), and (f) images. The bright regions in both cases are those in which the related CL emission is strong. (a) and (b) are the monochromatic (at 359 and 565 nm, respectively) CL images of the same columnar structures in the sample. (c) and (d) are the CL images of the cross sections of the columnar structures, related to (a) and (b), respectively. (e) and (f) supply the magnification of one of the hexagonal structures (the same) displayed by (c) and (d). Note that the dark and bright regions are complementary. The CL spectrum, i.e., the CL intensity vs. emission wavelength λ_{em}, is displayed between the (e) and (f) images. The two main peaks at 359 and 565 nm are attributed to GaN near band edge (NBE) emission and to Si-related defects, respectively. This suggests that Si-related defects segregate along preferential directions. (From Salviati G, Albrecht M, Zanotti-Fregonara C, Armani N, Mayer M, Guzzi M, Melnik YuV, Vassilevski K, Dmitriev VA, and Strunk HP (1999) Cathodoluminescence and transmission electron microscopy study of the influence of crystal defects on optical transition in GaN. *Physics Status Solidi* (*a*) 171: 325–339.)

and holes may be accompanied by light emission, which is named electroluminescence (EL). ZnS was reported to be the first example of an electroluminescent material in 1936 by G Destriau, working in Madam Curie's laboratory. The widespread applications of LEDs are based on EL of a *p–n* junction. The charge carriers are the electrons in a CB for the *n*-type material, and holes in a VB for the *p*-type. When a forward-bias voltage is applied to the diode, the energy levels bend, see **Figure 13**: the concentration of electrons in a CB near the junction on the *n*-side increases as that of holes in the VB near the junction on the *p*-side. The electrons and holes recombine by emitting photons, whose energy is equal to that associated with the energy gap E_g. Modern semiconductor device fabrication techniques allow bandgap engineering, and junctions can be produced from semiconductors or their alloys in which E_g corresponds to almost any wavelength in the visible light spectrum, as for example, GaAs and GaN LEDs that emit in the near IR and in the blue, respectively. The junction can also work as an active medium for diode lasers (e.g., laser pointers) as a feedback is provided by the reflective ends of the laser material and most of the light is produced by stimulated emission. The use of heterojunctions improves the light confinement.

Cathodoluminescence

Fast electrons (the J J Thomson cathode rays) supply energy enough to excite a phosphor and induce light emission as cathodoluminescence (CL). The color-TV screen operation is based on CL. The electrons emitted by the electron gun in the cathode-ray tube strike little triads of different phosphor dots, which emit blue, green, and red CL. The phosphors exploit the light emission from suitable impurities, for example, Cu and Ag in ZnS (blue and green) and Eu in Y_2O_2S (red). The CL induced by the electron beam striking the sample under study in an electron microscope is used nowadays to investigate its physical properties, as for example, the impurity mapping (see **Figure 14**).

Magnetic Domains

O Portmann, A Vaterlaus, C Stamm, and D Pescia, Laboratorium für Festkörperphysik der ETH Zürich, Zürich, Switzerland

Introduction

The Dirac equation for the relativistic quantum mechanical electron is most famous for having predicted the existence of antiparticles. One further important aspect of this equation is the explanation of the electron spin and the magnetic moment associated with it. When atoms are formed, the electron spins interact by means of the intra-atomic exchange interaction to produce atomic magnetic moments. The correct value of the atomic magnetic moments can be calculated empirically using Hund's rules and Pauli's principle. When atoms are brought together to form a body, the atomic wave functions change drastically: the atomic magnetic moments are, in general, reduced, but may remain finite in certain special cases such as Fe, Co, and Ni. Moreover, as soon as neighboring atoms are provided, the interatomic exchange interaction comes into play and may favor the parallel alignment of the neighboring magnetic moments. In this way, macroscopic regions of aligned magnetic moments are formed in the body, and the body is said to be in a ferromagnetic state.

This microscopic description of magnetism, based on the quantum mechanical exchange interaction, is not complete. Each individual magnetic moment can be viewed as an atomic current generating a magnetic field, which interacts with other magnetic moments and contributes another term to the total magnetic energy – the energy of the dipole–dipole interaction. This term is also called the magnetostatic energy, as it is described by the Maxwell equations of magnetostatics. In contrast to the exchange interaction, this term is purely classical. It is later shown that, depending for example on the shape and size of the body, this term perturbs the parallel alignment of the magnetic moments favored by the exchange interaction. Thus the parallel alignment does not extend over the whole body, but is restricted to elementary regions called magnetic domains. Within such domains, the magnetic moments are aligned, while the orientation of the magnetic moments changes upon moving to neighboring domains.

Another class of magnetic interactions arises because of the spin–orbit coupling also contained in the Dirac equation: magnetic anisotropies. A magnetic anisotropy energy determines one or more spatial directions along which the exchange-coupled magnetic moments within the domains prefer to be aligned, where "preferring" means that the total energy of the system is reduced when the moments pointf along that direction in space. Magnetic anisotropies play a crucial role in domain formation. In fact, the change of the magnetic moment direction between consecutive domains does not occur abruptly: a domain wall with finite width connects domains with different magnetic moment orientation and magnetic anisotropies stabilize this wall.

The purpose of this article is to account for the state-of-the-art knowledge on magnetic domains and the walls between them. Before going into details, it is important to estimate the energy scale of the various magnetic interactions, given by their typical strength per atom. The intra-atomic exchange interaction is of the order of eV, on a temperature scale this corresponds to 10^4 K. This energy is required to produce an excited state with no atomic magnetic moment. The interatomic exchange interaction is some 10 meV (100 K). This means that the excited state with misaligned nearest-neighbor magnetic moments is attained when the temperature exceeds some 100 K (at a temperature which is called the Curie temperature). Magnetic anisotropies range from μeV in three-dimensional solids to 0.1 meV in ultrathin films (0.01 to 1 K). The reason for this broad range is that the magnetic anisotropies are strongest when the symmetry of the system is lowered, for example, when the dimensionality is reduced. The magneto-static interaction is $\sim$0.1 meV (1 K). Clearly, the interactions relevant for domain formation are much smaller than the exchange interaction. Thus, it is not immediately evident why such small energies should have an impact in determining the total energy of the system and its ground-state magnetic moment configuration. This question is also carefully investigated in the remaining sections.

The Physical Basis of Magnetic Domains

The physical basis for the explanation of magnetic domains was laid down in a paper by Landau and Lifshitz in 1935. One can consider a body in a situation where each lattice site carries a magnetic moment vector (for simplicity, a spin vector is used, noticing that, according to Dirac's theory, the two vectors are proportional to each other). One important caveat: it will turn out that the relevant length scales intervening in domain formation are large with respect to the lattice constant. On these characteristic length scales, the number of spins is so large that one can give up the quantum description of the spin vector and consider it a classical vector. The strongest contribution to the total magnetic energy comes from the exchange interaction, which measures the energy required to turn two neighboring spins into an antiparallel configuration. If this energy is positive, the total exchange energy is minimized by a uniform spin configuration. The spin ensemble can also have a magnetic anisotropy energy contribution, which favors certain spatial directions for the spins, the so-called easy direction. In the simplest case of uniaxial anisotropy, two directions in space, say $\boldsymbol{e}$ and its negative, are energetically favored. Thus, the uniform spin configuration will be aligned either along $+\boldsymbol{e}$ or along $-\boldsymbol{e}$, as either of these directions minimizes the total energy arising from the exchange and the magnetic anisotropy. How stable is the resulting spin configuration with respect to rotations or spin nonuniformities? The magnetic anisotropy per spin is very small but it is not possible to rotate spins individually, as they are bound together by the exchange interaction. Thus, a rotation excitation would involve turning a macroscopically large amount of spins and this requires a large excitation energy which is not available at sufficiently low temperatures. If the body is divided into oppositely magnetized regions, it would not entail any lowering of the total energy; on the contrary, some energy must be introduced to form boundaries between oppositely magnetized regions, causing an increase of the total energy. A more complicated anisotropy term may have a larger symmetry, but in no case will the magnetic anisotropy lead to magnetic domains as there is no energy to be gained upon changing from one easy direction to another. The behavior is quite different when the dipolar interaction between the magnetic moments is considered. Each moment produces a magnetic field, which interacts with all the other magnetic moments by means of the Zeeman energy contribution. The most striking feature of this magnetostatic energy is that the magnetic fields arising from a magnetic moment are very long ranged, they decay only with the third power of the distance. This is in opposition to exchange and magnetic anisotropies, which are local. The energy due to the dipolar field is the most complicated (see Appendix A), but contains a distinct feature which makes it compete directly with the exchange interaction: one part of it favors an antiparallel alignment of the spins. Of course, the interaction is very weak, but its long-range character amplifies its role with respect to the competing exchange interaction. Thus, under certain circumstances, which Landau and Lifshitz showed to depend on the size and the geometry of the body, the dipolar interaction can provide enough energy gain to sustain a nonuniform spin configuration: magnetic domains arise.

The complexity of the dipolar field and the long-range character of the dipolar interaction makes it very difficult to find the spin configuration that minimizes the total energy. However, there are some rules of thumb that help in analyzing the physical situation. One of them is provided by eqn [3] in Appendix A. This equation has a simple meaning: the total magnetostatic energy of a body is the Coulomb energy of an effective magnetic charge distribution $\rho_M \doteq -\boldsymbol{\nabla} \cdot \boldsymbol{M}(\boldsymbol{x})$, where $\boldsymbol{M}(\boldsymbol{x})$ is the magnetic moment per unit volume. Its length is determined by the total magnetic moment in a sufficiently small cell centered at $\boldsymbol{x}$ divided by the volume of the cell, and its direction is given by the direction of the total magnetic moments within this cell. The size of this cell has to be chosen in such a way that it is small with respect to the smallest length occurring in domain formation, that is the size of the domain wall (see next section). The effective magnetic charge is provided by the divergence of $\boldsymbol{M}(\boldsymbol{x})$, thus minimizing the magnetostatic energy means avoiding regions where $-\boldsymbol{\nabla} \cdot \boldsymbol{M}(\boldsymbol{x})$ is too large. A sizeable divergence of $\boldsymbol{M}(\boldsymbol{x})$ exists, for instance, at the boundaries of a uniformly magnetized body. Such surface charges increase the energy of the uniform spin configuration above the value specified by the exchange interaction. To avoid such charges, the body can split into elementary regions of different magnetization. At the boundaries between such regions, the spin vectors make a finite angle so that the exchange energy is increased (at the walls) with respect to the uniform configuration. Despite this, Landau and Lifshitz have explicitly shown that by introducing domains, the total energy might effectively be lowered. In Appendix B, a simple case is worked out where the subtleties of such total-energy minimization calculations are shown.

At the end of this section, an example illustrating this "magnetic-charges" avoidance rule is discussed.

One can compare a small ferromagnetic plaquette with square geometry and a uniform spin configuration (see **Figure 1a**) to an identical plaquette with a particular nonuniform spin configuration where the magnetization vector circulates along a closed path within the plaquette (**Figure 1b**). The spin configuration in **Figure 1a** contains some effective magnetic charges appearing at the boundaries perpendicular to the magnetization vector. The spin configuration in **Figure 1b** is a very peculiar one, the magnetization vectors between two consecutive domains are orthogonal and no divergence develops at the boundary between two consecutive domains. The spin configuration in **Figure 1b** is free of magnetic charges and has no magnetostatic energy. One can show that when the plaquette is sufficiently large, the gain in magnetostatic energy overcomes the cost of introducing domain walls: the configuration in **Figure 1b** is the ground state. Experimentally, this closed path configuration is indeed observed, see **Figure 1c** as an illustration. The butterfly shape of the plaquette in **Figure 1c** is more complicated than the square plaquette just considered. Correspondingly, the experimental domain distribution (indicated by arrows), is more complex. It is also evident from **Figure 1c** that similar triangular plaquettes – the wings in the figure – have a slightly different domain distribution, showing that unresolved differences play a crucial role in determining the actual domain configuration. However, one essential element dominates the central parts of both wings: the domains are arranged in such a way that the magnetization vector circulates within the plane of the plaquette, avoiding the formation of magnetic charges, in agreement with the rule of thumb.

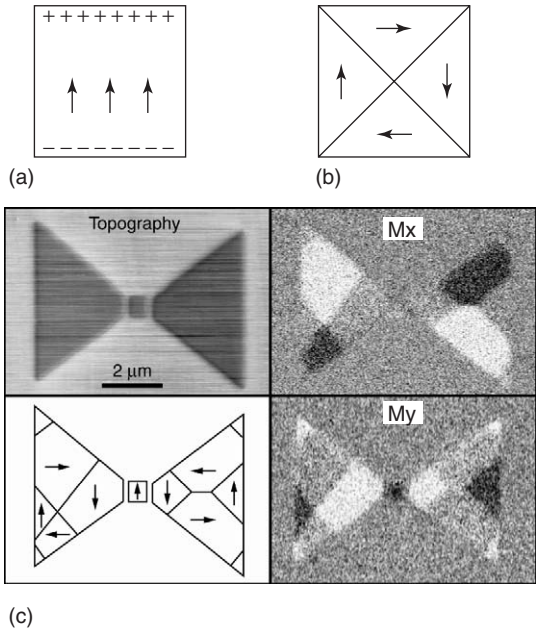

Figure 1 (a) and (b): Schematic domain distribution in a plaquette. In (a) the uniform magnetization produces magnetic surface charges, indicated in the figure. In (b) the magnetization vector follows a closed path, thus avoiding magnetic charges. (c) Image of the domain distribution in a plaquette with butterfly shape. The images were taken using scanning electron microscopy with polarization analysis (SEMPA). In SEMPA, a finely focused electron beam impinges onto the surface of a solid. Secondary electrons are ejected and used to map the topography of the surface while the beam is scanned across the surface. In the present case a $\sim$14 nm thick Co film was deposited onto a Cu(1 0 0) surface by molecular beam epitaxy (MBE) through a mask inserted between MBE source and substrate. In this mask, a butterfly-profile was carved in by focused ion beam milling, which gives rise to the laterally patterned Co film visible in the topography image. In SEMPA, not only the secondary electron current is measured, but their spin polarization is also detected. This allows mapping the surface magnetization vector. The in-plane horizontal (M_x) and vertical (M_y) components of $\boldsymbol{M}$ are reproduced in (c) (the component perpendicular to the film plane vanishes). The black-white constrast is indicative of a strong magnetization in opposite directions. The Cu-substrate is nonmagnetic and appears gray. From the contrast maps of the two in-plane components, the domain distribution can be reconstructed as schematically summarized by the arrows.

Domain Walls

Although it is the magnetostatic energy contribution that drives the rearrangement of the spin configuration into domains, it is the magnetic anisotropy that stabilizes the walls between them and makes the whole rearrangement process possible. For the sake of simplicity, the creation of a domain wall in a one-dimensional spin chain is illustrated. One can consider a chain extending along the x direction with fixed-length spin vectors $S(x)$ being allowed to rotate in the y–z plane. Thus, $S = S(0, \sin\theta(x), \cos\theta(x))$, S being the (dimensionless) length of the spin vector and θ the angle between the vector S and the y direction. The variable x is allowed to assume continuous values which is equivalent to say that, if any deviation from the parallel spin alignment occurs, it occurs over spatial length scales much larger than the lattice constant a. Assuming an exchange coupling between nearest neighbors of the simple form $-J \cdot S(x) \cdot S(x+a)$ ($J>0$ being the exchange constant), any deviation from the parallel spin alignment can be worked out to increase the exchange energy by an amount $\Delta_\Gamma = \{(\Gamma \cdot a)/2 \cdot \int \mathrm{d}x[\mathrm{d}\theta(x)/\mathrm{d}x]^2\}$ with the coupling constant $\Gamma = (J/2)S^2 z$ (z being the number of nearest neighbors, that is, 2 for a chain). A magnetic anisotropy term which favors the y direction for the spin is $\Delta_\lambda = (\lambda/(2a)) \int \mathrm{d}x \sin^2\theta(x)$ with the coupling constant λ measuring the energy required to turn the spin away from the y direction. Notice that, in accordance with the above discussion,

$\Gamma \gg \lambda$. The equilibrium $\theta(x)$ is found by setting the functional variation of $\Delta_\Gamma + \Delta_\lambda$ to zero, which produces the Euler equation of the variational problem:

$$\Gamma a \frac{d^2\theta}{dx^2} - \frac{\lambda}{a} \sin\theta \cos\theta = 0 \qquad [1]$$

One can study the stability of a wall by solving this equation with the following boundary conditions: $\theta = \pi$ (0) for $x = -\infty$ ($+\infty$), and $d\theta/dx = 0$ for $x = \pm\infty$. This establishes a spin profile with domains of opposite spins on the left- and right-hand side of $x = 0$. The solution to the Euler equation with these boundary conditions exists and was found in the work of Landau and Lifshitz:

$$\cos\theta = \tanh\frac{2x}{w} \qquad [2]$$

$w = 2a \cdot \sqrt{\Gamma/\lambda}$ being the width of the region near $x = 0$ over which the spin rotates from one domain to the domain of opposite magnetization, that is, the domain wall width. This solution is plotted in **Figure 2b** as a continuous curve. The wall energy (i.e., the energy required to establish a wall) per unit wall area can be calculated analytically by inserting the solution into the total energy expression: $\sigma_w = (1/(a^{\delta-1}))\sqrt{\lambda \cdot \Gamma}$. The prefactor contains the dimensionality of the system δ. For the interaction strengths discussed in the introduction, w is expected to be of the order of some 100 lattice constants, which is a mesoscopic scale. A direct measurement of the spin profile inside the domain wall at the surface of an Fe single crystal indeed gives ≈ 200 nm. As an example, one can consider the domain image of a head-on magnetization distribution recorded in a thin epitaxial Fe film on $W(1\,1\,0)$ (**Figure 2a**). The spatial resolution of the image is such that the continuous in-plane rotation of the magnetization vector from one direction into the opposite direction occurring at the boundary between the two domains can be detected in detail. The rotation is illustrated with a color code explained in the caption. The experimental profile of the magnetization component that changes sign, given by the circles in **Figure 2b**, follows the calculated profile (continuous curve in **Figure 2b**), obtained by fitting the experimental data with tanh $(2x/w)$.

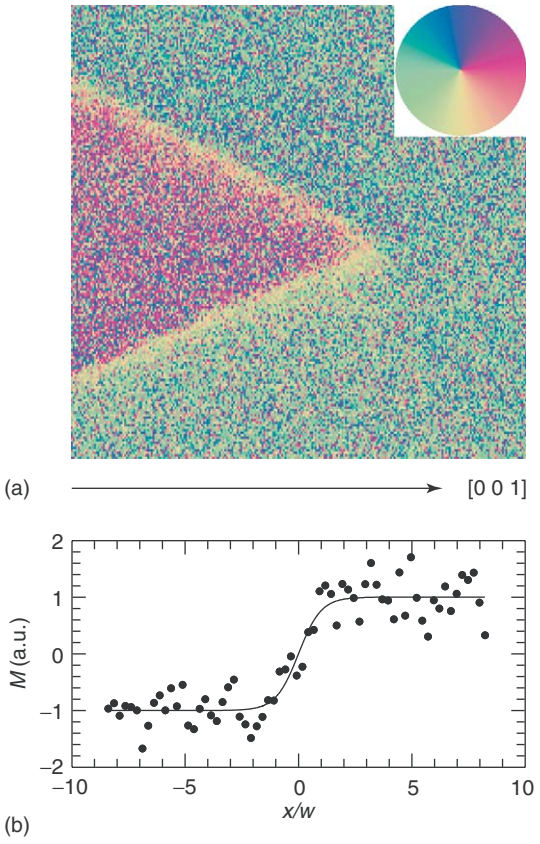

Figure 2 (a) Domain wall formation between head-on magnetized domains. The two domains, represented by different colors, are magnetized in opposite directions parallel to the horizontal axis (the [0 0 1]-direction of the cubic lattice, in this case). At the boundary between them, one recognizes that the magnetization vector rotates in the plane from one direction into the opposite one. A color code is used to represent the direction of the magnetization vector. Image size: $4.6 \times 4.6\,\mu m^2$ (b) The horizontal component of the magnetization vector (divided by its value well within the domains) is plotted along an axis x, drawn perpendicular to the domain wall (full circles). At the domain boundary, the value of the component makes a transition that can be fitted by the calculated tanh - profile (continuous curve), with a characteristic wall width $w \approx 140$ nm. To improve the statistical accuracy of the experimental profile, all experimental data points within a stripe going across the wall were averaged.

An Example of Magnetic Domains: Stripes

Having established the physical basis for domain formation, the details can be worked out, which will help to achieve a deeper understanding of the energy balance which leads to domain formation. As anticipated, magnetostatic charges have to be considered, which means that the geometry and size of the body are central to the problem. For one special geometry, the appearance of domains is illustrated (for many other geometries which have been investigated so far, see the "Further reading" section). The special case of ultrathin magnetic film extending to infinity in the x_1–x_2 plane and having a finite but small thickness d in the x_3 direction (**Figure 3a**) is worked out in detail. The magnetization vector is taken to be perpendicular to the film plane. The perpendicular magnetization in ultrathin films is a very special configuration, requiring a strong uniaxial

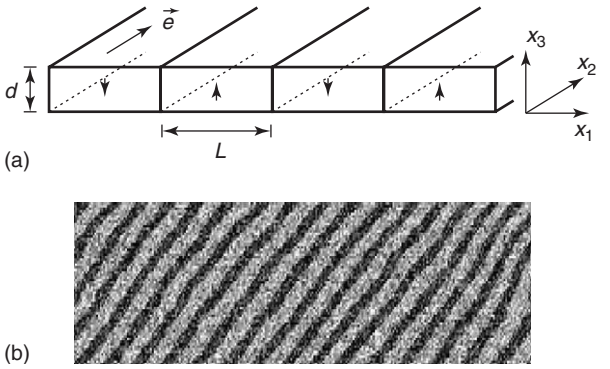

Figure 3 (a) Schematic view of an ultrathin film (thickness d) with a stripe configuration (stripe width: L) of alternating perpendicular magnetization. The geometrical elements used in Appendix B are also indicated. (b) Room temperature SEMPA image of the stripe phase in an ultrathin ($d \approx 0.3$ nm) Fe film deposited on Cu(1 0 0) by means of MBE. The image is 92.2 μm long. The component of the magnetization vector perpendicular to the film plane is shown. The black-white contrast is indicative of oppositely magnetized stripes.

magnetic anisotropy to overcome the demagnetizing effect of the dipolar interaction. This demagnetizing effect is best appreciated by comparing a uniform in-plane spin configuration with a uniform perpendicular spin configuration. The in-plane configuration has no magnetostatic energy, provided the film extends to infinity. The perpendicular configuration, on the other hand, produces opposite charges at the two boundaries of the film with vacuum. This gives rise to an electrical plane condenser geometry. Using eqn [4] in Appendix A, the magnetostatic energy (per unit area) can easily be calculated to be $2\pi M_0^2 d$ and must be overcome by a strong magnetic anisotropy favoring the perpendicular configuration in order for a perpendicular magnetization to appear.

The possibility of the existence of a nonuniform perpendicular spin configuration that might lower the energy of the system with respect to the uniform configuration in the given perpendicular magnetic configuration is examined. A possible nonuniform spin configuration with perpendicular magnetization is the one consisting of stripes of opposite perpendicular magnetization running parallel to say x_2 and repeating periodically along x_1, see **Figure 3a**. Such a configuration does certainly not introduce any extra magnetic anisotropy energy. Domain walls, however, are created and cause an increase of the exchange energy. The striped phase can only become energetically more favorable if the gain in magnetostatic energy is large enough to overcome the extra domain wall energy (this is shown to happen exactly in Appendix B). The stripes have an equilibrium width $L^* \propto w \cdot e^{\pi L_0/2d}$. L_0 is the so-called dipolar length $L_0 \doteq \sigma_w/(2\pi M_0^2)$, and is related to the characteristic dipolar energy per atom $(2\pi M_0^2 \cdot a^3)$. Using the characteristic values as discussed in the introduction, one obtains L_0 of the order of $100a$. Thus, in the ultrathin limit $d \approx a$, the equilibrium stripe width L^* can reach astronomical values at $T = 0$: the ground state will appear to be a uniform single-domain spin configuration because the stripe width might be much larger than the size of the sample. However, when the temperature is increased, the various coupling constants renormalize and the stripe phase can penetrate the sample as its width reduces to mesoscopic lengths. This situation is indeed observed to occur in several perpendicularly magnetized ultrathin films where the stripe phase has been observed to develop. An example is given in **Figure 3b** for Fe films on Cu(1 0 0).

Appendix A: Magnetostatic Energy of a Localized Distribution $M(x)$

A useful starting point for finding the magnetostatic energy of a continuous static distribution $\boldsymbol{M}(\boldsymbol{x})$, are the Maxwell equations of magnetostatics: $\boldsymbol{\nabla} \cdot \boldsymbol{B} = 0$ and $\boldsymbol{\nabla} \times (\boldsymbol{B} - 4\pi \boldsymbol{M}) = 0$. The magnetic field $\boldsymbol{H}$ defined as $\boldsymbol{H} \doteq \boldsymbol{B} - 4\pi \boldsymbol{M}$ can be written in terms of a magnetic potential, $\Phi_M : \boldsymbol{H} \doteq -\boldsymbol{\nabla}\Phi_M$. The first Maxwell equation now corresponds to the Poisson equation of an "effective magnetic charge" $\rho_M \doteq \boldsymbol{\nabla} \cdot \boldsymbol{M} : \boldsymbol{\nabla}^2 \Phi_M = -4\pi\rho_M$. Thus, the magnetostatic problem has been transformed into an electrostatic problem involving charges ρ_M. Their energy amounts to (Coulomb)

$$E_M = \frac{1}{2} \int \mathrm{d}^3x \, \mathrm{d}^3y \frac{\rho_M(\boldsymbol{x})\rho_M(\boldsymbol{y})}{|\boldsymbol{x} - \boldsymbol{y}|} \qquad [3]$$

This expression for E_M states that a possible way to minimize the magnetostatic energy is to avoid magnetic charges, that is to minimize the magnitude of $\rho_M \doteq -\boldsymbol{\nabla} \cdot \boldsymbol{M}$. A further useful expression for the energy involves the magnetic field $\boldsymbol{H}$:

$$\begin{aligned} E_M &= \frac{1}{2} \int \mathrm{d}^3x \, \mathrm{d}^3y \, \frac{\rho_M(\boldsymbol{x})\rho_M(\boldsymbol{y})}{|\boldsymbol{x} - \boldsymbol{y}|} = \frac{1}{2} \int \mathrm{d}^3x \rho_M(\boldsymbol{x})\Phi_M(\boldsymbol{x}) \\ &= -\frac{1}{8\pi} \int \mathrm{d}^3x \big(\nabla^2 \Phi_M(\boldsymbol{x})\big)\Phi_M(\boldsymbol{x}) \\ &= \frac{1}{8\pi} \int \mathrm{d}^3x \boldsymbol{H}^2(\boldsymbol{x}) \end{aligned} \qquad [4]$$

where the general solution of the Poisson equation $\Phi_M(\boldsymbol{x}) = \int \mathrm{d}^3y \rho_M(\boldsymbol{y})/|\boldsymbol{x}-\boldsymbol{y}|$ is used. According to eqn [4], minimizing E_M means searching for a spin configuration which avoids the formation of stray fields $\boldsymbol{H}$.

From eqn [3], an often quoted expression for E_M can be derived. After a partial integration, the surface integral vanishes provided the magnetization distribution is localized. Using $\nabla^2 1/|\boldsymbol{x}-\boldsymbol{y}| = -4\pi\delta(\boldsymbol{x}-\boldsymbol{y})$, one obtains

$$\begin{aligned} E_M &= -\frac{1}{2}\int \mathrm{d}^3x\mathrm{d}^3y \boldsymbol{M}(\boldsymbol{x})\cdot\boldsymbol{\nabla}_x \frac{\boldsymbol{\nabla}_y\cdot\boldsymbol{M}(\boldsymbol{y})}{|\boldsymbol{x}-\boldsymbol{y}|} \\ &= \frac{1}{2}\int \mathrm{d}^3x\mathrm{d}^3y \boldsymbol{M}(\boldsymbol{x})\cdot\boldsymbol{\nabla}_x\left(\boldsymbol{M}(\boldsymbol{y})\cdot\boldsymbol{\nabla}_y\frac{1}{|\boldsymbol{x}-\boldsymbol{y}|}\right) \\ &= \frac{1}{2}\int \mathrm{d}^3x\mathrm{d}^3y \left(\frac{\boldsymbol{M}(\boldsymbol{x})\cdot\boldsymbol{M}(\boldsymbol{y})}{|\boldsymbol{x}-\boldsymbol{y}|^3} \right. \\ &\quad \left. -3\frac{[\boldsymbol{M}(\boldsymbol{x})\cdot(\boldsymbol{x}-\boldsymbol{y})][\boldsymbol{M}(\boldsymbol{y})\cdot(\boldsymbol{x}-\boldsymbol{y})]}{|\boldsymbol{x}-\boldsymbol{y}|^5}\right) \\ &\quad + \frac{2\pi}{3}\int \mathrm{d}x^3 \boldsymbol{M}(\boldsymbol{x})^2 \end{aligned} \qquad [5]$$

This equation states that the magnetic "dipole" $\boldsymbol{M}(\boldsymbol{x})$ interacts with a $\boldsymbol{H}$ field

$$\begin{aligned} \boldsymbol{H}(\boldsymbol{x}) = \int \mathrm{d}y^3 \left(-\frac{\boldsymbol{M}(\boldsymbol{y})}{|\boldsymbol{x}-\boldsymbol{y}|^3}\right. \\ + 3\frac{[\boldsymbol{M}(\boldsymbol{y})\cdot(\boldsymbol{x}-\boldsymbol{y})](\boldsymbol{x}-\boldsymbol{y})}{|\boldsymbol{x}-\boldsymbol{y}|^5} \\ \left. -\frac{4\pi}{3}\boldsymbol{M}(\boldsymbol{y})\delta(\boldsymbol{x}-\boldsymbol{y})\right) \end{aligned} \qquad [6]$$

produced at $\boldsymbol{x}$ by all other dipoles at $\boldsymbol{y}$ (the last term is the own field of the dipole at $\boldsymbol{x}$). This expression for E_M is often called the dipolar energy due to the dipole–dipole interaction.

A third useful equation can be derived from eqn [4] using the identity $\int \mathrm{d}^3x \boldsymbol{H}\cdot\boldsymbol{B} = 0$, holding for a localized distribution $\boldsymbol{M}(\boldsymbol{x})$:

$$E_M = 2\pi\int \mathrm{d}^3x\, \boldsymbol{M}^2(\boldsymbol{x}) - \frac{1}{8\pi}\int \mathrm{d}^3x\, \boldsymbol{B}^2 x \qquad [7]$$

Accordingly, if the length of the magnetization vector is a constant, a spin configuration with a low magnetostatic energy requires maximizing the magnetic field $\boldsymbol{B}$.

Using the same identity, one can immediately derive

$$E_M = -\frac{1}{2}\int \mathrm{d}^3x\, \boldsymbol{H}\cdot\boldsymbol{M} \qquad [8]$$

Finally, one can transform eqn [7] into the interaction energy of a system of effective currents $\boldsymbol{J}_M \doteq c\boldsymbol{\nabla}\times\boldsymbol{M}$. With $\boldsymbol{B} = \boldsymbol{\nabla}\times\boldsymbol{A}$ and $\boldsymbol{\nabla}\times(\boldsymbol{\nabla}\times\boldsymbol{A}) = -\nabla^2\boldsymbol{A}$ (in the Coulomb gauge), one obtains $\boldsymbol{\nabla}^2\boldsymbol{A} = -4\pi/c\,\boldsymbol{J}_M$. Finally, from this Poisson equation for $\boldsymbol{A}$, one can obtain

$$E_M = 2\pi\int \mathrm{d}^3x\, \boldsymbol{M}^2(\boldsymbol{x}) - \frac{1}{2c^2}\int \mathrm{d}^3x\, \mathrm{d}^3y \frac{\boldsymbol{J}_M(\boldsymbol{x})\boldsymbol{J}_M(\boldsymbol{y})}{|\boldsymbol{x}-\boldsymbol{y}|} \qquad [9]$$

Thus, minimizing the magnetostatic energy means searching for a spin configuration that maximizes the curl of $\boldsymbol{M}$.

Appendix B: The Equilibrium Stripe Width

It is very instructive for the reader to follow in detail the appearance of domains for a very specific case. One can consider perpendicularly magnetized ultrathin films of thickness d extending over a large area $\Lambda_1 \times \Lambda_2$ in the $x_1 - x_2$ plane, see **Figure 3a**. The magnetization within each stripe points along $\pm x_3$. The stripes of width L are taken to be parallel to x_2. They are joined by walls with a finite width ω with $d \ll w \ll L$. Consecutive stripes have opposite perpendicular magnetizations. The total wall energy E_w amounts to $\sigma_w(\Lambda_1/L)\Lambda_2 \cdot d$. This is just the energy per unit wall area multiplied by the length of the wall Λ_2, the film thickness d, and the number of walls within the length Λ_1. Here, the wall energy per unit film area $\sigma_w d/L$ is the main interest.

The lowering of the magnetostatic energy upon introducing stripes can immediately be seen when one considers eqn [9]. A uniform perpendicular spin configuration is curl free, so that there is no effective current J_M anywhere in space and the total energy per unit area is simply $(2\pi M_0^2 \cdot d)$. The stripe configuration, instead, develops some curl (and correspondingly some magnetic field $\boldsymbol{B}$), thus necessarily lowering the magnetostatic energy.

The following calculation shows explicitly that the energy gain is enough to overcome the wall energy introduced by the stripes. First, the effective currents are found. The stripe magnetization distribution develops a curl at the boundaries (labeled with the index n) between consecutive stripes. Along these boundaries, effective current densities $\boldsymbol{J}_n = cj_n\boldsymbol{e}$ occur where $j_n = (-1)^n 2M_0/w$ ($n = 0, \pm 1, \ldots, \pm(N-1)$) and $j_{\pm N} = (-1)^{\pm N} M_0/w$. One contribution to the Coulomb energy, eqn [9] arises from the interaction of each current with the remaining currents. There are Λ_1/L of such interaction terms and the calculation of

this part of the interaction energy reduces to the computation of the sum of elementary integrals of the type

$$\int_{-\Lambda_2/2}^{\Lambda_2/2}\int_{-\Lambda_2/2}^{\Lambda_2/2} dx_2\, dy_2 \frac{1}{\sqrt{(x_2-y_2)^2+L_n^2}} \qquad [10]$$

($L_n = \pm n$, L and $n \neq 0$). Notice that the integration along (x_3, y_3) can be approximated by multiplying the remaining two-dimensional integrals with d^2. This is possible because d is considered small with respect to L, so that one can set $x_3 = y_3 = 0$ in the integrand. The integration over (x_1, y_1) can be approximated by a factor w^2, because w is considered to be much smaller than L, allowing one to set $(x_1 - y_1)^2 = L_n^2$ in the integrand. Thus, eqn [9] reduces to the elementary integral of eqn [10]. After computing these integrals, one is left with a sum that can be solved exactly because it contains in the limit $N \to \infty$ the product of Wallis. The other contribution arises from the self energy of each current. Under the integral of the self energy, $(x_1 - y_1)$ may be smaller than $|x_2 - y_2|$. Thus, the integrations over x_1, y_1 must be performed explicitly. There are again Λ_1/L such terms and their self energy per unit area contains the integral

$$\int_0^w\int_0^w dx_1\, dy_1 \int_{-\Lambda_2/2}^{\Lambda_2/2}\int_{-\Lambda_2/2}^{\Lambda_2/2} dx_2 \times dy_2 \frac{1}{\sqrt{(x_2-y_2)^2+(x_1-y_1)^2}} \qquad [11]$$

Summarizing all contributions, the total energy per unit film area is

$$2\pi M_0^2 d \cdot \left\{1 - \left[\left(\frac{3}{\pi}+\frac{2}{\pi}\ln\frac{2}{\pi}\right) - \frac{2}{\pi}\ln\frac{w}{d}\right]\frac{d}{L} + \frac{2}{\pi}\frac{d}{L}\ln\frac{d}{L}\right\} + \sigma_w\frac{d}{L} \qquad [12]$$

The equilibrium stripe width L^* is found by minimizing the total energy per unit area with respect to the variable $x \doteq d/L$.

$$L^* = w \cdot e^{\pi(b+1)/2} \cdot e^{\pi L_0/2d} \qquad [13]$$

where the numerical factor $b = -(3/\pi + 2/\pi \ln 2/\pi)$. Notice that the equilibrium stripe width is a nonanalytic function of d for small d. It can be readily verified that the total energy of the striped phase at the equilibrium stripe width is indeed lower than the total energy of the uniform perpendicular state, by an amount $-(2/\pi)(2\pi M_0^2 d/L^*)$.

Magnetic Interactions

G Hilscher and H Michor, Vienna Institute of Technology, Vienna, Austria

Introduction

Magnetism in matter is a purely quantum mechanical phenomenon according to the Bohr–van Leeuwens theorem: van Leeuwen demonstrated in 1918 that classical Boltzmann statistics applied rigorously to any dynamical system leads neither to a susceptibility nor to a magnetic moment, which means that classical mechanics cannot account for diamagnetism, and paramagnetism or any type of collective magnetic order. However, under the assumption that a molecule or atom has a finite magnetic moment $\boldsymbol{\mu}$, the diamagnetic and paramagnetic susceptibility was derived already in 1905 by Langevin using classical statistical thermodynamics and treating these moments without interactions. The assumption of a finite magnetic moment, however, requires quantized values for the spin S and angular momentum L that is a result of quantum mechanics. The coupling of spin and angular momentum to the total angular momentum J is a relativistic interaction, which can be treated as a perturbation for not too heavy elements (Russel Sounders or L–S coupling) and the ground state is

described by Hunds rules. Accordingly, magnetism arises from quantized motions of electrons giving rise to the fundamental unit of the magnetic moment, the Bohr magneton, defined by $\mu_B = eh/2m_e$ that takes the value 9.274×10^{-24} Am^2 or JT^{-1}. Thus, the magnetic moment of an atom or a molecule is given in units of μ_B (e.g., the magnetic moment of pure Fe in the metallic state is 2.2 μ_B per atom).

The magnetic properties of a system of electrons and nuclei are determined by the interactions of these particles with electromagnetic fields. These fields arise from two types of sources: first, there are fields due to sources external to the system such as applied electric and magnetic fields. Second, there are internal sources, which come from the charges and currents due to the particles of which the system is composed. Interactions with and between nuclear moments μ_N are not discussed here since μ_N is by a factor of $\sim$1800 smaller than μ_B.

A first step is to consider the magnetic moments associated with itinerant and/or localized electrons on the respective ions of a crystal to behave completely free without interacting with each other or with their surrounding. This leads to diamagnetism and paramagnetism.

In a free atom the quantum number J, the total angular momentum, is a good quantum number, which reflects the fact that a free atom has a complete rotational symmetry in the absence of external fields and its ground state is $2J + 1$ fold degenerate. In a crystal, however, the surrounding ions produce an electric field to which the charge of the central atom adjusts and the $2J + 1$ degeneracy is removed giving rise to a splitting of the ground multiplet. The object of the crystalline electric field (CEF) theory is to describe how the moments are affected by their local environment in a crystal. Finally, one has to consider the various interactions of magnetic moments with each other leading eventually to a long-range magnetic order.

Crystalline Electric Field Interactions

The charge distribution around a central ion produces an electric field with the local symmetry of the environment. This crystal field makes a contribution to the potential energy

$$V_C(\boldsymbol{r}) = \int \frac{e\rho(\boldsymbol{R})}{|\boldsymbol{r} - \boldsymbol{R}|}\,\mathrm{d}\boldsymbol{R} \approx e\sum_i \frac{q_i}{|\boldsymbol{r} - \boldsymbol{R}_i|}$$

where the charge distribution $\rho(\boldsymbol{R})$ in the point charge model is approximated by point charges q_i at the position $\boldsymbol{R}_i$. The denominator may be expanded in spherical harmonics. If V_C is small compared to the spin–orbit coupling (as in the rare-earth elements where the incomplete 4f shell is responsible for the magnetic moment), the eigenstates are adequately accounted for by the first-order perturbation theory. Provided that the ground state and the next excited states do not mix, the matrix elements of $V_C(\boldsymbol{r})$ are proportional to those obtained with operator equivalents written in terms of $\boldsymbol{J}$, which are called the Stevens operator equivalents $O_l^m(\boldsymbol{J}_i)$ and the CEF Hamiltonian reads

$$\hat{H}_{CF} = \sum_i \sum_{lm} B_l^m O_l^m(\boldsymbol{J}_i)$$

The CEF parameters B_l^m can, in principle, be calculated from the charge distribution of the environment, which yields reasonable results for insulators but is of limited success for metals.

The electrostatic interactions destroy the rotational symmetry of the ion and the electronic orbitals are linked to the symmetry of the lattice removing the $2J + 1$ degeneracy of the ground multiplet of the free ion. Schematically illustrated in **Figure 1** is the CEF splitting (e.g., Mn in the perovskite $LaMnO_3$) resulting from the interaction between the nonspherical d-orbitals and the electrostatic field of the environment, which is also nonspherical. As an example, the d_{xy}-orbital in an octahedral surrounding (a) is energetically favored in comparison to the $d_{x^2-y^2}$ orbital (b) in the same environment. Those lobes, which point to neighboring charges, have higher overlap and correspond to higher electrostatic energy than those that point between. This gives rise to the CEF splitting displayed in **Figure 1c**.

An improvement on the point charge approximation for d-transition metal ions is the ligand field theory which is an extension of the molecular orbital theory that focuses on the role of the d-orbitals of the central ion and their overlap with orbitals on surrounding ions (ligands). Also for rare-earth compounds, CEF parameters can be calculated from first principles using the density-functional theory which, however, should be checked experimentally as, for example, by inelastic neutron scattering.

It is instructive to consider two rather different cases, namely the 3d-transition metal series (Fe group) and the 4f series (rare earth), where the relative importance of the spin–orbit coupling and CEF splitting of the ground multiplet is inverted. The spin–orbit coupling which is proportional to Z^2 (atomic number) is much larger in the 4f series than in the 3d-transition metals since rare-earth elements are significantly heavier. Furthermore, the spatial extension of the 3d wave functions is much more delocalized than the 4f wave functions that are

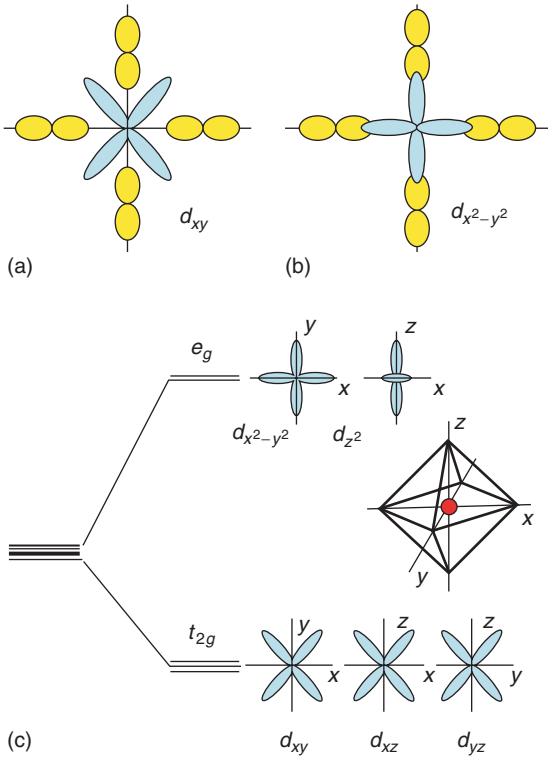

Figure 1 (a) The d_{xy}-orbital is lowered in energy with respect to the $d_{x^2-y^2}$-orbital in an octahedral environment. (b) Schematic crystal field splitting in an octahedral environment (c) The d_{z^2}-and $d_{x^2-y^2}$-orbitals are grouped together and called e_g levels (twofold degenerate). The d_{xy}, d_{xz} and d_{yz} are grouped together and called the t_{2g} levels (threefold degenerate).

additionally screened from CEF by the outer 6*s*- and 5*d*-shells. Thus, in rare-earth compounds CEF splitting is $\sim 10^2$ K and spin–orbit coupling of 10^4 K, which means that the Hunds rule ground state is usually observed both in metals and insulators and the effect of CEF interaction can be treated in terms of Stevens operators. In 3*d*-compounds, V_C is typically of the order of 10^4 K which is larger than the spin–orbit coupling (10^2 K) and V_C couples mainly to the orbital part of the wave function which lifts the orbital degeneracy of the 3*d*-states and Hunds rule ground state is usually not obeyed. If the CEF perturbation is strong enough and the symmetry low enough, the orbital degeneracy is completely removed. Thus, the orbital ground state is a singlet which is called the quenching of the orbital momentum (L is not anymore a good quantum number and virtually reduced to $L = 0$) and "spin-only" magnetic properties are observed. In 4*d*-and 5*d*-series (Pd and Pt groups), the situation is less clear-cut because the heavier ions have a larger spin–orbit splitting, and the CEF and spin–orbit interaction can be of comparable magnitude.

The impact of CEF interaction on the magnetic properties is important and in combination with spin–orbit interaction it is the principal source of magnetic anisotropy, which is the dependence of magnetic properties on the direction in the compound. Further, properties influenced by CEF are magnetoelastic phenomena and transport phenomena as well as thermodynamic properties as the specific heat.

Origin of Long-Range Magnetic Order – Exchange Interactions

In the previous section, magnetic ions embedded in the CEF environment of the crystal were considered but the interaction between the magnetic moments was neglected. The classical interaction between two magnetic dipoles $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ at a distance $\boldsymbol{r}$ between each other is known as the dipole–dipole interaction. As the magnetic energy is $E_M = -\boldsymbol{\mu}\cdot\boldsymbol{H}$, the dipolar energy reads

$$E_D = \frac{\mu_0}{4\pi r^3}\left[\boldsymbol{\mu}_1\cdot\boldsymbol{\mu}_2 - \frac{3}{r^2}(\boldsymbol{\mu}_1\cdot\boldsymbol{r})(\boldsymbol{\mu}_2\cdot\boldsymbol{r})\right]$$

Thus E_D/k_B is of the order of 1 K, if one considers two moments of $1\,\mu_B$ which are separated by 1 Å. Accordingly, this interaction cannot account for Curie temperatures of 1000 K, but nevertheless can become of relevance at low and ultra-low temperatures.

Dirac and Heisenberg discovered independently that electrons are coupled by exchange interactions among which direct, indirect, itinerant exchange, and superexchange can be distinguished. Direct, indirect, and itinerant exchange occurs in metallic systems. Direct and superexchange is important in nonmetallic systems.

Origin of Exchange

In order to show how the Pauli exclusion principle together with electrostatic interactions leads to magnetic effects, consider the simplest possible case – a two-electron system – where the Hamiltonian

$$\hat{H} = \sum_{i=1}^{2}\frac{p_i^2}{2m} + V(\boldsymbol{r}_1, \boldsymbol{r}_2)$$

does not depend on the spin. In quantum mechanics one cannot distinguish between identical particles, which means that the particle coordinates q_1 and q_2 can be permuted (exchanged) in the wave function and the system remains the same physically; the new wave function differs from the original one

by a phase factor: $\psi(q_1, q_2) = e^{i\phi}\psi(q_2, q_1)$. Permuting once more gives the original wave function. Thus $e^{2i\phi} = 1$ and $\psi(q_1, q_2) = \pm\psi(q_2, q_1)$, which means the wave function must be either totally symmetric or antisymmetric under permutation. Electrons (Fermions) have totally antisymmetric wave functions; so the spin part must either be an antisymmetric singlet state $\chi_S(S = 0)$ in the case of a symmetric spatial wave function or a symmetric spin triplet state $\chi_T(S = 1)$ in the case of an antisymmetric spatial state. The overall wave function for the singlet ψ_S and the triplet state ψ_T for two electrons where both the orbital and spin part is included reads:

$$\psi_S = \frac{1}{\sqrt{2}}\chi_S[\psi_1(\boldsymbol{r}_1)\psi_2(\boldsymbol{r}_2) + \psi_1(\boldsymbol{r}_2)\psi_2(\boldsymbol{r}_1)],$$

$$\text{with } \chi_S = \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)$$

$$\psi_T = \frac{1}{\sqrt{2}}\chi_T[\psi_1(\boldsymbol{r}_1)\psi_2(\boldsymbol{r}_2) - \psi_1(\boldsymbol{r}_2)\psi_2(\boldsymbol{r}_1)],$$

$$\text{with } \chi_T : |\uparrow\uparrow\rangle;\ \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle);\ |\downarrow\downarrow\rangle$$

If the interaction $V = e^2/r_{12}$ is absent, then these two states would have the same energy. For $V \neq 0$, the energies of the triplet and the singlet state are different

$$E_S = \int \Psi_S^* \hat{H} \Psi_S = U + J$$

$$E_T = \int \Psi_T^* \hat{H} \Psi_T = U - J$$

with

$$U = \int\int |\psi_1(\boldsymbol{r}_1)|^2 V(\boldsymbol{r}_1, \boldsymbol{r}_2) |\psi_1(\boldsymbol{r}_2)|^2 \, \mathrm{d}\boldsymbol{r}_1 \mathrm{d}\boldsymbol{r}_2$$

and $\Delta E = E_S - E_T = 2J$

$$J = \int\int \psi_1(\boldsymbol{r}_1)\psi_1^*(\boldsymbol{r}_2) V(\boldsymbol{r}_1, \boldsymbol{r}_2) \psi_2(\boldsymbol{r}_2)\psi_2^*(\boldsymbol{r}_1) \mathrm{d}\boldsymbol{r}_1 \mathrm{d}\boldsymbol{r}_2$$

where J is the exchange interaction or exchange integral, and U the Coulomb integral. The original Hamiltonian does not depend on the spin but produces an energetically favorable spin configuration for parallel spins. Thus $\hat{H}$ may now be replaced by an effective one $\hat{H}^{\text{spin}}$ acting upon the spin components only with the requirement that it should produce the same $\Delta E = E_S - E_T$. What will be the form of $\hat{H}^{\text{spin}}$?

For the two-electron system, the spin operators yield the following eigenvalues:

$$\hat{S}_i^2 = \hbar^2 S_i(S_i + 1) = \hbar^2 \tfrac{3}{4} \quad \text{and}$$

$$\hat{S}^2 = \hbar^2 S(S + 1) = \hat{S}_1^2 + \hat{S}_2^2 + 2\hat{S}_1 \cdot \hat{S}_2 = \hbar^2 \tfrac{3}{2} + 2\hat{S}_1^2 \cdot \hat{S}_2^2$$

Accordingly, the product $\hat{S}_1^2 \cdot \hat{S}_2^2/\hbar^2 = S(S + 1)/2 - 3/4$ of both operators gives $-3/4$ for the singlet $S = 0$ and $1/4$ for triplet state $S = 1$. Hence the original spin-independent Hamiltonian can be written in the form of an effective spin Hamiltonian yielding the same eigenvalues E_S and E_T:

$$\hat{H}^{\text{spin}} = \frac{1}{4}(E_S + 3E_T) - \frac{(E_S - E_T)\hat{S}_1 \cdot \hat{S}_2}{\hbar^2}$$

$$\hat{H}^{\text{spin}} = U - J\hat{S}_1 \cdot \hat{S}_2$$

with $U = 1/4(E_S + 3E_T)$ and $J = (E_S - E_T)/\hbar^2$. If $J > 0$, $E_S - E_T > 0$ and the "parallel" coupling of the spins in the triplet state with $S = 1$ is favored, while for $J < 0$ the "antiparallel" coupling in the singlet state is favored.

The generalization of this simple relation for the two-electron system to a many-body system is far from trivial. The result is the Heisenberg Hamiltonian

$$\hat{H}_{\text{Heisenberg}} = -\sum_{i>j} J_{ij}\hat{\boldsymbol{S}}_i \cdot \hat{\boldsymbol{S}}_j$$

where J_{ij} is the exchange interaction between the ith and jth spins. Frequently, J_{ij} is taken as a constant for the nearest neighbors (and next nearest neighbors) and zero otherwise. J_{ij} is of the order of 10^2–10^3 K for direct exchange in $3d$-compounds, 10–10^2 K for indirect exchange and superexchange. A reliable calculation of J_{ij} is a rather complex task in general.

A simple but straightforward approach to obtain a convenient expression for the exchange interaction is the mean field approximation where the exchange interaction between the ith spin and its neighbors $\sum_j J_{ij}\hat{\boldsymbol{S}}_j$ is approximated by a phenomenological molecular field H_m acting upon $\boldsymbol{S}_i$. In the Weiss molecular field model, the molecular field is set proportional to the magnetization $H_m = \lambda M$, where the molecular field constant λ is determined by the exchange interaction yielding fields $\mu_0 H_m$ of the order of 1000 T for $3d$-intermetallics such as Fe–Co alloys to account for their Curie temperatures of $\sim$1000 K ($\boldsymbol{\mu H} = k_B T_c$). Nevertheless, this phenomenological molecular field is a convenient fiction but not experienced by the electrons since exchange origins from Coulomb interaction.

Some general features of exchange interactions are noteworthy. If two electrons on an isolated atom are considered, J is usually positive and favors the parallel spin configuration (triplet state) associated with an antisymmetric orbital state which reduces the Coulomb repulsion by keeping them apart. This is consistent with Hund's first rule yielding maximum total spin under the constraint of the Pauli principle.

The situation is different for electrons on neighboring ions in molecules or in a solid. In contrast to the free electron description for a simple metal, the model of tightly bound electrons is used as an approximation not only for ionic solids but also for transition metal compounds. The total wave function is a linear combination of atomic orbitals (LCAO) centered on the respective ions (which has to be in overall antisymmetric realized by a Slater determinant.) The electrons can save kinetic energy by forming bonds because their common wave function is more extended than the original atomic orbital and comprises both ions. These molecular orbitals can be bonding (spatially symmetric) or antibonding (spatially antisymmetric) as shown schematically in **Figure 2a** for the hydrogen molecule. The latter are more localized associated with higher kinetic energy. This favors the "antiparallel" singlet state as observed in H_2.

In a d-transition metal, the atomic $5N$ d-states for spin up and down give rise to a band of $10N$ levels distributed quasicontinuously between the lower bonding and the upper antibonding levels yielding together with transfer integrals and hopping integrals, the bandwidth W (**Figure 2b**). One has to distinguish between interatomic terms of the exchange and Coulomb integrals (J_{ij} and U_{ij}, $i \neq j$) and intra-atomic terms J_{ii} and U_{ii}. According to the more or less localized character of the wave function, the interatomic terms are much weaker than the intra-atomic terms. The U terms tend to avoid two electrons with antiparallel spins in the same orbital and the exchange terms J favor electrons in different orbitals with parallel spins. The latter are about one order of magnitude smaller. Thus, one may define an average exchange energy $\bar{I}$ per pair of electrons per atom, which represents the interaction favoring "ferromagnetic" alignment. On the other hand, the transfer integrals associated with the bandwidth work in the opposite direction, since the creation of parallel spins implies the occupation of higher energies in the band (i.e., with higher kinetic energy). Following this very simplified approach, the balance between kinetic and exchange energy favors the appearance of a spontaneous magnetic order for the end of the $3d$-elements (Cr, Mn, Fe, Co, and Ni).

A proper description is performed in terms of the density-functional theory where the exchange correlation potential is added to the Coulomb correlation, which allows a straightforward determination of the exchange correlation. This treatment is called the local spin density approximation (LSDA).

To summarize, exchange can be explained in the following way: the Pauli exclusion principle keeps the electrons with parallel spins apart and so reduces their Coulomb repulsion. The difference in energy between parallel and antiparallel spin configuration is the exchange energy. This, however, is favorable for ferromagnetism if the increase in kinetic energy associated with parallel spins does not outweigh the gain in potential energy, as in the familiar examples of the H_2 molecule or the He atom. In metallic Fe,

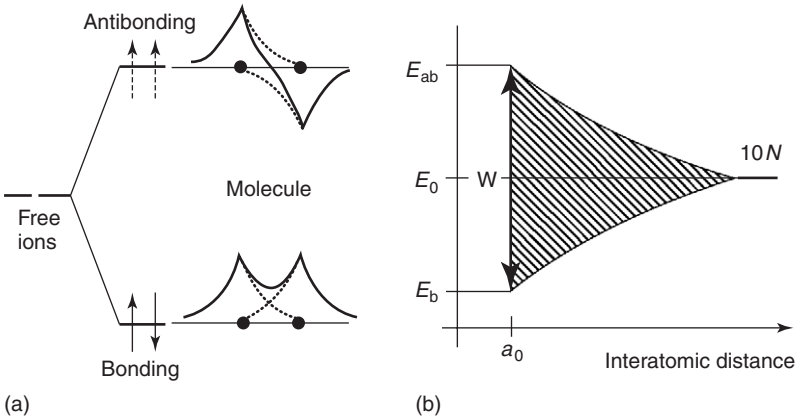

Figure 2 Schematical energy splitting of bonding (spatially symmetric) and antibonding (spatially antisymmetric) molecular orbitals in a molecule (a) yielding a singlet ground state as, e.g., in H_2 molecule. (b) Schematical formation of the bandwidth W in a solid by the quasicontinuous distribution of the $10N$ d-states between the lower and upper bonding states of the originally discrete and degenerated $5d$-atomic states for up and down spin of N transition metal atoms condensed to a crystal; E_b is the energy of the bonding state and E_{ab} of the antibonding state.

Co, and Ni, the number of parallel spins produces ferromagnetism because the cost in kinetic energy is not as great as in some other metals, where the gain in potential energy is significant yielding a paramagnetic ground state.

Direct Exchange

If there is sufficient overlap of the relevant wave functions (e.g., 3*d*-orbitals) between neighboring atoms in the lattice, the exchange interaction is called direct exchange. Although Fe, Co, and Ni are frequently referred to as typical examples for direct exchange, the situation is not that simple because of the metallic state where magnetism of itinerant electrons plays an important role. Accordingly, both the localized and band character of the electrons involved in transition metals and their intermetallics have to be taken into account as is seen in the model of covalent magnetism for transition metal intermetallics.

Indirect Exchange in Insulators – Superexchange

Superexchange is typical for insulators or materials on the border of a metal insulator transition where the ions with a magnetic moment are surrounded by ions which do not carry a moment but mediate the exchange. This type of exchange is observed in transition metal oxides. An archetypical example is MnO where two cations (Mn^{2+} in the $3d^5$ state with $S = 5/2$) are coupled via an anion (O^{2-} in the $2p^6$ state with $S = 0$); the ground state is shown schematically in **Figure 3a**. Because of the overlap of the wave functions, one of the *p*-electrons of the anion (O^{2-}) hops over to one of the cations (Mn^{2+}). The remaining unpaired *p*-electron on the anion enters into a direct exchange with the other cation. In principle, this exchange may be ferromagnetic or antiferromagnetic. The excited state shown in **Figure 3b** for an antiferromagnetic coupling is in most cases energetically in favor due to the interplay of two effects: the hopping of electrons between ligands, characterized by a hopping matrix element t being proportional to the bandwidth, and an average Coulomb interaction U between electrons on the same orbital. Superexchange involves oxygen *p*-orbitals and transition metal *d*-orbitals and is therefore a second-order process. In second-order perturbation theory, the exchange interaction is given by $J \propto -t^2/U$, and normally yields antiferromagnetic coupling.

Double Exchange

Double exchange is essentially a ferromagnetic type of superexchange in mixed-valent systems. Mixed-valency means that the transition metal ion on

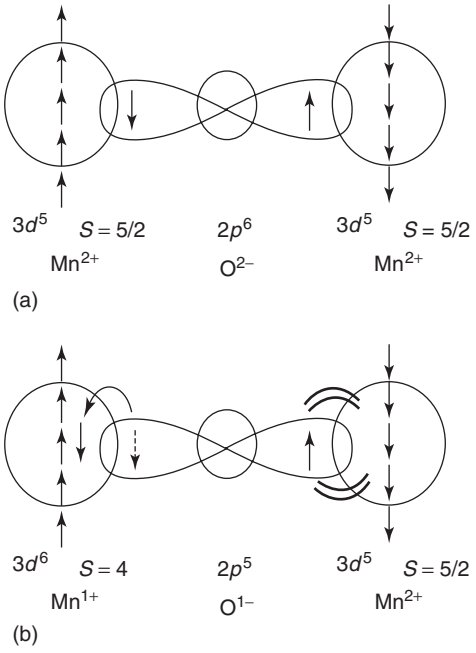

Figure 3 (a) Superexchange of a transition metal oxide as, e.g, MnO in the ground state, (b) hopping of electrons in the excited state favors antiferromagnetic coupling.

crystallographically equivalent lattice sites exhibits different ionic states, for instance, trivalent and tetravalent Mn in perovskites (La,Sr)MnO_3 or Fe^{2+} and Fe^{3+} in magnetite (Fe_2O_3). Due to the mixed valency, holes (i.e., unoccupied states) exist in the e_g states of the transition metal ion with a higher valency with respect to a cation of the same species with a lower valency. The simultaneous hopping of an electron from $Mn^{3+} \rightarrow O^{2-}$ and concomitantly from $O^{2-} \rightarrow Mn^{4+}$ is known as double or Zehner exchange. Hopping is favored if the neighboring ion is ferromagnetically aligned since kinetic energy is saved by delocalization, while it is hindered by antiferromagnetic alignment as shown schematically in **Figure 4**.

Indirect Exchange in Metals – RKKY Interaction

In transition metal alloys, intermetallic compounds, and diluted magnetic alloys where magnetic ions are dissolved in a weak paramagnetic or diamagnetic host (e.g., Fe–Au or Fe–Cu alloys), the magnetic moment carrying ions are separated by other ions and a direct overlap of wave functions responsible for the magnetic moment is hardly possible. Thus, the various types of indirect exchange interactions between magnetic moments are mediated by conduction electrons polarized by the local moment, which is known as RKKY interaction according to Ruderman, Kittel, Kasuya, and Yoshida. Under the assumption of a

spherical Fermi surface with radius k_F, the interaction is given by

$$J_{RKKY} \propto \frac{\cos(2k_F r)}{r^3}$$

The RKKY interaction is long ranged and oscillates as a function of the distance r from the polarizing local moment. Hence depending on the distance, the conduction electron polarization is positive or negative, yielding ferromagnetic or antiferromagnetic coupling with the next local moment at the position r, and is an important mechanism to describe complex magnetic structures. Archetypical examples are rare earths (R) and their intermetallics, where the localized 4*f*-electrons are responsible for magnetism without any overlap with their nearest-neighbor 4*f* wave functions. The 4*f*-moments in these R-intermetallics compare well with those of their free ion value of R^{3+} ions according to the Hund's rules and their Curie temperature are of the order of 10 to 10^2 K. In particular for systems containing *f*-electrons, the isotropic exchange interaction has to be extended by anisotropic terms. The anisotropy of the coupling is associated with the orbital moments of the electrons involved and the general exchange operator contains, besides the bilinear term $\hat{S}_i \cdot \hat{S}_j$, higher order isotropic interactions and all types of anisotropic exchange as, for example, Dzialoshinsky–Moriya exchange $\hat{S}_i \times \hat{S}_j$, which produces magnetic components perpendicular to the principal spin axis of the ferromagnetic or antiferromagnetic alignment. The 3*d*–4*f* exchange interactions, together with CEF effects, are the origin of the large magnetic anisotropy in R-3*d*-intermetallics needed for the high coercitivity of permanent magnets such as $Nd_2Fe_{14}B$ or $SmCo_5$ and Sm_2Co_{17}.

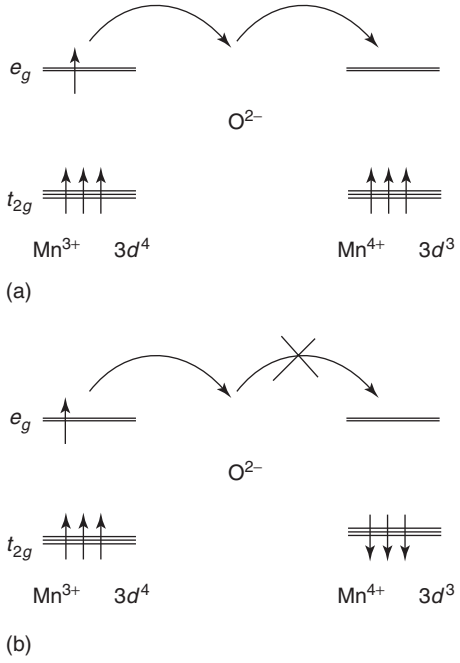

Figure 4 (a) Double exchange interaction favors hopping via an anion (O^{2-}) for ferromagnetic alignment of the transition metal ions by reducing kinetic energy, (b) while hopping is hindered by antiferromagnetic alignment.

Exchange Interactions in Free Electron Systems – Itinerant Exchange

Paramagnetism of the free noninteracting electron gas is described by the Pauli susceptibility $\chi_P = 2\mu_B^2 N(E_F)$, which relates the paramagnetic response of the system to an external field with the density of states $N(E)$ at the Fermi energy E_F. In the paramagnetic state, the number of up and down spins is equal ($n\uparrow = n\downarrow = n/2$); thus, the magnetic moment $m = \mu_B(n\uparrow - n\downarrow)$ given by the number of unpaired spins is zero; here, it is assumed that each electron carries a magnetic moment of 1 μ_B, since $S = \pm 1/2$ and gyromagnetic ratio $g = 2$ which is a good approximation for conduction electrons. If an external field H_0 is applied, the energy of an electron with spin up or down is $\pm\mu_B\mu_0 H$ depending upon the orientation of the spin with respect to the field. Thus, the external field splits the up and down spin bands with respect to each other by the energy $2\mu_B\mu_0 H$ (see **Figure 5**) yielding a small but finite magnetic moment $m = \mu_B(n\uparrow - n\downarrow)$ and a Pauli susceptibility $\chi_P = m/\mu_0 H_0$.

In the Stoner Wohlfahrth model, the susceptibility of the interacting electron gas, χ_S, is enhanced due to exchange interactions by a factor $S = (1 - I\,N(E_F))^{-1}$, known as the Stoner enhancement yielding,

$$\chi_S = \frac{2\mu_B^2 N(E_F)}{1 - IN(E_F)} = \chi_P S$$

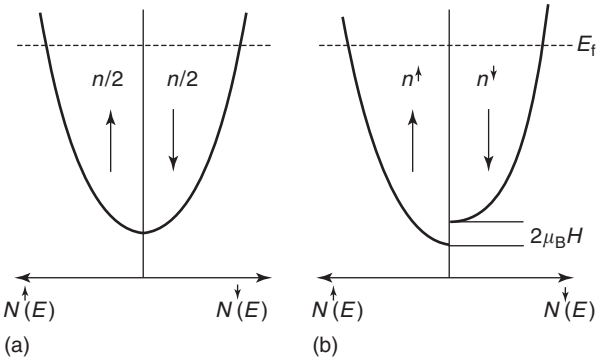

Figure 5 (a) Density of states of the free electron gas in the paramagnetic state, (b) splitting of the spin up and down bands by either an external field H_0 or by an effective exchange field H_{eff}.

The quantity I is the Stoner exchange factor describing phenomenologically, the exchange interactions of the interacting electron gas that can be interpreted as the above mentioned average exchange per pair of electrons $\bar{I}$ favoring their ferromagnetic alignment, that is, to increase $n\uparrow$ with respect to $n\downarrow$. In a more advanced treating, $\bar{I}$ corresponds to the Hubbard U which models the Coulomb interaction in the Hubbard Hamiltonian in combination with the hopping integrals t. If $IN(E_F)$ approaches 1, χ_S diverges and a second-order phase transition into a magnetically ordered state takes place. Thus $IN(E_F) \geqslant 1$ is the Stoner criterion for the onset of magnetism. That means for transition metals: a reasonably high density of states at E_F due to narrow enough d-bands together with exchange is needed for magnetic order. By analogy to the band splitting due to an external field in the paramagnetic state, the spontaneous moment in the ordered state arises from the spontaneously spin–split bands caused in a simple mean field model by an effective exchange field $H_{eff} = Im$.

Magnetic Materials and Applications

H Szymczak, Polish Academy of Sciences, Warsaw, Poland

Introduction

Magnetic materials play a prominent role in modern technology. They are key components of motors, generators, and transformers. In this article, various magnetic materials of technological importance are described with an emphasis on recent developments.

Magnetic materials have a long history of usage. According to Chinese data, the compass was discovered in China more than 4500 years ago. There are also claims that a natural magnet was discovered in Magnesia (Asia Minor) more than 3500 years ago. Magnetic materials have contributed vitally to the history of civilization.

Traditionally, only those materials that exhibit ferromagnetic or ferrimagnetic properties are called "magnetic." Only nine elements are ferromagnets. All are metals, of which three (Fe, Co, Ni) are iron-group metals and the other six (Gd, Tb, Dy, Ho, Er, Tm) are rare-earth metals. The transition metals Fe and Co are the basic elements for preparation of alloys and compounds with large Curie temperature (T_C) and a large spontaneous magnetization (M_s) (see **Table 1**). Some of the intermetallic compounds with rare-earth metals are characterized by a very high value of magnetocrystalline anisotropy and magnetostriction.

The primary criterion allowing for classification of magnetic materials is coercivity, which is a measure of stability of the remanent state. Soft magnetic materials are characterized by low values of coercivity ($H_c < 10^3\,A\,m^{-1}$), while the coercivity of hard magnetic materials (usually permanent magnets) is higher than $10^4\,A\,m^{-1}$. Finally, semihard magnetic materials (mostly storage media) have coercivities in between

Table 1 Magnetic properties of 3*d* and 4*f* magnetically ordered elements

Element	*Curie temperature* (K)	*Saturation moment* (μ_B)
Fe	1043	2.22
Co	1388	1.72
Ni	635	0.61
Gd	293	7.63
Tb	220	9.34
Dy	89	10.33
Ho	20	10.34
Er	20	9.1
Tm	32	7.14

the above two values. In addition, there exist a number of sophisticated magnetic materials with unusual properties, such as giant magnetostriction, giant magnetoresistance, and giant magnetoimpedance. All these materials are important for modern technology and will be considered here. In modern applications, magnetic properties are tailored through precision tuning of the material microstructure. Thus, a central issue in the development and application of both soft and hard magnetic materials is the connection between extrinsic magnetic properties (coercivity, remanence, hysteresis loop) and microstructure. A universal relation was established between the coercivity H_c and the anisotropy constant K_1:

$$H_c = 2\alpha K_1/\mu_o M_s - N_{eff} M_s \qquad [1]$$

where the microstructural parameters α and N_{eff} describe the effects of microstructure and domain structure.

The present technology allows one to obtain a wide spectrum of microstructures ranging from amorphous, nanocrystalline to single crystals. The corresponding coercivities may vary by a factor of 10^7 to 10^8 from extremely soft to extremely hard magnetic materials.

Soft Magnetic Materials

Typical requirements for a soft magnetic material are low coercivity, high initial permeability, and low high-frequency losses. These characteristics usually go along with the following properties of the media:

- low effective magnetic anisotropy,
- high remanence,
- small magnetostriction (to suppress magnetoelastic contribution to the magnetic anisotropy), and
- low conductivity.

There was a remarkable progress in production and applications of soft magnetic materials in recent years. The static permeability, for example, has been increased to huge values in materials with near-zero values of magnetic anisotropy and magnetostriction. The best soft magnetic materials have permeabilities as large as $\mu > 10^5$. The permeability μ describes the response of magnetic materials to a weak magnetic field. For small fields, this response is linear and may be characterized by the initial permeability μ_i. Generally, the permeability is determined by two mechanisms: the growth of some magnetic domains at the expense of others (wall mechanism) and the rotation of magnetization within each domain (rotation mechanism). The same two mechanisms are also responsible for the hysteresis loop in soft magnetic materials. There are two classes of losses in these materials: hysteresis losses (determined by the area of hysteresis loop) and eddy current losses (related to the DC electrical resistivity). After a thermal demagnetization or after rapid changing of magnetization, almost all soft magnetic materials show a slow decrease of their permeability as a function of time (t), according to a law:

$$\Delta\mu = -D \ln t \qquad [2]$$

This decay of permeability with time is called "disaccommodation." The disaccommodation is ascribed to an increase in the domain wall stiffness, which originates in the presence of mobile defects interacting with magnetization.

Iron and Soft Steels

Iron is a very good and relatively cheap soft magnetic material. It has a very high saturation magnetization at room temperature and a large Curie temperature (see **Table 2**). Pure iron or soft steels (low-carbon steels, silicon steels) are used in magnetic shielding, in power and distribution transformers, in small motors, in electromagnets, and in various electromechanical devices. In AC applications, low-carbon steels are used because of their high permeability and low core loss. Silicon steels are widely used in transformers, rotating power equipment, and relays. Silicon is added to pure iron to increase resistivity and permeability and to decrease magnetostriction and magnetocrystalline anisotropy. In silicon steels, the basic magnetostriction constants approach zero at a silicon level slightly greater than 6 wt.%. Such high

Table 2 Soft magnetic materials (crystalline)

Material	*Saturation induction* B_s (T)	*Coercivity* H_c ($A\,m^{-1}$)	*Initial permeability* μ_i

silicon content alloys are usually produced by a fast solidification technique. This melt-spinning technique was initially developed for amorphous alloys. Silicon steels are divided into two main categories: Fe–Si sheets with nonoriented grain texture and grain-oriented Fe–Si sheets. In the latter case, a preferred crystallographic texture leads to a reduction of core loss and increase of permeability. Annealing of iron and steels removes stresses and improves the time stability of magnetic parameters. In order to avoid the $\alpha \rightarrow \gamma$ phase transition of iron, the temperature of annealing should not exceed 1125 K. In the case of silicon steel, this temperature is even higher since silicon stabilizes the α-Fe phase.

Nickel–Iron Alloys

Nickel–iron alloys (known as "permalloys") are used for electronic transformers and inductor applications in the 1–100 kHz range. These are characterized by high initial permeability (see **Table 2**) and good ductility for forming into very thin strips. Fe–Ni alloys with 80% of Ni are characterized by the almost simultaneous vanishing of anisotropy and magnetostriction. The best alloys have the composition $Fe_{15}Ni_{80}Mo_5$. Alloys with very high permeability are mainly used in safety devices and in magnetic field shielding.

Iron–Cobalt Alloys

The most important iron–cobalt soft magnetic alloys are "Permendur" (49%Fe–49%Co–2%V) and "Supermendur" (see **Table 2**). The technological importance of these alloys is a consequence of their high saturation magnetization and high Curie temperature. They are characterized by high permeabilities and low coercivities. Because of high cobalt content, Fe–Co alloys are relatively costly and they are used only for special purposes where cost of the magnetic material is not of great importance, for example, in airborne medium-frequency electrical engineering and in high-temperature magnetic devices.

Soft Ferrites

The term "ferrite" refers to spinel ferrites with the general formula $MO\ Fe_2O_3$, where M is a divalent cation (e.g., Mg^{2+}, Zn^{2+}, Cd^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Cu^{2+}). The spinel structure is cubic, with a face-centered cubic oxygen anion lattice. Metallic ions are distributed between tetrahedral (a) and octahedral (d) sites. In the "normal spinel" structure, tetrahedral sites are occupied by divalent cations and the octahedral sites by trivalent cations. In the "inverse spinel" structure, the tetrahedral sites are occupied by trivalent cations while the octahedral sites are occupied by divalent and trivalent cations. Magnetism of ferrites is usually determined by antiferromagnetic interactions between magnetic cations located at octahedral and tetrahedral sites. It leads to a relatively low value of saturation magnetization. The Curie temperature in most ferrites is lower than that in metals. The anisotropy constant K_1 of soft ferrites is usually small and negative with the $\langle 1\,1\,1 \rangle$ axis being the easy magnetization direction. Additions of Fe^{2+} or Co^{2+} ions to the lattice provide positive contribution to K_1 and a tendency to change the easy magnetization direction (to $\langle 1\,0\,0 \rangle$ axis). It also gives a possibility to achieve a near-zero value of the anisotropy constant. The resistivity of ferrites is in the insulating range and much larger than that of metallic alloys. The dominant mechanism for the conduction in soft ferrites is the transfer of electrons between Fe^{2+} and Fe^{3+} ions on the octahedral sites. It means that resistivity of ferrites is dependent on the ferrous ions content. Resistivities of Mn–Zn ferrites range from 10^{-2} to $10\,\Omega\,m$, while Ni–Zn ferrites have resistivities $\sim 10^7\,\Omega\,m$. The hopping Fe^{2+}–Fe^{3+} also determines the frequency dependence of μ_i.

Ferrites have some disadvantages: low saturation magnetization (see **Table 2**), relatively low Curie temperature, and inferior mechanical properties. Despite these disadvantages, ferrites are widely used in modern technology. They are used in two main fields: power electronics (mainly Mn–Zn and Ni–Zn ferrites) and low-power techniques (Ni–Zn ferrites up to 300 MHz and Mn–Zn high-permeability ferrites up to some MHz).

Ferrimagnetic Iron Garnets

The basic formula of the ferrimagnetic rare-earth iron garnets is $\{R_3^{3+}\}[Fe_2^{3+}](Fe_3^{3+})O_{12}$, where R is either a rare-earth element or yttrium. These ions occupy dodecahedral {c} sites. The iron ions are distributed between tetrahedral (d) sites and octahedral [a] sites. Garnets crystallize in the cubic system. In a ferrimagnetic garnet, the magnetic moments of the octahedral and tetrahedral sublattices are antiparallel to each other. The moments of the Gd^{3+} and heavier R^{3+} ions couple antiferromagnetically to the net moment of the Fe^{3+} sublattices. The resulting magnetization of the garnet is the sum of these three contributions:

$$M(T) = |M_a(T) - M_d(T) + M_c(T)|$$

At low temperatures the rare-earth magnetization dominates. This effect is exactly canceled out by the net magnetization of iron sublattices at the "compensation temperature" T_{comp}. Below T_{comp}, the magnetization M_c lies parallel to a saturating field,

and above T_{comp} it is antiparallel. The moments of the light rare-earth ions couple ferromagnetically to the net moment of the Fe^{3+} sublattices and no compensation points exist. In the compound $Y_3Fe_5O_{12}$ (YIG) the most attractive property is the extremely narrow ferrimagnetic resonance line width, of the order of $50\,A\,m^{-1}$. Thus, YIG with various partial substitutions for Y finds wide applications in microwave devices. Garnets find major application at lower frequencies (<5 GHz). Above 5 GHz, spinel ferrites are commonly used. YIG exhibits a room temperature saturation magnetization $\mu_o M_s \approx 0.175$ T and a magnetocrystalline anisotropy $\sim 500\,J\,m^{-3}$. The saturation magnetization of light rare-earth garnets is slightly higher while it is much lower for heavy rare-earth garnets.

Amorphous Alloys

Amorphous alloys include two large classes: transition metal-metalloids with compositions near $(Fe, Co, Ni)_{80}$ $(B, C, Si)_{20}$ and transition metals – Zr, Hf. The former type offers greater potential for technical applications. Amorphous alloys are produced mainly by rapid ($\sim 10^6\,K\,s^{-1}$) quenching from the melt or by either sputtering or evaporation. The lack of long-range atomic order in amorphous magnetic alloys is responsible for: (1) high metallic resistivity ($\sim 10^{-6}\,\Omega\,m$), (2) absence of macroscopic magnetocrystalline anisotropy, (3) absence of grain boundaries and dislocations playing the role of pinning centers in crystalline magnetic materials, (4) a broad range of compositions available, yielding a continuous spectrum of property values, (5) outstanding mechanical properties, and (6) excellent resistance to corrosion.

The first class of amorphous alloys is divided into three groups (see **Table 3**):

1. iron-based amorphous alloys with a saturation induction B_s in the 1.1–1.8 T range with excellent high-frequency (up to 100 kHz) characteristics,
2. iron–nickel based amorphous alloys with a relatively low saturation induction but at the same time a low magnetostriction, and
3. cobalt-based amorphous alloys with a near-zero magnetostriction, a very high permeability, and low losses.

In addition to the applications of Fe-based alloys in electric utility and industrial transformers, amorphous metals are increasingly used in power electronics, telecommunication equipment, sensing devices, electric power conditioning, electronic article surveillance systems, etc. Slow crystallization of materials with a high resistance to crystallization allows a decreased critical cooling and enables stable bulk metallic glass formation. In this way, Fe-based bulk amorphous alloys with good soft magnetic properties are fabricated.

In soft magnetic amorphous ribbons and wires, the "giant magnetoimpedance effect" (GMI) is observed. This effect consists of drastic changes of the complex impedance (both real and imaginary components) of amorphous alloys upon application of an external magnetic field (of a few Oe) or mechanical stresses. Sensitivity of up to 500% of relative impedance change per Oe is observed in the very low-field region. The GMI effect is strongly dependent on the frequency of the applied field and on the magnetic anisotropies present in the material. That makes GMI materials quite convenient for application in sensors of current, position, level of liquid, and pressure. The sensors are employed in technologies such as car traffic monitoring, quality control steels, detection of earthquakes, and medicine.

Nanocrystalline Alloys

Nanocrystalline alloys consist of homogeneously distributed ultrafine grains with an average size of ~ 5–20 nm embedded in an amorphous matrix. They are prepared from amorphous ribbons (with the addition of Cu and Nb), which are subjected to a recrystallization annealing. The volume ratio of the crystalline phase ranges from 50% to 80% and can be controlled by the annealing temperature. Nanocrystalline alloys present a lower coercivity field than the amorphous samples, higher initial permeability than the Co-based amorphous alloys

Table 3 Soft magnetic materials (amorphous)

Material	*Curie temperature* (K)	*Saturation induction* (T)	*Coercivity* ($A\,m^{-1}$)	*Magnetostriction constant* (10^{-6})
$Fe_{81}B_{13.5}Si_{3.5}C_2$	370	1.61	3.2	30

$Fe_{56}Co_7Ni_7Zr_2Nb_8B_{20}$	508	0.71	1.7	10
$Fe_{72}Al_5Ga_2P_{11}C_6B_4$	605	1.07	5.1	2
$Fe_{40}Ni_{38}Mo_4B_{18}$	353	0.88	1.2	12
$Co_{67}Ni_3Fe_4Mo_2B_{12}Si_{12}$	340	0.72	0.4	0.5

Table 4 Soft magnetic materials (nanocrystalline alloys)

Material	*Curie temperature* (K)	*Saturation induction* (T)	*Coercivity* ($A\,m^{-1}$)	*Magnetostriction constant* (10^{-6})
$Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$	843	1.24	0.53	2.1
$Fe_{73.5}Cu_1Nb_3Si_{16.5}B_6$	833	1.18	1.1	~0
$Fe_{56}Co_7Ni_7Zr_2Ta_8B_{20}$	538	0.85	1.5	14
$Fe_{56}Co_7Ni_7Zr_2Nb_8B_{20}$	508	0.71	1.7	10
$Fe_{90}Zr_7B_3$		1.63	5.6	−1.1
$Fe_{86}Zr_7B_6Cu_1$		1.52	3.2	1
$Fe_{78}Si_9B_{13}$	688	1.56	2.4	27

(see **Table 4**), very low magnetostriction, and (due to the exchange softening) nearly zero effective magnetic anisotropy. The presence of Cu and Nb allows one to obtain well-differentiated microstructures. The resistivity of these materials is usually of the same order of magnitude as that of the amorphous ones, namely $1–1.5 \times 10^{-6}\,\Omega\,m$. The high permeability and weak energy loss of soft nanocrystalline alloys make them valuable for various sensors, safety devices, high-frequency transformers, and in many other applications.

Hard Magnetic Materials

The most important hard magnetic materials suited for permanent magnets are expected to have the following intrinsic magnetic properties:

1. *High Curie temperature*. This favors the 3*d* elements which exhibit direct exchange.
2. *High saturation magnetization at room temperature*. This again favors 3*d* elements (Fe, Co). The 3*d*–4*f* intermetallics based on the light rare earth which couple parallel with the 3*d* moment, are of special interest here.
3. *High uniaxial anisotropy*. Uniaxial anisotropy is necessary for the formation of high coercivity. The main contribution to a reasonably high anisotropy comes from the 4*f* ions. This anisotropy is of the single-ion type. To combine the best features of 3*d* and 4*f* components, a strong 3*d*–4*f* coupling is required.

Permanent magnets are characterized by an extremely wide hysteresis loop. The most important extrinsic parameter is the coercivity, H_c, connected with the total anisotropy via eqn [1].

Alnicos

Alnicos are a group of heat-treated Fe–Co–Ni–Al–Cu alloys which can be divided into two main subgroups: isotropic alloys containing 0–20 wt.% Co (alnicos 1–4) and anisotropic alloys with 22–24 wt.% Co and a titanium content of 5–8 wt.% (alnicos 5–9). The anisotropy in case of alnicos 5–9 is produced by controlled cooling or isothermal heat treatment in a saturating magnetic field. The main source of anisotropy is the shape anisotropy associated with elongated Fe–Co particles in an Ni–Al matrix aligned parallel to the magnetic field during spinodal decomposition of the alloy. Alnicos are widely used as permanent magnets (see **Table 5**). The most important applications are loudspeakers, watt-hour meters, electric motors, generators, and alternators.

Table 5 Magnetic properties of alnicos

Alloys	*Saturation induction* (T)	*Coercivity* ($A\,m^{-1}$)	*Energy product* $(BH)_{max}$ ($kJ\,m^{-3}$)
Alnico 3	0.5–0.6	54–40	10
Alnico 5	1.2–1.3	52–46	40–44
Alnico 7	0.74	85	24
Alnico 9	1.0–1.1	140–110	60–75

Hexagonal Ferrites

Hard ferrites have the general chemical formula $MFe_{12}O_{19}$, where M is Ba, Pb, or Sr. They have a hexagonal structure with Fe^{3+} ions located at five different crystallographic positions. The superexchange via bridging oxygen atoms leads to a collinear ferrimagnetic structure. The high magnetocrystalline anisotropy (see **Table 6**) has a crystal-field and dipolar origin. The intrinsic magnetic properties of hexagonal ferrites may be modified by chemical substitution. These ferrites exhibit a large coercivity ($200–300\,kA\,m^{-1}$) but a relatively low remanence (~0.4 T). They are produced by ceramic techniques and are often bonded in plastic. Owing to their low price, hexagonal ferrites are widely used in electric motors in automotive and acoustic industries (electrical equipment for vehicles, starter motors, etc.).

Cobalt–Samarium Magnets

Hard magnets based on $SmCo_5$ possess the highest uniaxial anisotropies of any class of magnets

Table 6 Intrinsic magnetic properties of $MFe_{12}O_{19}$ hexagonal ferrites

$Nd_2Fe_{14}B$	585	1.52		4.5	
Magnet (standard)			1000		260
Magnet (high remanence)			1250		400

($K \sim 10^7\,J\,m^{-3}$, see **Table 7**), while magnets based on Sm_2Co_{17} exhibit higher saturation magnetization and higher Curie temperature. Each of them has a uniaxial structure ($SmCo_5$ – hexagonal; Sm_2Co_{17} – hexagonal or rhombohedral). Chemical substitution in both compounds modifies their intrinsic and extrinsic magnetic properties. A small substitution of Cu for Co leads to precipitations of a nonmagnetic phase, which increases the coercivity. In this case, the coercivity mechanism is controlled by domain wall pinning on small $SmCo_5$ particles. A similar mechanism exists in $Sm_2(Co,Cu)_{17}$. The nucleation-controlled coercive force dominates in single-phase $SmCo_5$. The defects, which act as nucleation centers, are mostly associated with the surface of milled powder particles. The Curie temperature and saturation magnetization of Sm_2Co_{17} are substantially improved by partial Fe, Zr, and Cu substitution for Co. Fe is added to increase remanence, and Cu and Zr to form the required microstructure. In this case, the coercivity has a pinning-type character.

Neodymium–Iron–Boron Alloys

Permanent magnets based on $Nd_2Fe_{14}B$ have record values for the energy product $(BH)_{max}$. Except for the relatively low Curie temperature, the Nd–Fe–B magnets are superior to all other magnetic materials. The $Nd_2Fe_{14}B$ compound has a tetragonal structure. The Nd and Fe sublattices are aligned parallel to one another, giving a room temperature magnetization of 1.61 T, the largest of any rare-earth compound used for permanent magnets. The strong magnetocrystalline anisotropy of $Nd_2Fe_{14}B$ (see **Table 8**) results from the low symmetry of both the Nd and Fe sites. All components of $Nd_2Fe_{14}B$ can be partly substituted by metals or metalloids. Such substitution may lead to an improvement in the thermal stability of the magnetic properties above room temperature or/and to an improvement of the microstructure and performance of the magnet. For example, cobalt substitution improves the performance of $Nd_2Fe_{14}B$ by an increase of the Curie temperature, but at the same time the presence of cobalt decreases the magnetocrystalline anisotropy.

Small quantities of Dy are often substituted for Nd to improve the coercivity of Nd–Fe–B magnets. However, dysprosium reduces the magnetization of the system. Two principal fabrication routes for Nd–Fe–B magnets are: powder metallurgy (for oriented sintered magnets) and melt spinning (used mostly for bonded magnets). The optimum composition for sintered magnets was found to be $Nd_{15}Fe_{77}B_8$ which is both Nd- and B-rich with respect to the

stoichiometric $Nd_2Fe_{14}B$. The ideal two-phase microstructure in Nd–Fe–B sintered magnets consists of fully aligned grains of $Nd_2Fe_{14}B$ separated by the minimum amount of a nonmagnetic intergranular phase. Coercivity of sintered magnets is dominated by the nucleation mechanism. High remanence-oriented magnets have energy product of $\sim 400\,kJ\,m^{-3}$ and a remanence approaching 1.5 T. A different microstructure and magnetization is encountered in nanocrystalline Nd–Fe–B magnets produced by melt spinning. The origin of coercivity in melt-spun Nd–Fe–B magnets is similar to that established for sintered magnets. The nanocrystalline structure of Nd–Fe–B magnets may also be developed by mechanical alloying. Milling Fe, Nd, and B to form $Nd_2Fe_{14}B$ results in formation of α-Fe (of ~ 5 nm size) and an Nd-rich amorphous phase which should be heat treated to obtain high-coercivity material. A typical composition of these magnets is $Nd_{14}Fe_{80}B_6$. In case of fully dense isotropic nanomagnets, the characteristic energy products are $\sim 100\,kJ\,m^{-3}$ while the values of remanences are ~ 0.80 T. Mechanical alloying has also been used to synthesize other nanoscale two-phase mixtures of hard and soft magnetic phases. The exchange coupling between magnetically hard and soft phases can result in significant enhancement of the remanence. These nanocomposites are known as "exchange spring magnets." For this mechanism to be effective, the size of the soft grains should not exceed a few times the domain wall width for the hard phase ($\sim$20–30 nm). In such cases, the material behaves as if it were homogeneous, with anisotropy and magnetization being equal to the mean value of the constituent phases. Some typical examples are $Nd_2Fe_{14}B/Fe_3B$, $Nd_2Fe_{14}B/Fe$, and $Sm_2Fe_{17}N_3/Fe$.

Despite their relatively low Curie temperature and their susceptibility to corrosion, Nd–Fe–B magnets have found a great number of applications where high coercivity and energy result in design advantages. The applications include voice coil motors of hard disk drives and other small compact electronic products.

Giant Magnetostrictive Materials

Rare-earth metals have intrinsically huge magnetostriction because of the strong 4*f* electrons'–crystal lattice coupling. Although this coupling is indirect, it is huge because of the large spin–orbit coupling and the highly anisotropic localized nature of the 4*f* electrons. The relatively low magnetic ordering temperatures of rare-earth metals (R) (see **Table 1**) make use of the high value of magnetostriction at room temperature, possible only by combining them with 3*d* metals. Such a combination was realized most effectively in the Laves phase compound RFe_2, particularly in $TbFe_2$ (see **Table 9**), also known as "Terfenol." However, this compound has an intrinsically large magnetocrystalline anisotropy which limits its technical application. By addition of Dy atoms with a positive magnetocrystalline anisotropy, it is possible to compensate the negative magnetocrystalline anisotropy of terbium. The compound $Tb_{0.3}Dy_{0.7}Fe_2$ known as "Terfenol-D" maintains a giant magnetostriction (at low magnetic fields) with low magnetocrystalline anisotropy and relatively high Curie temperature. In the polycrystalline state, giant magnetostriction is possible only when the grains are aligned along the easy $\langle 1\,1\,1 \rangle$ direction and the effect is measured along this direction. This is because Terfenol-D alloys exhibit enormously large anisotropy in magnetostriction ($\lambda_{111} \gg \lambda_{100}$). These alloys are produced either by a directional solidification method, sintering, or by a polymer bonding. The last method has an advantage over the other two because including the polymer binder with a high electrical resistivity, the frequency limit of the polymer-bonded composites can be extended to hundreds of kHz. Favorable magnetostrictive properties are also observed in amorphous R–Fe alloys. The main industrial applications of "Terfenol-D" are linear actuators.

Manganites

Doped perovskite manganites $La_{1-x}A_xMnO_3$ (where A is Ba, Ca, Sr, or Pb) show a wide variety of magnetic field-induced phenomena, including the gigantic decrease of resistance under the application of a magnetic field. It is termed "colossal magnetoresistance effect (CMR)." By replacement of a trivalent rare earth by a divalent alkaline earth, the nominal valence of Mn can be continuously tuned between $3+$ (for $x = 0$) and $4+$ (for $x = 1$). The magnetic and magneto-transport properties of manganites are governed mainly by the mixed valence Mn^{3+}/Mn^{4+} ions and less affected by the oxygen ions. The *d*-electrons are subject to a variety of interactions, of which the most important are the double exchange, superexchange, and Jahn–Teller coupling. The double exchange interaction is responsible for a

Table 9 Magnetostriction constants for several rare-earth materials

Material	$T = 4.2$ K	*Room temperature*	
	λ_{111} (10^{-6})	λ_{111} (10^{-6})	*Polycrystal* (10^{-6})
$TbFe_2$	4400	2600	1750
$Tb_{0.3}Dy_{0.7}Fe_2$		1600	1200
Polymer-bonded Terfenol-D			536
$Tb_3Fe_5O_{12}$ garnet	2460		

strong correlation between magnetization and resistivity (or magnetoresistivity). The large resistance is related to the formation of small lattice polarons in the paramagnetic state. In these interactions, an important role is played by the e_g electrons on the Mn^{3+} ions. The orbital degeneracy leads to a variety of instabilities (such as magnetic, structural, and metal–insulator transitions, collapse of charge-ordered states under a magnetic field) and is responsible for a strong magnetoelastic coupling. The e_g electrons can be itinerant and hence play the role of conduction electrons, when electron vacancies or holes are created in the e_g orbital states of the crystal. The other characteristic feature of manganites is the appearance of unusual collective state of charge order, observed mostly for $x > 0.3$. This insulating state competes with two other basic phases in manganites, namely with the ferromagnetic metallic phase and the nonmetallic paramagnetic phase. A number of experiments have demonstrated that over wide ranges of compositions there can be a coexistence between the ferromagnetic metallic and charge-ordered insulating phases.

Magnetic Order

D Givord, CNRS, Grenoble, France

Introduction

Magnetism is a property of electrons within matter. Strong interactions exist between the atomic magnetic moments; they are of electrostatic origin, and are termed exchange interactions.

In the simplest case, the exchange interactions favor parallelism of all magnetic moments; this leads to ferromagnetic order. The properties of ferromagnetic materials can be described within the molecular field model. However, the experiment provides evidence for the local character of the interactions which cannot be explained within this model.

More generally, the exchange interactions may favor different types of coupling, and a large variety of different magnetic structures may exist. In the antiferromagnetic structures, the moments are arranged in two groups, termed sublattices. Within each sublattice, the moments are parallel, but they are antiparallel to the moments in the other sublattice. In many instances, the magnetic structure results from a competition between different interactions which cannot be satisfied simultaneously. This is, in particular, the case of the helimagnetic and modulated structures. When the arrangement of the magnetic atoms themselves is not periodic, spin-glass arrangements are found.

The most powerful technique for the study of magnetic structures is neutron diffraction, in which the neutron magnetic moment is used to probe the arrangement of the atomic moments.

Magnetic Moment and Magnetic Field

Magnetic Moment

Within matter, magnetism is due to electron motion around the nuclei. There are two contributions to the magnetic moment of an electron:

- the orbital moment, $\boldsymbol{m}_l$, is linked to the motion of the electrons in their orbits. It may be expressed as

$\boldsymbol{m}_l = -\mu_B \boldsymbol{l}$, where $\boldsymbol{l}$ is the orbital momentum and μ_B, the Bohr magneton, is the fundamental unit of magnetic moments ($1\mu_B = 0.927\,10^{-23}\,A\,m^2$). The quantum mechanical eigenvalues of $\langle l^2 \rangle$ are equal to $l(l+1)$ where l is an integer, called the orbital quantum number. The values $l = 0$, 1, 2 and 3 are associated to electrons of the *s*, *p*, *d*, and *f* shells respectively. The eigenvalues of $\langle l_z \rangle$ are integers, denoted m, where m is the magnetic quantum number; m is restricted between two limits, $+l$ and $-l$.

- the spin moment, $\boldsymbol{m}_s = -2\,\mu_B \boldsymbol{s}$ is related to the electron spin momentum, $\boldsymbol{s}$, most often referred to as the "spin." The spin is an entity of purely quantum mechanical nature. The eigenvalues of $\langle s^2 \rangle$ are equal to $s(s+1)$, where s, the spin quantum number, equal to 1/2. The eigenvalue of $\langle s_z \rangle$ are $+1/2$ and $-1/2$.

Due to the electrostatic interactions existing between electrons located on the same electronic shell of a given atom, the spin and orbital momentum of individual electrons are coupled together, according to the so-called Hund's rules. The resulting orbital momentum of the considered shell is noted as L, and the resulting spin, S. L and S are strongly coupled together by the spin–orbit coupling. For a full electronic shell, $L = 0$ and $S = 0$; magnetism is a property of partly filled electronic shells.

In the solid state, only two series of stable elements may show spontaneous magnetism (the actinides may be magnetic as well).

1. In the 3*d* transition series, to which Fe, Co, and Ni belong, magnetism is due to the progressive filling of the 3*d* shell. The orbital momentum is almost quenched. In the case where the 3*d* electrons are localized, the maximum value of the magnetic moment is approximately equal to $-2\mu_B S$. In 3*d* metallic systems, the magnetic 3*d* electrons have a certain itinerant character. The magnetic moments, expressed in μ_B, take a fractional value, which cannot be derived by the present simple considerations.
2. In the rare-earth series, from cerium to lutetium, magnetism results from the progressive filling of the 4*f* shells. The 4*f* electrons are fully localized. The maximum value of the moment is equal to $-g_J \mu_B J$, where J is equal to $L+S$ or $L-S$, depending on the considered element and g_J is the Landé factor.

Another magnetic moment may exist within matter, associated to the constitutive elements of the nucleus. The proton moment, μ_P, and the neutron moment, μ_N, amount to $\mu_B/1836$ and $\mu_B/865$ respectively.

Magnetic Moments in a Magnetic Field – Paramagnetism

When submitted to an applied magnetic field, $\boldsymbol{H}_{app}$, a magnetic moment, $\boldsymbol{m}$, tends to align along the field direction. The corresponding energy, called Zeeman energy, e_Z, is

$$e_Z = -\mu_0 \boldsymbol{m} \cdot \boldsymbol{H}_{app} \qquad [1]$$

An assembly of moments, $\boldsymbol{m}$, may be characterized by the magnetization, M, which is the moment per unit volume measured along the field direction, z:

$$M = N \langle m_z \rangle_T \qquad [2]$$

where N is the number of moments per unit volume and $\langle m_z \rangle_T$ is the thermal averaged value of m_z, the projection of $\boldsymbol{m}$ along $\boldsymbol{H}_{app}$.

At finite temperature, moment alignment is in competition with thermal activation which tends to create disorder; this characterizes paramagnetism. For a system of classical noninteracting moments, the magnetization, M, is given by

$$M = N m_0 \mathscr{L}(x) \qquad [3]$$

In expression [3], m_0 is the value of the moment at 0 K and $\mathscr{L}(x) = \coth(\chi) - 1/\chi$ is the Langevin function. The parameter x which enters into the Langevin function is the ratio between Zeeman energy and thermal energy:

$$x = \frac{\mu_0 \boldsymbol{m} \cdot \boldsymbol{H}_{app}}{k_B T} \qquad [4]$$

where μ_0 is the permittivity of vacuum ($= 4\pi \times 10^{-7}$ SI) and k_B is the Boltzmann constant.

For small x, the Langevin function may be expanded as $\mathscr{L}(x) \approx x/3 - x^3/45 + \cdots$. The high-temperature development of [3] is

$$M = C \frac{H_{app}}{T} \qquad [5]$$

where C is the Curie constant, given by

$$C = \frac{\mu_0 N m_0^2}{3k_B} \qquad [6]$$

A useful experimental parameter is the susceptibility, $\chi = M/H_{app}$. The reciprocal susceptibility $1/\chi$ varies linearly with T, with a slope $1/C$ (**Figure 1a**). This constitutes the Curie law.

For systems of quantum moments, the Langevin function must be replaced by a Brillouin function, $\mathscr{B}(x)$. The moment m_0 in expression [3] is equal to $-2\mu_B S$ (systems in which 3*d* localized electrons are involved) or $-g\mu_B J$ (rare-earth-based systems), the

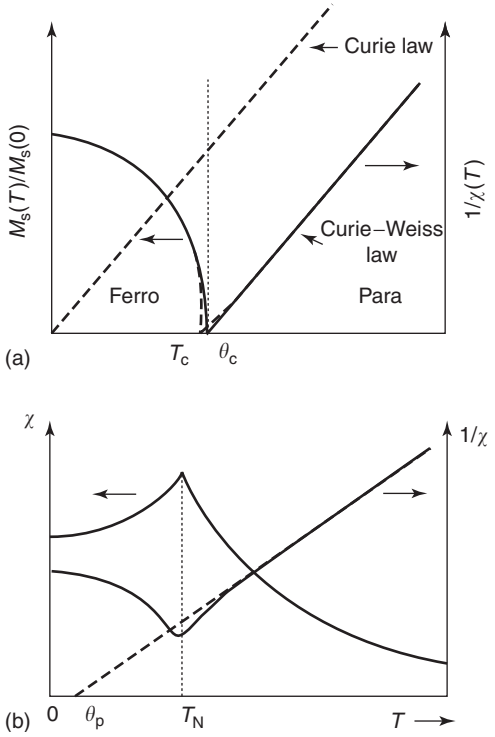

Figure 1 (a) In a system of noninteracting moments, the reciprocal susceptibility, $1/\chi(T)$, varies linearly with temperature with a slope $1/C$, where C is the Curie constant. In the presence of interactions, the molecular field model predicts a similar variation, but the representative curve is shifted towards higher temperatures. At $T = T_C$, the susceptibility becomes infinite. At $T < T_C$, a spontaneous magnetization, M_s, exists. This is ferromagnetism. The molecular field model does not properly give account for the existence of local fluctuations. These are responsible for the fact that the Curie temperature is lower than predicted and that the variation of $1/\chi(T)$ is not linear in the vicinity of T_C. (b) In an antiferromagnetic system, the susceptibility presents a maximum at the ordering temperature, T_N. In the paramagnetic state, the variation of $1/\chi(T)$ vs. T well above T_N is again linear.

maximum values of the projection of $\boldsymbol{m}$ along the field, whereas m_0 in expression [6] is replaced by μ_{eff}, the effective moment which is proportional to $\sqrt{S(S+1)}$ or to $\sqrt{J(J+1)}$.

Ferromagnetic Order

The Molecular Field Model

There is a category of magnetic materials, where the high-temperature susceptibility does not follow the Curie law, but is given by the expression

$$\chi = \frac{C}{T - T_C} \qquad [7]$$

where T_C is the Curie temperature (**Figure 1a**). Expression [7] constitutes the Curie–Weiss law.

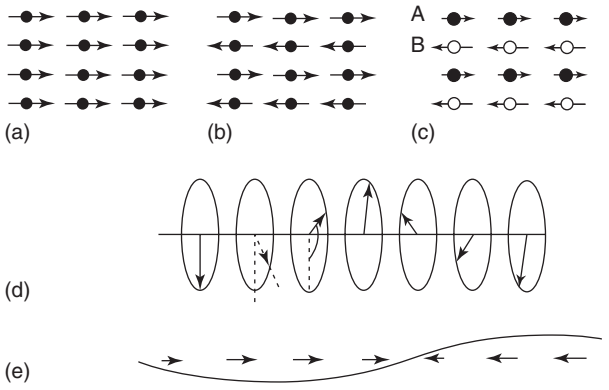

Figure 2 Schematic representations of various types of magnetic structures: (a) ferromagnetism, (b) antiferromagnetism, (c) ferrimagnetism, (d) helimagnetism, and (e) modulated structure.

It may be ascribed to interactions existing between the magnetic moments. To first approximation, these interactions are equivalent to a field, termed H_m created by the magnetic moments themselves. Within the molecular field theory of ferromagnetism, H_m is assumed to be proportional to the magnetization, M:

$$H_m = nM \qquad [8]$$

where n is the molecular field coefficient, such that

$$T_C = nC \qquad [9]$$

The value of the magnetization M may be obtained by replacing the applied field H_{app} in expression [4] by $H_{app} + H_m$ and by expressing that relations [3] and [8] must be satisfied simultaneously. Consider the special case where $H_{app} = 0$. At temperatures $T > T_C$, the only possible solution is $M = 0$; the moments are oriented at random and the system is paramagnetic, as it is in the absence of interactions. In this temperature range, the slope of the reciprocal susceptibility versus temperature is equal to $1/C$, as it is in noninteracting systems (**Figure 1a**). At $T = T_C$, the susceptibility diverges (it becomes infinite) and below T_C, a "spontaneous magnetization," M_s, exists within matter, indicating a certain degree of common alignment of all the moments. Such behavior characterizes ferromagnetic order (**Figure 2a**). The spontaneous magnetization, $M_s(T)$, progressively increases as temperature is decreased; at 0 K, it reaches the value $M_s = M_{s,0}$ ($\equiv N m_0$) of the magnetization at absolute saturation (**Figure 1a**).

Note that the magnetic energy density, associated with the formation of ferromagnetism, may be expressed as

$$E_{FM} = -\tfrac{1}{2}\mu_0 M_s H_m = -\tfrac{1}{2}\mu_0 n M_s^2 \qquad [10]$$

Beyond the Molecular Field Model: Evidence for Short-Range Order

The transition from a low-temperature ordered phase to a high-temperature disordered phase is a feature found in many physical systems. In the present case, the disordered phase is the paramagnetic phase and the ordered phase is the ferromagnetic one. First-order phase transitions are characterized by a discontinuity of thermodynamic variables such as the density or the entropy. In general, no such discontinuity exists at a paramagnetic–ferromagnetic transition. Landau has shown that "second-order" phase transitions are characterized by an abrupt symmetry change. In the paramagnetic phase, the system is invariant upon reversal of the magnetization; in the ferromagnetic phase, it is not invariant upon this reversal. In the vicinity of T_C, the magnetization is predicted to vary as

$$M_s = \sqrt{\frac{a}{2b}}(T_C - T)^{1/2} \qquad [11]$$

Here 1/2 is the critical exponent of the magnetization within the molecular field model. Experimentally, this critical exponent, denoted β, is found to be less than 0.5 (i.e., $\sim$0.3–0.4). This departure from the molecular-field-predicted value is due to the existence of local fluctuations of the magnetic state. Proper values of the critical exponents are obtained within the renormalization group theory.

Fluctuations cannot be explained within the molecular field model because H_m is proportional to M_s, a macroscopic quantity. Actually, the existence of magnetic fluctuations indicates that the magnetic interactions are short-ranged. The modification of the state for a given moment influences the state of the neighboring moments, but not that of moments which are at large distances. Magnetic disorder may proceed by keeping a certain degree of local order, while allowing the system to become disordered at the macroscopic level. The magnetic energy is reduced whereas the entropy is the same as for the case of homogeneous disorder. Due to short-range order, the experimental value of the Curie temperature is always lower than that predicted by the molecular field model. Close to T_C, the local correlations existing between moments lead to nonlinearity in the temperature dependence of the reciprocal susceptibility. At temperatures far above T_C, the influence of local fluctuations become negligible and the molecular-field-temperature dependence of the reciprocal susceptibility is recovered. The extrapolated intercept with the temperature axis gives the value of the so-called paramagnetic Curie temperature, θ_C, which is higher than T_C (**Figure 1**).

The local character of the magnetic interactions manifests itself as well in the ordered magnetic state, at low temperatures. The spontaneous magnetization decreases as $T^{3/2}$, more rapidly than predicted by the molecular field model. Specific excitations such as the spinwaves occur, which allow the local alignment of neighboring moments to be better preserved than in the case of random disorder, while allowing global disorder to develop.

Exchange Interactions

In a given ferromagnetic material, the strength of the molecular field may be derived from the value of the Curie temperature, T_C (see relation [9]). In Fe metal, the Curie temperature amounts to 1043 K, and in Co metal, it amounts to 1380 K; $H_m \approx 10^9\,\mathrm{A\,m^{-1}}$ is deduced.

From magnetostatics, it is known that a magnetic moment, $\boldsymbol{m}$, is the source of a dipolar magnetic field, $\boldsymbol{H}$, which, at point P, is expressed as

$$\boldsymbol{H} = \frac{1}{4\pi}\left[3\frac{(\boldsymbol{m}\cdot\boldsymbol{r})\boldsymbol{r}}{r^5} - \frac{\boldsymbol{m}}{r^3}\right] \qquad [12]$$

where $\boldsymbol{r}$ is the vector linking point O to point P. For $m \approx 2\,\mu_B$, which is the order of magnitude of the Fe or Co moment in metals, the corresponding magnetic field is of the order of $10^6\,\mathrm{A\,m^{-1}}$. This value is $\sim$1000 times smaller than the value derived from T_C. Except in rare cases, magnetic order cannot be attributed to dipolar interactions.

As shown by Heisenberg, the interactions at the origin of magnetic order are not magnetic in origin, but result from the repulsive electrostatic interactions existing between electrons. The Hamiltonian describing an ensemble of interacting electrons contains a term, called the exchange term, which results from electron indiscernibility. Magnetism emerges when account is taken of the Pauli exclusion principle. This stipulates that two electrons cannot occupy the same quantum state, defined by both space and spin variables. It imposes full antisymmetry of the wave function representative of the electron ensemble and, as a result, the interaction energy between electrons depends on their respective spin states.

It is often convenient to distinguish two terms in the exchange interactions. The intra-atomic interactions give rise to Hund's rules which govern the formation of atom magnetic moments; the inter-atomic exchange interactions are the source of the coupling between atom moments which allows magnetic order to be understood.

On the Connection between Exchange Interactions and Molecular Field

Within the Heisenberg theory, the exchange interaction between two spins i and j is generally

expressed as

$$e_{ij} = -2J_{ij}S_iS_j \qquad [13]$$

where J_{ij} is the exchange integral which represents the strength of the coupling between spins i and j. For an ensemble of N_T spins, the energy density is obtained by summing over all spins:

$$E_{ech} = -\frac{N_T}{V}\sum_{i,j\neq i} J_{ij}\mathbf{S}_i\mathbf{S}_j \qquad [14]$$

where V is the sample volume. Assuming that all atoms are identical, S_i and S_j may be replaced by S. Thus, the magnetic energy density can be written as

$$E_{ech} = -\frac{N_T S}{V}\left(\sum_{j\neq i} J_{ij}\right)S \qquad [15]$$

The first part of the right-hand expression in eqn [15] is proportional to the magnetization whereas the second part is proportional to the molecular field. Thus, this expression is equivalent to the molecular field expression of energy (eqn [10]); it also manifests the local character of magnetic interactions.

Magnetic Anisotropy

In ferromagnetic materials, the magnetic moments are aligned along well-defined crystallographic directions. This is the phenomenon of magnetic anisotropy. It is explained by considering that the electrons belonging to the magnetic shells interact with other charges in the environment, which constitute the so-called crystalline electric field (CEF). Due to the orbit asymmetry, the coupling energy depends on the orientation of the orbit within the CEF. A favored orientation of the orbital magnetic moment is intrinsically linked to the favored orientation of the orbit. Since the spin and orbital moments are linked, the total moment aligns along a preferred direction. This is the phenomenon of magnetic anisotropy. The anisotropy is high in rare-earth systems where a large orbital moment exists.

In uniaxial systems, there exists a unique easy direction of magnetization and a hard plane, perpendicular to the unique axis. The anisotropy field is the amplitude of the field applied in the plane and required to force the moments into this plane. In systems of higher symmetry, such as the cubic systems, there exist several easy directions and the anisotropy is weaker in general than in uniaxial systems.

Mechanisms of Magnetic Coupling

Exchange interactions constitute the general source of moment coupling. However, the details of the coupling mechanism may differ strongly from one system to another. In this section, this is illustrated by some representative examples.

Consider 3*d* electrons in iron, cobalt, nickel, or one of their alloys. The exchange-coupling existing between all electrons sitting on the same site favors a parallel coupling between their spins (Hund's rules). However, the 3*d* electrons have a certain degree of itinerant character, that is, they have a finite occupancy probability on the atom sites of the environment. An electron, arriving on another site, becomes exchange coupled to the electrons present on this site and again a parallel coupling between spins is favored. Thus, a parallel coupling between the two associated moments is favored. This mechanism explains high-temperature ferromagnetism observed in these systems.

In transition metal oxides, such as MnO, Fe_2O_3, CoO, or NiO, the fully localized 3*d* electrons are hybridized with the 2*p* electrons of oxygen. The *d* electrons, sitting on two different transition metal atoms but coupled to *p* electrons on the same oxygen atom, become indirectly coupled together. This mechanism constitutes super exchange. Often, it favors an antiparallel coupling between transition metal spins, that is, the exchange integral J is negative. Nonferromagnetic structures may result.

The 4*f* electrons of the rare-earth elements occupy an internal electronic shell, which is protected from the environment by more external shells, such as the 5*d* and 6*s* ones. The 4*f* electrons are strongly localized and bear well-defined magnetic moments. No interaction exists with 4*f* electrons on other sites. However, the 4*f* electrons are exchange coupled to the 5*d* and 6*s* electrons which become polarized. In metallic systems, the 5*d*, 6*s* electrons are itinerant. When they travel from one atom to the next, their polarization oscillates with a period which is characteristic of the band structure. Indirect interactions between the localized moments result in the RKKY type. They are the source of an indirect coupling between the 4*f* moments which is long-ranged and oscillatory.

Non-Ferromagnetic Types of Magnetic Orders

The possible existence of negative J values explains that diverse types of magnetic orders may exist, in addition to ferromagnetism.

Antiferromagnetism

Consider a system which contains one type of magnetic atoms, all bearing the same magnetic moment, but which may be separated into two groups, A and

B, called sublattices. Within the same sublattice, the exchange integrals J_{AA} and J_{BB} (coupling moments) are positive, whereas J_{AB} (the coupling moments belonging to different sublattices) are negative. The magnetic structure is such that all moments within a given sublattice are parallel to each other and antiparallel to the moments within the other sublattice. The resulting global magnetization is zero. Such a moment arrangement characterizes antiferromagnetism (**Figure 2b**). Amongst many other systems, it is found in the transition metal oxides MnO, CoO, or NiO.

Antiferromagnetism may be described within the molecular field model, by decomposing the molecular field into two separate contributions, one from each sublattice. Assuming that the two sublattices are identical, the molecular field may be expressed as

$$\boldsymbol{H}_{\mathrm{m}} = nM_{\mathrm{s}}^{\mathrm{sl}} - n'M_{\mathrm{s}}^{\mathrm{sl}} \qquad [16]$$

where $M_{\mathrm{s}}^{\mathrm{sl}}$ is the spontaneous magnetization within each sublattice, $n\,(>0)$ is the molecular field coefficient representative of the interactions within a given sublattice, and $n'\,(<0)$ is the molecular field coefficient representative of the interactions between sublattices. The coefficients n and n' are related to the J's through expressions which are similar to expression [19]. The magnetization of each sublattice is given by expression [3], but with

$$x = \frac{\mu_0 m(nM_{\mathrm{s}}^{\mathrm{sl}} - n'M_{\mathrm{s}}^{\mathrm{sl}})}{k_{\mathrm{B}}T} \qquad [17]$$

One looks for solutions of expressions [3] and [16] simultaneously. Above a critical temperature, T_{N}, called the Néel temperature, which is the equivalent of the Curie temperature for ferromagnetism, the sublattice magnetization is equal to zero; the slope of the reciprocal susceptibility versus T is the same as found in noninteracting and ferromagnetic systems, equal to $1/C$ (**Figure 1b**). At $T = T_{\mathrm{N}}$, magnetic order sets in. Below T_{N}, a nonzero magnetization exists within each sublattice.

In the ordered magnetic state, an applied magnetic field tends to align all moments along itself; it works against inter-sublattice exchange-coupling. As temperature decreases, the ratio of exchange-coupling energy to Zeeman energy increases. Thus, the magnetic susceptibility decreases. Combining this with the usual temperature decrease of the susceptibility in the paramagnetic state, it results that the magnetic susceptibility presents a maximum at T_{N}. This constitutes a common feature of antiferromagnetic-like structures, in which the global magnetization is zero.

From the point of view of quantum mechanics, Landau noted that the antiferromagnetic configuration described above, termed a Néel state, is not an eigenstate of the corresponding Hamiltonian. The actual ground state is a mixture of the two equivalent Néel states which are obtained by reversing the magnetization in the two sublattices; it is not magnetic. Due to the macroscopic nature of the antiferromagnetic domains, the Néel state is almost indistinguishable from the real ground state. Although not yet experimentally demonstrated, this is not the case in nanosystems.

Ferrimagnetism

Many transition metal oxides incorporate two different magnetic elements. The magnitude of the associated moments differs and a certain magnetization remains even when the moments are coupled antiparallel. Such ferrimagnetic structures (**Figure 2c**) are found in Fe oxides, such as γ-Fe_2O_3 and Fe_3O_4, where Fe moments in different ionic states coexist.

Ferrimagnetism is also found in rare-earth compounds with Fe, Co, or Ni, where an antiparallel coupling between the $3d$ moments and the rare-earth moments occur.

Helimagnetism and Modulated Structures

In the molecular field description of ferromagnetism, the molecular field is assumed to be a macroscopic entity. However, the local character of the magnetic interactions is established by experimental results which were mentioned above, and it emerges naturally in the Heisenberg description of the exchange interactions.

In the version of the molecular field model developed for the description of antiferromagnetism, the distinction between two different contributions gives to the molecular field a certain local character. In the spirit of a local description, the molecular field on a certain site, i, may be expressed in terms of the sum of the interactions of the moment, m_i, with all other j moments:

$$\boldsymbol{H}_i = \sum_j n_{ij} \langle m_j \rangle_T \qquad [18]$$

where the n_{ij}'s are molecular field coefficients. By analogy with the analyses described above, the magnetic moment, at temperature T, is given by

$$\langle m_i \rangle_{\mathrm{T}} = m_0 \mathscr{L}\left(\frac{\mu_0 m_0(H_i)}{k_{\mathrm{B}}T}\right) \qquad [19]$$

The high-temperature expansion of this expression is

$$T\langle m_i \rangle_T = C\sum_j n_{ij}\langle m_j \rangle_T \qquad [20]$$

with solutions of the type

$$\langle m_i \rangle_T = A\exp(\mathrm{i}\boldsymbol{k}\boldsymbol{R}_i) \qquad [21]$$

where $\boldsymbol{R}_i$ describes the atom positions and $\boldsymbol{k}$ is a vector. One defines the quantity $\mathscr{T}(\boldsymbol{k})$ which is the Fourier transform of the exchange interactions:

$$\mathscr{T}(\boldsymbol{k}) = C\sum_j n_{ij} \exp(\mathrm{i}\boldsymbol{k}(\boldsymbol{R}_i - \boldsymbol{R}_j) \qquad [22]$$

The critical temperature is given by

$$T_c = \mathscr{T}(\boldsymbol{k}_0) \qquad [23]$$

where T_c is the highest temperature for which the set of eqn [20] admits a nonzero solution, and the associated vector $\boldsymbol{k}_0$ which characterizes the magnetic structure is termed the propagation vector of the structure.

This approach may be illustrated by considering a linear chain of atoms, distant by a, such that the exchange interactions are positive between first neighbors (n_1), negative between second neighbors (n_2), and equal to zero for larger distances. For $n_1 \gg n_2$, the ferromagnetic solution is obtained (for n_1 large and negative, the structure is antiferromagnetic), but this is no more the case for $|n_2| > n_1/4$. When the magnetic moments are confined in the plane perpendicular to the chain by the magnetic anisotropy, a helimagnetic structure is found in which the moments rotate progressively from one to the next, along the chain (**Figure 2d**). This structure is found in some rare-earth metals, such as terbium or dysprosium. Reciprocally, when the moments are forced to align along the chain axis, a modulated structure occurs in which the amplitude of the moments oscillates periodically (**Figure 2e**). This occurs in thulium.

Helimagnetic and modulated structures belong to the large class of antiferromagnetic structures, which are characterized by the zero value of the spontaneous magnetization. However, in these two cases, the stable magnetic structure is the result of a compromise between the various interactions involved, and is said to be frustrated. The analysis of frustrated structures has recently been the topic of intense research, both theoretically and experimentally.

Spin-Glasses and Other Frustrated Systems

When the magnetic atoms do not form a periodic arrangement, another type of frustrated magnetic arrangement may exist. This is the case in substitutional alloys in which two or more types of atoms are randomly distributed on a given periodic lattice, or in amorphous alloys, obtained by very fast quenching from the melt. Since the magnitude and sign of interactions depend on the distance, it may be expected that the random distribution of atoms leads to a distribution of J values which is centered at 0 such that there are as many positive and negative interactions.

As long as the interactions n_{ij} are evenly distributed from positive to negative, with zero mean value, no stable magnetic order may exist. However, if eqn [20] is squared, one obtains

$$T^2 \langle m_i \rangle^2 = C^2 \left(\sum_j n_{ij} \langle m_j \rangle \right)^2 \qquad [24]$$

For a fully disordered system of infinite dimensions, the sum over the terms $n_{ij}n_{ij'} \langle m_j \rangle \langle m_{j'} \rangle$ is zero and eqn [24] can be expressed as

$$T^2 \langle m_i \rangle^2 = C^2 \left(\sum_j n_{ij}^2 \langle m_j \rangle^2 \right) \qquad [25]$$

This expression has a critical temperature given by

$$T_c = C \left(\sum_j n_{ij}^2 \right)^{1/2} \qquad [26]$$

Below T_c, the system is in a spin-glass state where the moments are randomly oriented. Equation [25] does not apply rigorously to finite-size systems. It has been a long debate to decide whether or not a real phase transition occurs in spin glasses. Experimentally, a peak is observed in the thermal variation of the magnetic susceptibility, but the temperature at which it occurs is found to depend on the time taken for the measurement (**Figure 3**). Initially, this type of measurement suggested that the spin-glass transition is not a real phase transition. Actually, it is now accepted that the spin glass transition constitutes a new class

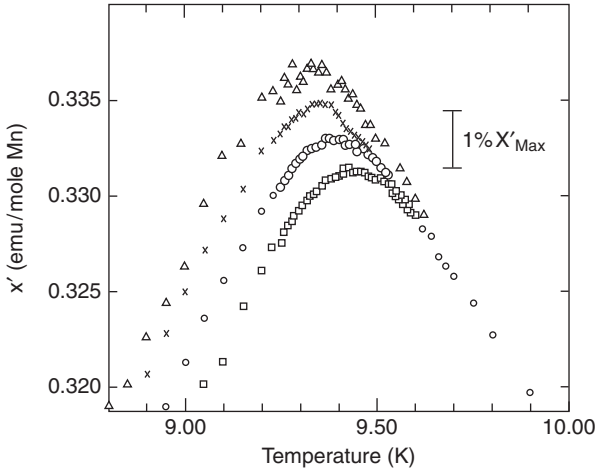

Figure 3 Thermal variation of the susceptibility in a spin glass: a Cu–Mn alloy containing 0.95% of Cu. The measurements of the susceptibility were realized under AC field of different frequencies (□ 1330 Hz, ○ 234 Hz, X 10.4 Hz, △ 2.6 Hz). The frequency dependence of the temperature at which the peak occurs in $\chi(T)$ is related to the fact that the critical slowing down of the magnetic fluctuations extends in spin glasses much farther from the value of the critical temperature than it does in other ordered magnetic systems.

of phase transitions in which the first derivative of the magnetic susceptibility versus temperature does not show any anomaly, but derivatives of higher orders do. The frequency dependence of the temperature at which the peak occurs in $\chi(T)$ is related to the fact that the critical slowing down of the magnetic fluctuations extends in spin glasses much farther from the value of the critical temperature than it does in other ordered magnetic systems.

Experimental Studies of Magnetic Structures

The macroscopic magnetic properties of magnetic materials may be derived from the magnitude of the stray field generated by the material magnetization, whether it is spontaneous or induced by the applied field. However, such measurements do not allow the moments of the various constitutive elements to be determined individually. Additionally, in the absence of applied field, antiferromagnetic-like materials do not generate any stray field. For this type of characterization, local probes such as Mössbauer spectroscopy in the case of Fe systems or NMR may be used. Neutron diffraction constitutes an invaluable tool for the study of magnetic arrangements. The neutron bears a small magnetic moment which probes the magnetism existing within matter. Neutron diffraction is the strict analog for the analysis of magnetic structures as X-ray diffraction is for the studies of crystallographic structures. Neutron diffractograms obtained with MnO are shown in **Figure 4**. In (a), the peak observed at 12° is due to the (1 1 1) reflection; it is characteristic of the face-centered cubic crystallographic structure of this compound. In (b), an additional peak is observed at ~6°. It can be indexed as 1/2, 1/2, 1/2. It is the signature of periodicity doubling. In an antiferromagnetic structure, the alternation of moment orientations leads to periodicity doubling (see scheme in the inset to **Figure 4**). The diffractograms shown in **Figure 4** have a special historical meaning. They constituted, when they were published, the first experimental proof of the existence of antiferromagnetism. Today, neutron diffraction has developed to a very sophisticated level; it allows very complex magnetic arrangements, including those found in spin glasses and other disordered systems, to be examined.

X-rays interact with the electrons within matter. Since spin–orbit coupling makes the bridge between electron distribution and magnetism, they probe magnetism as well. Although the magnetic interaction term is very small, magnetic studies using X-rays (X-ray magnetic circular dichroism and X-ray diffraction) have recently developed, thanks to the availability of very intense X-ray sources at synchrotron radiation facilities. A specific feature of X-ray studies is element selectivity, which occurs when the wavelength of the incident radiation corresponds to the characteristic energy of a given absorption edge for some element contained in the material examined.

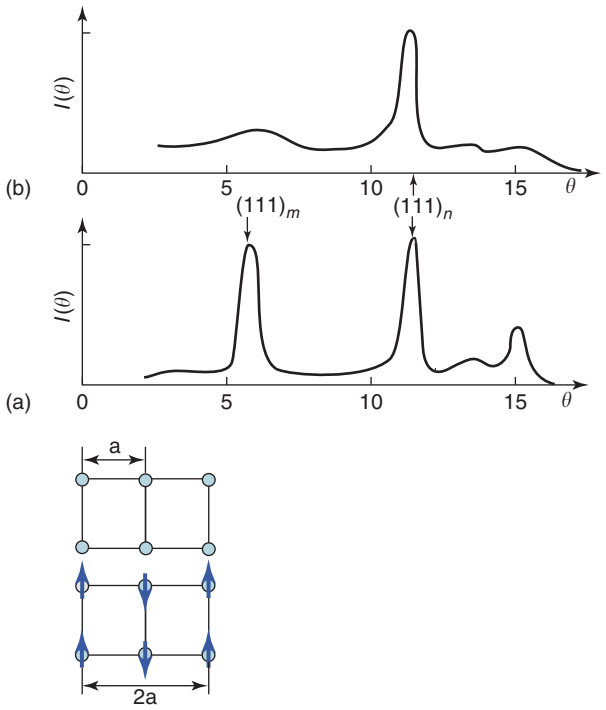

Figure 4 Neutron diffractograms obtained with MnO. (a) At 300 K, the material is paramagnetic. The observed (1 1 1) peak near $\theta = 12$ is characteristic of the cubic crystallographic structure. (b) The additional peak near $\theta = 6$ observed at 120 K reveal a doubling of the unit cell. It may be associated with the existence of an antiferromagnetic arrangement of the moments (inset).

Nomenclature

$\mathscr{B}$	Brillouin function
C	Curie constant

g_J	Landé factor
$\boldsymbol{H}_{\mathrm{app}}$	applied magnetic field (vector)
H_{app}	applied magnetic field (magnitude)
H_{m}	molecular field
J	exchange integral
$\boldsymbol{J}$	total angular momentum
$\boldsymbol{k}_0$	propagation vector
l	orbital quantum number
$\boldsymbol{l}$	orbital momentum
$\boldsymbol{L}$	orbital momentum
$\mathscr{L}$	Langevin function
m	magnetic quantum number
m_0	measured magnetic moment at 0 K
$\boldsymbol{m}$	magnetic moment
$\boldsymbol{m}_l$	orbital moment
$\boldsymbol{m}_{\mathrm{s}}$	spin moment
$\boldsymbol{m}_z$	projection of m along H_{app}
M	magnetization
M_{s}	spontaneous magnetization
$M_{\mathrm{s},0}$	magnetization at absolute saturation
n	molecular field coefficient
N	number of moments per unit volume
N_{D}	demagnetizing field coefficient
N_{T}	total number of moments
S	spin or spin angular momentum
T	temperature
T_{c}	critical temperature
T_{C}	Curie temperature
T_{N}	Néel temperature
v_{at}	atom volume
x	argument of the Langevin or Brillouin function
z	number of first neighbors
χ	magnetic susceptibility
μ_{B}	Bohr magneton
μ_{eff}	effective moment
μ_0	permittivity of vacuum

Magnetic Point Groups and Space Groups

R Lifshitz, Tel Aviv University, Tel Aviv, Israel

Introduction

Magnetic groups – also known as antisymmetry groups, Shubnikov groups, Heesch groups, Opechowski–Guccione (OG) groups, as well as dichromatic, 2-color, or simply black-and-white groups – are the simplest extension to standard point group and space group theory. They allow directly to describe, classify, and study the consequences of the symmetry of crystals, characterized by having a certain property, associated with each crystal site, that can take one of two possible values. This is done by introducing a single external operation of order two that interchanges the two possible values everywhere throughout the crystal. This operation can be applied to the crystal along with any of the standard point group or space group operations, and is denoted by adding a prime to the original operation. Thus, any rotation g followed by this external operation is denoted by g'.

To start with, a few typical examples of this two-valued property are given, some of which are illustrated in **Figure 1**. In the section "Magnetic point groups" the notion of a magnetic point group is discussed, followed by a discussion on magnetic space groups in the section "Magnetic space groups". The section "Extinctions in neutron diffraction of antiferromagnetic crystals" describes one of the most

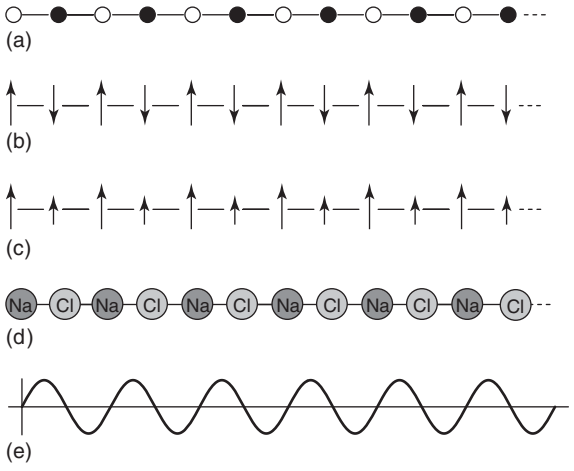

Figure 1 Several realizations of the simple 1D magnetic space group $p_p\bar{1}$. Note that the number of symmetry translations is doubled if one introduces an operation e' that interchanges the two possible values of the property, associated with each crystal site. Also note that spatial inversion $\bar{1}$ can be performed without a prime on each crystal site, and with a prime $(\bar{1}')$ between every two sites. (a) An abstract representation of the two possible values as the two colors – black and white. The operation e' is the nontrivial permutation of the two colors. (b) A simple antiferromagnetic arrangement of spins. The operation e' is time inversion which reverses the signs of the spins. (c) A ferromagnetic arrangement of two types of spins, where e' exchanges them as in the case of two colors. (d) A 1D version of salt. e' exchanges the chemical identities of the two atomic species. (e) A function $f(x)$ whose overall sign changes by application of the operation e'.

direct consequences of having magnetic symmetry in crystals which is the extinction of magnetic Bragg peaks in neutron diffraction patterns. A conclusion is given in the section "Generalizations of magnetic groups" by mentioning the generalization of magnetic groups to cases where the property associated with each crystal site is not limited to having only one of two possible values.

Consider first the structure of crystals of the cesium chloride type. In these crystals the atoms are located on the sites of a body-centered cubic (b.c.c.) lattice. Atoms of one type are located on the simple cubic lattice formed by the corners of the cubic cells, and atoms of the other type are located on the simple cubic lattice formed by the body centers of the cubic cells. The parent b.c.c. lattice is partitioned in this way into two identical sublattices, related by a body-diagonal translation. One may describe the symmetry of the cesium chloride structure as having a simple cubic lattice of ordinary translations, with a basis containing one cesium and one chlorine atom. Alternatively, one may describe the symmetry of the crystal as having twice as many translations, forming a b.c.c. lattice, half of which are primed to indicate that they are followed by the external operation that exchanges the chemical identities of the two types of atoms. A similar situation occurs in crystals whose structure is of the sodium chloride type, in which a simple cubic lattice is partitioned into two identical face-centered cubic (f.c.c.) sublattices.

Another typical example is the orientational ordering of magnetic moments (spins), electric dipole moments, or any other tensorial property associated with each site in a crystal. Adopting the language of spins, if these can take only one of two possible orientations – "up" and "down" – as in simple antiferromagnets, the same situation as above is seen, with the two spin orientations replacing the two chemical species of atoms. In the case of spins, the external prime operation is a so-called antisymmetry operation that reverses the signs of the spins. Physically, one may think of using the operation of time inversion to reverse the directions of all the spins without affecting anything else in the crystal.

Finally, consider a periodic or quasiperiodic scalar function of space $f(\boldsymbol{r})$, as in **Figure 1e**, whose average value is zero. It might be possible to extend the point group or the space group describing the symmetry of the function $f(\boldsymbol{r})$ by introducing an external prime operation that changes the sign of $f(\boldsymbol{r})$.

For the sake of clarity, the picture of up-and-down spins, and the use of time inversion to exchange them shall be adopted for the remaining of the discussion. It should be emphasized, though, that most of what is said here (except for the discussion of extinctions) applies equally to all the other two-valued properties. The magnetic crystal is described using a scalar spin density field $S(\boldsymbol{r})$ whose magnitude gives the magnitude of an atomic magnetic moment, or some coarse-grained value of the magnetic moment, at position $\boldsymbol{r}$. The sign of $S(\boldsymbol{r})$ gives the direction of the spin – a positive sign for up spins and a negative sign for down spins. Thus, the function $S(\boldsymbol{r})$ can be a discrete set of delta functions defined on the crystal sites as in **Figure 1b**, or a continuous spin density field as in **Figure 1e**.

Magnetic Point Groups

A d-dimensional magnetic point group G_M is a subgroup of $O(d) \times 1'$, where $O(d)$ is the group of d-dimensional rotations, and $1'$ is the time inversion group containing the identity e and the time inversion operation e'. Note that the term "rotation" is used to refer to proper as well as improper rotations such as mirrors.

Three cases exist: (1) all rotations in G_M appear with and without time inversion; (2) half of the rotations in G_M are followed by time inversion and the other half are not; and (3) no rotation in G_M is followed by time inversion. More formally, if G is any subgroup of $O(d)$, it can be used to form at most three types of magnetic point groups, as follows:

1. $G_M = G \times 1'$. Thus, each rotation in G appears in G_M once by itself, and once followed by time inversion. Note that in this case $e' \in G_M$.
2. $G_M = H + g'H$, where $G = H + gH$, and $g \notin H$. Thus, exactly half of the rotations in G, which belong to its subgroup H, appear in G_M by themselves, and the other half, belonging to the coset gH, are followed by time inversion. Note that in this case $e' \notin G_M$.
3. $G_M = G$. Thus, G_M contains rotations, none of which are followed by time inversion.

Enumeration of magnetic point groups is thus straightforward. Any ordinary point group G (i.e., any subgroup, usually finite, of $O(d)$) is trivially a magnetic point group of type 3, and along with the time inversion group gives another magnetic point group of type 1, denoted as $G1'$. One then lists all distinct subgroups H of index 2 in G, if there are any, to construct additional magnetic point groups of type 2. These are denoted either by the group–subgroup pair $G(H)$, or by using the International (Hermann–Mauguin) symbol for G and adding a prime to those elements in the symbol that do not belong to the subgroup H (and are therefore followed by time inversion). The set of magnetic groups (here magnetic

point groups G_M), formed in this way from a single ordinary group (here an ordinary point group G), is sometimes called the magnetic superfamily of the group G. For example, the orthorhombic point group $G = mm2 = \{e, m_x, m_y, 2_z\}$ has three subgroups of index 2 ($H_1 = \{e, m_x\}$, $H_2 = \{e, m_y\}$, and $H_3 = \{e, 2_z\}$), of which the first two are equivalent through a relabeling of the x and y axes. This yields a total of four magnetic point groups: $mm2$, $mm21'$, $m'm2'$ (equivalently expressed as $mm'2'$), and $m'm'2$.

Magnetic point groups of type 3 are equivalent to ordinary nonmagnetic point groups and are listed here only for the sake of completeness. Strictly speaking, they can be said to describe the symmetry of ferromagnetic structures with no spin–orbit coupling. Groups of this type are not considered here any further. Magnetic point groups of type 2 can be used to describe the point symmetry of finite objects, as described in the next section, as well as that of infinite crystals, as described in the section "Magnetic point groups of crystals." Magnetic point groups of type 1 can be used to describe the point symmetry of infinite crystals, but because they include e' as a symmetry element they cannot be used to describe the symmetry of finite objects, as is now defined.

Magnetic Point Groups of Finite Objects

The magnetic symmetry of a finite object, such as a molecule or a cluster containing an equal number of two types of spins, can be described by a magnetic point group. One can say that a primed or unprimed rotation from $O(d) \times 1'$ is in the magnetic point group G_M of a finite object in d dimensions, if it leaves the object invariant. Clearly, only magnetic point groups of type 2, listed above, can describe the symmetry of finite magnetically ordered structures. This is because time inversion e' changes the orientations of all the spins, and therefore cannot leave the object invariant unless it is accompanied by a nontrivial rotation. It should be mentioned that in this context, point groups of type 1 are sometimes called "gray" groups, as they describe the symmetry of "gray" objects which stay invariant under the exchange of black and white.

Magnetic Point Groups of Crystals

The magnetic point group of a d-dimensional magnetically ordered "periodic crystal", containing an equal number of up and down spins, is defined as the set of primed or unprimed rotations from $O(d) \times 1'$ that leave the crystal "invariant to within a translation". The magnetic point group of a crystal can be either of the first or of the second type listed above. It is of type 1 if time inversion by itself leaves the crystal invariant to within a translation. Recall that in this case, any rotation in the magnetic point group can be performed either with or without time inversion. If time inversion cannot be combined with a translation to leave the crystal invariant, the magnetic point group is of type 2, in which case half the rotations are performed without time inversion and the other half with time inversion.

Figure 2a shows an example of a magnetically ordered crystal whose magnetic point group is of type 1. This is a square crystal with magnetic point group $G_M = 4mm1'$ where time inversion can be followed by a translation to leave the crystal invariant. **Figure 2b** shows an example of a crystal whose magnetic point group is of type 2. This is a hexagonal crystal with point group $G_M = 6'mm'$. Note that all right-side-up triangles contain a blue circle (spin up), and all up-side-down triangles contain a green circle (spin down). Time inversion, exchanging the two types of spins, cannot be combined with a translation to recover the original crystal. Time inversion must be combined with an operation, such as the sixfold rotation or the horizontal mirror that interchanges the two types of triangles, to recover the original crystal. Note that the vertical mirror (the first m in the International symbol) leaves the crystal invariant without requiring time inversion, and is therefore unprimed in the symbol.

More generally, the magnetic point group of a d-dimensional magnetically ordered "quasiperiodic crystal (quasicrystal)," is defined as the set of primed or unprimed rotations from $O(d) \times 1'$ that leave the crystal "indistinguishable." This means that the rotated and unrotated crystals contain the same spatial distributions of finite clusters of spins of arbitrary size. The two are statistically the same though not necessarily identical. For the special case of periodic crystals, the requirement of indistinguishability reduces to the requirement of invariance to within a translation.

Figure 3 shows two quasiperiodic examples, analogous to the two periodic examples of **Figure 2**. **Figure 3a** shows an octagonal crystal with magnetic point group $G_M = 8mm1'$. One can see that time inversion rearranges the spin clusters in the crystal, but they all still appear in the crystal with the same spatial distribution. This is because any finite spin cluster and its time-reversed image appear in the crystal with the same spatial distribution. **Figure 3b** shows a decagonal crystal with magnetic point group $G_M = 10'm'm$. In this case, time inversion does not leave the crystal indistinguishable. It must be combined either with odd powers of the tenfold rotation, or with mirrors of the vertical type.

(a) An octagonal quasicrystal with magnetic point group $G_M = 8mm1'$ and magnetic space group p_p8mm, first appeared in an article by Niizeki (1990) *Journal of Physics A: Mathematical and General* 23: 5011. (b) A decagonal quasicrystal with magnetic point group $G_M = 10'm'm$ and magnetic space group $p10'm'm$ based on the tiling of Li, Dubois, and Kuo (1994) *Philosophical Magazine Letters* 69: 93.

Magnetic Space Groups

The full symmetry of a magnetically ordered crystal, described by a scalar spin density field $S(\boldsymbol{r})$, is given by its magnetic space group $\mathcal{G}_{\mathrm{M}}$. It was mentioned earlier that the magnetic point group G_{M} is the set of primed or unprimed rotations that leave a periodic crystal invariant to within a translation, or more generally, leave a quasiperiodic crystal indistinguishable. One still needs to specify the distinct sets of translations $\boldsymbol{t}_g$ or $\boldsymbol{t}_{g'}$ that can accompany the rotations g or g' in a periodic crystal to leave it invariant, or provide the more general characterization of the nature of the indistinguishability in the case of quasicrystals.

Periodic Crystals

As in the case of point groups, one can take any space group $\mathcal{G}$ of a periodic crystal and form its magnetic superfamily, consisting of one trivial group $\mathcal{G}_{\mathrm{M}} = \mathcal{G}$, one gray group $\mathcal{G}_{\mathrm{M}} = \mathcal{G}1'$, and possibly nontrivial magnetic groups of the form $\mathcal{G}_{\mathrm{M}} = \mathcal{H} + (g'|\boldsymbol{t}_{g'})\mathcal{H}$, where $\mathcal{H}$ is a subgroup of index 2 of $\mathcal{G}$. Only the latter, nontrivial groups are relevant as magnetic space groups consisting of operations that leave the magnetically ordered crystal "invariant." These nontrivial magnetic space groups are divided into two types depending on their magnetic point groups G_{M}:

1. *Class-equivalent magnetic space groups*. The magnetic point group G_{M} is of type 1, and therefore all rotations in G appear with and without time inversion. In this case the point groups of $\mathcal{G}$ and $\mathcal{H}$ are the same, but the Bravais lattice of $\mathcal{H}$ contains exactly half of the translations that are in the Bravais lattice of $\mathcal{G}$.
2. *Translation-equivalent magnetic space groups*. The magnetic point group G_{M} is of type 2. Here the Bravais lattices of $\mathcal{G}$ and $\mathcal{H}$ are the same, but the point group H of $\mathcal{H}$ is a subgroup of index 2 of the point group G of $\mathcal{G}$.

Enumeration of translation-equivalent magnetic space group types is very simple. Given a space group $\mathcal{G}$, all that one needs to do is to consider all subgroups H of index 2 of the point group G of $\mathcal{G}$, as explained earlier. The only additional consideration is that with an underlying Bravais lattice, there may be more than one way to orient the subgroup H relative to the lattice. For example, consider the magnetic point group $m'm2'$ which, as noted earlier, is equivalent to $mm'2'$. If the lattice is an A-centered orthorhombic lattice, then the x- and y-axes are no longer equivalent, and one needs to consider both options as distinct groups. It can be said that $Am'm2'$ and $Amm'2'$ belong to the same "magnetic geometric crystal class" (i.e., have the same magnetic point group), but to two distinct "magnetic arithmetic crystal classes." Translation-equivalent magnetic space groups are denoted by taking the International symbol for $\mathcal{G}$, and adding a prime to those elements in the symbol that do not belong to $\mathcal{H}$ and are therefore followed by time inversion.

Enumeration of class-equivalent magnetic space group types can proceed in two alternative ways. Given a space group $\mathcal{G}$, one may consider all distinct sublattices of index 2 of the Bravais lattice of $\mathcal{G}$. Alternatively, given a space group $\mathcal{H}$, one may consider all distinct superlattices of index 2 of the Bravais lattice of $\mathcal{H}$. It is also to be noted that if one prefers to look at the reciprocal lattices in Fourier space, instead of the lattices of real-space translations, the roles of superlattice and sublattice are exchanged. Although the lattice of $\mathcal{G}$ contains twice as many points as the lattice of $\mathcal{H}$, the reciprocal lattice of $\mathcal{G}$ contains exactly half of the points of the reciprocal lattice of $\mathcal{H}$.

Because of the different enumeration methods, there are conflicting notations in the literature for class-equivalent magnetic space groups. The OG notation follows the first approach (sublattices of $\mathcal{G}$), taking the International symbol for the space group $\mathcal{G}$ with a subscript on the Bravais class symbol denoting the Bravais lattice of $\mathcal{H}$. The Belov notation follows the second approach (superlattices of $\mathcal{H}$), taking the International symbol for the space group $\mathcal{H}$ with a subscript on the Bravais class symbol denoting one or more of the primed translations $\boldsymbol{t}_{e'}$ in the coset $(e'|\boldsymbol{t}_{e'})\mathcal{H}$. The Lifshitz notation, which follows a third approach (sublattices of $\mathcal{H}$ in Fourier space), resembles that of Belov but generalizes more easily to quasiperiodic crystals.

There is an additional discrepancy in the different notations which has been the cause of some confusion over the years. It is due to the fact that when $e' \in G_{\mathrm{M}}$, ordinary mirrors or rotations when unprimed may become glide planes or screw axes when primed, and vice versa. The only consistent way to avoid this confusion is to use only unprimed elements for the symbols of class-equivalent magnetic space group types. This is the approach adopted by both the Belov and the Lifshitz notations, but unfortunately not by the OG notation, having introduced errors into their list of magnetic space group types. In any case, there is no need to leave the $1'$ at the end of the symbol, as it is clear from the existence of a subscript on the lattice symbol that the magnetic point group G_{M} contains e'.

Consider, for example, all the class-equivalent magnetic space group types with point group 432. In the cubic system there are two lattice–sublattice

pairs: (1) The simple cubic lattice P has a face-centered sublattice F of index 2, and (2) The b.c.c. lattice I has a simple cubic sublattice P of index 2. Recall that the reciprocal of F is a b.c.c. lattice in Fourier space, denoted by I^*, and the reciprocal of I is an f.c.c. lattice, denoted by F^*. In the Belov notation one has F_s432, F_s4_j32, P_I432, and P_I4_j32 with $j = 1, 2, 3$. The subscript s is for "simple". In the Lifshitz notation, using Fourier space lattices, these groups become I_P^*432, $I_P^*4_j32$, $P_{F^*}432$, and $P_{F^*}4_j32$. In the OG notation these groups should become P_F432, P_F4_j32, I_P432, and I_P4_j32. Instead, they list P_F432, P_F4_232, I_P432, I_P4_132, $I_P4'32'$, and $I_P4_1'32'$, using primes inconsistently and clearly missing two groups. It is therefore recommended that one refrains from using primes when denoting class-equivalent magnetic space groups.

The reader is referred to the "Further reading" section for complete lists of magnetic space group types. However, some statistics are summarized. Starting from the 17 space group types in two dimensions, also known as the 17 plane groups, one can form a total of 80 magnetic space group types as follows: 17 trivial groups, 17 gray groups, and 46 nontrivial groups of which 18 are class-equivalent and 28 are translation equivalent. Starting from the 230 space group types in three dimensions, one can form a total of 1651 magnetic space group types as follows: 230 trivial groups, 230 gray groups, and 1191 nontrivial groups of which 517 are class-equivalent and 674 are translation equivalent. These numbers have no particular significance other than the fact that they are surprisingly large.

Quasiperiodic Crystals

Lattices and Bravais classes Magnetically-ordered quasiperiodic crystals, in general, possess no lattices of real space translations that leave them invariant, but they do have reciprocal lattices (or Fourier modules) L that can be inferred directly from their neutron diffraction diagrams. To be a bit more specific, consider spin density fields with well-defined Fourier transforms

$$S(\boldsymbol{r}) = \sum_{\boldsymbol{k}\in L} S(\boldsymbol{k}) \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} \qquad [1]$$

in which the set L contains, at most, a countable infinity of plane waves. In fact, the "reciprocal lattice" L of a magnetic crystal can be defined as the set of all integral linear combinations of wave vectors $\boldsymbol{k}$ determined from its neutron diffraction diagram, as one expects to see a magnetic Bragg peak at every linear combination of observed peaks, unless it is forbidden by symmetry, as explained in the next section. The "rank" D of L is the smallest number of vectors needed to generate L by integral linear combinations. If D is finite the crystal is quasiperiodic. If, in particular, D is equal to the number d of spatial dimensions, and L extends in all d directions, the crystal is periodic. In this special case, the magnetic lattice L is reciprocal to a lattice of translations in real space that leave the magnetic crystal invariant. The reciprocal lattices L of magnetic crystals are classified into Bravais classes, just like those of ordinary nonmagnetic crystals.

Phase functions and space group types The precise mathematical statement of indistinguishability, used earlier to define the magnetic point group, is the requirement that any symmetry operation of the magnetic crystal leaves invariant all spatially averaged nth-order autocorrelation functions of its spin-density field,

$$C^{(n)}(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_n) = \lim_{V\to\infty} \frac{1}{V} \int_V \mathrm{d}\boldsymbol{r} S(\boldsymbol{r}_1 - \boldsymbol{r}) \cdots S(\boldsymbol{r}_n - \boldsymbol{r}) \qquad [2]$$

One can prove that two quasiperiodic spin density fields $S(\boldsymbol{r})$ and $\hat{S}(\boldsymbol{r})$ are indistinguishable in this way, if their Fourier coefficients, defined in eqn [1], are related by

$$\hat{S}(\boldsymbol{k}) = \mathrm{e}^{2\pi\mathrm{i}\chi(\mathrm{k})} S(\boldsymbol{k}) \qquad [3]$$

where χ is a real-valued linear function (modulo integers) on L, called a "gauge function". By this it is meant that for every pair of wave vectors $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$ in the magnetic lattice L,

$$\chi(\boldsymbol{k}_1 + \boldsymbol{k}_2) \equiv \chi(\boldsymbol{k}_1) + \chi(\boldsymbol{k}_2) \qquad [4]$$

where "$\equiv$" means equal to within adding an integer. Thus, for each element g or g' in the magnetic point group G_{M} of the crystal, that by definition leaves the crystal indistinguishable, there exists such a gauge function $\Phi_g(\boldsymbol{k})$ or $\Phi_{g'}(\boldsymbol{k})$, called a "phase function", satisfying

$$S(g\boldsymbol{k}) = \begin{cases} \mathrm{e}^{2\pi\mathrm{i}\Phi_g(\boldsymbol{k})} S(\boldsymbol{k}), & g \in G_{\mathrm{M}} \\ -\mathrm{e}^{2\pi\mathrm{i}\Phi_{g'}(\boldsymbol{k})} S(\boldsymbol{k}), & g' \in G_{\mathrm{M}} \end{cases} \qquad [5]$$

Since for any $g,h \in G$, $S([gh]\boldsymbol{k}) = S(g[h\boldsymbol{k}])$, the corresponding phase functions for elements in G_{M}, whether primed or not, must satisfy the "group compatibility condition",

$$\Phi_{g*h\dagger}(\boldsymbol{k}) \equiv \Phi_{g*}(h\boldsymbol{k}) + \Phi_{h\dagger}(\boldsymbol{k}) \qquad [6]$$

where the asterisk and the dagger denote optional primes. A "magnetic space group," describing the symmetry of a magnetic crystal, whether periodic or aperiodic, is thus given by a lattice L, a magnetic point group G_{M}, and a set of phase functions $\Phi_g(\boldsymbol{k})$

and $\Phi_{g'}(\boldsymbol{k})$, satisfying the group compatibility condition [6].

Magnetic space groups are classified in this formalism into magnetic space group types by organizing sets of phase functions satisfying the group compatibility condition [6] into equivalence classes. Two such sets, Φ and $\hat{\Phi}$, are equivalent if: (1) they describe indistinguishable spin density fields related as in [3] by a gauge function χ; or (2) they correspond to alternative descriptions of the same crystal that differ by their choices of absolute length scales and spatial orientations. In case (1), Φ and $\hat{\Phi}$ are related by a "gauge transformation,"

$$\hat{\Phi}_{g*}(\boldsymbol{k}) \equiv \Phi_{g*}(\boldsymbol{k}) + \chi(g\boldsymbol{k} - \boldsymbol{k}) \qquad [7]$$

where, again, the asterisk denotes an optional prime.

In the special case that the crystal is periodic ($D = d$), it is possible to replace each gauge function by a corresponding d-dimensional translation $\boldsymbol{t}$, satisfying $2\pi\chi(\boldsymbol{k}) = \boldsymbol{k} \cdot \boldsymbol{t}$, thereby reducing the requirement of indistinguishability to that of invariance to within a translation. Only then does the point group condition [5] become

$$S(g\boldsymbol{r}) = \begin{cases} S(\boldsymbol{r} - \boldsymbol{t}_g), & g \in G_{\mathrm{M}} \\ -S(\boldsymbol{r} - \boldsymbol{t}_{g'}), & g' \in G_{\mathrm{M}} \end{cases} \qquad [8]$$

the gauge transformation [7] becomes a mere shift of the origin, and the whole description reduces to that given in the section "Periodic crystals." The reader is referred to references in the "Further reading" section for details regarding the enumeration of magnetic space groups of quasiperiodic crystals and for complete lists of such groups.

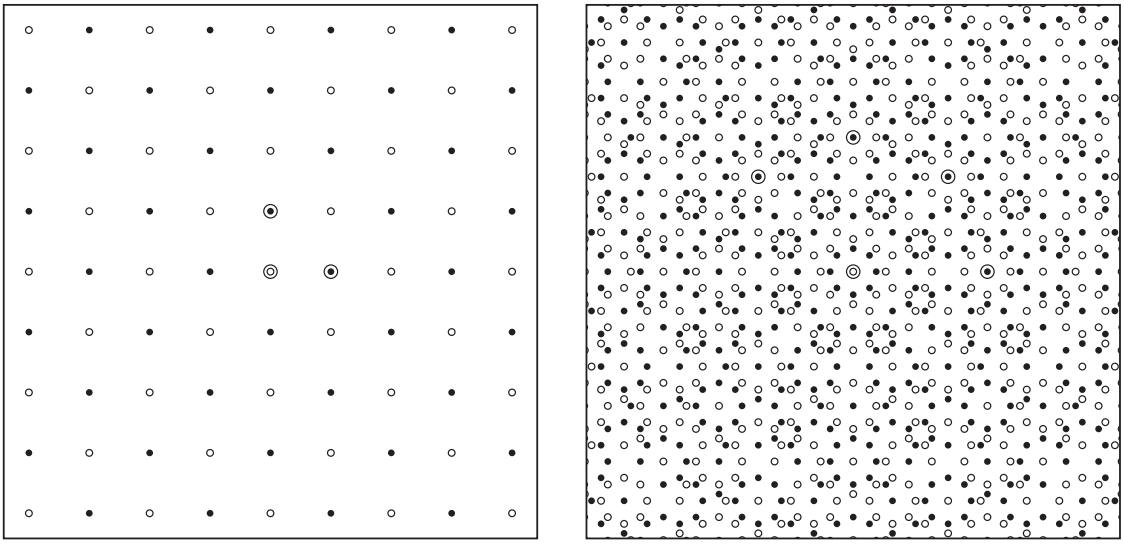
Extinctions in Neutron Diffraction of Anti-Ferromagnetic Crystals

It was said earlier that every wave vector $\boldsymbol{k}$ in the lattice L of a magnetic crystal is a candidate for a diffraction peak unless symmetry forbids it. One can now understand exactly how this happens. Given a wave vector $\boldsymbol{k} \in L$, all magnetic point-group operations g or g' for which $g\boldsymbol{k} = \boldsymbol{k}$ are examined. For such elements, the point-group condition [5] can be rewritten as

$$S(\boldsymbol{k}) = \begin{cases} \mathrm{e}^{2\pi\mathrm{i}\Phi_g(\boldsymbol{k})} S(\boldsymbol{k}), & g \in G_{\mathrm{M}} \\ -\mathrm{e}^{2\pi\mathrm{i}\Phi_{g'}(\boldsymbol{k})} S(\boldsymbol{k}), & g' \in G_{\mathrm{M}} \end{cases} \qquad [9]$$

requiring $S(\boldsymbol{k})$ to vanish unless $\Phi_g(\boldsymbol{k}) \equiv 0$, or $\Phi_{g'}(\boldsymbol{k}) \equiv 1/2$, or unless both conditions are satisfied when both g and g' are in G_{M}. It should be noted that the phase values in eqn [9], determining the extinction of $S(\boldsymbol{k})$, are independent of the choice of gauge [7], and are therefore uniquely determined by the magnetic space-group type of the crystal.

Particularly striking are the extinctions when the magnetic point group is of type 1, containing time inversion e'. The relation $(e')^2 = e$ implies – through



(a) (b)

Figure 4 Extinctions of magnetic Bragg peaks in crystals with magnetic point groups of type 1, containing time inversion e'. Both figures show the positions of expected magnetic Bragg peaks indexed by integers ranging from –4 to 4. Filled circles indicate observed peaks and open circles indicate positions of extinct peaks. The origin and the D vectors used to generate the patterns are indicated by an additional large circle. (a) corresponds to the square crystal in **Figure 2a** with magnetic space group p_p4mm, and (b) corresponds to the octagonal crystal in **Figure 3a** with magnetic space group p_p8mm.

the group compatibility condition [6] and the fact that $\Phi_e(\boldsymbol{k}) \equiv 0$ – that $\Phi_{e'}(\boldsymbol{k}) \equiv 0$ or $1/2$. It then follows from the linearity of the phase function that on exactly half of the wave vectors in L $\Phi_{e'}(\boldsymbol{k}) \equiv 1/2$, and on the remaining half, which form a sublattice L_0 of index 2 in L, $\Phi_{e'}(\boldsymbol{k}) \equiv 0$. Thus, in magnetic crystals with magnetic point groups of type 1 at least half of the diffraction peaks are missing. **Figure 4** shows the positions of the expected magnetic Bragg peaks corresponding to the square and octagonal magnetic structures shown in **Figures 2a** and **3a**, illustrating this phenomenon.

Generalizations of Magnetic Groups

There are two natural generalizations of magnetic groups. One is to color groups with more than two colors, and the other is to spin groups where the spins are viewed as classical axial vectors free to rotate continuously in any direction.

An n-color point group G_C is a subgroup of $O(d) \times S_n$, where S_n is the permutation group of n colors. Elements of the color point group are pairs (g, γ) where g is a d-dimensional (proper or improper) rotation and γ is a permutation of the n colors. As before, for (g, γ) to be in the color point group of a finite object it must leave it invariant, and for (g, γ) to be in the color point group of a crystal it must leave it indistinguishable, which in the special case of a periodic crystal reduces to invariance to within a translation. To each element $(g, \gamma) \in G_C$ corresponds a phase function $\Phi_g^\gamma(\boldsymbol{k})$, satisfying a generalized version of the group compatibility condition [6]. The color point group contains an important subgroup of elements of the form (e, γ) containing all the color permutations that leave the crystal indistinguishable without requiring any rotation g.

A spin point group G_S is a subgroup of $O(d) \times SO(d_s) \times 1'$, where $SO(d_s)$ is the group of d_s-dimensional proper rotations operating on the spins, and $1'$ is the time inversion group as before. Note that the dimension of the spins need not be equal to the dimension of space (e.g., one may consider a planar arrangement of 3D spins). Also note that because the spins are axial vectors there is no loss of generality by restricting their rotations to being proper. Elements of the spin point group are pairs (g, γ), where g is a d-dimensional (proper or improper) rotation and γ is a spin-space rotation possibly followed by time inversion. Here as well, elements of the form (e, γ) play a central role in the theory, especially in determining the symmetry constraints imposed by the corresponding phase functions $\Phi_e^\gamma(\boldsymbol{k})$ on the patterns of magnetic Bragg peaks, observed in elastic neutron diffraction experiments.

Magnetism, History of

J M D Coey and T R Ní Mhíocháin, Trinity College, Dublin, Republic of Ireland

Introduction

Magnetism is a science with more than two millennia of recorded history. The attraction of ferrous objects to a permanent magnet across a distance has been a source of curiosity since the iron age. Feeble permanent magnets are widespread in Nature in the form of rocks known as lodestones, which are rich in the mineral magnetite (Fe_3O_4). Outcrops of these rocks can be magnetized by the huge currents in lightning strikes and such natural magnets were known and studied in ancient Greece, Egypt, China, and Mesoamerica. Investigations of magnetic phenomena led to the invention of steel magnets – needles and horseshoes – then to electromagnetics, and eventually to the panoply of hard and soft materials that underpin the modern magnetics industry. Furthermore, magnetism has played a key role in clarifying basic concepts in condensed matter physics over the course of the twentieth century.

Early History

Aristotle attributed the first reflections on the nature of magnetic attraction to Thales, who was born in Milet in Asia Minor in 624 BC. Thales, an animist, credited the magnet with a soul on account of its ability to create movement. This idea was to persist in Europe until the seventeenth century. The magnet itself is believed to be named after Magnesia, a city in Lydia, which was a source of lodestone. In the fifth century BC, Empedokles postulated the existence of four elements, earth, water, air, and fire, and related magnetism to air with special effluvia somehow passing through pores in magnetic material, a theory echoed much later by Descartes. In the first century BC, Roman poet Lucretius mentions magnetic induction, and the ability of magnets both to attract and repel. However, the Greek approach of developing philosophy into which natural observations were supposed to fit was not conducive to open-minded exploration of the natural world.

A more productive approach was followed in China, where magnetism was linked to geomancy. The art of adapting the residences of the living and the tombs of the dead to harmonize with local currents of the cosmic breath demanded a knowledge of direction. A south-pointer consisting of a carved lodestone spoon free to rotate on a polished baseplate (**Figure 1**) was in use in the first century BC, and may have been known hundreds of years earlier. An important discovery, attributed to Zheng Gongliang in 1064, was that iron could acquire a thermoremanent magnetization when rapidly cooled from red heat in the Earth's magnetic field. A short step led to the suspended compass, which was described by Shen Kua around 1088 together with declination, the deviation of a magnetic needle from a North–South axis. Floating compasses were also developed around this time. The compass appeared in Europe about a hundred years later, being referred to by Alexander Neckham in 1190. Compasses (**Figure 2**) were an enabling technology for the great voyages of discovery of the fifteenth century, leading the Ming admiral Cheng Ho to the coasts of Africa in 1433, and Christopher Columbus to America in 1492. Columbus rediscovered declination, and landed on the continent where the Olmecs may already have displayed a knowledge of magnetism in massive stone carvings of human figures and sea turtles dating from the second millennium BC.

The first true experimentalist in Europe was the French crusader monk Petrus Peregrinus. In his paper "Epistola de Magnete," he recounted experiments

Figure 2 Fifteenth-century Portugese mariner's compass. (Courtesy of Boorstin D (1992) *Les Découvreurs*. Paris: Editions Robert Laffont.)

with floating pieces of lodestone and carved lodestone spheres called "terellae," which he had performed in Italy during the 1269 siege of Lucera. He discovered the poles of a magnet, related magnetic attraction to the celestial sphere, and included a proposal for a magnetic perpetual motion device, a common theme throughout the ages. However, credit for the inauguration of the experimental method in a recognizably modern form belongs to William Gilbert. Physician to the English queen Elizabeth I, Gilbert conducted a series of experiments on "terellae," and concluded that the Earth itself was a great magnet. The magnet itself did not align with the celestial sphere, but with the Earth's poles. He induced magnetism in iron by cooling in the Earth's field, and destroyed the magnetism by heating or hammering. He was at pains to dispel the accretion of superstition that clung to the magnet, preferring to rely on his own evidence. Gilbert's investigations are described in his masterwork "De Magnete" published in 1600. This was arguably the first scientific text.

From Navigation to Experimentation

Gilbert's theories dominated the seventeenth century until Edmund Halley's 1692 shell model for the Earth's magnetic structure, which greatly influenced compass technology and navigation. Magnetic research of the time was driven principally by naval interests. An early observation of a connection between electricity and magnetism was made in 1681, when a ship bound for Boston was struck by lightning. It was evident from the stars that "the compasses were changed; the north point was turn'd clear south," and with the compass so reversed, the ship was sailed to Boston.

The eighteenth century was marked by the professionalization of the scientist or "natural philosopher" as they were then known. Developments in magne tism were associated with improvements in naviga tion and the prestige of the great voyages of discovery. Accordingly, the natural philosopher with his mantle of theory was afforded social status, access to public funding, and credibility beyond that of artisans on the one hand, and "quacks" such as the colorful Anton Mesmer with his theories of "animal magnetism" on the other. Halley conducted magnetic surveys, producing charts of inclination and declination for seafarers (**Figure 3**). The English entrepreneur Gowin Knight, representative of this new breed of natural philosopher, greatly improved the quality of magnetic materials and compasses, coupling scientific endeavor with commercial enterprise.

The major technical breakthrough of the eighteenth century was the 1755 discovery of the horseshoe as the ideal magnet shape by the Swiss artisan Johann Dietrich. His invention, an ingenious practical solution to the problem of self-demagnetization in steel bar magnets, was enthusiastically promoted by Daniel Bernouilli.

This period also saw rapid developments in the harnessing of electricity, from the 1660 invention of the Leyden jar, culminating in Volta's 1800 invention of the Voltaic cell. A formal link between electricity and magnetism was not established until 1820 however, when during a public demonstration by Danish scientist Hans Christian Oersted, a suspended compass needle was seen to be deflected as he switched on an electric current. His report launched an experimental frenzy. Frenchman, François Arago immediately performed an experiment establishing that a current-carrying conductor behaved like a magnet. A week after Arago's report, André-Marie Ampère presented his paper to the French Academy suggesting that ferromagnetism in a body was caused by internal currents flowing perpendicular to the axis and that, by analogy, steel needles magnetized in a solenoid would show stronger magnetization. Together with Arago, he successfully demonstrated this theory in November 1820. Ten days later, the British scientist Humphrey Davy reported similar results. The electromagnet was invented by William Sturgeon in 1825, and 5 years later Joseph Henry used a powerful electromagnet in the USA to transmit the first electric telegraph.

Michael Faraday, however, revolutionized the nineteenth-century experimental science. He developed the concept of "magnetic field," working entirely by

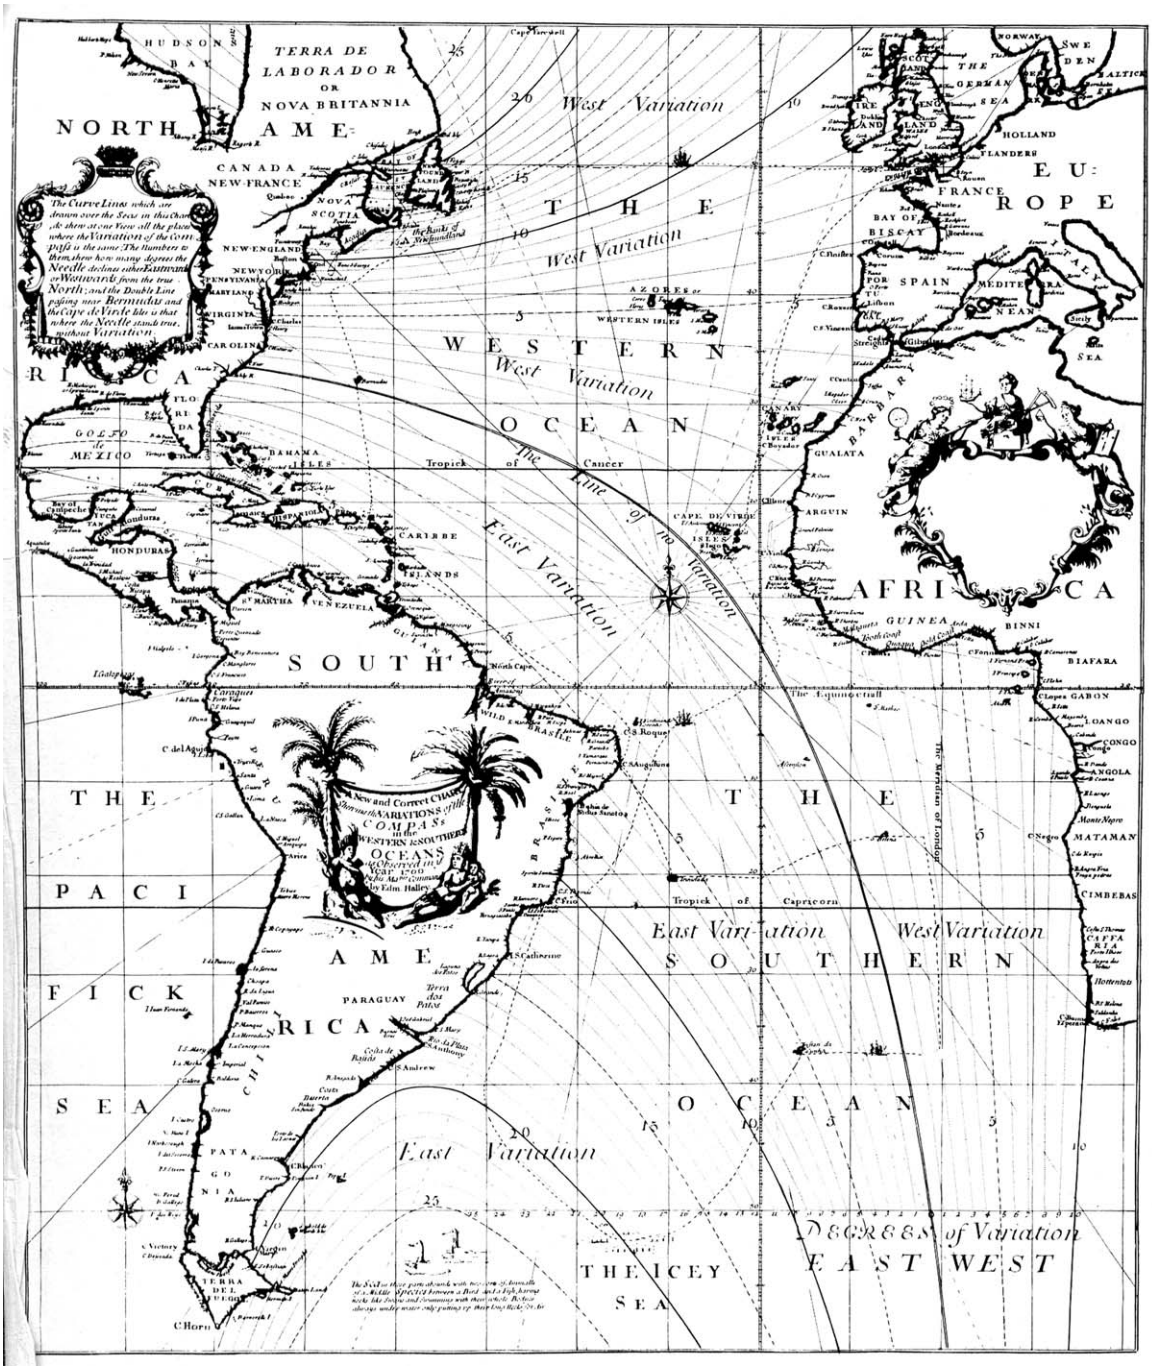

Figure 3 A section of Halley's world chart of magnetic variation published in 1700.

observation and experimentation, with no dependence on formal theory. Faraday classified materials as being either paramagnetic (substances such as iron which were easily magnetized and drawn toward stronger magnetic fields) or diamagnetic (materials which were not penetrated by magnetic fields and which were pushed away by the field). Working with an electromagnet, he discovered the phenomenon of "electromagnetic induction" which states that a flow of electricity can be induced by a changing magnetic field. His conviction that a magnetic field should have an effect on light led to his 1845 discovery of the Faraday effect which states that the plane of polarization of light is rotated upon passing through a medium in a direction parallel to its magnetization.

Figure 4 illustrates a collection of magnets from seventeenth to twentieth centuries.

Figure 4 Four centuries of magnets shown clockwise from the left: eighteenth-century horseshoe magnet; nineteenth-century electromagnet; seventeenth-century lodestone; and twentieth-century $Nd_2Fe_{14}B$.

A classical theory simultaneously emerged to account for magnetism and its relationship with electricity. Around 1824, Poisson developed a mathematical theory of "magnetostatics." Letters from Ampère to Fresnel and Faraday, found after his death, show that by 1822 he had considered the possibility, that the currents causing ferromagnetism were "molecular" rather than macroscopic in form. Weber formally presented the idea that molecules of iron were capable of movement around their centers, suggesting that they lay in different directions in an unmagnetized material, but aligned in one same direction in the presence of an applied magnetic field. This was the beginning of an explanation of hysteresis, the central phenomenon of magnetism, demonstrated experimentally by Ewing using a board of small, pivoting magnets. Ewing's achievements as a youthful professor at the University of Tokyo in the 1890s established the strong Japanese tradition of research on magnetic materials that still thrives today.

James Clerk Maxwell, the Scottish theoretician, "resolved to read no mathematics on the subject till he had first read through Faraday's 'Experimental Researches in Electricity.' " Maxwell's unprecedented equations formally defined the relationship between electricity and magnetism; that an oscillating electric charge produces an electromagnetic field. His theory considered electromagnetic waves traveling, through an all-pervading aether, at speeds close to that of light. In 1888, Heinrich Hertz showed that Maxwell's electromagnetic waves were, in fact, identical to those of light, radio, etc.

The century closed with Pierre Curie's 1895 discovery of the Curie point (the critical temperature above which materials lose their ferromagnetic behavior) and with the all-important discovery of the electron.

Units

By the middle of the nineteenth century, it became necessary to devise a standard set of units for electrical and magnetic quantities. The burgeoning telegraph industry, for example, needed a standard of electrical resistance to control the quality of electrical cables. Separate electrostatic and electromagnetic "cgs" unit systems based on the centimeter, gram, and second had come into existence. Maxwell and Jenkin proposed combining them in a coherent set of units in 1863. Their Gaussian (cgs) system was internationally adopted in 1881. Written according to this system, Maxwell's equations relating electric and magnetic fields contain factors of c, the velocity of light ($2.99792458 \times 108\,\mathrm{m\,s^{-1}}$). Maxwell also introduced the idea of dimensional analysis, based on three basic quantities of mass, length, and time. The magnetic field $\boldsymbol{H}$ and the induction $\boldsymbol{B}$ were measured in units of Oersted and Gauss, respectively, in the cgs system.

Another basic unit, of electric current, was adopted in the Système International d'Unités (SI) in 1948. The number of basic units and dimensions in any system is an arbitrary choice; SI uses four: the meter, kilogram, second, and ampere. It has been adopted worldwide for the teaching of science and engineering, employing the familiar electrical units of volt, ampere, and ohm. Maxwell's equations written in terms of two electric and two magnetic fields contain no factors of c or 4π in the SI system. The magnetic field $\boldsymbol{H}$, like the magnetization $\boldsymbol{M}$, has units of $\mathrm{A\,m^{-1}}$. The induction $\boldsymbol{B}$ is measured in tesla ($1\,\mathrm{T} \equiv 1\,\mathrm{kg\,s^2\,A^{-2}}$). Magnetic moments are measured in units of $\mathrm{A\,m^2}$, clearly indicating the origin of magnetism in electric currents, and the consequent absence of magnetic "poles" as real physical entities. The velocity of light is defined as exactly $299\,792\,458\,\mathrm{m\,s^{-1}}$. The two constants, the permeability, μ_0, and permittivity, ε_0, of free space are related by $\mu_0\varepsilon_0 = c^2$, μ_0 is defined to be $4\pi \times 10^{-7}\,\mathrm{kg\,s^2A^{-2}}$. At the present time, Gaussian cgs units remain in widespread use in magnetism, despite the manifest advantages of SI.

Fundamental Understanding – The Electron

The discovery of the electron in the closing years of the nineteenth century was a giant step toward a fundamental understanding of magnetism. The

elementary charged particle with mass $m_e = 9.11 \times 10^{-31}$ kg and charge $e = -1.60 \times 10^{-19}$ C had been named by the Irish scientist George Johnstone Stoney in 1891, several years before Jean Perrin identified negatively charged particles in a cathode ray tube, and Joseph John Thompson had measured their charge to mass ratio e/m_e by deflecting them in a magnetic field. In 1900 George Francis Fitzgerald suggested that magnetism might be due to rotation of these electrons. Electrons turned out to be the essential magnetic constituent of atoms and solids, as well as the carriers of electric current.

Thirty years were to elapse before contradictions at the heart of early twentieth century magnetism could be resolved. In these revolutionary years, classical physics and the lingering wisps of aether were blown away, and new principles of quantum mechanics and relativity were established. If, following Ampère, all magnetism is traceable to circulating electric currents, why does iron with a magnetization $M = 1.76 \times 10^6$ A m^{-1} not spontaneously melt? How can such a current be sustained indefinitely? In 1907, Pierre Weiss postulated the existence of an internal "molecular field" $\boldsymbol{H}_i$ proportional to the magnetization, $\boldsymbol{H}_i = n_W \boldsymbol{M}$, to account for the abrupt disappearance of ferromagnetism at the Curie point, T_C and paramagnetism at higher temperatures. He was at a loss, however, to explain why no trace of his enormous field ($n_W \approx 1000$) was detectable in the vicinity of a piece of fully magnetized ferromagnetic material. In the unmagnetized state, Weiss had correctly postulated the existence of domains magnetized in different directions to give no resultant moment. The "anomalous" Zeeman splitting of spectral lines in a magnetic field was a mystery. Bohr in 1911 and Van Leeuwen in 1919 had proved that at any finite temperature and in any magnetic or electric field, the net magnetization of any collection of classical electrons vanishes identically. Classical electron physics was incompatible with any kind of magnetism whatsoever!

By 1930, quantum mechanics and relativity had come to the rescue, and a new understanding of magnetism emerged in terms of the physics of Einstein, Bohr, Pauli, Dirac, Schrödinger, and Heisenberg. The source of magnetism in condensed matter was identified as being the "angular momentum" of elementary particles such as the electron. The perpetual currents in atoms were quantized in stationary states that did not decay, with angular momentum which was a multiple of Planck's constant $\hbar = 1.055 \times 10^{-34}$ J s. Weiss's "molecular field" was not a magnetic field at all, but a manifestation of electrostatic Coulomb interactions constrained by Pauli's exclusion principle, which forbade the occupancy of a quantum state by two electrons with the same spin. Spin, the intrinsic angular momentum of an electron, had been proposed by Compton in 1921; Goudsmit and Uhlenbeck demonstrated 4 years later that its value was $\hbar/2$. The corresponding electronic magnetic moment was one Bohr magneton, $\mu_B = e\hbar/2m_e$ or 9.24×10^{-24} A m^{-2}, twice as large as anticipated for orbital angular momentum. The problem of the electron's magnetism was finally resolved by Dirac in 1928 when he succeeded in writing Schrödinger's equation in a relativistically invariant form, obtaining the electron spin in terms of the 2×2 matrices previously proposed by Pauli. Together with Heisenberg, Dirac formulated the Hamiltonian $-2J\boldsymbol{S}_i \cdot \boldsymbol{S}_j$ to describe the coupling between the vector spins $\boldsymbol{S}_i$ and $\boldsymbol{S}_j$ of two many-electron atoms i and j. The value of the exchange integral J was directly proportional to Weiss's molecular field coefficient n_W.

Spin waves were found by Bloch and Slater in 1930 to be the elementary excitations of an array of atoms coupled by Heisenberg exchange interactions. The band theory of ferromagnetic metals developed by Slater and Stoner in the 1930s accounted for the nonintegral spin moments found in Fe, Co, and Ni, and their alloys.

The sixth Solvay conference, held in Brussels in October 1930 (**Figure 5**), was consecrated to magnetism. It followed 4 years of brilliant discovery in theoretical physics, which set out the modern electronic theory of matter. Yet, the immediate effect on the practical development of magnetism was slight. Dirac there made the perceptive remark "The underlying physical laws necessary for the mathematical theory of a large part of physics and the whole of chemistry are completely known, and the difficulty is only that the exact application of these laws leads to equations much too complicated to be soluble."

Magnetic Phenomenology

A less fundamental theoretical approach was needed. Louis Néel pursued a phenomenological approach to magnetism, oblivious to the triumphs of quantum mechanics. His extension of the Weiss theory to two oppositely aligned sublattices led to the idea of antiferromagnetism in 1932. This hidden magnetic order awaited the development of neutron scattering in the 1950s before it could be directly revealed. Néel later explained the ferromagnetism of oxides such as magnetite (Fe_3O_4), the main constituent of lodestone, in terms of two unequal, antiferromagnetically coupled sublattices. The spinel structure of magnetite has an "A" sublattice of iron sites in tetrahedral oxygen coordination, and twice as many sites in octahedral coordination forming a "B" sublattice.

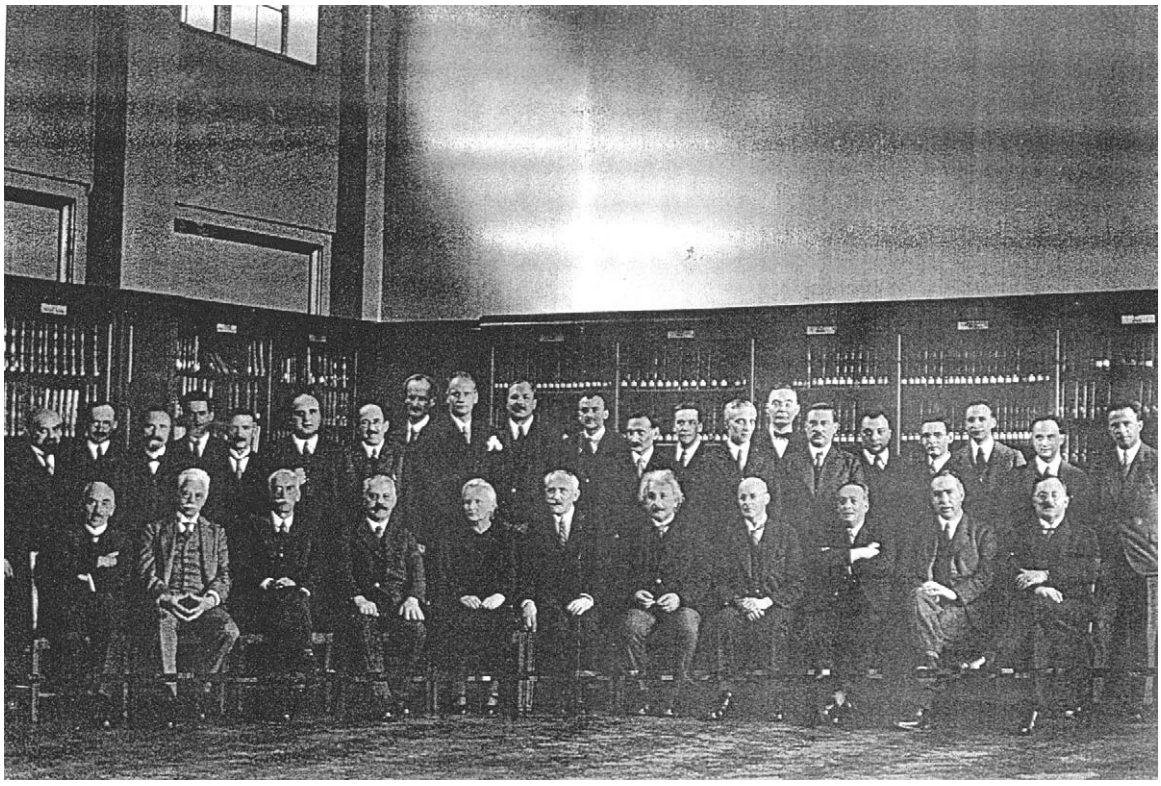

Figure 5 The 1930 Solvay Conference on Magnetism. (Courtesy of Université Libre de Bruxelles.) Back row: Herzen, Henriot, Verschaffelt, Manneback, Cotton, Errera, Stern, Piccard, Gerlach, Darwin, Dirac, Bauer, Kapitza, Brioullin, Kramers, Debye, Pauli, Dorfman, van Vleck, Fermi, Heisenberg. Front Row: de Donder, Zeeman, Weiss, Sommerfeld, Curie, Langevin, Einstein, Richardson, Cabrera, Bohr, de Haas.

The "B" sites are occupied by a mixture of Fe^{2+} and Fe^{3+}, and the "A" sites by oppositely aligned Fe^{3+}. This yields a spin moment of $4\mu_B$ per formula – a quantitative explanation of the magnetism of archetypical magnets in terms of lattice geometry and electron spin.

For many practical purposes, it is possible to ignore the atomic and electronic basis of magnetism, and simply regard the magnetization of a solid as a continuous vector. The hysteresis loop $\boldsymbol{M}(\boldsymbol{H})$ (**Figure 6**) is a record of the resultant of the metastable structure of domains and domain walls arising from the thermal and magnetic history of a particular sample. Evidence for discontinuous jumps in the Weiss domains as the magnetization was saturated was picked up by Barkhausen in 1919, and in 1931 the domains were visualized by Bitter. In 1932, Bloch introduced the idea of a domain wall as a region, where the magnetization rotates continuously from one direction to another. The exchange energy cost, written in the continuum approximation as $A(\nabla \boldsymbol{M})^2$, where $A \propto J$, is balanced by the gain in magnetostatic energy $(1/2)\int \mu_0 H^2 \, \mathrm{d}V$ associated with the magnetic field created by the ferromagnet throughout space, where V is the volume. Another term is needed to restrict the wall width; this is the anisotropy energy, which can arise intrinsically from spin–orbit coupling, a relativistic effect, or extrinsically from the sample shape. The sum of these free energy terms, together with the Zeeman energy in an external field, is minimized to yield the domain structure. This theory of "micromagnetism" was formulated by Brown in 1940.

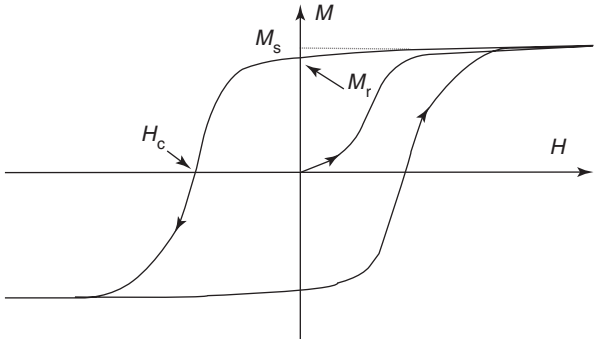

Figure 6 The hysteresis loop of $\boldsymbol{M}$ against $\boldsymbol{H}$ for a typical permanent magnet. M_s is the saturation magnetization, M_r the remanent magnetization at zero applied field, and H_c the coercive field required to reduce the magnetization to zero.

Domain walls in solids tend to be pinned by local crystal imperfections or microstructures, leading to

the metastable states represented on the hysteresis loop. The control of these has been due to as much metallurgical art as physical science. An important step was the development of a series of Co–Fe–Al–Ni alloys, the "alnicos" begun by Mishima in 1932. The mastery of coercivity gained over the course of the twentieth century (**Figure 7**) was spectacular.

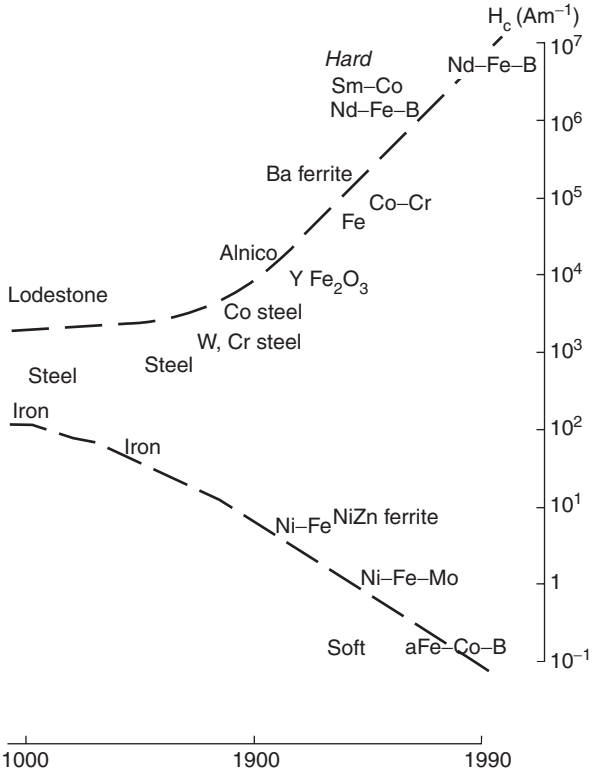

Figure 7 The development of coercivity in the twentieth-century.

Burgeoning applications of magnetism were a direct consequence. Microscopic quantum theory only began to contribute to this process in the 1970s after the advent of rare-earth permanent magnets such as $SmCo_5$ and $Nd_2Fe_{14}B$, when an understanding of the intrinsic, magnetocrystalline anisotropy helped in the design of new permanent magnet materials.

A fertile approach to the problem of hysteresis was to focus on magnetization reversal in single-domain particles. Stoner and Wolhfarth proposed an influential model for this in 1948. Meanwhile Néel, seeking to understand the remanent magnetism of baked clay, proposed a model of thermally driven "superparamagnetic" fluctuations of the magnetization of submicron-sized ferromagnetic particles the following year. The fluctuation time is dependent exponentially on the ratio of the energy barrier against magnetization reversal to the thermal energy. As a result, a component of magnetization became blocked on cooling in the Earth's magnetic field. Application of this idea of thermoremanent magnetization to cooling igneous rocks delivered a direct and convincing argument for continental drift, as rocks cooling at different times experienced fields of different polarity (**Figure 8**). This all led to the subfield of palaeomagnetism, and establishment of the theory of global plate tectonics, which had far-reaching consequences for Earth science.

Modern Developments

Magnetism since 1945 has been an area of rich and productive discovery, not least because of the enormous increase in numbers of scientists and engineers working in the field. Magnet ownership for citizens

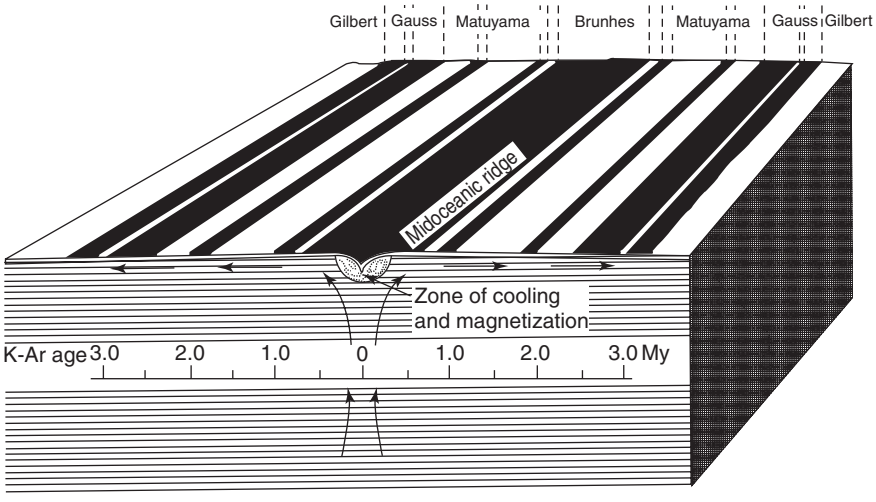

Figure 8 Sign of the thermoremanent magnetization measured across the floor of the Atlantic Ocean. Random reversals of the Earth's field, which are dated from other igneous lava flows, follow a chronological pattern which determines the rate of continental drift. (Courtesy of McElhinney MW (1973) *Palaeomagnetism and Plate Tectonics*. Cambridge: Cambridge University Press.)

of the developed world has skyrocketed from one or two magnets in 1945 to 100–200 sixty years later, or something in the order of a billion if one counts the individual magnetic bits on a hard disk in a personal computer! Countless citizens of the developing world share magnetism's bounty in the form of a cassette tape recorder.

Modern achievements can be classified as: (1) those contributing to a basic understanding of condensed matter, (2) those associated with new experimental probes, and (3) those leading to new materials and industrial technologies.

Theory

From a fundamental point of view, magnetism has proved a fruitful field for cultivating condensed matter theory. After yielding the first mean-field theory in the guise of Weiss's molecular field, magnetism has provided more sophisticated theories of phase transitions, and the data to support them. A fixed point was Onsager's 1944 solution of the two – dimensional Ising model, where spins are regarded as scalars which take values ± 1. The behavior of more complex and realistic systems such as the three-dimensional Heisenberg model was solved numerically using the renormalization group technique in the 1970s. The ability to tailor model magnetic systems having an effective spatial dimension of one or two with structures of chains or planes of magnetic ions and an effective spin dimension limited by anisotropy, has laid the foundation of the modern theory of phase transitions. The effect of disorder on antiferromagnetic interactions was studied intensively in spin glasses in the 1980s. The ground states of double chains and ladders continue to turn up surprises.

Correlations among the electrons in a metal, and their coupling to the crystal lattice, have generated a wealth of ground states and phenomena in solids such as superconductivity, heavy-fermion behavior, quantum Hall effect. A fecund line of enquiry was "Does a single impurity in a solid bear a magnetic moment?" This led to the definition, and eventually to the solution of the Kondo problem in 1980, which drew attention to the relation between magnetism and electronic transport in metals, which has been an immensely productive interface in terms of practical devices based on magnetoresistance. Long-range exchange interactions associated with the ripples of spin polarization created by a magnetic impurity in a metal led to an understanding of complex magnetic order in the rare-earth metals. Numerical methods, such as that based on spin-dependent density-functional theory, were successfully applied in the 1990s after the arrival of the cheap, powerful computers needed to calculate the magnetic ground-state properties of correlated electron systems.

Experimental Methods

The discovery of magnetic resonance, the sharp absorption of microwave or radio frequency radiation by Zeeman-split levels of an atom or nucleus in a magnetic field, was a landmark in modern magnetism. Significant mainly for the insight provided into solids and liquids at an atomic scale, electron paramagnetic resonance (EPR) and nuclear magnetic resonance (NMR) spectroscopies were complemented by that provided by the Mössbauer effect in 1958. Hyperfine interactions of nuclei and electrons provided a point probe of electric and magnetic fields at the center of the atom. In a magnetically ordered state, precession of the magnetic sublattices in a field leads to ferromagnetic resonance (FMR).

Of the new experimental probes of magnetism, neutron scattering was the most influential and generally useful. A beam of thermal neutrons from a nuclear reactor was first exploited for neutron diffraction by Shull and Wohlan in 1951, who used the magnetic scattering to reveal the antiferromagnetic order in MnO. Countless magnetic structures have been measured since, using the specially constructed facilities at Chalk River, Harwell, Brookhaven, Grenoble, and elsewhere. Excitations could be characterized by inelastic scattering of thermal neutrons, with the help of the three-axis spectrometer developed by Brockhouse. Complete spin–wave dispersion relations were used to provide a wealth of information on anisotropy and exchange.

Other beams produced at large-scale facilities that proved useful for probing magnetism were muons and synchrotron radiation. The intense, tunable ultraviolet and X-ray radiation from synchrotrons allowed the measurement of magnetic dichroism from deep atomic levels, and permitted the separate determination of spin and orbital contributions to the magnetic moment.

Increasing availability of commercial superconducting magnets from the late 1960s has led to diagnostic imaging of tissue based on NMR. Thousands of these scanners in hospitals across the world provide images of hearts, brains, and every sort of tumor. Superconducting magnets can now provide fields of over 20 T for NMR and general laboratory use. Coupled with SQUID sensors, ultrasensitive magnetometers capable of measuring magnetic moments of $10^{-11}\,\mathrm{A\,m^{-2}}$ are widely available. Larger fields of up to 30 T require expensive special installations with water-cooled Bitter magnets consuming many

megawatts of electrical power. Resistive/superconducting hybrids in Tallahassee, Grenoble, and Tokyo can generate steady fields in excess of 40 T. Still higher fields mean short pulses; the higher the field, the shorter the pulse.

Materials and Technology

A search for practical new magnetic materials led to the discovery of hard and soft ferrites in the early 1950s. The hard ferrites were the first materials whose coercive field exceeded their magnetization, making it possible for a magnet to have any desired shape, thereby breaking the centuries-old shape barrier by rendering bar and horseshoe magnets obsolete (**Figure 4**). The soft ferrites were indispensable for radiofrequency and microwave components. Rare-earth intermetallic compounds investigated from 1960 onward provided high-performance rare-earth permanent magnets, notably $Nd_2Fe_{14}B$ developed by Sagawa. Miniature electromagnetic drives that are incorporated in myriad consumer goods have been a consequence.

For many physical studies, magnetic materials were needed in special forms, especially single crystals or thin films. Crystal growers were assiduously cultivated by neutron scatterers and other condensed matter physicists. With large crystals, tensor properties such as susceptibility, magnetostriction, and magnetotransport could be measured in detail. After 1970, thin-film growth facilities (sputtering, pulsed-laser deposition, molecular beam epitaxy) began to appear in ultrahigh magnetism laboratories. Ultrahigh vacuum facilitated the study of surface magnetism at an atomic level, but much of the motivation was to investigate magnetooptics or magnetoresistance of metals. Thin films also contributed massively to magnetic storage. In recent years, nanoscale magnetic composites have extended the range of magnetic properties available in hard and soft magnets.

Magnetic recording dates from the late nineteenth century, when Poulsen recorded his voice on steel wire. It developed into analog tape recording in Germany in the 1930s. The first digital disk recording device made its appearance in the USA, launched by IBM, in 1956. A single bit then occupied $\sim 0.3\,mm^2$ on the disk surface and cost about 1¢. Fifty years later the same bit occupied $0.006\,\mu m^2$ and cost 0.000 000 005¢. This relentless miniaturization and perfection of rotating-disk technology for magnetic recording is a fascinating chapter in the history of technology (**Figure 9**). It was facilitated by a series of advances in thin film magnetic recording media with uniform crystallite size in the range 10–100 nm, and multilayer thin film read/write heads which could create and detect local magnetic fields. The read head had to pick up weak stray fields just above the disk surface. Inductive heads with coils were successively replaced by heads based on anisotropic magnetoresistance, and in 1997 by giant magnetoresistive heads. Giant magnetoresistance had been discovered by Fert and co-workers in an Fe–Cr multilayer in 1988. Reduced to its bare essentials, a sandwich of two ferromagnetic layers with a nonmagnetic metallic spacer known as a "spin valve," was needed to show the effect. Hundreds of millions were being produced annually by 2003. A variant that has been developed as a nonvolatile magnetic storage element is the magnetic tunnel junction used in magnetic random-access memory (MRAM). These magnetoresistive sensors and storage devices represented the first generation of spin electronic devices.

Future Prospects

Past record is no guarantee of future performance, so one must be wary of extrapolating the history of any science or technology very far into the future. Magnetism, like much of physics itself, has often

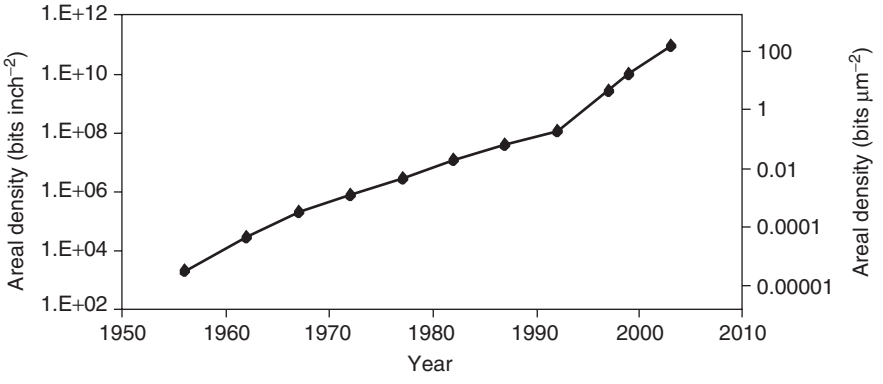

Figure 9 Exponential growth of magnetic recording density over the last 50 years.

been dismissed as "finished" in the past, only to confound the doomsayers with some new twist or unexpected development. The current focus on spin electronics and nanoscale magnetism will surely be sustained for some time to come, if only by momentum. A successful second generation of spin electronics may depend on the emergence of room temperature magnetic semiconductors, or at least effective spin injection into regular semiconductors.

Industrial applications of magnetism are based on the properties of about a dozen commercially produced magnetic materials. The discovery of just one more could animate the subject for a decade. It seems unlikely, though, that much advance will be achieved on the magnetic values on the hysteresis loop. There has been no advance in saturation magnetization in a century over that of $Fe_{35}Co_{65}$, but coercivity can be controlled, albeit with much care and effort, to almost any desired value. No Curie temperature has ever exceeded that of cobalt, which has been known since 1912. The new material will probably commend itself by a useful combination of magnetic and nonmagnetic (electrical, optical, mechanical, etc.) properties.

Magnetism has served the miniaturization of information technology and electromagnetic drives well, and may continue to do so in future. New frontiers in cell biology have to be explored. There have been half a dozen paradigm shifts – completely new ways of seeing the magnet and its field – during the 3000-year encounter of magnetism with human curiosity. Who can say there will never be another?

Nomenclature

$\boldsymbol{B}$	magnetic induction
c	speed of light ($2.99792458 \times 10^{8}\,\mathrm{m\,s^{-1}}$)
e	charge on an electron ($1.602 \times 10^{-19}\,\mathrm{C}$)
$\hbar$	Planck's constant ($1.055 \times 10^{-34}\,\mathrm{J\,s}$)
$\boldsymbol{H}$	magnetic field
$\boldsymbol{J}$	exchange integral
m_e	mass of an electron ($9.109 \times 10^{-31}\,\mathrm{kg}$)
$\boldsymbol{M}$	magnetization
n_W	Weiss molecular field coefficient
$\boldsymbol{S}$	spin vector
T_C	Curie temperature
ε_0	electric permittivity of free space ($8.854 \times 10^{-12}\,\mathrm{C^2N^{-1}m^{-2}}$)
μ_0	magnetic permeability of free space ($4\pi \times 10^{-7}\,\mathrm{Wb\,A^{-1}m^{-1}}$)
μ_B	Bohr magneton ($9.274 \times 10^{-24}\,\mathrm{J\,T^{-1}}$)

Magnetocaloric Effect

V K Pecharsky and K A Gschneidner Jr., Iowa State University, Ames, IA, USA

Introduction

The word "magnetocaloric" is derived from Greek *Magnes* (*lithos*) (literally, stone of Magnesia, ancient city in Asia Minor), that is, magnesian (stone) or "magnetite" that has been known for thousands of years to attract articles made from iron, and Latin "calor" for heat, which evolved into French "calorique" – the name of the invisible and indestructible fluid that, according to a theory prevailing in 1700s, was thought to be responsible for virtually everything related to heat. This two-part word describes one of the most fundamental physical properties of magnetic materials: that is, when a solid is exposed to a varying magnetic field, its temperature

may be measurably increased or decreased with both the sign and the magnitude of the temperature difference between the final and the initial states of the material dependent on numerous intrinsic and extrinsic factors. The chemical composition, crystal structure, and magnetic state of a compound are among the most important intrinsic material parameters. The temperature, surrounding pressure, and sign of the magnetic field change are examples of extrinsic variables that affect these magnetic-field-induced temperature changes and, therefore, play a role in defining the magnetocaloric effect (MCE).

Inherent to every magnetic solid, the magnetocaloric effect has exceptional fundamental importance because it covers length, energy, and timescales spanning over many orders of magnitude: from quantum mechanics to micromagnetics, from statistical to macroscopic thermodynamics, and from spin dynamics to bulk heat flow and thermal conductivity. Mapping out this vast landscape is an enormously challenging task, yet even partial successes along the way facilitate a better understanding of how to design novel magnetic solids; in other words, they help in creating an environment in which a material could be tailored to exhibit a certain combination of magnetic and thermal properties. In addition to its basic significance, the magnetocaloric effect is the foundation of near-room-temperature magnetic refrigeration, which is poised for commercialization in the foreseeable future and may soon become an energy-efficient and environmentally friendly alternative to vapor-compression refrigeration technology. Practical applications of the magnetocaloric effect, therefore, have the potential to reduce the global energy consumption, and eliminate or minimize the need for ozone depleting, greenhouse, and hazardous chemicals.

Discovery and First Application of the Magnetocaloric Effect

MCE was originally discovered in iron by E Warburg, who reported the phenomenon in 1881. The nature of the MCE was explained and its usefulness to reach temperatures below 1 K by adiabatically demagnetizing a paramagnetic substance was suggested independently in the mid-1920s by P Debye and W F Giauque. Namely, after cooling a paramagnetic material in a large magnetic field to as low a temperature as possible by conventional means, such as pumping on liquid helium, the material was to be thermally isolated from its surroundings, the magnetic field removed, and the sample was predicted to cool well below 1 K due to the magnetocaloric effect.

Together with his student D P MacDougall, W F Giauque was the first to verify this prediction experimentally. As Giauque and MacDougall wrote in their 12 April 1933 letter to the editor of the *Physical Review*, "On March 19, starting at a temperature of about 3.4 K, the material cooled to 0.53 K. On April 8, starting at $\sim$2 K, a temperature of 0.34 K was reached. On April 9, starting at $\sim$1.5 K, a temperature of 0.25 K was attained." They achieved these breakthroughs by using 61 g of hydrated gadolinium sulfate, $Gd_2(SO_4)_3 \cdot 8H_2O$, and by reducing the magnetic field from 0.8 to 0 T. Giauque and MacDougal conclude their short (about 200 words) letter that was published in 1 May 1933 issue of the *Physical Review* with the following statement: "It is apparent that it will be possible to obtain much lower temperatures, especially when successive demagnetizations are utilized." This technique is known as adiabatic demagnetization refrigeration and it is successfully employed today in ultra-low-temperature research – for example, nuclear adiabatic demagnetization has been and is being used to reach micro-kelvin temperatures.

Fundamentals of the Magnetocaloric Effect

The MCE occurs due to the coupling of a magnetic sublattice with an external magnetic field, which affects the magnetic part of the total entropy of a solid. Similar to isothermal compression of a gas during which positional disorder and, therefore, the corresponding component of the entropy of a system are suppressed, isothermal magnetizing of a paramagnet near the absolute zero temperature or a ferromagnet near its spontaneous magnetic ordering temperature – the Curie temperature, T_C – greatly reduces disorder of a spin system, thus substantially lowering the magnetic part of the total entropy. In a reversible process, which resembles the expansion of a gas at constant temperature, isothermal demagnetization restores the zero field magnetic entropy of a system. The MCE, therefore, can be measured as an extensive thermodynamic quantity – the isothermal magnetic entropy change, ΔS_M, which is illustrated in **Figure 1** as a difference between the two entropy functions taken at the same temperature and is marked by a vertical arrow.

When a gas is compressed adiabatically, its total entropy remains constant whereas velocities of the constituent molecules, and therefore, the temperature of the gas both increase. Likewise, the sum of the lattice and electronic entropies of a solid must be changed by $-\Delta S_M$ as a result of adiabatically magnetizing (or demagnetizing) the material, thus resulting in an increase (decrease) of the lattice vibrations and the adiabatic temperature change, ΔT_{ad}, which is

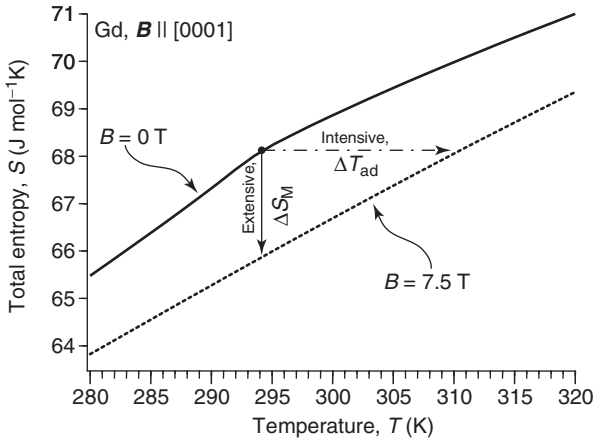

Figure 1 The total entropy of gadolinium in the vicinity of $T_C = 294$ K in 0 and 7.5 T magnetic fields. The data are for a high-purity single crystalline Gd with the magnetic field vector parallel to the [0001] crystallographic direction of the specimen. The vertical arrow illustrates ΔS_M; the horizontal arrow represents ΔT_{ad}.

an intensive thermodynamic quantity also used to measure and express the MCE. In **Figure 1**, ΔT_{ad} is illustrated as a difference between the two entropy functions taken at the same entropy and is indicated using a horizontal arrow. It is worth noting that in the case of a gas, it is a "change of pressure" that results either in the adiabatic temperature rise or drop, or the isothermal entropy change, while in the case of a magnetic solid it is a "change of the magnetic field" that brings about the MCE. Needless to say, no matter how strong the magnetic field around the sample, the MCE will remain zero as long as the field is kept constant.

For a given material at a constant pressure, the two quantitative characteristics of the magnetocaloric effect are functions of the absolute temperature (T) and the magnetic field change ($\Delta B = B_f - B_i$), where B_f and B_i are the final and initial magnetic fields, respectively, experienced by the material. The MCE can be easily computed provided the behavior of the total entropy (S) of a compound is known as a function of temperature in both the initial and final magnetic fields, e.g., see **Figure 1**:

$$\Delta S_M(T, \Delta B)_{\Delta B = B_f - B_i} = S(T, B)_{B=B_f} - S(T, B)_{B=B_i} \quad [1]$$

$$\Delta T_{ad}(T, \Delta B)_{\Delta B = B_f - B_i} = T(S, B)_{B=B_f} - T(S, B)_{B=B_i} \quad [2]$$

Equation [2], in which the entropy is the independent variable and the temperature is the dependent variable, is straightforwardly employed in direct measurements of ΔT_{ad}. Thus, the temperature of a sample is measured in both B_i and B_f, that is, before and after the magnetic field has been altered. The difference between the two temperatures yields the intensive MCE value, which is usually reported as a function of temperature for $B_i = 0$.

At equilibrium, both ΔS_M and ΔT_{ad} are correlated with the magnetization (M), magnetic flux density (B), heat capacity at constant pressure (C), and absolute temperature by one of the following fundamental Maxwell equations:

$$\Delta S_M(T, \Delta B)_{\Delta B = B_f - B_i} = \int_{B_i}^{B_f} \left(\frac{\partial M(T, B)}{\partial T} \right)_B dB \quad [3]$$

$$\Delta T_{ad}(T, \Delta B)_{\Delta B = B_f - B_i} = -\int_{B_i}^{B_f} \left(\frac{T}{C(T, B)} \times \frac{\partial M(T, B)}{\partial T} \right)_B dB \quad [4]$$

As immediately follows from eqns [1]–[4], materials whose total entropy is strongly influenced by a magnetic field and where the magnetization varies rapidly with temperature, are expected to exhibit an enhanced MCE. The latter peaks when $|(\partial M(T, B)/\partial T)_B|$ is the greatest, that is, around the T_C in a conventional ferromagnet or near the absolute zero temperature in a paramagnet. Usually, the MCE of a simple ferromagnet is gradually lowered both below and above the T_C, as is clearly seen in **Figure 2**.

Equations [3] and [4] are easily derived from general thermodynamics, yet both fail to describe the MCE in the vicinity of a truly discontinuous first-order phase transition when either or both $|[\partial M(T, B)/\partial T]_B|$ and $[T/C(T, B)]_B$ do not exist even if the phase volume change is negligibly small. (By definition, partial first derivatives of Gibbs free energy with respect to intensive thermodynamic variables, for example, T, P, or B, vary discontinuously at the first-order phase transition. As a result, the bulk magnetization is expected to undergo a discontinuous change at constant temperature; and the heat capacity is expected to be infinite during a first-order phase transformation. Thus, in theory, $[\partial M(T, B)/\partial T]_B$ and $[T/C(T, B)]_B$ do not exist at the temperature of the first-order transition. In reality, these changes occur over a few-kelvin-wide temperature range and both functions can be measured experimentally.) Equations [1] and [2], on the other hand, define the MCE regardless of the thermodynamic nature of the phase transformation that occurs, if any, in a material.

For a first-order phase transition, it is also possible to employ an approximation, which is based on the Clausius–Clapeyron equation:

$$\left(\frac{dB}{dT} \right)_{eq} = \left(\frac{\Delta S}{\Delta M} \right)_T \quad [5]$$

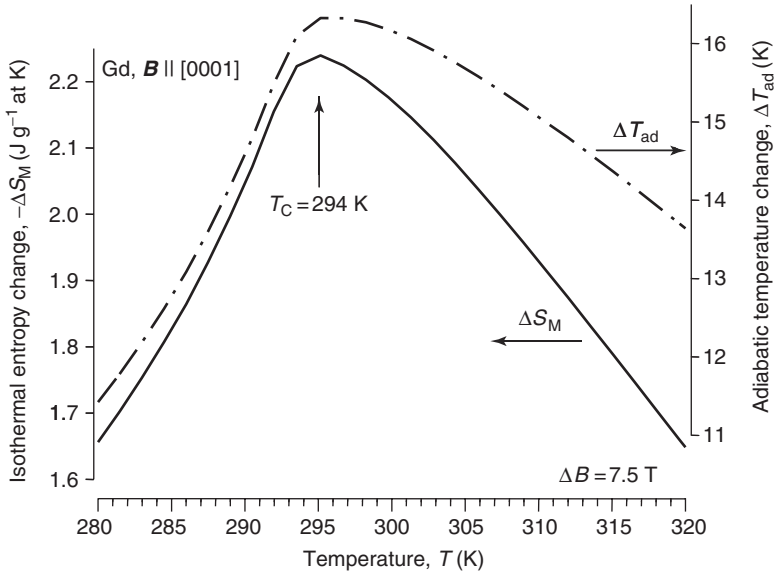

Figure 2 The extensive, ΔS_M, and intensive, ΔT_{ad}, MCE of the elemental Gd in the vicinity of its Curie temperature, $T_C = 294$ K, for a magnetic field change from 0 to 7.5 T. The data are for a high-purity single crystalline Gd with the magnetic field vector parallel to the [0001] crystallographic direction of the specimen.

In eqn [5], the left-hand-side derivative is taken under equilibrium conditions, that is, when Gibbs free energies of the two phases are identical to one another. For the right-hand side, $\Delta S = S_2 - S_1$ and $\Delta M = M_2 - M_1$, where the subscripts 1 and 2 correspond to the states of the material in the initial and final magnetic fields, respectively. Obviously, eqn [5] is only applicable when B_f is strong enough to complete the transformation from a state 1 to state 2 and when the quantity dB/dT at equilibrium is known. In other words, the B–T phase diagram for the system must be well established. By using the Clausius–Clapeyron equation, only an estimate of the extensive MCE, $\Delta S_M = \Delta S$, is possible.

Magnetic Order and the Magnetocaloric Effect

It is easy to see (Eqns [3] and [4]) that both ΔS_M and ΔT_{ad} are proportional to the derivative of bulk magnetization with respect to temperature at constant magnetic field. The ΔT_{ad} is also proportional to the absolute temperature and inversely proportional to the heat capacity at constant magnetic field. It is predictable, therefore, that any material should have the largest MCE when its magnetization is changing most rapidly with temperature. This, for example, occurs in the vicinity of a Curie temperature of a ferromagnet. (From eqn [4] it is not obvious that $\Delta T_{ad}(T)_{\Delta B}$ is at its maximum at the Curie temperature because heat capacity of a material ordering ferromagnetically also peaks around T_C. It can be shown, however, that the maximum of $\Delta T_{ad}(T)_{\Delta B}$ does indeed occur in the immediate vicinity of T_C, especially when $B_i = 0$ and $\Delta B \to 0$. By directly measuring $\Delta T_{ad}(T)_{\Delta B}$ in low magnetic fields, it is, therefore, possible to determine the Curie temperature of a ferromagnet.) The MCE will decrease below T_C, where the magnetization approaches saturation and becomes weakly dependent on temperature, and above the Curie temperature when the magnetization shows only a paramagnetic response, that is, it is proportional to T^{-1}, while its derivative maintains a proportionality to T^{-2}.

Conventional ferromagnets, therefore, typically display "caret-like MCE." This kind of behavior is easily recognizable in **Figure 2**, and it is also shown in **Figure 3a** for a $Gd_5Si_{2.5}Ge_{1.5}$ compound. The latter orders ferromagnetically via a second-order phase transformation at 312 K. As the ΔB increases, the magnitude of the MCE of a conventional ferromagnet also increases. The rate of change of the MCE with magnetic field, that is, the instantaneous derivative of the MCE with respect to ΔB is, however, the largest at the lowest B_f. The intensive measure of the MCE can vary from a fraction of 1 K T^{-1} to several K T^{-1}. Elemental Gd, for example, exhibits a $d[\Delta T(T, \Delta B)]/d(\Delta B)$ of ~ 3 K T^{-1} around T_C when B_f is on the order of 1 T. The derivative falls to ~ 1.8 K T^{-1} when B_f approaches 10 T. It is worth noting that away from absolute zero, $d[\Delta T(T, \Delta B)]/d(\Delta B)$ in conventional ferromagnetic materials is only weakly dependent on temperature (see **Figure 3a**).

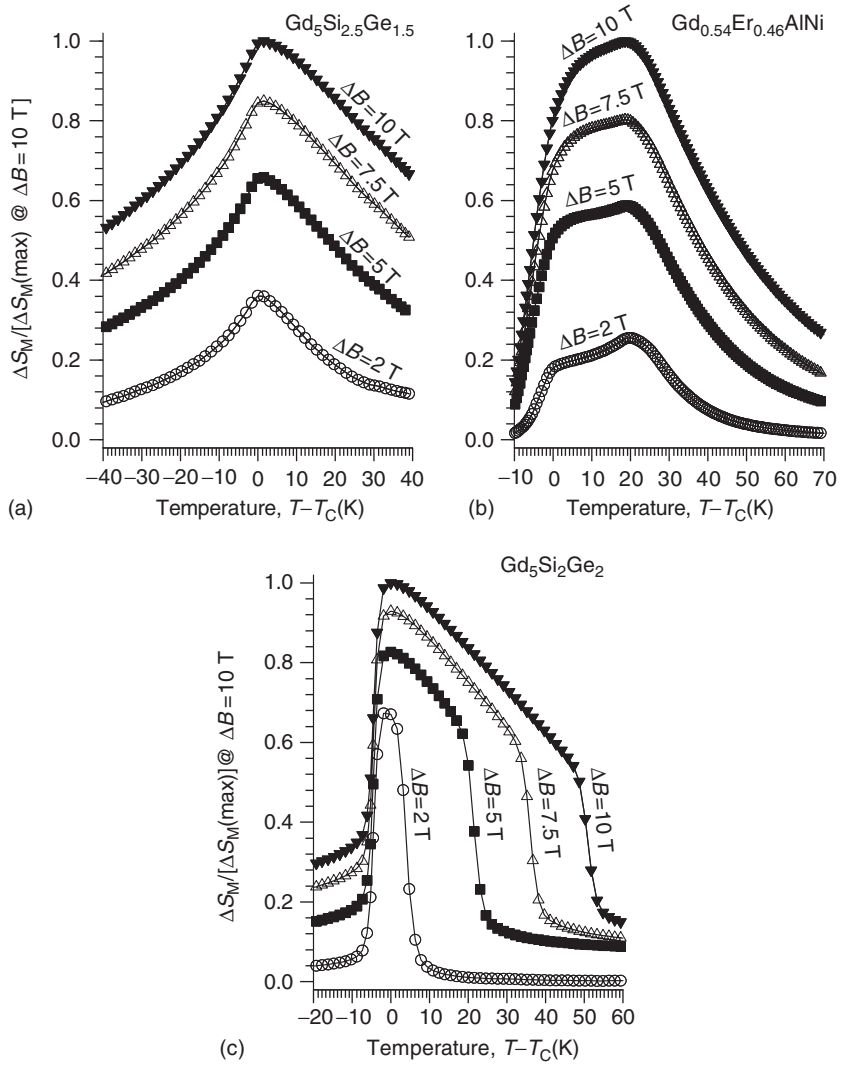

Figure 3 Normalized magnetocaloric effect of (a) $Gd_5Si_{2.5}Ge_{1.5}$ ($T_C = 312\,K$), (b) $Gd_{0.54}Er_{0.46}AlNi$ ($T_C = 14.5\,K$ (the normalization temperature) and 35 K) and (c) $Gd_5Si_2Ge_2$ ($T_C = 273\,K$) shown as a function of the reduced temperature for various magnetic field changes. In all cases, $B_i = 0$. The $\Delta S_M(max)$ values are $1.57\,J\,g^{-1}$, $0.63\,J\,g^{-1}$, and $2.61\,J\,g^{-1}$ at $\Delta B = 10\,T$ for $Gd_5Si_{2.5}Ge_{1.5}$, $Gd_{0.54}Er_{0.46}AlNi$, and $Gd_5Si_2Ge_2$, respectively.

Anomalous behaviors of the MCE are closely related to anomalous changes in the magnetic structures of solids causing unusual behaviors of the two functions, $[\partial M(T, B)/\partial T]_B$ and $[T/C(T, B)]_B$, which are carried over to both $\Delta S_M(T)_{\Delta B}$ and $\Delta T_{ad}(T)_{\Delta B}$ (see eqns [3] and [4]). One of the most commonly observed MCE anomalies is when a material undergoes two or more successive magnetic transitions in close proximity to one another. Then, instead of a conventional caret-like shape, a skewed caret, sometimes approaching a flat and an almost constant value as a function of temperature, that is, a "table-like MCE" can be observed. An example of such behavior is shown in **Figure 3b** for $Gd_{0.54}Er_{0.46}AlNi$. Both $\Delta S_M(T)_{\Delta B}$ (**Figure 3b**) and $\Delta T_{ad}(T)_{\Delta H}$ (not shown) of this material are almost constant between the two successive magnetic phase transition temperatures, which are $\sim 20\,K$ apart. Anomalous MCE behaviors may also be due to low-lying crystalline electric fields and strong quadrupolar and/or magnetoelastic interactions. Furthermore, the MCE can be adjusted over a broad range of behaviors by mixing two or more individual compounds or phases, each with a simple caret-like MCE, into a composite where the resulting isothermal magnetic entropy change will be a weighted sum of the corresponding values of the individual components.

Generally, a more complicated magnetic behavior results in an anomalous and a more complicated behavior of the MCE. For instance, upon cooling in a zero magnetic field, elemental Dy orders antiferromagnetically at $\sim 180\,K$ with a helical magnetic

structure, and then transforms from the helical antiferromagnetic state to a ferromagnet at ~90 K. When the magnetic field is between 0 and ~2 T, a few additional magnetic structures emerge in pure Dy between 90 and 180 K. Thus, when the magnetic field is low, the MCE of Dy shows a sharp step-like increase at ~90 K due to a first-order ferromagnetic–antiferromagnetic transition, and then goes through a minimum immediately followed by a weak maximum at ~180 K for $\Delta B = 1$ T (see **Figure 4**). The minimum exists because the application of a magnetic field to an antiferromagnet increases the magnetic entropy, thus inverting the sign of the MCE (in a ferromagnet the increasing field decreases magnetic entropy). When B_f is increased to 2 T, the magnetic field is strong enough to quench the first-order ferromagnetic–antiferromagnetic phase transition and it induces a noncollinear magnetic structure which yields a broad MCE maximum at ~127 K. Since a 2 T magnetic field is not strong enough to destroy this noncollinear structure, the slightly negative ΔT_{ad} is still observed at ~174 K. The latter is followed by a weak caret-type peak at ~181 K (**Figure 4**). Upon increasing the magnetic field to 5 T, it becomes strong enough to suppress all of the magnetic structures except the ferromagnetic phase and the MCE of Dy for $\Delta B = 5$ T has a single, somewhat skewed, caret-type peak at ~181 K.

Most magnetic materials on cooling undergo a second-order phase transition from a paramagnet to a ferromagnet with a conventional MCE behavior (**Figures 2** and **3a**), or from a paramagnet to an antiferromagnet with a skewed caret-like MCE if the magnetic field is large enough to destroy the antiferromagnetism and cause it to change to a ferromagnetic structure (**Figure 4**). A few materials, however, form a ferromagnetically ordered phase through a first-order magnetic phase transition, which may also be coupled with a change of the crystal lattice. One such example is illustrated in **Figure 3c**. Here, since the phase transition in $Gd_5Si_2Ge_2$ is of the first order, the $|[\partial M(T, B)/\partial T]_B|$ is larger than usual (but not infinite and undefined as could happen if the transition occurs infinitely fast at constant temperature, pressure, and magnetic field), and therefore, the MCE is also larger than usual (see eqns [3] and [4]). Technically, this behavior is known as the "giant MCE." If one compares the behavior of the giant MCE in $Gd_5Si_2Ge_2$ with that of the other two materials shown in **Figures 3a** and **3b** the most obvious difference is that at large magnetic fields the MCE versus temperature is extended considerably toward the high-temperature side of the peak, but the increase in the magnitude of the MCE with increasing field is affected to a much lesser extent than that in second-order phase transition compounds.

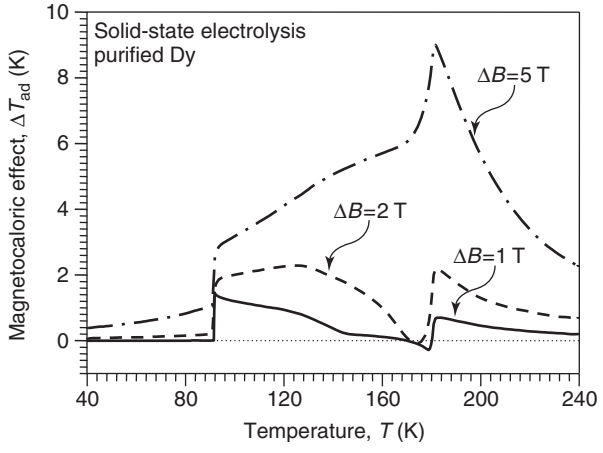

Figure 4 The magnetocaloric effect in ultrapure Dy calculated from the heat capacity data.

The MCE in first-order phase transition materials undergoing coupled magnetostructural transformations may be further enhanced by the added difference of the entropies of the two crystallographic modifications of the material, $\Delta S_{st} = \pm(S_{HF} - S_{LF})$, where HF and LF designate the high field and the low field phases, respectively:

$$\Delta S_M(T, \Delta B)_{\Delta B = B_f - B_i} = \int_{B_i}^{B_f} \left(\frac{\partial M(T, B)}{\partial T}\right)_B dB + \Delta S_{st} \qquad [6]$$

It is worth noting that unlike the first factor of the right-hand side of eqn [6], which represents the conventional contribution to the isothermal magnetic entropy change (see eqn [3]), ΔS_{st} is magnetic field independent provided the change from B_i to B_f is large enough to complete the structural transformation.

Although the last factor in eqn [6] is a hidden parameter in conventional measurements of the MCE, an estimate based on comparing the MCE exhibited by the closely related materials with and without magnetic field-induced structural transformations indicates that ΔS_{st} may account for more than a half of the total magnetic entropy change in magnetic fields below 5 T. Advanced magnetocaloric materials should, therefore, exist in solid systems where extensive structural changes are coupled with ferromagnetic ordering, and therefore, can be triggered by a magnetic field. Considering eqn [6], the strongest MCE should be found in novel compounds engineered in order to maximize the entropy of a structural transformation, ΔS_{st}. An extensive listing of ΔS_M and ΔT_{ad} values can be found in the reviews by Gschneidner and Pecharsky, and Tishin and Spichkin – see the "Further reading" section.

Active Magnetic Regenerator Cycle and Near-Room-Temperature Magnetic Refrigeration

Adiabatic demagnetization refrigeration, described at the beginning of this article, is a discontinuous process for all practical reasons because it may take as much as a few hours to repeat the refrigeration cycle and reach the target temperature. The history of continuous magnetic refrigeration can be traced to the work of S C Collins and F J Zimmerman, and C V Heer, C B Barnes and J C Daunt, who in the early 1950s built and tested two magnetic refrigerators operating between ~1 and 0.2 K by periodically magnetizing and demagnetizing iron ammonium alum. The apparatus built by Heer, Barnes, and Daunt operated at 1/120 Hz frequency (2 min per cycle) and on average extracted 12.3 $\mu J\,s^{-1}$ from the cold reservoir at 0.2 K.

It was not, however, until 1976 when G V Brown reported a near-room-temperature continuously operating magnetic refrigerator, that it became clear that magnetic refrigeration may be successfully utilized at significantly higher temperatures and achieve much larger temperature spans than the maximum observed MCE. Brown was able to attain a 47 K no-load temperature difference between the hot end (319 K) and cold end (272 K) of his unit by regenerating a column of fluid using Gd metal and a magnetic field change from 0 to 7 T and from 7 to 0 T. The achieved temperature difference was more than three times the MCE of Gd for $\Delta B = 7$ T (see **Figure 2**, where for a slightly greater $\Delta B = 7.5$ T, the maximum ΔT_{ad} of Gd is around 16 K at $T_C = 294$ K; the MCE is ~13 K and ~11 K at 319 K and 272 K, respectively).

Following the early work of Brown, the concept of active magnetic regenerator (AMR) refrigeration was introduced by W A Steyert in 1978 and developed by J A Barclay and W A Steyert in the early 1980s. It was subsequently brought to life in the later 1990s, when various magnetic refrigeration units were built in the US, Europe, and Japan. In the AMR cycle, shown schematically in **Figure 5**, a porous bed of a magnetic refrigerant material acts as both the refrigerant that produces refrigeration (i.e., temperature lift) and the regenerator for the heat transfer fluid. Assume that the bed is at a steady state with the hot heat exchanger at 18°C and the cold heat exchanger at 2°C. In **Figure 5a**, the initial temperature profile for the bed is in its demagnetized state in zero magnetic field (dashed line). When a magnetic field is applied to the refrigerant, each particle in the bed warms because of the MCE to form the final magnetized bed temperature profile (solid line). The amount each particle warms is equal to ΔT_{ad} reduced by the effect of the heat capacity of the heat transfer fluid in the pores between the particles. Next, the 2°C fluid flows through the bed from the cold end to the hot end (**Figure 5b**). The bed is cooled by the fluid, lowering the temperature profile across the bed (from the dashed line to the solid line), and the fluid in turn is warmed by the bed, emerging at a temperature close to the temperature of the bed at the warm end.

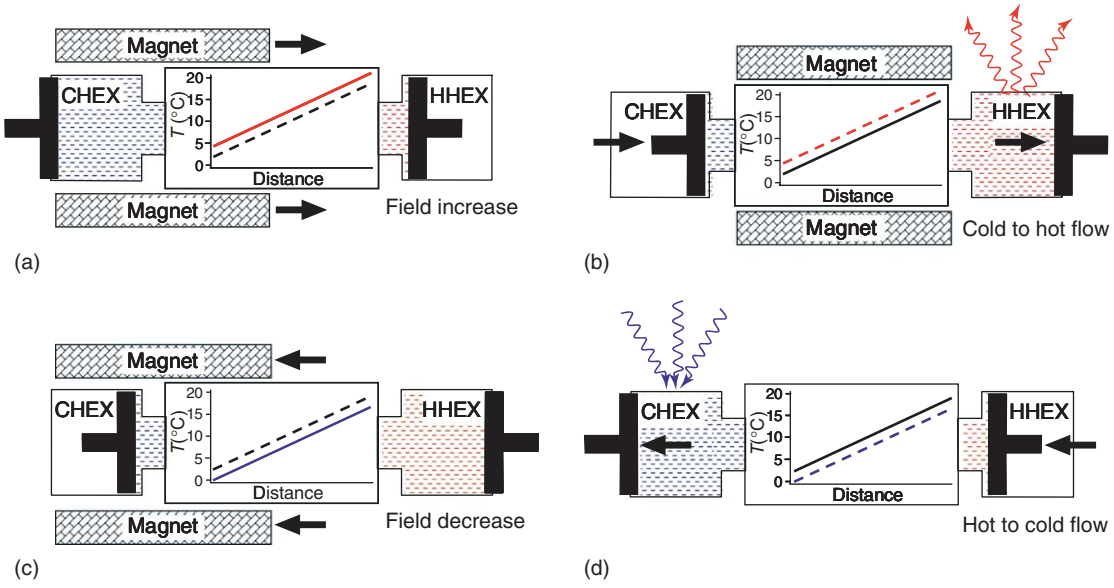

Figure 5 The four steps of the active magnetic regenerator cycle: magnetizing (a), flow from the cold heat exchanger (CHEX) to the hot heat exchanger (HHEX) (b), demagnetizing (c), and flow from HHEX to CHEX (d). This description follows that introduced by C B Zimm and A J DeGregoria in 1993.

This temperature is higher than 18°C, so heat is removed from the fluid at the hot heat sink as the fluid flows through the hot heat exchanger. After the fluid flow is stopped, the magnetic field is removed, cooling the bed by the MCE (from the dashed line to the solid line in **Figure 5c**). The refrigeration cycle is completed by forcing the 18°C fluid to flow from the hot to the cold end of the bed (**Figure 5d**). The fluid is cooled by the bed, emerging at a temperature below 2°C and removes heat from the cold sink as the fluid passes through the cold heat exchanger. After completion of this last step, the cycle is repeated beginning from step (a) (**Figure 5**).

The AMR cycle outlined above has several positive features useful for practical application in magnetic refrigeration devices. First, the temperature span of a single stage can greatly exceed that of the MCE of the magnetic refrigerant because the MCEs of the individual particles collectively change the entire temperature profile across the bed. Second, because the bed acts as its own regenerator, heat need not be transferred between two separate solid assemblies, but rather between the solid particles in a single bed via the action of a fluid. Third, the individual particles in the bed do not encounter the entire temperature span of the stage, and hence the bed may be made into layers, each containing a magnetic material with properties optimized for a particular temperature range.

The AMR refrigeration cycle has been successfully realized in a laboratory prototype magnetic refrigerator, which was recently designed and constructed by the Astronautics Corporation of America. The device is shown together with its schematic diagram in **Figure 6**. The refrigerator operates near room temperature in a magnetic field between 0 and ~1.5 T created by a permanent magnet. As the wheel spins, it brings one of its sections containing the magnetic refrigerant (the regenerator bed) into the high magnetic field volume, where the bed is heated due to the MCE (see **Figure 6a**). As long as this section of the wheel moves between the poles of the permanent magnet, it remains in the magnetized state and the heat exchange fluid (water) flows from the cold heat exchanger through the bed and into the hot heat exchanger. This corresponds to the second step of the AMR cycle shown in **Figure 5b**. While the wheel continues to spin, the same section exits from the high magnetic field volume. As the bed cools due to the MCE, the heat exchange fluid flow is reversed and it now flows from the hot heat exchanger through the bed toward the cold heat exchanger, thus completing steps (c) and (d) of the AMR cycle illustrated in **Figure 5**.

This permanent magnet-based rotating bed magnetic refrigerator was recently awarded US patent no. 6 526 759. The unit can operate at frequencies exceeding 1 Hz and it has achieved a maximum cooling power of 95 W and a maximum temperature span of 20°C. As tested by engineers at the Astronautics Corporation of America, the Carnot efficiency of this laboratory prototype system compares favorably with conventional vapor-cycle refrigeration devices, thus making magnetic refrigeration the first energy-efficient solid-state refrigeration technology.

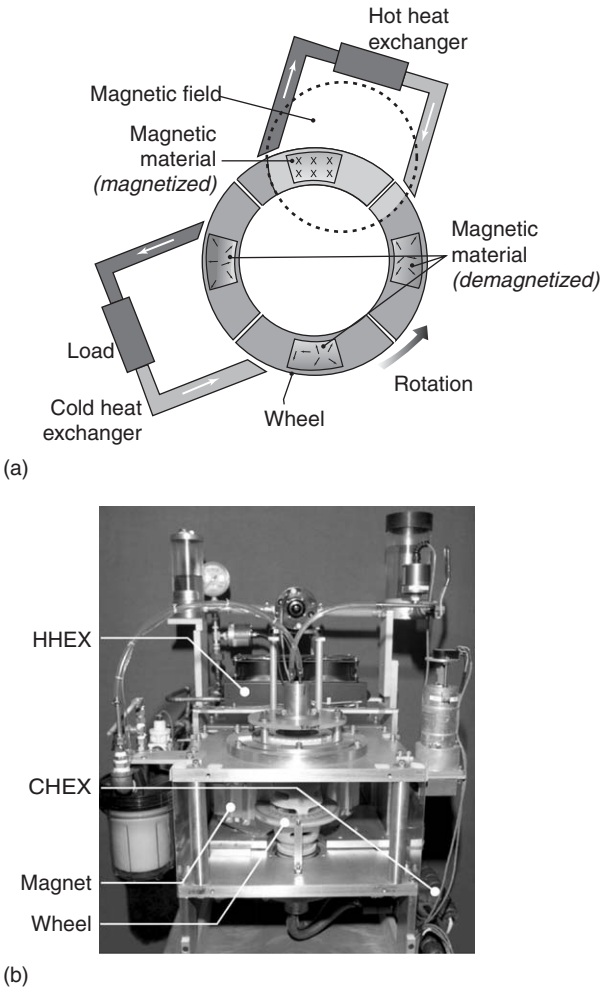

Figure 6 (a) The principal schematic diagram of the device and (b) laboratory prototype magnetic refrigerator designed and constructed by the Astronautics Corporation of America in 2001. A ~1.5 T magnetic field around the wheel filled with Gd spheres is produced by a permanent magnet. The refrigerator operates at ambient conditions with a maximum temperature span of ~20°C and maximum cooling power of 95 W. ((b) Courtesy of the Astronautics Corporation of America, 4115 N. Teutonia Avenue, Milwaukee, WI 53209.)

The Future of the Magnetocaloric Effect

Considering practical applications of the MCE, its extent is one of the most critical parameters defining

the performance of a magnetic refrigerator – the stronger the MCE the higher the efficiency of the device, all other things being equal. As is often the case with emerging technologies, numerous applications of magnetic refrigeration may stem from a reliable foundation formed by advanced magnetocaloric materials. For example, the availability of low-cost high-performance solids exhibiting enhanced MCE between ~ 250 and $\sim 350\,\mathrm{K}$ is an important requirement in order to facilitate commercialization of magnetic refrigeration for a variety of consumer uses – from home appliances to climate control in motor vehicles. In another example, when suitable magnetocaloric compounds supporting continuous magnetic cooling from ~ 300 to $\sim 20\,\mathrm{K}$ are developed, the energy penalty incurred during hydrogen liquefaction using the conventional gas-compression approach may no longer be a limiting factor preventing the widespread use of liquid hydrogen fuel in transportation. It is conceivable that many other areas where conventional refrigeration is inapplicable because of scaling difficulties and/or where thermoelectric refrigeration demands too much energy, magnetic refrigeration will eventually emerge as the cooling technology of choice.

To amplify the MCE, conventional wisdom calls for increasing the magnetic field change in addition to maximizing both the derivative, $|(\partial M(T, B)/\partial T)_B|$, and the region of magnetic fields and temperatures where the magnetization remains highly sensitive to temperature (see eqns [1]–[5]). Considering the current state-of-the-art of permanent magnet alloys and magnet design, it is quite unlikely that magnetic fields in excess of about 2 T at a reasonable cost will become common in the foreseeable future. That is why maximizing the MCE by manipulating chemical and phase compositions, atomic, microscopic, and magnetic structures of a material appears to be the most realistic option in order to reach the strongest possible MCEs in readily available magnetic fields. Although it remains a formidable challenge for basic science, a better understanding of the MCE, including the ability to control a variety of chemical, structural, and physical degrees of freedom that define the properties of solids will lead to improved existing materials and should eventually result in novel compounds exhibiting large MCE.

An especially promising area of research is the study of the extensive measure of the MCE, that is, the isothermal magnetic-field-induced entropy change that can be strongly enhanced by the added entropy of a structural transition (see eqn [6]). Provided the magnetic field completes the polymorphic transformation, this additional entropy is magnetic field independent, and therefore, may account for more than half of the observed MCE, especially in relatively weak magnetic fields. The design of novel materials exhibiting potent MCEs in weak magnetic fields is, therefore, possible by ensuring that (i) a structural transition can be triggered and completed (or nearly completed) by a weak magnetic field; (ii) the transformation has low thermal and magnetic field hystereses, that is, is reversible, and (iii) the difference between the entropies of different polymorphic modifications is maximized.

Introduction

Joule first observed magnetostriction effect on an iron bar; further experiments performed on Fe–Ni alloys allowed Ch E Guillaume to discover the Invar effect. Since then, a vast discipline in condensed matter studies has emerged. Magnetism and symmetry together lead to a variety of phenomena which, during the twentieth century, have been a key for the understanding of the theories of solids. The earliest magnetostriction theories were based on a phenomenological model proposed by R Becker and W Döring in 1939. The most complete and quantum-mechanical theory of magnetostriction was developed by E R Callen and B Callen. As a general phenomenon in magnetism, in the magnetostriction phenomenology one has two extreme situations in which theories can closely predict and explain the behavior of the solids, that is, local-moment and itinerant approaches. The first considers the magnetic electrons identified with a given atom or ion which makes possible a theoretical treatment within the framework of the mean field crystal electric field (CEF) theory. The itinerant approach should be considered within the framework of a many-body problem and encompasses band-structure calculations. Clear examples of local-moment systems are the rare-earth inter metallics; in these compounds the anisotropic and magnetostriction properties are driven by the 4*f* electron of the rare-earth (RE) ion. The strong spin–orbital coupling gives rise in TERFENOL to the largest magnetostriction effects ever observed at room temperature. On the other hand, the 3*d* alloys represent archetypical systems in which the itinerancy and the strong CEF interaction form the basis of the magnetoelastic effects. In these systems the possible unquenched orbital moment can produce relevant anisotropic and magnetostriction effects.

Current theories rely mainly on these two approaches; nevertheless, there exists a wide phenomenology (not very well understood but fascinating) that will be briefly described in this section. These are related to the magnetic fluctuations of the magnetic moment, which in general, produces large magnetovolume effects. Carrier localization is another source of magnetostriction, as discovered recently in magnetic oxides with colossal magnetoresistance (CMR); orbital instabilities also cause large anisotropic magnetostriction in related oxides, such as the cobaltites. Isotopic effect has also been recently reported in transition metal oxides in which electron–phonon interaction plays a key role in the magnetic and magnetotransport properties. There exists another source of large magnetoelastic effect when magnetic and structural transitions occur; thermal effects produce large spontaneous magnetostriction. These transitions can also be induced by applying a magnetic field and causing large magnetostructural effects of magnetoelastic nature. Other related effects are also important, such as the change of the elastic module due to the change of magnetization – the so-called ΔE effect. The inverse magnetostriction effect, that is, a change in the magnetization originated by an induced lattice deformation, is another example.

Shape memory alloys are also very interesting when, associated with the thermoelastic difussionless transformation, a magnetic transition takes place. In this case, twin boundaries can be displaced by a magnetic field producing large magnetostriction.

Spontaneous Magnetostriction

In the absence of applied magnetic field, only certain solids exhibit magnetostriction effect: the ferrimagnetic or ferromagnetic materials. The existence of long-range magnetic order produces a lattice deformation of magnetoelastic type due to the spin–lattice coupling. Nevertheless, as the overall magnetization is zero, due to the existence of magnetic domains, the magnetostriction is also zero and each domain is magnetostrictively deformed. This is because the random distribution of deformations is, on average, canceled out. Spontaneous magnetostriction is observed when the thermal expansion of the lattice does not follow the Gruneisen law:

$$\omega_{\mathrm{ph}} = (\Delta V/V)_{\mathrm{ph}} = \int k\gamma C_v(T)\ \mathrm{d}T \qquad [1]$$

This law accounts for phonons as contributing to the thermal expansion of the lattice. Below the ordering temperature, ferromagnets experience an additional contribution to the thermal expansion of magnetoelastic origin and isotropic ω_{mag} which can be obtained from the experiment as

$$\omega_{\mathrm{mag}} = (\Delta V/V)_{\mathrm{Experimental}} - (\Delta V/V)_{\mathrm{Gruneisen}} \qquad [2]$$

This contribution is associated with the establishment of a long-range magnetic order, and can be strongly enhanced due to the existence of magnetic moment instabilities (longitudinal fluctuation of the

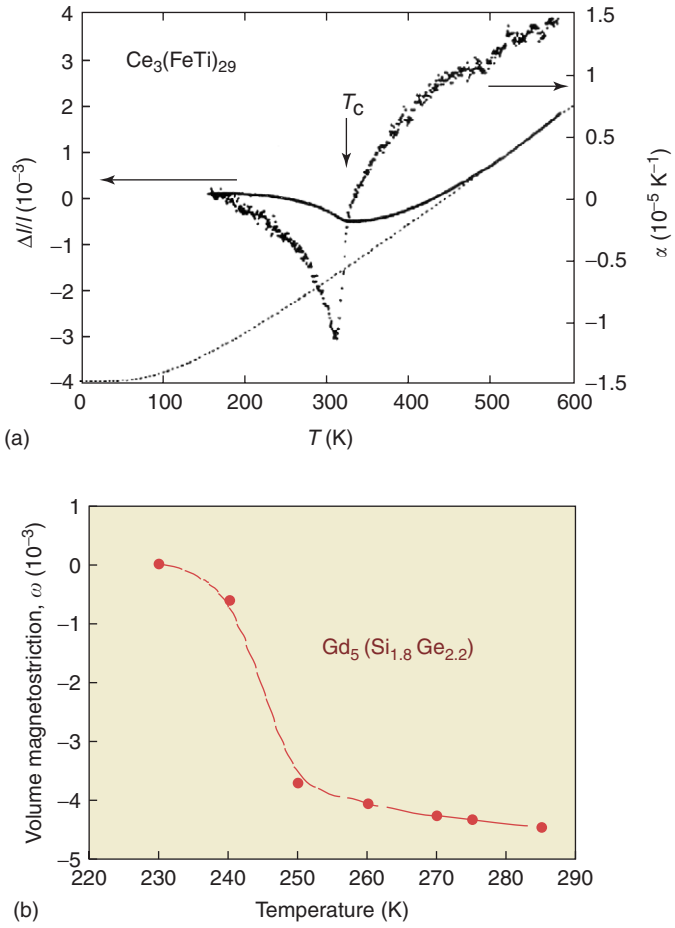

Figure 1 (a) Invar effect in rare-earth intermetallics $Ce_3(FeTi)_{29}$. Dotted line is the phonon contribution calculated using a Debye temperature of 450 K. The arrows show the curie temperature. The extra contribution to the thermal expansion is of magnetic origin. (b) Anomalous thermal expansion due to a magnetostructural transition with a large magnetocaloric effect associated.

magnetization) or structural transitions associated with the magnetic transition.

The first case can give rise to zero or negative thermal expansion coefficient – this is called Invar effect. Alloys such as FeNi, where this effect is relevant, are used in applications such as mechanical precision systems and in large cryogenic containers. Many rich intermetallic alloys present this behavior and an example is given in **Figure 1a**. In many structural transitions the magnetoelastic energy is quite large and a simultaneous structural and magnetic transition may occur; in these cases, a volume contribution also exists, and in general, large entropic content is involved in such transitions (e.g., in compounds with large magnetocaloric effect). **Figure 1b** shows the large volume anomaly observed in the magnetocaloric alloy $Gd_5Ge_2Si_2$.

Anisotropic Magnetostriction

As in magnetism, all materials have magnetostriction under an applied magnetic field. Usually, magnetostriction associated with diamagnetism and paramagnetism is quite small and is not discussed in this article. Ferromagnetic and ferrimagnetic compounds show magnetostrictive deformation when a magnetic field is applied. As already mentioned, the domains are deformed due to the magnetoelastic coupling; under the application of a magnetic field, the wall domain displacement favors an overall deformation of the lattice. To account for the anisotropic nature of the resulting strain, the deformation is measured along and perpendicular to the applied magnetic field. The strains are called parallel ($\lambda_{\parallel}$) and perpendicular ($\lambda_{\perp}$) magnetostriction, respectively. The anisotropic magnetostriction (λ_t) is defined as $\lambda_t = \lambda_{\parallel} - \lambda_{\perp}$. In crystalline materials, the strain depends on the direction of the measurements (β_i) and also the direction of the magnetization (α_i). As an example, for a cubic crystal

$$\begin{aligned}\Delta l/l[\alpha_x,\alpha_y,\alpha_z][\beta_x,\beta_y,\beta_z] &= \tfrac{3}{2}\lambda_{1\,0\,0}(\alpha_x^2\beta_x^2+\alpha_y^2\beta_y^2+\alpha_z^2\beta_z^2-\tfrac{1}{3}) \\ &\quad + 3\lambda_{1\,1\,1}(\alpha_x\alpha_y\beta_x\beta_y+\alpha_x\alpha_z\beta_x\beta_z+\alpha_y\alpha_z\beta_y\beta_z) \qquad [3]\end{aligned}$$

If the deformation is measured along the [1 0 0] axis ($\beta_x = 1, \beta_y = \beta_z = 0$), this expression becomes

$$\Delta l/l = \tfrac{3}{2}\lambda_{1\,0\,0}(\alpha_x^2 - \tfrac{1}{3}) \qquad [4]$$

As a consequence, $\lambda_{1\,0\,0}$ represents the change in length along the [1 0 0] axis when the easy magnetization direction is the [1 0 0] axis ($\alpha_x = 1$), that is, $\Delta l/l = \lambda_{1\,0\,0}$. The anisotropic magnetostriction is then

$$\begin{aligned}\lambda_{\mathrm{t}} &= (\Delta l/l)[1\,1\,1][1\,1\,1] - (\Delta l/l)[1\,1\,1][1\,0\,1] \\ &= \tfrac{3}{2}\lambda_{1\,1\,1}\end{aligned} \qquad [5]$$

Similarly, if the easy magnetization direction is along the [1 1 1] axis and the deformation is measured along this direction (i.e., $(\alpha_x = \alpha_y = \alpha_z = 1/\sqrt{3},\ \beta_x = -\beta_z = 1/\sqrt{2},\ \beta_y = 0)$,

$$\begin{aligned}\lambda_{\mathrm{t}} &= (\Delta l/l)[1\,1\,1][1\,1\,1] - (\Delta l/l)[1\,1\,1][1\,0\,1] \\ &= \tfrac{3}{2}\lambda_{1\,1\,1}\end{aligned} \qquad [6]$$

where $\lambda_{1\,0\,0}$ and $\lambda_{1\,1\,1}$ are related to the strain along the [1 0 0] and [1 1 1] directions when the magnetization is, respectively, along these directions:

$$\lambda_{\mathrm{t}} = \tfrac{3}{2}\lambda_{1\,0\,0} \quad \text{and} \quad \lambda_{\mathrm{t}} = \tfrac{3}{2}\lambda_{1\,1\,1} \qquad [7]$$

In an isotropic solid, there exists only one magnetostrictive strain parameter λ_{s}, such that the deformation along any direction is given by

$$\Delta l/l = \tfrac{3}{2}\lambda_{\mathrm{s}}(\cos^2\theta - \tfrac{1}{3}) \qquad [8]$$

where θ is the angle between the magnetization and the measurement deformation direction. Expression [8] is obtained for a cubic solid if $\lambda_{1\,0\,0} = \lambda_{1\,1\,1} = \lambda_{\mathrm{s}}$ in [3].

Single-Ion Theory of Magnetostriction

H B Callen and E Callen applied quantum mechanics and symmetry considerations to magnetostriction; with this formalism, it is possible to calculate (using microscopic models) the magnetostrictive deformations in a single crystal and, by appropriated averages, obtain information of the intrinsic magnetoelastic parameter from measurements performed in polycrystalline materials. As an example, the procedure is considered assuming cubic symmetry and the easy magnetization direction along the [1 0 0] axis.

The equation similar to expression [3], but written in terms of irreducible strains ε_i^{Γ}, is written as

$$\begin{aligned}\lambda[\alpha_1\alpha_2\alpha_3][\beta_1\beta_2\beta_3] =& \tfrac{1}{3}\varepsilon^{\alpha} + \tfrac{1}{6}\varepsilon_1^{\gamma}(2\beta_3^2 - \beta_2^2 - \beta_1^2) \\ &+ \tfrac{1}{2}\varepsilon_2^{\gamma}(\beta_1^2 - \beta_2^2) + 2\varepsilon_1^{\varepsilon}\beta_2\beta_3 \\ &+ 2\varepsilon_2^{\varepsilon}\beta_1\beta_3 + 2\varepsilon_3^{\varepsilon}\beta_1\beta_2\end{aligned} \qquad [9]$$

The definition of the ε_i^{Γ} strains in terms of the usual Cartesian ones is given in **Table 1**. From eqns [2] and [6], the tetragonal strain for the [0 0 1] direction of the magnetization is

$$h_1 = \sqrt{\tfrac{3}{2}}\varepsilon_1^{\gamma} + \tfrac{1}{\sqrt{2}}\varepsilon_2^{\gamma} \qquad [10]$$

Now, the CEF Hamiltonian referred to a frame of fourfold axes, and where the spontaneous magnetization is along the z-axis, parallel to [0 0 1], is

$$H_{\mathrm{c}} = \tilde{B}_4^0\left(\tilde{O}_4^0 + \sqrt{\tfrac{10}{7}}\tilde{O}_4^0\right) + \tilde{B}_6^0\left(\tilde{O}_6^0 + \sqrt{14}\tilde{O}_6^0\right) \qquad [11]$$

where the $\tilde{B}_4^0$ are the CEF parameters and O_n^m the Stevens DEF operators written in the Buckmaster notation (tabulated by Hutchings). The Zeeman and exchange interactions can be written as

$$H_{\mathrm{Z}} + H_{\mathrm{ex}} = -g\mu_{\mathrm{B}}(\boldsymbol{H} + \lambda\langle\mu\rangle)\boldsymbol{J} \qquad [12]$$

where $\langle\mu\rangle$ is the thermal statistical average of the magnetic moment, $\boldsymbol{J}$ the RE angular momentum and λ the mean-field exchange constant.

In the presence of magnetoelastic coupling, the corresponding Hamiltonian, up to second order terms, is

$$\begin{aligned}H_{\mathrm{ms}} =& -M_0^{\alpha}\varepsilon^{a} - M_2^{\gamma}\left(\varepsilon_1^{\gamma}\tilde{O}_2^0 + \sqrt{2}\varepsilon_2^{\gamma}\tilde{O}_2^2\right) \\ &- M_2^{\varepsilon}(\mathrm{i}\varepsilon_1^{\varepsilon}\tilde{O}_2^1 - \mathrm{i}\varepsilon_2^{\varepsilon}\hat{O}_2^1 + \varepsilon_3^{\varepsilon}\hat{O}_2^2)\end{aligned} \qquad [13]$$

where M_i^{Γ} are the magnetoelastic coupling parameters. The elastic energy is given by

$$\begin{aligned}E_{\mathrm{el}} =& \tfrac{1}{2}C^{\alpha}(\varepsilon^{\alpha})^2 + \tfrac{1}{2}C^{\gamma}\left[(\varepsilon_1^{\gamma})^2 + (\varepsilon_2^{\gamma})^2\right] \\ &+ \tfrac{1}{2}C^{\varepsilon}\left[(\varepsilon_1^{\varepsilon})^2 + (\varepsilon_2^{\varepsilon})^2 + (\varepsilon_3^{\varepsilon})^2\right]\end{aligned} \qquad [14]$$

where C^{Γ} are irreducible symmetric elastic constants. The equilibrium strains (ε_2^{γ}) are formed by minimizing the average energy $\langle H_{\mathrm{ms}}\rangle + E_{\mathrm{el}}$ with respect to the strains, and are given by

$$\begin{aligned}\bar{\varepsilon}_1^{\gamma} &= \frac{M_2^{\gamma}}{C^{\gamma}}\langle\tilde{O}_2^0\rangle, \qquad \bar{\varepsilon}_2^{\gamma} = \frac{M_2^{\gamma}}{\sqrt{2}C^{\gamma}}\langle\tilde{O}_2^0\rangle \\ \bar{\varepsilon}_2^{\varepsilon} &= \frac{M_2^{\varepsilon}}{C^{\varepsilon}}(-\mathrm{i}\langle\hat{O}_2^1\rangle), \text{ etc.}\end{aligned} \qquad [15]$$

The statistical average values $\langle\cdots\rangle$ are evaluated using the energy levels and wave functions which

diagonalize the unperturbed Hamiltonian $H_c + H_Z + H_{ex}$. This theoretical approach allows calculating the field and thermal dependence of the magnetostriction on single crystals. As an example, **Figure 2** shows the experimental results of the irreducible deformations obtained from magnetostriction measurements in an $HoAl_2$ single crystal. The magnetoelastic coefficient is obtained from the fit of these results.

Magnetostriction in Oxides

Magnetic oxides are characterized by strong localization of the magnetic electrons on the ionic sites, which are separated by oxygen ions. The magnetic interactions in magnetic oxides are of indirect origin, such as the superexchange between ions of the same ionic valence or double exchange, in which the existence of mixed valence is necessary. Magnetostriction in magnetic oxides has been widely studied. It could be noted that the results obtained in ferrimagnetic oxides (e.g., ferrites and garnets) show only weak anisotropic magnetostriction due to the quenching of the orbital moment by the strong crystal electric field interaction. Exceptions to this low value of the magnetostriction were found in titanium, chromium, and cobalt ferrites. De Lacheisserie has summarized the magnetostriction in these compounds. There exist other sources of large spontaneous magnetovolume effect occurring in antiferromagnetic oxides, such as V_2O_3 and Fe_3O_4. In these compounds, these effects occur either due to the existence of a Mott transition, in the case of the vanadium oxides, or to the existence of the charge ordering (Verwey transition in the case of magnetite). These effects are not related to orbital degrees of freedom. Another source of magnetostriction has been found in compounds with cooperative Jahn–Teller effect transition. In this case, the removal of the orbital degeneracy brings about a lowering of the symmetry, giving rise to structural transitions. This is a thermal effect in which tunneling between energetically equivalent distortions becomes unstable as temperature changes, resulting in a new ground state where the distortions are long-range ordered (cooperative Jahn–Teller effect). Under certain conditions, it is possible to induce the transition by the application of a magnetic field. This source of magnetovolume effect does not have its origin in the spin–orbit coupling but in the electron–phonon interaction. Nevertheless, the bibliography on this topic is scarce. In fact, the magnetostriction in manganites was completely ignored until the recent discovery of the CMR phenomena. The upsurge of interest in mixed-valent manganites $R_{1-x}M_xMnO_3$ (R = rare earth, M = Ca, Sr, Ba) has attracted the interest of the scientific community. Ibarra and co-workers discovered a large and unusual magnetostriction in the paramagnetic phase of the CMR compound $La_{0.6}Y_{0.07}Ca_{0.33}MnO_3$. In this compound, the magnetic ions are Mn^{3+} and Mn^{4+}. In both ions, the relativistic spin–orbit coupling is irrelevant, given the lack of orbital moment in Mn^{4+} (t_{2g}^3) and in Mn^{3+} (t_{2g}^4) due to the Jahn–Teller distortion. This compound has a paraferromagnetic transition at $T_c = 260\,K$. Associated with this transition, there exists a metal–insulator transition with an abrupt change of resistance. The metallic phase has a low resistance, which is intrinsically related to the high mobility of the carriers in the ferromagnetic phase due to the nature of the double-exchange interaction. In the paramagnetic phase, the resistance increases as the temperature decreases, showing a semiconductor or polaronic behavior (see **Figure 3a**). Under the application of a magnetic field, the transition can be induced. This is the origin of the intrinsic CMR in this compound. As in the Invar compounds, there exists a volume anomaly at this transition, with an extra contribution over the phonon contribution to the thermal expansion as shown clearly in **Figure 3b**. In this case, such an effect is due to the carrier localization. As the Curie temperature is approached from the paramagnetic phase, the carriers are magnetic polarons (namely, the charge and a magnetic cloud). The thermal expansion effect is related to the formation of these magnetic clusters called "magnetic polarons."

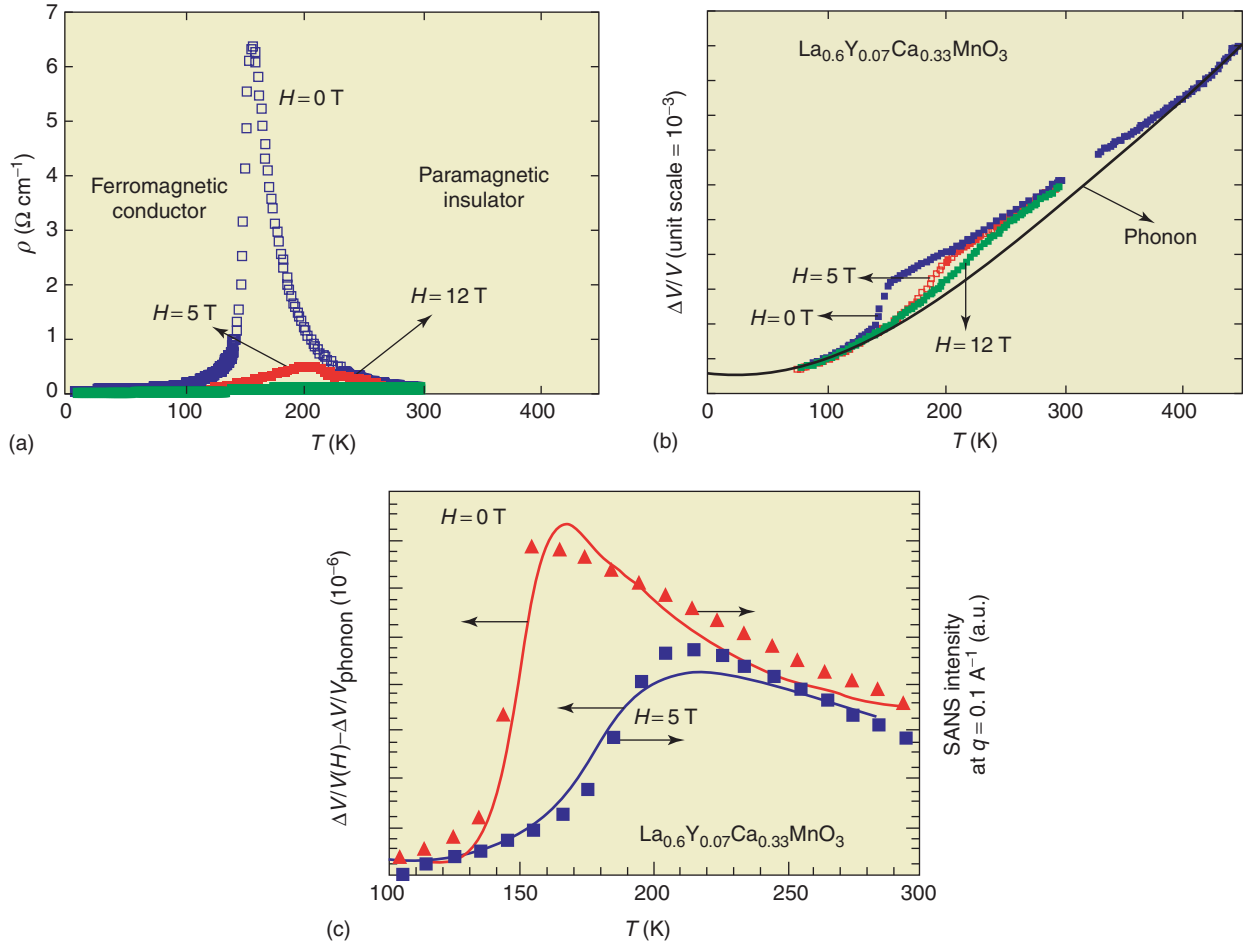

Figure 3 (a) Thermal dependence of the resistivity in the $(LaY)_{2/3}Ca_{1/3}MnO_3$ magnetic oxide. Under an applied magnetic field the resistivity drastically decreases giving rise to the colossal magnetoresistance effect. (b) Thermal expansion of $(LaY)_{2/3}Ca_{1/3}MnO_3$. The line is the phonon contribution calculated by using the Gruneisen law. (c) Anomalous thermal expansion compared with the SANS contribution in $(LaY)_{2/3}Ca_{1/3}MnO_3$.

The thermal dependence of the intensity of the small-angle neutron scattering (SANS) also showed a similar dependence, as shown in **Figure 3c**. Under the application of a magnetic field, the same dependence is kept for both magnitudes with a large change in the volume of the sample. This field dependence at one temperature is shown in **Figure 4**, where a large volume magnetostriction is observed. This large magnetostriction in magnetic oxides is a result of a growing magnetic cluster and percolation raising the ferromagnetic state and, as a consequence, the shrinkage of the lattice.

In the above-mentioned compounds, the anisotropic magnetostriction is negligible because the observed deformation is not related to an orbital effect.

There exists a family of magnetic oxides as the mixed valence cobaltites $La_{1-x}Sr_xCoO_3$ in which an orbital instability gives rise to a large magnetostriction. Unlike the manganites, the cobaltites display a large anisotropic magnetostriction while the volume

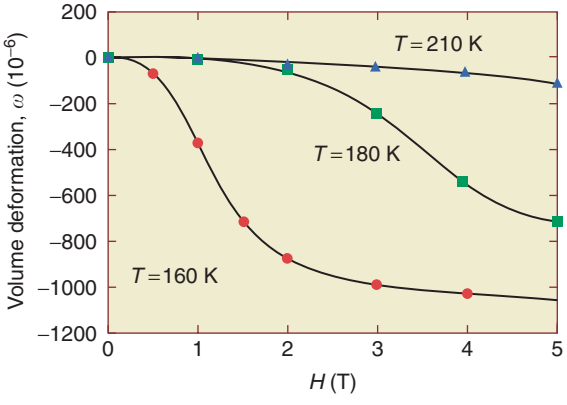

Figure 4 Volume magnetostriction (isotropic) in the paramagnetic phase of the $(LaY)_{2/3}Ca_{1/3}MnO_3$.

(isotropic) magnetostriction is negligible. The Co^{3+} ion in $LaCoO_3$, due to the comparable value of the crystal electric field (Δ_{CEF}) and intra-atomic exchange interaction (J_{ex}), can adopt different

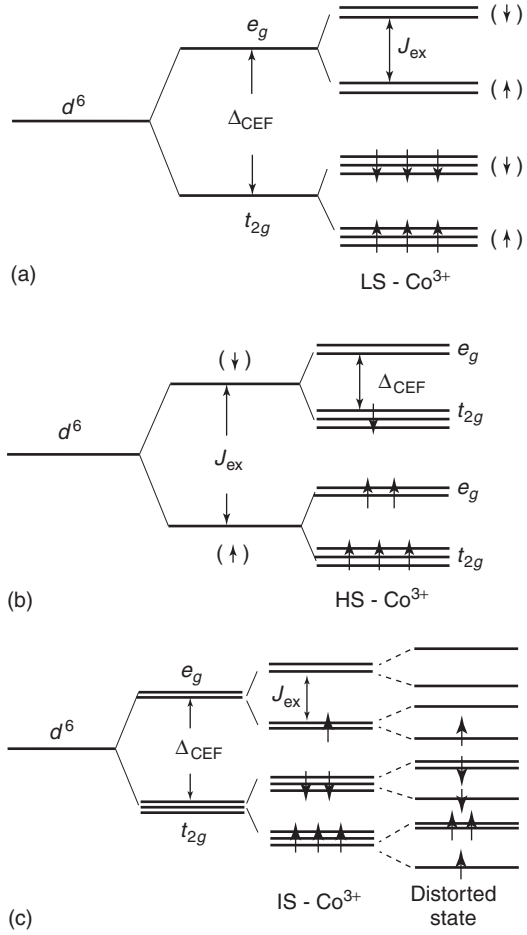

Figure 5 Energy levels splitting of the different Co^{3+} spin states in: (a) the low-spin (LS) state ($\Delta_{CEF} > J_{ex}$, t_{2g}^6, $S = 0$) is diamagnetic. (b) high-spin (HS) state ($\Delta_{CEF} > J_{ex}$, $t_{2g}^4\ e_g^2$, $S = 2$), and (c) intermediate spin (IS) state ($t_{2g}^5\ e_g^1$, $S = 1$).

spin/electronic configurations with difference in energies that can be thermally excited. This situation can be schematized as in **Figure 5**. At low temperatures, this compound is diamagnetic and it is paramagnetic above 90 K. Within the paramagnetic phase, a transition from a low-spin (LS) to an intermediate-spin (IS) state takes place at 90 K. Under hole doping in $La_{1-x}Sr_xCoO_3$, mixed-valent Co^{3+} and Co^{4+} ions appear. The interplay of double-exchange and superexchange interaction in these compounds gives rise to complex magnetic structures. In the composition $0.25 \leqslant x \leqslant 0.5$, the compounds show cluster glass behavior: short-range ferromagnetically correlated clusters embedded in a nonmagnetic matrix; no spontaneous thermally induced transition have been found between different spin states. In these compounds, the volume magnetostriction is negligible. However, the anisotropic magnetostriction is large (see **Figure 6**). This is a unique effect considering that the system is magnetically disordered and it is explained within the framework of a field-induced

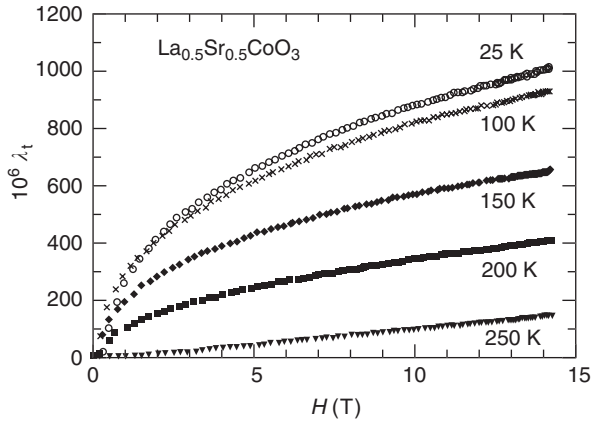

Figure 6 Huge anisotropic magnetostriction in $La_{1-x}Sr_xCoO_3$.

spin-state transition. Under the application of a magnetic field, there exists a change from the LS state to an IS state that is closer in energy. As shown in **Figure 5** the IS Co^{3+} is a Jahn–Teller ion. Under Jahn–Teller distortion, the doubly degenerated e_g splits into two singlets ($L = 0$), and the triplet t_{2g} into a singlet and a doublet ($L = 1$). The singlet t_{2g} states are occupied by two electrons with opposite spins and the doublet levels by three electrons. Due to the degeneracy of this level with nonzero angular moment, a strong intra-atomic spin–orbit coupling is created, which couples to the lattice strain giving rise to a large anisotropic magnetostriction. These results constitute a nice example of CMR arising from an orbital instability as a consequence of a transition from the LS to the IS state.

Isotopic Effect on Magnetostriction

In the polaronic regime of the manganites, the carriers have an effective bandwidth W_{eff} given by

$$W_{eff} \propto W e^{-\gamma E_b/\hbar\omega} \qquad [16]$$

Here, W is the bare conduction bandwidth, E_b the binding energy of the polaron, ω the characteristic frequency of the optical phonon, and γ a dimensionless parameter ($0 < \gamma \leqslant 1$) which depends on the ratio E_b/W in such a way that as E_b/W decreases, W_{eff} increases. In the strong Hund coupling limit (high-spin state, $J_H \gg W_{eff}$), $T_c \propto W_{eff}$. In this way the stability of the long-range ferromagnetic metallic state can be related to the phonon vibrational modes, that is, the lattice. Zhao and co-workers found an extraordinary effect in mixed-valent $La_{1-x}Ca_xMnO_3$. In $La_{0.8}Ca_{0.2}MnO_3$, the isotopic exchange of the natural ^{16}O isotope by ^{18}O gives rise to a decrease of 10 K in T_c. These results can be explained by considering the isotopic mass effect on the phonon frequency ($\omega \propto M^{-1/2}$). Therefore, an increase in the oxygen

mass will decrease ω and consequently will decrease W_{eff}. The result is, as expected, a less stable ferromagnetic metallic state, that is, one with a lower T_c. **Figure 7** shows the results of thermal expansion in isotope exchange manganite $La_{2/3}Ca_{1/2}MnO_3$. At a certain temperature (see arrows in **Figure 7a**) the same compound can be either metallic ferromagnetic (^{16}O) or insulator paramagnetic (^{18}O). This gives rise to a large spontaneous isotopic magnetovolume effect within the temperature range in which the oxygen isotopic exchange is able to destabilize the ferromagnetic metallic phase. **Figure 7b** displays the isotopic contribution to the thermal expansion. The isotopic effect can be more drastic if manganites in the composition range close to a border line separating ferromagnetic metallic and antiferromagnetic charge/orbital states are considered. In this case, the subtle balance between the electronic correlations can be strongly affected by a variation of the intensity of the electron–phonon interaction which can be driven by oxygen isotope exchange.

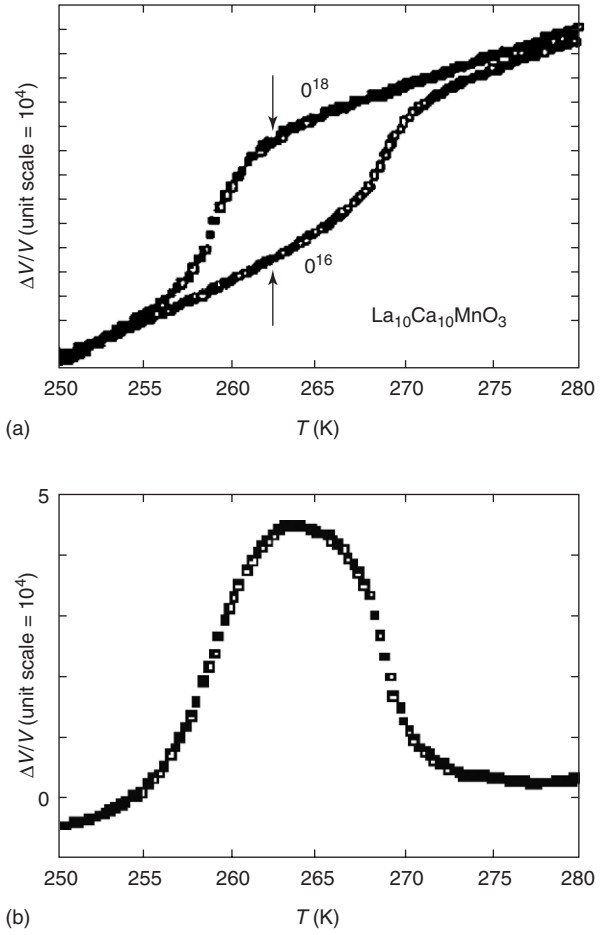

Figure 7 Volume thermal expansion of the $La_{2/3}Ca_{1/3}MnO_3$ compound: (a) comparison of the results for the ^{18}O and ^{16}O isotope compounds. Arrows show the curie temperature. (b) Differential isotope volume thermal expansion.

This is the case in $(La_{0.5}Nd_{0.5})_{2/3}Ca_{1/3}MnO_3$. The compound with ^{18}O isotope is an insulator over the whole temperature range, whereas the ^{16}O sample exhibits a metal–insulator transition at 150 K. This transition is strongly affected by external pressure or an applied magnetic field which can induce the insulator–metal transition. The volume thermal expansion results are shown in **Figure 8**. The solid line is the calculated phonon contribution using the Gruneisen law ($\theta_D = 500$ K). The thermal expansion of the ^{18}O sample follows the insulator behavior down to the lowest temperatures, in good agreement with electrical resistivity measurements. In contrast, the ^{16}O sample shows a different behavior. Above 150 K, the thermal expansion follows the behavior of an insulator, but below this temperature the behavior obtained partly corresponds to an insulator or a metal state. This suggests the existence of static phase segregation in which insulating antiferromagnetic charge/orbital region co-exists with ferromagnetic metallic regions. As is shown in **Figure 9**, large magnetostriction is present at values of a critical field at which a transition from the insulator into the metallic state takes place. For the ^{18}O sample at 5 K

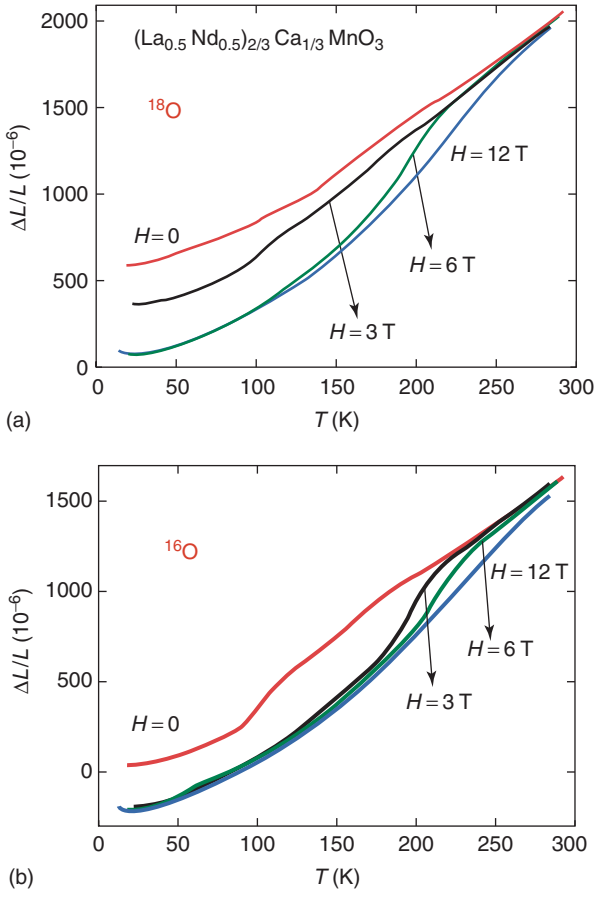

Figure 8 Volume thermal expansion of the $(La_{0.5}Nd_{0.5})_{2/3}Ca_{1/3}MnO_3$. (a) ^{18}O isotope and (b) ^{16}O isotope.

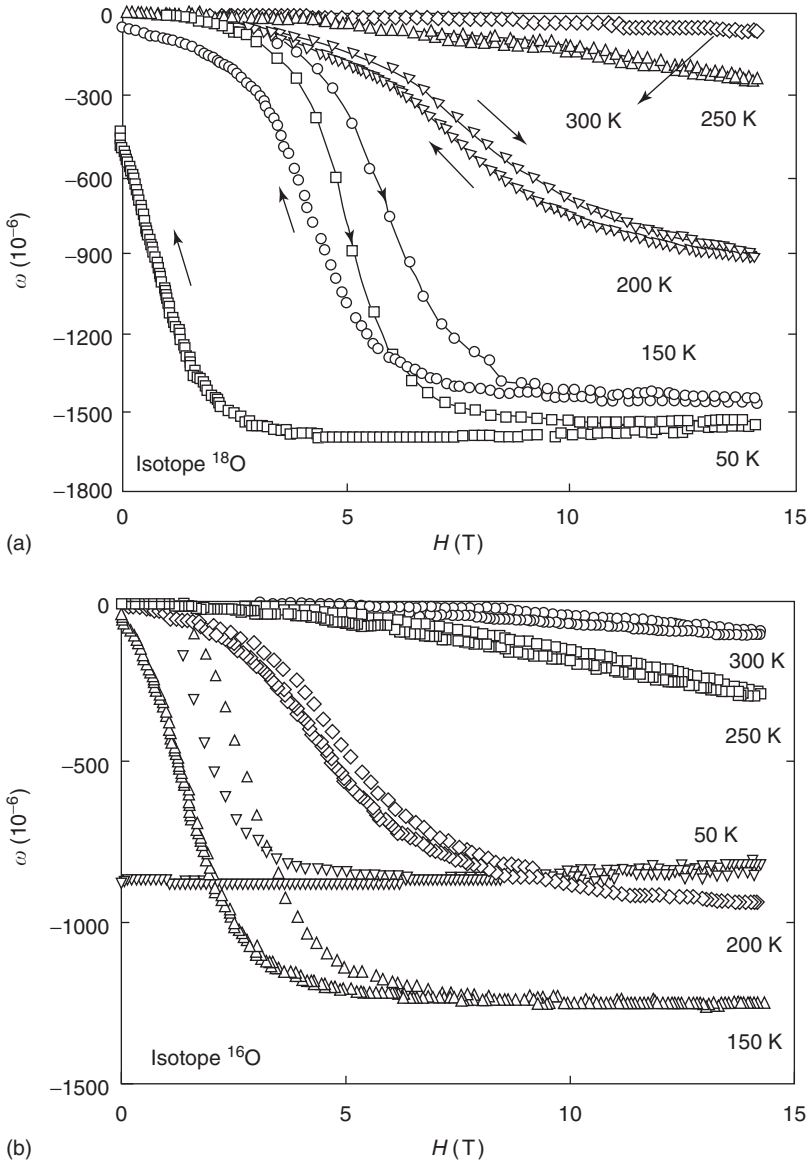

Figure 9 Volume magnetostriction of $(La_{0.5}Nd_{0.5})_{2/3}Ca_{1/3}MnO_3$: (a) ^{18}O isotope and (b) ^{16}O isotope.

the saturation magnetostriction is $\omega = 1.6 \times 10^{-3}$. However, in the ^{16}O the value obtained at the same temperature is $\omega = 0.8 \times 10^{-3}$. This constitutes a relevant observation in the field of magnetostriction in which the oxygen isotopic exchange gives rise to a magnetovolume effect of 0.8×10^{-3}.

Magnetoresistance Techniques Applied to Fermi Surfaces

S J Blundell, University of Oxford, Oxford, UK

Introduction

Magnetoresistance is the change of resistance with a magnetic field. The experimental use of magnetoresistance techniques to determine the Fermi surfaces of various metals has a long and successful history. This is partly due to the relative ease with which resistance measurements can be made, and also because there are many variables which can be adjusted. These include temperature, magnetic field strength, and the orientation with respect to the crystal axes of both the magnetic field and the current density. As described below, the presence of open and closed orbits can be easily distinguished by the field dependence of the magnetoresistance while the area of the Fermi surface pockets can be measured by the frequency of field-dependent magnetoresistance oscillations. The angle dependence of the magnetoresistance also reveals intricate features of the electron band structure.

Free Electron Gas Model – Single Carrier

In order to gain insight into the phenomenon of magnetoresistance, it is valuable to start with a very simple model. Consider a gas of charge carriers in a metal (n per unit volume, each with charge q and effective mass m^*). The forces on the charge carriers due to the applied electric and magnetic fields, $\boldsymbol{E}$ and $\boldsymbol{B}$, imply that the equation of motion for the ith carrier can be written as $m^*\dot{\boldsymbol{v}}_i = q(\boldsymbol{E} + v_i \times \boldsymbol{B})$, where $\boldsymbol{v}_i$ is the carrier's velocity. In the absence of a driving field, the current density $\boldsymbol{J} = q\sum_i \boldsymbol{v}_i$ would relax according to

$$\frac{\mathrm{d}\boldsymbol{J}}{\mathrm{d}t} = -\frac{\boldsymbol{J}}{\tau} \qquad [1]$$

where τ is the relaxation time. The equation of motion of the current density in the presence of electric and magnetic fields can hence be written as

$$\frac{\mathrm{d}\boldsymbol{J}}{\mathrm{d}t} = -\frac{\boldsymbol{J}}{\tau} + \frac{nq^2\boldsymbol{E}}{m^*} + \frac{q}{m^*}\boldsymbol{J} \times \boldsymbol{B} \qquad [2]$$

In the steady state, and in the absence of a magnetic field, this simplifies to $\boldsymbol{J} = \sigma_0 \boldsymbol{E}$, where $\sigma_0 = nq\mu = nq^2\tau/m^*$ is the conductivity and μ is the mobility. In the presence of a magnetic field, as well as in the steady state, eqn [2] can be rearranged to give

$$\boldsymbol{E} = \frac{\boldsymbol{J}}{\sigma_0} + \frac{\boldsymbol{B} \times \boldsymbol{J}}{nq} = \underline{\underline{\rho}}\boldsymbol{J} \qquad [3]$$

where $\underline{\underline{\rho}}$ is the resistivity tensor. The magnetic field, therefore, induces a transverse electric field $\boldsymbol{B} \times \boldsymbol{J}/nq$ which is perpendicular to both $\boldsymbol{B}$ and $\boldsymbol{J}$ (this is the Hall effect). If the magnetic field is along the z-axis, the resistivity tensor is given by

$$\underline{\underline{\rho}} = \frac{1}{\sigma_0}\begin{pmatrix} 1 & -\gamma & 0 \\ \gamma & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \qquad [4]$$

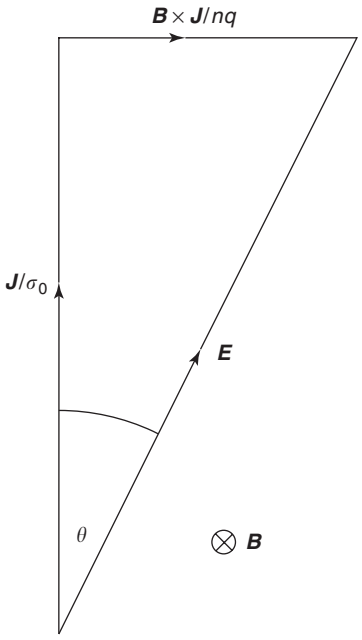

Figure 1 The current density $\boldsymbol{J}$ and electric field $\boldsymbol{E}$. The diagram also shows the Hall angle θ.

where $\gamma = \omega_c \tau = \mu B$ is the mean angle turned between collisions, and $\omega_c = qB/m^*$ is the cyclotron frequency. This predicts a Hall resistivity $|\rho_{xy}| = \gamma/\sigma_0 = 1/nq$, but the diagonal components of the resistivity tensor are all equal to $1/\sigma_0$ and do not depend on the magnetic field. This single-carrier free electron model has, therefore, failed to predict any nonzero magnetoresistance.

This can be understood by reference to **Figure 1** which shows the steady-state balance between the current density and the electric field. In an experiment, the direction of $\boldsymbol{J}$ is normally determined by the position of the electrical contacts. The magnetic field only introduces an electric field perpendicular to the current density (which is known as the Hall field) but leaves the component of the electric field parallel to $\boldsymbol{J}$ unchanged. It is this latter component which determines the resistance, and hence there is no magnetoresistance. The angle between $\boldsymbol{E}$ and $\boldsymbol{J}$ is known as the Hall angle, θ, and is related to γ by $\tan\theta = \gamma$. It turns out also that even the inclusion of some anisotropy in the effective mass does not help in predicting a nonzero magnetoresistance.

Free Electron Gas Model – Two Carriers

Nonzero magnetoresistance can be obtained by introducing more than one type of carrier into the model. In this case, an equation of motion can be written for the current density due to each type of carrier, so that

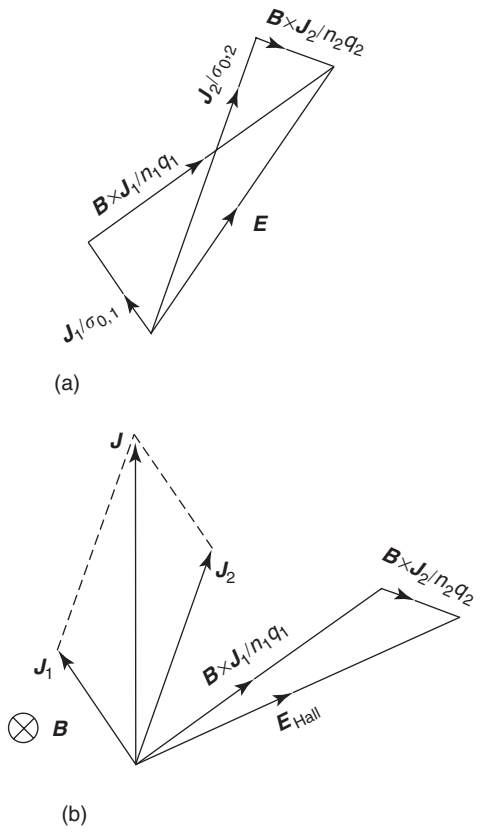

Figure 2 (a) The relationship between the current density $\boldsymbol{J}_1$, $\boldsymbol{J}_2$, and electric field $\boldsymbol{E}$ for two carriers (with charges q_1 and q_2 and number densities n_1 and n_2). The symbols $\sigma_{0,1}$ and $\sigma_{0,2}$ are the zero-field conductivities of carriers 1 and 2 respectively. (b) The total current density $\boldsymbol{J} = \boldsymbol{J}_1 + \boldsymbol{J}_2$. The Hall field $\boldsymbol{E}_{\text{Hall}} = \boldsymbol{B} \times (\boldsymbol{J}_1/n_1 q_1 + \boldsymbol{J}_2/n_2 q_2)$ has a component which is parallel to $\boldsymbol{J}$.

$$\frac{\mathrm{d}\boldsymbol{J}_\alpha}{\mathrm{d}t} = -\frac{\boldsymbol{J}_\alpha}{\tau_\alpha} + \frac{n_\alpha q_\alpha^2 \boldsymbol{E}}{m_\alpha^*} + \frac{q_\alpha}{m_\alpha^*}\boldsymbol{J}_\alpha \times \boldsymbol{B} \qquad [5]$$

where the subscript α labels the carrier. The total current density $\boldsymbol{J}$ is given by the sum of the contributions from each carrier, so that

$$\boldsymbol{J} = \sum_\alpha \boldsymbol{J}_\alpha = \left(\sum_\alpha \underline{\underline{\sigma_\alpha}}\right)\boldsymbol{E} \qquad [6]$$

In particular, the resistivity tensor is given by $\underline{\underline{\rho}} = (\sum_\alpha \underline{\underline{\sigma_\alpha}})^{-1}$. The effect of this can be demonstrated easily using the case of two carriers which is shown in **Figure 2**. Nonzero magnetoresistance results, since the application of a magnetic field ensures that the two current densities $\boldsymbol{J}_1$ and $\boldsymbol{J}_2$ are no longer parallel. The magnetic field can now induce a Hall electric field which has a component parallel to the total current density. Hence, the component of $\boldsymbol{J}$ which is parallel to $\boldsymbol{E}$ can be dependent upon the magnetic field.

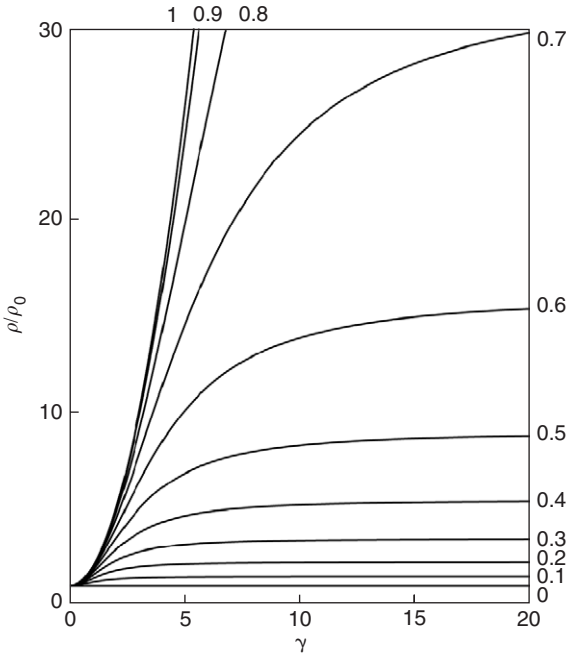

Figure 3 Calculated magnetoresistance (shown as resistivity ρ normalized to the zero-field resistivity ρ_0) for a simple two-carrier model of electrons and holes for different values of the parameter $c = n_+/n_-$.

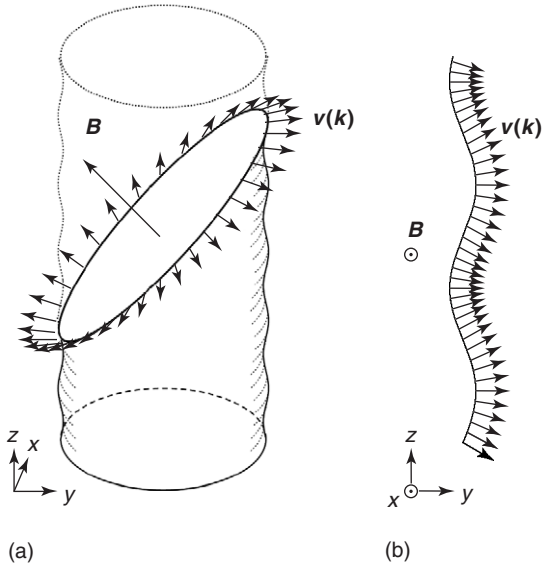

Figure 4 Example of (a) a closed orbit and (b) an open orbit. The vectors on the orbits show the real-space velocity of the electron, given by $\boldsymbol{v} = \hbar^{-1}\partial E(\boldsymbol{k})/\partial \boldsymbol{k}$, which is a vector normal to the Fermi surface. With the magnetic field $\boldsymbol{B}$ oriented as in (a), a closed orbit results. With $\boldsymbol{B}$ along the *x*-direction, an open orbit on the same Fermi surface can result, as shown in (b). (Adapted from Blundell S (2001) *Magnetism in Condensed Matter*. Oxford: Oxford University Press.)

This effect can be demonstrated in a very simple model consisting of two types of carriers, electrons and holes, with equal mobilities but opposite charges. Suppose the number density of electrons is n_- and of holes is n_+. The magnetoresistance can be easily calculated (see **Figure 3**) for different values of the parameter c given by $c = n_+/n_-$. For $c = 0$, there is no magnetoresistance because there is only one type of carrier. As c increases, there is a magnetoresistance which is initially quadratic in B (and so quadratic in γ because $\gamma \propto B$) but it saturates at high field. The magnetic field at which ρ saturates increases as c increases until c reaches unity (known as "perfect compensation" between the electrons and holes), at which point this field becomes infinite and the magnetoresistance never saturates.

Electron Orbits

The free electron model with two carriers successfully predicts nonzero magnetoresistance, and such a model can be very useful in understanding real data in simple metals and semiconductors. However, a free electron model is very often too simplistic to describe the band structures of many other real metals accurately. The electronic band structure is quantified in terms of the energy $E(\boldsymbol{k})$ as a function of the wave vector $\boldsymbol{k}$ of electrons, and this function determines the shape and size of the Fermi surface. It should be noted that magnetoresistance techniques can be used to measure many of the parameters associated with the Fermi surface. In order to understand how this comes about, it is necessary to first consider the types of orbit which may occur on the Fermi surface due to the application of a magnetic field.

Electron motion on the Fermi surface can be described semiclassically by the equation

$$\hbar\dot{\boldsymbol{k}} = -e\boldsymbol{v} \times \boldsymbol{B} \qquad [7]$$

where $\boldsymbol{k}$ is the electron wave vector on the Fermi surface, and

$$\boldsymbol{v} = \frac{1}{\hbar}\frac{\partial E(\boldsymbol{k})}{\partial \boldsymbol{k}} \qquad [8]$$

is the real-space electron velocity (which is always perpendicular to the Fermi surface, using this definition). Hence the electron motion is perpendicular to $\boldsymbol{B}$ but remains on the Fermi surface. This is because in a time dt, the change in $\boldsymbol{k}$ is $\mathrm{d}\boldsymbol{k} \propto (\partial E(\boldsymbol{k})/\partial \boldsymbol{k}) \times \boldsymbol{B}$ and hence is both normal to $\boldsymbol{B}$ and in the plane of the Fermi surface. The orbit of an electron in $\boldsymbol{k}$-space is, therefore, defined by the intersection between the Fermi surface and a plane normal to $\boldsymbol{B}$. The orbits that result can, therefore, either be "closed orbits" or "open orbits" and examples of both are shown in **Figure 4**.

Integration of the equation of motion yields

$$\hbar[\boldsymbol{k}(t) - \boldsymbol{k}(0)] = -e[\boldsymbol{R}(t) - \boldsymbol{R}(0)] \times \boldsymbol{B} \qquad [9]$$

where $\boldsymbol{R}(t)$ is the real-space position of the electron wave packet. Thus, the projection of the electron motion in real space on a plane normal to $\boldsymbol{B}$ is rotated by $\pi/2$ with respect to the $\boldsymbol{k}$-space trajectory and scaled by a factor η given by

$$\eta = \hbar/eB \qquad [10]$$

Thus as $|\boldsymbol{B}|$ increases, the real space orbits wind up more and more tightly.

Boltzmann Transport Equation

For a given orientation of the magnetic field, the conductivity σ_{ij} can be calculated using the Boltzmann transport equation

$$\sigma_{ij} = \frac{e^2}{4\pi^3}\int \mathrm{d}^3k\left[-\frac{\partial f_0(\boldsymbol{k})}{\partial E(\boldsymbol{k})}\right]v_i(\boldsymbol{k},0) \times \int_{-\infty}^{0} v_j(\boldsymbol{k},t)e^{t/\tau}\,\mathrm{d}t \qquad [11]$$

where $f_0(\boldsymbol{k}) = (\exp([E(\boldsymbol{k})-\mu]/k_\mathrm{B}T)-1)^{-1}$ is the Fermi function and μ is the chemical potential. This expression for the conductivity tensor (sometimes known as the Chambers formula) is an integral (which at absolute zero is taken over all states at the Fermi surface) of the velocity–velocity correlation function for each Fermi surface orbit. This can change dramatically as the direction of the magnetic field is changed, because this alters the paths of all the Fermi surface orbits. The components of the conductivity tensor can be very sensitive to whether the orbits are open or closed, so that these two cases may be distinguished by differing magnetoresistance behavior.

High-Field Behavior

Figure 4a shows a closed orbit around a cylinder of Fermi surface which lies along the z-direction. The velocity $\boldsymbol{v}(\boldsymbol{k})$ is always normal to the Fermi surface so that as the magnetic field B increases, the velocity–velocity correlation function decreases as the components of the velocity are very effectively averaged. Ignoring for the moment the weak corrugation of the Fermi surface along the z-direction, and taking $\boldsymbol{B}\|z$, then in high fields ($\gamma \gg 1$), the conductivity tensor is dominated by the closed orbits and is given by

$$\underline{\underline{\sigma}} \sim \sigma_0 \begin{pmatrix} \gamma^{-2} & \gamma^{-1} & 0 \\ -\gamma^{-1} & \gamma^{-2} & 0 \\ 0 & 0 & 1 \end{pmatrix} \qquad [12]$$

using the Boltzmann transport equation. Thus in high fields, $\sigma_{xx} \propto B^{-2}$. The components of the resistivity tensor can be obtained by inverting the conductivity tensor (e.g., in this case $\rho_{xx} = \sigma_{yy}/(\sigma_{xx}\sigma_{yy} - \sigma_{xy}\sigma_{yx})$), so that in a compensated metal (where there are an equal number of electrons and holes, so that $\sigma_{xy} = 0$) such as bismuth, $\rho_{xx}, \rho_{yy} \propto B^2$ (this occurs in magnesium and zinc also, but at very high fields in these materials, the quadratic increase is interrupted by a magnetic breakdown). In an uncompensated metal, $\sigma_{xy} \propto B^{-1}$ at high fields so that ρ_{xx} and ρ_{yy} saturate at high fields.

For an open orbit along z (see **Figure 4b**), with $\boldsymbol{B}$ along the x-direction, the component of velocity along z is similarly averaged (so that $\rho_{zz} \propto B^2$) but the component of velocity along y quickly reaches a nonzero average value as B increases (so that ρ_{yy} quickly saturates). Suppose one is trying to pass a current in the x-direction, but an open orbit is carrying current in the y-direction, giving a term $\sigma_{yy} = s\sigma_0 \gg \gamma^{-2}\sigma_0$ where s is a constant. Then

$$\underline{\underline{\sigma}} \sim \sigma_0 \begin{pmatrix} 1 & 0 & 0 \\ 0 & s & \gamma^{-1} \\ 0 & -\gamma^{-1} & \gamma^{-2} \end{pmatrix} \qquad [13]$$

In this case, $\rho_{xx} \propto \gamma^2 \propto B^2$ and a quadratically increasing field dependence is found. Suppose, however, that an open orbit carries current in the x-direction. Then

$$\underline{\underline{\sigma}} \sim \sigma_0 \begin{pmatrix} s & \gamma^{-1} & 0 \\ -\gamma^{-1} & \gamma^{-2} & 0 \\ 0 & 0 & 1 \end{pmatrix} \qquad [14]$$

and ρ_{xx} is found to saturate.

Angle-Dependent Magnetoresistance Oscillations

As described above, the magnetoresistance can depend quite dramatically on the direction of the applied magnetic field, and in some cases very large angle-dependent magnetoresistance oscillations at constant field can be found. Experimentally, angle-dependent magnetoresistance oscillations are measured by rotating a sample in a fixed magnetic field while monitoring the resistivity of the sample. Angle-dependent magnetoresistance oscillations can be observed at much higher temperatures and in much lower applied fields than Shubnikov–de Haas oscillations (described below in the following section). This is because Shubnikov–de Haas oscillations arise from the movement of Landau levels through the Fermi energy and, therefore, require that the temperature is low enough for the Fermi surface to be sharply defined; this restriction does not apply so stringently to angle-dependent magnetoresistance

oscillations since they do not originate from the motion of energy levels through the Fermi surface.

Consider now the angle-dependent magnetoresistance oscillations due to Fermi surface orbits around the warped cylindrical Fermi surface pocket shown in **Figure 4a**, this time including the corrugations along the z-axis. The electron dispersion can, in this case, be written as

$$E(\boldsymbol{k}) = \mathscr{E}(\boldsymbol{k}_{\parallel}) - 2t_{\perp}\cos(k_z d) \qquad [15]$$

where $t_{\perp}$ is the interlayer transfer integral, and $\boldsymbol{k}_{\parallel} = (k_x, k_y)$ and k_z are, respectively, the components of the wave vector, parallel and perpendicular to the conducting planes. This dispersion is appropriate for a highly anisotropic metal with a layered structure, so that the conductivity is much larger with the current in-plane than out-of-plane. If the magnetic field is perpendicular to the planes, both neck and belly orbits will occur around the Fermi surface. At certain inclination angles (known as Yamaji angles) of the magnetic field, all orbits will have identical area S. The average velocity in the z-direction is proportional to $\partial S/\partial K_z$ (where K_z labels the k_z position of the orbit) and thus vanishes when S is not a function of K_z. This leads to minima in the conductivity and hence angle-dependent magnetoresistance oscillation peaks at the Yamaji angles, connected with the vanishing of the electronic group velocity perpendicular to the 2D layers. The angles θ_n at which the maxima occur are given by $k_{\parallel}^{\max} d\tan(\theta_n) = \pi(n \pm 1/4) + A(\phi)$, where the signs "$-$" and "$+$" correspond to positive and negative θ_n, respectively, d is the effective interplane spacing, $k_{\parallel}^{\max}$ is the maximum Fermi wave vector projection on the plane of rotation of the field, $A(\phi)$ is a function of ϕ and $n = \pm 1, \pm 2, \ldots$. Here, positive n correspond to $\theta_n > 0$ and negative n to $\theta_n < 0$. The gradient of a plot of $\tan\theta_n$ against n may thus be used to find one of the dimensions of the Fermi surface and, if the process is repeated for several planes of rotation of the field, the complete Fermi surface may be mapped out. The function $A(\phi)$ is determined by the inclination of the plane of warping; hence, this may also be found.

Analogous angle-dependent magnetoresistance oscillations can be found for open orbits. The mechanism is similar and easier to understand. If a magnetic field is applied in the plane of a corrugated sheet in the Fermi surface, electrons will be driven along in straight lines perpendicular to the field but in the plane of the sheet. For each Fourier component of corrugation of this sheet, the velocity is more effectively averaged when electrons are not traveling along the axis of the corrugation (**Figure 5a**) than when they are (**Figure 5b**); thus, sharp resistance minima are obtained when the orbits run along a Fourier component of the corrugation (when the magnetic field lies along a so-called "magic angle").

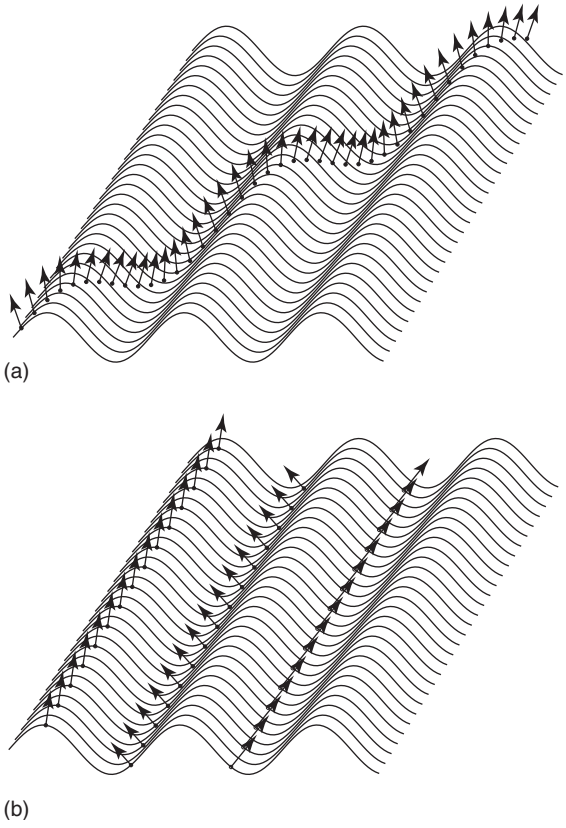

Figure 5 If a magnetic field lies in the plane of the quasi-one-dimensional sheets, all orbits become straight lines when viewed normal to that plane, along an axis which is also perpendicular to the magnetic field direction. For a given Fourier component of the corrugation, the velocity is more effectively averaged when electrons (a) are not traveling along the axis of the corrugation than (b) when they are. (Reproduced from Blundell SJ and Singleton J (1996) *Physical Review B* 53: 5609–5619.)

Other angle-dependent magnetoresistance effects are also possible, including those relating to closed orbits around small hillocks in the Fermi surface. In the semiclassical picture, all the angle-dependent magnetoresistance oscillations are caused by the degree to which the velocity components of the electrons are averaged over the series of orbits that appear at a certain inclination angle. Such an effect for a quasi-two-dimensional system is shown in **Figure 6**. In strongly correlated materials, it is also possible to see effects which are more complex in origin and reflect many-body effects associated with electron–electron correlations or special regions of k-space where the scattering rate takes a large value (Fermi surface hot spots).

Orbit Quantization

Magnetic fields also have a quantizing effect on the electron motion if the orbit is closed. The

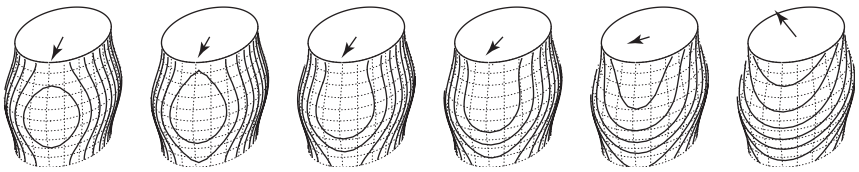

Figure 6 In a quasi-two-dimensional system, the Fermi surface may consist of a weakly warped cylinder. The figure shows how the electron orbits around this Fermi surface change as the direction of the magnetic field is rotated away from a direction lying in the quasi-two-dimensional layers. The direction of the applied magnetic field is shown by the arrow in each case. The electron orbits always lie on the Fermi surface but in a plane perpendicular to the magnetic field direction.

Bohr–Sommerfeld quantization rule $\oint \boldsymbol{p} \cdot \mathrm{d}\boldsymbol{q} = (n + \alpha)h$ (where $\boldsymbol{p}$ and $\boldsymbol{q}$ are momentum and position, respectively, n is an integer, and α is a geometrical factor which can often be taken to be 1/2) can be applied to this problem, and using $\hbar\boldsymbol{k} = \boldsymbol{p} + e\boldsymbol{A}$ yields

$$\oint (\hbar\boldsymbol{k} - e\boldsymbol{A}) \cdot \mathrm{d}\boldsymbol{R}_{\perp} = (n + \alpha)h \qquad [16]$$

where $\boldsymbol{R}_{\perp}$ is the projection of $\boldsymbol{R}$ onto a plane normal to $\boldsymbol{B}$, and $\boldsymbol{A}$ is the magnetic vector potential. Using Stokes' theorem leads to

$$\boldsymbol{B} \cdot \oint \boldsymbol{R} \times \mathrm{d}\boldsymbol{R}_{\perp} - \int_S \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{S} = (n + \alpha)\frac{h}{e} \qquad [17]$$

and the magnetic flux through the real space orbit is given by $\Phi = \int_S \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{S} = 1/2 \oint \boldsymbol{R} \times \mathrm{d}\boldsymbol{R}_{\perp}$, this reduces to

$$\Phi = (n + \alpha)\Phi_0 \qquad [18]$$

where $\Phi_0 = h/e$ is the flux quantum. Since the area of the corresponding orbit in $\boldsymbol{k}$-space, S, is scaled up from this by a factor $\eta = \hbar/eB$, it is expected that

$$S = (n + \alpha)2\pi eB/\hbar \qquad [19]$$

so that S grows as $|\boldsymbol{B}|$ increases. When S matches S_{ext}, the extremal cross section of the Fermi surface, the free energy reaches a maximum. If the field increases further, the highest occupied Landau level becomes depleted of electrons and the free energy decreases, as does the density of states at the Fermi energy. These oscillations in the free energy and density of states as a function of magnetic field give rise to oscillations in many properties related to either the free energy or the density of states. These so-called "quantum oscillations" include not only the oscillations in the magnetization (the de Haas–van Alphen effect) but also those in the magnetoresistance (the Shubnikov–de Haas effect). Maxima in the free energy occur when $S_{\mathrm{ext}} = S$, so are governed by a periodicity

$$\Delta\left(\frac{1}{B}\right) = \frac{2\pi e}{\hbar S_{\mathrm{ext}}} \qquad [20]$$

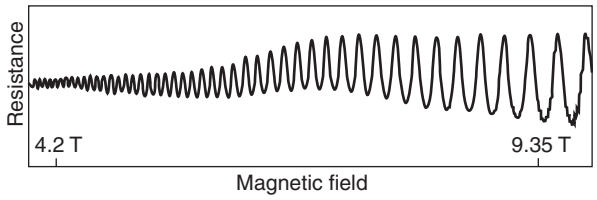

Figure 7 Shubnikov–de Haas oscillations for $AuSb_2$ recorded at 1.45 K with the current parallel to ⟨1 1 0⟩ and the magnetic field parallel to ⟨1 1 1⟩. The data show two frequencies. (Reprinted with permission from Ahn J and Sellmyer DJ (1970) *Physical Review B* 1: 1285–1297; © American Physical Society.)

or equivalently by a frequency F in reciprocal field equal to $F = S_{\mathrm{ext}}(\hbar/2\pi e)$. In fact, orbits around all cross sections of the Fermi surface (in any plane perpendicular to $\boldsymbol{B}$) give oscillatory contributions to the free energy, but the contributions from adjacent "slices" cancel out with each other so that the net effect is as if the only contribution is from extremal cross sections. Hence, measurements of these oscillations allow a precise determination of the extremal cross-sectional area of closed sections of the Fermi surface. An example of this is presented in **Figure 7** which shows Shubnikov–de Haas oscillations measured in the metallic compound $AuSb_2$. Two frequencies are clearly visible in the data, each corresponding to a different extremal cross-sectional area of the Fermi surface.

The form of the quantum oscillations can be described by the so-called Lifshitz–Kosevich formula, which is not described in detail here. Its precise form depends on whether the Fermi surface is three dimensional or two dimensional, it includes the contribution from harmonics of the fundamental frequencies, and it contains various damping factors which are discussed in the next section. This formula is valid for de Haas–van Alphen oscillations but the situation for Shubnikov–de Haas oscillations is more complex. Moreover, Shubnikov–de Haas oscillations can be harder to observe than de Haas–van Alphen oscillations in most metals because they can be swamped by the conductivity of the major portions of the Fermi surface. The Shubnikov–de Haas effect is more dramatic in semimetals or high mobility doped semiconductors where the Fermi surface is small

enough for the Shubnikov–de Haas effect to be readily seen. Two-dimensional metallic systems (whose Fermi surfaces typically contain weakly warped cylinders and sheets) are also ideal for observing Shubnikov–de Haas oscillations, since the entire Fermi surface, or at least a very large fraction of it, typically contributes to the quantum oscillations.

Phase Smearing

Shubnikov–de Haas oscillations are strongly affected by both temperature and scattering. These effects lead to phase smearing of the oscillations and a consequent reduction in the oscillation amplitude.

In the case of temperature, the blurring of the boundary between occupied and unoccupied states (governed by the Fermi function) leads to a damping factor for the oscillation amplitude equal to

$$R_{\mathrm{T}} = \pi\lambda/\sinh(\pi\lambda) \qquad [21]$$

where λ is given by

$$\lambda = 2\pi p\left(\frac{k_{\mathrm{B}}T}{\hbar\omega_{\mathrm{c}}}\right) = \frac{2\pi pm^{*}k_{\mathrm{B}}T}{e\hbar B} \qquad [22]$$

where the cyclotron frequency $\omega_{\mathrm{c}} = eB/m^{*}$ and the formula is quoted for the pth harmonic of the oscillations. When $\lambda \gg 1$, this reduces to $R_{\mathrm{T}} \propto \exp(-\pi\lambda)$, and shows that the amplitude of the oscillations becomes strongly reduced when the temperature becomes significantly larger than $\hbar\omega_{\mathrm{c}}/2\pi pk_{\mathrm{B}}$. Measurements of the temperature dependence of the oscillation amplitude can be used to extract the effective mass m^{*}.

The effect of scattering leads to a damping factor (known as the Dingle factor) $R_{\mathrm{D}} = \exp(-p\pi/\omega_{\mathrm{c}}\tau_q)$, where τ_q is the quantum lifetime of an electron in a magnetic quantum state. This can be cast in a similar form to R_{T} by rewriting it as

$$R_{\mathrm{D}} = \exp(-2\pi^2 pmk_{\mathrm{B}}T_{\mathrm{D}}/e\hbar B) \qquad [23]$$

where T_{D} is known as the Dingle temperature, and is given by

$$T_{\mathrm{D}} = \frac{\hbar}{2\pi k_{\mathrm{B}}\tau_q} \qquad [24]$$

This quantity can be extracted from the field dependence of the oscillation amplitude. The quantum lifetime τ_q is due to all scattering events, including those which result from static spatial fluctuations in the background potential of the sample. This can be different to the relaxation time τ considered earlier, which controls the mobility and low-field magnetoresistance. The relaxation time is weighted by a scattering angle factor $(1 - \cos\theta)$, where θ is the angular deviation in a particular scattering event, and is therefore much less influenced by small-angle scattering events. Thus, $1/\tau_q \propto \int W(\theta)\,\mathrm{d}\theta$ and $1/\tau \propto \int W(\theta)(1 - \cos\theta)\,\mathrm{d}\theta$, where $W(\theta)$ is the scattering cross section for scattering through an angle θ.

Landau levels (seperated in energy from each other by $\hbar\omega_{\mathrm{c}}$) are also spin split (by an amount $g\mu_{\mathrm{B}}B$) so that the energy levels are given by

$$E = \left(n + \frac{1}{2}\right)\frac{\hbar eB}{m^{*}} \pm \frac{1}{2}g\mu_{\mathrm{B}}B \qquad [25]$$

where n is the Landau level index and g is the electronic g-factor. The effect of the spin splitting of Landau levels in a magnetic field also leads to a phase smearing, and in this case it is given by $\phi = 2\pi g\mu_{\mathrm{B}}B/\hbar\omega_{\mathrm{c}}$. This results in a damping factor R_{S} given by

$$R_{\mathrm{S}} = \cos\frac{p\phi}{2} = \cos\frac{p\pi gm^{*}}{2} \qquad [26]$$

The Shubnikov–de Haas oscillations are, therefore, attenuated by a net damping factor $R_{\mathrm{T}}R_{\mathrm{D}}R_{\mathrm{S}}$.

Spin Zeros

An interesting effect can occur in the case of a quasi-two-dimensional Fermi surface, such as those which may occur in layered metals. If the magnetic field is tilted by an angle θ away from the direction normal to the layers, then the energy levels are given by

$$E = \left(n + \frac{1}{2}\right)\frac{\hbar eB\cos\theta}{m^{*}} \pm \frac{1}{2}g\mu_{\mathrm{B}}B \qquad [27]$$

Increasing the angle θ reduces the separation between Landau levels by reducing the field perpendicular to the highly conducting planes, $B\cos\theta$. When $B\cos\theta$ is such that the spin-up and spin-down sections of different Landau levels are degenerate, then the separation between successive energy levels is equal to $\hbar\omega_{\mathrm{c}}$. At this angle the Shubnikov–de Haas oscillations having the fundamental frequency F will dominate, taking their maximum amplitude. However, when $B\cos\theta$ is such that the spin-up and spin-down sections of different Landau levels are equally spaced at $(1/2)\hbar\omega_{\mathrm{c}}$, then the dominant oscillations will be those with frequency $2F$ and the amplitude of the fundamental oscillations will be at a minimum. These two situations are known as spin-maxima and spin-zeros, respectively. This effect can also be observed using magnetoresistance measurements.

An Example of Field and Angle-Dependent Magnetoresistance

The graph in **Figure 8** shows magnetoresistance data for a quasi-two-dimensional organic superconductor known as κ-(BEDT-TTF)$_2$Cu(NCS)$_2$. This material

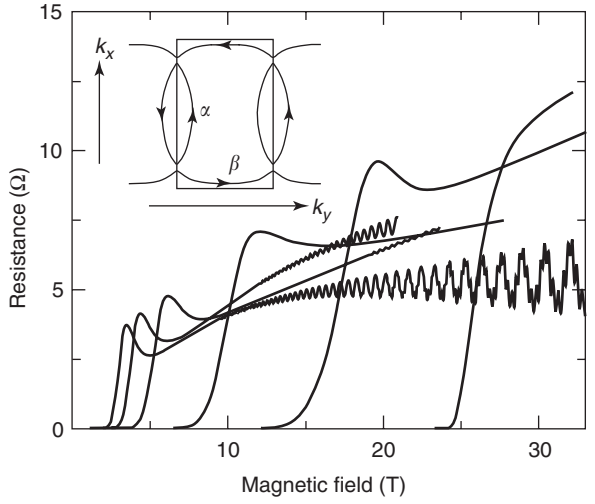

Figure 8 Magnetoresistance of the organic superconductor κ-(BEDT-TTF)$_2$Cu(NCS)$_2$ measured for various angles between the magnetic field and the conducting planes. The critical field for superconductivity is found to increase as the field is tilted into the conducting planes (right-hand trace). In some of the other traces, clear Shubnikov–de Haas oscillations are visible, due to the α-orbit. At high magnetic field, a second frequency is also visible which is the β-orbit and occurs due to a magnetic breakdown (see text). The inset shows the Fermi surface in the k_x–k_y plane and shows both the α-orbits and the open orbits, which, following magnetic breakdown, gives rise to the β-orbit. (Adapted from Nam MS, Symington JA, Singleton J, Blundell SJ, Ardavan A, *et al.* (1999) *Journal of Physics*: *Condensed Matter* 11: L477–L484.)

consists of alternating layers of the organic BEDT–TTF molecules (stacked side-to-side so that the molecular orbitals overlap) and layers of $Cu(NCS)_2^-$ anions. Two of the BEDT–TTF molecules jointly donate an electron to the anion, and the charge transfer leaves behind a hole on the BEDT–TTF molecules. This means that the bands formed by the overlap of the BEDT–TTF molecular orbitals are partially filled, leading to a metallic behavior. The transfer integrals, which parametrize the ease of hopping of electrons between BEDT–TTF molecules, are large within the BEDT–TTF planes but small in the direction perpendicular to the BEDT–TTF planes. This results in two-dimensional electronic properties. In this salt, the BEDT–TTF molecules associate into dimers, each of which collectively donates one electron to the anions, leaving behind a mobile hole. Because the dispersion is nearly isotropic in the conducting planes, the Fermi surface is approximately circular and has the same area as the first Brillouin zone. The Fermi surface cuts the Brillouin zone boundaries and at these points, a gap opens up which splits the Fermi surface into open and closed sections (see inset to **Figure 8**). The closed section has an area corresponding to $\sim$15% of the first Brillouin zone (this is known as the α pocket) but magnetic breakdown at fields above $\sim$20 T allow quasiparticles to bridge the energy gap

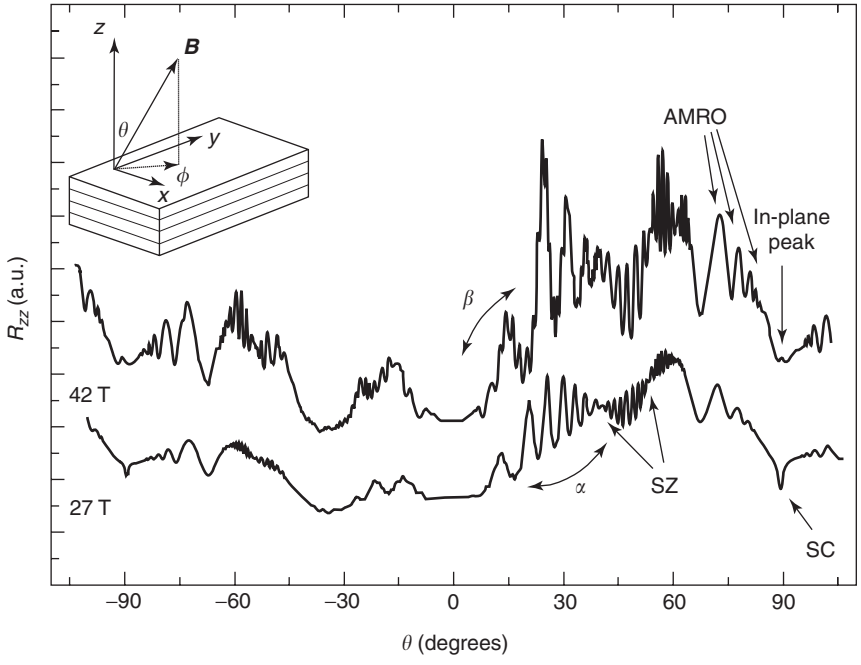

Figure 9 Typical angle dependence of the magnetoresistance of the organic superconductor κ-(BEDT-TTF)$_2$Cu(NCS)$_2$ at 0.49 K and 27 T (lower), and 42 T (upper). The data have been offset for clarity. Some representative features are indicated; Shubnikov–de Haas oscillations due to closed orbits around small pockets in the Fermi surface (α-orbits) and the breakdown orbit (β-orbit); spin-zeros in the Shubnikov–de Haas amplitudes (SZ); the onset of the superconducting transition (SC); angle-dependent magnetoresistance oscillations (AMRO), whose positions are field independent; and the resistive peak in the presence of an exactly in-plane magnetic field (in-plane peak). The inset diagram is included to illustrate the measurement geometry. (From Goddard P, Blundell SJ, Singleton J, McDonald RD, Ardavan A, *et al.* (2004) *Physical Review B* 69: 174509.)

between the two sections of the Fermi surface and make the large β-orbit, around the circular Fermi surface (see **Figure 8**).

The angle-dependent magnetoresistance shown in **Figure 9** contains a large number of features and demonstrates many of the effects described above. The plots are not symmetrical about $\theta = 0°$, reflecting the monoclinic symmetry of the crystal structure. In the upper plot, the field perpendicular to the layers around $\theta = 0°$ is sufficient for the effects of magnetic breakdown to be observed and the fast Shubnikov–de Haas oscillations due to the β-orbit are clearly seen, this time as a function of the angle (this occurs because the oscillations depend on the component of the magnetic field, $B\cos\theta$). The slower oscillations due to the α-orbit are seen in both plots and persist to higher angles. The amplitudes of these oscillations are modulated and they disappear at certain angles corresponding to spin-zeros. The positions of the features at θ-angles greater than $\sim \pm 70°$ are seen to be independent of the magnitude of the magnetic field, which reveals that they are angle-dependent magnetoresistance oscillations. Only orbits which are extremal contribute to the Shubnikov–de Haas signal, but all orbits, whether extremal or not, give rise to this angle-dependent background magnetoresistance.

In the 42 T data shown in **Figure 9**, a small peak is observed when the field lies very close to the in-plane direction, $\theta \approx 90°$. This is the in-plane peak feature (labeled SQUIT, for "suppression of quasiparticle interlayer transport"), which is due to the efficient averaging effect of closed orbits produced on the side of a corrugated cylinder in the Fermi surface when the magnetic field lies in the conducting planes (see **Figure 6**). The peak suggests a coherent nature to the interlayer transport. For highly anisotropic materials, the angular width of the in-plane peak (in radians) is approximately $2v_{\perp}^{\max}/v_{\parallel}$, where $v_{\perp}^{\max}$ is the maximum of the out-of-plane component of the quasiparticle velocity and $v_{\parallel}$ is the in-plane component parallel to the plane of rotation.

Close to $\theta = 90°$ in the lower plot, the in-plane peak is obscured by the large dip that indicates the onset of a superconducting transition. This occurs because there is a considerable anisotropy in the upper critical field of this material, and a field of 27 T is not sufficient to suppress the superconducting state when applied in a nearly in-plane direction.

These types of magnetoresistance techniques have now been applied to many systems, including superconducting cuprates, organic metals, and correlated oxides, as well as elemental metals.

Manganites

V Z Kresin, University of California at Berkeley, Berkeley, CA, USA

Introduction

Manganites were discovered in 1950 (Jonner and van Santen). The materials are named after the manganese ion which is a key ingredient of the compounds due to its mixed-valence state. Unlike the usual ferromagnetics, the transition of manganites to ferromagnetic state is accompanied by a drastic increase in conductivity. Such transition from an insulating to a metallic and magnetic state is a remarkable fundamental feature of these materials. Another fundamental property is the colossal magnetoresistance effect

(CMR); one can observe a thousandfold (!) change in the resistance in the presence of a moderate applied magnetic field.

The chemical composition of the manganites is $A_{1-x}\,R_x\,MnO_3$; usually A≡La, Pr, Nd and R≡Sr, Ca, Ba. The compound $La_{1-x}Sr_xMnO_3$ is the most studied material.

Structure

The parent (undoped) compound $LaMnO_3$ has a perovskite structure which is a distorted cubic lattice. The ideal crystal unit is shown in **Figure 1**. It is essential that the Mn ions are caged into oxygen octahedron, so that it is surrounded by six oxygen ions (**Figure 2**). Each oxygen ion is shared by neighboring octahedra. The fivefold orbital degeneracy is split by the crystal field into two well-separated terms, t_{2g} and e_{2g} (**Figure 3**). The t_{2g}-level contains three electrons forming the so-called "*t*-core." The last *d*-electron (e_{2g}-electron) is in a loosely bound state. The e_{2g}-electron plays a crucial role in conduction and in other properties of manganites as well as in determining its magnetic order.

Doping: Phase Diagram

The phase diagram of manganites is very rich and contains many different phases. The parent compound, $LaMnO_3$, is an insulator and its transition to the conducting state is provided by doping. The doping is realized through a chemical substitution, for example $La^{3+} \rightarrow Sr^{2+}$, that is, by placing a divalent ion into the local La^{3+} position. Such substitution leads to the change in the valence of the manganese ion valence: $Mn^{3+} \rightarrow Mn^{4+}$. That is why manganites are often called "mixed-valence magnetic oxides." The four-valent state of the Mn means that the ion loses its e_{2g}-electron. The missing electron can be described as a hole which is spread over the unit cell, being shared by eight Mn ions (see **Figure 1**)

As a result, one obtains a crystal $La_{1-x}Sr_xMnO_3$, where a number of La centers are randomly substituted by the Sr-ions. Even in the presence of some holes, the crystal, at first, continues to behave as an insulator. This is due to the fact that each hole is localized and the localization corresponds to the formation of local polarons. Such insulating state is preserved with an increase in doping up to some critical value $x = x_c \approx 0.16$–0.17. At $x = x_c$, the material makes a transition into the conducting (metallic) state which persists with further doping up to $x \approx 0.5$–0.6, depending on the chosen composition.

It is remarkable that the transition at $x = x_c$ is also accompanied by the appearance of the ferromagnetic state. As was noted above, the correlation between conductivity and magnetism is the most fundamental feature of manganites. The conductivity of the best samples of the Sr-doped films at low T is of order

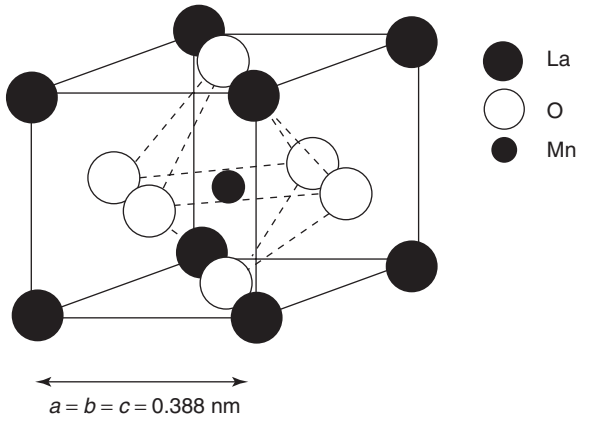

Figure 1 The ideal structure of the parent compound, $La\,MnO_3$.

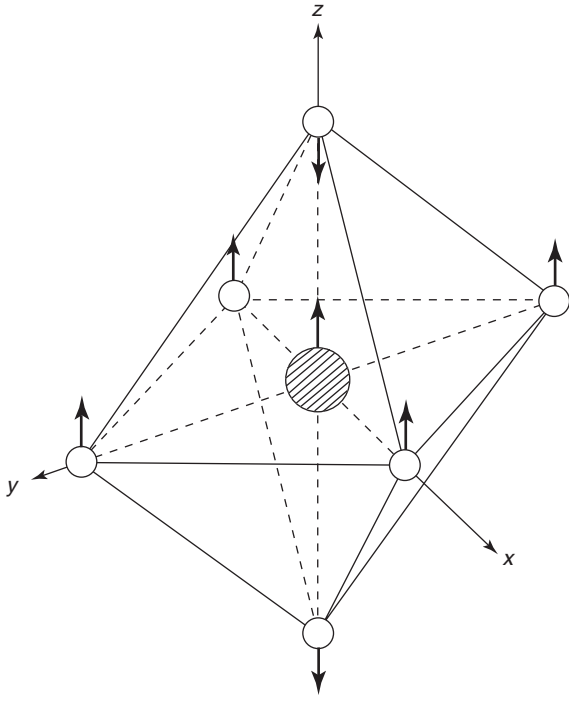

Figure 2 MnO_6 octahedron.

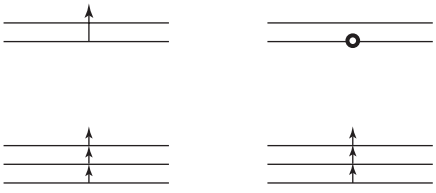

Figure 3 Electronic structures of the Mn^{3+} and Mn^{4+} ions.

$\sigma = 10^4 - 10^5\,\Omega^{-1}\,\mathrm{cm}^{-1}$, and this corresponds to a typical metallic regime.

Continuous increase in doping leads to the transition from the metallic to insulating state. For many compounds one can observe a peculiar charge-ordered state. The right end of the phase diagram (e.g., $SrMnO_3$) describes the compound which does not have the e_{2g}-electrons. Naturally, this material is an insulator.

If the compound is in the metallic ferromagnetic state (e.g., it corresponds to $0.2 < x < 0.5$ for $La_{1-x}Ca_xMnO_3$), and temperature is increased (at fixed x), then at T_C (T_C is the Curie temperature) one can observe transition to the low-conducting paramagnetic state which contains local distortions. The conductivity in this state has a hopping polaronic nature.

Main Interactions: Hamiltonian

The loosely bound e_{2g}-electron is the key player in the physics of manganites. Its Hamiltonian can be written in the form:

$$\hat{H} = \hat{H}_t + \hat{H}_{\mathrm{H}} + \hat{H}_{\mathrm{JT}} \qquad [1]$$

where

$$\hat{H}_t = \sum_{i,\delta} \hat{t}_{i,i+\delta} \qquad [2]$$

$$\hat{H}_{\mathrm{H}} = -J_H \sum_i \hat{\sigma} \cdot S_i \qquad [3]$$

$$\hat{H}_{\mathrm{JT}} = \sum_i g\hat{\tau}_i Q_i \qquad [4]$$

Here $\hat{t}$ is the two-by-two hopping matrix, $\hat{\sigma}$ is the Pauli spin matrix, S_i is the spin of the t-core, $\hat{\tau}$ is the pseudospin matrix, and Q_i is the normal mode.

The first term on the right side of eqn [1] describes the hopping of the e_{2g}-electron. The second term is the Hund's interaction which polarized the carrier's spin, and the last term corresponds to the Jahn–Teller effect which reflects the double degeneracy of the e_{2g}-term. The strength of the Hund's interaction is of the order $J_{\mathrm{H}} \approx 1$ eV; this is the largest scale of the energy. It is also essential that, because of the Hund's interaction, the conducting e_{2g}-electrons are spin-polarized. As for the hopping and the Jahn–Teller terms, they are of order $t \approx g \approx 0.1$ eV, so that $t \approx g \ll J_{\mathrm{H}}$.

The nature of the ferromagnetic spin alignment in manganites is different from that for usual ferromagnets. The concept, so-called "double exchange" mechanism was introduced in 1951 by Zener. Qualitatively, the nature of the mechanism is as follows. If one of the Mn^{3+} ions becomes four-valent (e.g., as a result of the $La^{3+} \rightarrow Sr^{2+}$ substitution, implying $Mn^{3+} \rightarrow Mn^{4+}$), a hole appears on this site. It allows for another e_{2g}-electron localized initially at the neighboring Mn^{3+} ions to jump on the new vacant place (this can be described as the hole moving in the opposite direction). But the e_{2g}-electron is spin-polarized because of the Hund's interaction with its t-core. Relative orientation of spins of the e_{2g}-electron and the "vacant" t-core drastically affects the hopping. For example, if the direction of the spin of the core for the Mn^{4+} ion is opposite to that one for the e_{2g}-electron of the neighboring Mg^{3+} ion, then the hopping is spin forbidden. At the same time, such hopping as any increase in a degree of delocalization is energetically favorable. As a result, the ground state of the ferromagnetically ordered system (all spins are polarized along one direction) energetically is below the state which is not ordered. That is why the t-cores become ferromagnetically ordered, and this, in its turn, favors "jumping" of the e_{2g}-electrons, and, therefore, conductivity. Such mechanism (it is called "double exchange") leads to ferromagnetism and to a strong correlation between ferromagnetism and conductivity.

Metallic Phase: CMR Phenomenon

Consider the sample in the metallic ferromagnetic state with a fixed carrier concentration, (e.g., $x = 0.3$) and then increase the temperature. Such ferromagnetic state persists up to the Curie temperature. For example, for the $La_{0.7}Sr_{0.3}MnO_3$ to the value of $T_C \cong 170$ K. Above this temperature the compound makes the transition into paramagnetic state. In addition, resistivity drastically increases (almost insulating state).

The conductivity of the metallic manganites is provided by the delocalized e_{2g}-electrons. It is essential that these electrons are in the double-degenerate state. This leads to the two-band picture. Presence of the two energy bands allows to explain the absence of the electron–hole symmetry for the phase diagram. In addition, this feature is important for analysis of various properties of manganites. For example, optical properties are, mainly, due to the interband transitions.

The value of the Fermi energy in the metallic manganites is small relative to ordinary metals. Its value depends on the doping level and is of the order of EF ≈ 0.2 eV. As for conductivity, its value depends strongly on the quality of the samples. As was mentioned above, for the best samples it reaches the value $\sigma \approx 10^5\ \Omega^{-1}\ \mathrm{cm}^{-1}$.

The charge transfer in the conducting ferromagnetic manganites is provided by spin-polarized electrons. Because of such spin specifics a total number

of carriers in the band of the metallic manganites is twice less than in usual metals. That is why the conducting state in manganites is called "half-metallic."

The magnetoresistance is a very important parameter of manganites. It is defined as

$$\Delta R/R_H = [R(T,H) - R(T,0)]/R(T,H) \qquad [5]$$

The magnetoresistance has a sharp peak near the Curie temperature for the manganite, and the change in resistivity caused by an applied magnetic field can be huge. Such phenomenon which is dubbed as the colossal magnetoresistance effect (CMR) has been initially observed in the ferromagnetic metallic films by Jin *et al*. in 1994. It turns out that for $La_{0.67}Ca_{0.33}MnO_3$ films $\Delta R/R_H \approx -1.3x10^3$(!); $H \approx 5$ T.

The CMR phenomenon is discussed now. Below T_C the sample is characterized by usual metallic conductivity. Contrary to it, above T_C it has a large resistivity (low conducting state with hopping polaronic transport). The presence of an external magnetic field allows to establish ferromagnetic ordering at temperatures higher than T_C ($H = 0$). The magnetic order provides metallic conductivity, because of the double exchange mechanism, and this leads to a large shift $\Delta R_H = R(T, H) - R(T, 0)$. The shift is negative, in accordance with the experimental observation and corresponds to the transition from a low conducting (almost insulating) to a metallic state.

Insulating State

The undoped material $LaMnO_3$ is an insulator and its magnetic ordering corresponds to the so-called A-structure. This structure is characterized by the presence of the ferromagnetically ordered layers with an opposite direction of the magnetization for the neighboring layers. In other words, ferromagnetism in layers is combined with the antiferromagnetic ordering in the direction perpendicular to the layers. The value of the Neel's temperature is relatively low ($\approx 10^2$ K).

The insulating behavior can be explained in the framework of the band picture. However, this picture should be modified in accordance with the Hamiltonian (eqn [1]). Unlike ordinary metals, the band is filled by spin-polarized electrons. Moreover, the degeneracy of the e_{2g}-state leads to the two-band situation. In addition, one should take into account the Jahn–Teller distortion. Because the O ion is shared by neighboring manganese octahedra, the cooperative Jahn–Teller effect is dealt with. If one includes all these factors, the energy bands appear to be filled, and the compound is the band insulator.

Doping leads to creation of holes, but it does not mean that the sample becomes a conductor. Initially holes are localized by Coulomb forces and form polarons. Such process is a favorable one for the layered system, because in the 2D case there is no energy barrier for the polaron formation. The transition to the metallic ferromagnetic state occurs at finite doping level $x = x_c$.

Percolative Transition

The doping leads to the situation when at some critical concentration of the dopant, x_c, one can observe the transition from insulating to metallic state. This transition can be described in terms of the percolation theory. Indeed, doping leads to the formation of the compound $A_{1-x}B_xMnO_3$. A position of atom B, which is a substitution for a parent atom, is completely random, and the statistical distribution of dopants leads to the percolation picture. As a result of initial doping metallic clusters are formed. These clusters are created inside the insulating matrix and eventually form the percolation "path." In accordance with the Zener's double-exchange mechanism, there is ferromagnetic order inside the clusters. The transition to the metallic ferromagnetic state corresponds to formation of the infinite cluster and, correspondingly, to an appearance of the macroscopic phase. The transition occurs at $x = x_c \approx 0.17$, and this value is, indeed, an invariant of the percolation theory. Therefore, the metal–insulator transition in manganites is a percolation phenomenon (**Figure 4**).

The percolative nature of the metal–insulator transition implies the inhomogeneity of the system, that is, one is dealing with a coexistence of two phases: metallic and insulating. This is the "phase-separation" phenomenon. This concept for the doped oxides was introduced by Gor'kov and Sokol in 1987. Manganites as well as the high-temperature superconducting cuprates are examples of such systems. Macroscopic properties at $x < x_c$ are determined by the insulating matrix, but the sample contains metallic ferromagnetic inclusions. In a similar way, the sample at $x > x_c$, being in the ferromagnetic metallic phase, contains insulating regions.

The percolative transition occurs also in the metallic sample with a fixed-level doping (e.g., $x \approx 0.3$) at $T = T_C$. The fast increase in conductivity $\sigma(T)$ at $T < T_C$ is described by the expression

$$\sigma(T < T_C) \propto (T_C - T)^{\gamma} \qquad [6]$$

where γ is a critical index.

The percolative nature of the transition at $T = T_C$ also implies the intrinsic inhomogeneities of the sample, that is, the phase separation. This means that, even below T_C, the sample, being in the metallic

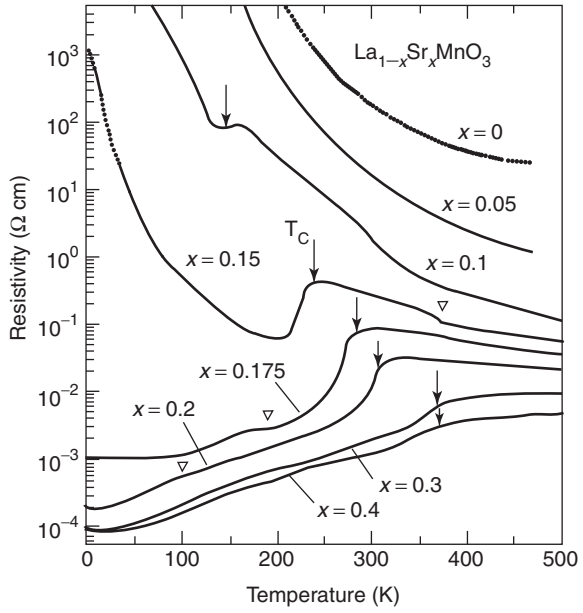

Figure 4 Temperature dependence of resistivity (for various levels of doping). The transition to the metallic state occurs at $x \approx 0.17$. (Reproduced with permission from Urishibara A, Moritomo Y, Arima T, Asamitsu A, Kido G, *et al.* (1995) Insulator–metal transition and gaint magnetoresistance in $La_{1-x}Sr_xMno_3$. *Physical Review B* 51: 14103.)

ferromagnetic state, contains inclusions of the low-conducting paramagnetic phase.

The concept of intrinsic inhomogeneity as well as the percolation picture has a strong experimental support. Various experimental techniques, such as scanning tunneling microscopy (STM), neutron scattering, X-rays absorption fine structure spectroscopy, and heat capacity data allow us to prove the picture of phase separation. For example, one can measure electronic contribution ($\propto T$) to heat capacity at $x < x_c$. The inelastic neutron scattering as well as the X-rays spectroscopy display the presence of two different bond lengths corresponding to mixed phases. An intensive study of manganites continues. Search for new materials, synthesis of high-quality samples, and a detailed theoretical and experimental analysis of all regions of the phase diagram will lead to new insights and interesting potential applications.

Mass Transport

R Livi, Università di Firenze, Florence, Italy

Introduction

Transport processes concern a wide range of phenomena in hydrodynamics, thermodynamics, physical chemistry, electric conduction, magnetohydrodynamics, etc. They typically occur in physical systems (gases, liquids, or solids) made of many particles (atoms or molecules) in the presence of inhomogeneities. Such a situation can result from nonequilibrium conditions (e.g., the presence of a macroscopic gradient of density, velocity, and temperature), or simply from fluctuations around an equilibrium state.

The kinetic theory of transport phenomena provides a unified description of these apparently unlike situations. It is based on the assumption that even in nonequilibrium conditions, gradients are small enough to guarantee that local equilibrium conditions still hold. In particular, the kinetic approach describes the natural tendency of the particles to transmit their properties from one region to another of the fluid by colliding with the other particles and eventually establishing global or local equilibrium conditions.

The main success of the kinetic theory is the identification of the basic mechanism underlying all the above-mentioned processes: the transport of a microscopic quantity (e.g., the mass, momentum, or energy of a particle) over a distance equal to the mean free path $\bar{\ell}$ of the particles, that is, the average free displacement of a particle after a collision with another particle. By this definition, it is implicitly assumed that the system is a fluid, where each particle is supposed to interact with each other by collisions and propagate

freely between successive collisions. Simple considerations yield the following definition

$$\bar{\ell} = \frac{1}{\sqrt{2}\sigma n} \qquad [1]$$

where n is the volumetric density of particles, which depends on the thermodynamic conditions of the system, and σ is the total cross section of collisions between particles (e.g., for the ideal case of spheric particles of radius R, $\sigma = 4\pi R^2$). For instance, in a gas at room temperature and pressure $\bar{\ell}$ is typically $\mathcal{O}(10^{-5})$cm, three orders of magnitude larger than the typical size of a particle, $\mathcal{O}(10^{-8})$cm. It is worth stressing that, reference is made to the simple case of a homogeneous isotropic system, where $\bar{\ell}$ is the same at any point and in any direction in space.

In the section "Transport in the presence of a gradient," the general case of nonequilibrium conditions are analyzed and the definition of transport coefficients is provided. In the section "Brownian motion," the process of mass transport due to fluctuations close to equilibrium is described, by relying upon the basic example of Brownian motion.

Transport in the Presence of a Gradient

Without prejudice of generality, a system is considered where a uniform gradient of the quantity $A(\vec{x})$ is established along the z-axis, and $A(x, y, z) = A(x', y', z) = A(z)$ for any x, x', y, and y'. In particular, it is assumed that $A(z)$ is a microscopic quantity, which slowly varies at constant rate along the coordinate z of an arbitrary Cartesian reference frame. Consider also a unit surface S_1 located at height z and perpendicular to the z-axis. Moving from the surface S_1 a particle will run a distance $\pm\bar{\ell}$ moving either upward or downward along the z-axis, respectively. Assuming that local equilibrium is established by collisions, the particle variable will change its original value $A(z)$ into $A(z \pm \bar{\ell})$. The net transport of the quantity $A(z)$ through S_1 amounts to the number of crossings of S_1 from each side in the unit time. Consistently with the assumption of local equilibrium, the same average velocity $\bar{v}$ is attributed to all particles crossing S_1. Isotropy and homogeneity of the system also imply that 1/3 of the particles move on average along the z-axis, half of them upward and half downward. Accordingly, S_1 is crossed along z in the unit time interval by $1/6n\bar{v}$ particles in each direction. The net amount of $A(z)$ transported through S_1 in the unit time is given by

$$\Phi(A) = \tfrac{1}{6} n\bar{v}[A(z - \bar{\ell}) - A(z + \bar{\ell})] \qquad [2]$$

Since $\bar{\ell}$ is very small compared with the macroscopic length of the fluid, one can use the approximation $A(z \pm \bar{\ell}) \simeq A(z) \pm \bar{\ell}\,\partial A/\partial z$ and rewrite eqn [2] as

$$\Phi(A) = -\frac{1}{3} n\bar{v}\bar{\ell}\frac{\partial A}{\partial z} \qquad [3]$$

The minus sign on the right-hand side of this equation indicates that A is transported in the direction opposite to the orientation of the gradient. This calculation can be performed more carefully by introducing explicitly the Maxwell distribution function of particle velocities at equilibrium. Nonetheless, one recovers the same result.

The simplest case is the presence of a density gradient along the z-axis, that is, $A(z) = n(z)$. It induces a mutual transport of particles, which diffuse through the system and

$$\Phi(n) = -\frac{1}{3} n\bar{v}\bar{\ell}\frac{\partial n}{\partial z} = D\frac{\partial n}{\partial z} \qquad [4]$$

where the quantity $D = 1/3n\bar{v}\bar{\ell}$ defines the diffusion coefficient of particles inside the fluid.

This definition can be easily extended to the case of a mixture of two different species of particles, labeled by the indices 1 and 2, which diffuse into each other. One can define the mutual diffusion coefficient as

$$D_{1,2} = \frac{n_1\bar{v}_1\bar{\ell}_1 + n_2\bar{v}_2\bar{\ell}_2}{3(n_1 + n_2)} \qquad [5]$$

The other cases of physical interest correspond to the situations where a gradient of velocity or temperature are present. In the former case, it is assumed that the fluid flows with constant macroscopic velocity $v(z)$ parallel to the (x,y) plane. In such a situation, there is a net transport of kinetic momentum $mv(z)$ (m is the mass of a particle), yielding a strain stress $\Phi(mv(z))$ between the fluid layers on the (x, y) plane:

$$\Phi(mv(z)) = -\frac{1}{3} nm\bar{v}\bar{\ell}\frac{\partial v(z)}{\partial z} = \eta\frac{\partial v(z)}{\partial z} \qquad [6]$$

where the quantity $\eta = 1/3nm\bar{v}\bar{\ell}$ defines the viscosity of the fluid. By substituting eqn [1] into the previous expression, one finds $\eta = m\bar{v}/3\sqrt{2}\sigma$. This implies that the viscosity of an ideal fluid is independent of its density, that is, of the pressure. This counterintuitive conclusion was first derived by J C Maxwell and its experimental verification sensibly contributed to establish in the scientific community a strong consensus on the "atomistic" approach of kinetic theory. It is worth stressing that such a conclusion does not hold when dealing with very dense fluids.

It remains to consider the case when $A(z)$ is the average kinetic energy of particles $\bar{\varepsilon}(z)$. At equilibrium, the energy equipartition condition yields the relation $n\bar{\varepsilon}(z) = \rho C_V T(z)$, where $\rho = mn$ is the mass

density of particles, C_V is the specific heat at constant volume, and $T(z)$ is the temperature at height z. The net flux of kinetic energy $\Phi(\bar{\varepsilon})$ can be read as the heat transported through the fluid along the z-axis

$$\Phi(\bar{\varepsilon}) = -\frac{1}{3}\rho C_V \bar{v}\bar{\ell}\frac{\partial T(z)}{\partial z} = \kappa\frac{\partial T(z)}{\partial z} \qquad [7]$$

where the quantity $\kappa = 1/3\rho C_V \bar{v}\bar{\ell} = mC_V\bar{v}/3\sqrt{2}\sigma$ defines the heat conductivity. Also κ is found to be independent of $2n$.

One can conclude that the transport coefficients, that is, the diffusion constant D, the viscosity η, and the heat conductivity κ, are closely related to each other and depend on a few basic properties of the particles, such as their mass m, their average velocity $\bar{v}$, and their mean free path $\bar{\ell}$. By comparing eqns [6] and [7] one finds the remarkable relation

$$\frac{\kappa}{\eta} = \alpha C_V \qquad [8]$$

According to the results herein reported, the value of the proportionality constant is $\alpha = 1$. In real systems this constant takes different values, which depend on specific features of particle interaction (e.g., $\alpha = 5/2$ for realistic models of monoatomic gases). The conceptual relevance of this relation is that it concerns quantities that originate from quite different conditions of matter. In fact, on the left-hand side is the ratio of two transport coefficients associated with macroscopic nonequilibrium conditions, while on the right-hand side is a typical equilibrium quantity, the specific heat at constant volume. After what has been discussed in this section, this observation is far from mysterious: by assuming that even in the presence of a macroscopic gradient of physical quantities, equilibrium conditions set in locally, the kinetic theory provides a unified theoretical approach for transport and equilibrium observables.

Brownian Motion

The basic example of transport properties emerging from fluctuations close to equilibrium is Brownian motion. This phenomenon had been observed by R Brown in 1828: small pollen particles in solution with a liquid exhibited an erratic motion, whose irregularity increased with decreasing particle size (typically, 10^{-3} cm). The long scientific debate about the origin of Brownian motion lasted over almost one century and raised strong objections to the atomistic approach of the kinetic theory (see the section, "Introduction"). In particular, the motion of the pollen particles could not be apparently consistent with an explanation based on collisions with the molecules of the liquid, subject to thermal fluctuations. In fact, pollen particles have exceedingly larger mass and size with respect to molecules. An easy calculation, based on orders of magnitude, yields the conclusion that the amount of velocity acquired by a pollen particle in a collision with a molecule is typically $10^{-6}\,\mathrm{m\,s^{-1}}$, so that the corresponding instantaneous displacement could not be practically observed, "a fortiori," with the optical devices available to R Brown in 1828. The kinetic approach implies also that the number of collisions per second of the Brownian particle with liquid molecules is gigantic and random. Thermal equilibrium conditions and the isotropy of the liquid make equally probable the sign of the small velocity variations of the pollen particle. On observable timescales, the effect of the many collisions should average to zero and the pollen particle should not acquire any net displacement from its initial position in the fluid. This way of reasoning is actually wrong, as Albert Einstein argued in his theory of Brownian motion. Einstein's methodological approach, based on the combination of simple models with basic physical principles, was very effective: he first assumed that the Brownian macroscopic particles should be considered as "big mass molecules," so that the systems composed by the Brownian particles and the solvent, where they were suspended, could be considered a mixture of two fluids at thermal equilibrium. This implies the validity of Vant'Hoff law

$$P(\boldsymbol{x}) = k_B T n(\boldsymbol{x}) \qquad [9]$$

where P is the osmotic pressure between the fluids, T is the equilibrium temperature of the solution, n is the volumetric density of Brownian particles (the "solute" of the binary mixture) and k_B is the Boltzmann constant ($k_B = 1.380658\,10^{-23}\,\mathrm{JK^{-1}}$). According to the classical kinetic theory one should not be allowed to write an equation of state like [9] for a collection of the macroscopic Brownian particles. They should be better described by the laws of dynamics, rather than by those of thermodynamics. Einstein's other point of view can be justified by considering that, despite their macroscopic dimension, the Brownian particles are not subject to standard macroscopic forces: they experience microscopic forces originated by thermal fluctuations of the fluid molecules and in this sense they can be assimilated in any respect to soluted particles. The macroscopic nature of the Brownian particles should be recovered in the timescales associated with the collision and dissipation processes inside the fluid. Einstein guessed that Brownian motion looks random on a much larger timescale than the one needed for dissipating the energy acquired by Brownian particles through collisions with molecules. In practice, this amounts

to the assumption that the dissipation mechanism should be described by the macroscopic Stokes' law

$$F = m\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = -6\pi\eta R\boldsymbol{v} \qquad [10]$$

where F is the friction force proportional to the velocity v of the Brownian particle of radius R and η is the viscosity of the solvent. Accordingly, the energy dissipation process of Brownian particles has to occur on the timescale

$$t_\mathrm{d} = \frac{m}{6\pi\eta R} \qquad [11]$$

For $R \simeq 10^{-4}$ cm and for a standard solvent (e.g., water) one has $t_\mathrm{d} = \mathcal{O}(10^{-7})$s.

On a timescale much larger than t_d the Brownian particles are expected to exhibit a diffusive motion, as a consequence of the many random collisions with the solvent molecules. On the other hand, the kinetic theory associates diffusion with transport of matter in the presence of a density gradient (see the section "Introduction"). Einstein then assumed that some ideal external force should be responsible for creating such a gradient yielding a flux of Brownian particles

$$\boldsymbol{J}_\mathrm{B} = D\boldsymbol{\nabla}n \qquad [12]$$

At a microscopic level the flux of Brownian particles $\boldsymbol{J}_\mathrm{B}$ is defined as the product of their velocity $\boldsymbol{v}$ times their density n. For $t \gg t_\mathrm{d}$, the velocity $\boldsymbol{v}$ is given by eqn [10] and one can also write

$$\boldsymbol{J}_\mathrm{B} = \frac{\boldsymbol{F}n}{6\pi\eta R} \qquad [13]$$

The numerator on the right-hand side of this equation is the definition of the pressure gradient, which, according to Vant'Hoff law [9], is proportional to the density gradient. In formulas

$$\boldsymbol{F}n = \boldsymbol{\nabla}P = k_\mathrm{B}T\boldsymbol{\nabla}n \qquad [14]$$

By substituting eqn [14] into eqn [13] and comparing with eqn [12], one obtains the remarkable relation

$$D = \frac{k_\mathrm{B}T}{6\pi\eta R} \qquad [15]$$

Perrin showed that this formula provides very good quantitative agreement with experimental data.

In summary, Einstein's approach derives from the assumption that for $t < t_\mathrm{d}$ it still makes sense attributing a velocity to the Brownian particle (see eqn [10]), while for $t > t_\mathrm{d}$ the particle is assumed to diffuse, as it would in the presence of an ideal density gradient (eqn [12]). It is worth stressing that the last hypothesis is purely phenomenological, since direct inspection of the movement of Brownian particles revealed its diffusive nature. Einstein's theory of Brownian motion is based on the matching between different dynamical regimes.

The Langevin Approach

A mechanical approach taking explicitly into account both dynamical regimes was later proposed by P Langevin. For the first time deterministic and stochastic forces were introduced into the same equation. The deterministic component is the friction term $-\gamma\boldsymbol{v}$, acting on the Brownian particle: γ is the friction coefficient, which amounts to $\gamma = 6\pi\eta R$ in the Stokes regime and $\boldsymbol{v}$ is the three-dimensional velocity vector of the Brownian particles, whose components are denoted by v_i, $i = 1, 2, 3$. The stochastic component associated with the effect of collisions with the solvent molecules is a random, time-dependent force $\boldsymbol{\xi}(t)$, whose components are analogously denoted by ξ_i, $i = 1, 2, 3$. Symmetry arguments indicate that each one of these components can be assumed to be independent, isotropic, uncorrelated in time (at least for $t > t_\mathrm{d}$) and Gaussian, since it results from the combination of a very large number of collisions, which can be considered approximately as independent events. Accordingly, the average of the stochastic force is null and its time-correlation function can be approximated by a Dirac delta for $t > t_\mathrm{d}$. In the formulas:

$$\langle \xi_i(t) \rangle = 0 \qquad [16]$$

$$\langle \xi(t)_i \xi_j(t') \rangle = \Gamma\delta_{ij}\delta(t - t') \qquad [17]$$

where the brackets $\langle\ \rangle$ indicate the statistical average, Γ is a suitable dimensional constant and δ_{ij} is a Kronecker delta. Langevin equation is a Newton equation containing the stochastic force $\boldsymbol{\xi}$. For each component of the three-dimensional velocity vector it reads

$$m\frac{\mathrm{d}v_i}{\mathrm{d}t} = -\gamma v_i + \xi_i(t) \qquad [18]$$

This equation can be formally integrated, yielding the solution

$$v_i(t) = \exp\left(-\frac{\gamma}{m}t\right) \times \left[v_{0i} + \int_0^t \mathrm{d}\tau \frac{1}{m}\exp\left(\frac{\gamma}{m}\tau\right)\xi_i(\tau)\right] \qquad [19]$$

where v_{0i} is the ith component of the initial velocity. Accordingly, $v_i(t)$ is a stochastic solution which assumes properties similar to $\xi_i(t)$ (see eqns [16] and [17]), namely

$$\langle v_i(t) \rangle = v_{0i}\exp\left(-\frac{\gamma}{m}t\right) \qquad [20]$$

and

$$\langle v_i^2(t)\rangle = \exp\left(-\frac{2\gamma}{m}t\right) \times \left[v_{0i}^2 + \int_0^t \mathrm{d}\tau \frac{1}{m^2}\exp\left(\frac{2\gamma}{m}\tau\right)\Gamma\right] \quad [21]$$

$$= \frac{\Gamma}{2m\gamma}\left[1 - \exp\left(-\frac{2\gamma}{m}t\right)\right] + v_{0i}^2 \exp\left(-\frac{2\gamma}{m}t\right) \quad [22]$$

As time t grows the average velocity vanishes exponentially with the rate m/γ, while the average squared velocity approaches the value

$$\lim_{t\to\infty} \langle v_i^2(t)\rangle = \frac{\Gamma}{2m\gamma} \quad [23]$$

In order to bridge this purely mechanical approach with Einstein's theory, establishing a relation with thermodynamics remains. This is naturally obtained by attributing a thermal origin to the fluctuations of the stochastic force. In particular, if one assumes that the Brownian particles and the solvent are at thermal equilibrium with temperature T, the energy equipartition principle establishes that the average kinetic energy per degree of freedom in the limit of very large times is proportional to the temperature

$$\lim_{t\to\infty} \left\langle \tfrac{1}{2} m v_i^2(t)\right\rangle = \tfrac{1}{2} k_\mathrm{B} T \quad [24]$$

By comparison with eqn [23] one obtains the remarkable relation

$$\Gamma = 2\gamma k_\mathrm{B} T \quad [25]$$

where the amplitude of velocity fluctuations is found to depend on the frictional coefficient of the fluid, thus yielding the basic example of a fluctuation–dissipation relation.

On the other hand, this relation cannot be directly tested by experimental observations, that is, records of the erratic trajectories of Brownian particles sampled at time intervals much larger than t_d. The very predictive content of the Langevin equation can be extracted by computing the average displacement vector $\boldsymbol{r}$, whose components are related to those of $\boldsymbol{v}$ by the straightforward relation $r_i(t) = \int_0^t \mathrm{d}\tau v_i(\tau),\ \ i = 1, 2, 3$. The information of interest is contained in the expression of the squared average displacement $\langle r_i^2(t)\rangle$. Simple calculations yield the result

$$\langle r_i^2(t)\rangle = v_{0i}^2 t^2, \quad t \ll \frac{m}{\gamma} \quad [26]$$

$$\langle r_i^2(t)\rangle = \frac{2k_\mathrm{B}T}{\gamma}t, \quad t \gg \frac{m}{\gamma} \quad [27]$$

It is important to observe that this mechanical approach is able to account at the same time for the "ballistic" regime, expected for times smaller than the relaxation time $t_\mathrm{d} = m/\gamma$, and also for the asymptotic diffusive regime. The diffusion constant is expressed by the relation

$$D = \frac{k_\mathrm{B}T}{\gamma} \quad [28]$$

which is found to be equivalent to eqn [15] in the Stokes friction regime, where $\gamma = 6\pi\eta R$.

The Fokker–Planck Approach

The statistical content of the Langevin approach emerges explicitly from the properties attributed to the random force in eqn [17]. The statistical average $\langle\ \rangle$ can be interpreted as the result of the average over many different trajectories of the Brownian particle obtained by different realizations of the stochastic force components ξ_i in eqn [18]. By taking inspiration from Boltzmann kinetic theory one can get rid of mechanical trajectories and describe from the very beginning the evolution of Brownian particles by a suitable distribution function $f(\boldsymbol{x}, t) : f(\boldsymbol{x}, t)\mathrm{d}\boldsymbol{x}$ represents the probability of finding the Brownian particle at a position in between $\boldsymbol{x}$ and $\boldsymbol{x} + \mathrm{d}\boldsymbol{x}$ at time t. One can introduce the transition rate $W(\boldsymbol{x}', \boldsymbol{x})$, such that $W(\boldsymbol{x}', \boldsymbol{x})\mathrm{d}\boldsymbol{x}'\Delta t$ represents the probability that in the interval of time Δt the Brownian particle "jumps" from the neighborhood of $\boldsymbol{x}$ to $\boldsymbol{x}'$. In this approach, any reference to instantaneous collisions with the solvent molecules is lost, and one has to assume that $\Delta t \gg t_\mathrm{d}$. As proposed by Fokker and Planck, one can write the evolution equation for $f(\boldsymbol{x},\ t)$: as a "master equation," that is, a balance equation where the variation in time of $f(\boldsymbol{x},\ t)$ emerges as the result of two competing terms: a gain factor, due to jumps of particles from any position $\boldsymbol{x}'$ to $\boldsymbol{x}$, and a loss factor, due to jumps from $\boldsymbol{x}$ to any $\boldsymbol{x}'$. In formula

$$\frac{\partial f(\boldsymbol{x}, t)}{\partial t} = \int_{-\infty}^{+\infty} \mathrm{d}\boldsymbol{x}' [f(\boldsymbol{x}', t) W(\boldsymbol{x}, \boldsymbol{x}') - f(\boldsymbol{x}, t) W(\boldsymbol{x}', \boldsymbol{x})] \quad [29]$$

In this equation, it has been implicitly assumed that volumes are preserved in position space by the Brownian process, in particular $\mathrm{d}\boldsymbol{x}' = \mathrm{d}\boldsymbol{x}$. On the other hand, large displacements of the Brownian particles are highly improbable and one can reasonably assume that the rate function $W(\boldsymbol{x}', \boldsymbol{x}) = W(\boldsymbol{x}'; \boldsymbol{\chi})$ is significantly different from zero only for very small values of $|\boldsymbol{\chi}| = |\boldsymbol{x}' - \boldsymbol{x}|$. This allows to introduce a formal Taylor series expansion in eqn [29] around $\boldsymbol{\chi} = 0$. By considering terms only up to the second order, one obtains the Fokker–Planck equation

$$\frac{\partial f(\boldsymbol{x}, t)}{\partial t} = -\boldsymbol{\nabla}[\boldsymbol{\mu}_1 f(\boldsymbol{x}, t)] + \frac{1}{2}\Delta[\boldsymbol{\mu}_2 f(\boldsymbol{x}, t)] \quad [30]$$

where

$$\boldsymbol{\mu}_1 = \int_{-\infty}^{+\infty} \mathrm{d}\boldsymbol{\chi} W(\boldsymbol{x}';\boldsymbol{\chi})\boldsymbol{\chi} = \left\langle \frac{\delta \boldsymbol{x}}{\delta t} \right\rangle = \langle \boldsymbol{v} \rangle \quad [31]$$

$$\boldsymbol{\mu}_2 = \int_{-\infty}^{+\infty} \mathrm{d}\boldsymbol{\chi} W(\boldsymbol{x}';\boldsymbol{\chi})|\boldsymbol{\chi}|^2 = \left\langle \frac{|\delta \boldsymbol{x}|^2}{\delta t} \right\rangle \quad [32]$$

The first term on the right-hand side of eqn [30] represents the contribution of viscous friction, while the second term is the diffusive contribution. Notice that $\boldsymbol{\mu}_1$ and μ_2 are both average quantities: the former amounts to the average speed of a Brownian particle, which in general results from the balance of external forces acting on the Brownian particle with the viscous friction force produced by the solvent; the latter amounts to the average squared displacement per unit time, which, in a homogeneous isotropic medium, corresponds to the definition of the diffusion constant D. Accordingly, in the absence of external forces the viscous term can be neglected and eqn [30] reduces to the standard form of a macroscopic diffusion equation

$$\frac{\partial f(\boldsymbol{x},t)}{\partial t} = D\Delta f(\boldsymbol{x},t) \quad [33]$$

The solution of this equation is

$$f(\boldsymbol{x},t) = \frac{1}{(4\pi D t)^{3/2}} \exp\left(-\frac{|\boldsymbol{x}-\boldsymbol{x}_0|^2}{4Dt}\right) \quad [34]$$

where $\boldsymbol{x}_0$ is the initial position of the Brownian particle. The average squared displacement is given by the expression

$$\langle |\boldsymbol{x}|^2 \rangle = \int_{-\infty}^{+\infty} \mathrm{d}\boldsymbol{x}|\boldsymbol{x}|^2 f(\boldsymbol{x},t) = |\boldsymbol{x}_0|^2 + 6Dt \quad [35]$$

This statistical treatment of Brownian motion can be easily generalized in the presence of external forces acting on the Brownian particle. For the sake of simplicity, the case of an elastic force acting on the Brownian particle $\boldsymbol{F} = -\lambda \boldsymbol{x}$, where λ is the elastic constant, is illustrated. The mobility of Brownian particles is denoted as v (e.g., in the Stokes regime $v^{-1} = 6\pi\eta R$). The average viscous force is then given by $-\langle \boldsymbol{v} \rangle / v$ and it must be balanced by the elastic force, that is $\langle \boldsymbol{v} \rangle / v + \lambda \boldsymbol{x} = 0$. This relation implies

$$\boldsymbol{\mu}_1 = -\lambda v \boldsymbol{x} \quad [36]$$

Since eqn [35] still holds, one also obtains

$$\mu_2 = \langle |\boldsymbol{x}|^2 \rangle / t = 6D \quad [37]$$

where, without prejudice of generality, one can set $\boldsymbol{x}_0 = 0$. Equation [30] then reduces to

$$\frac{\partial f(\boldsymbol{x},t)}{\partial t} = \lambda v \boldsymbol{\nabla} \cdot \boldsymbol{x} f(\boldsymbol{x},t) + 3vk_\mathrm{B}T\Delta f(\boldsymbol{x},t) \quad [38]$$

where the generalized Einstein's relation $D = vk_\mathrm{B}T$ has been used. The solution of eqn [38] reads

$$f(\boldsymbol{x},t) = \sqrt{\frac{\lambda}{2\pi k_\mathrm{B}T(1-\mathrm{e}^{-2\lambda v t})}} \times \exp\left(-\frac{\lambda(\boldsymbol{x}-\boldsymbol{x}_0\mathrm{e}^{-\lambda v t})^2}{2k_\mathrm{B}T(1-\mathrm{e}^{-2\lambda v t})}\right) \quad [39]$$

One can easily obtain

$$\langle \boldsymbol{x} \rangle = \boldsymbol{x}_0 \mathrm{e}^{-\lambda v t} \quad [40]$$

$$\langle |\boldsymbol{x}|^2 \rangle = |\boldsymbol{x}_0|^2 \mathrm{e}^{-2\lambda v t} + \frac{k_\mathrm{B}T}{\lambda}(1-\mathrm{e}^{-2\lambda v t}) \quad [41]$$

In the limit $t \to \infty$ these relations reduce to

$$\langle \boldsymbol{x} \rangle = 0 \quad [42]$$

$$\langle |\boldsymbol{x}|^2 \rangle = \frac{k_\mathrm{B}T}{\lambda} \quad [43]$$

It can be concluded that asymptotically the distribution of Brownian particles is a Gaussian centered around the origin (which has been chosen as the equilibrium position of the elastic force), with variance $k_\mathrm{B}T/\lambda$.

Mechanical Properties: Anelasticity

W Benoit, Institut de Physique de la Matière Complexe (IPMC-FSB), Lausanne, Switzerland

Introduction

The concept of anelasticity was conceived by Zener in 1948 and published in his monograph, "Elasticity and anelasticity of metals." The ideal elastic behavior is defined by three conditions: (1) the strain response to each level of applied stress has a unique equilibrium value, (2) the equilibrium response is achieved instantaneously, and (3) the response is linear. If only the second condition is not met, a time dependence with the response appears and the behavior known as anelasticity is produced. Consequently, anelasticity implies that, in addition to an elastic response, there also exists a time-dependent nonelastic response. In this sense, anelasticity differs from the related topics of "internal friction" or "mechanical spectroscopy," which does not possess such a unifying theoretical base. The more general behavior by additionally lifting the condition (1) of complete recoverability is known as linear viscoelasticity, which thus includes anelasticity as a special case. The purpose here is to show how anelasticity is described and how internal friction measurements are interpreted to get an insight into microscopic mechanisms, which are responsible for the mechanical behavior of solids. The first part comprises the formal theory using two different viewpoints: rheological approach and thermodynamics. In the second part, mechanical spectroscopy is described and different applications, that have been used to study the behavior of point defects, dislocation dynamics and grain boundary sliding, are discussed.

Rheology

Rheology solves the problem of the deformation of solids by postulating, for every kind of material, an equation between the stress σ, the deformation ε, and their time derivatives. Moreover, in the development of the rheological equations, it is useful to build mechanical models, which simulate qualitatively the behavior described by these equations. To describe the anelastic behavior, the models can be expressed with two ideal bodies (1) the Hooke solid that is conveniently represented by a spring, with the law $\varepsilon = J\sigma$, where J is the compliance or the inverse of the Young modulus E; (2) the Newtonian liquid is represented by a dashpot with the law $\sigma = \eta\dot{\varepsilon}$, where η is the viscosity. To describe anelastic behavior, these two elements can be coupled either in parallel (Voigt model) or in series (Maxwell model). It is convenient to write the viscosity η of the dashpot as $\tau/\delta J$, where τ is a relaxation time. The model of a spring in series with a Voigt unit (**Figure 1a**) can easily be calculated to obtain the differential stress–strain equation:

$$\left.\begin{aligned}\varepsilon &= \varepsilon_1 + \varepsilon_2\\ \varepsilon_2 &= J_U\sigma\end{aligned}\right\} \Rightarrow \varepsilon_1 = \varepsilon - J_U\sigma$$

and

$$\sigma = \frac{\varepsilon_1}{\delta J} + \eta\dot{\varepsilon}_1 \Rightarrow \sigma = \frac{1}{\delta J}(\varepsilon - J_U\sigma) + \frac{\tau}{\delta J}(\dot{\varepsilon} - J_U\sigma)$$

Finally, one obtains

$$J_R\sigma + \tau J_U\dot{\sigma} = \varepsilon + \tau\dot{\varepsilon} \quad \text{with} \quad J_R = J_U + \delta J \quad [1a]$$

J_R and J_U are called the relaxed compliance and the unrelaxed compliance, respectively. This equation is the more general form of the so-called "standard anelastic solid." In order to define the relaxation parameters, the following experiment can be performed: a mechanical stress σ_0 is abruptly applied at time $t = 0$ (**Figure 2**) and held constant, while the strain ε is recorded as a function of time. Equation [1a] then has the following solution:

$$\varepsilon = \sigma_0(J_R - \delta J e^{-t/\tau})$$

Thus, the strain relaxation behavior of the standard anelastic solid is such that under a unit-applied stress, the strain increases from an instantaneous value $J_U\sigma$

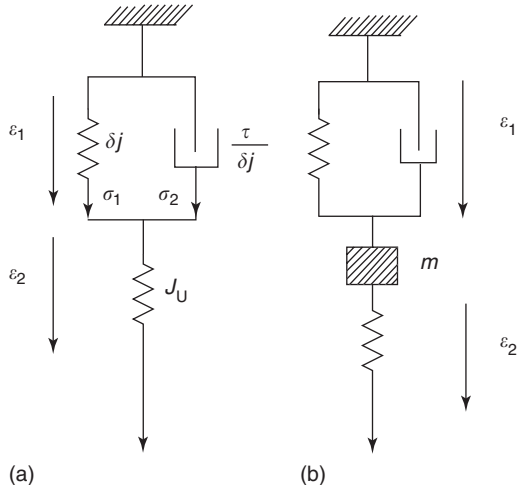

Figure 1 Rheological models: (a) standard anelastic solid: a Voigt unit (a spring and a dashpot in parallel) in series with a spring, (b) model with a mass, which may display resonance or relaxation behavior.

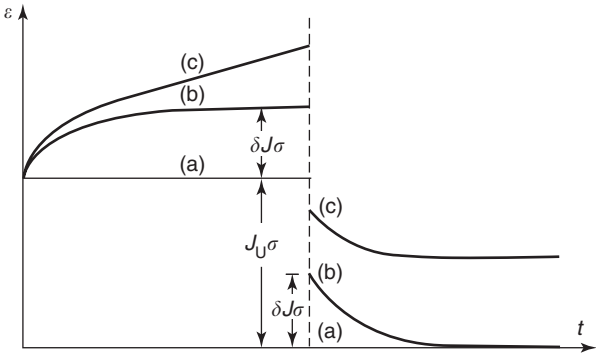

Figure 2 Creep and elastic after effect for (a) ideal elastic solid, (b) anelastic solid, and (c) linear viscoelastic solid.

to a final equilibrium value $J_R\sigma$, with a relaxation time τ. It is convenient to define a dimensionless quantity Δ, called the relaxation strength

$$\Delta = \frac{\delta J}{J_U} \text{ and then } J_R = J_U(1+\Delta)$$

The standard anelastic model can be generalized by introducing a second, third, … Voigt unit in series with the first one. The differential stress–strain equation can be calculated to obtain a linear equation with constant coefficients

$$a_0\sigma + a_1\dot{\sigma} + a_2\ddot{\sigma} + \cdots + a_n\frac{\mathrm{d}^n\sigma}{\mathrm{d}t^n} = b_0\varepsilon + b_1\dot{\varepsilon} + b_2\ddot{\varepsilon} + \cdots + b_n\frac{\mathrm{d}^n\varepsilon}{\mathrm{d}t^n}$$

This higher-order equation can also represent a resonance behavior depending on the value of the constant. Effectively, by adding a mass to the Voigt unit (**Figure 1b**), the stress–strain equation becomes

$$J_R\sigma + \tau J_U\dot{\sigma} + \delta J m J_U\ddot{\sigma} = \varepsilon + \tau\dot{\varepsilon} + \delta J m\ddot{\varepsilon} \qquad [1b]$$

This equation is also a linear differential equation of second order in ε and σ. Nevertheless, depending on the relative value of m and $\tau^2/\delta J$, this model represents a relaxation or resonant behavior. In the resonant case, the resonant frequency is given by ω_0 with $\omega_0^2 = 1/\delta J m$ (**Figure 3**). It is important to mention that, in solids, there is no example where a resonant behavior has been observed.

Thermodynamics

In this section, the basis behind the classical thermodynamic approach of anelasticity is described. The underlying idea behind such a description is that pseudo-equilibrium can be established within the solid. Thermodynamic functions, as for example, the free energy, are not only a function of the classical external state variables (stress σ, strain ε, temperature

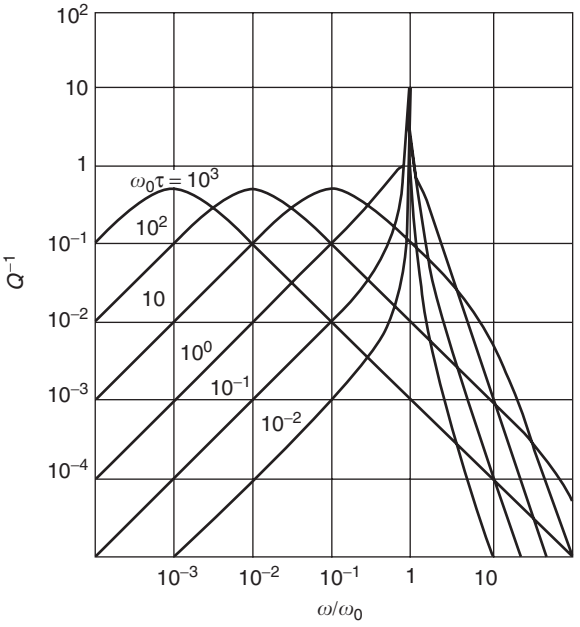

Figure 3 Frequency dependence of the internal friction for different values of the parameter $\omega_0\tau$.

T, and entropy s), but also a function of some internal variables. Such internal variables are related to microscopic mechanisms in the material and may be, for example, either a short-or a long-range order parameter, the proportion of point defects having a typical orientation, or the swept area of dislocations. In the following, only the simplest case for which the state of a solid is completely defined by the temperature, the state of stress and only one internal variable ξ is considered. Consequently, the free energy g is given by

$$g = g(\sigma, T, \xi) \quad \text{and} \quad \mathrm{d}g = -\varepsilon\mathrm{d}\sigma - s\mathrm{d}T - A\mathrm{d}\xi$$

where ε, s, and the affinity A are conjugate variables to σ, T, and ξ, respectively. The complete equilibrium at constant stress and temperature is given by $\mathrm{d}g = 0$, therefore $A = 0$. By taking as a reference state the following values of the variable, $T = T_0$ for the temperature (assuming that this value stays constant), $\sigma = 0$ for the stress, and $\xi = 0$ for the internal variable, the Gibbs function g may be expanded as a Taylor series to quadratic terms in the variables σ and ξ

$$g(\sigma, \xi, T_0) = g(0, 0, T_0) - \frac{1}{2}J_U\sigma^2 - \kappa\sigma\xi + \frac{1}{2}\beta\xi^2$$

where J_U is the unrelaxed compliance. The conjugate variables are then given by

$$\begin{aligned} \varepsilon &= J_U\sigma + \kappa\xi \\ A &= \kappa\sigma - \beta\xi \end{aligned} \qquad [2]$$

In this way, the value of ε is zero for $\sigma = 0$ and $\xi = 0$. The term $\varepsilon_{an} = \kappa\xi$ is the anelastic strain in which κ corresponds to the coupling between the internal variable ξ and the mechanical strain. When σ is assumed to be constant, but different from zero, one has to set $A = 0$ for complete equilibrium, and the equilibrium value $\bar{\xi}$ is given by

$$\bar{\xi} = \frac{\kappa}{\beta}\sigma = \alpha\sigma \qquad A = -\beta(\xi - \bar{\xi}) \qquad [3]$$

One may then consider A as a driving force toward a complete equilibrium state. From the thermodynamics of irreversible processes, it is expected that the rate $\dot{\xi}$, for small departures from equilibrium, depends linearly upon affinity,

$$\dot{\xi} = MA \text{ and consequently,}$$
$$\dot{\xi} = \frac{-1}{\tau}(\xi - \bar{\xi}) \quad \text{or} \quad \tau\dot{\xi} + \xi = \alpha\sigma \qquad [4]$$

where $\tau = 1/M\beta$ a relaxation time. Eliminating ξ and $\dot{\xi}$ in eqns [2] and [4], a differential stress–strain relation is obtained:

$$\varepsilon + \tau\dot{\varepsilon} = J_R\sigma + \tau J_U\dot{\sigma}, \quad J_R = J_U + \kappa\alpha = J_U + \delta J$$

This equation is equivalent to eqn [1] of the standard anelastic solid.

Mechanical Spectroscopy

In the first part, the relaxation parameters were measured using quasistatic experiments (**Figure 2**). Nevertheless, it is generally more convenient to use dynamic methods. In that case, an alternative stress $\sigma = \sigma_0 e^{i\omega t}$ is imposed on the system, and the phase lag δ between the strain $\varepsilon = \varepsilon_0 e^{i(\omega t - \delta)}$ and the applied stress is measured. The complex compliance is then given by

$$J^*(\omega) = J_1(\omega) - iJ_2(\omega) \quad \text{and consequently } tg\delta = \frac{J_2}{J_1}$$

It is easy to show that, in the linear case, the ratio of the energy ΔW, dissipated in the form of heat during one cycle, to the maximum stored elastic energy W is related to the loss angle δ by

$$\text{IF} = Q^{-1} = \frac{1}{2\pi}\frac{\Delta W}{W} = tg\delta$$

where Q^{-1}, the inverse of the quality factor of a resonant system, is commonly called the internal friction (IF, sometimes called damping) of a material. It generally and strongly depends on the frequency as well as on the temperature.

In order to calculate $tg\delta$ or the IF due to a relaxation mechanism, alternative stress, $\sigma = \sigma_0 e^{i\omega t}$ and strain $\varepsilon = \varepsilon_0 e^{i(\omega t - \delta)}$ are introduced in the equation of the standard anelastic solid (1), and one then obtains

$$\varepsilon + i\omega\tau\varepsilon = J_R\sigma + i\omega\tau J_U\sigma$$

The ratio between the stress and the strain gives the complex compliance $J^* = J_U + \delta J/(1 + \omega^2\tau^2) - i\delta J(\omega\tau)/(1 + \omega^2\tau^2) = J_1 - iJ_2$. Assuming $\delta J \ll J_U$, the IF is then given by classical Debye equations,

$$tg\delta = \frac{J_2}{J_1} = \Delta\frac{\omega\tau}{1 + \omega^2\tau^2} \quad \text{and} \quad \frac{\delta J_1}{J_U} = \Delta\frac{1}{1 + \omega^2\tau^2} \qquad [5]$$

where $\Delta = \delta J/J_U$. The second equation corresponds to the so-called modulus defect. In **Figure 3**, the IF is plotted as a function of the frequency for both cases of a relaxation and a resonant behavior. In the case of a relaxation behavior, a maximum is observed for $\omega\tau = 1$. For thermally activated mechanisms, an Arrhenius law is often valid, with

$$\tau = \tau_0 \exp(E/kT)$$

where τ_0 is the limit relaxation time (inverse of the attempt frequency), k the Boltzmann constant, and E the activation energy of the mechanism. The importance of such a relation is that the quantity τ may be varied over a wide range simply by changing the temperature. For the case of a Debye peak, the condition that $\ln\omega\tau = 0$ at the peak maximum gives

$$\ln\omega = \ln\omega_0 - \frac{E}{kT_P}, \quad \text{where } \omega_0\tau_0 = 1 \qquad [6]$$

If a series of peaks is measured at a number of different frequencies, a straight-line plot can be made (Arrhenius plot) of $\ln\omega$ as a function of $1/T_P$ whose slope is then E/k.

Experimental Methods

In order to measure the IF, different methods can be used, depending on the frequency range. In the very low frequency range (10^{-5}–10 Hz), a forced vibration is imposed on the system, and the phase lag between stress and strain is directly measured either as a function of the frequency or as a function of the temperature (**Figure 4**). Between 10^{-1} and 10^{+5} Hz, methods based on resonant systems vibrating at a natural frequency are used. The damping of the free vibration system is then given by $Q^{-1} = (1/n\pi)\ln(A_i/A_{i+n})$, where A_i and A_{i+n} are the ith and the $(i+n)$th amplitude of the free vibration respectively (**Figure 5**). This method is more suited to measure very low damping, but it is difficult to carry out measurements as a function of the frequency.

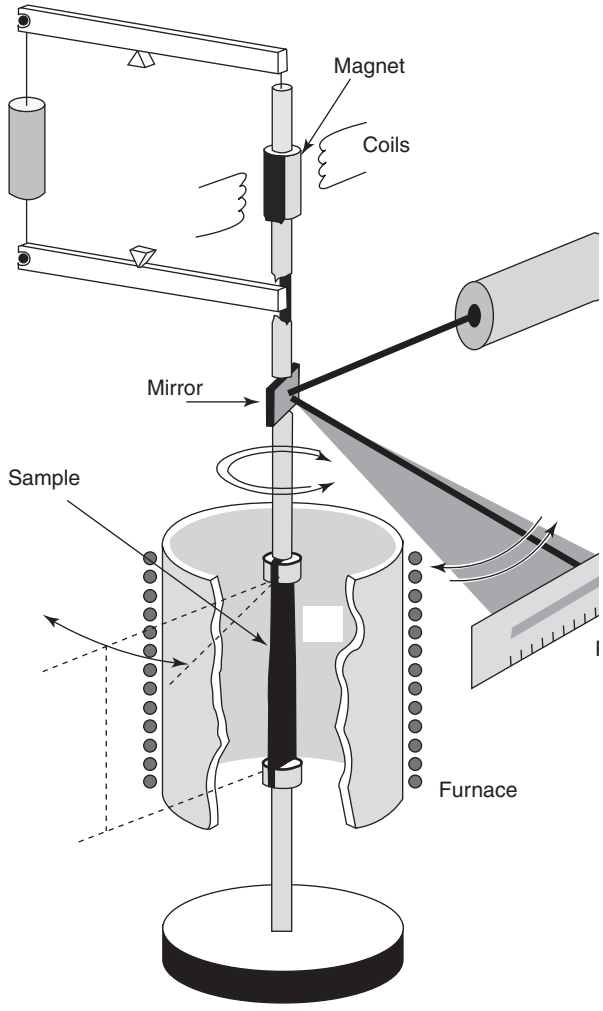

Figure 4 Inverted torsion pendulum: force vibration is imposed to the system and the phase lag δ is directly measured; frequency range: 10^{-5}–10 Hz; temperature range: 4–1800 K.

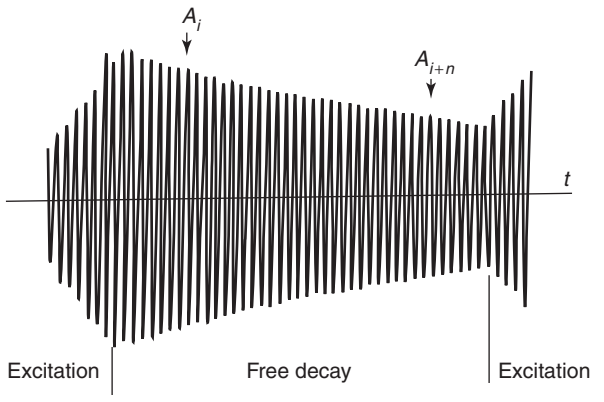

Figure 5 Free decay of natural vibrations, $Q^{-1} = (1/n\pi) \ln (A_i/A_{i+n})$.

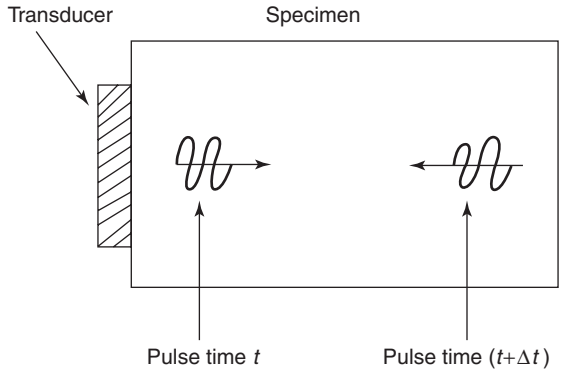

Figure 6 Ultrasonic attenuation measured by the echo technique.

In the MHz range, wave propagation methods are used (**Figure 6**). Bonding an appropriate transducer to one end of the sample generates a pulse or a wave packet, whose length is small compared to the specimen length. The velocity v and attenuation $\alpha(U = U_0 \exp - \alpha x)$ of such a pulse is determined by the echo technique: the time to return to the starting point after suffering a reflection of the free end, and the decrease in amplitude after successive reflections. The attenuation α is directly related to the IF by $Q^{-1} = \alpha\lambda/\pi$, where λ is the wavelength.

Microscopic Approach

The physical origin of the anelastic relaxation process is discussed in terms of atomic models. The cases of point defects, dislocations, and grain boundaries are considered successively. For these three cases, it is successively shown how to find the corresponding eqns [2]–[4] in order to obtain the anelastic behavior given by eqn [1].

Point Defect Relaxations

Point defects in the crystal lattice produce a local elastic distortion that is called an elastic dipole (by analogy with electric dipole), and as a result of this elastic dipole, there is an interaction between the defect and the stress applied to the crystal. It will be more easy to directly consider the particular case of the anelastic relaxation produced by interstitial solutes (e.g., C,N,O…) in dilute solution in body-centered cubic (b.c.c.) metals.

These interstitial impurities are responsible for an IF relaxation peak called Snoek relaxation. These impurities occupy the octahedral sites of the b.c.c. host lattice, as presented in **Figure 7**. So they create an elastic dipole with a tetragonal symmetry that has a single fourfold symmetry axes lying along the major axes of the octahedron. The interstitial sites may be subdivided into three groups, since the tetragonal axis may lie along each one of the cube axes

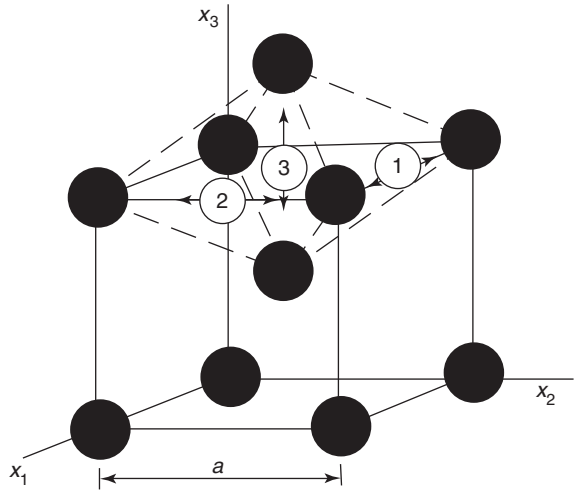

Figure 7 Octahedral sites in the b.c.c. lattice. Without external stress, all these sites are equivalent to each other.

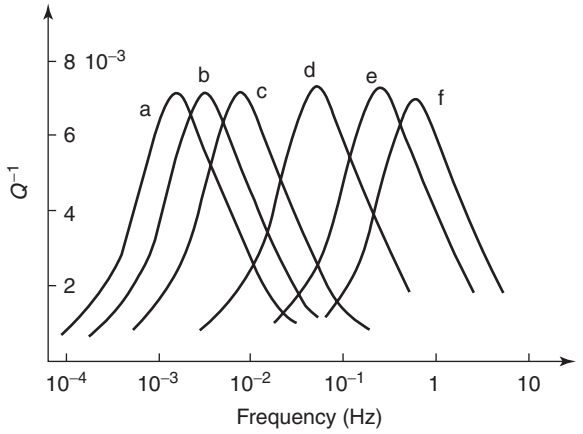

Figure 8 Snoek peak observed in Nb containing 0.15 at.% of oxygen.

x_1, x_2, x_3. It is then possible to mark the defects that have their tetragonal axis parallel to x_1, with the orientation index $p = 1$ and for x_2 and x_3, $p = 2$ and $p = 3$, respectively. If the total concentration of defects is N_0, then $N_0 = \sum_{p=1}^{3} N_p$, where N_p is the number of defects per volume unit with their tetragonal axis in the p direction. At the equilibrium, without applying an external stress all of the sites are equivalent ($N_1 = N_2 = N_3 = N_0/3$), and the extra deformation, due to the defects is the same in the three directions. When an external stress is applied in one direction, one type of defects is favored, consequently $N_1 \neq N_2 \neq N_3$. To simplify, consider only one uniaxial stress parallel to x_1 (i.e., $\sigma = \sigma_{11}$); the corresponding strain $\varepsilon = \varepsilon_{11}$ is given by

$$\varepsilon = J_U \sigma + \delta\lambda(N_1 - N_0/3)$$

where $\delta\lambda = (\partial\varepsilon/\partial N_1)_{N\text{const}}$, that is, the variation of the strain due to the migration of one defect from the position 2 or 3 to 1 and vice versa. The comparison with eqn [2] leads to $\kappa = \delta\lambda$ and $\xi = N_1 - N_0/3$. Moreover, thermodynamics of an irreversible process shows that

$$\dot{N}_1(T) = -\frac{1}{\tau}(N_1(t) - \bar{N}_1)$$

which is similar to eqn [4]. In order to obtain eqn [3], Boltzmann statistics are used and the equilibrium value $\bar{N}$ at each stress σ and temperature T is calculated. It is found that

$$\bar{\xi} = \bar{N}_1 - N_0/3 = \alpha\sigma \quad \text{with } \alpha = \frac{2N_0}{9kT}\delta\lambda$$

Finally $\delta J = \alpha\kappa = (2N_0/9kT)(\delta\lambda)^2$ and the relaxation strength is given by $\Delta = \delta J/J_U = 2N_0/(9J_U kT)(\delta\lambda)^2$. Consequently, the relaxation strength is proportional to the concentration of interstitial solutes, and the determination of Δ is an easy way to measure, with a very high accuracy, the concentration of carbon, nitrogen, or oxygen in solid solution of b.c.c. metals. Nowick and Berry also show that $\tau = a^2/36D$, where a is the side of the cube and D the diffusion coefficient of the impurities ($D = 1/2 v_D a^2 \exp(-E/kT)$, where v_D is the Debye frequency $\approx 10^{13}$ Hz). Therefore, $\tau = \tau_0 e^{E/kT}$, with E, the migration energy of the impurities and $\tau_0 \approx 10^{-14}$ s the pre-exponential factor. In conclusion, the IF and the modulus defect are given by the Debye eqn [5] with

$$\Delta = \frac{\delta J}{J_U} = \frac{2N_0}{9J_U kT}(\delta\lambda)^2$$
$$\tau = \tau_0 e^{E/kT} \approx 10^{14} e^{E/kT} \qquad [7]$$

Figure 8 presents an experimental result obtained in a force pendulum. The damping is plotted as a function of the frequency for different temperatures. The height of the peak is proportional to the concentration of the impurities and allows one to measure this concentration precisely. Plotting $\ln v_p$ (v_p being the frequency of the maximum) as a function of the temperature (**Figure 9**), the slope of the line gives E/k, that is, the migration energy of the impurity and the pre-exponential factor τ_0, which exactly corresponds to the predicted value of 10^{-14} s (**Table 1**).

When the Snoek peak is investigated for single crystals with different orientations, significant anisotropy of the relaxation strength is observed. From this type of measurements, it is possible to deduce the symmetry of the elastic dipole and to describe the position of the defect in the crystal lattice.

IF peaks observed in substitutional solid solutions are called Zener peaks and have been extensively studied for many different metallic structures (f.c.c.,

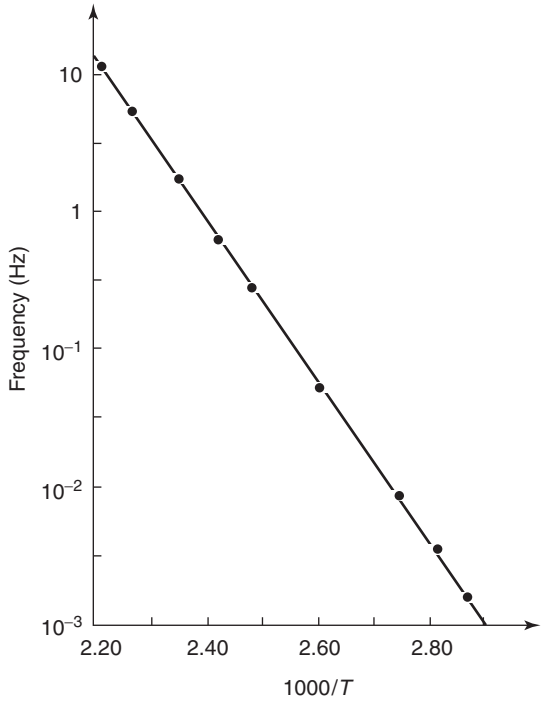

Figure 9 Arrhenius plot in case of oxygen Snoek peak (**Figure 8**).

The activation energy corresponds to the migration energy of the defects.

h.c.p., and b.c.c.) as well as ceramics. However, in that case, the symmetry of the dipole due to one defect is similar to the symmetry of the crystal, and no stress-induced ordering mechanism is possible. Therefore, the key point in the theory is the proposal that the relaxation is due to a stress-induced reorientation of solute atom "pairs" present in the solid solution in a nearest-neighbor configuration. As a consequence, the relaxation strength Δ becomes proportional to the square of the concentration of defects, while the activation energy always corresponds to the migration energy of the substitutional atoms.

Dislocation Relaxation

It is well known that dislocation displacement gives rise to shear strain, and correspondingly, that the application of a shear stress produces dislocation motion. Consequently, a dislocation displacement meets the conditions for an internal variable that can result in an anelastic behavior. Nevertheless, this motion should be sufficiently restricted to be reversible. Such a restriction occurs when dislocations move in a potential is due to either internal stresses or obstacles (e.g., point defects) which impede a long-range dislocation motion. Equation [2] can easily be rewritten as

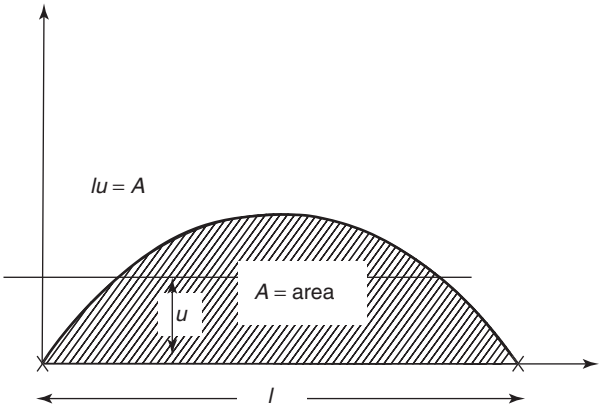

Figure 10 Dislocation segment of length l pinned at points bows into an arc. Definition of the internal variable u.

$$\varepsilon = J_U\sigma + \Lambda b u \qquad [8]$$

The second term, the anelastic strain, is due to the dislocation motion and is given by the Orowan equation where u, the internal variable, is the mean distance traveled by the dislocations (**Figure 10**), $\boldsymbol{b}$ the Burgers vector of the dislocations, and Λ the density of mobile dislocations.

To calculate the time dependence of the mean displacement u, it is necessary to write the motion equation of the dislocation. In case of small values of the external stress σ, it is assumed that dislocations move in a potential valley that gives rise to a restoring force Ku, so that the equation of movement becomes

$$m\ddot{u} = \sigma b - Ku - B\dot{u} \qquad [9]$$

where m is the inertial mass per unit length of dislocation, σb the magnitude of the force applied on the dislocation through a stress σ (Peach–Koehler force), and B a damping or drag term. The B term characterizes all the mechanisms that are able to control the motion of dislocations, for example, the interaction with phonons at high velocity (or high frequency), the motion through the Peierls valleys, the dragging of point defects, etc. Eliminating u between eqns [8] and [9] gives an equation of the form [1b], and consequently, the IF has the shape obtained in **Figure 3**. The experimental results (**Figure 11**)

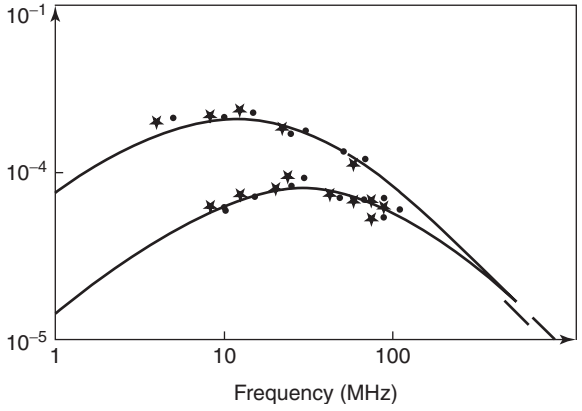

Figure 11 Dislocation relaxation measured in the MHz range for gold.

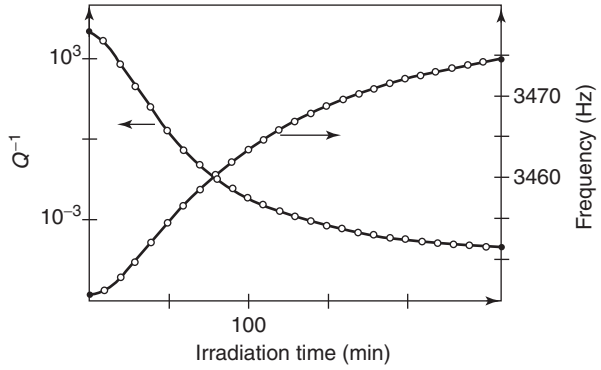

Figure 12 Effect of fast neutron irradiation on Young's modulus and internal friction of silver. Measurements in the KHz range.

prove that the dislocation motion is overdamped, that is, the inertial term $m\ddot{u}$ is negligible in eqn [9] and consequently,

$$B\dot{u} + Ku = b\sigma \qquad [10]$$

Eliminating u between eqns [8] and [10], one obtains

$$\left(\frac{\Lambda b^2}{K} + J_U\right)\sigma + \frac{B}{K}J_U\dot{\sigma} = \varepsilon + \frac{B}{K}\dot{\varepsilon}$$

an equation similar to that of the standard anelastic solid [1a], and consequently the IF as well as the modulus defects are always given by the Debye equation [5] with

$$\Delta = \frac{\Lambda b^2}{KJ_U} \quad \text{and} \quad \tau = \frac{B}{K} \qquad [11]$$

Moreover assuming that the restoring force Ku is due to the line tension γ of the dislocations with $\gamma \approx 0.5b^2/J_U$, it can be shown that, for a dislocation of length l vibrating like a string, $K = 12\gamma/l^2$ and consequently

$$\Delta = \frac{\Lambda l^2}{6} \quad \text{and} \quad \tau = \frac{Bl^2}{12\gamma} \qquad [12]$$

It has been shown that the relaxation, due to the interaction between phonon and dislocation, is responsible for the relaxation peak appearing in the MHz range (**Figure 11**). Moreover, in the low-frequency range of the Debye relaxation [5]

$$Q^{-1} = \Delta\omega\tau \propto \Lambda l^4 \quad \text{while} \quad \frac{\delta J}{J_U} = \Delta \propto \Lambda l^2 \qquad [13]$$

During neutron or electron irradiation, point defects (interstitial or vacancies), that can diffuse to the dislocation and pin them, are created. This pinning point modifies the dislocation length l, which decreases. Consequently, a strong decrease of the damping and of the modulus defect (Young modulus increases) that verifies the dependence predicted by eqn [13] (**Figure 12**) is observed. From the evolution of these two values, it is possible to follow the evolution of the dislocation network (l and Λ).

At much lower frequency, in the KHz and Hz range, other relaxation phenomenon due to the motion of dislocation are observed. For instance, mobile point defects are able to influence the damping term B. Dragging of mobile point defects exerts a retarding force, which leads to

$$\tau = \frac{B}{K} = \frac{s\frac{kT}{Gb^3}}{6\nu_D} \times \frac{l}{b}\exp\left(\frac{E_{PD}^M}{kT}\right)$$
$$= \tau_0 \exp\left(\frac{E_{PD}^M}{kT}\right)$$

where s is the number of point defects that migrate with a migration energy E_{PD}^M, and a Debye frequency ν_D. Then a relaxation peak, as a function of the temperature, is observed. Hasiguti peaks in f.c.c. metals (**Figure 13**) have been attributed to the dragging of intrinsic point defects induced either by cold-work or irradiation. The Snoek–Köster peaks, observed after cold-work of b.c.c. metals, are due to the dragging of interstitial impurities (H, C, O, N).

At low temperature, dislocations that lie in a close-packed direction of the lattice are more stable. Consequently, the potential energy of such a dislocation is a periodic function and the glide plane is similar to a corrugated iron. This periodic potential is called the Peierls potential. To minimize its energy, a dislocation, which lies in an arbitrary direction, develops a kinked structure (**Figure 14**), and the motion of dislocations is then controlled by the creation and motion of these kinks.

Several relaxation processes also characterize the kink dynamics. Considering the kink motion, the relaxation time becomes $\tau = \tau_0 \exp(H_K^M/kT)$, where

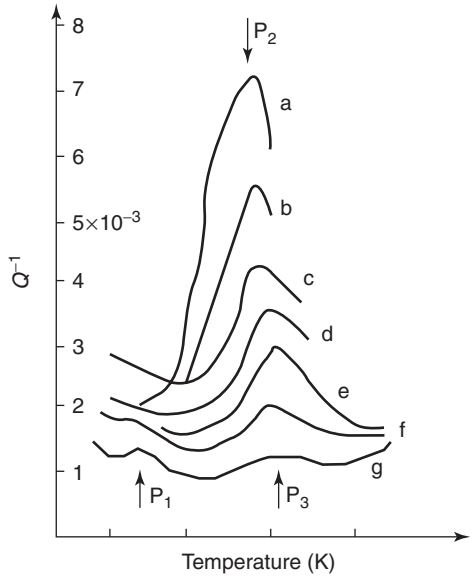

Figure 13 Hasiguti peaks observed in cold-worked gold. Curves a–g correspond to different annealing temperatures between 200 and 300 K.

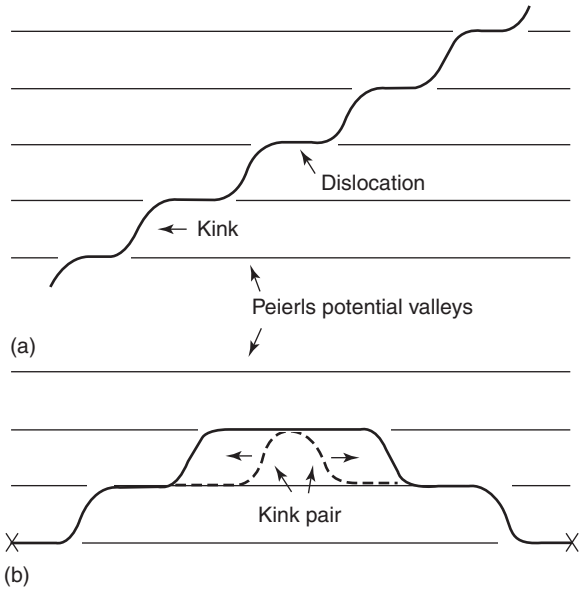

Figure 14 (a) Kinked structure of a dislocation and (b) the mechanism of kink pair formation.

H_K^M is the kink migration enthalpy. On the other hand, there exists a mechanism whereby the thermally activated kink pair formation controls the dislocation motion, which has been extensively studied. In this case, τ takes the form $\tau = \tau_0 \exp(H^{KPF}/kT)$, where H^{KPF} is the kink pair formation enthalpy. The kink dynamics has been extensively studied in f.c.c. (Bordoni relaxation), b.c.c. (α and γ relaxation), (**Figure 15**) and h.c.p. metals. From the measurement of the activation energy of these different relaxation peaks, it is possible to deduce a value of the Peierls energy or Peierls stress (**Table 2**).

The kink dynamics is now extensively studied in semiconductors, covalent crystals as well as in ceramics where it controls the mechanical properties of these materials. The experiments are difficult because it is necessary to create enough dislocations, that is, to extensively cold-work the specimen without breaking it!

Grain Boundary Relaxations in Metals

An important relaxation peak at 285°C at a frequency of 0.8 Hz in polycrystalline aluminum has been observed (**Figure 16**). This peak, called *Kê* peak, was not observed in single crystals and consequently, was attributed to grain-boundary sliding (GBS).

A simple model can be developed to explain the main characteristic of a relaxation peak due to the GBS, either in a polycrystal or in a bamboo structure. If a specimen with a bamboo structure is subjected to an applied stress σ, the boundary will shear plastically at constant rate $\dot{\varepsilon}$. The strain is then given by the sum of the elastic part and a plastic part due to the grain boundary sliding, that is

$$\varepsilon = J_U \sigma + \beta s u$$

where s is the grain-boundary density (cm^2/cm^3), u the shear displacement taking place along the grain boundary, and β a constant. The stress is given by

$$\sigma = ku + \frac{\eta}{\gamma\delta}\dot{u}$$

where the first term is due to the elastic deformation occurring in the two adjacent crystals, and the second term to the friction process due to the grain-boundary viscosity η. δ is the grain-boundary width. β and γ are geometrical parameters not too far from unity. Eliminating u between these two equations, one effectively obtains the equation of the standard anelastic solid with $\tau = \eta/\gamma\delta k$, the relaxation time, and $J_R = J_U + \beta s/k$, the relaxed compliance. Consequently, the damping and the relaxation strength are respectively given by the Debye eqns [5]

$$\text{with} \quad \Delta = \frac{\beta s}{k J_U} \quad \text{and} \quad \tau = \frac{\eta}{\gamma\delta k}$$

From the relaxation time, *Kê* deduced a value of the grain-boundary viscosity and this was considered as a very important experimental data deduced from IF measurements. In the case of a bamboo structure, k is a constant, the relaxation peak has a relaxation strength Δ that is proportional to the grain-boundary density s, and a relaxation time that is independent of s. In the case of a polycrystal, the counter stress ku is

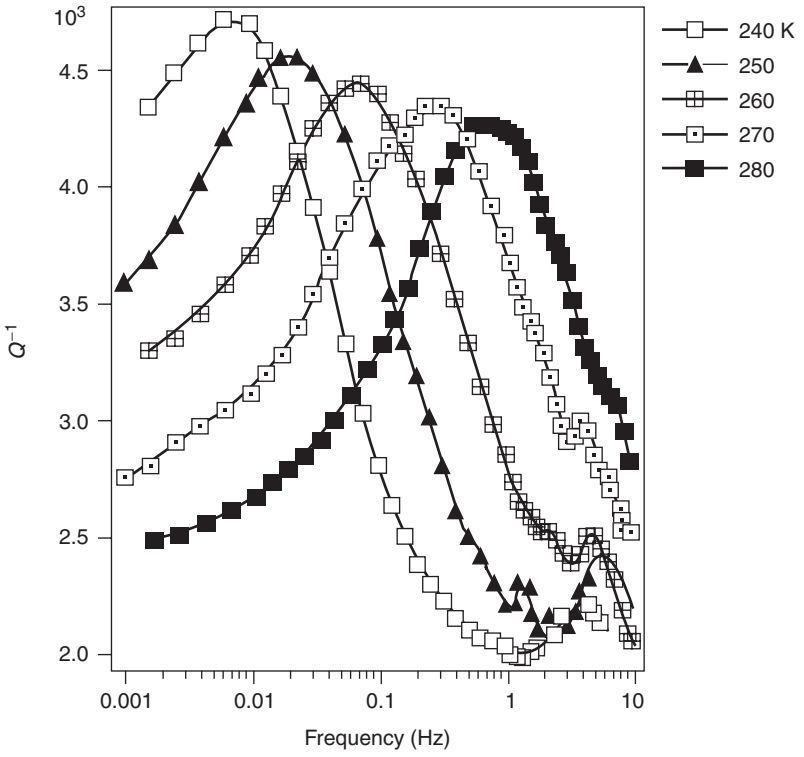

Figure 15 Relaxation peak observed in deformed Nb around room temperature. This dislocation peak (γ peak) is interpreted by a kink pair formation mechanism on screw dislocation.

Table 2 α, α', and γ are relaxation peaks observed in b.c.c. metals

Material	$T\alpha$ (K)	$E\alpha$ (eV)	$2H_K$ (edge) (eV)	$T\alpha'$ (K)	$E\alpha'$ (eV)	H_K^M (screw)	$T\gamma$	$E\gamma$ (eV)	$2H_K$ (screw)
Nb	40	0.075	0.08	40	0.07	0.07	250	0.59	0.56
Ta	31	0.057	0.062	22	0.034	0.034	350	0.71	0.74

From the relaxation parameters, the kink formation energy (H_K) and the kink migration energy (H_K^M) can be deduced for edge and screw dislocations.

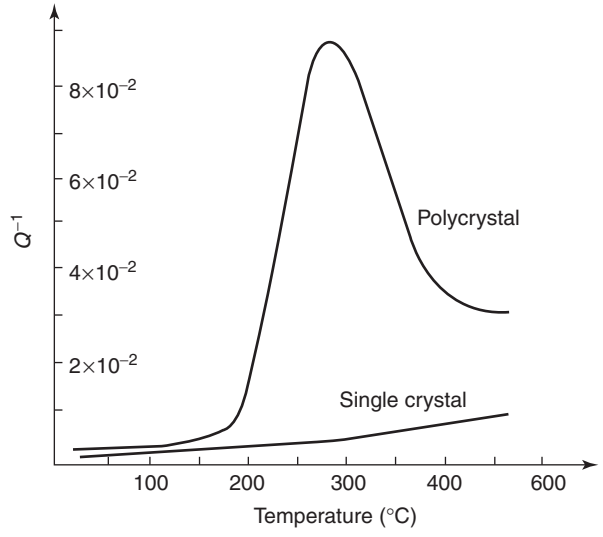

Figure 16 *Kê* peak in Al. *Kê* interpreted this peak by a grain-boundary sliding mechanism.

due to the elastic deformation of the grains between corners, and consequently, k is proportional to s and the relaxation strength does not depend on the grain size. Both effects have been observed. Assuming that the viscosity η is correlated with grain-boundary atomic self-diffusion,

$$\eta = \frac{kT}{Da} \quad \text{with}$$

$$D = D^{GB} = \frac{1}{2} va^2 = \frac{1}{2} v_D \exp\left(\frac{-E^{GB}}{kT}\right) a^2$$

where D^{GB} is the self-diffusion coefficient in the grain boundaries, a the atomic parameter, v_D the Debye frequency, and E^{GB} the self-diffusion activation energy in the boundary, that is, approximately 0.5–0.7 E^L (E^L = the self-diffusion energy in the lattice). Assuming that k and s are proportional, it is concluded that Δ should be independent of the grain size and than τ should be proportional to the grain size.

Table 3 Expected temperature of the grain boundary peak ($f = 1$ Hz) assuming $\tau_0 = 10^{-10}$ for Al, Cu, Ni, and Fe

Metal	E^{SD} (eV)	E^{GB} (eV)	T_p (K)
Al ($d = 0.02$ cm)	1.48	0.89	520
Al ($d = 0.08$ cm)			559
Cu	2.04	1.22	749
Ni	2.9	1.74	952
Fe	2.45	1.47	805

These peaks have been effectively observed at the expected temperature.

Effectively, the relaxation time τ is given by eqn [2]:

$$\tau = \frac{\eta}{\gamma\delta k} = \frac{2}{\gamma\beta}\cdot\frac{J_U kT}{va^3}\cdot\frac{\Delta}{s}$$

with $a^3/J_U = 4\,\text{eV}$, $kT = 4.31\times10^{-2}$ at $500\,\text{K}$, $\Delta \cong 0.5$ and $s \approx d^{-1}$, one obtains

$$\tau_0^{GB} = 10^{-15}\frac{d}{\delta}$$

Assuming a polycrystal of aluminum with grain size d in the range of 0.02–0.08 cm ($\frac{d}{\delta} = 0.4\times10^6 - 1.6\times10^6$), the limit relaxation time is approximately given by $\tau_0 \approx 4\times10^{-10}$–$1.6\times10^{-9}$. With this limit relaxation time and the values E^{SD} given in the literature for self-diffusion activation energy ($E^{GB} = 0.6E^{SD}$), one finds the expected temperatures of the grain-boundary peaks that correspond approximately to the measured values (**Table 3**).

Hysteretic and Nonlinear Effects

In addition to the relaxation phenomenon described above, which were attributed to anelastic effects, dislocation motion as well as the domain boundary motion in ferromagnetic or martensitic materials lead to internal friction with a hysteretic nature or vibration-amplitude-dependent damping, which strictly falls outside the scope of anelasticity. Often it is possible to consider a damping curve as composed of two parts, the first part being independent of amplitude, and the second part being dependent on amplitude. For example, it was earlier observed that the damping of high-purity annealed metals increases and becomes strongly strain amplitude dependent above strain amplitudes $\sim10^{-7}$. Such a nonlinear effect cannot be described as an anelastic mechanism. A mechanism for this effect involves breaking away from pinning points distributed along the length of dislocations. Nevertheless, depending on the temperature, dislocations can break away from pinning points (hysteretic effect at low temperature) or drag the pinning points (relaxation effect at high temperature); consequently, the separation between these different effects (anelastic, hysteretic, or strain amplitude dependent) is not evident.

In this article, it is shown that the measurement of internal friction is a very powerful method to study the dynamic behavior of point defects, dislocations, and grain boundaries in crystalline materials. Currently, it is intensively applied to study the rheologic behavior of glasses, polymers, as well as various new materials.

Mechanical Properties: Creep

T G Langdon, University of Southern California, Los Angeles, CA, USA

Introduction

When a crystalline solid is subjected to a very high stress, it breaks catastrophically; but when it is subjected to a relatively low stress, which is insufficient to cause failure, it gradually deforms plastically over a period of time in the process known as "creep."

Creep occurs in all crystalline materials from metals to ceramics to intermetallics to rocks. It occurs in single crystals, polycrystalline materials, composites, and in all materials where the presence of an atomic lattice can deform plastically through the movement

of crystalline defects. It is an important process in a very wide range of situations – from the deformation occurring in gas turbine blades and nuclear reactors to the formation of mountains and the flow within the mantle of the Earth and other planetary bodies.

Creep is a diffusion-controlled process so that the creep rate is dependent upon the rate of diffusion. This means in practice that, although creep occurs at all temperatures above absolute zero, creep generally becomes important, and the creep rates become reasonably rapid, only in situations where the temperature is at or above approximately one-half of the absolute melting temperature of the material. Although this requirement may appear somewhat limiting, nevertheless creep occurs in many simple situations. For example, it occurs in the creep of ice flows and glaciers or in the creep of parts made from metallic lead where the low melting temperature of 600 K means that flow occurs easily even at ambient temperatures. Examples of the creep of lead can be seen by examining the distortions of old lead tiles or piping on the medieval cathedrals of Europe. Thus, creep is an important flow process that has an exceptionally wide range of applicability.

The Variation of Strain Rate with Time

A typical creep curve for a crystalline solid is shown schematically in **Figure 1** in a plot of the strain, ε, against the time, t. It is apparent that there is an initial instantaneous strain, ε_o, which occurs immediately upon application of the load and this is followed by three distinct regions of creep: the primary region (I), the secondary or steady-state region (II) and the tertiary region leading to ultimate fracture (III). In broad terms, the primary stage is a region of hardening in which a substructure develops in the material whereas the secondary region represents a period in which there is a balance between the processes of hardening and recovery so that the creep rate remains constant. The tertiary stage is a region in which the strain rate accelerates due to the accumulation of creep damage within the material: examples of creep damage are the occurrence of necking in tensile testing or the development of internal cracks or cavities. In practical situations, it is imperative to avoid the occurrence of region III since it inevitably leads to a failure of the material.

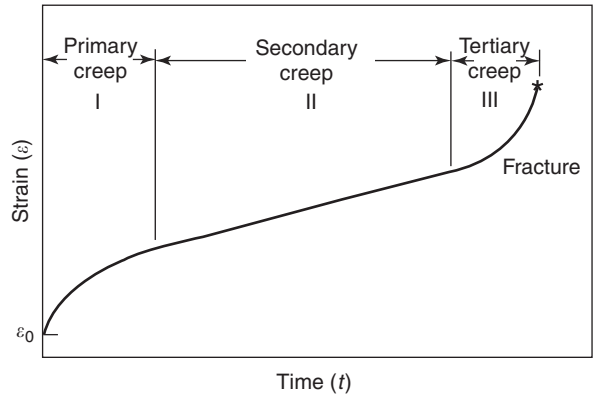

Figure 1 Typical creep curve of strain vs. time.

The steady-state or secondary region is often dominant in the creep behavior of materials in practical situations, and it is important, therefore, to develop an understanding at the atomistic level of the flow processes occurring in this region. The results from laboratory experiments generally show that the steady-state creep rate, $\dot{\varepsilon}$, varies with the applied stress, σ, through a power-law relationship of the form

$$\dot{\varepsilon} = A_1 \sigma^n \qquad [1]$$

where A_1 is a constant and n is termed the stress exponent for creep. However, when creep tests are conducted at exceptionally high applied stresses, experiments show the creep rate varies exponentially with the applied stress through a relationship of the form

$$\dot{\varepsilon} = A_2 \exp(B\sigma) \qquad [2]$$

where A_2 and B are appropriate constants. The point of transition, from power-law creep and eqn [1] at lower stresses to an exponential form of creep and eqn [2] at high stresses, is generally termed power-law breakdown.

Equation [1] is relatively simple because it relates the steady-state strain rate only to the magnitude of the applied stress. In practice, however, the measured creep rates depend also upon the testing conditions, such as the temperature, and upon microstructural conditions, such as the grain size of the material. It is usually possible to express eqn [1] in a more rigorous form by expressing the steady-state creep rate through a relationship of the form

$$\dot{\varepsilon} = \frac{ADGb}{kT}\left(\frac{b}{d}\right)^p \left(\frac{\sigma}{G}\right)^n \qquad [3]$$

where A is now a dimensionless constant, D is the diffusion coefficient, G is the shear modulus of the material, b is the Burgers vector, k is Boltzmann's constant, T is the absolute temperature, d is the grain size, and p is the exponent of the inverse grain size. The diffusion coefficient can be expressed explicitly in the form

$$D = D_0 \exp\left(-\frac{Q}{RT}\right) \qquad [4]$$

where D_0 is a frequency factor, Q is the activation energy for the rate-controlling diffusive process, and

R is the gas constant. Thus, it follows from an inspection of eqn [3] that, for any selected material, the steady-state creep rate is defined exclusively by the values of only four terms: A, Q, p, and n. This conclusion follows since all of the other terms in eqn [3] are either constants (such as b and k) or they depend on the precise testing conditions (such as G and T).

Equation [3] provides a general representation of the creep process, and all specific creep mechanisms have relationships of this form. Thus, an important objective in creep investigations is to measure the values of n, p, and Q for a material under any selected testing conditions, and then to interpret these results in terms of theoretical creep mechanisms that have been developed at the atomistic level.

The strains occurring in high-temperature creep can be broadly identified in terms of three different types of behavior. First, and probably dominant in most practical situations, plastic flow occurs within the grains of polycrystalline materials through processes, such as the intragranular glide and climb of dislocations. All of these intragranular processes may give a total strain which can be designated as ε_g. A strain may also develop through the processes of diffusion creep where strain accumulates through the flow of vacancies moving in response to the applied stress. The strain due to the flow of vacancies in diffusion creep is designated ε_{dc}. Finally, there may be an additional strain due to the occurrence of grain boundary sliding in polycrystalline materials, where the grains slide or move over each other in response to the applied stress with the movement taking place at, or very close to, the grain boundaries. The strain from this process is ε_{gbs}. Thus, the total strain accumulated in the flow process, ε_t, is given by the summation of these three separate strains through a relationship of the form

$$\varepsilon = \varepsilon_g + \varepsilon_{gbs} + \varepsilon_{dc} \qquad [5]$$

In practice, care must be taken in differentiating between ε_{gbs} and ε_{dc}, since diffusion creep requires accommodation through the movement of adjacent grains in the process termed Lifshitz sliding and grain boundary sliding, generally termed Rachinger sliding, which requires accommodation in the form of some limited intragranular deformation in order to maintain coherency at the grain boundaries.

The Development of Substructure in Creep

The primary stage of creep shown in **Figure 1** is related to the development of a substructure. For example, when creep occurs through the intragranular climb of dislocations, a substructure is formed consisting of an array of subgrain boundaries where the angles of misorientation are low (typically $\sim 2^\circ$) and arrays of dislocations within the subgrains. If creep occurs through the flow of vacancies, as in diffusion creep, no substructure develops and there is an instantaneous region of steady-state creep immediately following the application of the load.

In intragranular dislocation creep, the two important and measurable substructural quantities are the average subgrain size, λ, and the average density of dislocations within the subgrains, ρ. It is now well established, from a very large number of experimental measurements, that the values of λ and ρ are both dependent upon the magnitude of the applied stress.

If measurements are taken of the subgrain size, it is found that the value of λ varies inversely with the applied stress through a relationship of the form

$$\frac{\lambda}{b} = \zeta\left(\frac{\sigma}{G}\right)^{-1} \qquad [6]$$

where ζ is a constant having a value close to ~ 20. Similarly, if measurements are taken to determine the dislocation densities within the subgrains, where the dislocations contained within the subgrain walls are ignored, it is found that ρ varies with stress raised to a power of 2 through a relationship of the form

$$b\rho^{1/2} = \varphi\left(\frac{\sigma}{G}\right) \qquad [7]$$

where φ has a value close to ~ 1.

It is important to note that the relationships given by eqns [6] and [7] apply to both metals and ceramics, and it is reasonable to anticipate that they apply to all crystalline materials. The general trends of these two relationships are depicted schematically in **Figures 2** and **3**, where the shaded regions incorporate a large number of individual measurements taken on either metals or ceramics.

Creep in Pure Metals and Solid-Solution Alloys

There is a good understanding of the creep of pure polycrystalline metals. Two mechanisms tend to be dominant with the rate-controlling process dependent upon the level of the applied stress. At very low stresses, diffusion creep becomes rate-controlling and this can occur either through the diffusion of vacancies through the crystalline lattice in Nabarro–Herring diffusion creep or through the diffusion of vacancies along the grain boundaries in Coble diffusion creep. Both of these mechanisms require a stress exponent of $n = 1$ in eqn [3], but the processes are different because Nabarro–Herring creep requires

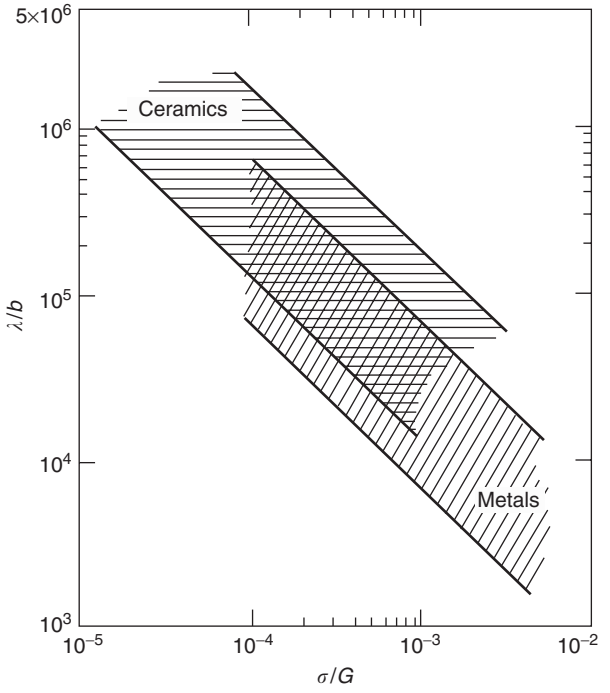

Figure 2 Representation of eqn [6] showing similar subgrain sizes in metals and ceramics.

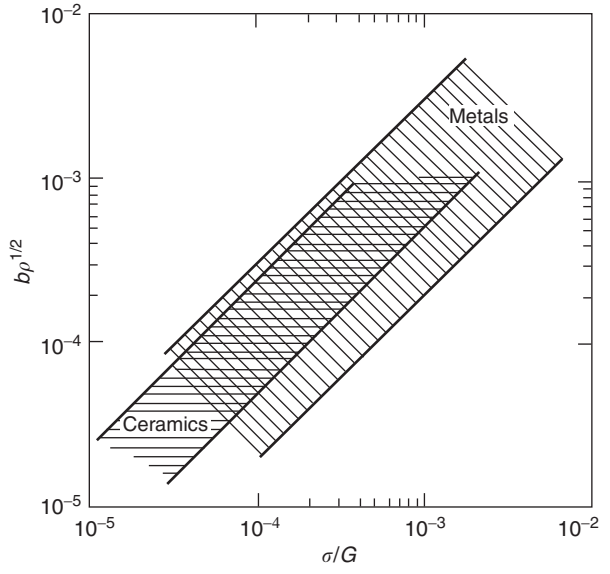

Figure 3 Representation of eqn [7] showing similar dislocation densities in metals and ceramics.

$p = 2$ and $D = D_l$, where D_l is the diffusion coefficient for lattice self-diffusion, and Coble creep requires $p = 3$ and $D = D_{gb}$, where D_{gb} is the diffusion coefficient for grain boundary diffusion. It is apparent, however, that both of these forms of diffusion creep give a stress exponent of 1, and thus they tend to become dominant at very low stresses. There is also an additional process, termed Harper–Dorn creep, which appears to be a dislocation mechanism occurring at low stresses with $n = 1$. The region at low stresses with $n = 1$ is generally designated the region of Newtonian viscous flow. Over a very wide range of intermediate stresses, creep occurs by the intragranular movement of dislocations, the climb process is rate-controlling, and the stress exponent is close to $n \approx 5$ although the precise value of n depends upon the stacking-fault energy of the metal. For pure aluminum, for example, the value of n is ~ 4.4. In experiments on high-temperature creep of pure metals, the region with $n \approx 5$ extends over a wide range of stresses with transitions to $n = 1$ at low stresses in diffusion creep, and an exponential dependence on stress at very high stresses in the region of power-law breakdown given by eqn [2]. For simplicity, the region with $n \approx 5$ where dislocation climb is the rate-controlling process, is generally designated class M or pure metal behavior.

The situation for metallic solid-solution alloys is often more complex. In solid-solution alloys, diffusion creep occurs as in pure metals but there may be a significant difference in the region of intragranular dislocation creep at intermediate stresses. Intragranular creep occurs through the movement of dislocations within the grains, where these dislocations move by both the glide and climb processes. In pure metals, the glide process occurs very quickly so that climb is always the rate-controlling step; but in solid-solution alloys, the glide process may be relatively slow because solute atom atmospheres may form around the moving dislocations and the glide process then involves the dragging of these solute atmospheres. Thus, in the solid-solution alloys there may be experimental conditions where the rate of glide, $\dot{\varepsilon}_g$, is slower than the rate of climb, $\dot{\varepsilon}_c$. Since dislocations move through both glide and climb, the formation and dragging of solute atmospheres provide a potential for introducing different transitions into the creep behavior.

An example is illustrated schematically in **Figure 4** where the creep strain rate, $\dot{\varepsilon}$, is plotted logarithmically against the applied stress, σ. At very low stresses, creep occurs by diffusion creep, and $n = 1$ in either Nabarro–Herring or Coble creep. As the stress level is increased, there is an initial region where $n \approx 5$ as in pure metals but at a well-defined stress given by σ_1 there is a transition to $n = 3$. At an even higher stress defined as σ_2, there is an increase in the creep rate and thereafter, at σ_3, the creep rate again reverts to the line for $n \approx 5$. Finally, at even higher stresses, there is evidence for an increase in the creep rate in the region of power-law breakdown. All of the regions depicted in **Figure 4** are well documented

experimentally and basically this result represents the standard behavior of pure metals (class M) but with an additional process superimposed between σ_1 and σ_3 which applies only to solid-solution alloys: this process is termed class A behavior since it occurs only in alloys.

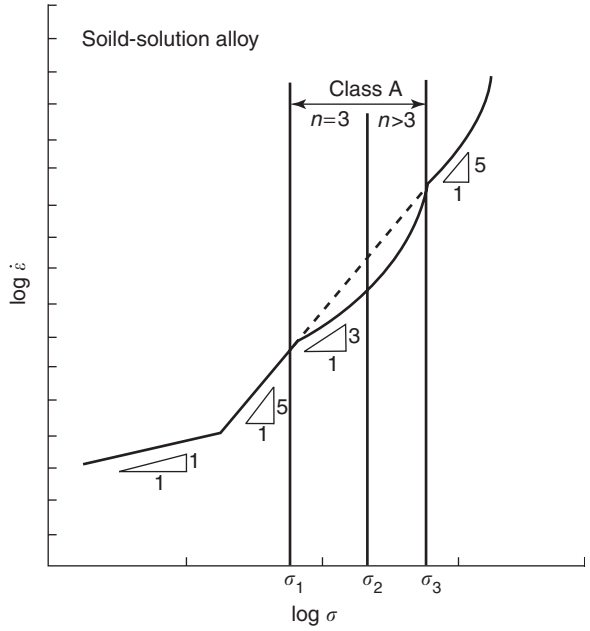

Figure 4 Strain rate vs. stress for a typical solid-solution alloy showing the different transitions in creep behavior.

The region with $n = 3$ in **Figure 4** represents a transition from climb-controlled behavior with $n \approx 5$ at the lower stresses to glide-controlled behavior and the dragging of solute atmospheres with $n = 3$ at the higher stresses. The transition from $n \approx 5$ to $n = 3$ is well represented by a simple relationship, which denotes the stress delineating the transition to a glide-controlled regime: this stress is given, in normalized form, by the following expression:

$$\frac{\sigma}{G} > \Psi\left(\frac{kT}{eGb^3}\right)\left(\frac{1}{c}\right)^{1/2}\left(\frac{\tilde{D}}{D_l}\right)^{1/2}\left(\frac{Gb}{\Gamma}\right)^{3/2} \qquad [8]$$

where e is the solute–solvent size difference, c is the concentration of the solute, $\tilde{D}$ is the coefficient for interdiffusion of the solute atoms in the matrix, D_l is the coefficient for lattice self-diffusion, Γ is the stacking-fault energy, and Ψ is a constant having a value which has been estimated as $\sim 3 \times 10^{-7}$.

The validity of eqn [8] is illustrated in **Figure 5** where the term on the right-hand side of eqn [8] is plotted against the normalized stress, σ/G, and the line at 45° represents the theoretical transition from climb-control or class M with $n \approx 5$ on the left to glide-control or class A with $n = 3$ on the right. The two solid points on the horizontal lines for the Al–3.3%Mg and Al–5.6%Mg alloys show the transition points derived experimentally and used to determine the value of $\Psi \approx 3 \times 10^{-7}$. The remaining alloys shown in **Figure 5** are plotted according to the ranges

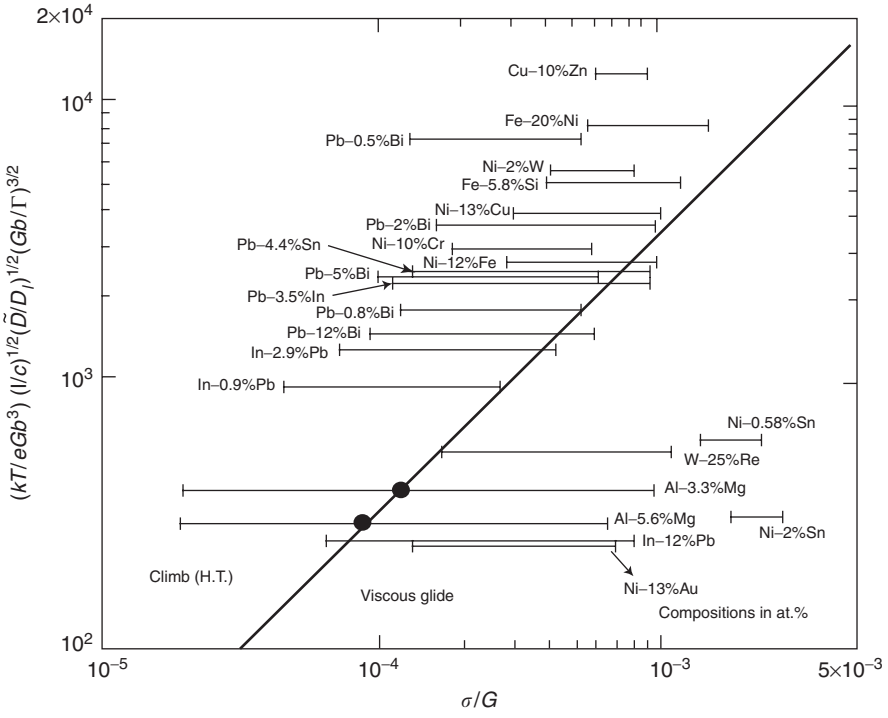

Figure 5 Representation of eqn [8] showing the transition from dislocation climb (on left) to glide (on right).

of normalized stress used experimentally, and all of these alloys lie in the correct positions relative to the published experimental data.

A second transition occurs in **Figure 4** at the point designated σ_2 where the stress exponent increases above $n = 3$ but the behavior remains within the region associated with class A. This transition occurs because at high-stress levels, the dislocations break away from their solute atmospheres so that $n > 3$. The theoretical breakaway stress, σ_b, is given by

$$\sigma_b = \frac{\alpha W_m^2 c}{b^3 kT} \qquad [9]$$

where W_m is the binding energy between the solute atom and the dislocation, and α is a dimensionless constant having a value of ~ 0.2. Thus, it follows from eqn [9] that glide is rate-controlling and $n = 3$ at stresses below σ_b, but the solute atmospheres no longer impede the dislocation mobility so that $n > 3$ at applied stresses above σ_b. Using eqn [9], the transition marking the breakaway is given in normalized form by the expression

$$\frac{\sigma}{G} > \frac{W_m^2 c}{5Gb^3 kT} \qquad [10]$$

where eqn [10] delineates the upper limit of the $n = 3$ region. Equation [10] is plotted schematically in **Figure 6** where the line at 45° represents the breakaway condition and the horizontal lines delineate experimental results plotted over the appropriate ranges of normalized stress. Each horizontal line in **Figure 6** shows a solid point denoting the approximate experimental transition from a well-defined region with $n = 3$ to a region where there appears to be a breakdown and $n > 3$. It is apparent from inspection of **Figure 6** that, despite some minor scatter, these solid points tend to be in excellent agreement with the predictions of eqn [10].

It is important to note that eqn [10] predicts a breakaway condition that depends upon the solute concentration since the normalized stress is a linear function of c. The effect of a change in the value of c is illustrated schematically in **Figure 7**, where the data are again presented in the logarithmic form of $\dot{\varepsilon}$ versus σ. This plot shows the transitions, with increasing stress, from $n = 1$ at low stresses for diffusion creep or Harper–Dorn creep to $n \approx 5$ in a climb-controlled region, and then to $n = 3$ where glide is rate-controlling, and to $n > 3$ when the dislocations break away from their atmospheres. Ultimately, the behavior reverts to $n \approx 5$ at even higher stresses when the concentration c_1 is small, but there is no additional region with $n \approx 5$ at high stresses when the concentration is high as in the alloy with a concentration of

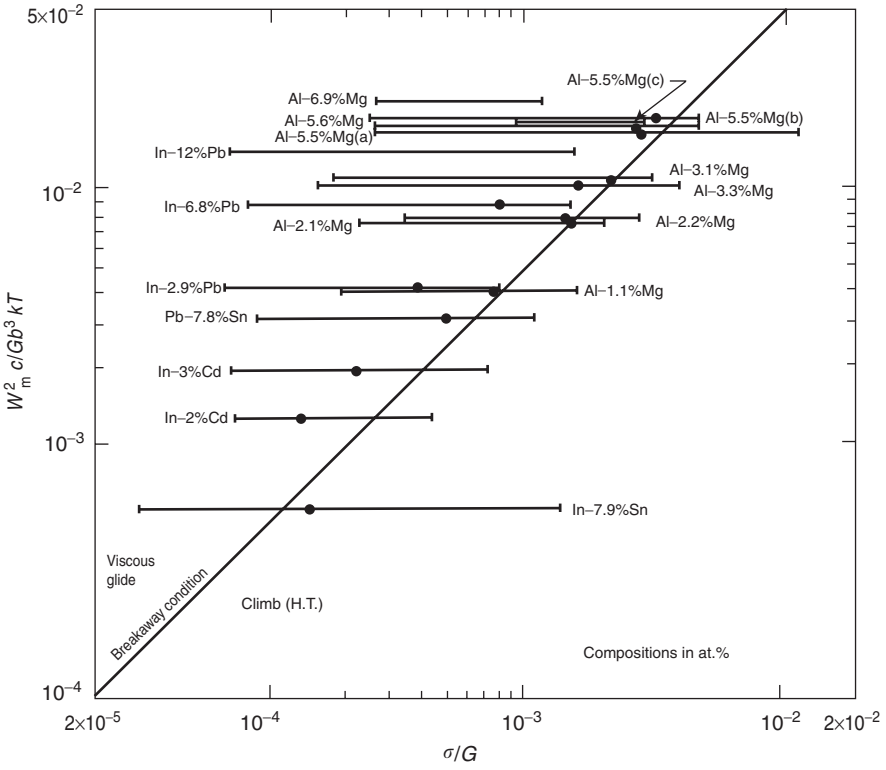

Figure 6 Representation of eqn [10] showing the breakaway of dislocations from the solute atom atmospheres.

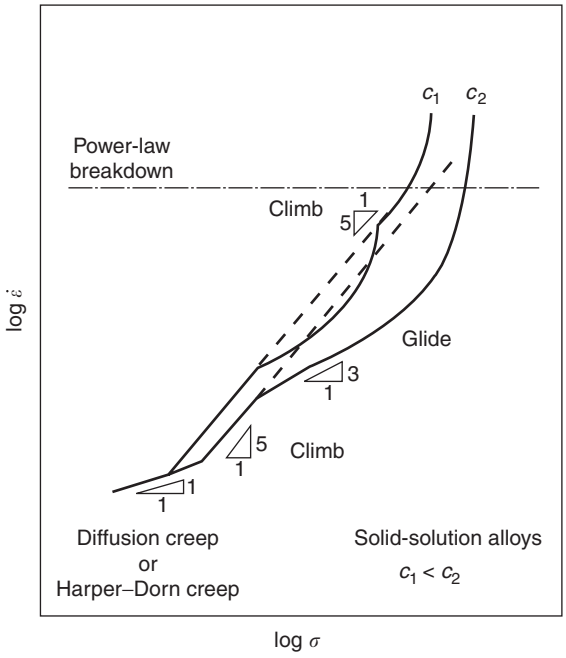

Figure 7 Schematic illustration of the effect of the solute concentration, c, on the transitions in behavior in solid-solution alloys.

c_2. At the very highest stresses, there is a conventional power-law breakdown and a transition to eqn [2].

Mechanical Properties: Elastic Behavior

K Bowman, Purdue University, West Lafayette, IN, USA

Introduction

When we say that something is elastic we usually think that it is something that springs back to its original shape after we stretch, bend, twist, or compress it. The elastic properties of materials are those that govern the change in shape and the tendency of the material to return the bonds between atoms or molecules back to their original condition. Of course, we can exceed the level at which the material can completely recover its original shape resulting in permanent deformation (plastic deformation) or fracture. Even if plastic deformation or fracture intercedes, the shape change that the material which is elastic has undergone will reverse, returning the material back to its unstretched state.

The model for the elastic response of materials most commonly used is that of a spring. The response of a spring is well known for a linear relationship between force and displacement even to relatively large extensions or strains. When we apply this model to solid materials the mechanical response is approximately linear to very small strain levels. Although this nearly linear response may have been known for quite a long period in man's history, it was not until the seventeenth century that Robert Hooke defined the essential relation showing the proportionality between a tensile stress and the resulting tensile strain. That the changes in shape in all dimensions held similarly near linear responses became understood subsequently through the work of Thomas Young, S D Poisson, and others. **Figure 1** shows the linear relationships between normal stress,

σ (force divided by the cross-sectional area perpendicular to it) and normal strain, ε (the displacement normalized to the length over which it is measured).

By the twentieth century, it became apparent that the simple relations developed to describe elastic properties could vary with the direction of loading in single crystals, oriented polycrystals, and oriented molecules. This directionality is often called anisotropic elasticity. If a material does not possess this directional variation in properties, it is called isotropic. With isotropic elasticity, only two of the material properties called elastic constants are necessary to fully describe the elastic response of a material. More recently, researchers have increasingly probed the larger strain response of materials that can be decidedly nonlinear. Many biomaterials demonstrate this extended range of elasticity that is often called hyperelasticity.

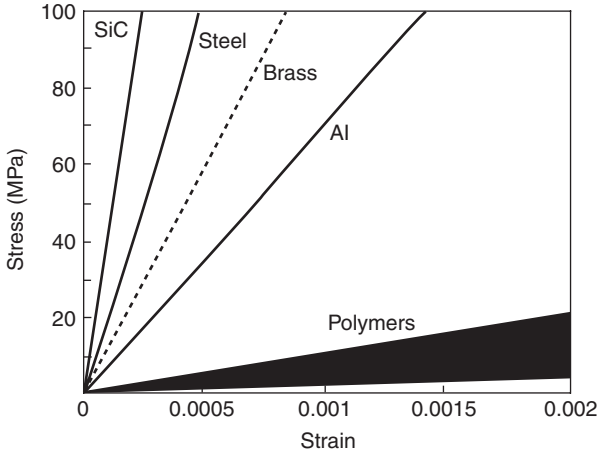

Figure 1 The stress vs. strain behavior for a number of materials measured from tensile loading experiments on commercial materials. The elastic constant called Young's modulus is the slope of each of these curves. (Adapted from Bowman KJ (2004) *An Introduction to Mechanical Behavior of Materials*. Wiley; © Wiley. Defining Elastic Constant

Isotropic Materials

Elastic constants are the constants describing mechanical response of a material when it is elastic. The isotropic elastic constants for some common materials are given in **Table 1**. If the engineering approximation that this mechanical response is linear is made, one can define a set of constants that relate any applied stress to the corresponding strain. When the material can also safely be treated as isotropic, the number of independent elastic constants required to completely describe the elastic response of a material is two. Any further elastic constants can then be defined in terms of the other two.

For a simple tension or compression test, the easiest elastic constant to define is Young's modulus, E. Young's modulus is the elastic constant defined as the proportionality constant between stress and strain:

$$E = \frac{\sigma}{\varepsilon} \qquad [1]$$

Young's modulus has the same units as stress, which is normally expressed in terms of pascals (Pa), equivalent to newtons per square meter, or pounds per square inch (psi). Strain is, of course, a dimensionless proportionality between a change in length and an original length. The Young's modulus is the slope of the linear elastic response for a number of materials as shown in **Figure 1**.

Another elastic constant that can be obtained in a tension or compression test wherein the strain along the loading direction and orthogonal to it is called Poisson's ratio, ν. Poisson's ratio is the ratio between

Table 1 Approximate elastic properties of various materials (and dilute alloys) at room temperature

Material	*Young's modulus, E* (GPa)	*Shear modulus,* μ (GPa)	*Poisson's ratio,* ν
Aluminum and aluminum alloys	69–72	24–26	0.35
Copper and copper alloys	125–135	47–50	0.34
Irons and steels	205–215	80–84	0.29
Stainless steels	190–200	75–78	0.33
Titanium and titanium alloys	115	42–44	0.32
Aluminum oxide	380–390	155–165	0.25
Silicon carbide	440–460	195–200	0.14
Glass	70–90	28–32	0.27
Polyethylene (PE)	0.2–2	[a]	0.4
Polymethylmethacrylate (PMMA)	2–3	[a]	0.4
Polystyrene (PS)	2–4	[a]	0.35
Bone[b]	5–30	3–8	0.25–0.5
Tendon[b]	0.8–1.5		

[a] These values are typically about one-third of Young's modulus.

[b] Bone and tendon are not only strongly anisotropic, but the stiffness also varies with type, position, and moisture content.

Adapted from Bowman KJ (2004) *An Introduction to Mechanical Behavior of Materials*. Wiley; © Wiley. This material is used by permission of John Wiley and Sons, Inc.

width or diameter strain, ε_1, of a tension or compression specimen and the strain along the tension or compression axis, ε_3. This dimensionless proportionality constant can be written as

$$\nu = \frac{-\varepsilon_1}{\varepsilon_3} \quad [2]$$

So far, the possibility of stresses occurring in multiple directions have not been considered. To do so, one needs to extend the idea of assigning a coordinate system to the stress state as shown in **Figure 2a**. If such a multiaxial loading condition is considered, the relations between a set of normal stresses and the corresponding strains as given by Hooke's law can be written as

$$\begin{aligned} \varepsilon_1 &= \frac{\sigma_1 - \nu(\sigma_2 + \sigma_3)}{E} \\ \varepsilon_2 &= \frac{\sigma_2 - \nu(\sigma_1 + \sigma_3)}{E} \\ \varepsilon_3 &= \frac{\sigma_3 - \nu(\sigma_2 + \sigma_1)}{E} \end{aligned} \quad [3]$$

This relation enables a set of normal stresses to be translated into corresponding strains using just the Young's modulus and Poisson's ratio.

A type of stress called a shear stress, τ, can also be defined which can produce a shear strain, γ. For shear stresses, the force is applied across the area and it results in a shearing of the material. Just as for normal stresses, shear loading can result in a mechanical response that is elastic and nearly linear, but the shape change is called a shear strain as shown in **Figure 2b**. The specific case in **Figure 2b** shows τ_4, which consists of a shear displacement in the y-direction on the z-face and in the negative y-direction on the negative z-face. To have a stable distortion, a similar pair of forces would need to be applied on the y-faces to cancel the rotational moment imposed by τ_4. The elastic constant that describes the linear relation between τ and γ is called the shear modulus, μ.

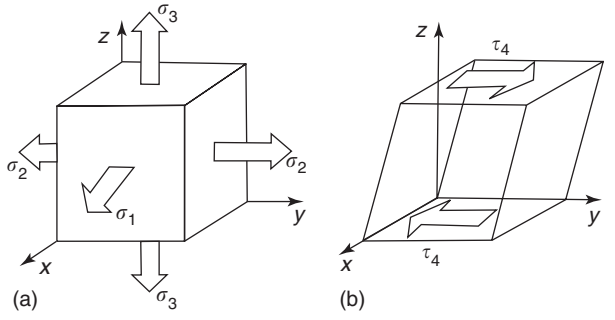

Figure 2 (a) Normal stresses referenced to an orthogonal coordinate system and (b) shear stresses and resulting distortion called shear strain.

So, one can write

$$\mu = \frac{\tau}{\gamma} \quad [4]$$

For isotropic materials, the relation between these three elastic constants is

$$E = 2\mu(1 + \nu) \quad [5]$$

Values for all three elastic constants are given for a number of materials at room temperature in **Table 1**. The values are given as ranges to represent variations expected from alloying.

Because elastic constants are related to bonding, they generally scale with melting temperature and the type of bonding. The strength and the type of bond determines the relationship between an applied force and changes in the distance between atoms. The spacing between atoms or molecules in a material that is not under stress comes about from a balance between attractive and repulsive forces that prevent the atoms or molecules from getting too close, and attractive forces that bring the atoms together. The sum of these two opposite forces is called the interatomic potential. Application of a stress to the material changes the balance point. Because the relationship between force and displacement is nearly linear, the elastic properties of materials can be described using linear relationships. As materials increase in temperature, they undergo increased thermal vibration that leads to thermal expansion. This increase in lattice constants also leads to a reduction in elastic constants with increasing temperature as indicated by **Figure 3**.

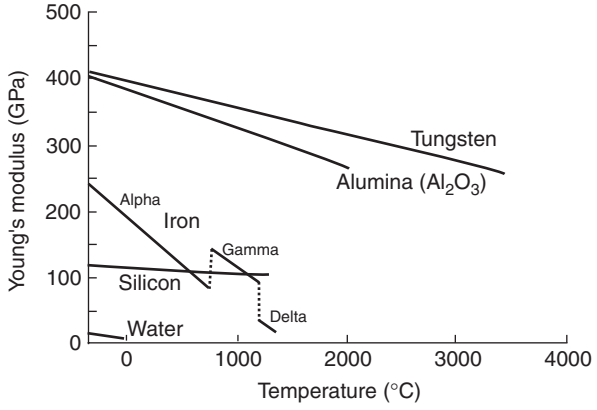

Figure 3 The dependence of Young's modulus on temperature for a number of materials. The curve for iron shows the values of Young's modulus for the three phases found in iron as a function of temperature. (Adapted from Bowman KJ (2003) *An Introduction to Mechanical Behavior of Materials*. Wiley; © Wiley. This material is used by permission of John Wiley and Sons, Inc.)

Anisotropy

When a material is anisotropic, the elastic constants vary with the direction along which the material is mechanically loaded. Even single-crystal materials have significant elastic anisotropies such that, the Young's modulus in one-crystal direction can be much different from that along another crystal direction. For example, in copper, elastically stretching the crystals along the cube axes of its unit cell requires one third as much stress as along the body-diagonal of the unit cell to produce the same strain. In iron single-crystals, the ratio between the smallest and largest Young's moduli is over two.

Because many engineering applications use materials that are comprised of many crystals or polycrystalline, the impact of directional processing (rolling, vapor deposition, extrusion, etc.) on producing elastic anisotropy was only recognized fairly recently. Developing ways to describe the relationship between oriented polycrystalline materials and the intrinsic single crystal properties has been an important area of research. Many newer applications of materials, including single crystals of superalloys used at high temperatures in jet turbines and the single crystals used in silicon computer chips, employ materials that have strongly anisotropic elastic properties.

Fiber-reinforced polymer composite materials posses directional properties that correspond to the arrangement of the fibers, which are normally stiffer than the polymer matrix material. Although models for fiber composite materials have existed for many years, their predictive capacity is often limited. The effects of the interfacial bonding, fiber arrangement and size scales, and their influence on anisotropic elasticity are not particularly well understood.

The importance of including elastic anisotropy in predictions of performance has also entered in evaluation of elastic constants of natural composite materials such as bone. Like nearly all natural materials, directional growth processes lead to elastic anisotropy. This elastic anisotropy depends on the type of bone, location on the bone, and the age of the bone. All three of these factors affect the ratio between the collagen and mineral contents of bone. The elastic properties and corresponding anisotropy have been increasingly recognized in the increasing fragility of bone with age and bone diseases, such as osteoporosis.

Defective growth patterns that occur in osteoporosis, bone diseases such as cancer or Paget's disease, can lead to bones with reduced elastic properties and strength. The mineral crystal content of bones is critical to maintaining stiff and strong bones. Bone mineral density (BMD) is measured to evaluate the condition of bone in aging patients, and provides a very potent indicator of decreasing elasticity and greater likelihood of bone fracture. One of the recently recognized limitations of bone density measurements is that it does not take into account the detailed structure of the bone mineral content, which can strongly affect the elastic properties of the bone. The morphology and preferred orientation of the bone mineral content results in strong elastic anisotropy such that the Young's modulus of a bone along its length can be nearly twice that in the radial direction. This anisotropy also plays a role in the lifetime of joint replacements. Many knee and hip replacements are principally constructed of metals or ceramics that have much higher elastic stiffnesses and lower degrees of anisotropy than does bone (see **Table 1**). The mismatch in elastic properties can lead to failure of the hip replacement.

Specification or the anisotropic elastic constants are usually facilitated through writing tensor relations between stress and strain. When the elastic constants are specified such that individual stresses are reported in terms of strains, the coefficients are called stiffnesses, c_{ij}, such that

$$\sigma_i = c_{ij}\varepsilon_j \qquad [6]$$

In eqn [6] the strain term on the right-hand side is the sum of all possible values of j.

When the elastic constants are written such that the individual strains are reported in terms of stresses, the coefficients are called compliances, s_{ij} such that

$$\varepsilon_i = s_{ij}\sigma_j \qquad [7]$$

In eqn [7], the stress term on the right-hand side is the sum of all possible values of j. The Young's modulus is the inverse of the compliance since a single applied stress can be related to the strain in the same direction, for example, for a stress applied in the x-direction.

$$\varepsilon_1 = s_{11}\sigma_1$$

Measuring Elastic Constants

For isotropic materials, direct measurements of elastic constants as shown in **Figure 1** is an effective approach to evaluate elastic constants such as Young's modulus and Poisson's ratio. Using tension and compression tests to measure anisotropic elastic constants requires testing of multiple specimens at a number of orientations. Easier approaches use other characteristics of the material that are related to elastic properties.

Probably, the easiest approach for measuring the anisotropic elastic constants of materials is to use measurements of sound velocity in a material. By

transmitting ultrasound pulses and measuring the time it takes for the pulse to propagate through the material, a quick and easy assessment of the elastic properties can often be made. When waves are propagated through a material, they interact with the mass of the atoms and the strength of the bonds between the atoms. The number of independent elastic constants required to fully describe the elasticity of materials is directly related to the symmetry of the crystals. For cubic crystals, three independent elastic constants are required to describe the elastic constants. For crystals and bulk materials with orthogonal symmetry (such that the character of the materials can be described by an orthogonal coordinate system), at least nine independent elastic constants must be determined.

Two types of waves are readily propagated through the bulk of materials, normal waves and shear waves. When normal waves are propagated through a material in the x-direction, the velocity is related to the normal stiffness as

$$v_1 = \sqrt{c_{11}/\rho} \qquad [8]$$

where ρ is the density and c_{11} is the normal stiffness. The normal stiffness c_{11} relates a stress to a strain in the same direction when the material is constrained such that, all other strains are held to zero.

For shear waves the velocity is related to the shear stiffness by the relation

$$v_4 = \sqrt{c_{44}/\rho} \qquad [9]$$

A recent development has been finding the anisotropic elastic constants using the resonant frequencies of crystals. The technique can be accomplished on a single specimen by oscillating the sample over a wide range of frequencies and finding the resonant values.

Increasing interest in nanoscale materials has led to the development of techniques to evaluate the elastic constants of thin films and particles of materials on size scales approaching a nanometer. Carbon nanotubes, which are derived from research on carbon C_{60} or "bucky balls," consist of several hundreds of carbon atoms and have diameters in the order of 1 nm. Many early predictions of their elastic properties overpredicted the Young's modulus. The planar structure of graphite leads to a very high Young's modulus within the planes of 1000 GPa and a Young's modulus across the planes that is more than a hundred times lower. The elastic constants of carbon nanotubes are also strongly anisotropic with values along the tube axis of several hundred GPa and values in the radial direction of less than 10 GPa.

Similar challenges in assessing the elastic properties are apparent in thin films as nanoindentation and scanning microscopy processes usually produce load versus displacement relations that are nonlinear due to loading geometry. When the loading behavior is modeled, it is often difficult to directly compare the elastic constants recovered to those for bulk materials. This can lead to scientists erroneously deciding that the thin film possesses an elastic behavior different from what is observed in the bulk. Thin film effects and other scaling impacts on elastic properties should always be evaluated carefully.

The Fundamental Nature of Elastic Constants

The details of the relationship between bonding and the elastic properties of materials has become more interesting as measurement techniques have improved and computer modeling has become more sophisticated. It has long been understood that elastic constants decrease almost monotonically as materials undergo greater thermal vibration at higher temperatures (see **Figure 3**). Once the melting temperature is reached the material loses its ability to support a load and the elastic constants fall to zero.

The balance between attractive forces and repulsive forces is often modeled with relatively simple expressions that can fail to accurately predict thermal expansion and elasticity and their temperature dependences. Although the approximate temperature dependence shown in **Figure 3** is useful for engineering calculations, in careful measurements, the elastic constants change rapidly as phase transformations are approached. It is apparent that the thermodynamic changes that occur at a phase transformation are signaled by strongly nonlinear changes in properties as the phase transformations are approached. The effects of alloying elements on elastic properties in solid solutions have also been shown to depend on the electronic structures of the materials, relative atomic radii, and other details of the components.

Many of the most advanced models for elastic response rely on constructing computer models that simulate the atomic arrangement in the material with assigned bonds between each of the atoms. Then virtual experiments can be conducted on a computer to simulate either the direct elastic response or the response of the lattice to wave propagation.

Extremes of Elasticity: Hyperelasticity

Materials with more than one type of fundamental bond, for example, ceramic and polymeric glasses, and materials tested under conditions at which they can sustain very high stress levels without failure, can

become decidedly nonlinear in their response. Understanding this nonlinearity and its effects of material performance has resulted in the study of what is called hyperelasticity. Hyperelastic responses are particularly observable in compressive loading with superposed hydrostatic stresses and complex localized stress states such as plane strain fracture and indentation loading. Many models for mechanical processes that rely on assumptions of linear elasticity may require substantial modification to describe the effects of hyperelasticity.

Mechanical Properties: Fatigue

F McBagonluri, University of Dayton Research Institute, Dayton, OH, USA
W Soboyejo, Princeton University, Princeton, NJ, USA

Introduction

Fatigue is a deleterious damage mechanism that occurs in advanced engineering structural components subjected to alternating loadings. Fatigue damage is driven by initiation and propagation stages. Different types of fatigue mechanisms have been identified in structural components, based primarily on loading conditions and prevailing loading environment. Most of these fatigue mechanisms manifest as fretting, dwell, thermomechanical, and multi-axial.

The result of fatigue failures is high casualty numbers and major financial losses. In fact, over 80% of mechanical failures in engineering structures and components are attributed to fatigue failures. Attempts to eliminate or reduce the incidence of fatigue failures have been the principal driving force behind the tremendous amount of research investments into the investigation of the initiation and propagation stages of fatigue.

Research in fatigue began over a century and a half ago following a series of industrial and railway accidents and the desire to reduce incidence of such failures. Much of the research was driven by the desire to understand the premature failures of components subjected to cyclic loading conditions at stress levels that were substantially below the pertinent design loads under monotonic loading.

The first systematic study of fatigue failures is usually attributed to the German engineer A Wöhler (1858–1871). In his preliminary studies, Wöhler concluded that when subject to cyclic loading conditions, the strengths of steel railway axles were lower than their static strengths. He concluded that the fatigue life was determined by the load range and not by the maximum load, as previously thought.

Ewing and Rosenhain, and Ewing and Humfrey conducted the first mechanistic studies of fatigue. In their studies conducted on Swedish iron, they identified the stages of fatigue crack initiation and propagation. In a series of investigations, they inferred, from

published optical micrographs of the surfaces of cyclically damaged specimens, that slip bands developed in the grains of polycrystalline materials subjected to alternating loads. They inferred that these slip bands increased with fatigue deformation, leading ultimately to crack formation.

Empirical models for characterizing fatigue damage evolution were developed by many researchers over the years to provide tools for the modeling of fatigue behavior. For instance, Basquin developed stress-based laws to characterize stress–life (S–N) curves of metals. He showed that a log–log plot of stress versus cycles exhibited a linear relationship over a large range of stresses.

Coffin and Manson, working independently in the early 1950s, noted that plastic strains were primarily responsible for cyclic damage. They proposed an empirical relationship between the number of load reversals to fatigue failure and the plastic strain amplitude. This formulation, known also as the Coffin–Manson relationship, is the most widely used approach for strain-based characterization of fatigue damage. Coffin and Manson also found that the plastic strain–life data can be linearized on a log–log scale. These relationships were combined to relate total strain range to life-to-failure. This relationship is called the strain–life relation. In the strain–life approach, the transition fatigue life represents the life at which the elastic and plastic strain ranges are equivalent.

The mathematical framework for the quantitative modeling of fatigue failure came later, and was primarily driven early by the stress analyses work of Inglis and later by the energy concepts of Griffith. This was followed by the work of Irwin. Irwin showed that the amplitude of the stress singularity ahead of a crack could be expressed in terms of the stress intensity factor, K. This formulation was developed based on the representation of the crack-tip stresses by the stress functions proposed originally by Westergaard, and the elasticity solutions of Love.

Paris and co-workers observed that the increment of fatigue crack advance per stress cycle, da/dN, can be related to the range of the stress intensity factor, ΔK, under constant amplitude cyclic loading. This observation set the stage for the direct application of linear elastic fracture mechanics to fatigue problems. In this approach, fatigue damage is characterized by fatigue cracks under conditions of small-scale plastic deformation at the crack tip. When gross plasticity occurs at the crack tip, the problem is considered to be one amenable to elastic–plastic or plastic analysis.

Elber provided further insights into the application of linear elastic fracture mechanics (LEFM) to fatigue. In studies of fatigue crack growth that were conducted by him as a graduate student in Australia, he noted that fatigue cracks could remain closed, even under cyclic tensile loads. He showed that the effective value of ΔK given by eqns [1] and [2]

$$\Delta K_{\text{eff}} = K_{\max} - K_{\text{cl}} \quad [1]$$

$$\Delta K_{\text{eff}} = K_{\max} - K_{\text{op}} \quad [2]$$

controls the fatigue crack growth rate, da/dN. Note that K_{cl} and K_{op} are the respective crack-closure and crack-opening stress intensity factors.

Further progress in fatigue investigations led to the breakdown of the similitude concept, in which cracked components in different dimensions were assumed to exhibit the same amount of crack growth, when subjected to the same far-field stress intensity factor range, ΔK. Following the pioneering work of Pearson, small cracks were found to exhibit anomalous crack growth behavior, with relatively fast growth rates occurring at ΔK level below the long crack fatigue threshold.

Mechanisms of Fatigue

Fatigue Crack Initiation

In most engineering structures and components, regions of high stress concentration are preferred crack initiation sites. The formation of microcracks around notches, scratches, inclusions, and along or across grain boundaries represent the onset of fatigue damage evolution. In metallic structures, microcracking is often driven by slip processes. Ewing and Humfrey referred to these slip bands as persistent slip bands (PSBs), in apparent reference to the fact that these bands were restored after electropolishing and then refatiguing. Fatigue crack initiation can occur by any one of the following identified processes:

1. From regions of localized strain hardening or softening resulting from slip step accumulation occurring at the surfaces of structures subjected to high plane strain amplitudes.
2. Formation of intrusions and extrusions on the surfaces of engineering structures resulting from sequential slip at the intersection of slip planes.
3. Microcrack formation along crystallographic planes of maximum shear stress by mode II mechanisms.
4. The coalescence of microcracks to form macrocracks, which are amenable to LEFM characterization.

Fatigue Crack Propagation

Fatigue crack propagation generally occurs in two stages, namely stage I and II. In stage I, crack

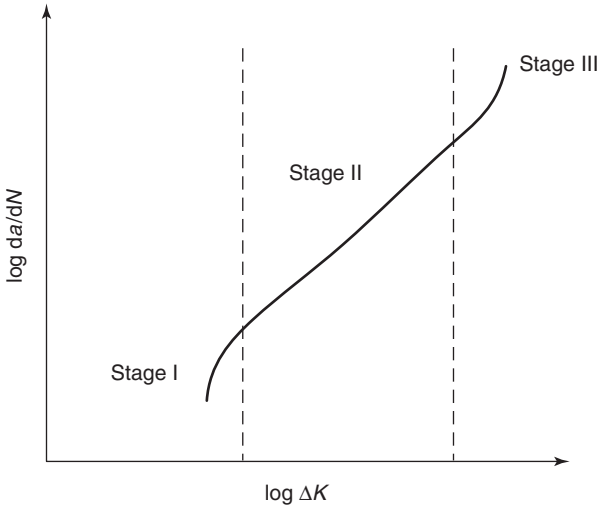

Figure 1 Schematics of the three distinct regimes of fatigue crack propagation.

propagation rate is characterized by low stress intensity factors. The crack growth behavior at this stage is associated with a threshold stress intensity value, ΔK_{th}, below which fatigue crack growth is negligible. Fatigue crack growth in the threshold is affected by stress ratio, frequency of loading, and prevailing environmental conditions.

Stage II fatigue crack growth is characterized by high ΔK and long crack lengths. In this region, crack growth rates are extremely high and most fatigue life is usually expended prior to this stage. On a plot of log da/dN versus log ΔK, the stage II region is linear (**Figure 1**). The Paris–Erdogan formulation is generally used to characterize fatigue crack growth within this regime. In variable-amplitude loading, the Forman and Walker fatigue crack propagation models are used.

Empirical Approaches

Stress-Based

The stress–life method, based on Wohler's S–N diagram, was the first quantitative approach. The stress–life approach is used in applications where the applied stress is essentially within the elastic range, and the material has a long cyclic life.

In general, the stress–life approach is used in situations where the fatigue life is in excess of 10^3 cycles. In addition, the stress–life approach excludes the true stress–strain behavior and assumes that only elastic strains are effective within the loaded structure. This assumption introduces significant computational errors, since plastic strains resulting from plastic deformation are a recognized crack initiation protocol. Thus, computational results using the stress–life approach are only informative when the degree of plastic straining is negligible, as in high cycle fatigue (HCF), where plastic strains are relatively small.

Stress–life data are usually represented by S–N curves, in which the stress range or stress amplitudes are plotted against the log of the number of cycles to failure, N. The S–N data for body-centered cubic materials generally exhibit an endurance limit, that is, a stress below which the specimens appear to have infinite life. In the case of face-centered cubic and hexagonal-closed-packed metals, a fatigue limit is often defined as a stress corresponding to a specified fatigue life, for example, 10^7 cycles.

Strain–Based

The strain–life method is one of the two classes of empirical approaches for the characterization of fatigue life in structural components. The other approach is the stress–life approach that was discussed in the preceding section. The strain–life model is based on the observation that in many structural components, the response of the material in critical locations, such as notches, is strain or deformation dependent.

Thus, the principal assumption for calculating fatigue life of a component under constant amplitude cyclic loading is that the strain range, $\Delta\varepsilon$, controls fatigue life. In the strain–life approach, the plastic strain is used directly to quantify the structural response to fatigue. However, in the stress–life approach, the plastic strain is not accounted for. The strain-based approach stipulates that at long fatigue lives, beyond the transition life, N_t, the elastic strain dominates the fatigue life, while the plastic strain is negligible with increasing life. In this case, fatigue strength (σ_f'/E) dominates fatigue.

In the case of short fatigue lives, the plastic strain is dominant and fatigue ductility (ε_f') is the controlling fatigue parameter. In general, most engineering structures are designed such that the nominal loads remain elastic. However, due to stress concentrations around notches, localized plasticity is often encountered in engineering structures and components.

One key attribute of the strain–life approach is that it disregards the presence of precracks. Fatigue-life prediction using the strain–life approach requires the following essential inputs: (1) cyclic stress–strain response and strain–life data, (2) stress–strain history obtained from critical locations such as notches, (3) damage counting techniques such as cycle counting, (4) mean stress effect models, and (5) damage summation techniques such as Miner's rule. In the strain–life approach (see **Figure 2**), the relationship between

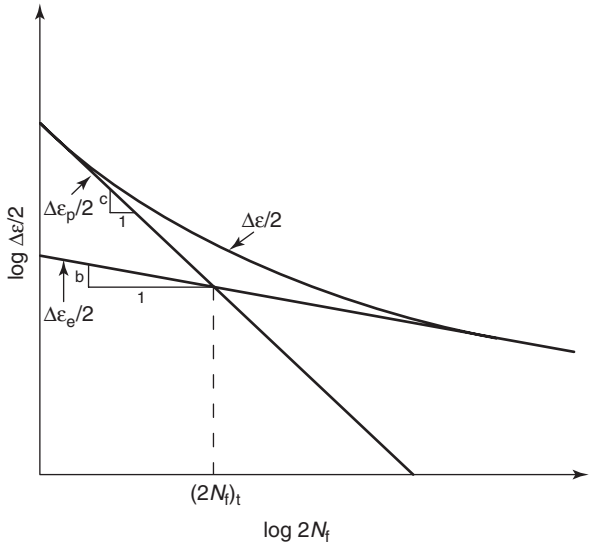

Figure 2 Schematics of the plot of elastic and plastic strain amplitude vs. life showing total strain amplitude.

the total strain amplitude and the number of load reversals to failure is given as

$$\frac{\Delta\varepsilon}{2} = \frac{\sigma'_f}{E}(2N_f)^b + \varepsilon'_f(2N_f)^c \qquad [3]$$

where ε'_f is the fatigue ductility, c is the fatigue ductility exponent, σ'_f is the fatigue strength coefficient, $\Delta\varepsilon$ is the strain amplitude range, $2N_f$ is the number of load reversals to failure, and b is the Basquin's exponent.

Variable-Amplitude Fatigue

Under service conditions, most engineering structures and components are exposed to a host of load spectra. For instance, an aircraft under turbulent conditions may be exposed to unique load spectra, compared to the conditions that are inherent to normal operating scenarios. It is, therefore, important to design for a wide range of loading conditions that can occur under unintended and uncontrollable service conditions.

The extensive literature on fatigue crack growth shows that experimental test data often differ considerably from predictions of crack growth under variable-amplitude loading conditions. Under constant-amplitude loading, the crack growth increment, Δa, is dependent only on the present crack size and the applied load. However, under variable-amplitude loading, the increment of fatigue crack growth is also dependent on the preceding cyclic loading history. In most cases, the interactions that occur under variable-amplitude loading adversely affect the fatigue lives of engineering components and structures.

LEFM Approaches

Fundamentals of Fracture Mechanics

The concept of linear elastic fractures has been applied to the design of engineering structures for nearly five decades. LEFM assumes that the material is isotropic and linearly elastic. Based on these assumptions, the stress field near the crack tip is often calculated using the theory of elasticity and Westergaard stress function. Within the framework of LEFM, crack growth occurs when the crack-tip stress intensity factor, K, exceeds the material fracture toughness, K_{Ic}. LEFM formulations are usually derived for either the plane stress or plane strain conditions associated with the three basic modes of loadings on a cracked body, namely, crack opening, sliding, and tearing.

The formulation of LEFM assumes that under applied loading conditions, crack tips produce a $1/\sqrt{r}$ singularity. The stress fields near a crack tip of an isotropic linear elastic material can be expressed as a product of $1/\sqrt{r}$ and a function of θ with a scaling factor K. The stress intensity factor plane strain formulations for mode I stress fields in Cartesian coordinates are

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{zz} \end{Bmatrix} = \frac{K_I}{\sqrt{2\pi r}}\cos\frac{\theta}{2}\begin{bmatrix} 1-\sin\frac{\theta}{2}\sin\frac{3\theta}{2} \\ 1+\sin\frac{\theta}{2}\sin\frac{3\theta}{2} \\ \sin\frac{\theta}{2}\cos\frac{3\theta}{2} \end{bmatrix} \qquad [4]$$

In practical applications, the magnitude of the maximum stress near the crack tip and whether it exceeds the fracture toughness of a given material is usually of interest to design engineers. Hence, the stress intensity factor, K, which is a function of the loading and geometry, is expressed in terms of the "applied stresses," σ at a location expressed in polar coordinate by $r \to 0$ and $\theta = 0$ (where r and q are cylindrical coordinates of a point with respect to a crack tip). The solution of crack problems using the fracture toughness approach requires: (1) the determination of the crack geometry, (2) the calculation of the stress intensity factor, K, (3) the determination of the fracture toughness, K_C of the material (usually obtained from a material handbook), and (4) ensuring that the failure criteria $K \geqslant K_C$ is satisfied.

Fracture Mechanics and Fatigue

Paris and co-workers proposed that the increment of fatigue crack advance per stress cycle, da/dN, could be related to the range of the stress intensity factor, ΔK, under constant-amplitude cyclic loading. They

formulated the relationship given by

$$\frac{da}{dN} = f(\Delta K, K_{max}) \quad [5]$$

where

$$\Delta K = K_{max} - K_{min} = C(Y\Delta\sigma\sqrt{\pi a})^m \quad [6]$$

where K_{max} and K_{min} are the maximum and minimum stress intensity factors, respectively.

Paris and Erdogan, in their subsequent work, established that the fatigue crack advance per stress cycle could be related to the stress intensity range as follows:

$$\frac{da}{dN} = C(\Delta K)^m \quad [7]$$

where C and m are material constants.

In practical applications, two independent fracture mechanics parameters are required to characterize the state of stress at the evolving crack tip. A combination of any two of the following can be used: K_{max}, K_{min}, ΔK, and R.

Using eqn [3] and assuming a constant Y, both sides of eqn [7] can be integrated:

$$\int_{a_0}^{a_f} \frac{da}{a^{m/2}} = CY^m(\Delta\sigma)^m\pi^{m/2}\int_0^{N_f} dN \quad [8]$$

For $m > 2$:

$$N_f = \frac{2}{(m-2)CY^m(\Delta\sigma)^m\pi^{m/2}}\left[\frac{1}{(a_0)^{(m-2)/2}} - \frac{1}{(a_f)^{(m-2)/2}}\right] \quad [9]$$

For $m = 2$:

$$N_f = \frac{1}{CY^2(\Delta\sigma)^2\pi}\ln\frac{a_f}{a_0} \quad [10]$$

The constants C and m are material parameters that are usually determined experimentally. Typically, m values are in the range of 2–4 for most metals. For intermetallics, m is generally between 6 and 20. However, for ceramics, m can be as high as 100. For cases where Y depends on crack length, the above integrations are usually performed numerically. It is also important to note that the crack growth rate in the Paris regime is weakly sensitive to load ratio and is driven by ΔK.

The initial crack, a_0, can be determined using nondestructive die penetrants inspection, ultrasonics, or X-ray techniques. If no cracks are detected, one can assume a crack length to be at the resolution of the detection system. The critical crack length can be determined from the failure criterion when $K_{max} \rightarrow K_C$.

Fatigue Crack Growth Laws

Numerous fatigue propagation (see **Figure 1**) models have been developed in an attempt to characterize fatigue damage evolution in engineering materials. However, none of these models capture all aspects of the mechanisms of fatigue crack propagation. For instance, the extent of crack growth over a range of stress levels cannot be determined *a priori* from these models. However, these models do highlight the processes associated with the crack-tip opening during crack propagation.

Forsyth and Ryder proposed that fatigue crack extensions were the result of sporadic bursts of brittle and ductile fracture and that the contribution of each mechanism to crack propagation was a function of the ductility of the pertinent material. They also proposed that cracking occurs by necking, which obstructs the material until void coalescence occurs. These voids are usually created during forward cycling.

Fatigue crack propagation models include models by Paris, Forman, Walker, and Elber. The application of these models to practical engineering situations depends on the material type and loading conditions. Paris–Erdogan and Forman's models are used for constant-amplitude loading, while Walker and Elber models are used for variable-amplitude loading. These variable-amplitude loading models incorporate crack-growth retardation or acceleration, and threshold effects.

Paris' model In the mid-ΔK regime, the law shows that the crack advance per stress cycle is related to the stress intensity range. This is given by

$$\frac{da}{dN} = A(\Delta K)^m \quad [11]$$

where A and m are material constants determined experimentally.

Forman's model The Forman's equation is a form of the Paris' law that takes the effect of the applied stress ratio into consideration. It provides an empirical model for fatigue life estimation with mean stress effects. The Forman equation is given by

$$\frac{da}{dN} = \frac{c(\Delta K)^n}{K_f(1-R) - \Delta K} \quad [12]$$

where c is a pre-exponential constant, n is the power law exponent, K_f is a material constant, R is the stress ratio, and ΔK is the stress intensity factor range.

Walker's model The Walker's equation also accounts for stress ratio effects. The Walker and Forman's relationships are equivalent to Paris' law when $R = 0$, and the crack growth rate depends solely

on the ΔK:

$$\frac{da}{dN} = c[K_{max}(1-R)^m]^n \quad [13]$$

where K_{max} is the maximum stress intensity factor, R is the stress ratio, c is a pre-exponential constant, m is the power-law exponent, and n is a material constant.

Multiparameter law The multiparameter law proposes a fatigue life prediction approach using the combined effect of multiple variables on fatigue crack growth. The formulation is based on the multiple regression analysis and involves the representation of crack growth rate, da/dN, as a multiple variable statistical expression. Examples of such variables include stress intensity factor range, ΔK, crack-closure stress intensity factor, K_{cl}, and stress ratio, R.

Elber's model (crack-closure model) Elber formulated a crack-closure technique by modifying Paris' equation to include the dependence of the crack growth rate on the stress ratio. According to Elber, the plastic zone evolves around the crack tip, when the yield stress of the material is exceeded. Subsequently, a wake of plastically deformed material is developed and is encapsulated by the surrounding elastic medium as the crack grows. When the loaded component is being unloaded, the plastically deformed material causes crack surfaces to contact at zero tensile loads.

Elber concluded that crack closure retards fatigue crack growth rate by reducing the stress intensity range, ΔK. He introduced the effective stress intensity range, ΔK_{eff}, for use in Paris' law given by eqn [14]. The resulting modified Paris' law is given by eqn [16]:

$$\Delta K_{eff} = K_{max} - K_{op} = U\Delta K \quad [14]$$

where

$$U = \frac{\Delta K_{eff}}{\Delta K} \quad [15]$$

$$\frac{da}{dN} = D[\Delta K_{eff}]^P \quad [16]$$

where K_{max} is the maximum stress intensity, K_{op} is the stress intensity at which the crack opens, U is the so-called Elber closure ratio, and D is a pre-exponential constant.

Fatigue Fracture Modes

The surface morphologies of fatigue cracks are classified as follows:

- *Transgranular cleavage*. This occurs along defined planes in crystal structures. Cleavage formation is the result of high stress along the three axes where significant deformation occurs at low temperatures. Cleavage morphology is characterized by cleavage steps, feather markings, herringbone structure, and microtwins. Such morphologies are often observed in the near-threshold region.
- *Fatigue striations*. These occur generally in the mid-ΔK and high-ΔK regimes. In general, the striation spacings correspond to the crack growth rate under HCF conditions. However, under low cycle fatigne (LCF) conditions striations are sometimes not definable and hence cannot be correlated with crack growth rates.
- *Combined striations and static fracture modes*. At high-ΔK levels, a combination of fatigue striations and static fracture modes is observed, with the incidence of static modes increasing with increasing ΔK. The static modes often include secondary cracks and ductile dimples that are akin to those observed under monotonic loading. More detailed reports on fatigue fracture modes can be found in the "Further Reading" section.

The Short Crack Problem

Studies of fatigue behavior of short cracks (**Figure 3**) have attracted considerable attention since the total fatigue life of many components may be dominated by the short crack regime. These studies have altered the fatigue limit concept, from a damage limit to a critical propagation limit.

As a result of the successful application of the concepts of LEFM to the growth of long cracks, significant attempts have been made to apply similar methods to modeling the behavior of short cracks. The extent of localized plasticity, however, violates the assumptions of LEFM. This so-called short crack problem was first observed by Pearson. It has been attributed to the synergistic interactions between the effects of microstructure and localized plasticity.

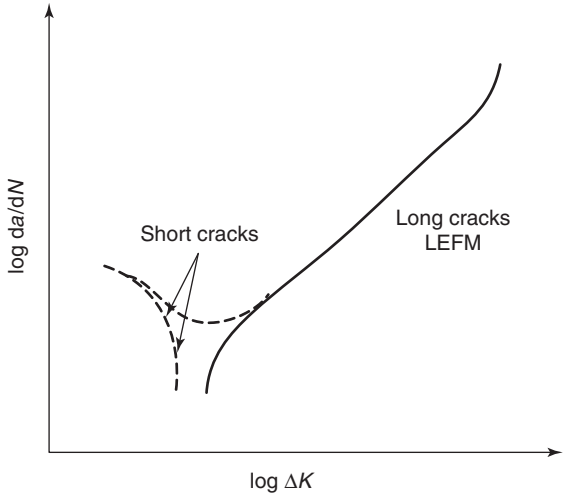

Figure 3 Schematic of typical fatigue crack growth behavior of short and long cracks.

A classification scheme for short cracks was proposed by Ritchie and Lankford by comparing their lengths to appropriate plasticity and microstructural length scales. For instance, mechanically small cracks have lengths that are comparable to their estimated plastic zone sizes; microstructurally short cracks are those that have lengths comparable to the microstructural dimensions of the pertinent continua. Physically, short cracks refer to those cracks that have dimension of $\leqslant 1$ mm.

Three common phenomena have been advanced to explain why small/short cracks can grow at higher growth rates than long cracks. These include: (1) limited crack-closure effects when the small crack has little or no wake ("physically small"), (2) inhomogeneous sampling of the microstructure when the cracks are smaller than relevant microstructural dimensions ("microstructurally small"), and (3) similarity between small crack lengths and the plastic zone size.

Summary and Concluding Remarks

The study of fatigue in mechanical components spans over a century and a half of effort, and is still an ongoing process. A basic understanding of fatigue damage stages currently finds applications in various fields such as biomedical, aerospace, and automotive. With the development of new materials and manufacturing processes, the quest to develop mechanistically based life prediction protocols should become more intense. The short crack problem, which defies the conventional LEFM approach to fatigue modeling, needs further research to develop models that include short crack effects. Recent advances in MEMS technology will provide nano- and microscopic damage information required to develop constitutive-based life prediction protocols.

Mechanical Properties: Plastic Behavior

G Gottstein, M Goerdeler, and G V S S Prasad, Institut für Metallkunde und Metallphysik, Aachen, Germany

Deformation Fundamentals

Crystallographic Slip

Metals are crystalline except for very special conditions. Metals and alloys generally crystallize in a face-centered cubic (f.c.c.), body-centered cubic (b.c.c.), and hexagonal close-packed (h.c.p.) crystal structure. There is unambiguous evidence that metals retain their crystal structure during plastic deformation. This conservation principle of crystal plasticity has serious consequences for the deformation process and material properties. In a noncrystalline material, a macroscopic shape change can be accommodated on an atomistic level by a respective atomic rearrangement. If a macroscopic deformation of a crystal is also copied on an atomistic level, the crystal structure would change (**Figure 1a**); this is however contrary to observation. The crystal structure can be conserved, if the shape change on an atomistic level is accommodated by a displacement along crystallographic planes in multiples of translation vectors of the crystal lattice (**Figure 1b**). This phenomenon is referred to as crystallographic glide (or crystallographic slip). As a result, crystal plasticity proceeds by a structure

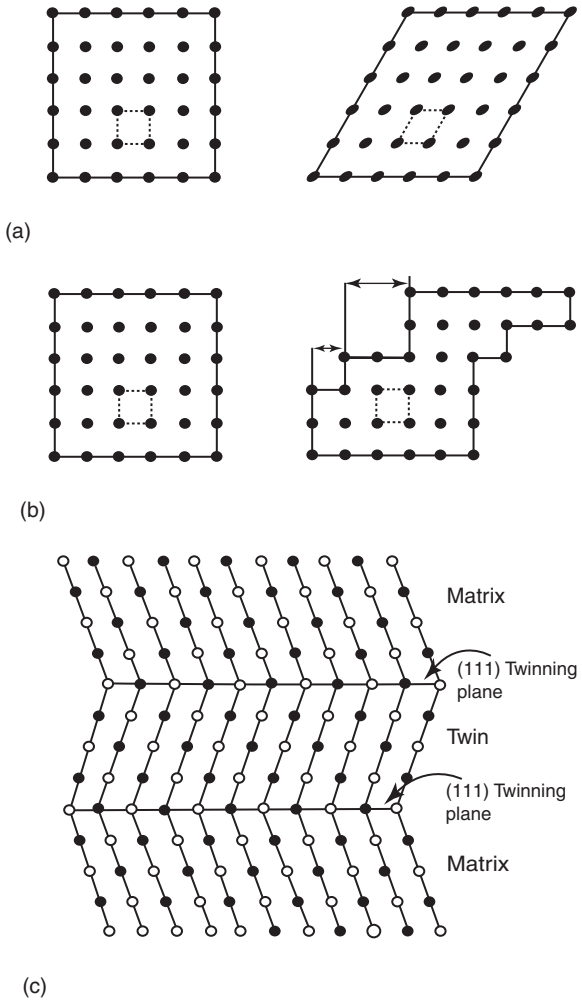

Figure 1 Plastic deformation of crystals (dotted lines = unit cell): (a) with change of crystal structure; (b) by crystallographic glide; and (c) by deformation twinning.

conserving simple shear deformation. In principle, there are an infinite number of planes and translation vectors to accomplish an imposed shape change. Due to energetic reasons, crystallographic glide is confined only to a few crystallographic planes (slip planes) and directions (slip directions), normally the most densely packed planes and directions in a crystal. A slip plane and a slip direction constitute a slip system and the most prominent slip systems of the three major crystal structures of metals are given in **Table 1**. The mechanism of crystallographic glide is related to the motion of crystal dislocations. The glide plane of a dislocation and the direction of its Burgers vector correspond to the slip plane and slip direction, respectively. On an atomistic level, therefore, plastic deformation of a metal requires the generation and motion of crystal dislocations.

Dislocations are crystal defects and, therefore, cause a distortion of the atomic arrangement, which manifests itself into a long-range stress field. Via their stress field, dislocations interact with each other. This constitutes a glide resistance, which is macroscopically felt as a yield stress and eventually causes immobilization of moving dislocations. The traveling distance (slip length) of a moving dislocation is normally much smaller than the macroscopic dimension of the deformed body; therefore, dislocations are stored in the crystal and the dislocation density grows with progressing deformation which in turn increases dislocation interaction and thus the flow stress. The relation between flow stress σ and dislocation density ρ can be represented by the Taylor equation

$$\sigma = \alpha M G \boldsymbol{b} \sqrt{\rho} \qquad [1]$$

where the dislocation density $\rho(\mathrm{m}^{-2})$ is defined as the total dislocation line length per unit volume – typically $10^{10}\mathrm{m}^{-2}$ for annealed and $10^{16}\mathrm{m}^{-2}$ for heavily deformed metals, $\boldsymbol{b}$ is the Burgers vector (slip vector), G is the shear modulus, and M is the Taylor factor which relates the applied stress to the shear stress in the glide system and depends on crystallographic texture (see below). Typically, $M \sim 3$, and the geometrical constant $\alpha \sim 0.5$.

Any change in the glide resistance of the moving dislocations will affect the flow stress. This is the reason for work hardening (increasing dislocation density), other strengthening mechanisms (grain size, solute atoms, particles, precipitates, etc.), and softening by recovery and recrystallization (decreasing dislocation density). It is important to note that the macroscopic deformation behavior can be related to the microscopic properties of the crystal dislocations. The force $\boldsymbol{K}$ on a dislocation due to a stress σ applied to a crystal is given by the Peach–Koehler equation

$$\boldsymbol{K} = \sigma \boldsymbol{b} \times \boldsymbol{s} \qquad [2a]$$

or the magnitude of the force K in the slip system due to the resolved shear stress τ

$$K = \tau \boldsymbol{b} \qquad [2b]$$

The imposed strain rate is reflected by the dislocation velocity through the Orowan equation

$$\dot{\varepsilon} = \rho_{\mathrm{m}} \boldsymbol{b} v \qquad [3]$$

where ρ_{m} is the density of the mobile dislocations moving with an average velocity v. The velocity, of course, depends on the applied stress σ. One can imagine the dislocations as rigid rods, moving with velocity v due to a force K, and this process is experienced macroscopically as a plastic deformation with strain rate $\dot{\varepsilon}$ at a flow stress σ.

Table 1a Slip systems of the major metallic crystal structures

Crystal structure	*Slip plane*	*Slip direction*	*Number of nonparallel planes*	*Slip directions per plane*	*Number of slip systems*
f.c.c.	{1 1 1}	$\langle 1\,\bar{1}\,0\rangle$	4	3	$12 = (4 \times 3)$
	{1 1 0}	$\langle \bar{1}\,1\,1\rangle$	6	2	$12 = (6 \times 2)$

Twinning

While crystallographic glide by dislocation slip is the dominating deformation mechanism in metals, deformation twinning is also observed to accommodate a plastic strain, particularly at low temperatures in metals and many intermetallics. A deformation twin has an atomic arrangement that is the mirror image of the parent crystal. Due to the mirror symmetry, the crystallographic structure is conserved, but the crystal has a different shape (**Figure 1c**). The generation of a twin corresponds to a simple shear deformation by a displacement parallel to the twinning plane (mirror plane). In contrast to the dislocation glide, the shear strain γ is constant for a given crystal structure, for example, $\gamma = \sqrt{2}/2$ for cubic crystals. Twinning plane and displacement direction constitute a twin system in analogy to a slip system (**Table 1**).

Since for a given shear strain, the atomic displacement increases with growing distance from the twinning plane (**Figure 1c**), twins are usually thin, and their formation requires high stresses which are available only at low temperatures because the material strength increases with decreasing temperature. Deformation twinning is liable to occur if the flow stress is high and the twin boundary energy (approximately half of the stacking fault energy (SFE)) is low. The f.c.c. metals and alloys with low SFE undergo deformation twinning, such as silver at room temperature or copper at liquid nitrogen temperature. As the SFE decreases upon alloying, most alloys are prone to twinning during low-temperature deformation, for example, copper alloys, such as α brass (Cu–Zn) where twinning constitutes the major low-temperature deformation mechanism. Deformation twinning is most prominent in materials where dislocation slip cannot fully accommodate the imposed strain, for example, in h.c.p. metals and alloys with $c/a > 1.63$ owing to their low number of crystallographic slip systems. For an arbitrary deformation, a crystal needs to activate five independent slip systems to satisfy the five independent elements of the strain tensor. (A slip system of a set is independent, if its deformation cannot be accomplished by the other systems of the set.)

In h.c.p. metals with $c/a > 1.63$ (e.g., zinc), there is only slip on the basal plane and therefore, there are only two independent slip systems. This is sufficient to deform single crystals to very large strains. However, the individual grains of a polycrystal have to deform compatibly with the adjacent grains to avoid occurrence of holes or overlap. This can be accomplished only if the individual grains can undergo an arbitrary shape change at their boundaries, for which five independent slip systems are required. Therefore, polycrystals of zinc, for example, have to activate mechanical twinning for deformation. Owing to the high stresses and the less perfect adaptation to the shape change of neighboring grains in a polycrystal by twinning, the strain to fracture is smaller than in material deforming only by dislocation slip. Also, due to crystallographic effects, h.c.p. metals and alloys with $1.63 \leqslant c/a \leqslant 1.73$ cannot deform to a large degree by twinning, since twinning ceases to comply with the imposed shape change due to crystal reorientation and the fact that only one sense of twinning shear is crystallographically possible (the opposite shear $-\gamma$ does not generate a twin orientation). This is the reason why polycrystalline h.c.p. magnesium ($c/a = 1.63$) and its alloys are not ductile at ambient temperature. Note that hexagonal metals such as titanium, beryllium, or zirconium are very ductile even at low temperatures since their ratio $c/a < 1.63$, which favors nonbasal slip and thus, provides sufficient independent slip systems.

Deformation Microstructure

When gliding dislocations become immobile, they are stored in the crystal. The spatial distribution of these stored dislocations can occur at random or in distinct patterns. Most metals and alloys reveal nonstatistical dislocation distributions. Typically, dislocations arrange in cellular patterns, that is, in high dislocation density (cell) walls, which enclose volumes (cells) of considerably lower dislocation densities. For most commercial cold forming processes – such as rolling, the cellular arrangements are superimposed by deformation inhomogeneities, which typically have a band-like shape and can assume macroscopic dimensions to be recognized by the bare eye. In rolled materials, besides microscopic microbands, which appear like distinctly framed elongated dislocation cells under the microscope, there are two major types of deformation inhomogeneities namely, deformation bands and shear bands which can best be recognized in micrographs of the lateral surface. Deformation bands are elongated microstructural features that extend parallel to the rolling direction and that gradually accommodate a large misorientation to the matrix. Shear bands are deformation inhomogeneities, which extend under an angle of 30–35° to the rolling direction. Copper-type shear bands comprise clusters of elongated cells, which are confined to grain dimensions. In contrast, brass-type shear bands have (macroscopic) dimensions comparable to the sample thickness. Their internal structure is composed of very small granular features, typically globular grains of nanometer size. The origin and structure of shear bands are far from being understood, but they are generally assumed to be due to local softening (like texture softening) or enforced macroscopic shear in case of obstructed dislocation glide. Brass-type shear bands occur typically in alloys with low SFE (e.g., alpha brass). Copper-type shear bands are formed during cold rolling of f.c.c. metals and alloys with higher SFE.

Hardening Behavior

The mechanical properties of a material are typically measured in a uniaxial tension test, where the force is recorded to elongate a cylindrical specimen at constant speed. The force F divided by the initial cross section q_0 defines the engineering stress, and the length change Δl divided by the original length l_0 defines the engineering strain. If force and elongation are normalized by the instantaneous cross section q or length of the specimen l, they are referred to as true stress and true strain, respectively. The hardening curve is the dependence of the true stress on true strain. The true stress at a given strain is called the flow stress.

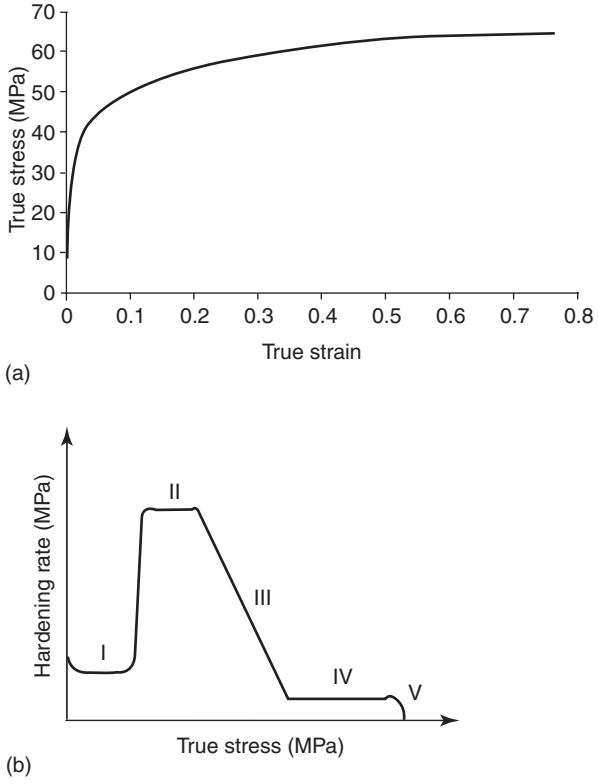

Figure 2 (a) True stress–true strain curve of an Al–1%Mn alloy (AA3103), measured at 300°C and a constant true strain rate of 0.1 s^{-1}; (b) $d\sigma/d\varepsilon$ vs. σ.

The storage of dislocations during deformation leads to an increased glide resistance for moving dislocations which is experienced as an increased flow stress with increasing strain (**Figure 2a**). The rise of stress σ with strain ε, is referred to as strain hardening or work hardening, and the slope of the hardening curve $d\sigma/d\varepsilon$ is the work-hardening coefficient or hardening rate. It is conventionally measured in uniaxial tension or compression tests. While the hardening curves of different materials or at deformation conditions vary considerably, there is a characteristic shape of the engineering stress–strain curve, namely after yielding a curve with a single maximum, although the strength level and hardening rate can be very different.

Of particular interest for forming processes is the hardening behavior for large strain deformation, for example, sheet rolling. A typical true stress–strain behavior for large strain deformation exhibits, after yielding, some transient with high but decreasing hardening rate until a low but constant rate is attained (**Figure 2b**), that is, the stress increases linearly with strain, and eventually a steady state (constant flow stress) is attained. Correspondingly, the

large strain-hardening curve exhibits five distinct stages:

1. Right after yielding, transition to athermal hardening (observed only in single crystals oriented for single slip);
2. Athermal hardening with constant high hardening rate $d\sigma/d\varepsilon \approx G/30$ (extended range only in single crystals at low temperatures);
3. Dynamic recovery range, hardening rate decreasing linearly with stress;
4. Large strain hardening with constant low hardening rate; and
5. Transition to steady state or unstable microstructure, usually not attained during cold deformation.

The important stages of the flow curves of commercial metals and alloys for industrial forming processes are stages 3 and 4. Their extent and level depends on material composition and processing and, thus, is history dependent! The hardening behavior reflects the glide resistance of the moving dislocations and, therefore, depends on the dislocation structure S, which is strongly dependent on processing history, that is, at strain rate $\dot{\varepsilon}$ and temperature T:

$$\sigma = \sigma(\dot{\varepsilon}, T, S) \qquad [4]$$

For this particular reason, the macroscopic strain is not a state parameter and, therefore, a prediction of flow stress as an empirical function of strain $\sigma(\varepsilon)$ is physically wrong although, due to simplicity, it has been a longstanding engineering practice.

Texture

A simple shear deformation is always accompanied by a rigid-body rotation, because the displacement gradient tensor is not symmetrical. Since plastic deformation in metallic materials proceeds by simple shear mechanisms (dislocation glide, mechanical twinning), the grains in a polycrystal change their crystallographic orientation during deformation – except for a few orientations which are stable under the imposed deformation conditions – and rotate toward the stable orientations. For a given forming process, such as rolling, wire drawing, or extrusion typical orientation distributions, that is, crystallographic textures develop, depending on deformation mechanism. An orientation distribution is most adequately represented in orientation space, where each orientation is represented by one point. The orientation distribution after large strain deformation is confined to a small volume in orientation space. For instance, the rolling texture of f.c.c. materials appears like a tube in orientation space (**Figure 3**) and can essentially be understood as consisting of only a few (ideal) orientations with some scatter. Crystallographic textures cause anisotropic mechanical properties, which make themselves felt during thermomechanical processing, metal forming, and in-service behavior.

Softening: Recovery and Recrystallization

During plastic deformation, dislocations are introduced to accommodate the imposed shape change. Dislocations, however, are crystal defects which are

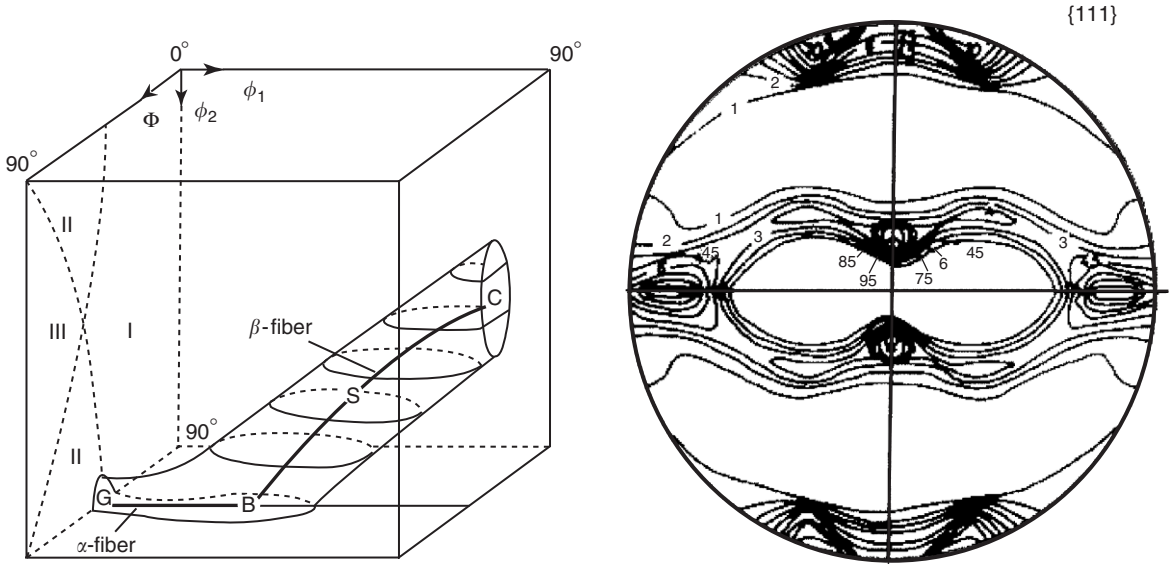

Figure 3 Rolling texture of pure copper: three-dimensional representation in orientation (Euler) space, {1 1 1} polefigure.

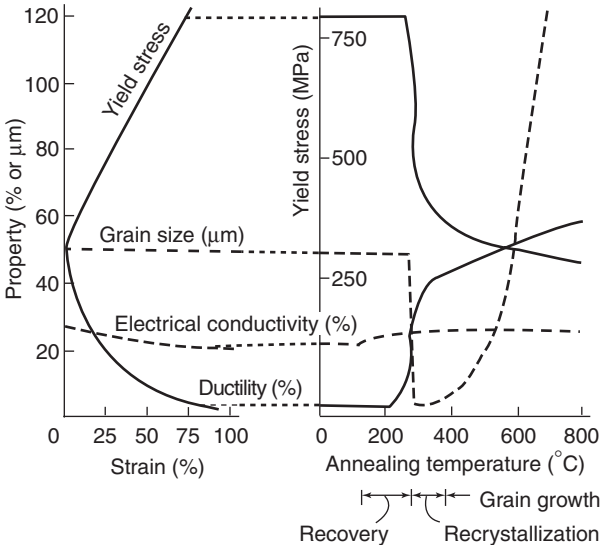

Figure 4 The effect of cold forming and annealing on the properties of a Cu–35%Zn alloy.

not stable in thermodynamic equilibrium; thus, the crystal strives to remove them. At low temperatures, the dislocation arrangement is in mechanical equilibrium and, therefore, stable. At elevated temperatures, however, thermally activated processes destabilize the dislocation structure and substantially change or even remove the deformation-induced microstructure which drastically affects microstructure, texture, and mechanical properties (**Figure 4**). There are two major restoration processes: recovery and recrystallization. They are termed static processes if they occur subsequent to deformation during annealing, or are referred to as dynamic recovery and dynamic recrystallization if they proceed during deformation. Dynamic recovery is also strain induced and is, therefore, an integral part of the strain-hardening process at any temperature. Dynamic recrystallization is an important phenomenon during hot working (see below) and liable to occur for $T > 0.5T_m$ (T_m – melting temperature). While recovery essentially consists of a dislocation rearrangement in the as-deformed structure, a completely new microstructure is formed atom by atom during recrystallization. Recrystallization proceeds by nucleation of virtually dislocation-free grains, which grow at the expense of the deformed matrix. The moving grain boundaries of the expanding nuclei are capable of absorbing the deformation-induced dislocations so that finally an almost dislocation-free granular structure is generated. Typical dislocation densities of recrystallized polycrystals are $10^{10}\,m^{-2}$ compared to up to $10^{16}\,m^{-2}$ for heavily deformed materials.

Recovery and recrystallization have different kinetics and different impact on properties. Invariably either process causes a softening of the material, and fully recovered and fully recrystallized materials have comparable yield stresses. The texture development is very different, however. The deformation texture is essentially retained during recovery or slightly increased in sharpness. During recrystallization, a completely new and different texture is generated. The recrystallization texture can be very sharp, like the cube texture in rolled and annealed aluminum, which gives rise to strong anisotropy during subsequent forming of the sheet. Typically, specific types of deformation textures, as shown in **Figure 3** for rolling, transform to specific recrystallization textures in f.c.c. and b.c.c. materials. However, small changes in chemical composition or processing history can totally alter the recrystallization texture, even if the deformation texture appears unchanged. Advanced codes for recrystallization structure and texture prediction with high spatial and temporal resolution (e.g., cellular automata or Monte Carlo simulation approaches) are now available which can be interfaced to FEM or superimposed to real deformation microstructures to account for spatial variation of the microstructure.

At temperatures above $0.5T_m$, recrystallization can also occur concurrently with deformation. This is referred to as dynamic recrystallization and makes itself felt by either a single-peak or multiple-peak flow stress behavior. A typical flow curve of a dynamically recrystallizing material and its associated microstructure are shown in **Figure 5**. Dynamic recrystallization typically occurs during the hot working of low SFE materials. Important examples are austenitic steels and copper alloys. It limits the flow stress and therefore, keeps hot working forces low and at the same time, it improves ductility (strain to fracture). The dynamically recrystallized grain size depends only on the flow stress and thus can be controlled by the strain rate and deformation temperature.

Modeling

For engineering practice, the mechanical behavior of materials must be known (e.g., the hardening curve). Most commonly, it is measured and fit to empirical functions. These functions, however, do not have any predictive power and cannot be used beyond the tested limits. For predictions of mechanical properties with the change of materials chemistry or processing conditions, microstructural models have to be used, since microstructure defines the state variables of materials properties.

Advanced work-hardening models are based on the dislocation theory. These models can either be statistical dislocation density-based models or dislocation

dynamic models (**Figure 6a**). Statistical models follow a common scheme, namely, the formulation of a structure evolution equation ($d\rho/d\varepsilon$) and a kinetic equation of state ($\sigma = f(\rho, T, \dot{\varepsilon})$) to relate the structure with the glide resistance. These relations are formulated as differential equations and hence can account for the transient microstructure evolution. The total change of dislocation density $d\rho$ in a strain increment $d\varepsilon$ reflects the structure evolution due to production of dislocations $d\rho^+$ and dynamic recovery (e.g., annihilation, dipole formation, lock formation) $d\rho^-$:

$$d\rho = d\rho^+ - d\rho^- = (f_1 - f_2)\, d\varepsilon \qquad [5]$$

The functions f_1 and f_2 have to be determined from the dislocation theory. They depend on the particular processes considered, and their actual values vary with the dislocation structure. The major problem is a proper incorporation of dislocation patterning in the theory. It is a common conception that the dislocations are arranged in a cell structure (**Figure 6b**), but different approaches have been proposed for the dominant stress and strain rate controlling processes. Due to the nonhomogeneous dislocation distribution, the flow stress will be a volume (V) weighted average of the flow stress in cell walls σ_w and cell interiors σ_i

$$\sigma = \sigma_w V_w + \sigma_i V_i \qquad [6]$$

In a dislocation dynamics model, the dislocations are modeled as line defects in a continuum and represented by their stress field. Since the continuum theory of dislocations is well established, the equations of motion can be formulated and the dislocation arrangement can be calculated from eqns [2] and [3]. However, the fundamental approach and the applicability to arbitrary deformation conditions have to be paid for by a substantial investment in computer power and computation time.

Owing to the long-range stress fields and the self-interaction of curved dislocations in three-dimensional dislocation dynamics, the problem becomes intractable for today's and tomorrow's high-power computers. Simulations with two-dimensional geometry are

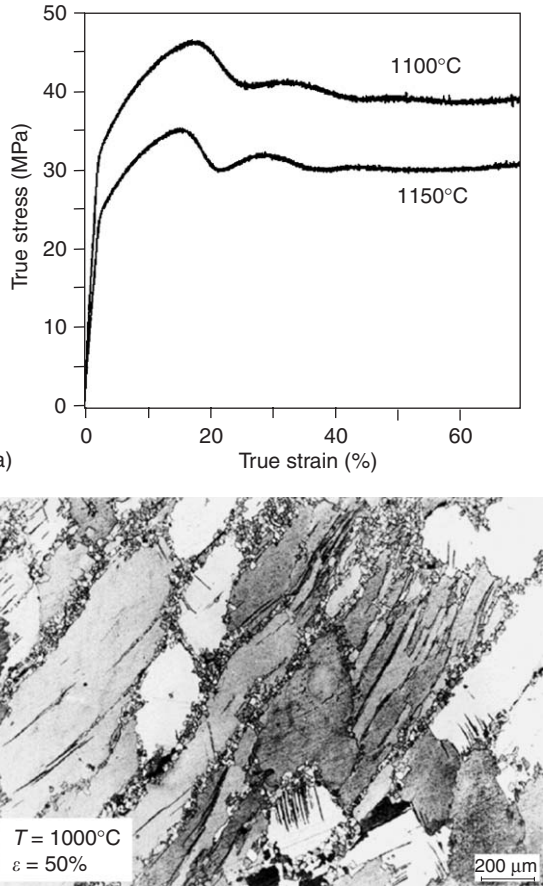

Figure 5 (a) Stress–strain curves of dynamically recrystallizing material (alloy 800 H); (b) the first recrystallized grains form predominantly at grain boundaries (necklace structure in Ni_3Al).

possible and have been performed but can only be applied to problems of two-dimensional geometry such as thin films. For bulk deformation, two-dimensional dislocation dynamics are of limited use.

Applications

Plasticity is the main prerequisite for metal forming, for example, rolling, forging, wire drawing, to produce semi-finished products and for the final shaping of parts, for example, by sheet forming. The excellent formability of metals is one of the reasons for their extensive industrial use. During the classical processing route of a metallic part, from the liquid state to the finished product, the material undergoes multiple deformation and heat treatment cycles. For example, consider the fabrication of an aluminum (or steel) can from a sheet (**Figure 7**).

After casting and homogenization the material is hot rolled, cold rolled, and annealed before the final part is produced from the sheet by deep drawing. While the material undergoes a shape change and experiences work hardening during rolling, it softens during interstand times and during back annealing. Since the microstructure changes during each processing step and as the microstructure determines the properties of the final part, processing has to be fine-tuned to meet terminal material specifications. These processes and the respective microstructural evolution can now be simulated by advanced computer codes.

Nomenclature

$\boldsymbol{b}$	Burgers vector
F	external force
G	shear modulus
K	Peach–Koehler force (scalar)
$\boldsymbol{K}$	Peach–Koehler force (vector)
l	instantaneous length of the specimen
l_0	original length of the specimen
M	Taylor factor
q	instantaneous cross section of the specimen
q_0	initial cross section of the specimen
$\boldsymbol{s}$	dislocation line vector
S	dislocation structure
T	temperature
T_m	melting point
V_i	volume fraction of the cell interiors
V_w	volume fraction of the cell walls
α	geometric constant
γ	shear strain
Δl	change in length of the specimen
ε	strain
$\dot{\varepsilon}$	strain rate
v	average velocity of a dislocation
ρ	dislocation density
ρ_m	mobile dislocation density
σ	stress
σ_i	flow stress in the cell interiors
σ_w	flow stress in the cell walls
τ	shear stress

Mechanical Properties: Strengthening Mechanisms in Metals

A C Lund and C A Schuh, Massachusetts Institute of Technology, Cambridge, MA, USA

Introduction

The strength of metallic materials depends in considerable detail upon the structure at many length scales, from the fundamental atomic interactions at $\sim 10^{-10}$ m to interaction among macroscopic structural components as large as $\sim 10^{-3}$ m. The mechanisms responsible for strengthening metals have been the subject of considerable study for many decades, and are relatively well understood for traditional microstructural length scales. At low temperatures, the strength of crystalline metals is in large part governed by the interaction of dislocations with one another and with other features of the microstructure. Therefore, the main focus of this article is on these interactions, and the general scaling laws that relate these microscopic processes with macroscopic measurements of strength. In metals with microstructural components large enough to be regarded as continua, additional strength can be derived by sharing of the applied load between phases, which is discussed briefly. Finally, the limitations of these various strengthening mechanisms are discussed for cases where the temperature is high or the characteristic microstructural length scale is very fine.

Low-Temperature Dislocation-Based Strengthening Mechanisms

In crystalline metals, strength and other mechanical properties are governed by the prevalence and mobility of defects in the crystal structure. At low temperatures (i.e., below about one-third of the melting point), the most important defects in this regard are dislocations, which can be regarded as the "carriers" of plastic strain. Hence, the primary goal of most forms of metal strengthening is to regulate the movement of dislocations, which is generally accomplished through the introduction of obstacles. The four main strengthening mechanisms at ambient temperature, that is, work hardening, solid solution strengthening, particle hardening, and grain-boundary strengthening, are all variations upon this theme. Each of these mechanisms has been studied and modeled in considerable detail, and the reader is referred to the "Further reading" section for more exhaustive discussions. Here these concepts are explored within the framework of a relatively general scaling law that predicts the shear strength increment $\Delta\tau$ gained by incorporating obstacles of spacing L in the structure:

$$\Delta\tau \propto \frac{1}{L} \qquad [1]$$

This additional stress is required to allow dislocations to bypass the obstacles, and the proportionality constant depends in large part upon whether dislocations can cut through the obstacles ("soft" obstacles), or must bypass them by bowing ("hard" obstacles).

In what follows, how eqn [1] applies for the important mechanisms listed above is discussed broadly, assuming pure metals or dilute alloys, and neglecting details such as the crystallography of defects or the underlying crystal structure of the base metal. Furthermore, the homogeneous nucleation of dislocations is not considered to contribute to strength, since most engineering metals and alloys already contain an appreciable density of dislocations ($\sim 10^{10}$–10^{14} m^{-2}) prior to plastic flow.

Work Hardening

The principle underlying work hardening is that plastic flow induces structural changes which make subsequent plastic flow ever more difficult; the more it is deformed, the stronger a metal becomes. During plastic flow of a polycrystalline metal, work is dissipated by the motion and interaction of dislocations. Strain energy is stored through a net increase in dislocation line length through processes such as bowing around various obstacles and pinning points, and the sequential emission of new dislocations from, for example, Frank–Read sources.

As dislocations entangle, they can form sessile kinks or jogs which act as pinning points along the dislocation line, such that the obstacle spacing L is proportional to $\rho^{-1/2}$, with ρ the dislocation density. When this scaling is introduced into eqn [1], it yields the classical parabolic-hardening law used widely for polycrystalline metals:

$$\Delta\tau = \alpha\mu b\sqrt{\rho} \qquad [2]$$

where the constants α, μ, and b have now been introduced. In this formulation μ is the shear modulus, b is the magnitude of the Burger's vector, and α is a temperature-dependent proportionality constant ~ 0.2–1 in the athermal limit.

Equation [2] has been experimentally validated for many metals; an example of data compiled for copper is shown in **Figure 1**. Perhaps counter-intuitively, the

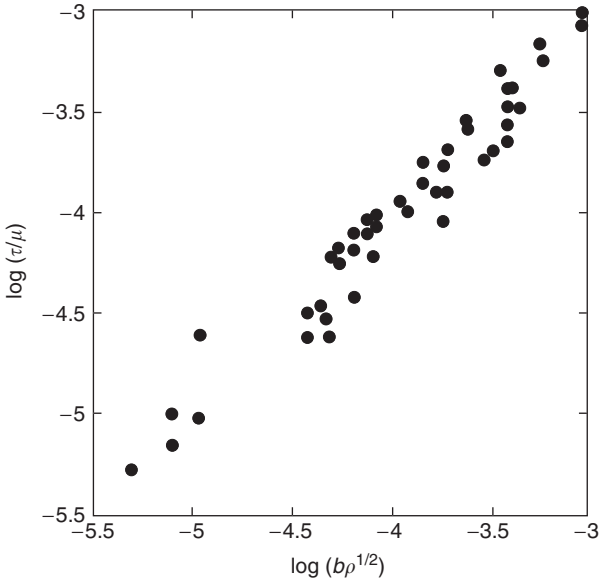

Figure 1 Data relating the shear strength of copper (normalized by the shear modulus μ) to the square root of dislocation density (normalized by the Burger's vector magnitude). The dislocation density has been obtained by chemical etching and optical microscopy on planar cross sections. (Data from Mecking H and Kocks UF (1981) Kinetics of flow and strain hardening. *Acta Metallurgica* 29: 1865–1875.)

nature of the dislocation distribution does not affect the general relevance of eqn [2]. For example, in some materials dislocations self-assemble into inhomogeneous spatial configurations. In such cases, it is possible to parametrize, for example, the average dislocation cell size, and use it to produce additional scaling laws; these ultimately reduce to either eqn [2] or other very similar relationships.

Although eqn [2] is surprisingly general in its applicability, it is important to note that $\Delta\tau$ from work hardening is fundamentally limited by the maximum value of ρ that can be sustained in a given metal. With large amounts of plastic strain, the dislocation density can increase by orders of magnitude before saturating at a temperature- and material-dependent value as high as $10^{16}\,\mathrm{m}^{-2}$. This saturation is a consequence of "dynamic recovery," wherein the production of new dislocation line length is offset by annihilation processes which become more active with increasing dislocation density. Nonetheless, strain hardening can increase a metal's strength by orders of magnitude compared with the stress required to move an isolated dislocation.

A topic of current research interest is the effect of nonuniform deformation on strain-hardening behavior, in which plastic strain gradients are necessitated by the test or microstructural geometry. Plastic strain gradients require the presence of "geometrically necessary" dislocations to accommodate them, so it has been speculated that higher total dislocation densities will result whenever such gradients exist. These effects become increasingly important at fine length scales, for example, in very small specimens or thin films, nanoindentation experiments, or for metals with fine scale microstructural features; in these cases, the strain gradients resulting from nonuniform deformation are steeper owing to the reduced dimensionality. In general, strain gradient effects are believed to occur in metals at length scales below $\sim 100\,\mu\mathrm{m}$.

Solid Solution Strengthening

For pure metals, the addition of a low concentration of a second component in solution can provide soft barriers to the motion of dislocations through the crystal. Solutes interact with dislocations through two main effects. First, solute atoms change the local values of elastic constants, which in turn change the line energy of a dislocation. Solute atoms which stiffen the matrix repel dislocations, while those which make the matrix more compliant attract them. Second, solute atoms added to a pure metal create distortions in the crystalline lattice, and the associated stress fields can interact with dislocations; again the interaction can be either attractive or repulsive, depending upon the size mismatch of the solute atoms with respect to the matrix and their position with respect to the dislocation core. Whether the solutes repel or attract dislocations, the net result is strengthening, as additional stress is required to force a dislocation to approach or depart, respectively, the vicinity of a solute atom.

Within a slip plane, the density of solute atoms is given by their concentration, c, and the spacing between solutes goes as $b \times c^{-1/2}$. Therefore, eqn [1] takes a parabolic form with respect to concentration:

$$\Delta\tau = \beta\mu b\,\frac{\sqrt{c}}{b} \qquad [3]$$

where the proportionality constant β depends upon how strongly the solute atoms interact with dislocations. In the case of substitutional alloying additions, the stress field around solute atoms is approximately spherical, which leads to rather mild interactions and values of β much less than unity. For some crystal symmetries, the strain field associated with an interstitial solute can be nonspherical, providing much harder obstacles to dislocation motion, and values of β near unity. A common important example in this regard is the interstitial sites in a body-centered cubic lattice, where the distortion accompanying a solute is tetragonal. Models are available to predict β with reasonable accuracy in each of these cases. **Figure 2** shows some classical data sets for substitutional and

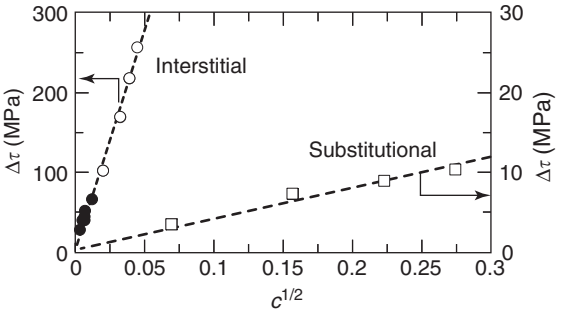

Figure 2 Classic examples of the concentration dependence of the solid solution strength increment $\Delta\tau$. Solutes with symmetric strain fields such as the substitutional case of Cu dissolved in Al (□) generally have a modest strengthening effect, while asymmetric strain fields associated with, for example, interstitial C in Fe (●) or N in Nb (○) produce more significant strengthening. (Data are from Wert CA (1950) *Journal of Metals* 188: 1242–1244, Evans PRV (1962) *Journal of the Less-Common Metals* 4: 78–91, and Koppenaal TJ and Fine ME (1962) *Transactions of the Metallurgical Society of AIME* 224: 347–353.)

interstitial alloying, where the parabolic form of eqn [3] is validated and the relative strengths of the two obstacle types are apparent.

Particle Strengthening

In the same vein as solid solution atoms, fine dispersed particles can also serve as dislocation pinning points. When second-phase particles are present by virtue of nucleation and growth processes, the metal is said to be "precipitation strengthened," whereas the extrinsic incorporation of fine particles is generally referred to as "dispersion strengthening." In the simplest case these particles can be assumed to be "hard" obstacles to dislocation motion, and their strengthening effect is based upon the spacing of the particles, L. Unlike solute atoms or dislocation locks, particles have finite sizes that can be of similar order to the interparticle spacing, λ. Therefore, the effective obstacle spacing is given by $L \approx (\lambda - 2r)$, where r is the average radius of the particles. For small particles, the spacing of obstacles in the slip plane of a dislocation goes roughly as $v_f^{1/2} r^{-1}$, so the familiar parabolic strengthening law is recovered using eqn [1]:

$$\Delta\tau = \gamma\mu b \frac{\sqrt{v_f}}{r} \qquad [4]$$

The proportionality constant γ is close to unity for hard particles, for example, for dispersed ceramic particulates or very large precipitated particles in a metallic matrix.

In many cases the particulate obstacles are, at least in principle, capable of being sheared by the passage of a dislocation. In these cases, the obstacles are said to be "soft," and the energy penalty associated with shearing them is the source of strengthening. Some notable examples by which such soft obstacles can promote strengthening are as follows:

1. Coherent particles with a lattice parameter mismatch to the matrix phase create strain fields that interact with dislocations in a manner similar to that described above for solid solution strengthening.
2. The shearing of particles creates additional interfacial area and thereby increases the total interfacial energy of the system.
3. In "order strengthening," an incident dislocation creates an antiphase boundary (with an attendant interfacial energy term) in a chemically ordered particle.
4. The difference in elastic modulus between particle and matrix changes the dislocation energy as it traverses the particle, providing an obstacle to either its entrance or exit from the particle.

All of these "soft" obstacle strengthening mechanisms, as well as some more obscure ones, tend to obey the scaling law of eqn [4], with different scaling parameters γ that can also be functions of the particle size r. However, it should be noted that some derivations for case (2) can yield a linear volume fraction dependence.

Apart from the volume fraction dependence of particle strengthening described in detail above, the absolute magnitude of the average particle dimension also has a measurable impact on the strength required to pass a dislocation. Larger average particle sizes promote strengthening by creating "harder" obstacles, because a passing dislocation must traverse a larger area of precipitate, requiring more energy via mechanisms (2) and (3) above, while the stress field of a coherent particle also increases with size and enhances strength via mechanism (1). However, a larger average particle size necessitates a proportionally wider interparticle spacing if their volume fraction is held constant; this effect leads to a weakening via eqn [1]. Therefore, for a constant v_f, increasing the average particle size gives rise to a "cutting-to-bowing" transition, with the material strength first increasing and then decreasing with average particle size. These two regimes correspond to shearing of soft obstacles for small particle sizes (cutting), and pinning of dislocations at hard obstacles for larger particle sizes (bowing). An example of such a transition is shown for the technologically relevant nickel–aluminum system in **Figure 3**, in which the particles are precipitates of the Ni_3Al phase.

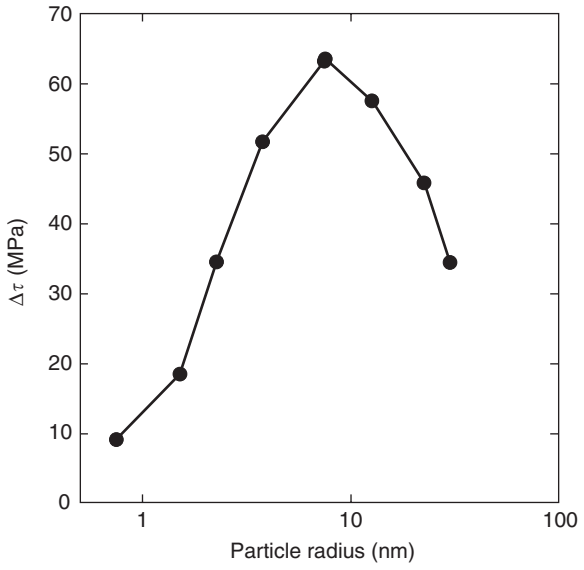

Figure 3 The strengthening of Ni due to the presence of a constant volume fraction dispersion of fine Ni_3Al precipitates with a given average radius. Over the range of radii <10 nm, increasing the precipitate size promotes strengthening, but beyond this range causes weakening. These regimes correspond to the "cutting" and "bowing" mechanisms, respectively. (Data from Brown LM and Ham RK (1971) Dislocation–particle interactions. In: Kelly A and Nicholson RB (eds.) *Strengthening Methods in Crystals*, pp. 12–135. London: Applied Science Publishers.)

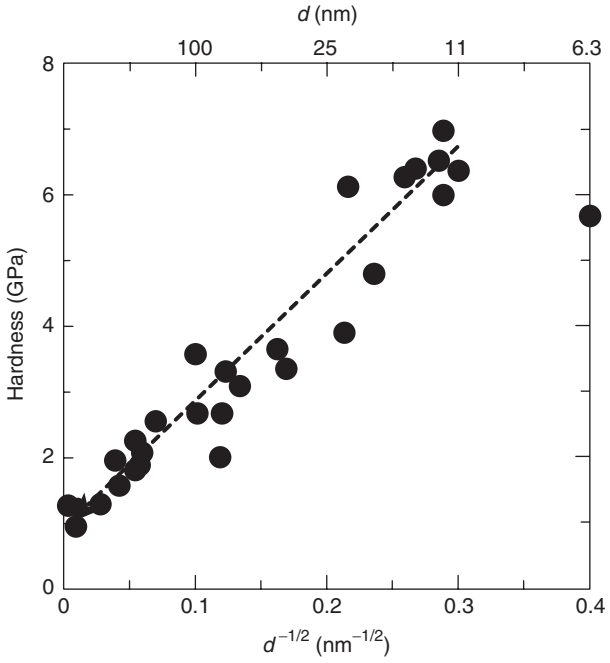

Figure 4 A typical "Hall–Petch" plot showing the hardness (which is proportional to the yield stress) of nickel as a function of the reciprocal square-root grain size, *d*. (Data are collected in Schuh CA *et al.* (2002) *Scripta Materialia* 46: 735–740, from various other sources.)

Grain-Boundary Strengthening

Because the adjacent crystals at a grain boundary have a misorientation between both the slip plane traces and the slip directions, dislocations cannot, in general, transmit through grain boundaries without an additional increment of applied strain energy. For more extreme misorientations, the stress required for transmission can be higher than that required to activate a new dislocation source in the adjacent grain. In either case, dislocations on a common slip plane in the first grain tend to pile up at the grain boundary, until the stress at the head of the pileup becomes large enough to activate slip in the second grain. In this manner, grain boundaries present very "hard" obstacles to dislocation motion, but they are not point obstacles in the same vein as solute atoms or particles. Therefore, the scaling law of eqn [1] does not simply apply to the case of boundary strengthening, although a similar parabolic hardening law does emerge from analysis of the slip transmission problem:

$$\Delta\tau = \kappa \frac{1}{\sqrt{d}} \qquad [5]$$

where d is the average grain size of the metal and κ is a material-specific constant with units of $(\text{length})^{1/2}$; eqn [5] is commonly referred to as the Hall–Petch relationship.

In **Figure 4** the hardness, which is linearly proportional to strength, is plotted for pure Ni as a function of the reciprocal square root of grain size. The data from multiple authors indicate that the strength increases linearly with $d^{-1/2}$, and eqn [5] holds over orders of magnitude in grain size, from hundreds of microns in standard engineering materials down into the increasingly important nanocrystalline regime. As evidenced by the conformity of the data from various authors working on different specimens, eqn [5] is quite robust. Potentially complicating issues such as distributions of grain size or grain-boundary misorientation tend to be subsidiary to the scaling law of eqn [5], and are subsumed in the constant κ. Far stronger variations are observed from one material to another, most particularly depending on the number of slip systems available.

A current topic of particular interest in the area of grain-boundary strengthening is the validity of the Hall–Petch relationship at grain sizes in the nanometer range, where extreme strength has been reported. However, at a grain size of zero, the Hall–Petch relationship would predict an unphysical infinite strength, so it has been widely speculated that eqn [5] will break down at nanometer length scales. Recent experimental and computational work has supported this speculation, including the experimental data for nickel shown in **Figure 4** below ~ 12 nm. This

breakdown is associated with the activation of deformation mechanisms normally associated with high temperature, as will be discussed in more detail in a later section.

Low-Temperature Continuum-Level Strengthening

On a coarser structural scale, it is possible to strengthen a base metal by adding a second phase that can bear a disproportionate fraction of the load. This is often desirable when the base metal has properties critical to the application, such as low density, high ductility, conductivity, or corrosion resistance, but lacks sufficient mechanical strength. The concept of load sharing is the basis of many technological structural materials from reinforced concrete to advanced polymeric composites. In the area of metallurgy, load sharing operates in microstructures with second phases formed *in situ*, such as steels containing coarse iron carbide or martensite phases, as well as in metal–matrix composites such as SiC-reinforced aluminum.

The load-sharing mechanism arises completely due to mismatch between the mechanical properties of the constituent phases, and, from a mechanistic perspective, can be regarded as independent of microscale mechanisms; dislocation interactions with coarse second phases are less important than the global transfer of load that results from such interactions. Accordingly, continuum mechanical approaches are generally used to derive the strengthening effect from load transfer. If the two phases or components of the microstructure are initially deformed only elastically, then the only variable controlling the strength of the dual-phase structure is the fraction of the applied stress that is carried by each. The total applied stress σ partitions such that the average stress carried by each phase (σ_1 and σ_2 for phase "1" and "2," respectively) obeys

$$\sigma = \sigma_1(1 - v_f) + \sigma_2 v_f \qquad [6]$$

where v_f is the volume fraction of phase 2. Although this rule is generally true for any dual-phase structure when the stresses are averaged over the volume of the material, eqn [6] is not always useful to predict, for example, yield strength. This is because the local values of stress may be significantly concentrated, leading to local yielding in one of the phases. Despite this limitation, eqn [6] illustrates the basic principle of load transfer, where a stronger phase can relieve the stress borne by the weaker, giving a strength intermediate between the two components. Accurate predictions of yield and fracture strengths for dual-phase materials are dependent on the details of the composite geometry, for which a vast literature exists. The reader is referred to the "Further reading" section for more detailed treatments of specific cases.

Limitations of Strengthening Mechanisms due to Thermal Activation

The strengthening mechanisms described above can all be understood on an athermal basis, and are best applied in the limit where diffusional rearrangement of matter is slow. When dislocation motion and diffusion have similar timescales, for example, at high temperatures, the above scaling laws no longer strictly apply. In these cases, new physics are required to accurately predict the strength and rheology of metals. Although it is beyond the scope of this article to treat diffusive deformation mechanisms in detail, it is important to appreciate the limitations on the mechanisms described above for cases in which (1) bulk diffusion and (2) interfacial or grain-boundary diffusion are active at the deformation temperature.

Bulk Diffusion Effects

For many of the strengthening mechanisms described above, the motion of dislocations (particularly those of edge character) is considered to be restricted to a plane. However, the climb of edge dislocations out of their slip plane can occur by the absorption or emission of vacancies at the dislocation core. In many cases, this enables an additional means for obstacle bypass, albeit one that is rate-limited by the diffusive flow of vacancies to (or from) the dislocation core. The supply of vacancies needed to enable dislocation climb can flow either through the bulk, which generally requires temperatures above about two-thirds of the melting temperature, T_m, or along the core of the dislocation itself, which can be significant at somewhat lower temperatures above about $T_m/3$.

For solid-solution strengthened materials, diffusion can also lead to mobility of the obstacles themselves. In cases where there is an attractive interaction between solute atoms and dislocations, there is a tendency for these features to move in tandem. For example, at temperatures where the solute mobility is high, the motion of dislocations becomes a viscous process as the solute atoms follow the moving dislocation. At somewhat lower temperatures, the phenomenon known as "strain-aging" can occur, whereby plastic deformation initially detaches dislocations from solute pinning points, but extended time or thermal exposure can allow solutes to redistribute and again pin the dislocations. For substitutional solid solutions, the solute can be regarded as essentially immobile at temperatures

below approximately $T_m/2$, while for interstitial solid solutions this limit can be considerably lower, down even to ambient temperature.

In multiphase microstructures, high temperatures or long durations can also lead to evolution of the size and spacing of precipitated obstacles. During this so-called "coarsening" process, the volume fraction of precipitate phase remains constant while the average precipitate size increases linearly with the cube root of time. As described above, a limited amount of such particle growth can be beneficial, but the maximum strength associated with the cutting-to-bowing transition generally occurs at very fine precipitate sizes, such that microstructural coarsening usually leads to weakening. This issue is sometimes suppressed in practice through the addition of slow diffusing elements that decelerate coarsening. Finally, coarsening is not usually an issue for dispersion-strengthened materials, which employ particles with low solubility and/or diffusivity in the matrix.

Intercrystalline Diffusion Effects

Additional time-dependent deformation mechanisms are associated with the diffusive rearrangement of atoms in intercrystalline regions such as grain and phase boundaries or triple junctions. For example, it is possible for strain to be accommodated solely by the diffusional flow of atoms along grain boundaries, from interfaces under net compression to those in net tension. For fine microstructures, grains can even become mobile relative to one another through the operation of viscous "grain-boundary sliding" and stress-induced grain rotations. Although these mechanisms do not directly influence all of the dislocation-based strengthening mechanisms described earlier, they can negate the expected scaling laws set forth above when they operate at a lower stress level than the athermal mechanisms. For example, the Hall–Petch scaling law that describes grain-boundary strengthening is known to fail at high temperatures, where finer grains actually promote weakening due to the dominance of diffusive deformation mechanisms. For these reasons it is common to develop coarse microstructures or even single crystals for high-temperature structural metals. Continuum-level load sharing can also be frustrated by interfacial diffusion and sliding between phases in a composite structure, increasing the fraction of load borne by the weaker matrix phase.

Because interfaces tend to have excess free volume, they also represent "short-circuit" diffusion paths that are more easily activated, and therefore intercrystalline diffusion can become significant at even lower temperatures than bulk diffusion. Additionally, since the net amount of matter that can be transported along interfaces scales with the interface density, these processes are also accelerated in microstructures of fine scale. For example, it is presumed that the high density of crystalline interfaces in nanocrystalline materials leads to diffusional deformation mechanisms even at room temperature, again leading to the breakdown of the Hall–Petch boundary strengthening law.

Nomenclature

b	Burger's vector magnitude (length)
c	concentration of solute (atomic fraction)
d	grain size (length)
L	spacing between obstacles (length)
r	average particle radius (length)
T_m	melting temperature (K)
ν_f	volume fraction of particles
α	dimensionless constant for work hardening
β	dimensionless constant for solid solution strengthening
γ	dimensionless constant for particle strengthening
$\Delta\tau$	additional strength increment (force/area)
κ	constant for grain-boundary strengthening (length$^{1/2}$)
λ	interparticle spacing (length)
μ	shear modulus (force/area)
ρ	dislocation density (length^{-2})
σ	stress (force/area)

Mechanical Properties: Tensile Properties

K K Chawla, University of Alabama at Birmingham, Birmingham, AL, USA

Introduction

Tensile test is one of the most simple and important tests that can be done on a material to obtain its mechanical characteristics. It is commonly used with metals and polymers, and its importance is beginning to be appreciated even for brittle materials such as ceramics and glasses. The correct interpretation of the various types of tensile test requires a detailed knowledge of the procedure as well as the test machine. Two types of machines are used: (1) an endless screw-driven machine that has a constant speed of rotation or (2) a servo-hydraulic machine. The variables involved in a tensile test are stress, strain, and time. Generally, one of these variables is kept constant during the test. In a tensile test, one gets a uniform stress field over a relatively large effective volume of test material. These are important for evaluating inherent flaw distributions and the resultant strength distributions.

Tensile Test

In all tensile tests, a long specimen is subjected to a tensile force along its length. The material, in response to the applied force, undergoes some deformation. Commonly, the specimens are flat or round in cross section. The end of a sample is anchored to a fixed part of the machine while the other end is secured to the crosshead that can move at a constant speed. As the specimen is elongated, the applied force is measured by means of a load cell which is put in series with the specimen. It is very important to realize that all of the displacement of the crosshead is not transmitted to the gauge length section of the specimen. A part of the displacement is transmitted to the load cell, grips, coupling between specimen and the grips, and the machine frame. Thus, it is preferable to measure the specimen elongation "directly" by means of an extensometer. The output of such a test is thus a force–elongation record which can be transformed into engineering stress–engineering strain or true stress–true strain curves. The ends of the specimen are fixed in grips and a tensile force is applied by the machine such that the reduced section or gauge length is, at a given instant, under a constant force. The longitudinal deformation over the gauge length can be measured by means of an extensometer or strain gauge. Many testing systems, either screw-driven or closed-loop servo-hydraulic machines, with a variety of accessories are available. Modern machines come with a variety of options such as on-board programs to test different materials, Windows-based software, etc. **Figure 1** shows a schematic of a screw-driven machine.

The variables involved in a tensile test are stress, strain, and time. Stress is the load divided by the area while strain is the amount of deformation divided by the length over which the deformation takes place. True stress and true strain quantities can be defined. Engineering stress is the load divided by the original area of cross section of the sample while true stress is the load divided by the instantaneous area of cross section. Engineering strain is defined as

$$e = (l - l_o)/l_o$$

where l_o is the original gauge length and l is the distance between gauge marks after the force is applied. There is another type of strain, viz., true strain (also called natural or logarithmic strain) ε that describes deformation incrementally and is defined as

$$\varepsilon = \int dl/l = \ln(l/l_o)$$

It can be readily shown that for small values of engineering strain, $e = \varepsilon$. Engineering strain can be written as

$$e = (l - l_o)/l_o = l/l_o - 1, \quad l/l_o = 1 + e$$

Or, true strain, $\varepsilon = \ln(l/l_o) = \ln(1 + e)$.

If the series expansion of $\ln(1 + e)$ is examined, it is found that at low strains, indeed, $e = \varepsilon$. Commonly, one obtains a load–displacement curve by pulling on the sample at a constant rate of displacement or constant rate of force. Such a constant strain rate tensile test is very convenient to evaluate the strength and ductility of a material in a reasonable time. **Figure 2** shows the tensile stress versus strain curve for an aluminum sample: a typical stress–strain curve for a ductile metal. The initial response of a material to a force is linear elastic. This is also called Hookean behavior because the material obeys Hooke's law in this region. Hooke's law says that $E = \sigma/\varepsilon$, where E is Young's modulus, σ is the stress, and ε is the strain. In this linear region, the deformation is called elastic which means that it is reversible. When the force is removed, the material returns to its original dimensions. At some point during a tension test, a strain is reached where the deformation is no longer recoverable on unloading, that is, there is permanent or plastic deformation. The stress at which this irreversible deformation starts is called the yield stress or yield point. Frequently, it is difficult to determine exactly the yield

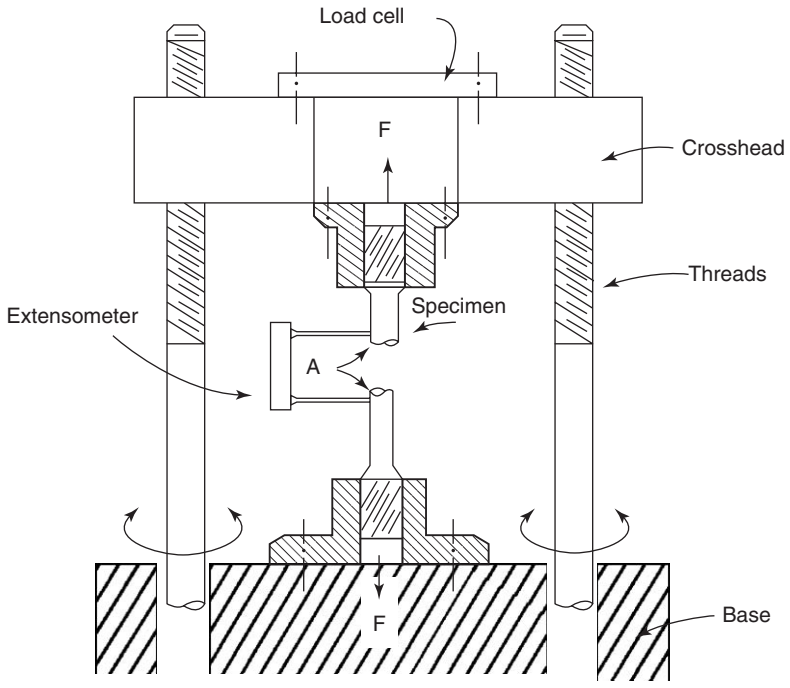

Figure 1 Schematic of a screw-driven machine.

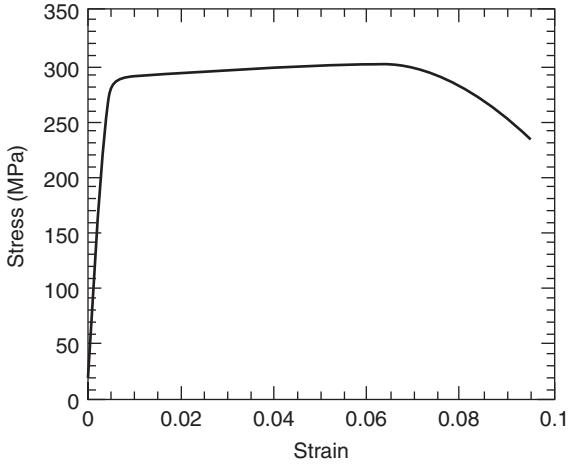

Figure 2 An engineering stress–strain curve in tension of an aluminum sample.

point. In order to avoid any ambiguity, an offset yield strength is defined. For example, 0.2% yield strength is strength obtained by drawing a line parallel to the elastic portion with an offset of 0.2% on the strain axis. Sometimes the stress–strain curve beyond the yield stress is called flow curve. For a perfectly plastic material, after attaining the yield stress, the stress will remain constant. In real material, as shown in **Figure 2** for aluminum, the flow stress increases with increasing strain. This is called "strain hardening" or "work hardening." The internal structure of material is changing during deformation, resulting in an increase in material strength. Concomitantly, the cross-sectional area of the specimen is decreasing and so the specimen is able to support a lower load. The maximum in the engineering stress–strain curve corresponds to the point state where the increase in load-carrying ability due to strain hardening is balanced by the decrease in load-carrying ability due to a decrease in the cross-sectional area. In a tensile test, this maximum in stress is called the ultimate tensile strength (UTS). Beyond UTS, the stress drops off. The extent of the stress–strain curve beyond the yield point is a measure of a material's ductility. When a material responds to a stress which is higher than its yield stress by deforming, it has some ductility. Low-ductility materials will break instead of deforming plastically. Materials showing such a behavior are called ductile materials. In ductile materials, the deformation after the maximum point is not uniform. At UTS, a unique phenomenon associated with tensile testing intervenes. It is called necking. Necking refers to a localized region where plastic deformation is concentrated in the sample. When necking occurs, the cross-sectional area is smaller than the rest of the gauge length, so the stress to continue deformation is smaller. The two phenomena, ductility and necking, are explored in the following two sections.

Ductility

A material is considered to be ductile if it is capable of undergoing a large amount of plastic deformation

before failure. The subject is of great importance in engineering because the phenomenon of ductility allows a material to redistribute localized stresses. A material that is unable to deform plastically before failure is called a brittle material. The ductility of a material can be measured easily in the tensile test. There are two quantities that can be obtained as measures of ductility. The first is the strain-to-fracture, e_f, which is defined as a percentage, as follows:

$$e_f = \frac{l_f - l_o}{l_o} 100$$

where l_f is the length at fracture and l_o is the original gauge length.

The other quantity is the reduction in area at fracture (RA). This is also given as a percentage and is defined as

$$\text{RA} = \frac{A_o - A_f}{A_o} 100$$

where A_f is the final cross-sectional area at fracture and A_o is the original area of cross section.

In a ductile material, after the beginning of necking, the load continues to fall until fracture occurs. All the deformation in this final stage (i.e., after the outset of the necking phenomenon) is concentrated in the region of the neck and its neighborhood. Thus, one may regard the total elongation of a tensile sample to consist of two components, viz.,

1. uniform elongation until the onset of necking, and
2. localized elongation after the onset of necking.

The localized strain and the uniform strain can be related by the following expression:

$$l_f - l_o = a + e_u l_o$$

where l_o is the original specimen length, l_f is the final specimen length, a is the local strain after the onset of necking, and e_u is the uniform strain. Clearly, the quantity $e_u l_o$ represents uniform elongation. The quantities a and e_u are constants that depend on the conditions of the test.

For the strain-to-fracture,

$$e_f = \frac{l_f - l_o}{l_o} = \frac{a}{l_o} + e_u$$

This equation implies that e_f is not an absolute material property for a given strain rate and temperature. It varies with the original gauge length, l_o. The uniform elongation, e_u, however, does not depend on l_o. Thus, the uniform elongation, e_u, is a better indicator of the ductility of a material.

Necking or Plastic Instability

Necking or plastic instability is a phenomenon that is unique to tensile testing. In ductile metals, necking starts at the maximum load in tension. A nonstrain-hardening, perfectly plastic material would become unstable in tension and start necking right in the beginning of the plastic yielding. Real metals, however, do show the phenomenon of strain hardening, that is, their capacity to bear load increases with strain. This effect is opposed by the gradual decrease in the cross-sectional area of the specimen with straining. Necking or localized plastic deformation starts at the maximum load, the point at which the increase in stress due to the decrease in cross-sectional area surpasses the increased load-bearing capacity due to strain hardening. This plastic instability condition is defined by $dP = 0$, that is, a small change in load equals zero. The applied load in a tensile test can be written as

$$P = \sigma A$$

where σ is the true stress and A is the instantaneous area of cross section. At necking,

$$dP = \sigma dA + A d\sigma = 0$$

or

$$-\frac{dA}{A} = \frac{d\sigma}{\sigma} \qquad [1]$$

From the condition of volume constancy during plastic deformation (i.e., the volume before plastic deformation is the same as that after the plastic deformation),

$$d\varepsilon = \frac{dl}{l} = -\frac{dA}{A} \qquad [2]$$

From eqns [1] and [2], at necking, one obtains

$$\frac{d\sigma}{d\varepsilon} = \sigma \qquad [3]$$

Thus, one can obtain the necking point corresponding to the maximum load. It is the point at which the strain-hardening rate equals the value of true stress.

Necking conditions in terms of engineering strain At necking, eqn [3] is valid. Then, denoting engineering strain by e, one can write

$$\frac{d\sigma}{d\varepsilon} = \frac{d\sigma}{de}\frac{de}{d\varepsilon} = \frac{d\sigma}{de}\frac{dl/l_o}{dl/l} = \frac{d\sigma}{de}\frac{l}{l_o} \qquad [4]$$

Now

$$\frac{l}{l_o} = \frac{l + \Delta l}{l_o} = 1 + e \qquad [5]$$

Thus, from eqns [4] and [5], one obtains

$$\frac{d\sigma}{d\varepsilon} = \frac{d\sigma}{de}(1+e) \qquad [6]$$

From eqns [3] and [6], one gets

$$\frac{d\sigma}{d\varepsilon} = \frac{\sigma}{1+e} \qquad [7]$$

Equation [7] gives what is called the "construction of Considére" for determining the maximum load point, that is, onset of necking. One can obtain the necking point corresponding to the maximum load starting from the true stress–true strain curve by finding the point on this curve at which the slope is unity or by finding the point at which the strain-hardening rate equals the value of stress.

Flow Curve of Metals

In shaping or processing of materials, large plastic strains are involved. Under such conditions, it becomes important to use true stress and true strain rather than engineering stress and engineering strain. For many metals, the flow curve, true stress–true plastic strain, can be expressed as

$$\sigma = K\varepsilon^n$$

where n is called the strain-hardening exponent and K is the strength coefficient. A log–log plot of this relationship gives slope n, and $K = \sigma$ at $\varepsilon = 1$. The strain-hardening exponent n can vary between 0 (ideally plastic) and 1 (elastic). For most metals, $0.1 < n < 0.5$. Note that the strain-hardening rate is not the same as the strain-hardening exponent. In fact,

$$n = \frac{d(\log \sigma)}{d(\log \varepsilon)} = \frac{d(\ln \sigma)}{d(\ln \varepsilon)} = \frac{d\sigma}{\sigma}\frac{\varepsilon}{d\varepsilon}$$

or

$$\frac{d\sigma}{d\varepsilon} = n\frac{\sigma}{\varepsilon}$$

At necking, $d\sigma/d\varepsilon = \sigma$, and $\varepsilon = \varepsilon_u$, the true uniform strain. Therefore,

$$n = \varepsilon_u$$

This important result shows that the true strain at the onset of necking is numerically equal to the strain-hardening exponent n. Thus, the higher the value of n, the greater the strain that the material can take before necking will intervene. This information can be very useful in material processing because it tells how much a material will deform plastically in a uniform manner before the onset of necking.

Tensile Behavior of Polymers

In metals and ceramics, one can distinguish between elastic and plastic strains rather easily. In polymers, the elastic and plastic strains are more difficult to distinguish and the stress depends both on the strain and the strain rate, more so than in metals. In metals and ceramics, for moderately high temperatures, the slope of the elastic part, that is, Young's modulus, is fairly constant. Strain rate also has a small effect. In metals, elastic deformation involves stretching of the atomic bonds; hence, it is not very time dependent. In polymers, chains can undergo uncoiling even in the elastic region, that is, elastomeric or rubbery materials can show nonlinear, elastic behavior. In thermoplastic polymers, when necking begins, the stress to continue deformation drops as in metals. However, unlike metals, the neck does not get smaller but grows along the sample; the chains become aligned and, eventually, the stress to continue the deformation increases as secondary bonds form between the chains. **Figure 3** shows schematically tensile stress–strain curves for a variety of polymeric materials. Thermoset polymers such as epoxy show a brittle behavior. Thermoplastic polymers such as polyamide (nylon) or polyethylene show ductile behavior, while elastomers or rubbers show nonlinear, elastic deformation.

Machine–Specimen Interaction

An experimental tensile stress–strain curve is obtained by causing the specimen to interact with a testing

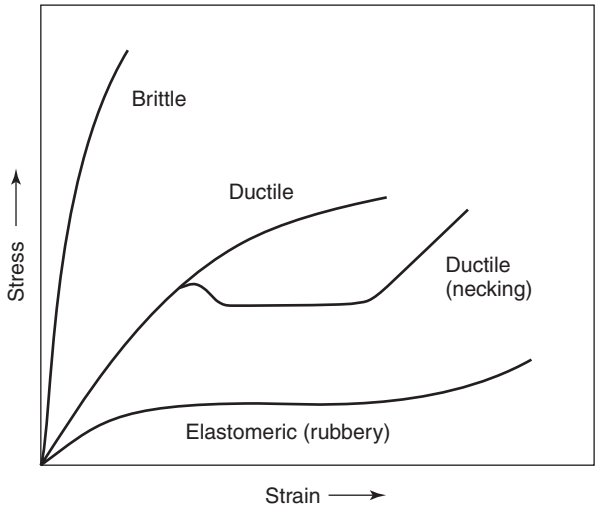

Figure 3 Stress–strain curves for a variety of polymeric materials. Thermoset polymers such as epoxy show a brittle behavior. Thermoplastic polymers such as polyamide (nylon) or polyethylene show ductile behavior, while elastomers or rubbers show nonlinear, elastic deformation.

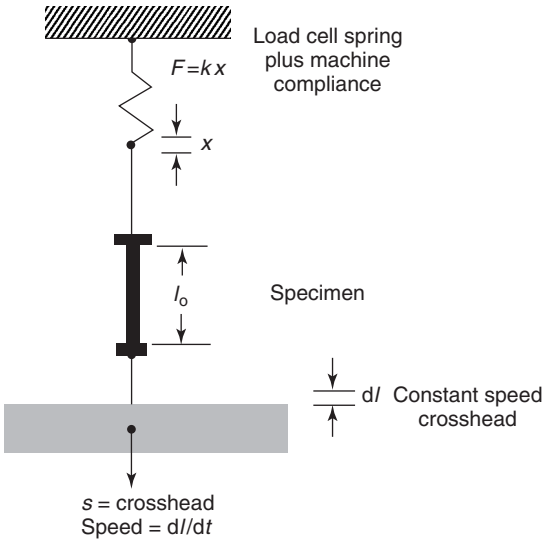

Figure 4 Machine–specimen interaction.

machine. The specimen is connected to a crosshead by means of joints, couplings, grips, etc. The crosshead moves at a constant speed, v, to deform the specimen. However, not all of the crosshead movement is translated into the deformation of the gauge length of the specimen. A part of the crosshead motion goes into the "elastic" strain of the deforming fixture and the specimen (the gauge length and the extra-gauge length portion), and the rest of the crosshead motion goes into the "plastic" deformation of the specimen. **Figure 4** shows a schematic of the specimen–machine linkage.

One can represent the elastic strain of the deforming fixture and sample by the deformation of a spring. The elastic deformation of the spring, Δx_{el}, is given as

$$\Delta x_{el} = F/K$$

where F is the applied force and K is the effective spring constant. Let Δl_p be the plastic deformation of the sample, then, the total crosshead displacement is given as

$$\Delta l_{total} = vt = \Delta x_{el} + \Delta l_p = F/K + \Delta l_p$$

where t is the total time of the crosshead motion and v is the crosshead velocity. Also,

$$\Delta l_{total} = vt = \Delta x_{sp} + \Delta x_m = F/K_m + \Delta x_{sp} \qquad [8]$$

where Δx_{sp} is the total displacement of the specimen gauge length, that is, elastic + plastic, and Δx_m is the elastic displacement of the machine and is equal to F/K_m, K_m being the machine constant. The term "machine" represents everything outside the specimen gauge length. Equation [8] can be written as

$$\Delta x_{sp} = vt - F/K_m$$

A testing machine having a high stiffness, K_m, is called a hard machine, while one having a low K_m is called a soft machine. An expression for the energy stored in the machine can be written as

$$U = \frac{K_m x^2}{2} = \frac{P^2}{2K_m}$$

In the "elastic regime," one can write

$$\Delta l_{total} = \text{machine displacement} + \text{specimen displacement}$$

A load–extension curve of a sample, obtained via crosshead displacement and not via an extensometer, would give force versus Δl_{total}. The slope of this curve in the elastic regime is E^* (the apparent Young's modulus):

$$\Delta l_{total} = vt = F/K_m + \sigma l_o/E$$

$$\frac{F}{A} = \sigma = E^* \frac{\Delta l_{total}}{l_o}$$

$$\frac{1}{E^*} = \frac{1}{\sigma}\frac{\Delta l_{total}}{l_o}$$

Now, an expression for Δl_{total} involving the real Young's modulus, E, can be written as follows:

$$\frac{\Delta l_{total}}{l_o} = \frac{F}{Kl_o} + \frac{\sigma}{E}$$

or

$$\frac{1}{\sigma}\frac{\Delta l_{total}}{l_o} = \frac{F}{Kl_o}\frac{1}{\sigma} + \frac{1}{E}$$

$$\frac{1}{E^*} = \frac{A}{Kl_o} + \frac{1}{E} \qquad [9]$$

Equation [9] is the equation of a straight line ($y = mx + c$), and it relates the real and the apparent Young's moduli. Note that as

$$l_o \to \infty, \quad A/Kl_o \to 0, \quad E^* \to E$$

A plot $1/E^*$ versus $1/l_o$, obtained by testing specimens of different gauge length, yields the true Young's modulus of the material.

Tensile Testing of Brittle Materials

In the elastic deformation of brittle materials, very small strains are involved. Any nonaxial loading or initial curvature can result in substantial error because the extensometer will give signals due to bending as well as tensile strains in the specimen. Use of two strain gauges mounted on the opposite sides of the specimen can help. Under this condition, the average change in length recorded by the two gauges

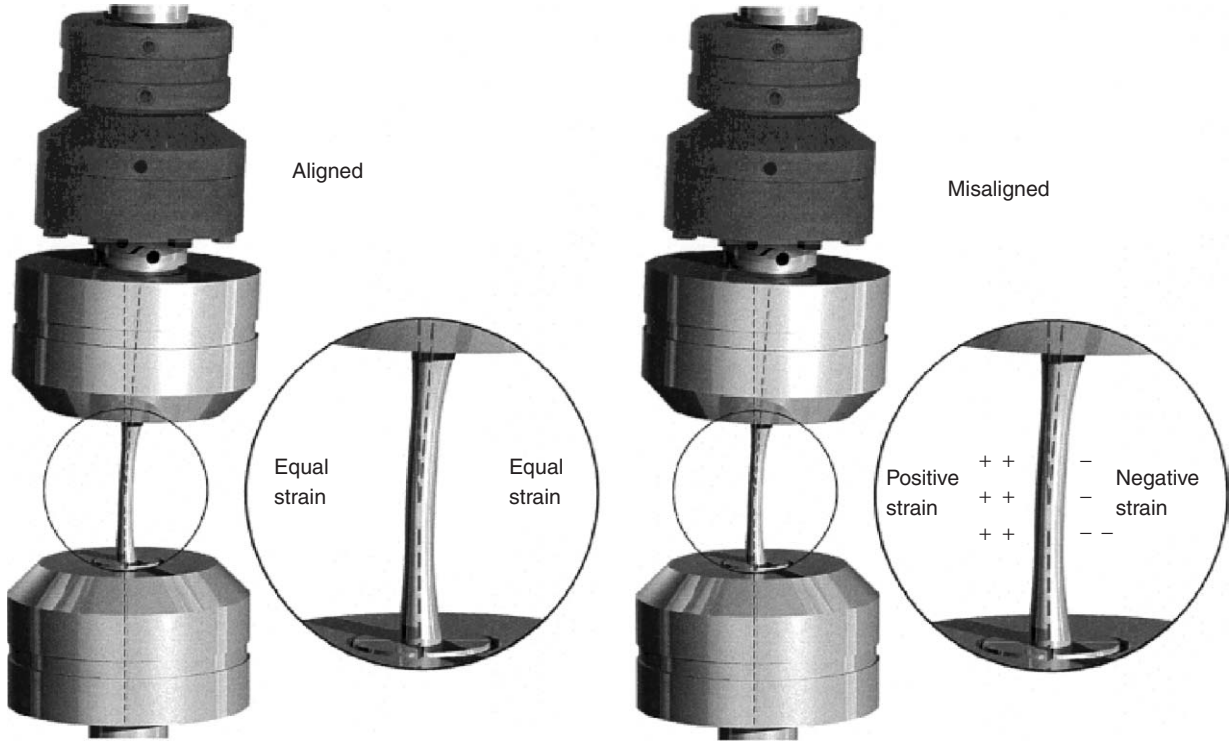

Figure 5 Aligned and misaligned grips. The misaligned grip results in parasitic bending strains in addition to the tensile strain. (Courtesy of MTS Systems Corp.)

will be independent of bending. Thus, axial alignment becomes extremely important for tensile testing of brittle materials such as alumina or silicon carbide. Any nonaxiality will lead to bending of the specimen as shown in **Figure 5**. With ductile metals, nontriaxiality is not a serious problem because the specimen will straighten after the plastic deformation begins.

Tensile testing is widely used to obtain mechanical characteristics of nonbrittle solids such as metals. Brittle materials such as ceramics and glasses are frequently tested in flexure (three-point or four-point). Although flexure tests are easy to perform, results generally do not reflect randomly occurring defects in highly stressed parts, for example, in a turbocharger rotor. In a bend test, only a small material volume of the test piece experiences the maximum load. In a tensile test, on the other hand, the whole gauge length of the specimen is subjected to a uniform stress. This is the reason that the strength values obtained from a bend test are considerably higher than those from a tensile test. In a tensile test, one gets a uniform stress field and a relatively large effective volume of the test material. These are important for evaluating inherent flaw distributions and the resultant strength distributions. One major problem in tensile testing of ceramic and ceramic composites is the bending moments that might be introduced during specimen alignment, gripping, and testing. Such accidental bending moments are sometimes referred to as "parasitic" bending moments. **Figure 5** shows the aligned and misaligned states of a specimen in the grips. Various grip designs have been developed to take care of this problem of parasitic bending moments. One such development involves a hydraulic, self-aligning grip system that results in a condition of "near-zero bending moment" during a tensile test. The specimen grip is self-aligning and has a built-in flexible coupling consisting of eight tiny hydraulic pistons. These pistons reduce bending in the specimen to near zero, $<1\%$ bending in the gauge length. With proper attention to the gripping of the sample, tensile tests on ceramics can be performed at temperatures up to 1300°C without much problem.

Gripping Devices

In tensile testing of any specimen, one of the important items is the type of gripping device to be used to transmit the applied load to the test specimen. This is especially true for tensile testing of brittle materials, which must not be nicked, damaged, or bent during gripping. Any misaligned or nonuniform loading or point and/or line contacts can produce Hertzian-type stresses leading to crack initiation and fracture of the specimen in the gripped region.

Gripping devices are classified as having active or passive grip interfaces. "Active grip interfaces" require a continuous application of a mechanical, hydraulic, or pneumatic force to transmit the load applied by the test machine to the test specimen. Generally, these types of grip interfaces require the load to be applied normal to the surface of the gripped section of the specimen. Transmission of the uniaxial load applied by the test machine is then accomplished via friction between the specimen and the grip faces. Thus, important aspects of active grip interfaces are uniform contact between the gripped section of the specimen and the grip faces, and the constant coefficient of friction over the grip/specimen interface. For cylindrical specimens, a one-piece split-collet design is commonly used. Generally, close dimensional tolerances are required for concentricity of both the grip and specimen diameter. In addition, the diameter of the gripped section of the specimen and the unclamped, open diameter of the grip faces must be within similarly close tolerances in order to promote uniform contact at the specimen/grip interface. For flat specimens, flat-face, wedge-grip faces act as the grip interface. In this case too, close tolerances are required for the flatness and parallelism as well as the wedge angle of the grip faces. In addition, the thickness, flatness, and parallelism of the gripped section of the specimen must be within similarly close tolerances in order to promote uniform contact at the specimen/grip interface. "Passive grip interfaces" transmit the applied load to the test specimen through a direct mechanical link. Generally, these mechanical links transmit the test loads to the specimen via geometrical features of the specimens such as a button-head.

Membrane and Protein Aggregates

O G Mouritsen, University of Southern Denmark, Odense, Denmark

Introduction

Membranes constitute Nature's preferred architecture for nano- and microencapsulation technology of living matter. All cells are bounded by one or several membranes and whereas cells of eubacteria and archaebacteria are bounded by a single plasma membrane, all eukaryotic cells have in addition internal membranes encapsulating the nucleus and the various organelles. Hence, biological membranes are the most abundant cellular structure in living matter.

Membrane assemblies are composed of lipids, proteins, and carbohydrates as illustrated in **Figure 1**. Lipids and many membrane-bound proteins are amphiphilic molecules, and the aqueous membrane system is therefore determined by self-assembly processes that are mainly controlled by the long-range hydrophobic effect. The hydrophobic effect has a substantial entropic component, and details of membrane structure and dynamics are therefore very sensitive to temperature.

The biophysics of membrane and protein assemblies is conveniently studied in model systems consisting of

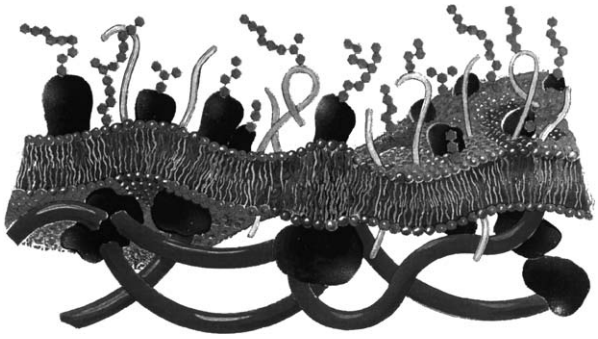

Figure 1 Schematic illustration of the plasma membrane of a eukaryotic cell with a lipid bilayer core incorporated with proteins. On the outside is a carbohydrate coat and on the inside a polymeric cytoskeleton.

bilayers of lipid molecules in which proteins as well as other molecules that interact with membranes are incorporated. Such bilayers can be in the form of free liposomes (or vesicles) in water or in the form of planar bilayers on solid supports as shown in **Figure 2**. Although lipid bilayer membranes are liquids under physiological conditions, the membranes are highly structured interfaces which belong to the class of lyotropic smectic liquid crystals.

Proteins can be associated with lipid bilayers in several different ways, some of which are illustrated in **Figure 3**. In order to understand the interactions between lipids and proteins and how membrane function is controlled by these interactions, it is important first to understand the cooperative properties of lipid bilayers and how these are manifested in terms of the trans-bilayer and the lateral structure of lipid bilayers.

Trans-Membrane Structure and Curvature Stress

The forces that are operative and which stabilize a lipid bilayer, once it is formed, have to be distributed over the $\sim d = 5\,\text{nm}$ thick bilayer sheet. The major force derives from the interfacial tension, γ, which operates between the hydrophilic and the hydrophobic parts of the bilayer as shown in **Figure 4**. The tensile force, which is $\sim 50\,\text{mN}\,\text{m}^{-1}$, is counterbalanced by two repulsive forces, the lipid head-group repulsion and the entropic chain pressure in the core of the bilayer. Since these forces are centered in different planes, a trans-bilayer lateral stress (or pressure) profile, $\pi(z)$ builds up with enormous pressure densities of the order of $2\gamma/d$, that is, typically several hundred atmospheres.

An important determinant of the lateral stress profile is the effective shape of the lipid molecules. Molecules with conical shape will exhibit propensity for forming nonlamellar and curved structures. Each monolayer of the lipid bilayer can hence display a spontaneous curvature which leads to a curvature stress field in a bilayer as illustrated in **Figure 5**. Under appropriate conditions, the bilayer cannot support the resulting strain and hence nonlamellar lipid phases are formed.

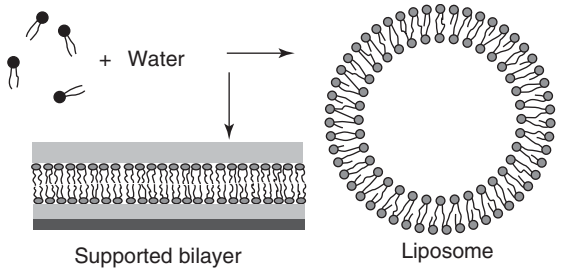

Figure 2 Spontaneous formation of lipid bilayer membranes when lipid molecules are mixed with water.

Lateral Membrane Structure

Membranes are structured laterally on different length and time scales. The structuring is determined

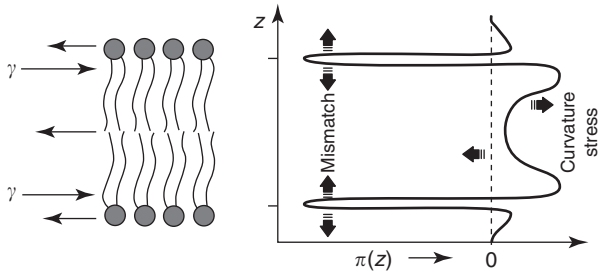

Figure 4 Left: lipid bilayer with indication of the forces that act within the layer. γ is the interfacial tension between the hydrophilic and hydrophobic parts. Right: corresponding lateral pressure profile, $\pi(z)$. The effects of hydrophobic mismatch and curvature stress on the profile are indicated.

by the collective properties of the assembly and not only by the chemical properties of the individual lipids and proteins. Cooperative phenomena and phase equilibria in membranes are manifested in terms of differentiated regions or domains sometimes called rafts which persist on length scales from nanometer to micrometer. There is accumulating evidence that lipid domains support various membrane functions. **Figure 6** shows examples of lipid domains in membranes of pulmonary surfactants in a supported lipid membrane studied by atomic force microscopy and in giant liposomes studied by fluorescence microscopy. Both images refer to membranes with integral membrane proteins and it is seen that lateral structure may arise on different length scales.

The physical interactions between the molecules in a lipid membrane determine a so-called persistence (or coherence) length, ξ_L, which is a measure of the effective range over which the interactions operate and lead to structure and fluctuations in structure. The actual value of the persistence length is not only determined by the molecular interactions but it is also dependent on thermodynamic conditions and composition. The persistence length is a measure of the lipid cooperativity (or fluctuations) which in turn is the underlying source of the domain formation. Roughly, the persistence length is the average size of the domains. The range over which different proteins can "feel" each other through the lipid bilayer is also set by ξ_L. Hence, the small (nanometer) scale structure of membranes is intimately related to lipid–protein interactions. The extension, ξ_P, of the annulus of lipid molecules around a protein which is perturbed by the protein is proportional to ξ_L. Hence the lateral organization of proteins in a lipid bilayer can to some extent be modulated by altering the persistence length, for example, by changing temperature or by adding specific substances, such as drugs, that will change ξ_L.

Lipid–Protein Interactions

All integral membrane proteins have a similar structural motif with a hydrophobic domain, α-helical or β-sheet, that traverses the hydrophobic core of the lipid-bilayer membrane as illustrated in **Figure 7**. The number of membrane-spanning parts of the amino acid sequence ranges from a single one to more than 12. The hydrophobic domain contains some of the evolutionary most conserved sequences found in proteins. This suggests that the trans-bilayer coupling between lipids and proteins may be an ancient mechanism that has generic as well as fundamental implications for membrane protein interactions and hence for biological function.

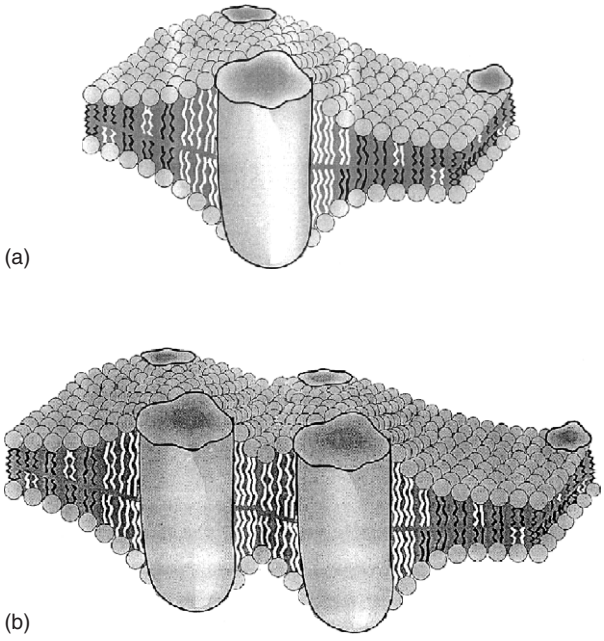
The physical constraint imposed on integral membrane proteins by the lipid bilayer thickness suggests that a mechanical hydrophobic matching principle may be operative. Hydrophobic matching means that the hydrophobic length, d_P, of the trans-membrane domain is matched to the hydrophobic thickness, d_L, of the lipid bilayer as illustrated in **Figure 8**. In order to compensate for a possible mismatch, the soft lipid bilayer yields, and the lipid molecules closest to the protein stretch out or compress in order to cover the hydrophobic core of the protein. This leads to a perturbed region around the protein over a range ξ_P.

The radial structure of the perturbed region of the lipids can be estimated by considering a single protein in a membrane and neglecting the entropy of mixing of lipids and proteins. The free energy of the system can be written in terms of a free-energy density g as

$$G = \int \mathrm{d}^d r \, g\left[d_L(r), \frac{\mathrm{d}}{\mathrm{d}_r}\{d_L(r)\}\right]$$

where r is the radial distance from the protein. Within the Gaussian approximation for g, minimization of G in the case of a relaxed boundary condition leads to

Figure 7 Schematic illustration of a trans-membrane protein (bacteriorhodopsin) imbedded in a lipid bilayer.



(a)

(b)

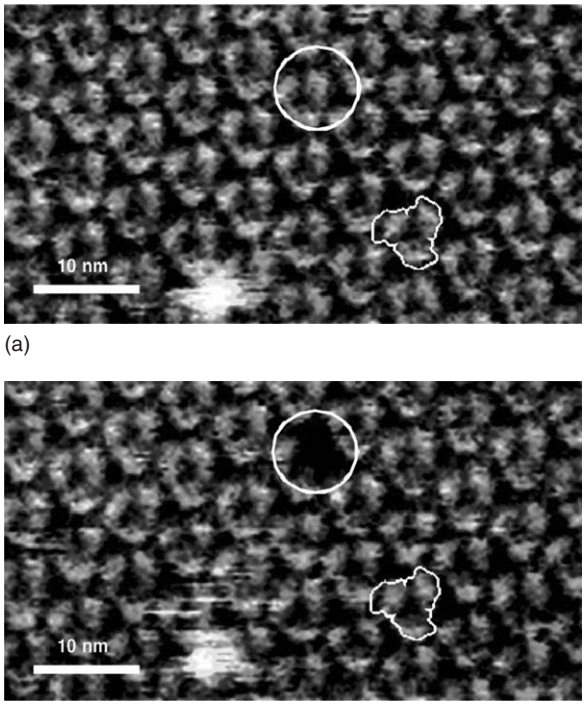
Figure 8 Schematic illustration of integral membrane proteins embedded in a lipid bilayer that is hydrophobically thinner than the hydrophobic domain of the protein. (a) Hydrophobic matching implies formation of a region of lipids around the protein that conform to the hydrophobic matching condition either by stretching the acyl chains or by recruiting the better-matched lipid species at the interface. (b) Hydrophobic matching implies a lipid-mediated mechanism for protein attraction and aggregation in the plane of the membrane.

the profile

$$d_{\mathrm{L}} = d_{\mathrm{P}} + (d_{\mathrm{L}}^{\mathrm{o}} - d_{\mathrm{L}})\exp(-r/\xi_{\mathrm{P}})$$

where $d_{\mathrm{L}}^{\mathrm{o}}$ is the hydrophobic thickness of the unperturbed lipid bilayer. A typical size of ξ_{P} lies in the range of one to a few nanometers.

Hydrophobic mismatch and the possibly imposed local curvature stress may therefore be a controlling mechanism for the way proteins interact with lipids in membranes. This mechanism could also be the basis for lipid sorting at the lipid–protein interface as illustrated in **Figure 8a** in the case of a membrane



(a)

(b)

Figure 9 Two-dimensional crystalline array of the integral membrane protein bacteriorhodopsin in a lipid-bilayer membrane. The figure illustrates how a single bacteriorhodopsin molecule (a) sitting in a two-dimensional crystal can be pulled on by the tip of an atomic force microscope leaving a hole in the crystal inside the circle in (b). (Courtesy of Daniel Müller.)

that is too thin to accommodate the protein. For a lipid bilayer with a single lipid species, this perturbed interface region in **Figure 8a** is characterized by a larger average lipid-bilayer thickness and a higher conformational chain order. Since lipid bilayers and membranes under physiological conditions are liquids, the perturbed region is a statistical entity in the sense that lipids diffuse in and out of the region. Hydrophobic matching provides a physical mechanism for protein organization in membranes. This is illustrated in **Figure 8b** in the case of two proteins. In that case, if the distance between the proteins becomes comparable to the persistence length, the annuli of the proteins overlap which tends to lower the free energy and hence facilitates an effective lipid-mediated attractive protein–protein interaction. An example of a two-dimensional crystalline aggregate formed by integral membrane proteins in a lipid membrane is shown in **Figure 9**.

Physical Triggering of Proteins

Figure 10 shows how a conformational change in an integral membrane may be triggered by hydrophobic matching condition.

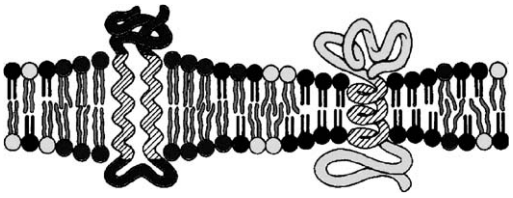


Figure 10 Schematic illustration of triggering the function of an integral membrane protein by changing the hydrophobic mismatch. London: Academic Press, with permission.)

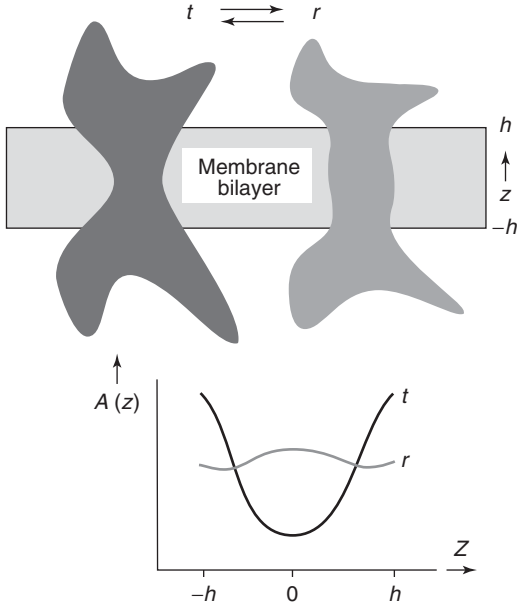

Figure 11 Schematic illustration of the change in cross-sectional area profile, $A(z)$, of an integral membrane protein that undergoes a shape change during a conformational transition from state *t* to state *s*. The area profile change couples to the lateral pressure profile, $\pi(z)$, of a lipid bilayer shown in **Figure 4**. (Courtesy of Robert S Cantor.)

It may well be that it is not the hydrophobic thickness as such that provides the direct mechanic coupling between the lipid bilayer and the protein, but rather some other membrane property which is related to the hydrophobic thickness. The lateral pressure profile shown in **Figure 4** is the most obvious candidate. Changes in this profile can lead to conformational changes in the protein as illustrated in **Figure 11**, provided the protein has a noncylindrical shape, for example, as the hourglass form of a helix bundle.

The work

$$W = -\int_z \pi(z)[A_t - A_r]\mathrm{d}z$$

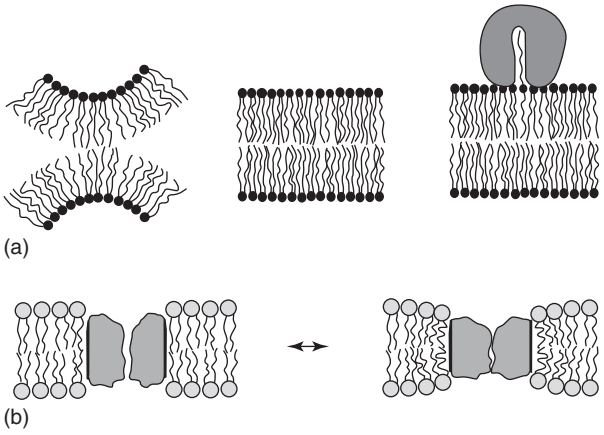

Figure 12 Schematic illustrations of the influence of lipid-bilayer curvature stress on protein function. (a) From left to right, a hypothetical situation of two relaxed lipid monolayers with intrinsic curvature leading to a lipid bilayer with built-in curvature stress which may be partially released upon binding to a peripheral protein via the extended chain-conformation mechanism. that is involved in such a change can be large enough to induce a conformational change in the protein. This mechanism suggests a way of manipulating membrane proteins and their function by changing the hydrophobic thickness of a membrane or by changing the lateral pressure profile, for example, by shifting the balance of the pressure between the head-group and acyl-chain part of the bilayer. A number of drugs may have their action by acting directly on the lipids, changing hydrophobic thickness or pressure profile, and thereby indirectly couple to the protein and its function. This mechanism has been suggested to be operative in the case of general anesthetics.

Similarly, the curvature stress and the way it can be released provide a mechanism for triggering of protein binding to membrane surfaces and for the opening and closing of membrane channels as illustrated in **Figure 12b**.

Lipid-Mediated Protein Function

There is a substantial amount of experimental evidence that indirectly points to the presence of hydrophobic matching in reconstituted membrane–protein systems and in real cell membranes. The degree of matching influences the functioning of membrane channels, pumps, and transporters, as well as how integral membrane proteins are inserted into, secreted through, and folded within the membrane. For example, it has been found for a number of membrane channels, ion pumps, and sugar transporters that they, when incorporated into lipid bilayers of different thickness, function optimally for a certain

narrow range of thicknesses, where they presumably are hydrophobically well matched. Thickness alterations induced internally or by external stimuli may therefore be seen as a way of triggering these proteins to enhance or suppress their function as pictured schematically in **Figure 10**. A couple of specific examples are described below.

The first example is the integral membrane protein melibiose permease which is a cation/sugar symporter from *E. coli*. This protein catalyzes cell accumulation of α-galactosides such as melibiose. When incorporated into membranes of different hydrophobic thickness, it is found that the function of melibiose permease is at an optimum for a particular bilayer thickness. Another example refers to **Figure 13** which shows how the activity of the integral membrane protein Na,K–ATPase varies with membrane thickness. The figure shows that the activity of this ion pump is maximal for a certain type of lipid and hence for a specific membrane thickness. If cholesterol is added to the membrane, the maximum is seen to move toward lipid membranes made of shorter lipids. This can be rationalized via the hydrophobic matching principle, recalling that cholesterol tends to thicken fluid membranes which in turn will compensate for the shorter lipids.

This latter observation suggests a more general principle to be operative by which cholesterol may be used as a regulator of membrane function and the sorting and targeting of proteins, possibly via hydrophobic matching. The following serves as an illustration.

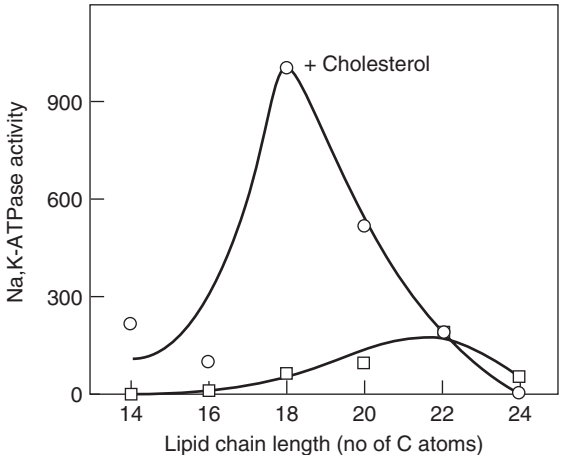

Figure 13 Schematic illustration of the dependence of protein function of the average hydrophobic length of the lipid molecules. An optimum occurs at a given length corresponding to a specific bilayer thickness. After incorporation of cholesterol, which acts as to thicken fluid lipid membranes, the optimum is shifted toward shorter lipids, rendering the actual membrane thickness at the optimum the same as without cholesterol. (Courtesy of F Cornelius.)

Proteins are synthesized at the ribosomes placed in the endoplasmatic reticulum. From there they are transported via the Golgi to the various parts of the cell where they belong, for example, in the plasma membrane. This transport, which is referred to as the secretory pathway, requires a sorting of the proteins which is performed in the Golgi. Some proteins carry specific tags that will actively target them to their destination, others will passively flow through the cell. The sorting along the secretory pathway may be performed by means of a gradient in the hydrophobic thickness of the membrane systems which the proteins have to pass on their way to their target. Indeed, the membrane contents of cholesterol and sphingomyelin, which both tend to enlarge membrane thickness, are found to increase going from the endoplasmatic reticulum, via the Golgi, to the plasma membrane.

A substantial part of the lipids found in natural membranes, for example, phosphatidylethanolamine lipids, have propensity for nonlamellar structures and therefore lead to a curvature stress and an instability which may be locally released in connection with protein binding, protein insertion, membrane fusion, and conformational changes in the cycle of protein functions. As an example, protein kinase C is one of the most important enzymes, which are involved in the signal transduction system of the cell. Upon stimulation of the cell by, for example, neurotransmitters, hormones, and growth factors, protein kinase C becomes activated upon binding to the plasma membrane, leading to a complicated cascade of biochemical signals that eventually influence cell growth, cell differentiation, as well as exocytosis. A requirement for binding to the membrane and hence for activation of the enzyme is lipids with acidic head groups, such as phosphatidylserine, and the presence of calcium ions. Calcium ions require water for solvation, and in the competition for water the membrane surface becomes dehydrated leading to a larger curvature stress. This curvature stress could be released if some lipid molecules assume an extended chain conformation as illustrated in **Figure 12a** by flipping one of the acyl chains to the outside of the membrane. This flip would normally be energetically very costly because of the hydrophobic effect. However, if the chain can be accommodated in a putative hydrophobic crevice in a protein it will both release the curvature stress of the membrane and simultaneously facilitate the membrane anchoring and hence the activation of the enzyme. Protein kinase C has such a hydrophobic crevice. A similar mechanism has been shown to facilitate binding of cytochrome *c* to membranes.

The integral membrane protein rhodopsin is a seven-helix trans-membrane protein. Rhodopsin is the light-sensitive protein in the visual pigment of our

retina which, upon activation of light, initiates the signaling pathway that eventually leads to vision. An essential stage of this process involves a certain transition between two conformational states of rhodopsin, the so-called M-I and M-II states. The M-II state is believed to correspond to a more elongated form of rhodopsin than the M-I state. The transition therefore implies a change in hydrophobic mismatch. Studies have shown that the M-II state requires the presence of lipids that have propensity for forming nonlamellar phases. The retinal rod outer segment membranes, in which rhodopsin exhibits its function, are known to have almost 50% of the polyunsaturated fatty acid docosahexaenoic acid which, due to the many double bonds, indeed supports curved structures.

There is a particular class of membrane proteins, the mechanosensitive channels, that have evolved to facilitate ion conductance in response to a stress exerted by the membrane. These proteins are nanomachines, which work as transducers of mechanical strain dissipated from the membrane. The most well-studied example is the bacterial large conductance mechanosensitive channel (MscL) from *E. coli*. Hydrophobic matching and curvature stress concepts can be used to interpret the experimental data for the conductance of MscL and how it varies when nonlamellar lipid species are incorporated into the membrane. MscL is a helix bundle protein and experiments as well as molecular dynamics simulations have supported a mechanism for channel opening that involves an iris-like expansion of the conducting pore.

Finally, evidence is available for insertion of peptides and proteins into lipid bilayers being controlled by hydrophobic matching. Proteins are more readily inserted and correctly folded into membranes to which their hydrophobic domain is hydrophobically matched. It is the same mechanism that may be in operation as the molecular sieve in the secretory pathway.

Memory Devices, Nonvolatile

G Baccarani and E Gnani, University of Bologna, Bologna, Italy

Introduction

The key attribute of nonvolatile memory devices is their ability to retain the stored information for several years both under ON and OFF power conditions. Owing to this property, they have found widespread use in a variety of professional systems, such as computers, phone exchanges, measurement setups, robotic and control systems, automotive and medical electronics systems, as well as commodities and consumer products, such as cell phones, personal digital assistants (PDAs), digital video recorders and still cameras, digital TV (DTV), set top boxes, GPS-based navigation systems, toys, radio-frequency identification devices (RFIDs), and smart cards.

To date, the nonvolatile memory market has become a sizeable fraction of the whole memory market, and is largely dominated by the flash electrically erasable and programmable read-only memory (EEPROM) devices. Owing to the pervasiveness of flash memories, the problem of integration of flash arrays within logic circuits has been thoroughly investigated, and the problems associated with the harmonization of technological processes which are not fully compatible have been successfully tackled, thus making it possible to produce systems on chip with embedded flash arrays.

This article is organized as follows: the next section introduces the classification and illustrates the general features of nonvolatile memories. In the section "Read-Only Memory" (ROM), the ROM circuit functions are illustrated. The section "Electrically-Programmable Read Only Memory" (EPROM) addresses the structure and operation principles of the EPROM cell, along with its main working issue, namely: reliability. The following section is devoted to the description of the structural and functional properties of the EEPROM. In the next section, the

architectural options and the functional properties of the flash memory arrays are discussed along with reliability issues. The final section addresses a number of new memory concepts which are still within a development stage, and have not emerged as real products yet, such as the magnetic RAM (MRAM), the ferroelectric RAM (FeRAM), and phase-change memory.

Nonvolatile Memory Classification

Nonvolatile semiconductor memories are generally classified according to their functional properties with respect to the programming and erasing operations, as shown in the flow chart depicted in **Figure 1**.

ROMs are programmed at the mask level during the fabrication process by suitably interconnecting logic gates in order to generate appropriate logic functions of the input data. Therefore, the reading operation is carried out by a logic computation using combinational logic circuits, which can be manufactured by a standard CMOS process. ROMs, however, suffer a lack of flexibility, which dramatically restricts their application range.

EPROMs are based, instead, on a different physical principle, and store information by controlling the threshold voltage of a special MOSFET structure with two overlapping gates, the lower of which is electrically floating. Injecting electrons into the floating gate changes the conduction threshold of the cell. A low threshold voltage characterizes a conductive cell, and is associated with a logical "1," while a high threshold voltage represents a logical "0." The natural threshold of a virgin cell is low since the floating gate is electrically neutral; hence it automatically stores a logical "1." Writing (or programming) the cell, by which its content is turned into a logical "0," means injecting electrons into the floating gate. The physical mechanism by which electrons can be injected into the floating gate is typically channel hot-electron injection over the $Si–SiO_2$ energy barrier.

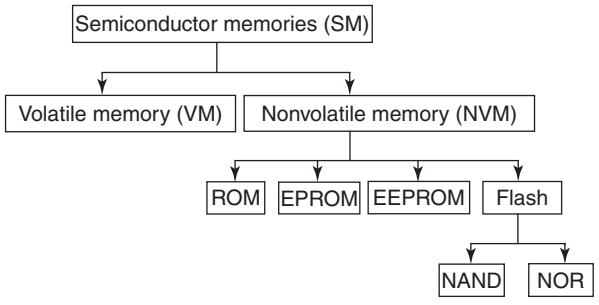

Figure 1 Nonvolatile memory classification according to functional criteria.

EPROMs can be electrically programmed on field and be optically erased by exposing the cell array to ultraviolet (UV) light. Erasing the memory, however, requires a long exposure of the cell array (30 min or so) so that electrons confined within the floating gate can be emitted by a photoelectric effect. This requires a special package with a cover transparent to UV light.

EEPROMs can be electrically programmed and erased on field, which makes them more flexible than EPROMs. This, however, occurs at the expense of a larger cell, which contains a selection transistor in addition to the EEPROM device. For a given silicon area, this larger cell size implies a smaller capacity and a higher cost per bit.

Flash EEPROMs combine, instead, the EPROM's cell size with the EEPROM's flexibility and are thus largely preferred in new applications, such as cell phones, PDAs, and smart cards. In flash memories, all the cells of a sector are erased in parallel, which justifies their "flash" name, and reprogrammed afterwards. This makes the long erasure time (several tenths of a second) acceptable at the system level.

Read-Only Memory

ROMs functionally behave as encoders, for they associate an M-bit output word, which is the memory content, to an N-bit input word representing a physical address. The ROM output can always be expressed as a sum of products of the input bits. Therefore, the reading process occurs in two steps: first, a decoder which generates the min-terms of the N-input bits, raises one of the 2^N word lines high; next, an encoder generates the output word by OR-ing the min-terms from the selection of the physical address. The output word is thus computed by activating a combinational logic circuit; hence, the content of the memory is defined at the mask level during the fabrication process, and no programming changes are possible afterwards.

In view of their functional task, the decoder is often called the AND plane and the encoder is referred to as the OR plane of the ROM. Actually, the logic gates used to generate both the OR and the AND planes are often NOR gates because of speed considerations (**Figure 2**). NAND gates can sometimes be used for small ROMs with a density advantage, but are unpractical for a number of input bits in excess of 4 to 8.

Figure 2a illustrates the typical structure of the AND plane for the simple case of a two-bit structure. The *p*-channel MOSFETs with grounded gate act as pull-up transistors of pseudo *n*-MOS logic gates. The *n*-channel MOSFETs are connected in a NOR configuration. Indicating the input bits with A and B

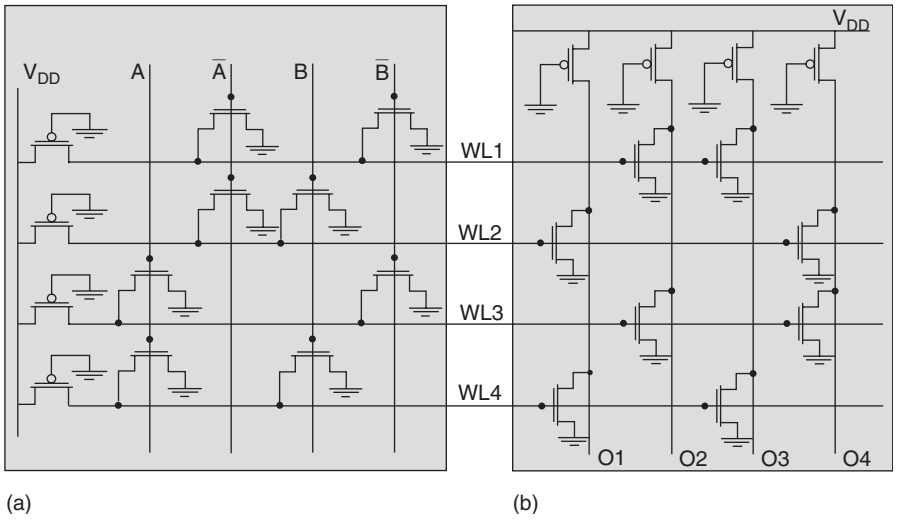

Figure 2 NOR-based implementation of a ROM: (a) AND plane; (b) OR plane.

and their complements with A′ and B′, the output nodes of the AND plane, referred to as $WL_n (n = 1, \ldots, 4)$ turn out to be

$$WL_1 = (A' + B')' = AB$$
$$WL_2 = (A' + B)' = AB'$$
$$WL_3 = (A + B')' = A'B$$
$$WL_4 = (A + B)' = A'B'$$

where De Morgan's theorem has been applied. Thus, the min-terms of the two input bits are generated by NOR operations.

The OR plane, again implemented by NOR gates possibly followed by inverters, is shown in **Figure 2b**. The latter realizes the following Boolean equations

$$O_1 = WL_1 + WL_3 = (WL_2 + WL_4)'$$
$$O_2 = WL_2 + WL_4 = (WL_1 + WL_3)'$$
$$O_3 = WL_2 + WL_3 = (WL_1 + WL_4)'$$
$$O_4 = WL_1 + WL_4 = (WL_2 + WL_3)'$$

Thus, the truth table implemented by the ROM in **Figure 2** is the following:

A	*B*	*WL*$_1$	*WL*$_2$	*WL*$_3$	*WL*$_4$	*O*$_1$	*O*$_2$	*O*$_3$	*O*$_4$
0	0	0	0	0	1	0	1	0	1
0	1	0	0	1	0	1	0	1	0
1	0	0	1	0	0	0	1	1	0
1	1	1	0	0	0	1	0	0	1

A similar procedure can be followed using a NAND implementation of the above Boolean equations.

Electrically-Programmable Read Only Memory

EPROMs rely on a cell structure with two overlapping gates, as shown in **Figure 3**. The lower gate is fully surrounded by silicon dioxide and is thus electrically floating. The upper gate is instead accessible and is referred to as control gate. Due to the need of two polycrystalline silicon levels, the EPROM fabrication technology is not fully compatible with the standard CMOS technology.

Electrons traveling from source to drain under large gate and drain voltages can possibly achieve an energy exceeding the Si–SiO_2 potential barrier, which is $\sim$3.1 eV. If such an electron undergoes a redirecting collision with a final momentum normal to the silicon surface, it can overcome the potential barrier and be injected into the oxide conduction band. If the floating-gate voltage V_{FG} exceeds the drain voltage V_D, the field in the oxide will favor electron injection into the floating gate, where it gets trapped. As more and more electrons are injected and trapped into the floating gate, its potential V_{FG} is lowered and the threshold voltage of the control gate V_{TC} increases.

The basic relationship connecting the floating-gate voltage V_{FG} with the charge injected into the floating gate Q_{inj} and the cell voltages is

$$V_{FG} = \alpha_G V_{CG} + \alpha_S V_S + \alpha_D V_D + \alpha_B (V_B + \Phi_{MS}) + Q_{inj}/C_T$$

where V_{CG} is the control-gate voltage, V_S is the source voltage, V_D is the drain voltage, V_B is the bulk voltage, and Φ_{MS} is the work function difference between the heavily doped n^+ polycrystalline silicon gate and the underlying p-doped silicon substrate. Also, α_G, α_S, α_D, and α_B are coupling coefficients

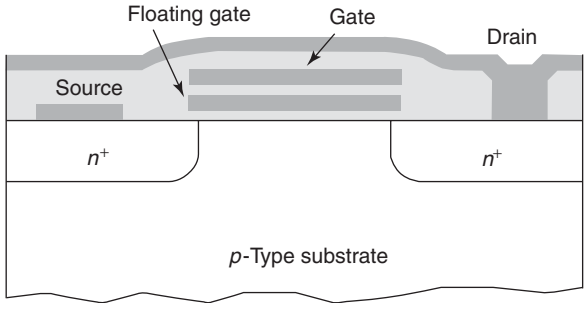

Figure 3 Cross section of a floating-gate EPROM cell.

expressed by the ratios of the gate, source, drain, and bulk capacitances C_{GG}, C_{GS}, C_{GD}, and C_{GB} with respect to the total capacitance of the floating gate $C_T = C_{GG} + C_{GS} + C_{GD} + C_{GB}$. The above equation shows that V_{FG} is a linear combination of the external voltages, with weighting factors given by the coupling coefficients, and that a negative charge Q_{inj} lowers the floating-gate voltage.

When V_{FG} equals the threshold voltage for current conduction within the EPROM cell V_{TF}, the control-gate threshold voltage V_{TC}, reads:

$$V_{TC} = (1/\alpha_G)V_{TF} - (\alpha_S/\alpha_G)V_S - (\alpha_D/\alpha_G)V_D - (\alpha_B/\alpha_G)(V_B + \Phi_{MS}) - Q_{inj}/C_{GG}$$

It may be seen from the above equation that the threshold voltage experienced by the control gate increases if electrons are injected into the floating gate. Strictly speaking, the gate-source, gate-drain, and gate-bulk capacitances are nonlinear; thus, the coupling factors are bias dependent. Quite often, however, such factors may be treated as constants. Furthermore, if $V_S = V_D = V_B = 0$, the above equation may be simplified to give

$$V_{TC} = (1/\alpha_G)V_{TF} - (\alpha_B/\alpha_G)\Phi_{MS} - Q_{inj}/C_{GG}$$

The channel hot-electron (CHE) injection methodology requires both a large gate and a large drain voltage to be applied to the EPROM cell. Thus, a large current flows while programming, with substantial power dissipation. This process is rather inefficient, since only a small fraction of the electrons moving from the source to the drain is indeed injected into the floating gate, and the required time to program the cell may be as large as a few hundred microseconds. After being injected into the floating gate, electrons lose their kinetic energy by emitting phonons, and become permanently trapped within a deep (3.1 eV) potential well.

As already pointed out, native cells are conductive when the control-gate voltage is at the high level; hence they are naturally programmed with a logical "1." Charge injection shifts the threshold voltage above 5 V, and the cell exhibits an off-state when read out. Thus, the high-voltage threshold indicates a logical "0."

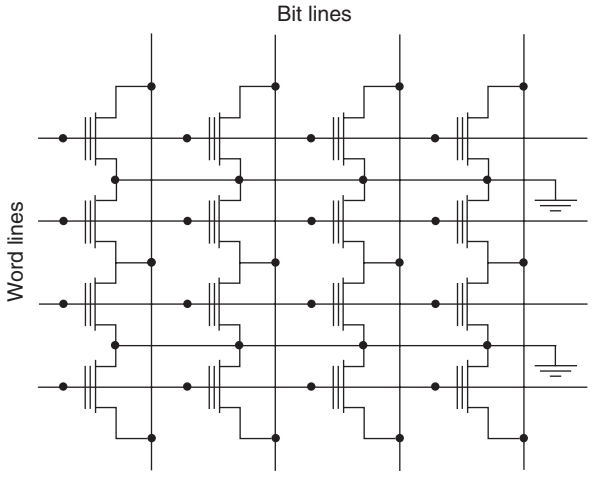

Figure 4 EPROM cell array organization.

The success of floating-gate EPROMs is largely due to the small cell size and the resulting high bit capacity, as well as to the on-field programming ability. Erasing the content of the memory can only occur by exposing the device to UV light for quite some time. This need requires a special package with a cover transparent to UV light. Electrons absorbing a high-energy photon by photoelectric effect can reach an energy exceeding the $Si–SiO_2$ potential barrier, and be ejected either into the control gate or into the silicon substrate.

The memory cell only contains a floating-gate device with its source connected to the ground, its drain connected to the bit line, and its control gate connected to the word line, as shown in **Figure 4**.

When the cell is addressed, the word line is raised high, and the bit line is set by the sense amplifier to an intermediate voltage of ~ 1 V. If a substantial current flows across the cell, the latter is detected to contain a logical "1." Otherwise, it will contain a logical "0."

EPROM memories must typically ensure a data retention of 10 years. This implies that the gate oxide and the inter-poly dielectric, which is often made by a silicon nitride (Si_3N_4) layer sandwiched by two silicon dioxide layers and is referred to as ONO, behave as ideal insulators. Besides, leakage currents must be very small even under the influence of external voltages. When a cell is programmed, all cells connected to the same word line are subject to a large positive gate voltage.

Hence, electrons can possibly tunnel into the floating gate from the channel, if the cell is in its conductive

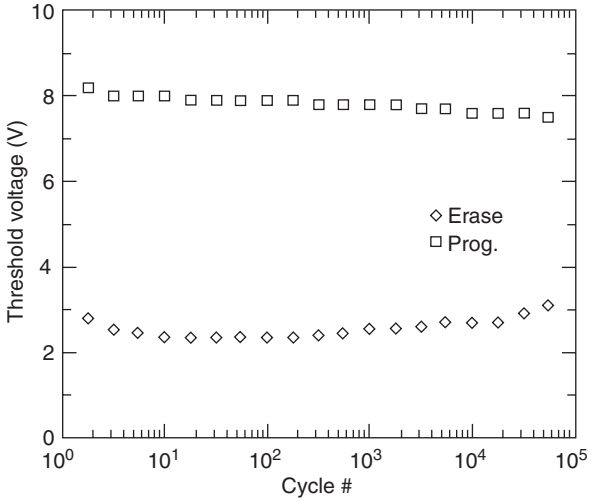

Figure 5 Aging effect on the threshold voltages of EPROM cells.

state, or into the control gate from the floating gate if the cell is in the off-state. In the former case, the gate disturbance tends to convert a logical "1" into a logical "0" while, in the latter, the opposite occurs. Likewise, all cells connected to the same bit line experience a relatively large drain voltage and, due to the low gate voltage, electron tunneling can occur from the floating gate into the drain. In this case, the disturbance generated by cell programming tends to convert a logical "0" into a logical "1."

A read disturbance additionally occurs when a cell is read out, despite the relatively smaller gate and drain voltages. The high drain voltage heats up electrons traveling from the source to the drain of the addressed cell. Hence, some hot-electron injection into the floating gate may occur in this case too. Due to the unlimited number of readings of the cell content, the drain disturbance must be carefully controlled. In order to prevent this effect, the drain is usually kept by the sense circuitry at a voltage ~ 1 V, well below the energy threshold for hot-electron injection.

The cumulative effects of gate and drain disturbance during write and read operations tend to reduce the high threshold voltage of the cells storing a logical "0," and to increase the low threshold voltage of the cells storing a logical "1." Thus, the aging effect manifests itself with a closing window between the high and low threshold voltages, as shown in **Figure 5**.

Electrically Erasable and Programmable Read-Only Memory

EEPROMs provide a further improvement over the functionality of EPROMs by allowing the information

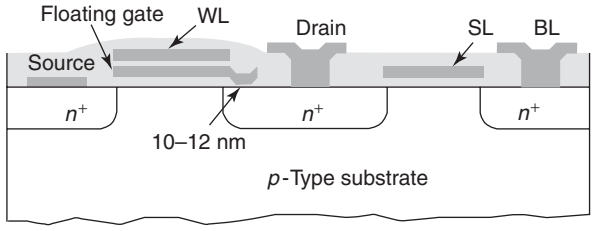

Figure 6 Schematic cross section of a floating-gate EEPROM (FLOTOX) cell.

to be electrically written and erased at the bit level. The basic cell differs from the EPROM cell in that the floating gate extends over the drain region, where a small oxide area is thinned down to 10–12 nm to allow for electron tunneling into and out of the floating gate. This device, shown in **Figure 6**, is referred to as FLOTOX.

The physical mechanism used to program and erase the EEPROM cell is electron tunneling across the thin oxide region between the floating gate and the drain. In order to let electrons tunnel into the floating gate, the control gate must be biased at a large positive voltage, while the drain is kept at zero voltage.

Likewise, cell erasing is carried out by applying a large negative voltage to the control gate, while keeping the drain at zero or positive voltage. In doing so, a large oxide field close to 10 MV cm^{-1} is applied to the tunnel oxide. The large field shapes the energy barrier to become triangular and reduces the tunneling distance. Fowler–Nordheim tunneling then occurs and either fills or depletes the floating gate of the formerly injected charge, thus raising the threshold voltage above V_{DD} or lowering it down below zero.

The poor threshold voltage control of an erased device, however, requires that the basic memory cell contains an additional MOSFET, referred to as selection transistor, connected in series with the FLOTOX device, as shown in **Figure 7**. The drain of the selection transistor is connected to the bit line BL, its gate is connected to the select line SL, and the gate of the FLOTOX device is connected to the word line WL. When the cell is not addressed, the select line SL is at zero voltage, which ensures that no leakage current flows even when the floating-gate device has a negative threshold voltage.

When the memory cell is addressed, both the word line WL and the selection line SL are raised at V_{DD}, thus allowing current to flow across the cell if the FLOTOX device has a low threshold voltage. Otherwise, no current flows, and the sense amplifier will detect a logical "0."

In order to program the floating-gate device, the word line is raised at the large positive voltage V_{PP} and the select line is raised at V_{DD}, while keeping the

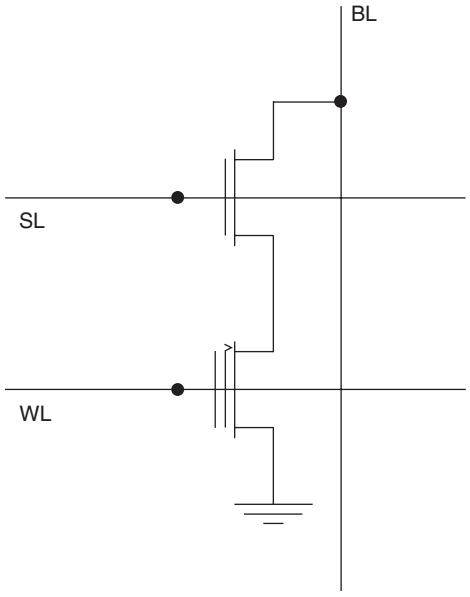

Figure 7 Circuit schematics of the EEPROM cell array.

bit line at ground potential. The V_{PP} voltage is chosen so that electron tunneling may occur into the floating gate. When the cell must be erased, the word line is negatively biased in order to generate the appropriate voltage across the tunnel oxide; the selection line is positively biased, so that the bit line can set the drain voltage of the floating-gate device at the appropriate level. Due to the small tunneling currents, several hundred microseconds may be needed to complete an erasure cycle.

The repeated electron tunneling across the thin oxide is responsible for reliability problems due to electron trapping within the oxide itself. This aging process deteriorates the electron mobility due to added Coulomb scattering and, most importantly, deteriorates the oxide integrity with resulting data retention problems.

Flash EEPROM

Flash EEPROMs are electrically erasable and programmable read-only memories. The basic flash cell is structurally similar to the EPROMs and programming can still be carried out by channel hot-electron injection into the floating gate. However, the cell can be electrically erased by Fowler–Nordheim tunneling through the gate oxide. As opposed to EEPROMs, however, erasing is only carried out in parallel at the sector level, and is followed by reprogramming each individual cell in order to set its threshold voltage at the appropriate high- or low-voltage levels. Therefore, the flash cell does not require the selection transistor for correct operation. An electron micrograph of a flash cell referred to as ETOX is shown in **Figure 8**.

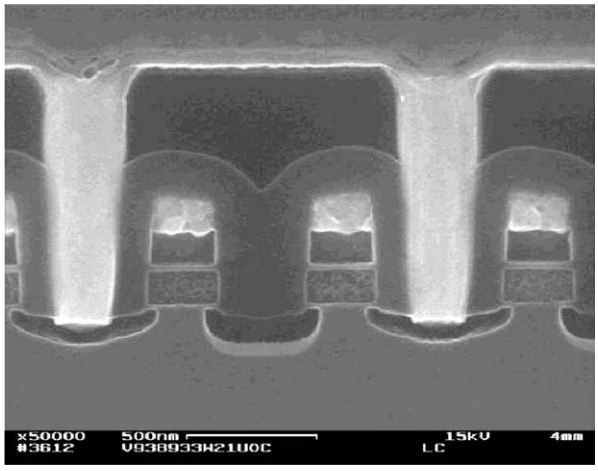

Figure 8 Scanning electron micrograph of the ETOX flash cell in 0.18 μm technology. (Courtesy of ST Microelectronics.)

The cross section is cut along the bit line, which is connected to the drain of the cell by a vertical tungsten plug. The tungsten silicide word line is perpendicular to the cross section, and appears in the micrograph as the light rectangular area overlapping the control gate of the cell. The polycrystalline silicon gates are self-aligned; the source and drain regions are shared by two neighbor mirrored cells. The lateral cell extension, measured between the source and drain mid-axes, is ~ 500 nm in this technology.

Cell programming requires a supply voltage $V_{PP} \approx 10$–12 V to be applied to the control gate, and a drain voltage $V_D \approx 5$–6 V. The former high-voltage supply is internally generated by a special circuit referred to as "charge pump." Electrons traveling from the source to the drain can eventually reach an energy exceeding the Si–SiO_2 potential barrier, and be injected into the floating gate.

Electron tunneling from the floating gate may occur either at the source side, if the latter extends laterally below the floating gate, or uniformly across the channel. In order to let it happen, it is necessary to set the control gate at a large negative voltage $V_{CG} \approx -12$ V, and the source at a large positive voltage $V_S \approx 5$ V, while keeping the drain floating. In doing so, the oxide field becomes large enough to reduce the tunneling distance down to a few nanometers. The negative voltage is again generated on a chip by a charge pump. The use of negative voltages requires a triple-well CMOS process to be worked out, with the external *p*-well biased at the most negative voltage, in order to prevent shorting of the *p*–*n* junctions with the *n*-layer biased at negative voltages.

Flash Array Architecture

From the standpoint of the cell array organization, nonvolatile memories can be based either on a NOR

or a NAND architecture. The former has a shorter access time, but the latter is denser and, thus, cheaper. A growing number of useful applications is not so critical as far as speed is concerned, while cost is always a critical issue: hence the NAND architecture is gaining momentum in the market place of flash memories.

The array organization of the NOR architecture is shown in **Figure 9a**. Cells within the same row share the word line, while cells within the same column share the bit line. Successive rows are mirrored in order to access the same common source line crossing the array parallel to the word lines. The common source lines of a sector are shorted and kept at ground potential during a read, but are raised at a positive voltage when an erasing operation takes place for the whole array sector. Because of the common source configuration of the flash cells during a read, this cell array organization is referred to as an NOR architecture.

The array organization of the NAND architecture is illustrated in **Figure 9b**. A number of cells, typically 8 or 16, are connected in series rather than in parallel, which allows for a compact layout and a higher cell density within the array. This is due to the small number of contacts to the bit line and the absence of the common source lines within the array; hence, a reduced word-line pitch becomes possible. In series with the flash cells, two select transistors are present at the top and bottom of the NAND column.

The information is stored as a charge within the floating gate. In this case, however, a logical "1" is associated with a negative threshold voltage, while a logical "0" is represented by a positive threshold voltage. Also, both programming and erasing are carried out by Fowler–Nordheim tunneling into, and out, of the floating gate.

The word lines are normally at V_{DD}. In this configuration, the unaddressed cells act as ON pass gates regardless of their actual threshold, which is typically much smaller. A read operation is carried out by lowering the word line down to 0 V, and detecting either a current, or no-current flow, on the bit line. In the former case, the threshold voltage of the addressed cell must be negative; in the latter case, instead, the threshold voltage of the addressed cell is positive. Reading a current through a series of several cells and two select transistors is, however, a slow operation: the random access time is, in fact, of the order of several microseconds.

In order to program a cell, the control gate is driven to a large positive voltage $V_{PP} \approx 15$ V, while the corresponding bit line is kept at 0 V. This ground potential is transferred to the source and drain of the addressed cell via the selection transistor and the series flash cells, with a negligible voltage drop due to the small tunneling currents flowing into the floating gate. To prevent program disturbances of the unselected cells on the same word line, all the remaining bit lines must be kept at V_{DD} and the unselected word lines at a voltage $V_m \approx 10$ V, large enough to ensure a good pass-gate function irrespective of the cell threshold voltage, yet sufficiently small to prevent electron tunneling into the floating gate of the unselected cells.

To erase a sector, electrons are injected from the floating gates to their respective channels, again by Fowler–Nordheim tunneling. This process is carried out by grounding all the word lines, and forcing a high voltage (up to 20 V) to the *p*-well of the array. In order to do so, all the peripheral circuits must be isolated from the *p*-well by lowering to ground both the select lines; otherwise the *n*–*p* junctions would become forward biased and overload the charge pumps. Compared with the NOR architecture, the erase operation is much faster, since it does not

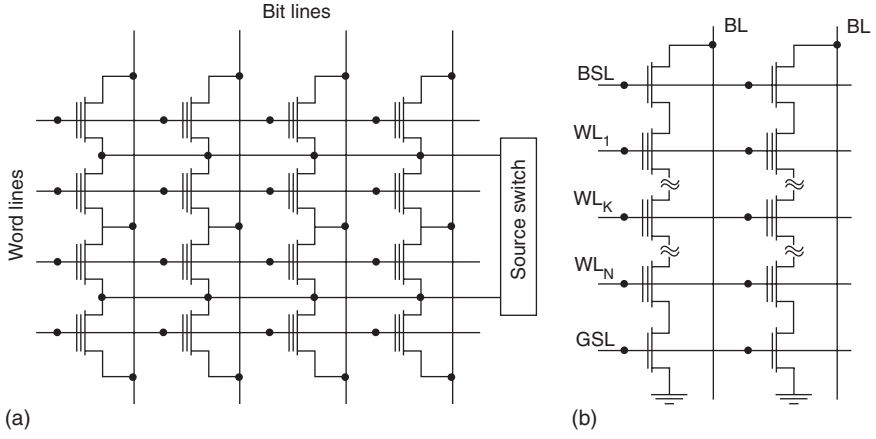

Figure 9 Flash EEPROM cell array organization: (a) NOR architecture and (b) NAND architecture.

require the program to be performed successive to "0." It should be noticed that the erase operation is made easier if the coupling coefficient α_B is small, so that the oxide field is maximized for a given *p*-well voltage.

In flash NAND architectures, the required voltage drops to ensure Fowler–Nordheim tunneling are not shared between a negative and a positive voltage generated by two distinct charge pumps. This requires a large negative voltage to be generated on chip, thus making the charge pump design more difficult. On the other hand, electron tunneling does not require high currents; hence, power consumption is reduced with respect to the NOR architecture.

Multi-Bit Memory Storage

The capacity of a flash EEPROM can be increased by storing two bits per cell, if four different threshold voltages, rather than two, can be accommodated within the cell. For a reliable operation, it is requested that the standard deviation associated with the statistical distribution of the threshold voltages be much smaller than the average separation between their central values. This may be accomplished with a tighter control of the injected charge within the floating gate, and with a more sophisticated reading procedure. More specifically, the threshold voltage must be monitored while programming, and the number and duration of writing pulses controlled by a suitable logic.

The reading procedure requires a number of steps involving two successive comparisons of the output current with three reference currents made available by suitably programmed dummy cells. In doing so, the memory capacity is doubled for a given array size, at the expense of a degraded access time.

Reliability of the Flash EEPROM

The read and write operations of the flash cell are similar to those of EPROMs: therefore, flash memories are subject to the same kind of read and program disturbances illustrated in **Figure 4**. As opposed to the EPROM, however, flash memories can undergo multiple program and erase cycles; hence their reliability problems are much more severe. The large oxide fields, which are needed for electron tunneling to occur, may be responsible for a degradation of the gate oxide.

The "endurance" of an EPROM cell refers to the property of experiencing multiple write and erase operations without affecting the memory performance. Connected with the endurance is the data retention, that is, the property of maintaining the written data unaltered for a long time (10 years) with or without any power supply. Charge loss in flash memories may be caused by: (1) defects in the gate oxide, (2) defects in the inter-poly dielectric (ONO), and (3) mobile ion contamination.

The degradation of the gate oxide typically occurs due to electron trapping during the write and erase cycles. This degradation may be responsible for premature oxide breakdown or low-voltage leakage, referred to as "stress-induced leakage current" (SILC). The latter is an anomalously large current flowing across the gate oxide in a relatively small, but significant number of cells. The SILC seems to be due to the percolation of electrons through a number of defects located within the oxide. This would justify the statistical nature of the SILC, which affects only a small percentage of the flash cells.

Experimentally, it has been found that the percentage of cells affected by the SILC is a strong function of the oxide thickness which, therefore, cannot be scaled below 8–10 nm. Similar considerations apply to the inter-poly dielectric, which has a lower limit at $\sim$10–12 nm. The nonscalability of the gate oxide and the inter-poly dielectric, in turn, does not allow the programming and erasing voltages to be reduced, in sharp contrast with the scaling trend of the CMOS technology. Besides, the generation of large programming and erasing voltages by means of charge pumps operating at small supply voltages, is a rather inefficient process, which makes the functionality of flash memories rather cumbersome.

Due to the above problems, two evolutionary approaches are currently being pursued: the nanocrystal memory and the SONOS memory. In the first approach, the floating gate would be replaced by a large number of silicon nanocrystals embedded within the gate oxide. Both programming and erasing would be carried out by electron tunneling across the gate insulator. The advantage of nanocrystals is twofold: first, if a leaky percolation path exists, only one nanocrystal would be affected and not the entire floating gate; next, the gate dielectric could be made as small as 2 nm, with a substantial advantage for the scaling properties of the cell, since electron tunneling across a thin gate insulator is known to generate less oxide defects.

The second approach, referred to as SONOS, is based on the use of an oxide–nitride–oxide gate dielectric, which improves upon a former nonvolatile memory, now obsolete, called MNOS. Electrons injected into the oxide would be permanently trapped within the nitride layer, which has a smaller barrier than the oxide, thus affecting the device threshold voltage. The trapping of each individual electron would make the tunneling across the oxide nearly impossible at low applied voltages, thus preventing

the SILC effect. Erasing would again occur by electron tunneling, by applying a large negative voltage to the gate of the SONOS cell.

New Memory Types

In addition to the semiconductor memories illustrated in the previous sections, which dominate the memory market, different device concepts are currently being investigated. Some of them, such as Magnetic RAMs (MRAMs) and Ferroelectric RAMs (FeRAMs), have been around for many years, but never succeeded in becoming truly competitive products. These memories are based on the properties of either ferromagnetic or ferroelectric materials, which are characterized by a hysteresis of their *M–H* and *P–E* relationships, respectively. Here *M* is the magnetic moment and *H* the magnetic field; *P* is the electric polarization and *E* the electric field. MRAMs, while not being competitive in density and cost with DRAMs, have comparable access times, an excellent radiation hardness, and are nonvolatile. As such, they have mainly been used in military and space applications.

Unlike MRAMs, ferroelectric memories are very appealing because of the simplicity of the basic cell, which promises a small size and a high density, as well as an easy approach to read/write operations. The major technological problems are connected with the use of ferroelectric materials, such as Pb(Zr, Ti)O_3, referred to as PZT, due to their difficult quality control, instability, and contaminating nature.

An entirely new approach is based on the use of chalcogenide materials, that is, an alloy of Ge, Sb, and Te (GST), which undergoes a phase change when heated up to high temperatures. More specifically, if a polycrystalline GST alloy is heated up to the melting temperature ($\sim$650°C), it turns into an amorphous state when it cools down. On the other hand, if an amorphous material is heated up to 500°C, it turns back into a polycrystalline state. The final state is indefinitely conserved at room temperature; hence, these materials can provide a nonvolatile memory function. Due to the large resistance change associated with a phase change, it is straightforward to read the stored information by a simple current measurement.

Magnetic RAM

Magnetic memories are based on the properties of ferromagnetic materials, such as iron (Fe), cobalt (Co), and nickel (Ni), which exhibit a strongly nonlinear and hysteretic *M–H* relationship, as shown in **Figure 10**. The residual magnetization of the above materials after the field return to zero is due to the alignment of the electron spin, which is conserved at room temperature.

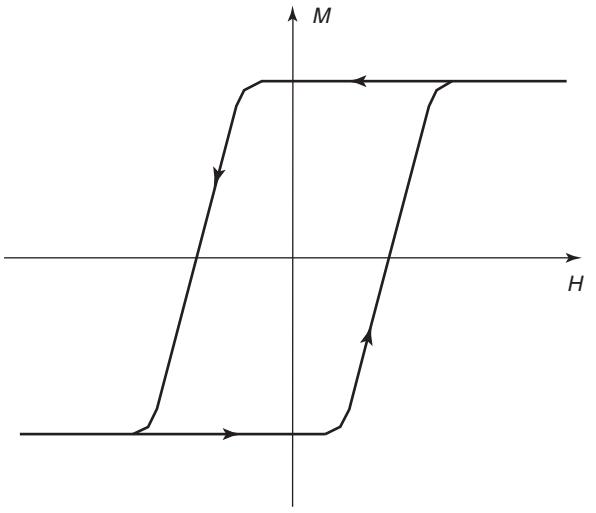

Figure 10 Magnetic moment against magnetic field in typical ferromagnetic materials.

Magnetic core memories were used in early mainframe computers, where a matrix of current carrying wires was used to program magnetic rings referred to as nuclei. Recent memory devices keep storing the information on magnetic elements, but the sensing scheme is now entirely different, and is based on the effect of magnetoresistance (MR), that is, a resistance change of a thin metallic layer due to the presence of a magnetic field. Magnetoresistance, however, is a small effect, with resistance changes of $\sim$1%.

More interesting from this standpoint is the giant magnetoresistance effect, which occurs when a thin metal layer, typically Cu, is sandwiched between two magnetic films consisting of NiFe. When the magnetic moments are parallel, the "up" electrons do not scatter, and only the "down" electrons scatter at the interface with the magnetic materials. When the magnetic moments in the two films are in opposition, instead, both type of electrons scatter and a significant resistance increase, which can be as large as 15%, typically occurs. The plot of magnetoresistance versus magnetic field is qualitatively shown in **Figure 11**. The effect according to which electrons with long mean free paths travel with low resistance when the magnetic materials have parallel alignments is called "spin valve," and the discipline which investigates the properties of materials due to the electron spin is called "Spintronics."

Several different configurations of magnetic films have been proposed for data storage in MRAMs. These include: (1) the anisotropic MRAM, (2) the spin-valve MRAM, (3) the pseudo-spin valve (PSV) MRAM, (4) the magnetic tunnel junction (MTJ), and

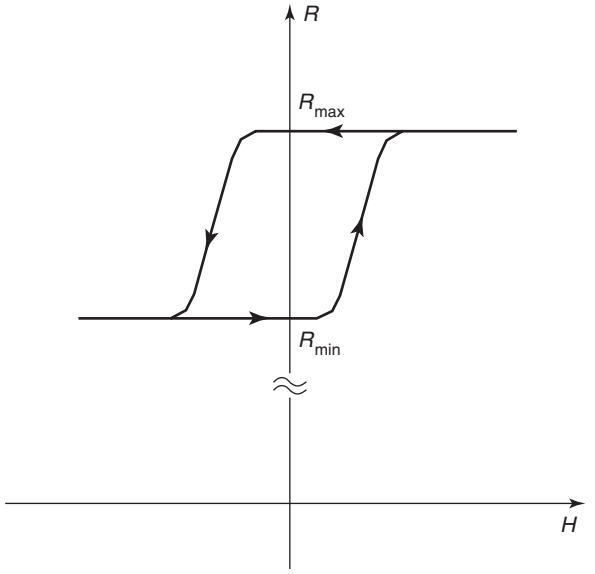

Figure 11 Plot of resistance against magnetic field showing the GMR effect.

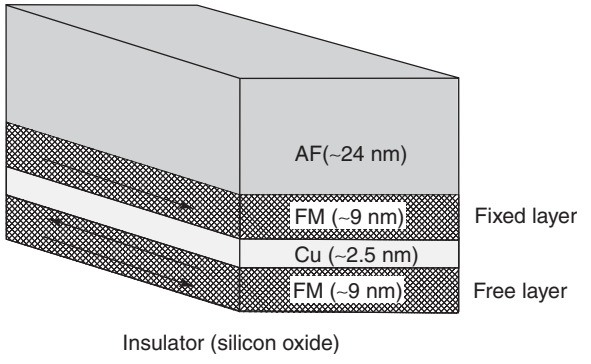

Figure 12 Schematic view of the spin-valve memory cell.

(5) the Hall effect MRAM. In what follows, only the spin-valve MRAM and the MTJ are discussed.

A schematic view of the spin valve is shown in **Figure 12.** A thin Cu layer ($\approx$2.5 nm) is sandwiched by two ferromagnetic films ($\approx$9 nm) made by a NiFe alloy. A much thicker pinning layer made by an anti-ferromagnetic material, such as FeMn or IrMn, is deposited on top of the upper magnetic layer. In spin-valve MRAMs, the magnetic moment of the magnetic layer adjacent to the anti-ferromagnetic material is pinned, while the other magnetic layer is free to switch from parallel to antiparallel orientation under the influence of an external magnetic field. When the magnetic moments of the two magnetic layers are parallel and the cell resistance is low, a logical "1" is associated with the state of the cell. When the polarizations of the two magnetic layers are antiparallel, and the cell resistance is high, a logical "0" is associated with the state of the cell.

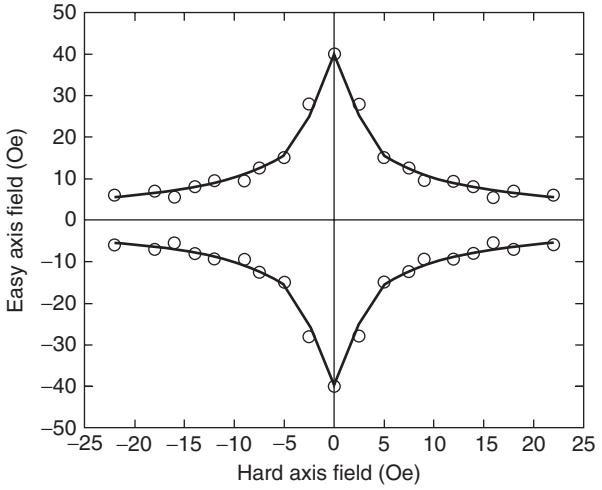

Figure 13 Switching threshold locus of the spin-valve memory cell (Asteroid curve).

Normally, a ferromagnetic material can be polarized at random directions. If, however, the magnetic film is narrower than the magnetic domain width, the film exhibits only two polarization states. This makes the switching threshold well defined.

The spin valve is located at the intersection of two conductors (word lines) whose orientations are parallel and perpendicular to the magnetization vector. For a write operation, orthogonal current pulses I_x and I_y generate longitudinal and transverse magnetic fields H_y and H_x, respectively, whose vector sum switches the magnetic moment in the free magnetic layer. The cell switch occurs in less than 2 ns. The use of two perpendicular components of the magnetic field lowers the switching threshold of the cell, as shown in **Figure 13.** This figure plots on the H_x–H_y plane the locus of the magnetic field components at which the spin-valve cell undergoes a switching. The asteroid shape of the curve indicates that combining suitable values of H_x and H_y allows much smaller magnetic fields to be used, to the advantage of the stability of the pinned-layer polarization. The same plot indicates that the normal component of the electric field (easy-axis field) switches the cell at a smaller field than the longitudinal component (hard-axis field).

To read the cell state, a specific polarization is forced on the free layer: if the cell switches, the voltage across the sense line will then change according to the resistance change. If the cell does not switch, no resistance change is sensed. In the former case, a positive voltage change indicates that the switching occurred from the parallel to the antiparallel polarization, meaning that the original cell state represented a logical "1," while a negative voltage change is the signature of a logical "0." The cell is

then written in the other direction in order to restore the original cell state. This cell can also be read by comparison of a sense current with a reference current, if an access transistor is used for each cell. In this case, the read can be nondestructive.

One of the major problems connected with MRAMs is that the resistance change of the conducting layer is still rather small for the needs of a large-scale production environment. Furthermore, the latter decreases with increasing temperature. Also, the pinning field decreases with the cell width. For submicron geometries, a spin valve that permits the polarization of both magnetic layers to switch appears to be a solution. The pseudo-spin-valve cell offers this possibility.

An alternative to the GMR spin-valve technology is the MTJ RAM. The latter is based on a thin insulating layer, typically Al_2O_3, sandwiched by two magnetic films as shown in **Figure 14** and, in this case, the current flows normal to the insulator surface. The detection mechanism is referred to as "spin-polarized tunneling," and its occurence depends on the relative orientation of the magnetization vectors in the two magnetic layers.

The resistance increase when the magnetic polarization becomes antiparallel is larger in this case, being $\sim$40% of its original value, and a higher memory density appears to be possible due to the perpendicular current flow with respect to the magnetic layers. Process uniformity is more critical, however, due to the extremely small insulator thickness, which is only a few tenths of a nanometer.

The memory organization may or may not use an access transistor, which acts as an isolation device. For a write, the access transistor is off. Current flows in orthogonal wires running above and below the cell, inducing a magnetic field, which changes the polarization of the free magnetic layer. The pinned magnetic layer is fixed. The programming wires are organized in a cross-point architecture, and the combination of the currents is designed to be just above the switching threshold of the MTJ. The read word line turns on the access transistor, as shown in **Figure 15**, and the current flowing across the MTJ is sensed on the bit lines.

A twin-cell organization improves the read reliability. In this case, the twin cells are forced to be always written in two opposite states. The data is read by detecting the resistance difference between the MTJs of the twin cells. This doubles the signal available for sensing, and improves the tracking properties with respect to a remote reference cell.

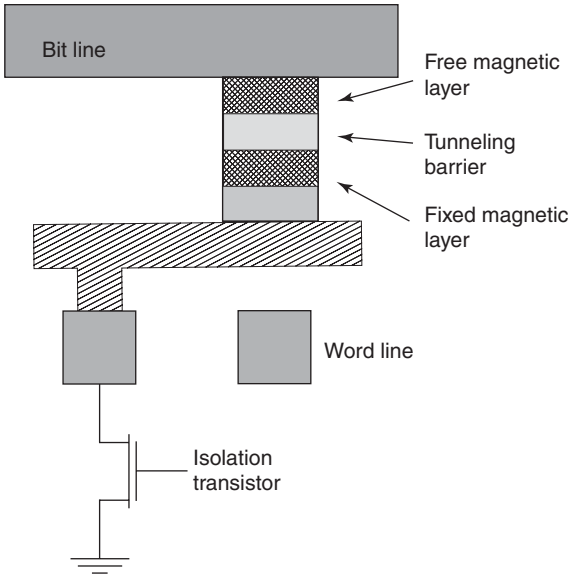

Figure 14 Schematic view of the MTJ memory cell.

Ferroelectric RAM

Ferroelectric materials exhibit a hysteretic *P–E* relationship, shown in **Figure 16**, which can be taken advantage of to fabricate memory devices.

In FeRAMs, the information is stored within the ferroelectric insulator of a capacitor in the form of an upward or a downward polarization. If a positive voltage is applied to the capacitor with an upward polarization, no change occurs in the compensating charge, and a small voltage shift is observed in the external circuit. If the polarization is downward, instead, the biased domains switch, causing a compensating charge to flow in the capacitor and the external circuit, and changing the capacitor voltage by a greater amount.

This means that the stored information can only be read by erasing the content of the memory, which

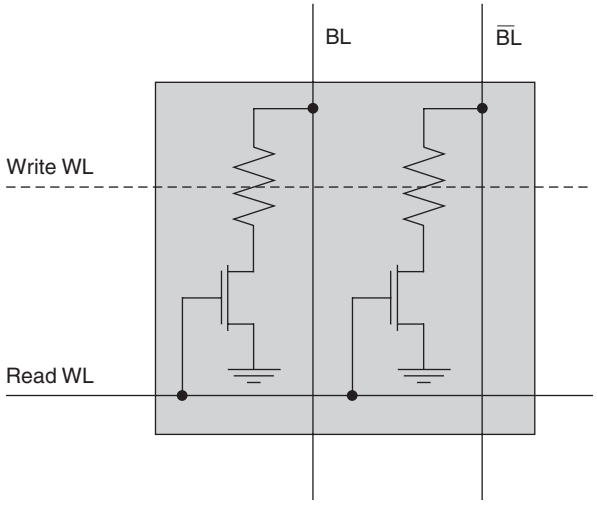

Figure 15 Cell array organization of an MTJ memory.

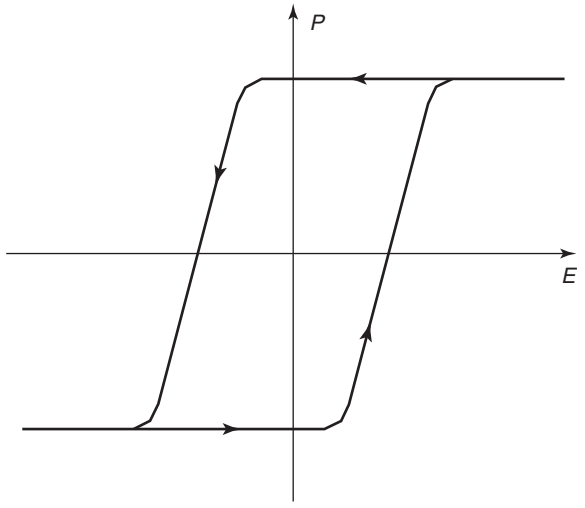

Figure 16 Plot of the electric polarization vs. electric field for a ferroelectric material.

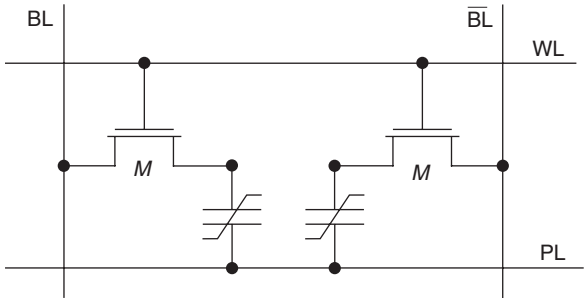

Figure 17 Circuit schematic of the 2T2C cell of a ferroelectric memory.

must then be restored to its previous state. The basic cell of a FeRAM contains either two transistors and two capacitors (2T2C), or one transistor and one capacitor (1T1C). The former cell is shown in **Figure 17**.

Two ferroelectric capacitors are connected to the bit line BL and to the bit line bar BL′ via two pass transistors driven by the same word line WL. The information is written by placing V_{DD} and 0 on BL and BL′, turning on the word line, and then cycling the plate line from 0 to V_{DD} to 0. When the plate line is at zero voltage, the ferroelectric capacitor on the bit line held at V_{DD} is polarized in a positive direction. When the plate line is pulsed to V_{DD}, the capacitor bias goes back to zero and the polarization is not affected. The other capacitor, instead, is polarized in the negative direction when the plate line goes to V_{DD}, and its state remains unmodified when it returns to zero. Therefore, the two capacitors always have opposite polarizations after cycling the plate line.

The cell is read by turning on the word line, presetting the bit lines at zero voltage in a high-impedance

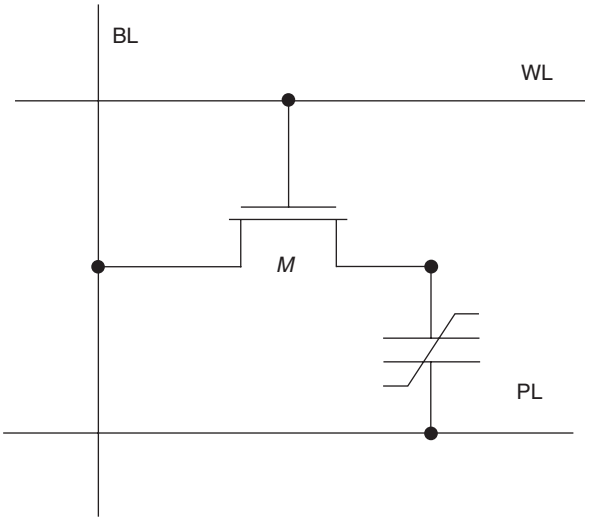

Figure 18 Circuit schematic of the 1T1C cell of a ferroelectric memory.

state, and switching the plate line to V_{DD} and back to 0. One of the ferroelectric capacitors will flip and the other will not, which generates a differential charge reading on the bit lines. The read is destructive, and the status of the cell must be restored. This may be accomplished by taking the plate line low, and letting the sense amplifier inject the read charge back into the cell. This will restore the original polarization on the flipped capacitor.

The read access time of a FeRAM is $\sim$70 ns, quite comparable with the access time of DRAMs and flash EEPROMs. The write access time is again $\sim$70 ns, that is, much faster than the write operation of a flash memory. Likewise, the write endurance of the FeRAM, which ranges between 10^8 and 10^{12} cycles depending on the ferroelectric material, is much better than the endurance of commercial nonvolatile memories.

In recent times, the 1T1C cell memory has been worked out. The cell structure is a simplified version of the 2T2C cell, as shown in **Figure 18**.

A logical "0" can be written in the cell by setting the bit line to 0, raising the word line and the plate line to V_{DD} and, after switching the ferroelectric material to a negative polarization, lowering the word line and, subsequently, the plate line down to 0. Writing a logical "1" can be accomplished instead by setting the plate line to zero, raising the word line and the bit line to V_{DD} and, after the positive polarization of the ferroelectric material, lowering the word line and, subsequently, the bit line.

Reading is accomplished by turning on the word line while setting the bit line at 0 V in a high-impedance state, and cycling the plate line from 0 to V_{DD}. For a cell in the "0" state, there will be a minimal

voltage change on the bit line, since the capacitor does not switch its polarization. For a cell in the "1" state, there will be a much larger voltage change on the bit line since the capacitor switches its polarization and the compensating charge flows in the bit line. This voltage change is compared with a reference voltage suitably set at an intermediate value between the expected low- and high-voltage levels. This switch from "1" to "0" requires a flip-back of the capacitor to restore the previous state before the word line is turned off.

The obvious advantage of the 1T1C cell with respect to the 2T2C cell is due to its smaller size, and, thus, higher density. However, the differential reading of the 2T2C cell is carried out on two capacitors which are one next to the other, and whose electrical properties are expected to track very well due to their vicinity and common history. Conversely, the reading of the 1T1C cell must be compared with a reference voltage generated elsewhere within the chip. The use of a ferroelectric dummy cell to generate the reference voltage has the potential advantage of tracking the chip-to-chip variations of the ferroelectric storage capacitors. However, the dummy cell would be switched many more times than the storage cells, thus generating a reliability problem due to fatigue; besides, the dummy cell being far away from the storage cells, additional factors such as uniformity of the ferroelectric material and temperature dependence of the *P–E* relationship come into play.

Phase-Change Memory

Phase-change memories (PCMs) are based on the peculiar properties of chalcogenide materials, that is, compounds based on sulfur, selenium, or tellurium, such as GeSe, AsS, GeAsTe, or GeSbTe (GST). The latter is the most frequently used material in PCMs. Memory switching in these materials is primarily a thermal process, which involves a phase transformation from a crystalline to an amorphous state, and vice versa, under the influence of a heat source. When the heating process stops, the material retains its new state, thus exhibiting memory. In practice, this transformation is achieved by passing a constant current through the sample for some time. The transition to an amorphous state (reset) occurs by resistive heating up to the local melting of the GST. The resistance change between the two states is $\sim$2–3 orders of magnitude, so that reading can easily be accomplished by low-bias nondestructive detection of the cell resistance.

A schematic cross section of two PCM cells is shown in **Figure 19**. The cell core is basically given by a crystalline GST layer, which is located between a vertical resistive heater and a horizontal metal line (bit line). The vertical resistor is connected to the emitter of a *p–n–p* bipolar transistor, the base of which is connected to the word line. In a process variant, the access transistor can be a MOSFET, rather than a BJT.

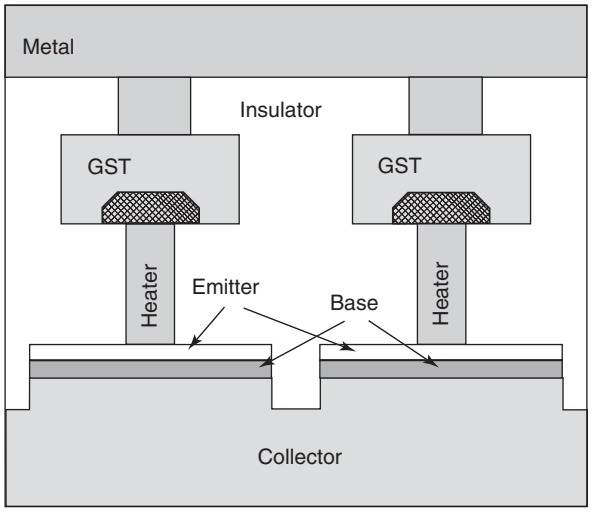

Figure 19 Schematic cross section of two PCM cells.

In order to let a phase change occur, the GST layer is heated by a current pulse. With present technologies, a 100 ns current pulse up to 0.4 mA makes the material crystalline and turns it to a low-resistance state (set). If the current pulse increases above 0.4 mA, the melting temperature of $\sim$650°C is reached at the interface of the GST film with the heater. During the cool-down process, the latter turns to a high-resistance amorphous state (reset).

An obvious concern of this technology is the thermal cross-talk between adjacent cells. In principle, the local heating of the GST layer up to the melting temperature during a reset could spread around heat and, possibly, set a neighbor cell. Thermal simulations, however, seem to indicate that this is not the case, and that no appreciable thermal cross-talk would, in fact, occur down to the 65 nm node of the ITRS. This is mainly due to the linear scalability of the reset current with the contact area for a given cell geometry. If all the physical dimensions of the cell are scaled down by a common factor k, instead, one would expect the set and reset resistances, as well as the thermal resistance, to increase by the same factor k, and the programming currents to decrease by k at constant voltage.

The scalability of the PCM cell, the elimination of large voltages required by the flash-memory technology, the reduced writing and erasing time, and the addressability of every single cell make this new

nonvolatile memory technology a promising candidate for low-voltage, high-density, low-cost, future-generation products.

Memory Devices, Volatile

G Baccarani and E Gnani, University of Bologna, Bologna, Italy

Introduction

Modern computer architectures rely on a hierarchy of memories, which differ in access times and density. The higher speed is typically achieved at the expense of a larger cell area, smaller memory capacity and, thus, higher cost per bit. At the upper levels of the hierarchy one finds registers, which are deeply rooted within the logic circuits of the processor, and three levels of cache memory, with the first two levels usually embedded within the processor chip. Caches typically employ static random access memories (SRAMs) based on either six or four transistors per cell. At the next level, the computer central memory uses dynamic random-access memories (DRAMs) based on the one-transistor memory cell. At the lower levels of the hierarchy, one finds several mass-memory devices, namely, magnetic disks optical disks, such as CDs and DVDs, and flash memory cards. Magnetic tapes are used to archive large amount of data to be seldom retrieved. As opposed to SRAMs and DRAMs, which are volatile memories, mass-memory devices are nonvolatile, that is, they retain the stored information upon power loss or shutdown. This is an essential requisite, which allows information to be safely stored and retrieved whenever necessary.

To date (2004), memory devices have found widespread use not just within computers, but also in a variety of professional systems, such as telecommunication networks and phone exchanges, robotic and control systems, automotive and medical electronics systems, as well as commodities and consumer products, such as cell phones, personal digital assistants (PDAs), digital video recorders and still cameras, digital TV (DTV), set-top boxes, GPS-based navigation systems, toys, and smart cards. Despite this wide variety of applications, which require a different throughput, latency and power consumption, and the related diversification of the memory market, the emphasis, in what follows, is on unifying factors, such as basic physical principles, and general architectural features, which allow one to treat this subject within the constraints of a tutorial presentation.

This treatment specifically addresses semiconductor memories (mass memory devices based on magnetic and optical storage are discussed elsewhere in the encyclopedia) and is split into two parts: one part is devoted to volatile memories, which are by far the most widespread devices in view of their excellent performance and density; the other part is devoted instead to nonvolatile memories, which are being used only when the nonvolatility is an essential requisite of the application.

The classification of semiconductor memories is presented in the next section. The section "Volatile memories" discusses the general features of such devices, including access time, packing density, and reliability issues. The section "Static random access memory (SRAM)" is devoted to the description of the basic cell topologies, cell-array organization, and sense-amplifier operation. The section "Dynamic random access memory (DRAM)" addresses the structural and functional properties of the one-transistor memory cell, the organization of the cell array, the structure and operation of the sense amplifier and the memory architecture. Finally, the section "Content-addressable memory (CAM)" contains a short description of the structure and operation of associative memories, as well as their basic application as a tag memory of set-associative caches.

Memory Classification

Semiconductor memories can be classified according to both structural and functional criteria. Following

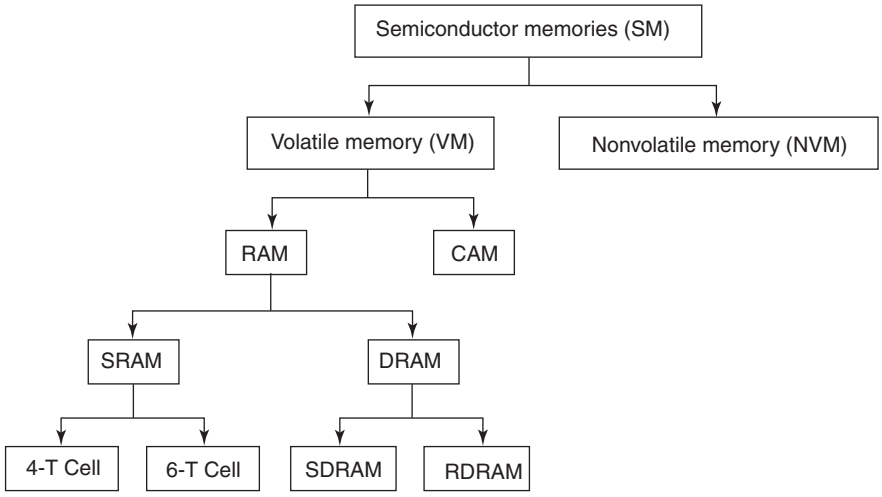

Figure 1 Semiconductor volatile memory classification according to functional criteria.

the latter approach, they are split first into volatile and nonvolatile memories, as indicated in **Figure 1**. As pointed out in the section, "Introduction," volatile memories do not retain the stored information if the power supply is turned off, while nonvolatile memories do retain the stored information in the above conditions. Also, volatile memories can be written and read on field in very short times. Nonvolatile memories, instead, can only be read on field in very short times, whereas repeated programming and erasing operations may not be possible or, if possible, typically require much longer times. Different physical approaches are used to store information in the above memories.

Most volatile memories are randomly accessed, and are thus referred to as random access memories (RAMs). Sequential memories, where bits are written and read sequentially, are rarely used, being outperformed by RAMs both in terms of speed and power consumption.

Content-addressable memories (CAM) are functionally and structurally different from RAMs. In the latter memories, every single bit, byte, or word can be accessed from the knowledge of its physical address. CAMs are, instead, addressed by an associative search using a data word as input, and provide an address as a result of this search.

Volatile memories store the information either statically (SRAM) or dynamically (DRAM). In the former case, the storing mechanism is based on a regenerative circuit characterized by two stable states. In the latter, information is stored as a charge on a capacitor.

SRAMs use a basic cell containing either six or four transistors per cell. The former type of cell is obviously larger, but is compatible with the standard CMOS technology, and is typically used for small, fast, embedded SRAMs employed in first- and second-level caches. The latter type requires a thin-film transistor (TFT) technology not compatible with the standard CMOS process. On the other hand, it provides a higher density and is usually preferred for large third-level caches outside the processor chip.

Dynamic RAMs may be characterized by different architectures. In the past, DRAMs used to be asynchronous and could start a memory cycle whenever two external commands referred to as row address strobe (RAS) and column address strobe (CAS) were successively asserted. More recently, the need to improve the cycle time of DRAMs has suggested more sophisticated architectures, which operate synchronously under the control of the system clock. To date, the synchronous DRAM (SDRAM) is the most widely used memory architecture. An improved performance is made possible by the Rambus DRAM (RDRAM), by which a careful design of the memory board allows for very large clock frequencies.

Volatile Memories

The most important parameter characterizing the memory performance is the access time, that is, the time elapsed between a read request and the availability of the requested word. The cycle time is, instead, the minimum time between successive read requests; its inverse is the memory throughput. The access time of SRAMs may vary from one to a few nanoseconds, depending on the memory size and the resulting capacitances of the word and bit lines. Therefore, these memories are used at the highest levels of the hierarchy within advanced computers and PCs.

DRAMs feature the smallest bit size and are typically used for the computer central memory. To date,

a central memory of 1 GB or more is common practice for high-end desktop and even portable PCs. Servers or mainframes typically employ several tens or hundreds of giga bytes of central memory; hence, the one-transistor DRAM cell is by far the most largely produced semiconductor device in modern industry. Under the assumption of an average main memory of 1 GB and a worldwide production of 100 million computers per year, it turns out that $\approx 10^{18}$ DRAM cells are manufactured every year.

The access time of DRAMs is $\sim$40–60 ns. Therefore, accessing data stored within the central memory of a computer requires several tens of clock cycles for a modern processor.

Volatile memories can suffer data loss due to soft errors, which are caused by the interaction of energetic nuclear particles, such as α, β, and cosmic rays, with the silicon substrate. These events may occur due to the radioactive decay of some impurity atoms contained within the package material and/or the metal layers of the memory chip. Alternatively, as for cosmic rays, these energetic particles may come from the outside space and occasionally hit the memory device. A charged energetic particle penetrating through a semiconductor substrate generates a large number of electron–hole pairs, which are then separated by the electric field within the device-active region. The generated carriers can possibly compensate the charge stored within a cell capacitor, and modify its state. Even static memories are not immune to soft errors, for an energetic particle impinging onto a bi-stable circuit can upset it and change its state. In both cases, a soft error would occur.

In order to ensure the full reliability of the system, several strategies are pursued. At the device level, the geometry of the space charge region is designed in such a way as to drain excess carriers generated by the energetic particle by reverse-biased *p–n* junctions, so that the charge stored within a cell capacitor can hardly suffer a substantial change; also, the bits of a word are not stored at consecutive physical locations, so that, at most, one bit of a word can be changed due to the occurrence of a soft error. At the system level, a few more parity bits are stored together with a 32-bit word. When a word is retrieved from the memory, the examination of the parity bits makes it possible to detect the occurrence of one or more soft errors and also correct the wrong bit.

Static Random Access Memory

The simplest bi-stable circuit is obtained by cross-connecting two CMOS inverters M_1–M_2 and M_3–M_4, as shown in **Figure 2**. Clearly, such a circuit can be biased in either of the two states, characterized by

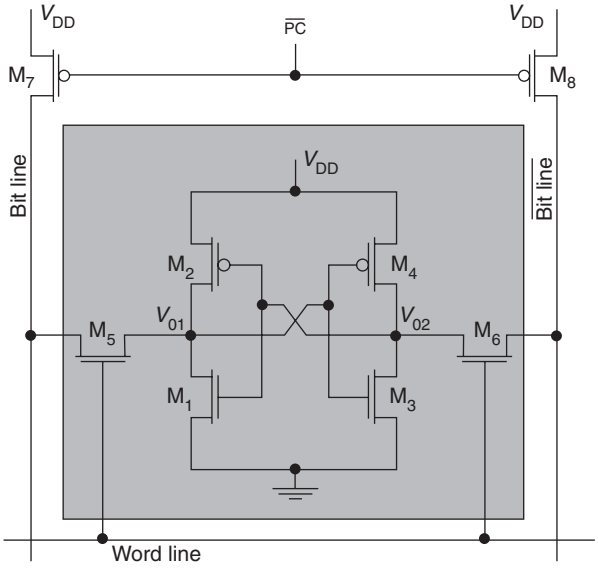

Figure 2 The six-transistor CMOS SRAM cell.

$V_{01} = 0$, $V_{02} = V_{DD}$ or $V_{01} = V_{DD}$, $V_{02} = 0$, respectively. By associating the logical value "0" to the former, and the logical value "1" to the latter bias condition, one stores one bit of information within such a circuit. So long as the power supply is on, this cell will indefinitely preserve the stored information, hence the definition of static memory.

In order to access the information, however, two more devices M_5 and M_6 are needed within the cell, as shown in the same figure. These devices act as pass transistors, which isolate the cell if the word line is low, or connect the cell to the bit lines if the word line is high. Hence, the total number of transistors per cell is six. The bit lines, which are shared by all cells within the same column, provide the readout information to the sense amplifier, that is, the circuit which generates a logic output data from a slight unbalance of the bit lines.

In four-transistor memory cells, the pullup metal-oxide-semiconductor field effect transistor (MOSFETs) M_2 and M_4 are replaced by either passive resistors, as shown in **Figure 3**, or TFTs made by polycrystalline silicon.

In the former case, their resistance R must be very large, since the standby current consumption of a cell is given by V_{DD}/R. The resistance value is thus defined according to the need of supplying the minimum current to preserve the high voltage of the node. In practice, $R \approx 1$–$10\ G\Omega$, which can be achieved using lightly doped polycrystalline silicon films. The use of TFTs as pullup devices reduces the leakage current by nearly two orders of magnitude with respect to the passive resistor cell, and improves the current-drive capability of the pullup devices in the on state.

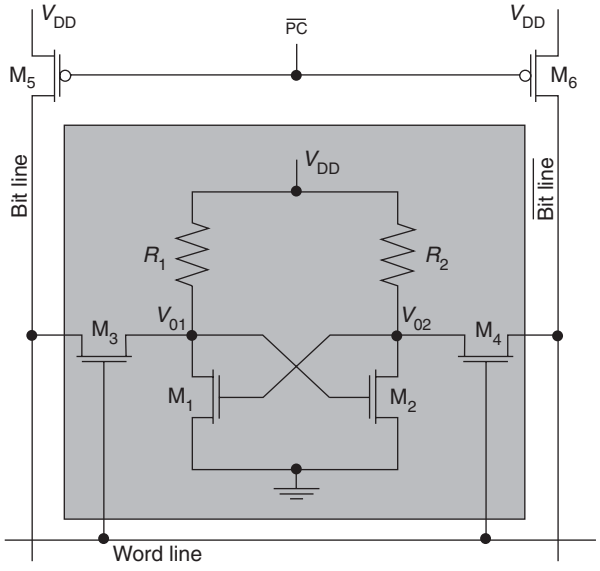

Figure 3 The four-transistor CMOS SRAM cell.

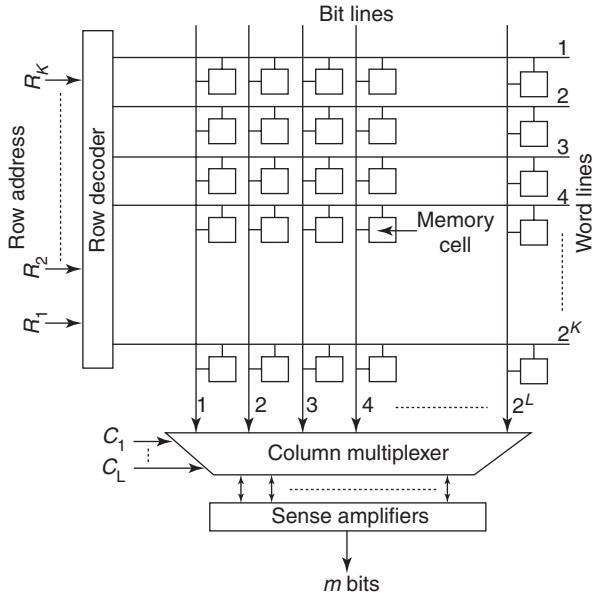

Figure 4 SRAM cell array organization.

This improvement can be achieved at the expense of a more complex technology, involving an additional masking step, and the deposition of an undoped polycrystalline silicon film.

Cell Array Organization

The cell array of an SRAM is organized as indicated in **Figure 4**. A row decoder receives the row address of the cell at the input and raises the corresponding word line high. Hence, all the cells pertaining to the above row become connected to the respective bit lines.

The output multiplexer acts as a column decoder, and selects the appropriate bit, byte, or word. The corresponding bit lines are then connected to the sense amplifier(s), which detect the stored information within the selected cells. If the depth of the column decoder is too large, it may be worth interposing the sense amplifiers between a first partial column decoder, acting on the bit lines which carry analog signals, and a second column decoder, acting on the digital outputs of the sense amplifiers. Clearly, reducing the number of sense amplifiers is an advantage from the standpoint of power consumption, but, on the other hand, interposing too many pass transistors between the bit lines and the inputs of the sense amplifier could be detrimental to the accuracy of the readings.

It should be noticed that, if the row decoder receives a K-bit address and the column decoder gets an L-bit address, then the array contains 2^K rows and 2^L columns. Thus, a total number of 2^N cells is present within the array, with $N = K + L$. The number of selected outputs m depends on the memory organization: if the SRAM is fully decoded, $m = 1$. In this case, one single bit is read from, or written into, the array. Alternatively, m can be either 8 (byte decoding), 16 (half-word decoding), or 32 (word decoding).

Cell Reading and Writing

A reading cycle proceeds as follows: (1) the bit lines, precharged at V_{DD}, are turned to a high-impedance state, (2) the word line is raised, thus connecting the cells within the addressed row to the bit lines, (3) the pull-down transistors of the addressed cells discharge one of the two bit lines, while leaving the other at V_{DD}, (4) the selected bit lines are connected to the sense amplifiers via the column decoder, (5) the sense amplifiers read the content of the addressed cells and make the bit information available to the output circuitry, (6) the row and column decoders are reset, and (7) the bit lines are reset to V_{DD}.

Likewise, a writing cycle proceeds as follows: (1) the row and column decoders are activated, thus connecting the addressed cell to the respective bit lines and the latter to the output circuitry, (2) either one of the two bit lines connected to the cell via the column decoder is discharged to zero, (3) the bit line connected to ground either confirms the status of the cell or upsets the cell in order to make it biased according to the desired input, (4) the row and column decoders are reset, and (5) the bit lines are precharged to V_{DD}.

The timing of the above operation sequence is controlled by internally generated voltages.

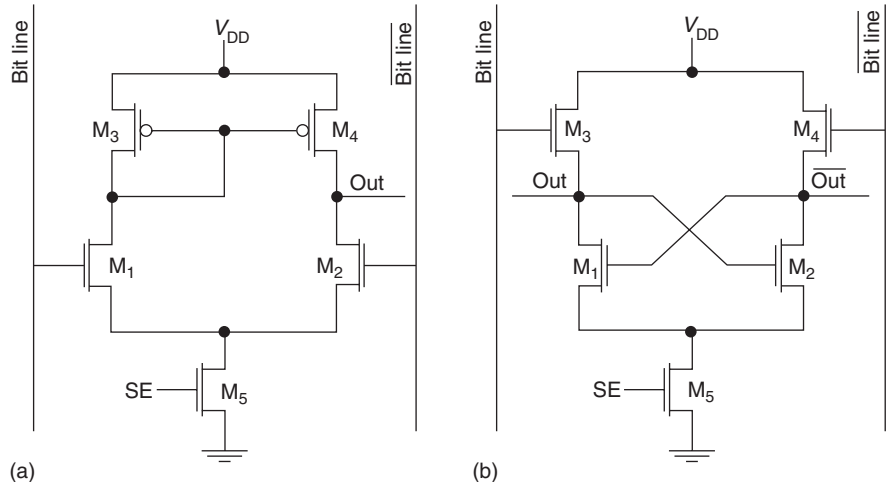

Figure 5 SRAM sense amplifier. (a) voltage amplifier, (b) level shifter.

Sense Amplifier

For static memories, the sense amplifier is often the standard one-stage CMOS differential amplifier with single-ended output, as shown in **Figure 5a**.

The function of the sense amplifier is, in this case, that of allowing for a quick reading of the differential signal on the bit lines, so that the discharging process can be stopped as soon as possible, to the advantage of speed and power consumption. One major drawback of this simple scheme is that, the bit lines being pre-charged to V_{DD}, the differential-pair M_1, M_2 operate in the triode region, with a severe degradation of the voltage gain.

A better solution is a two-stage scheme, with interposition of a differential-level shifter, shown in **Figure 5b** between the bit lines and the voltage amplifier. This circuit features a positive feedback intended to increase the differential voltage gain of the level shifter above 1. Most important, the appropriate DC bias of the differential pair optimizes the amplifier gain, resulting in an excellent performance of the sense amplifier.

Dynamic Random Access Memory

Information can be dynamically stored as a charge on a capacitor, as indicated in **Figure 6**. If the capacitor is charged, its voltage $V_c = V_{DD}$; otherwise, $V_c = 0$. Here again the MOSFET acts as a pass transistor, which can either isolate the cell or connect it to the bit line. In order to charge the cell capacitor to V_{DD}, the word line must be driven to a higher supply voltage V_{PP}. A disadvantage of this storage scheme is that, due to the transistor leakage current, the charge is not indefinitely conserved within the capacitor but, rather, leaks out in a time approximately a few milliseconds. This requires the information to be refreshed some thousand times per second; hence, the definition of dynamic memory.

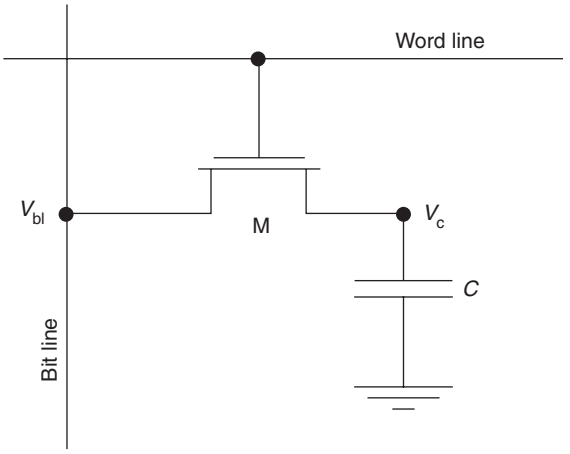

Figure 6 The one-transistor DRAM cell.

The cell capacitance must be as large as possible to ensure a long retention time as well as a safer reading of the stored information. At the same time, it must occupy a small silicon area, in order to allow for a large density and a small cost per bit. These conflicting requirements are pursued with either a trench or a stacked cell. In the former case, schematically shown in **Figure 7a**, the capacitor is placed in a deep trench engraved within the silicon substrate by reactive-ion etching. The trench surface is thermally oxidized and filled with polycrystalline silicon, which acts as the upper electrode of the capacitor and is electrically connected to the MOSFET source. The plate electrode is formed instead by the silicon substrate. In a recent implementation, even the pass transistor of the cell is fabricated along the trench sidewall and is therefore vertically oriented.

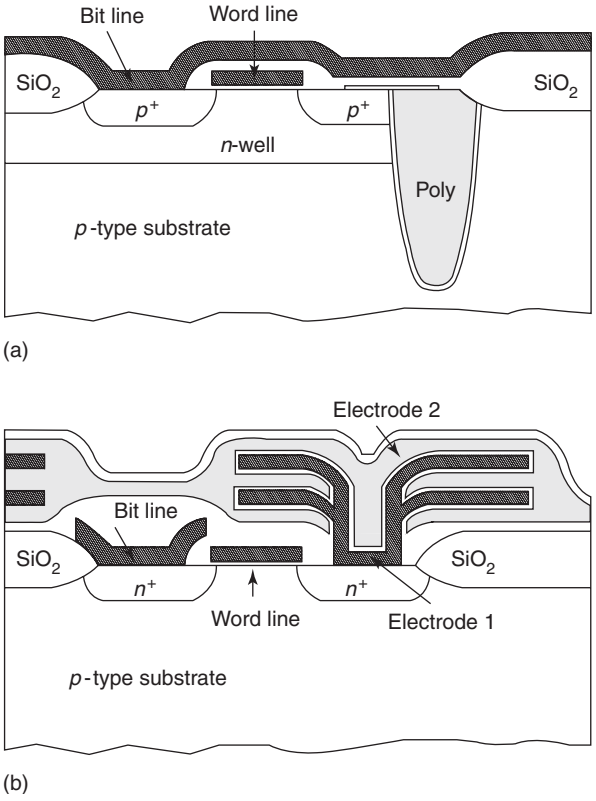

Figure 7 Schematic view of DRAM-cells. (a) DRAM-trench cell and (b) DRAM-stacked cell.

The stacked cell, shown in **Figure 7b**, aims to deploy a large capacitance by extending the surface of the upper electrode in a complex elevated structure. This is achieved by a double-fin structure, generally made by polycrystalline silicon, which is electrically insulated and surrounded by the second electrode, representing the capacitor plate.

An electron micrograph, showing a realistic image of a trench cell, is represented in **Figure 8a**. The aspect ratio of the trench cell is remarkably elongated, stressing the need for a large capacitance, typically larger than 35 fF, within a small silicon area. The polycrystalline silicon finger is electrically connected to the source of the *p*-channel transistor, whose drain is shorted to the bit line via a tungsten plug.

Figure 8b shows instead an electron micrograph of a realistic stacked cell. The double-fin structure represents the upper electrode of the cell capacitor and appears to be light as the silicide layer overlapping the transistor gate. The latter is connected to the word line by vertical W plugs shown in the upper part of the micrograph. The cell connection to the bit line is not shown in this cross section.

DRAM Cell Array Organization

The DRAM cell array may be organized as indicated in **Figure 9**. The bit line is split into two identical

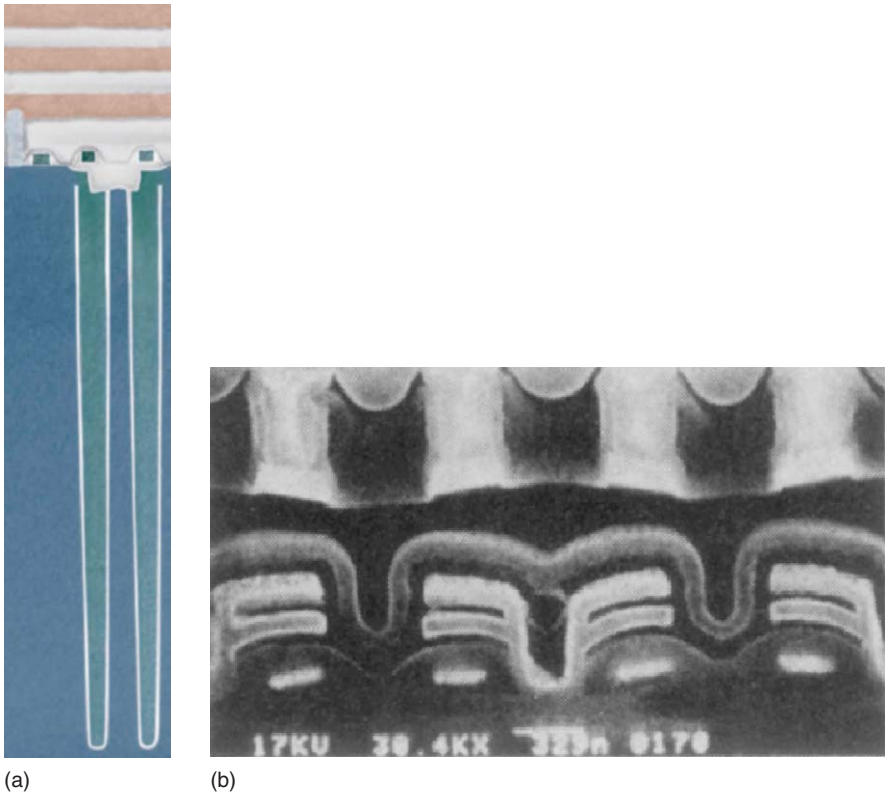

Figure 8 Electron micrographs of DRAM cells. (a) Trench cell (courtesy of IBM Corporation), and (b) stacked cell. (Courtesy of Fujitsu Ltd.)

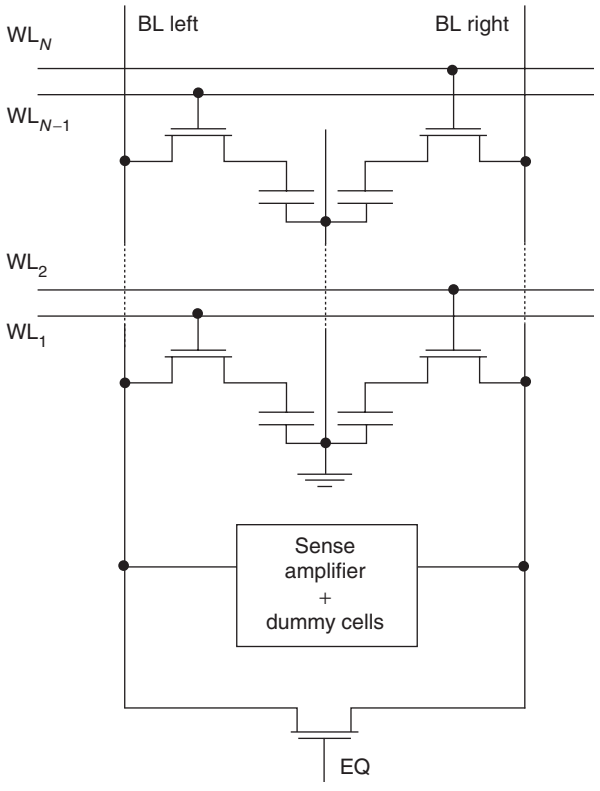

Figure 9 Folded bit-line organization of the DRAM cell array.

segments connected to the sense amplifier, which allows for a differential reading of the stored information and halves the bit-line capacitance for a given column size. In the folded bit-line architecture, shown in the same figure, both segments of the bit line are laid out on the same side of the sense amplifier. The bit-line folding makes it easier to match the layout of the sense amplifier onto the wider pitch of the two half-columns, and allows for an easy placement of the column decoders.

The bit lines are initially precharged at $V_{DD}/2$ by turning on transistor EQ, and are then kept in a high impedance state. As for SRAMs, the row decoder addresses a row of cells and turns the corresponding pass transistors on, thus connecting the cell capacitors to their respective bit lines. Due to the large capacitance ratio between the parasitic bit line and the cell capacitances C_{bl} and C_c, respectively, the bit-line voltage is only slightly affected. More specifically, the voltage change ΔV_{bl} of the bit line connected to the cell equals

$$\Delta V_{bl} = [C_c/(C_{bl} + C_c)](V_c - V_{DD}/2)$$

where V_c is the cell voltage, which may be either 0 or V_{DD}. If the ratio $C_o/C_{bl} \approx 0.1$, the voltage change ΔV_{bl} is only a few hundred millivolts. Due to an unavoidable offset of the sense amplifier, the cell capacitance must be as large as possible, while being dimensionally small to allow for a high bit density.

It is clear from the previous expression that the bit-line voltage increases with respect to $V_{DD}/2$ if the cell voltage $V_c = V_{DD}$, and decreases if $V_c = 0$. The second input of the sense amplifier is connected to a reference voltage generated by a dummy cell precharged at $V_{DD}/2$, as the bit lines. Therefore, the properties of the sense amplifier must be the following: (1) It must detect and amplify a small voltage difference between the two bit lines, eventually generating logic levels and (2) upon reading, it must refresh the content of the cell by reestablishing the original value of the charge stored within the capacitor.

DRAM Sense Amplifier

The schematic of the DRAM sense amplifier is reported in **Figure 10**. Here M_1–M_4 form a regenerative, bi-stable circuit connected to ground via M_5 and to V_{DD} via M_6. An additional pass transistor M_7 may either connect or isolate the two bit lines, thus enabling their precharge to $V_{DD}/2$. Two dummy cells are located on the opposite sides of the sense amplifier and their capacitor is precharged to $V_{DD}/2$ by a suitable circuit: their function is that of balancing the two bit lines by letting them undergo the same transient conditions before readout.

At the start of a reading, SE is low, keeping M_5 and M_6 off; the bit lines are precharged to $V_{DD}/2$ and left in a high-impedance state. Thus, the cross-coupled transistors M_1–M_4 are self-biased on their respective thresholds, and the voltages V_3 and V_4 set at $V_{DD}/2 - V_{Tn}$ and $V_{DD}/2 + |V_{Tp}|$, respectively, V_{Tn} and V_{Tp} being the threshold voltages of the *n*- and *p*-channel MOSFETs, respectively.

The reading sequence is the following: (1) the word line of the addressed cell is activated, thus connecting its capacitor to the corresponding bit line, and so is the word line connected to the dummy cell on the opposite side of the addressed cell, (2) SE is gradually raised high, allowing the sense amplifier to unbalance and reach its final state, (3) the sense amplifiers are readout via a column multiplexer, (4) the word lines are reset to their low value, (5) the signal SE is switched low, thus turning off M_5 and M_6, (6) the bit lines are shorted by raising the signal EQ, which drives them and the dummy-cell capacitors to $V_{DD}/2$, and (7) M_7 is turned off by lowering EQ and leaving the bit lines in a high-impedance state. So doing the initial reading conditions of the sense amplifier are reset.

It may be worth pointing out that, following the gradual raise of SE in step 2, M_5 and M_6 turn on lowering V_3 and raising V_4. The cross-coupled

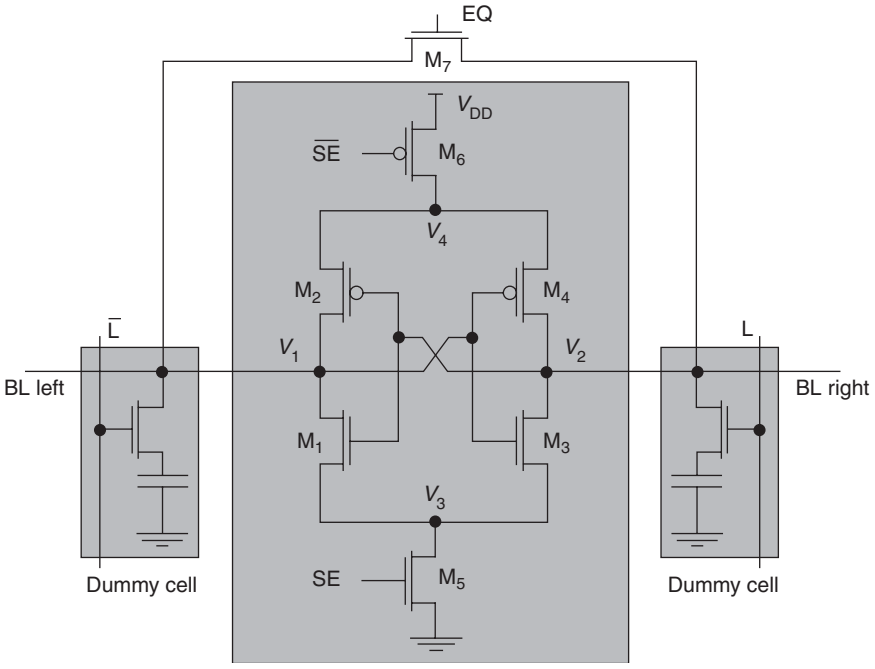

Figure 10 Schematic depiction of the DRAM sense amplifier.

transistors M_1–M_4 turn on and unbalance the sense amplifier according to the initial voltage mismatch. If the initial bit-line voltage $V_{bl}^{(left)} > V_{DD}/2$, which reflects the content of a logic "1" in the addressed cell, the transient drives it to V_{DD} while the right bit-line voltage $V_{bl}^{(right)}$ goes to zero. The opposite situation occurs if $V_{bl}^{(left)} < V_{DD}/2$, which reflects the content of a logical "0" within the same cell. Thus, reading the addressed cell restores the original voltage within the cell capacitor, which makes the reading nondestructive. Also, if the two bit-line capacitances are equal, precharge to $V_{DD}/2$ is simply achieved with no additional power consumption by connecting them via M_7.

DRAM Architecture

The block diagram of a DRAM bank is shown in **Figure 11**. The row addresses are delivered to the row decoders, which activate one word line. All the cells associated with that word line are thus connected to the bit lines, and their content is readout by the sense amplifiers. The column addresses set the column decoder (actually a simple multiplexer) and select the requested bytes or words, which are delivered to the output registers. Multiple column readings can be performed in sequence for any given row address. This improves the data rate of the DRAM. The above structure may be mirrored and replicated as many times as needed. The size of a DRAM bank is defined according to conflicting constraints: increasing the size of the cell array makes the layout more compact for a given DRAM capacity, but deteriorates the access time and, ultimately, the reading integrity, due to the larger word- and bit-line capacitances.

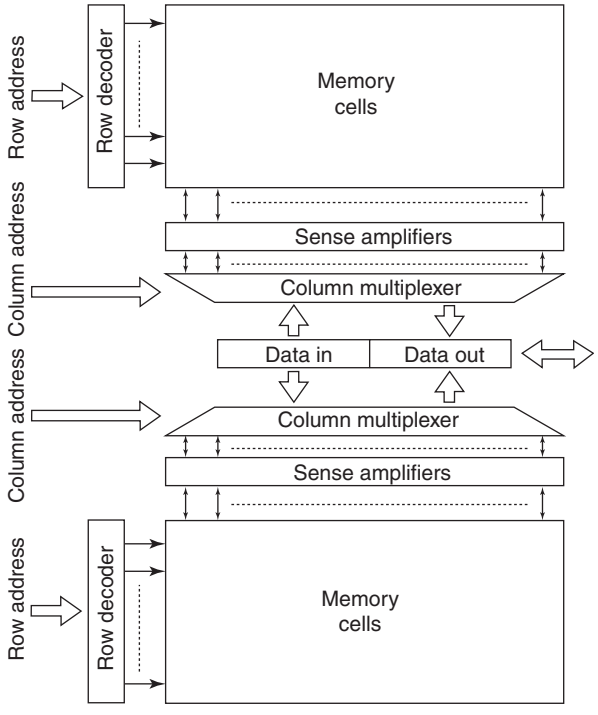

Figure 11 DRAM bank architecture.

In order to save package pins, a multiplexed addressing scheme, where the row and column addresses are presented in sequence to the same bus, is typically used. In this addressing scheme, two main control

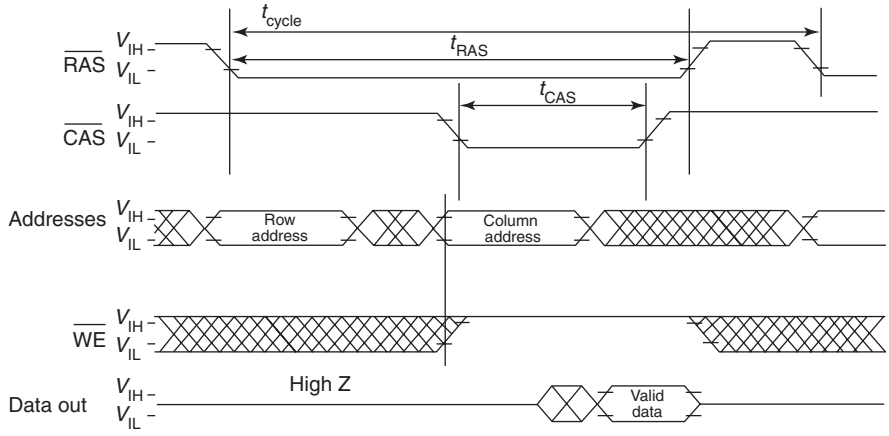

Figure 12 Timing diagram of the DRAM input signals.

signals must be provided to the DRAM, namely, RAS and CAS. Another control signal, write enable WE, indicates if the intended operation is a read or a write.

The timing diagram of a read operation is shown in **Figure 12**, where the control signals RAS′, CAS′, and WE′ are shown in complementary form. The RAS′ signal is switched low only after valid row address bits are present at the DRAM input buffer. In turn, the CAS′ signal goes low only when valid column address bits and a valid WE signal are set to their respective values. The time t_{CAS} is the minimum time that CAS′ must be kept low to generate valid output data; the time t_{RAS} is the minimum time that RAS′ must be kept low to generate valid output data; finally, the cycle time t_{cycle} is the minimum time needed between two successive RAS′ commands.

Synchronous DRAM

Early DRAM architectures used to operate asynchronously under the control of the external commands outlined in the previous section. To date, most DRAM chips are synchronous devices driven by the system clock, and are thus referred to as SDRAMs. Synchronous operation has several advantages: most notably, the possibility of a pipelined DRAM architecture with concurrent row and column addressing, and high-speed I/O operations. Taking advantage from the inherent parallelism of the memory core, this architecture improves the DRAM data rate, which is the most important performance parameter, while leaving its latency scarcely affected. Due to the hierarchical memory organization in modern computers, entire data blocks are, in fact, retrieved from the central memory when a block miss occurs at a higher level of the hierarchy. To date, SDRAM data rate may be as large as $1.6\,\mathrm{GB\,s^{-1}}$. This comes at the penalty of extra latches and buffers, as well as high-speed circuitry to support the I/O interface.

SDRAM commands, addresses, and data are latched to the rising edge of the system clock. Basic SDRAM commands are chip select (CS), RAS, CAS, WE, data mask (DM), and data strobe (DQS). The CS signal is used to let the chip know that the commands coming in over the bus are intended for it. RAS, CAS, and WE retain the usual meanings of row and column address strobe and write enable, respectively. DM masks the input data during a write; DQS is instead a bi-directional edge aligned data strobe which toggles at the same time as the output data. This is made possible by a delay locked loop (DLL), which shifts the output data in order to align DQ and DQS. The bus width is most often 64 bit.

The basic SDRAM operations are: activate (ACT), read (RD), or write (WR) followed by a precharge. SDRAM operation can be configured for CAS latency and burst length by setting the 12 bits of the load mode register (LMR). The burst length determines the amount of data transferred in consecutive cycles between the memory controller and the memory after applying one start address.

The typical delay between the RAS and CAS signals is two clock cycles, and the CAS latency is again two clock cycles; thus, the access time is four clock cycles. The SDRAM cycle time t_{cycle} depends, in this case, on the bus width and the burst length.

Rambus DRAM

The direct RDRAM architecture is based on a system approach, which maximizes the data rate on the memory board by carefully synchronizing data, addresses, and commands with the clock signal. The key elements of this technology are the following: (1) a 16-bit wide, 800 MHz channel, (2) an on-board interface that allows the memory controller talk to the RDRAM and, (3) an in-line memory module called RIMM.

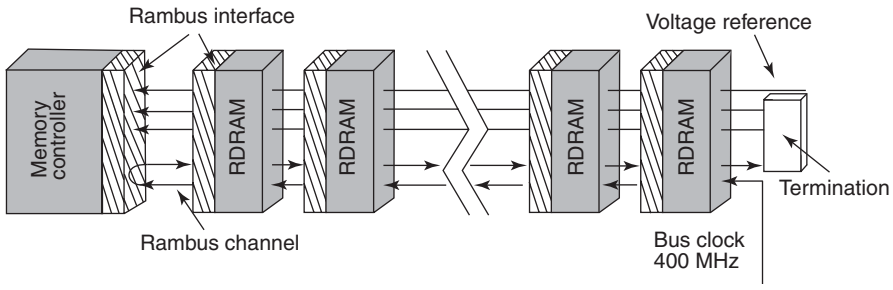

Figure 13 Direct Rambus DRAM architecture.

A Rambus channel includes a controller and a variable number of RDRAM chips connected together via a linear common bus. As shown in **Figure 13**, the controller is located at one end, and the RDRAMs are distributed along the bus, which is terminated at the opposite end with the characteristic impedance of the lines connected to the high-voltage level. Therefore, the bus driver operates in the open-drain configuration. The 400 MHz clock signal is generated at this same end; it propagates along a bus line connecting the clock generator to the controller, and turns back to the terminating end of the bus line. All commands, addresses, and data moving from the controller to the RDRAM chips and back are synchronized on the edges of the clock which propagates in the same direction. In doing so, the clock skew is minimized.

The channel uses 18 data pins, two of which for error correction code (ECC), cycling at $800\,\mathrm{MB\,s^{-1}}$ per pin to provide a bandwidth of $1600\,\mathrm{MB\,s^{-1}}$. This is achieved by latching data on both the rising and the falling edges of the clock signal.

The RDRAM has a pipelined microarchitecture, which fully supports concurrent RAS and CAS operation, as well as read/write buffering. Also, it provides 16 bytes every 10 ns on the internal bus. The Rambus interface transforms the 10 ns internal bus into an external, two-byte wide, 1.25 ns external bus.

All signal wires have an equal loading and fan-out and are routed parallel to each other on the top trace of a PCB with a ground plane located underneath. The addition of more RDRAM chips linearly increases the load and the delay, but leaves the phase relationships of the clock, data, addresses, and commands unaltered. Also, the memory granularity is simply given by the memory capacity of one chip.

Content-Addressable Memory

As already stated in the introduction, modern computers rely on a hierarchy of memories comprising three levels of cache in addition to the central memory. This complex organization is due to the design consideration that smaller memories are faster, and to the locality principle, according to which programs tend to reuse either data which have already been used in previous cycles (temporal locality), or data sets stored next to the used data (spatial locality).

Cache memories are classified according to the criteria by which the central memory is mapped onto it. In a fully associative cache, data blocks can be stored anywhere within the cache, as opposed to direct-mapped memories, where the block address uniquely defines its location. In most cases, cache memories are *n*-way set associative; this means that the cache memory is split into several sets, each containing *n* blocks: the block address uniquely defines the set where it must be stored, but the location of the block inside the set (way) is free.

In any case, a tag memory containing a list of the block addresses stored within the cache is needed. When a new instruction or a new data is requested by the processor, an associative search must be performed on the tag memory in order to find out if the block containing that instruction or data is stored within the cache and, in case it is, in what location. As opposed to standard memories, the input of the tag memory is a data and its output is the local block address within the cache. The tag memory is, therefore, a CAM. The basic cell of a CAM, shown in **Figure 14**, contains ten transistors.

The information bit is stored within a static latch made by the two cross-coupled inverters I_1 and I_2; two pass transistors M_1 and M_2 driven by the write line (WL) connect the latch outputs to the input data D and its complement D′. Two couples of pass transistors M_3–M_4, M_5–M_6, driven by the input data D and D′ and by the latch outputs as shown in the figure, connect to ground a precharged match line (ML). If the stored bit is opposite to the data D, either of the two couples of pass transistors is on and discharges the match line. Otherwise, the match line remains biased at V_{DD}. The former case indicates that no match occurs between the input and the stored data; the latter indicates the opposite condition.

The above cells are organized within an array, and all the cells of a column, sharing the same write line

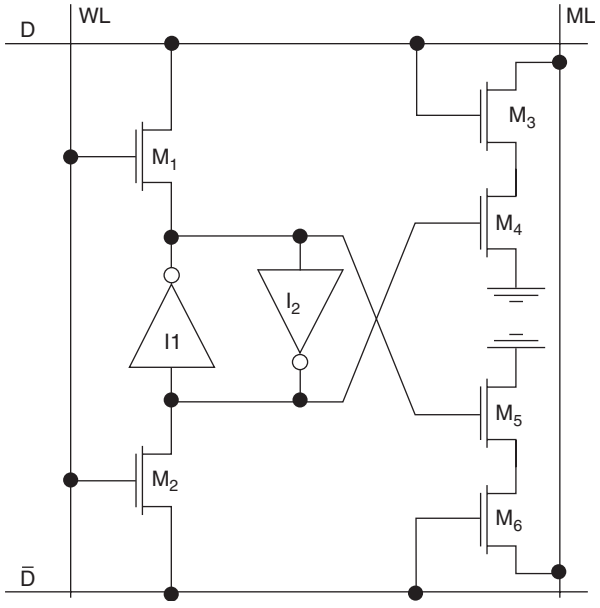

Figure 14 The ten-transistor CAM cell.

and the same match line, contain the address of one memory block. If any one of the above cells does not match its input bit *D*, it drives the match line to ground, indicating that no match occurs between the input word and the stored address. If none of the column matches the input word, this means that a block miss is occurring; all the match lines are at ground potential and an NOR gate raises the block-miss signal high.

If, on the other hand, all the input bits of a column match their respective bits stored within the cells, the match line remains high. This is an indication that the requested block is stored within the cache, and the high match line indicates the internal address of the block within the cache memory.

Meso- and Nanostructures

A Horsfield, University College London, London, UK

Introduction

Meso- and nanostructures are "small" structures. It is possible to assign a rough length scale to them (micrometers and below), but it is more instructive to define smallness in terms of the physical phenomena that it makes possible, as these are what make small structures important. In the following section, selected phenomena are briefly described, together with the principal characteristics that structures need in order to exhibit them. In the section "Contemporary structures", some contemporary structures in which these phenomena can be observed are listed. These structures are organized into categories according to the number of their dimensions which are not small. New structures are being invented constantly, so this list should be seen as illustrating possibilities rather than being comprehensive. However, some structures – such as carbon nanotubes – will remain important for the foreseeable future.

Phenomena

The following phenomena are all a consequence of smallness in one or more dimensions, though they vary in the way smallness is exploited. Many make use of the wave nature of the electron, while others (notably Coulomb blockade) have a classical origin.

Continuum Electronic States Become Discrete

In an infinite solid, the electronic states form continuous bands of states (Bloch states). When the system is large but finite, the states are discrete, but have very small energy separations, so that a continuum description remains accurate. As the size of the system is reduced, the energy spacing between levels increases roughly as $1/L^2$, where L is the size of the system (quantum confinement). When the spacing is large enough (the system size is small enough) that it exceeds any broadening (e.g., thermal), then this discreteness can be exploited. In order to obtain discrete states, the structures need to be small in three dimensions with weak coupling of the discrete states to the environment (e.g., quantum dots). Thus, nonlinear

optical effects such as photo-induced blue shifts (electron excitation leads to modification of the electronic structure, and hence to a changed response to photons) are then possible. If the system is placed between two macroscopic metallic leads, then the discrete states become resonances and resonant tunneling can be observed.

Small semiconducting crystals in solution can also be used for the direct conversion of light into chemical or electrical energy. Absorption of a photon produces both an electron in an excited state and a hole. The excited electron can be donated to a molecule (reduction), or an electron can be extracted from a molecule into the hole state (oxidation). This process can be used to create free radicals (such as $OH^{\bullet}$), and thus catalyze reactions.

Individual Electrons Become Detectable

For very small devices, the transfer of one electron from the environment onto the device can change the combined energy of the device and its environment substantially. For a charge transfer δQ, the total energy change can be approximated by $\delta E = (V_D - V_E)\delta Q + \delta Q^2/2C_D$, where V_D and V_E are potentials for the device and environment, respectively, and C_D is a capacitance for the device. If this energy change is positive, then energy must be provided from outside for the charge transfer to take place. This energy might be provided through thermal excitation, in which case the transfer will not occur unless $k_B T > \delta E$, where T is the temperature of the environment and k_B is the Boltzmann constant. If the potential of the environment can be adjusted, then the transfer of charge can always be made possible by ensuring that $V_E > V_D + \delta Q/2C_D$. The blocking of charge flow through a small device (Coulomb blockade) has been observed in both metals and semiconductors. No current flows until a large enough bias $(V_E - V_D)$ is applied to overcome the charging energy of the device. To observe this phenomenon, the device must have a sufficiently small capacitance $(\delta Q^2/2C_D > k_B T)$. Quantum dots can provide this.

Ferromagnets Have Only One Domain and a Low Anisotropy Energy

Macroscopic ferromagnets acquire domains in order to minimize the energy due to the magnetic field. When a magnetic field is applied, the atomic magnetic moments align through movement of the domain walls. If the size of the ferromagnet is smaller than that of one domain, then alignment with the magnetic field can only occur by the concerted rotation of all the moments. There is an energy penalty for this (anisotropy energy). However, the smaller the ferromagnet, the lower the anisotropy energy. Thus, if the magnetic particle is small enough, then a collection of them can behave as a paramagnet with a very large susceptibility (superparamagnetism). If the particle is elongated, it forms a single domain, while if it is circular it tends to form a vortex state.

Excitons Bind More Strongly

In semiconductors and insulators, an electron can be excited from the valence band into the conduction band, creating a hole in the valence band and leaving an electron in the conduction band. The hole and electron can bind to form a new quasiparticle (exciton). In small structures, the electrons and holes have their movement restricted, which, together with the change in electron and phonon spectra, leads to increased binding of the exciton. This means that in small structures, many excitons can be observed, even at high temperatures (such as room temperature). They have been seen in quantum wells and quantum dots.

The Wavelength of the Electron Strongly Influences Conduction

This is most easily seen in "quantum conductance." In the effective mass approximation, with coherent states, the wave functions (or, more exactly, the envelope functions) and energies for electrons in a one-dimensional conductor are $\psi_k(x) = e^{ikx}/\sqrt{L}$ and $\varepsilon_k = \hbar^2 k^2/2m^*$, respectively, where L is the length of the wire. States with $k > 0$ carry electrons from left to right, while those with $k < 0$ carry electrons from right to left. When more states with wave vectors of one sign are populated with electrons than those with the opposite sign, a net electric current is achieved. If right traveling states with energies $\varepsilon_k < \mu_R$, and left traveling states with energies $\varepsilon_k < \mu_L$ are populated, the net current is $I = 2e(\mu_R - \mu_L)/h$. As the applied bias is $V = (\mu_R - \mu_L)/e$, the quantum unit of conductance $\sigma = I/V = 2e^2/h$ is obtained. For a three-dimensional wire with square cross section of length l, the wave functions and energies are

$$\psi_{nmk}(\boldsymbol{r}) = \frac{2}{\sqrt{Ll^2}} e^{ikx} \sin\left(\frac{n\pi}{l}y\right) \sin\left(\frac{m\pi}{l}z\right)$$

$$\varepsilon_{nmk} = \frac{\hbar^2}{2m^*}\left(k^2 + \left(\frac{n\pi}{l}\right)^2 + \left(\frac{m\pi}{l}\right)^2\right)$$

where n and m are positive integers. As the chemical potential of the electrons is increased from zero, the band with $n = m = 0$ is first filled. Once the chemical potential exceeds $\hbar^2\pi^2/(2m^*l^2)$, two further bands ($n = 1$, $m = 0$ and $n = 0$, $m = 1$), and so on are filled. These partially filled bands carry a current, each

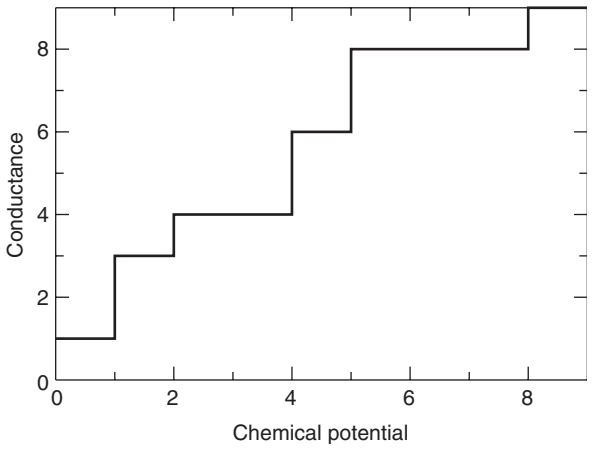

Figure 1 The change in differential conductance in units of $2e^2/h$, vs. the mean chemical potential of the electrons in units of $\hbar^2\pi^2/(2\,m^*l^2)$, for the model system described in the text.

having the same conductance. Therefore, a conductance of the form shown in **Figure 1** results. To observe the quantum conductance, the temperature of the system must be much smaller than the characteristic change in the chemical potential between the conductance steps (the narrower the channel through which the conduction occurs, the higher the temperature can be); the conduction needs to be ballistic, so the length of the conduction channel (L) needs to be less than the electron mean free path.

Electrical Resistance Is Not Proportional to the Length of the Wire

For macroscopic systems, doubling the length of a wire doubles its resistance. This is because, the scattering of electrons by defects can be considered as an incoherent process (one scattering event does not interfere with the next one). For small systems in which the electron wave function remains coherent, there can be interference between electron waves scattered off different defects, and this can have the effect of limiting the range of the wave function of the electron (localization). As a result, the resistance from two pieces of wire joined together is not just the sum of the two individual resistances, but includes an extra term which is the product of the two resistances. If, on the one hand, the wire is long compared to the localization length of the electron wave function, then the resistance grows exponentially with the length of the wire (strong localization). If, on the other hand, the wire is short compared to the localization length, then the resistance deviates from the macroscopic result by a term that is quadratic in the length of the wire (weak localization). In terms of the conductivity, the correction for weak localization is of the order of the quantum of conductance.

Quantum Interference Becomes Measurable

If two leads are attached to a small conducting ring, and a magnetic field is applied perpendicular to that ring, then the conductance of the system will vary as the magnetic field is adjusted (Aharonov–Bohm effect). The dependence of conduction on magnetic field is $G(B) = G_0(1 + \cos(eBS/\hbar + \phi))$, where e is the electronic charge, B is the magnetic field strength, S is the area enclosed by the ring, and ϕ is a phase angle. To observe this phenomenon, there must be ballistic transport throughout the ring. Thus, the ring must be small enough so that only a small amount of inelastic scattering is experienced by the electrons.

Contemporary Structures

Some contemporary meso- and nanostructures are described below. They have been selected because they are of interest at the moment. They represent the kind of structures that exhibit interesting behavior on account of their size. New structures are constantly being developed, so the following can only be considered as a snapshot.

Zero Large Dimensions

Nanostructured materials These materials are formed from a large number of very small microcrystals, and have a very fine microstructure (the grain size can be as small as 1 nm). This can produce improved mechanical properties. The nanostructured materials are, therefore, being investigated as materials for medical implants. They can be made by consolidating microcrystals with clean surfaces. This process is used to make ceramics for which the rate of densification varies inversely with particle size, leading to reduced sintering times. These structures can also be made by deposition of atoms or molecules, using chemical or physical vapor deposition, or by crystallization and precipitation. A nonchemical approach is to start from a metal with much larger grains and introduce further grain boundaries by severe plastic deformation (e.g., by ball milling).

Colloidal semiconducting nanoparticles These nanostructures are small crystals (radius < 100 nm) that are suspended in a fluid. They have been made from many semiconducting materials using chemical precipitation, hydrolysis, etching of silicon wafers, radiolysis, and sonolysis. The size of these nanocrystals can be controlled by chemical means such as the use of surface stabilizers. The crystalline structure defines the electronic properties (such as effective mass), and is influenced by the preparation conditions such as temperature and pressure. These nanoclusters contain

defects (which also depend on the method of synthesis) which can trap electrons and holes and increase their recombination rates. This can be probed using photoluminescence.

Dyes can be attached to the surface, and then pass charge to the nanocrystal once they undergo photoexcitation. This charge transfer can be extremely fast, taking as little as a few hundred femtoseconds, while giving a quantum efficiency close to 1. The addition of dyes allows low-energy excitations to take place. The selectivity and efficiency of photochemical reactions can also be improved by coating the surface with a noble metal. For example, for the photocatalytic production of hydrogen from water, a platinum coat can act as a sink for photogenerated electrons which then catalyze the production of hydrogen.

Nanocrystals can self-assemble to form superlattices with the gaps between dots being controlled by capping agents. Templates, such as liquid crystals, can be used to assist the alignment of the nanocrystals.

Strained layer islands Self-assembly allows one to create nanostructures without processing. The advantage is the absence of damage caused by processing, while the disadvantage is the limited amount of control one has over the structures that are formed. One particularly interesting form of self-assembly is the creation of small islands (or huts) during epitaxy that can act as quantum dots. They are formed during the deposition of one material (the epilayer) on another (the substrate) when the two materials have slightly different lattice constants.

In order to understand why islands form, consider the following argument. If the two materials are lattice matched so that there is no strain at the interface, then as the material is deposited to form the epilayer, there are two possible outcomes. If it is energetically favorable for the deposited material to cover the substrate, then a uniform epilayer will form (Frank–van der Merwe growth). On the other hand, if there is an energy penalty, then the substrate will remain exposed to the vacuum and the deposited material will tend to form islands (Volmer–Weber growth). If the materials have different lattice constants, there will be a strain at the interface which leads to an excess energy that increases with the thickness of the epilayer. Once one layer of material has been deposited onto the substrate, the next layer will be deposited onto this. Additional material will go down as a uniform layer until adding further material increases the strain energy so much that it exceeds any energy gain from forming a new layer. Subsequent material goes down to form islands (Stranski–Krastanov growth). This mechanism applies to materials whose lattice constants differ only by a few percent.

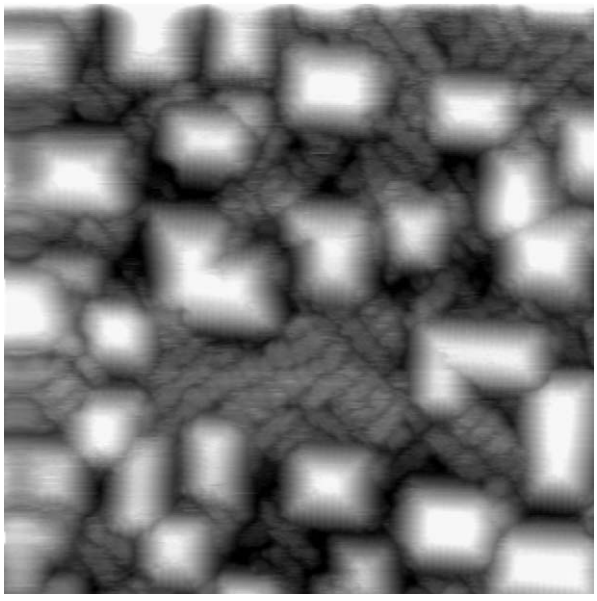

Figure 2 Germanium hut structures grow on a silicon surface. (Courtesy of J Owen.)

Because of the strain, these islands are lattice matched to the substrate. For given materials and deposition conditions, the islands have fixed shapes and sizes. The islands have flat tops and sloping sides (see **Figure 2**). As more material is added, more islands are produced. The size is governed by kinetics and so is strongly influenced by temperature and deposition rate. If material continues to be added after the maximum density of islands has been reached, then dislocations form and the islands grow in size. These large islands are no longer lattice-matched with the substrate.

If a layer of islands is covered with a buffer layer and then more of the island material is deposited on top of that, further islands will grow that lie directly above the first set of islands. This is because of strain in the buffer layer induced by the first layer of islands.

One Large Dimension

Porous silicon Porous silicon can be made by etching crystalline silicon with hydrofluoric acid. Fine tubular structures are formed, with columns having widths less than 5 nm being possible. This is a very fragile material and can degrade in $\sim$1 h under ambient conditions. These narrow columns result in confinement of the electrons, which leads to intense luminescence. Passivation with hydrogen improves the luminescence, which suggests that surface defects may play a role.

Carbon nanotubes For the purpose of this article, Buckminster fullerenes such as C_{60} are considered as

very short nanotubes. Carbon nanotubes can be considered as sheets of graphite rolled up into tubes, possibly with the ends of the tubes capped. Nanotubes are a very important form of nanostructure because of the exceptional properties they have, which are given as follows:

- they are chemically very stable;
- they are mechanically strong and are able to recover from extreme deformations;
- they provide coherent electron transport; and
- the electronic structure can be tuned by varying the helicity and diameter of the tube.

Nanotubes can be single-walled (SWNT) or multiwalled (MWNT). An SWNT consists of just one graphite sheet rolled into a tube. The typical radius of the tube is between 1 and 2 nm. Tubes tend to pack together into triangular lattices with a lattice parameter of 1.7 nm. Similarly, an MWNT consists of several coaxial graphite tubes, with the separation between the walls being 0.34 nm, which is close to the interlayer spacing in graphite.

Nanotubes can be either metallic or semiconducting, depending on the helicity and diameter of the tubes. Simple models that neglect the curvature of the tubes can give a good idea of trends, though more accurate calculations are needed to obtain precise results. Calculations (supported by experiment) show that about one-third of the tubes are metallic while about two-thirds are not, and that for semiconducting tubes, the bandgap varies inversely with the diameter of the tube.

Nanotubes are very stiff (MWNT have a Young's modulus of ~ 1.8 Tpa), and can recover reversibly after severe deformations. This makes them ideal for applications such as tips for surface probe microscopes (such as scanning tunneling microscopes and atomic force microscopes).

It is possible to insert material inside a nanotube. Strong capillary forces allow fluids to be held within. They have been filled with molten salts such as metal oxides, sulfides, and chlorides. Currently, there is interest in the so-called peapod structures in which C_{60} and other Buckminster fullerenes are inserted within nanotubes.

Carbon is not the only material that can form such tubes; some clays (which are layered silicates) can also have a tubular form (e.g., the aluminosilicate imogolite). MWNTs of WS_2 and MoS_2 in which there are alternating layers of metal and sulfur have been made. They had diameters of up to a few tens of a nanometer and had lengths of a micrometer. Both SWNTs and MWNTs have been made from boron nitride (BN). Tubes made from BN are always semiconducting (with a large gap) independent of tube diameter or helicity.

Quantum wires There are many structures that fall into this category. Here three types of quantum wires are considered.

The (0 0 1) surface of silicon has long rows of atoms that are paired up to form dimers. The atoms within the dimers are very reactive because each one is only bonded to three other atoms while it would like to be bonded to four (they each have one dangling bond). Hydrogen can be used to satisfy this bonding requirement: one hydrogen atom will bond to each dangling bond. It is possible to remove (using a scanning tunneling microscope) one hydrogen atom from each dimer, which results in a chain of dangling bonds which behave like a wire. However, the wire is a semiconductor because of the Peierls distortion. It is possible to attach metals and other atoms to the dangling bonds. The metals tend to form clusters, which grow into wires as more metal is deposited. These wires are generally of poor quality.

It is possible to grow self-assembling wires on the silicon surface. For example, if rare-earth metals are deposited and then annealed, they will form an alloy with the composition XSi_2. This alloy will have a lattice constant in one direction that matches the silicon, but in a perpendicular direction it will not match. This results in the growth of long straight wires to minimize elastic strain energy. The following metals have been used to produce wires: Dy, Er, Gd, and Sc. In a similar way, bismuth forms nanolines when it is deposited on silicon and then annealed between 570°C and 600°C (see **Figure 3**). The wires are always 1.5 nm wide, and can be several hundred nanometers long. They are never kinked or defective, and are always semiconducting.

Long single-crystal semiconductor wires can be grown using a vapor–liquid–solid technique. This requires a small catalyst (such as gold), the size of which determines the radius of the crystal wire. The catalyst is molten, and causes the material used to make the wire, which is present as a vapor, to bind to the interface between the catalyst and the substrate on which it is sitting. This causes a column of the material to grow underneath the catalyst (See **Figure 4**). This technique has been used to produce wires made of Si, Ge, Si/Ge, GaAs, GaN, InP, CdS, ZnSe, and CdSe.

Two Large Dimensions

Heterostructures Silicon-based heterostructures were originally considered as a way to overcome the problem of the indirect bandgap in silicon. To obtain efficient light emission, a direct bandgap is

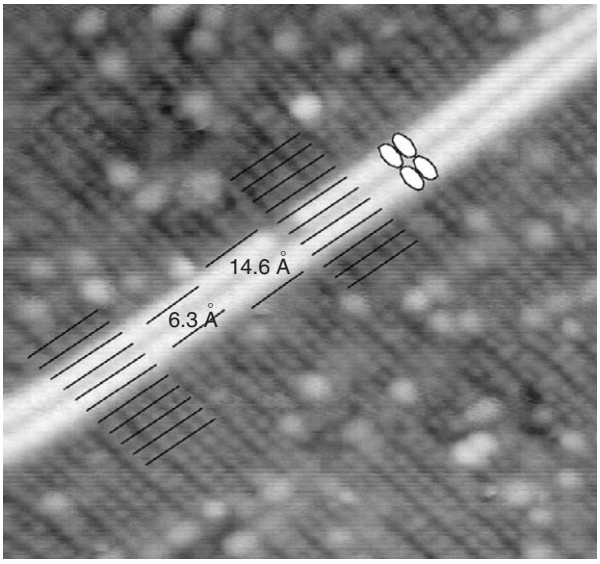

Figure 3 Lines of Bi that are self-aligned on the surface of silicon. (Courtesy of J Owen.)

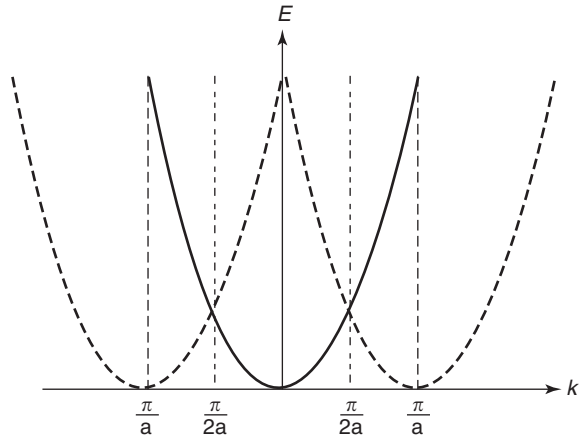

Figure 5 The hard line is the band structure for a one-dimensional system with a lattice constant *a*. Its Brillouin zone runs from $-\pi/a$ to π/a. If the cell size is doubled, then the Brillouin zone runs from $-\pi/2a$ to $\pi/2a$, and the band structure consists of both the hard line and the broken lines. Thus, at the center of the Brillouin zone states that used to be at the zone boundaries are found. This is band folding.

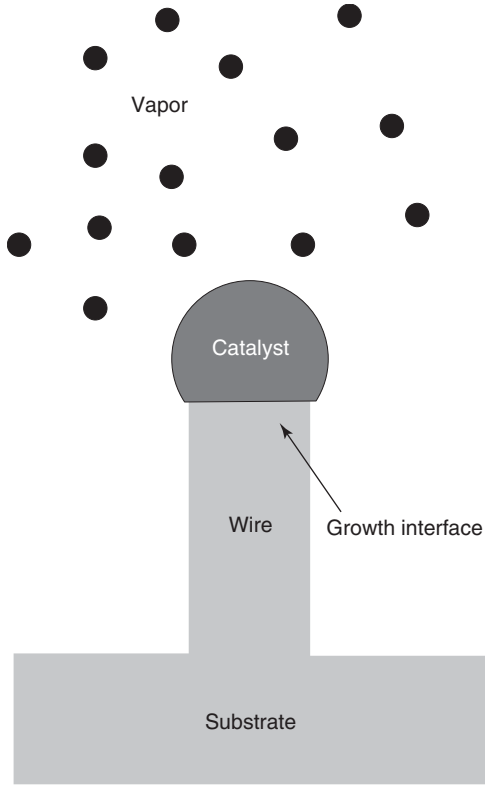

Figure 4 The geometry for the vapor–liquid–solid technique.

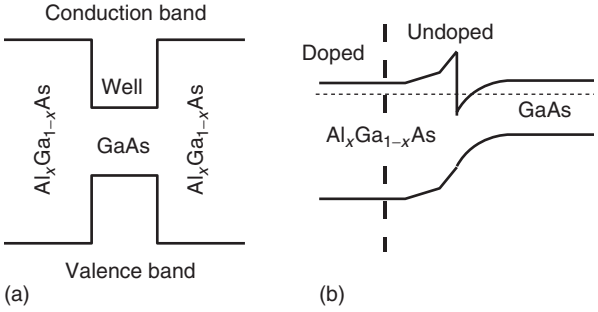

Figure 6 Quantum well band edge profiles. (a) The electron donors are in the GaAs layer which forms a well because of its reduced bandgap compared to the surrounding $Al_xGa_{1-x}As$. (b) The donors are on the left-hand side of the system, and the well is created by the realignment of the bands that takes place to ensure that the electron chemical potential (horizontal dotted line) is uniform everywhere.

required. It was thought that this might be achievable in Si by increasing the size of the unit cell in one direction and by making a layered structure with alternating layers of Si and another material (e.g., Ge). This has the effect of folding the band structure in onto itself, bringing the conduction-band minimum closer to being directly above the valence-band maximum (see **Figure 5**). Unfortunately, increasing the period of the superlattice has the effect of reducing the optical matrix elements; thus, only short period superlattices can be used. However, these heterostructures also produce quantum wells.

Quantum wells Here, the example of GaAs/$Al_xGa_{1-x}As$ is given to illustrate this type of structure. If a GaAs layer ($\sim$10 nm thick) is grown between two thicker layers of $Al_xGa_{1-x}As$, the GaAs layer acts as a two-dimensional layer for electrons and holes. This is because the GaAs layer has a bandgap of 1.4 eV, while the surrounding $Al_xGa_{1-x}As$ has a

bandgap of 1.9 eV (for $x = 0.3$), producing a well depth of 0.25 eV for both electrons and holes (see **Figure 6a**). If during the molecular beam epitaxy growth of the GaAs layer electron donor atoms are included, a two-dimensional electron gas will be produced. The ionized donors scatter the electrons very strongly. This can be remedied by using modulation doping, in which only one interface is needed, and where the donors are outside the quantum well (see **Figure 6b**). With this approach, the scattering can be made so low that the electron mean free path can exceed 10 μm. The dimensionality of the electron gas can be further reduced by attaching contacts through which a bias is applied, and which can squeeze the electrons into a wire (of variable width). This has been used to study quantum conduction.

Metallic Bonding and Crystals

D J Willock, Cardiff University, Cardiff, UK

Metals form an important class of technological materials that are exploited widely for their ductility and high electrical and thermal conductivities. The general physical definition of the metallic state is based on these macroscopic properties. In this article, the electronic structure of metals is considered using a simple extension of the linear combination of atomic orbitals used to describe bonding in molecules applied to the solid state. This makes it possible to define the metallic state precisely using the crystal orbitals responsible for bonding and so consider the importance of the metallic state in the cohesive energy of solids and its influence on structure.

The types of bonding discussed in this section of the encyclopaedia can be broadly divided into localized effects (involving only a few atoms in the vicinity of the chemical bond) and delocalized effects (involving cooperative interactions between many atom centers). Localized interactions include covalent and hydrogen bonding while ionic and van der Waals interactions may be classed as delocalized. The concept of the metallic bond is little more difficult to define rigorously and has been the subject of much recent debate. Broadly speaking, the metallic bond can be considered as the sharing of electron density by multiple atomic centers in condensed phases. What allows one to distinguish metallic bonding from other situations is the electronic character of the bond. The classic view of the metallic bond in solids is the "sea of electrons" concept which gives the impression of delocalization

of the electrons in metallic systems. The metallic bond in this picture is an extreme example of the covalent bond and it has been suggested that the metallic bond as a concept can be subsumed into this class of bonding. However, the metallic state requires a combination of delocalized crystal orbitals and a knowledge of their occupation, and is actually a collective property of the entire electron density rather than a few specific states. In this article, these ideas are expanded and the influence of the metallic state of a solid on its stability and structure are considered.

The limit of very weak interaction between the atomic cores and the valence electrons is usually employed to build a model of the electronic states in metals using the nearly free electron approximation. In this article, the opposite approach will be used in which crystal orbitals are built up from atomic orbitals. This gives a better insight into the chemical bonding nature of the metallic state.

Band Structure

The idea of a chemical bond as the sharing of electron density between atoms can be rationalized by the formation of molecular orbitals from atomic orbitals. For example, a hydrogen atom has a $1s^1$ configuration, and when the orbitals from two atoms overlap in molecular H_2 they can combine in two ways. First, overlap between the 1*s* orbitals can be constructive, leading to a buildup of charge between the two nuclei and giving an interaction between the atoms that lowers the energy compared to the atomic state. This favors H_2 formation through the formation of a bonding orbital (σ in **Figure 1**). The alternative is destructive interference between the atomic orbitals in the overlap region. This leads to a lowering of the electron density compared to two noninteracting atoms at the same positions. If this molecular orbital is occupied, a destabilizing contribution to the energy is obtained and the total energy is higher than that of the isolated atom states. This molecular orbital is, therefore, antibonding in nature (σ^* in **Figure 1**). In molecular H_2, each atom supplies a single electron and so the bonding orbital is fully occupied (two electrons) and the antibonding orbital is not occupied; so overall the bond is favored.

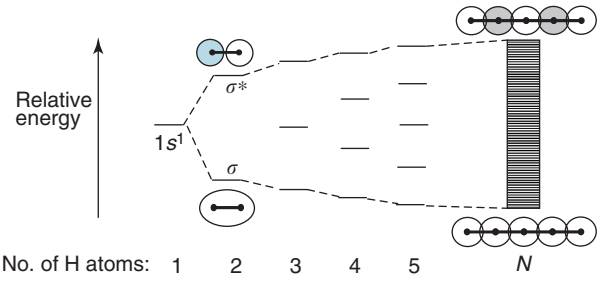

Figure 1 Schematic illustration of the buildup of a band of states from the aggregation of H atoms. *N* is the number of atoms in a bulk sample and will be of the order of the Avagadro constant ($6.022 \times 10^{23}\,mol^{-1}$). Insets show the molecular orbitals for the H_2 molecule and for the top and bottom of the condensed phase band of states.

Figure 1 also shows a schematic representation of the interactions of atomic orbitals in larger aggregations of H atoms. The difference in energy of the molecular orbitals and atomic orbitals is influenced by two main factors. First, the degree of overlap between atomic orbitals: the more the overlap, the bigger the perturbation from the atomic state. Second, the energy of the two atomic orbitals: when these are well matched, the difference between the energies of the molecular and atomic states is greater than when they are very different in energy. In the case of the H_2 molecule, the orbital energies for the atomic states are identical and so this is optimal. If a third H atom is included, the additional *s*-orbital will interact only weakly with the molecular orbitals of the H_2 molecule since the bonding and antibonding states are well separated in energy from the atomic state of the new atom. As more atoms are introduced to produce the one-dimensional (1D) solid, the same number of molecular orbitals is formed as 1*s* orbitals that are supplied, but the energy range for the set of orbitals increases only slowly with the number of atoms. Making the leap to the 1D solid with some large number of atoms (*N* in **Figure 1**), there will be *N* crystal orbitals spread over an energy range not too dissimilar to the gap between the H_2 bonding and antibonding orbitals. There are now too many crystal orbitals to illustrate, but the extreme cases of all bonding between neighboring atoms and all antibonding are shown in **Figure 1**. In general, states at the bottom of the band will be stabilizing for crystal formation from gaseous atoms since they are lower in energy than the atomic 1*s* states. The states above the band center in this situation are destabilizing since they have higher energies than the atomic 1*s* states. In this simple example, a filled band has zero contribution to the lattice energy overall.

Tight-Binding Approximation

The approach of building up condensed phase crystal orbitals based on the molecular orbital theory can be given some mathematical structure by defining the linear combinations of atomic orbitals that are present in the lD chain (**Figure 2**).

The appropriate linear combination of atomic orbitals will be

$$\psi_p = \sum_n c_{pn}\chi_n$$

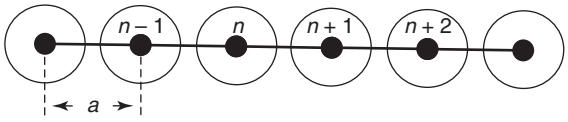

Figure 2 An idealized 1D array of atoms. Each atom contributes a single *s*-orbital to the system. The lattice parameter is shown as the separation between neighbors so that the unit cell contains a single atom.

where c_{pn} is the coefficient for the pth crystal orbital for the local atomic function, χ_n, at site n in the lattice. From the discussion above, if there are N atomic orbitals in the crystal there must be N values of p. The possible values of p can be found by considering the effect of crystal translational symmetry on the electron density.

The density of electrons at any point x along the chain is related to the crystal wave functions via

$$\rho(x) = \sum_{p}^{N_e/2} \psi_p^*(x)\,\psi_p(x)$$

where N_e is the number of electrons to be accommodated in the crystal orbitals. The density of electrons can be observed experimentally using X-ray diffraction, whereas the crystal orbitals are not experimental observables. Translational symmetry implies that the density must be the same at all equivalent points in the crystal. In the 1D lattice with repeat unit, a, the densities at a point x and at any point $x + na$ (where n is any integer) must be the same. The wave functions need not have the same property but this restriction on the density can be met if, for any crystal orbital:

$$\psi_p^*(x + na)\psi_p(x + na) = \psi_p^*(x)\psi_p(x)$$

To achieve this, the wave functions can be written in terms of Bloch states:

$$\psi_k(x) = \sum_n \exp(\mathrm{i}k\,x)\chi_n(x)$$

Here, k is the wave vector for the state, controlling the periodicity of the phase pattern of the crystal orbital along the atomic row and $\mathrm{i} = \sqrt{-1}$. The wave vector is commonly used as the label for the crystal state as has been done above, and it is related to the integer p via

$$k = \frac{2\pi p}{Na}, \quad p = -N/2, \ldots, -1, 0, 1, \ldots, N/2$$

The k-vectors defined in this way have reciprocal length units. The integer p has $N+1$ values; however, the $p = -N/2$ and $p = N/2$ cases are equivalent and so the required N orbitals ($2N$ states) are generated. **Figure 3** shows some illustrative examples of periodic wave functions with different k-vector values.

The allowed values of k in this scheme range from $-\pi/a$ to π/a. Now, another lattice or line of points could be constructed for the values of k that give Bloch functions for the lattice. This line would be related to the real space row of atomic sites but the points on it would give periodicities of waves with reciprocal length units, that is, they are points in reciprocal space. The range of allowed values of k defines the distance in reciprocal space occupied by the unique Block states which are known as the Brillouin zone.

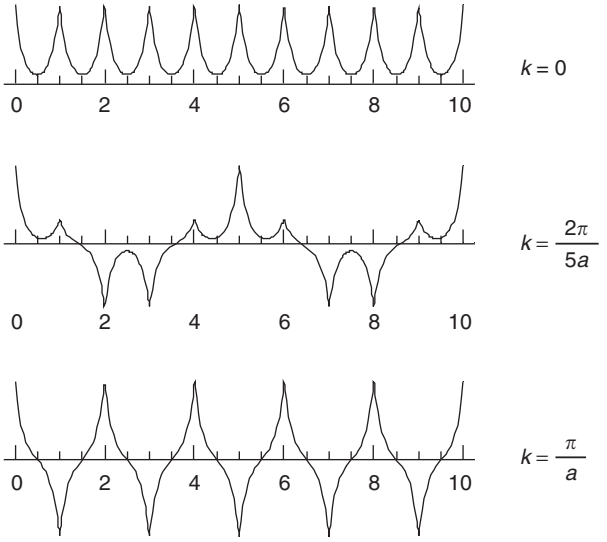

Figure 3 Plots of the real part of a periodic wave function based on Bloch functions. The radial part of each local atomic function is modulated by the periodic function with the *k*-vector indicated. The atomic positions are numbered on the axes.

Using the crystal orbitals in the Schrödinger equation gives the orbital energy as a function of the wave vector k:

$$E_k = \frac{\int_{-\infty}^{\infty} \psi_k^* H \psi_k \,\mathrm{d}x}{\int_{-\infty}^{\infty} \psi_k^* \psi_k \,\mathrm{d}x}$$

Here, H is the Hamiltonian describing the interaction of the electron in the crystal orbital with the line of atoms. The crystal orbitals in terms of Bloch states allow the numerator and denominator of this expression to be written as

$$\int_{-\infty}^{\infty} \psi_k^* H \psi_k \,\mathrm{d}x = \sum_n^N \sum_m^N \exp(\mathrm{i}k(na - ma)) \times \int_{-\infty}^{\infty} \chi_n(x) H \chi_m(x)\,\mathrm{d}x$$

and

$$\int_{-\infty}^{\infty} \psi_k^* \psi_k \,\mathrm{d}x = \sum_n^N \sum_m^N \exp(\mathrm{i}k(na - ma)) \times \int_{-\infty}^{\infty} \chi_n(x) \chi_m(x)\,\mathrm{d}x$$

in which m and n are integers identifying sites along the row of atoms, and now the integrals required are over the local atomic functions. In order to obtain a qualitative insight into the band structure, the simplifying tight-binding approximations can be used which give the integrals required for the numerator values:

$$\int_{-\infty}^{\infty} \chi_n^*(x) H \chi_m(x)\, \mathrm{d}x = \alpha, \quad m = n$$
$$\int_{-\infty}^{\infty} \chi_n^*(x) H \chi_m(x)\, \mathrm{d}x = \beta, \quad m = n \pm 1$$
$$\int_{-\infty}^{\infty} \chi_n^*(x) H \chi_m(x)\, \mathrm{d}x = 0, \quad m < n-1 \text{ or } m > n+1$$

In other words, the on-site term is given by the parameter α, the term corresponding to the nearest neighbors is given by the parameter β, and all other terms are simply ignored. This concentration on local interactions is the reason why the approximation itself is called "tight binding."

Although the interaction contributions are considered in this way, the crystal orbitals are still delocalized along the entire chain of atoms. For the denominator, the tight-binding approximation is even more severe:

$$\int_{-\infty}^{\infty} \chi_n^*(x) \chi_m(x)\, \mathrm{d}x = 1, \quad m = n$$
$$\int_{-\infty}^{\infty} \chi_n^*(x) \chi_m(x)\, \mathrm{d}x = 0, \quad m \neq n$$

Using these integral values in the energy expression gives the formula

$$E_k = \alpha + 2\beta \cos ka$$

so that the energy of a particular crystal orbital depends on the local energy terms and the wave vector of the orbital. For a given system, the local interaction integrals are simply fixed parameters. In general, the relationship between the energy E_k and the wave vector of the state, k, is termed the dispersion relation.

This model can now be applied to the band of states for the 1D chain of hydrogen atoms for which the local functions are the *s*-orbitals on each H atom. When $k = 0$, the exponential factor in the crystal orbital is 1 and so all site orbitals are in phase giving a low-energy contribution. In contrast, when $k = \pm\pi/2$, the complex exponential gives a wave that changes sign between the neighboring atoms and so all neighboring orbitals have an antibonding interaction, a high-energy contribution. **Figure 4** shows the dispersion relation for a line of *s*-orbitals from the tight-binding approximation. The low-energy states are around $k = 0$, whereas for k near its limiting values of $\pm\pi/a$, the energy of the states is higher than the energy for the isolated atomic orbitals, implying that β is negative. The overall bandwidth is 4β, so the strength of interaction between neighboring sites controls the bandwidth.

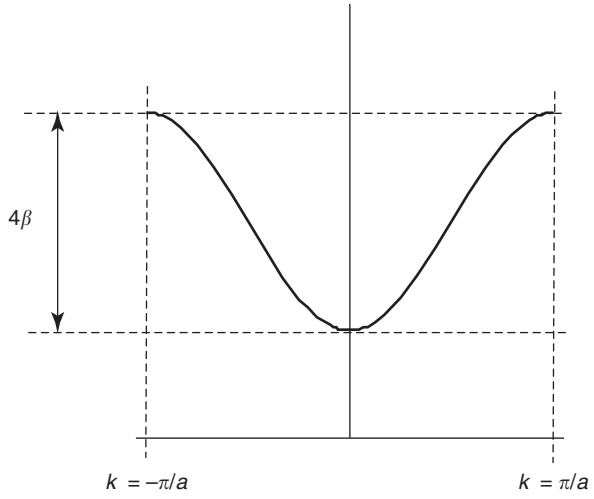

Figure 4 The dispersion relation for a line of *s*-orbitals from the tight-binding approximation.

The values of k that have been defined are evenly spaced in reciprocal space with the allowed values occurring at intervals of $2\pi/Na$. However, the relationship between the energy and the wave vector is not linear. In particular, near the Brillouin zone boundary, the dispersion curve flattens out so that many k-vectors in this region have almost the same energy. In one dimension, a similar effect is seen at the zone center. The density of states (DOS), $N(E)$, is defined as the number of energy levels within a small energy increment as a function of the state energy. In one dimension, the regions in which the dispersion curve flattens out lead to a higher DOS than in regions in which the dispersion curve is steep.

Band Filling and Metallic Behavior

The metallic state can now be defined based on the occupancy of the crystal orbitals. For the line of *s*-orbitals from hydrogen atoms, there are N-crystal orbitals, and the Pauli exclusion principle dictates that each orbital can contain a maximum of two electrons with opposite spins. The crystal orbitals, therefore, give rise to $2N$ electron states, each hydrogen atom delivers one electron and so the states are half-filled. It is assumed that states are simply filled from the lowest energy upwards until all electrons have been placed in crystal orbitals. However, since the separation of states within a band is extremely small, this strict ordering is only possible at 0 K. At any finite temperature, an electron at the top of the occupied levels can be promoted to the unoccupied

states by thermal excitation. The probability of occupancy of a state, $f(E_k)$, is controlled by the Fermi–Dirac statistics:

$$f(E_k) = \frac{1}{\exp((E_k - E_F)/k_B T) + 1}$$

Here, E_F is the Fermi energy which, in metals, corresponds to the energy of the highest occupied state at 0 K, k_B is the Boltzmann constant, and T is the temperature. More generally, E_F is defined from this formula as the energy at which the probability of occupancy is exactly one-half.

Figure 5 shows plots of the Fermi–Dirac probability function at different temperatures. At 0 K it can be seen that the low-energy states are filled up to E_F, but above E_F all states are empty. At higher temperatures, however, electrons from below the Fermi energy can be promoted to higher states, leading to a tail feature. These promotions can only occur if there are states available to receive the electrons that are excited. In the 1D H example, the band of $2N$ states is half-filled and so there are states available for the thermally excited electrons to move into. This is the factor which gives rise to electrical and thermal conduction in metals; filled and empty states are so close to each other that the promotion of electrons at energies close to E_F can occur easily. These electrons, at the interface between the occupied and unoccupied states, are active in transport giving rise to the metallic behavior of the solid. Accordingly, condensed H is expected to be a metal. The construction of the crystal orbitals also shows that the occupied states are those which are largely bonding and so solid H is favored over separated gas-phase H atoms. The liquid state of H has been achieved at low temperature and very high pressure using shock wave pressure methods and is found to have metallic conductivity. However, under most circumstances, $N/2$ diatomic molecules is an even more stable situation and so the diatomic gas is the normal state.

There are a few less exotic examples of solids with 1D aspects to their electronic structure than those for H. For example, the solid formed by salts of the $[Pt(CN)_4]^{2-}$ anion contains square planar complexes stacked in the crystallographic c-direction. In the simple $K_2[Pt(CN)_4]$ salt (**Figure 6a**), neighboring Pt centers are 3.48 Å apart. Within each complex, the Pt atom is in the $2+$ oxidation state and so has a d^8 electron configuration. The interaction with the CN ligands puts the energy of the molecular antibonding orbital involving the $d_{x^2-y^2}$ atomic orbital above the other d-orbitals, and so this is unoccupied. The dispersion curves of the bands formed between the metal centers depend on the symmetry of the orbitals with respect to the chain direction. **Figure 7** shows each orbital type and their arrangement along the line of complexes for the $k = 0$ wave vector. The d_{z^2} orbital forms a bonding arrangement similar to the s-orbitals used in the hydrogen example, and so the dispersion curve for this band will be similar to **Figure 4**. The d_{xz} and d_{xy} orbitals form a degenerate set of bands in which the $k = 0$ orbital is bonding. However, the bond has π-symmetry rather than σ (**Figure 7b**). This leads to a weaker overlap between neighbors and so a smaller value of the tight-binding β-parameter leading to a narrower range of energies in the band than for d_{z^2}. d_{xy} and $d_{x^2-y^2}$ orbitals, both have δ-symmetry bonding interactions at $k = 0$, (**Figure 7c**) so the bands are narrower still. The $6p$ orbitals of Pt are empty within the complex; however, the molecular orbital involving the Pt p_z orbital is only just higher in energy than $d_{x^2-y^2}$. The symmetry of the p_z orbital gives σ antibonding at $k = 0$ (**Figure 7d**) while at $k = \pm\pi/a$ each alternate p_z orbital is inverted, giving a bonding arrangement.

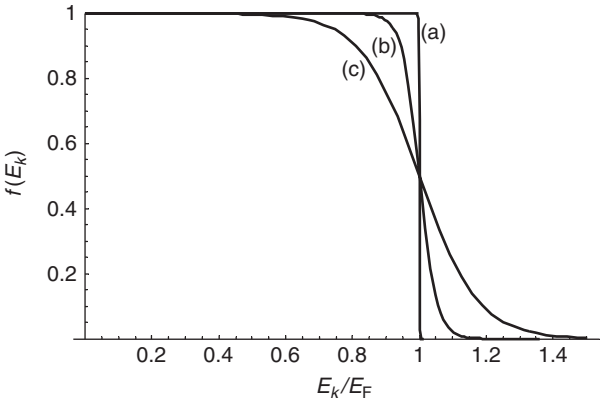

Figure 5 Plots of the Fermi–Dirac statistics function for temperatures of (a) 0 K, (b) 300 K, and (c) 1000 K.

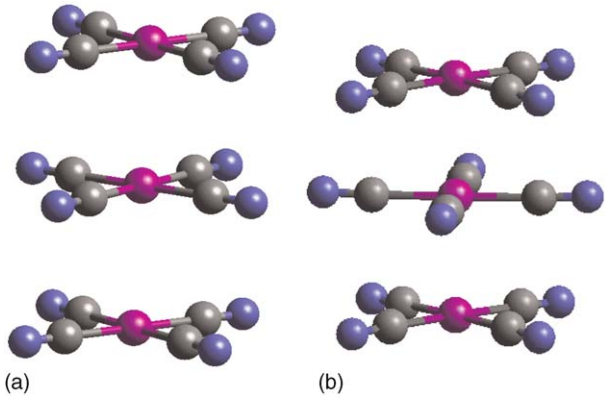

Figure 6 Chain structures formed by $[Pt(CN)_4]^{2-}$ in the solid state. (a) From $K_2[Pt(CN)_4]$, (b) from $K_2[Pt(CN)_4]Br_{0.3}$. For clarity cations, dopants, and water of crystallization have been omitted.

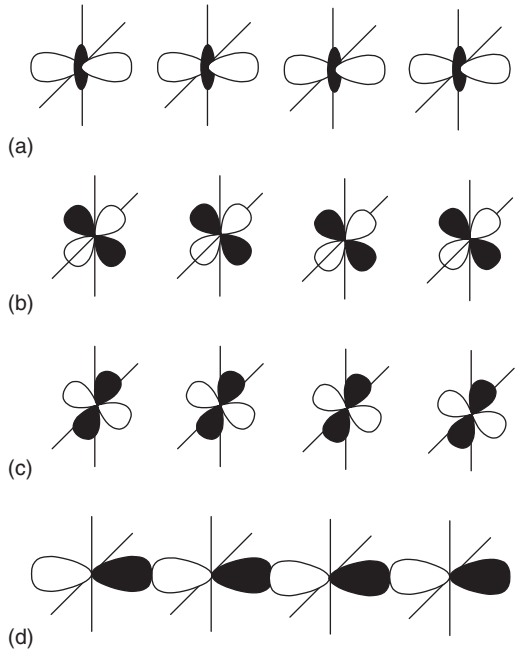

Figure 7 The arrangement of orbitals for the $k = 0$ wave vector case for a chain of atoms along the *z*-axis (which runs left to right in each diagram). (a) d_{z^2}, (b) d_{xy} or d_{yz}, (c) d_{xy}, $d_{x^2-y^2}$ have the same bonding symmetry but with orbitals rotated 45° in the *xy* plane, (d) p_z.

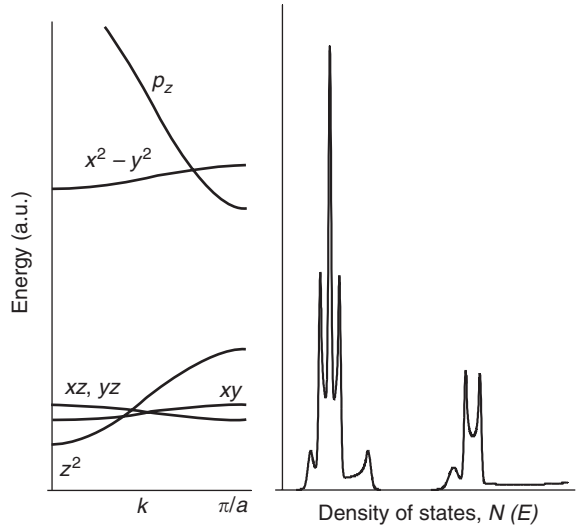

Figure 8 The dispersion curves and DOS for the bands formed along the stacking direction in $K_2[Pt(CN)_4]$ by the Pt centered orbitals.

For orbitals with this symmetry, states at the Brillouin zone boundary are lower in energy than at the center, so the dispersion relation appears inverted compared to those constructed so far. **Figure 8** shows a sketch of the dispersion curves for these bands in the Pt complex stacks. The four occupied complex orbitals involving d_{z^2}, d_{xy}, d_{xz}, and d_{yz} have similar energies and so form a continuous band of states; however, the strength of interaction between neighbors is not the same in all of them and so they have different energy ranges as discussed above. The $d_{x^2-y^2}$ and p_z orbitals form another overlapping set of bands. The p_z orbital states on the complexes are above the $d_{x^2-y^2}$; however, the interaction between neighbors is stronger in the former case and so the p_z-band is wider, leading to the lowest unoccupied states being p_z in nature.

So for $K_2[Pt(CN)_4]$, there is a bandgap between the occupied and unoccupied states, so the material is actually a semiconductor in the chain direction. However, metallic behavior can be induced by the addition of halide dopant ions to give chemical formulas such as $K_2[Pt(CN)_4]\ Br_{0.3}$. This is a level of "dopant" much greater than that used in classical semiconductors such as silicon and so the concentration of extrinsic carriers is correspondingly higher. The halide anions withdraw electrons from the Pt chains giving a free Fermi surface in the *c*-direction. Measurements confirm that the electrical conductivity is 10^4–10^5 times greater along the stack direction than perpendicular to it. The structure of the material is also strongly affected by this change to a metallic form. The Pt–Pt distance in the doped material is 2.89 Å, not much greater than in Pt metal (2.78 Å). This reduction in Pt–Pt distance can be understood in terms of the bonding character for the chain states. In the $K_2[Pt(CN)_4]$ material there is a completely filled band of states, and so both bonding and antibonding character crystal orbitals are occupied. When the dopant is added, charge is withdrawn from the high-lying antibonding states and the free Fermi surface corresponds to an overall bonding character from the crystal orbitals. The increased bonding along the chain direction leads to the observed shortening of the Pt–Pt distance. To accommodate this, there is also a rotation of alternate complexes to avoid steric clashes between CN ligands, as can be seen in **Figure 6b**.

The Density of States in Three Dimensions

In three dimensions, the wave vector has three components:

$$\boldsymbol{k} = k_x\hat{\boldsymbol{x}} + k_y\hat{\boldsymbol{y}} + k_z\hat{\boldsymbol{z}}$$

where $\hat{\boldsymbol{x}}$, $\hat{\boldsymbol{y}}$, and $\hat{\boldsymbol{z}}$ are unit vectors in their respective Cartesian directions. Each component can take any of the set of values:

$$k_i = \frac{2\pi p_i}{L}, \quad p = -L/2a, \ldots, -1, 0, 1, \ldots, L/2a$$

where L is a dimension of the sample and a is the unit cell dimension in the ith direction.

The relationship between the state energy and the wave vector now involves a vector dot product between reciprocal and real space vectors. The allowed values of k can be thought of as points in a 3D reciprocal space, the range of allowed values is defined by a reciprocal space lattice with the primitive vectors:

$$\boldsymbol{a}^* = \frac{2\pi}{V_c}\,\boldsymbol{b}\times\boldsymbol{c}, \qquad \boldsymbol{b}^* = \frac{2\pi}{V_c}\,\boldsymbol{c}\times\boldsymbol{a}, \qquad \boldsymbol{c}^* = \frac{2\pi}{V_c}\,\boldsymbol{a}\times\boldsymbol{b}$$

Now, the periodicity of the lattice will be different according to the direction considered. This means that rather than the Brillouin zone defining a single range for $|\boldsymbol{k}|$, its extent will depend on the direction taken so that the Brillouin zone is actually a volume of the reciprocal space. The first Brillouin zone is the shape formed by the Wigner–Seitz cell in this lattice. This is the primitive cell constructed by taking the intersections of planes placed at the half-way point between each reciprocal lattice point. At all points on the surface of this volume, the k-vector will have a value of $\pm\pi/a$ (a now being the repeat distance in the corresponding direction in the real space lattice) and so the cell defines the states near the set of unique k-vectors for the lattice.

The shape of the Brillouin zone is linked to the structure adopted by the metal. Examples of the Brillouin zone for two common structures found in elemental metals, body-centered cubic (b.c.c.) and face-centered cubic (f.c.c.), are shown in **Figure 9**.

In this picture, when E_F is far from the Brillouin zone edge, the k-vectors of the states at the Fermi level define the surface of a sphere centered on the origin. The DOS in 3D is now affected by the number of possible k-vectors that have equivalent state energies. For large values of $|\boldsymbol{k}|$, near the zone boundaries, there are many k-vectors with the same magnitude but with different directions in reciprocal space, leading to a high degree of degeneracy. This, coupled with the flattening of the dispersion relation, leads to a high DOS at large $|\boldsymbol{k}|$. In contrast to the 1D situation, however, at the zone center, there are only a few wave vectors of the same length, and so although the dispersion relation may flatten out there is no longer a significant increase in the DOS. Indeed at the zone center, $|\boldsymbol{k}| = 0$, and so all three components are zero and there is only one state.

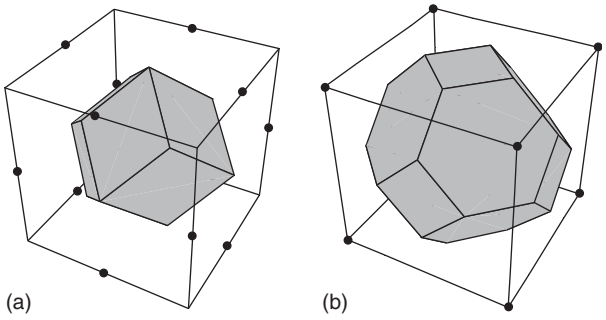

Figure 9 The first Brillouin zone for the real space lattices of: (a) b.c.c. structures and (b) f.c.c. structures. Note that the reciprocal space lattice of the b.c.c. lattice is actually f.c.c. and vice versa.

Dependence of Metallic Structure on the Density of States

The shape and volume of the Brillouin zone control the electron density at which the Fermi surface touches the Brillouin zone boundary. Near the boundary, the dispersion curve flattens off leading to an increased DOS. Differences in the reciprocal lattices between structures will affect the point at which this occurs and so different lattices will have different total electronic energies at a given density.

For example, **Figure 9** shows the shape of the Brillouin zones for the f.c.c. and b.c.c. lattices. The points in the diagrams represent the points in the reciprocal space lattice at the spacing set by the reciprocal space vectors:

$$\boldsymbol{a}^* = \frac{2\pi}{a}(-\hat{\boldsymbol{x}}+\hat{\boldsymbol{y}}+\hat{\boldsymbol{z}}), \qquad \boldsymbol{b}^* = \frac{2\pi}{a}(\hat{\boldsymbol{x}}-\hat{\boldsymbol{y}}+\hat{\boldsymbol{z}}),$$
$$\boldsymbol{c}^* = \frac{2\pi}{a}(\hat{\boldsymbol{x}}+\hat{\boldsymbol{y}}-\hat{\boldsymbol{z}}) \qquad \text{for f.c.c.}$$

and

$$\boldsymbol{a}^* = \frac{2\pi}{a}(\hat{\boldsymbol{y}}+\hat{\boldsymbol{z}}), \qquad \boldsymbol{b}^* = \frac{2\pi}{a}(\hat{\boldsymbol{x}}+\hat{\boldsymbol{z}}),$$
$$\boldsymbol{c}^* = \frac{2\pi}{a}(\hat{\boldsymbol{x}}+\hat{\boldsymbol{y}}) \qquad \text{for b.c.c.}$$

where a is the length of the cube side in the real space unit cells. From these formulas, it can be seen that the reciprocal space primitive vectors for the f.c.c. lattice are the same as the real space b.c.c. primitive vectors and vice versa.

Figure 10 shows a sketch of the DOS for the f.c.c. and b.c.c. lattices. At low electron density, all occupied states are well within the Brillouin zone boundary and so the DOS simply increases with the state energy since the number of degenerate k-vectors increases. As the wave vectors approach the Brillouin zone boundary, the dispersion curve levels out and the degeneracy of states increases giving a greater DOS. However, if the energy is increased further, the number of available states decreases again since only the sections of volume furthest from the center of the Wigner–Seitz cell are still available. This leads to a peak in the DOS in the vicinity of the Brillouin zone boundary. Because of the geometry of the reciprocal space lattices, the peak occurs at lower energy for

the f.c.c. real space lattice than for the b.c.c. case. For a metal with electron density at the f.c.c. peak, the f.c.c. structure will be preferred because the Fermi energy will be lower than in the b.c.c. lattice. However, if the density of electrons is near the b.c.c. peak, the f.c.c. DOS begins to fall dramatically and so a lower-energy electron configuration is possible in the b.c.c. structure.

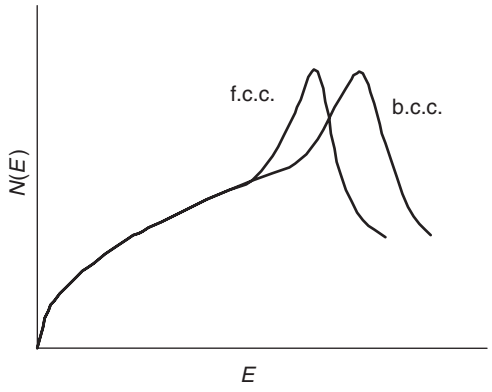

Figure 10 Schematic diagram of the DOS for the f.c.c. and b.c.c. crystal systems. The peaks correspond to the point when the *k*-vector just touches the Brillouin zone boundary.

The DOS of real metals is more complex than this illustration using a single band in f.c.c. and b.c.c. structures. However, the example does serve to show that the DOS will influence the relative total electronic energy of alternative metal lattices. Or, conversely, the electron density of a metal can have a dramatic influence on its optimal structure.

This idea has been tested using higher-level calculations on the first row transition metals to obtain the band structures and DOSs for the valence shells in b.c.c., f.c.c., and h.c.p. structural alternatives, as shown in **Figure 11**. The shape of the DOS for each structure is largely controlled by the interaction of the metal *d*-orbitals in the different crystallographic directions since the overlap of the spherical *s*-orbitals is less influenced by the lattice geometry. At low energies, the calculated DOS are all very similar. At 0.35 eV, corresponding to three electrons per atom, the b.c.c. plot shows a distinct dip and so at this point an increase in electron density with this structure must occupy higher-energy states than are required in the close packed lattices. Integration of the occupied state energies shows that in this regime the close packed lattices are indeed lower in energy than in b.c.c., and under standard conditions the early

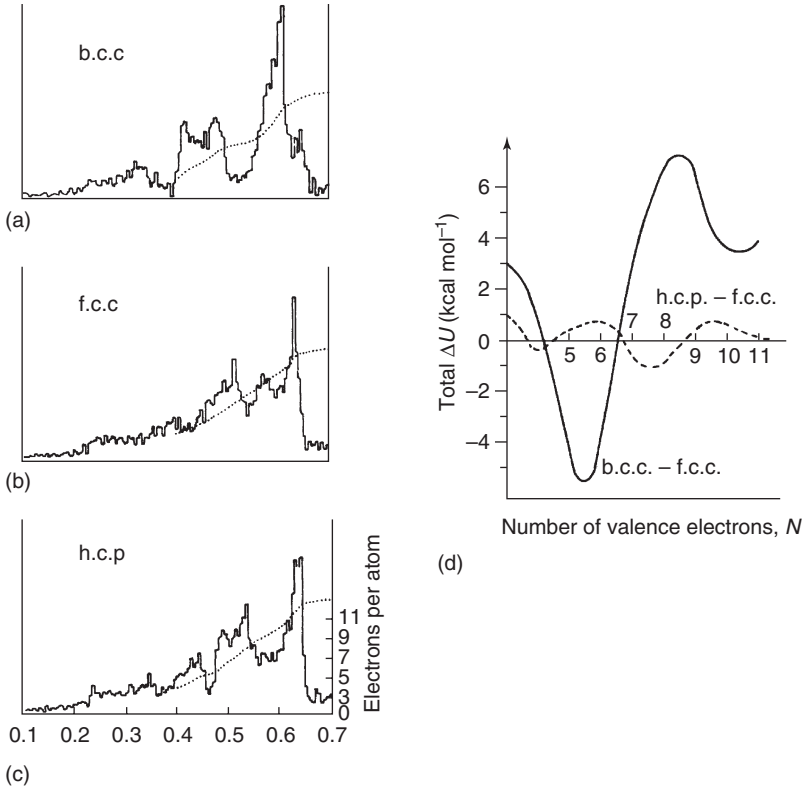

Figure 11 The DOS for (a) b.c.c., (b) f.c.c., and (c) h.c.p. structures. The dotted line in each diagram is the integrated DOS and shows the level of the Fermi energy in the metal with the number of electrons per atom indicated on diagram (c). (d) The total electronic energy of the b.c.c. and h.c.p. structures relative to that of the f.c.c. as a function of electron density. (Reproduced from Pettifor DG (1977) A physicist's view of the energetics of transition metals. *Calphad* 1(4): 305–324, with permission from Elsevier.)

transition metals, Sc ($3d^1 4s^2$) and Ti ($3d^2 4s^2$), have the h.c.p. structure suggested in **Figure 11d**. Just above 4 eV, there is a peak in the b.c.c. DOS and so the total energy at the corresponding electron densities favors the b.c.c. structure. Vanadium and chromium with five and six valence electrons, respectively, both adopt this lattice. Manganese has a complex structure which has not been included in this study, whereas Fe ($3d^6 4s^2$) has a b.c.c. structure at room temperature against the predicted f.c.c. lattice from **Figure 11d**. However, magnetic effects seem to dominate this choice of structure for Fe since above the Curie temperature, the f.c.c. structure is observed. For higher electron densities, the close packed structures are preferred, with the choice of f.c.c. or h.c.p. finely balanced. This is not surprising since the first neighbor interactions are identical in the two structures. Even so the total electronic energies indicate that at seven and eight valence electrons, h.c.p. is more stable than f.c.c. while the situation is reversed for nine and ten outer electrons. This trend is, indeed, observed with the structures of Co, Ni being h.c.p. and Cu, Zn adopting the f.c.c. structure.

Metalloproteins, Electron Transfer in

A R Bizzarri and S Cannistraro, University of Tuscia, Viterbo, Italy

Introduction

In the energy-capture machinery of biology, especially in photosynthesis and in mitochondria, there are chains of redox enzymes containing metal ions, including iron, heme-iron, copper, manganese arranged in order so as to assist electron flow and generate charge separation which represent the first step in the energy-capture process. The ability of transition metals to exist in more than one stable oxidation state makes them suitable catalysts for biological processes that require transfer of electrons. The oxidation/reduction centers are placed in order of their potentials, expressed in terms of free-energy differences, so that the directionality of the electron flow is thermodynamically determined. Along the bioenergetic pathways, electrons flow down a gradient of potential energy that spans a range of less than 1.2 eV.

However, biological material is not constituted by regular arrays of lattice pointing to allow electrons to travel over long distances as delocalized Bloch waves; therefore, the familiar concepts of metallic conduction, through partly filled conduction bands, cannot apply. Instead, biology employs redox centers which are localized potential wells, among which electron transfer (ET) occurs through a hopping mechanism from center to center. The redox centers are nearly always found buried beneath the protein surface, the protein coating serving as an insulator which protects the redox center from short-circuiting ETs. Electrons can be transported across protein-domain interfaces or along a redox chain which consists of a number of proteins (see, for instance, **Figure 1**), the related processes involving several reaction steps.

In ET intra-protein, the redox centers are held at a fixed distance and in a fixed orientation with respect to each other in order to presumably adapt optimally to physiological needs. When two redox centers that are consecutive in the ET train are located on different proteins, ET requires proteins first to form a docking or associative complex in which the partners assemble transiently through complementary contact surfaces. The mutual approach, initially, may be governed by long-range electrostatic forces reflecting the overall charges on the two partners. At shorter ranges, either hydrophobic or Coulomb interactions between opposite charge patches, or combinations of both, determine the structure of the docking complex and the relative orientation of the partners. Generally, for successful ET within a docking complex, the partners should have motional degrees of freedom that allow them to perform a rolling or sliding motion with respect to each other.

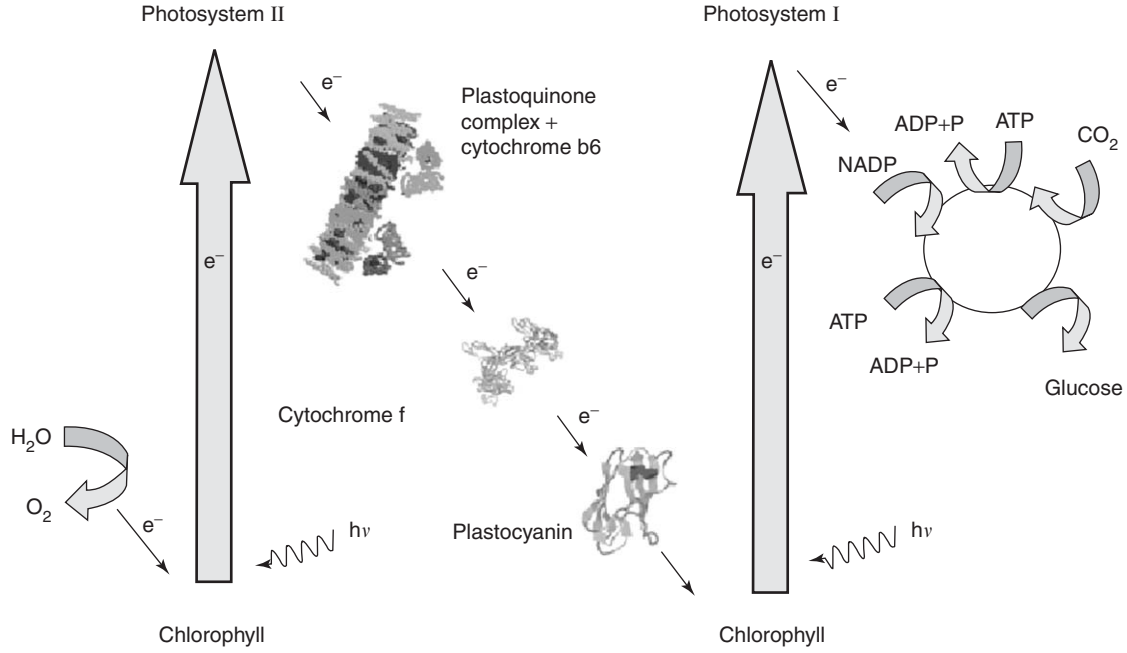

Figure 1 Photosynthesis pathways as found in green plants. Electrons are extracted from water by photosystem II and driven through a complex coupled ET pathway to the CO_2 reduction cycle by photosystem I.

The peculiarity of ET processes mediated by metalloproteins is that they occur over long distances, in a very fast, directional and efficient way, the donor and the acceptor proteins having redox centers separated by distances between 5–25 Å. In contrast to usual chemical reactions which involve the making and breaking of bonds and proceed via a well-defined reaction coordinate, the reactants and products of a protein ET are often chemically indistinguishable.

ET reactions in metalloproteins are usually termed as outer-sphere ETs, since they take place with no or very weak coupling between donor and acceptor sites of the electron.

Typical ET rate constants for biological processes lie in the order of 10^2–$10^3\,s^{-1}$. Optimization of biological ET for speed seems to be necessary to compete with back reactions, especially to prevent charge recombination to occur.

Several factors are suggested to influence the ET efficiency, such as the distance between the redox centers, the role of the protein medium, the possible existence of conducting pathways, the role of the solvent medium, and the assistance of the protein and solvent dynamics. Indeed, the dynamics of the intervening medium through which an electron passes can finely tune the ET process. In particular, a prominent role is played by low-frequency, collective vibrational modes.

Different kinds of ET metalloproteins can be found in biological processes. Among others are cytochromes in which the active site is the heme consisting of iron coordinated to the porphyrin group, and the redox potentials for the Fe^{+3}/Fe^{+2} couple ranging from 5 to 260 mV. Iron–sulfur proteins are characterized by iron–sulfur clusters centered on the iron with redox potentials covering a range, from -700 to 500 mV. Blue copper proteins, in which the copper ion directly coordinates to amino acid residues in a distorted tetrahedral arrangement, are characterized by peculiar spectroscopic properties and a redox potential for the Cu^{+2}/Cu^{+1} couple from 130 to 680 mV.

More recently, understanding the mechanism of electron transduction through biological macromolecules has assumed fundamental importance not only in increasing the knowledge of the ET process, ubiquitous in biology, but also in the development of novel, improved bioelectronic devices.

The ET Rate: A General Overview

The ET theory describes the transition of an electron from a donor D to an acceptor A, the reactant and product, DA and D^+A^-, representing the system before and after the ET process, respectively. The states $|DA\rangle$ and $|D^+A^-\rangle$ can be expressed by the combination of the wave functions for the two redox centers:

$$|DA\rangle = (\overline{\Phi}_D\Phi_A), \qquad |D^+A^-\rangle = (\Phi_D\overline{\Phi}_A)$$

where Φ_D and Φ_A are the complete wave functions describing the nuclear and electronic motions of the

two redox centers, the bar denoting the electron participating in the transition.

The traditional transition-state theory of the rates for chemical reactions involves motion along a potential energy surface in which the reactant atoms gain energy from thermal collisions, surmount an activation energy barrier to achieve a transition state, and spontaneously decay into the product. In contrast to these, usually called adiabatic reactions, where formation of the transition state leads almost inevitably to the product, the probability of long-distance ET for such a transition is small. Accordingly, a nonadiabatic description for the ET reaction is more appropriate.

For nonadiabatic ET reactions, the first-order rate constant k_{ET}

$$|DA\rangle \overset{k_{ET}}{\rightarrow} |D^+A^-\rangle$$

can be conveniently expressed by Fermi's golden rule obtained from the time-dependent quantum mechanical perturbation theory:

$$k_{ET} = \frac{2\pi}{\hbar} V_R^2 \rho \qquad [1]$$

where $\hbar$ is the Planck's constant divided by 2π, V_R^2 is the square of the quantum matrix element for electronic coupling between donor and acceptor, averaged over all possible thermal fluctuations of the system, ρ is the density of states, that is, the number of states per unity interval of energy.

The electronic coupling V_R^2 is the principal origin of the distance dependence of the ET constant rate. The simplest model, neglecting the role of the intervening medium, predicts that V_R^2 falls off exponentially with the distance R between the donor D and the acceptor A according to $e^{-\beta R}$, where β is an attenuation factor. In order to obtain ET rates in the order of 10^2–$10^3\,s^{-1}$, R must be in the range 10–20 Å (see also in the following).

Under the requirement of the Franck–Condon principle, stating that during the almost instantaneous ET process the nuclei do not change either their positions or their momenta, the ET rate can be expressed in the form

$$k_{ET} = \frac{2\pi}{\hbar} V_R^2 F_C \qquad [2]$$

where F_C is the Franck–Condon weighted density of states reflecting the overlap of the donor and acceptor nuclear and solvational wave functions.

Accordingly, ET will occur at nuclear configurations for which the total potential energy of the reactants and surrounding medium is equal to that of the products and the surrounding medium. The quantity F_C is a sum of the square of the overlap integrals $S_{v_{DA}v_{D^+A^-}}$ of the vibrational wave functions of the reactants (v_{DA}) with the corresponding ones of the products ($v_{D^+A^-}$), weighted by Boltzmann factors:

$$F_C = \sum_{v_{DA}} \sum_{v_{D^+A^-}} S^2_{v_{DA}v_{D^+A^-}} p(v_{DA}) \qquad [3]$$

with

$$S_{v_{DA}v_{D^+A^-}} = \int \chi_{v_{DA}} \chi_{v_{D^+A^-}}\, dx$$

where $\chi_{v_{DA}}$ and $\chi_{v_{D^+A^-}}$ are the wave functions for the states v_{DA} and $v_{D^+A^-}$, respectively, x being the oscillation coordinate; $p(v_{DA})$ is the equilibrium Boltzmann probability of finding the system in the vibrational state v_{DA}. The sum is over any given set of the vibrational quantum numbers $(v_{DA}, v_{D^+A^-})$ of the reactant DA and the product D^+A^-, including the solvent, such a sum being, however, limited by the fact that only a small number of states have a finite overlap and hence contributes to the final term.

The calculation of F_C can be extremely problematic and different expressions for the Frank–Condon factor can be obtained depending on the approximations done. Classical, semiclassical, and quantum mechanical approaches, according to the treatment of the nuclear motions, have been followed to work out useful expressions for F_C.

When all the vibrational frequencies are relatively small, for example, $\hbar\omega \ll k_B T$, the vibrational manifold of DA and D^+A^- can be treated as a continuum and the passage across the activation barrier can be described classically in terms of the activated complex theory, properly modified for nonadiabatic reactions. Accordingly, the ET rate is related to the free activation energy, ΔG^*, of the reaction as follows:

$$k_{ET} = k_{ET}(0) e^{-\Delta G^*/k_B T} \qquad [4]$$

where the pre-exponential factor $k_{ET}(0)$ defines the limiting rate of the reaction.

Generally, classical results are valid only at temperatures high enough so that the vibrations are fully excited. The classical approach is discussed in the next section where the expression worked out by Marcus for F_C, and hence for the ET reaction rate, is presented. When $\hbar\omega \geq k_B T$, the discrete nature of the vibrational manifold must be taken into account. The ET rate may become temperature independent and a quantum mechanical view is more appropriate. Moreover, under these conditions, electron tunneling may become important. This aspect is briefly presented in the following.

Marcus Theory of ET

The simplest theoretical treatment of the rate of ET in metalloproteins is due to Marcus using a classical

harmonic oscillator model, which generates parabolic potential energy curves. Indeed, this approach represents the most insightful and used theoretical framework to interpret experimental ET results in metalloproteins.

The ET process can be seen as an electron jump from DA to D^+A^- and requires one to match the Franck–Condon principle, which implies that the nuclear configuration and, in addition, the conservation of energy are the same immediately after the ET as before. Under these requirements, the electron jump takes place in the vicinity of the crossover, nuclear configuration C (**Figure 2**).

Thermal fluctuations and/or vibrations in some coordinates will be required for reaction to occur. Since the charge distribution of the protein matrix is different before and after the ET process, the surrounding medium will be polarized differently in the two states. Therefore, the coordinates involved in the ET reaction include vibrational coordinates of the protein, and the vibrational and orientational coordinates of the surrounding solvent. All the fluctuating nuclear coordinates relevant to the ET reaction are usually lumped together into the so-called reaction coordinate Q. The dependence of the potential energy curves of the reactant DA and the product D^+A^- on Q is assumed to be quadratic, according to the harmonic approximation, and unchanged by the ET reaction (**Figure 2a**).

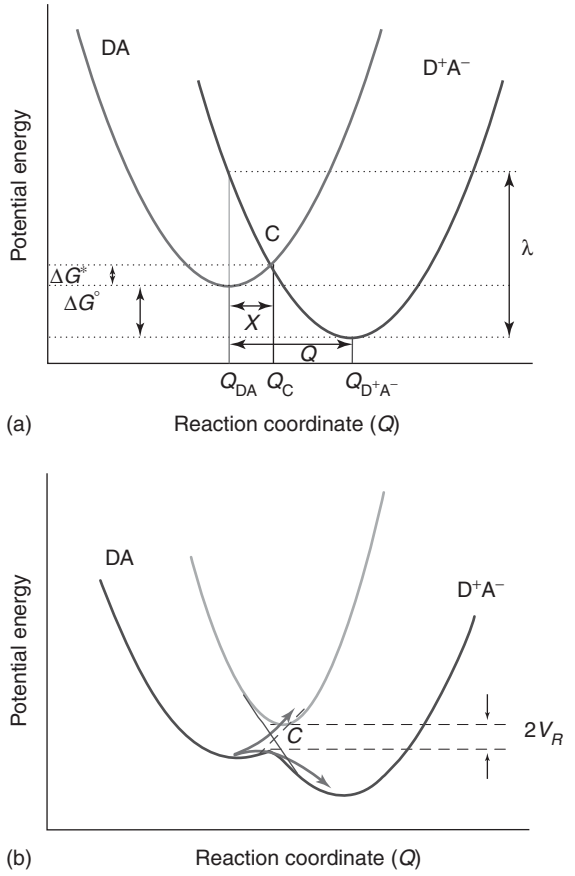

Figure 2 (a) The harmonic potential energy of the reactant (DA) and product (D^+A^-) as a function of the reaction coordinate Q. ΔG° is the standard free energy, λ is the reorganization energy, and ΔG^* is the free energy of activation. (b) Influence of the electronic coupling on the potential energy curves. In both cases, the ordinate represents the potential energy of the nuclei of the whole system: donor + acceptor + medium.

In the nonadiabatic case, the passage through C does not usually cause transition from DA to D^+A^-. Once the system reaches the intersection of the potential curves C, the probability of going from DA to D^+A^- depends on a number of factors such as the extent of coupling of the electronic orbitals of the two reactants, which in turn depends on the separation distance of the two reactants, the separation between the two potential energy curves over a vertical distance being given by $2V_R$, where V_R is the electronic coupling element between DA and D^+A^- (**Figure 2b**). If the gap is large enough, as it occurs in adiabatic reactions, the transition DA to D^+A^- will take place each time the crossing point is reached. Conversely, for small V_R as in nonadiabatic ET reactions, the electron, for most of the times it reaches the crossing point, continues its motion along the curve DA (upward-running arrow in **Figure 2b**). Only once in a while, the electron will make the transition to D^+A^- when the crossing is reached (downward-running curve in **Figure 2b**).

In the framework of the Marcus theory, the electron jumping from the equilibrium coordinate Q_{DA} of DA to the equilibrium coordinate $Q_{D^+A^-}$ of D^+A^- can be described in terms of the free energy of activation, ΔG^* which is related to two experimental observables, ΔG°, the standard free energy and λ, the reorganization energy. ΔG^* is the energy required to reach the point C from DA, overcoming the activation barrier. The standard free energy or driving force, ΔG°, is the energy difference between the ground states of DA and D^+A^-, respectively, and can be expressed as

$$\Delta G^\circ = zF(E^\circ_A - E^\circ_D) \qquad [5]$$

where z is the number of electrons transferred, F is the Faraday constant, and E°_A and E°_D are the midpoint potentials of the acceptor and donor centers.

The reorganization energy λ is the free energy required to move all the atoms from their equilibrium positions before the ET to the equilibrium positions they would have after the ET without transferring the electron. By referring to **Figure 2a**, the activation barrier ΔG^* and the reorganization energy λ are

$$\Delta G^* = \tfrac{1}{2} k_H X^2, \qquad \lambda = \tfrac{1}{2} k_H Q^2 \qquad [6]$$

where X is the distance between the equilibrium coordinate Q_{DA} and the coordinate of the crossing point C, and Q is the distance between the equilibrium coordinates Q_{DA} and $Q_{D^+A^-}$, k_H being the force constant of the harmonic potential energy corresponding to both DA and D^+A^-.

The difference between the free energy and the activation energy can be expressed as

$$\begin{aligned}\Delta G^* - \Delta G^\circ &= \tfrac{1}{2} k_H (Q - X)^2 \\ &= \tfrac{1}{2} k_H Q^2 + \tfrac{1}{2} k_H X^2 - k_H Q X \end{aligned} \quad [7]$$

By rearranging eqns [6] and [7], one gets

$$X = \frac{\lambda + \Delta G^\circ}{k_H Q} \quad [8]$$

and finally

$$\Delta G^* = \frac{1}{2} k_H \frac{(\lambda + \Delta G^\circ)^2}{k_H^2 Q^2} = \frac{(\lambda + \Delta G^\circ)^2}{4\lambda} \quad [9]$$

Therefore, from eqn [4], the ET rate can be expressed by

$$k_{ET} = k_{ET}(0) \exp\left[\frac{-(\Delta G^\circ + \lambda)^2}{4\pi\lambda k_B T}\right] \quad [10]$$

where the pre-exponential factor $k_{ET}(0)$ assumes the form

$$k_{ET}(0) = \frac{2\pi}{\hbar} V_R^2 \left(\frac{1}{4\pi\lambda k_B T}\right)^{1/2} \quad [11]$$

leading to the final expression:

$$\begin{aligned} k_{ET} = &\frac{2\pi}{\hbar} V_R^2 \left(\frac{1}{4\pi\lambda k_B T}\right)^{-1/2} \\ &\times \exp\left[\frac{-(\Delta G^\circ + \lambda)^2}{4\pi\lambda k_B T}\right] \end{aligned} \quad [12]$$

The ET rate can be modulated by thermodynamic (ΔG°) and intrinsic (λ) factors and, in addition, it varies with the temperature. Notably, the optimal rate is obtained when $-\Delta G^\circ$ matches λ, such a condition having been exploited to extract information on V_R and λ from k_{ET} values (see below).

As already mentioned, the final Marcus expression provides a sound approach to describe the ET processes in metalloproteins. However, while it takes into account the temperature dependence of the ET rate at high temperature, it fails at low temperatures, at which a deviation from an Arrhenius-like behavior, or even temperature-independence (at very low T), has been observed.

Quantum Mechanical Theories of ET

A semiclassical approach has been followed by Hopfield to derive an expression for the ET rate. He treated oscillators classically, but assumed quantized energy levels. By introducing the probability distributions $D_D(E)$ and $D_A(E')$, corresponding to the energy required to remove an electron from the donor and to give an electron to the acceptor, respectively, the density of states in eqn [1] can be expressed by

$$\rho = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} D_D(E) D_A(E') \, dE \, dE' \quad [13]$$

He assumed, moreover, that both the distributions follow a Gaussian form

$$\begin{aligned} D_D(E) &= \frac{1}{(2\pi\sigma_D^2)^{1/2}} \exp\left[\frac{-(E + E_D - \lambda_D)^2}{2\sigma_D^2}\right] \\ D_A(E') &= \frac{1}{(2\pi\sigma_A^2)^{1/2}} \exp\left[\frac{-(E' + E_A + \lambda_A)^2}{2\sigma_A^2}\right] \end{aligned} \quad [14]$$

with standard deviations σ_D and σ_A, respectively; E_D is the energy of the ground state of the reduced form of the donor and E_A is the reduced form of the acceptor; $D_D(E)$ is centered below E_D by an amount λ_D because ordinarily, the nuclear configuration in the initial reduced state will not be an equilibrium configuration for the final, oxidized state; for the same reason, the center of $D_A(E')$ is displaced upwards from E_A by an amount λ_A.

By taking into account the Franck–Condon principle and the conservation of energy in the process ($E = E'$), eqn [13] becomes

$$\begin{aligned} \rho = F_C &= \int_{-\infty}^{+\infty} D_D(E) D_A(E) \, dE \\ &= \frac{1}{(2\pi\sigma^2)^{1/2}} \exp\left[\frac{-(\Delta E - \lambda)^2}{2\sigma^2}\right] \end{aligned} \quad [15]$$

where $\sigma^2 = \sigma_D^2 + \sigma_A^2$, $\lambda = \lambda_D + \lambda_A$, and $\Delta E = E_A - E_D$ being the energy gap of the reaction.

By assuming that both the donor and the acceptor have a quadratic dependence on the nuclear coordinate with the same force constant k_H, and a spacing between energy levels equal to $\hbar\omega_D$ and $\hbar\omega_A$ for the donor and the acceptor respectively, it comes out that

$$\begin{aligned} \sigma_D^2 &= \hbar\omega_D \lambda_D \coth(\hbar\omega_D / 2k_H T) \\ \sigma_A^2 &= \hbar\omega_A \lambda_A \coth(\hbar\omega_A / 2k_H T) \end{aligned}$$

Therefore, the resulting ET rate becomes

$$k_{ET} = \frac{2\pi}{\hbar} V_R^2 \left(\frac{1}{2\pi\sigma^2}\right)^{-1/2} \times \exp\frac{-(\Delta E - \lambda)^2}{2\sigma^2} \quad [16]$$

Notably, in the limit of high temperatures, σ approaches $k_B T$ and eqn [16] results in being formally similar to the Marcus expression, once $-\Delta E$ is identified by ΔG^*. Conversely, at very low temperatures, the Frank–Condon factor F_C becomes temperature independent, in agreement with some experimental data.

However, the limiting expression at low temperature is not in complete agreement with experimental data. Significant improvements can be reached by a full quantum mechanical approach also taking into account the vibrations coupled to changes of the electronic state. A variety of quantum mechanical treatments with different degrees of approximations have been developed. Under the assumption that the system consists of a single group of harmonic oscillators and that there is a single prevailing mode, from eqn [3], the Levich–Degonadze–Jortner expression can be derived for F_C:

$$F_C = \frac{1}{\hbar\omega} e^{-S(2n+1)} \left(\frac{n+1}{n}\right) \times \frac{\Delta E}{2\hbar\omega} I_P\left[2S\sqrt{n(n+1)}\right] \quad [17]$$

where $\hbar\omega$ is the characteristic frequency, ΔE is the energy gap of the reaction, S is equal to $\lambda/\hbar\omega$, I_P is the modified Bessel function of the order P, and n is given by

$$n = [e^{\hbar\omega/kT} - 1]^{-1}$$

The ET rate can be then expressed by

$$k_{ET} = \frac{2\pi}{\hbar} V_R^2 \frac{1}{\hbar\omega} e^{-S(2n+1)} \left(\frac{n+1}{n}\right) \times \frac{\Delta E}{2\hbar\omega} I_P\left[2S\sqrt{n(n+1)}\right] \quad [18]$$

In the limit of very high temperature, eqn [18] again reduces to the Marcus expression. In addition, it well reproduces the experimental trend with temperature. However, it does not include the coupling of low-frequency vibrational modes of the redox center to the ET process. In order to take into account for low-frequency modes, a correction to eqn [18] has been done by including the oscillator zero-point energy considering the change of frequency, leading to an expression similar to eqn [12], containing $-\Delta G^\circ$ instead of ΔE.

Dependence of ET Rate on the Protein Matrix

A crucial aspect of the ET process is represented by the dependence of k_{ET} on the medium between the redox centers. To obtain information on the variation of k_{ET} with the nature of the medium, first it is necessary to eliminate, or at least to minimize, the dependence of k_{ET} on both the driving force and the reorganization energy. In the framework of the Marcus theory, this can be achieved by extrapolating k_{ET} when $\Delta G^\circ = -\lambda$. According to eqn [12], the exponential trend on the driving force and reorganization energy disappears. The resulting rate remains only weakly dependent on λ ($k_{ET} \sim 1/(\lambda)^{1/2}$), and its change with the medium is mainly reflected by V_R.

The dependence of V_R on the intervening medium can be cast in the form

$$V_R^2 = V_R^{o2} f_M^2 \quad [19]$$

where V_R^o represents the electronic coupling between DA and D^+A^- when the redox centers are in van der Waals contact, and f_M is a dimensionless attenuation factor which varies between 1 (van der Waals contact) and 0 (infinite distance). The dependence of f_M on the detailed structure of the medium connecting the two redox centers has been widely investigated. Only two cases are considered in the following.

In the first approach, the protein intervening medium is pictured as an organic glass, the random, disordered connections between the two redox centers constituting the overall path of ET. In this framework, the distance between the donor and the acceptor centers is the parameter governing the ET rate. The dependence of f_M^2 on the distance, R, between the center of the edge atom of the donor and that of acceptor can be expressed by

$$f_M^2 = e^{-\beta(R-R_o)} \quad [20]$$

where the exponential coefficient of decay, β, quantitatively describes the nature of the intervening medium with respect to its efficiency to mediate the ET process, for instance, through the propagation of the relevant wave functions. A variation of ET rates over 12 orders of magnitude can satisfactorily be accounted for by a distance dependence as in eqns [19] and [20], with $\beta = 1.4\,\text{Å}^{-1}$ and $R_o = 3.6\,\text{Å}$. More generally, values of β in the range 0.7–1.4 Å^{-1} are found to reproduce the experimental k_{ET} values of metalloproteins.

An alternative description of the dependence of f_M^2 with the nature of the medium invokes the so-called pathway model which is, in some sense, based on the mechanism of super-exchange, owing to the fact that the electronic coupling between the donor and

acceptor wave functions is mediated by a third center that connects the two wave functions. A pathway is defined as a combination of interacting bonds that link the donor and the acceptor. Three types of steps are distinguished, depending on whether the transfer occurs between atoms that are connected through a covalent bond (C), a hydrogen bond (H), or not connected at all (S); in the latter case, the electron must be transferred through space. The corresponding attenuation factor for a transfer path can be expressed as

$$f_{\mathrm{M}} = \prod_{i}^{N_{\mathrm{C}}} \varepsilon_i^{\mathrm{C}} \prod_{j}^{N_{\mathrm{H}}} \varepsilon_j^{\mathrm{H}} \prod_{k}^{N_{\mathrm{S}}} \varepsilon_k^{\mathrm{S}} \qquad [21]$$

where N_{C}, N_{H}, N_{S} are the number of C, H, and S paths, respectively; ε are the individual attenuation factors corresponding to a particular step in the transfer path. Semi-empirical expressions for the ε-factors are

$$\varepsilon_{\mathrm{C}} = 0.6, \qquad \varepsilon_{\mathrm{H}} = 0.36\mathrm{e}^{[-1.7(R-2.8)]},$$
$$\varepsilon_{\mathrm{S}} = 0.6\mathrm{e}^{[-1.7(R-1.4)]}$$

in which R is the distance between the two atoms exchanging the electron. Such an approach predicts that α-helices are characterized by a lower conductivity than β-sheets.

Reorganization Energy in the ET Process

When an electron is transferred in an intermolecular process, through the protein matrix, the distribution of charge is different before and after the transfer, as already mentioned. These changes have to be accommodated by the local dielectric properties contributed by polarizability, local bonds, reorientation of polar side chains, dissociation or association of protolytic groups, movements of ions in the solvent, reorientation of solvent dipoles, etc. Additionally, the local structure of the redox center might undergo changes in configuration. All these physical effects are accounted for by the reorganization energy λ.

Marcus originally divided the reorganization energy into changes occurring at the redox center (inner sphere) and those occurring in the surrounding protein/water matrix (outer sphere). Accordingly, λ can be separated into: $\lambda = \lambda_{\mathrm{i}} + \lambda_{\mathrm{o}}$ where λ_{i} is the contribution to the reorganizational energy of the inner shell of atoms, close to the redox center, while λ_{o} refers to atoms further out, generically called "solvent."

The inner-sphere reorganization energy λ_{i}, which reflects redox-dependent nuclear perturbations of the redox centers, such as changes in bond lengths and angles, can be expressed in terms of the inner shell normal vibrational modes:

$$\lambda_{\mathrm{i}} = \frac{1}{2}\sum_{j} k_{\mathrm{H}j} Q_j^2 \qquad [22]$$

where Q_j is the displacement from the equilibrium position of the jth normal coordinate caused by the ET; the constant $k_{\mathrm{H}j}$ being given by

$$k_{\mathrm{H}j} = \frac{f_j^{\mathrm{DA}} f_j^{\mathrm{D^+A^-}}}{f_j^{\mathrm{DA}} + f_j^{\mathrm{D^+A^-}}} \qquad [23]$$

where f_j^{DA} and $f_j^{\mathrm{D^+A^-}}$ are the force constants at the equilibrium for DA to $\mathrm{D^+A^-}$, respectively.

The outer-sphere reorganization energy, λ_{o}, which reflects changes in the surrounding medium, such as changes in solvent orientation, can be estimated from the polarizability of the solvent, as considered to be a continuous polar medium:

$$\lambda_{\mathrm{o}} = \frac{Ne}{4\pi\varepsilon_{\mathrm{o}}}\left[\frac{1}{2R_1} + \frac{1}{2R_2} - \frac{1}{R}\right]\left[\frac{1}{D_{\mathrm{OP}}} - \frac{1}{D_{\mathrm{S}}}\right] \qquad [24]$$

where Ne is the charge transferred from the donor to the acceptor; R_1 and R_2 are the radii of the two spherical reactants when in contact and $R = R_1 + R_2$; D_{OP} is the square of the refractive index of the medium and D_{S} is the static dielectric constant; ε_{o} is the permittivity of space.

For redox centers that are buried within a protein, λ_{o} may also include configurational changes in the protein matrix and, for interprotein reactions, in the interface between the donor and the acceptor proteins. It is to be noted that the higher the dielectric constant of the solvent, the larger is the value obtained for λ. Furthermore, for nonpolar solvent, λ_{o} vanishes and such a condition can be exploited to obtain information on λ_{i}.

In the framework of the Marcus theory (see eqn [12] and **Figure 2a**), a decrease in the driving force, for constant λ, will displace the product potential energy upward, causing ΔG^* to increase and consequently the ET rate to decrease. Similarly, at constant $-\Delta G^\circ$, an increase in λ will increase the horizontal displacement of the product from the reactant, imposing a higher activation barrier. Depending on the sign of the quantity $(\Delta G^\circ + \lambda)$, one can distinguish the so-called normal region $[(\Delta G^\circ + \lambda) > 0]$, the activationless region $[(\Delta G^\circ + \lambda) = 0]$, and the inverted region $[(\Delta G^\circ + \lambda) < 0]$. These conditions are qualitatively illustrated in **Figure 3**.

In the normal region $[(\Delta G^\circ + \lambda) > 0]$, an increase in the driving force accelerates the ET process, while it slows down in the inverted region, thus representing one of the most celebrated predictions of the Marcus expression. Notably, when $[\Delta G^\circ + \lambda = 0]$, the ET rate is least affected by variations of T and λ. For

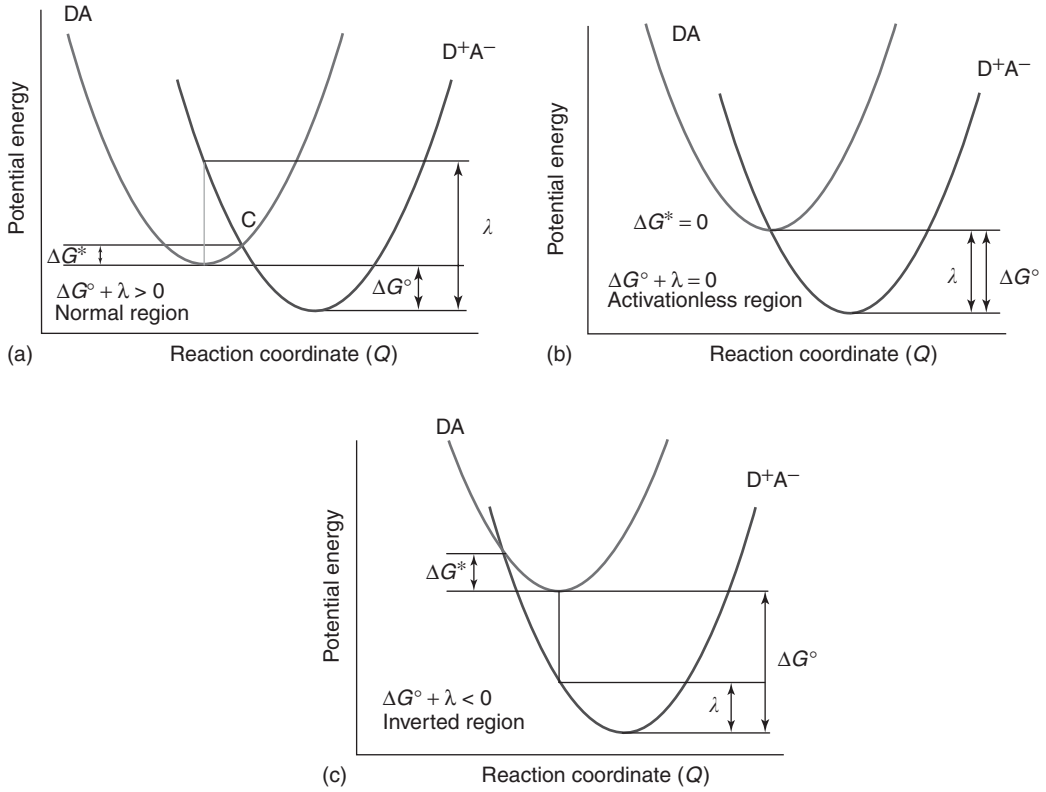

Figure 3 The harmonic potential energy of the states DA and D^+A^- as a function of the reaction coordinate Q, according to the Marcus theory, for three representative cases: $\Delta G^\circ + \lambda > 0$, normal region; $\Delta G^\circ + \lambda = 0$, activationless region; $\Delta G^\circ + \lambda < 0$, inverted region.

$[(\Delta G^\circ + \lambda) < 0]$, the slower the ET rate, the greater is the energy liberated in the reaction, such a condition being involved in the phenomenon of chemiluminescence. Furthermore, in the inverted region, the extent of electron tunneling may become more relevant.

The reorganization energy λ constitutes a crucial parameter in the ET process. Many evaluations by *ab initio* quantum mechanical calculations of λ have been done. However, despite their importance, direct and precise measurements of the reorganization energy λ are quite difficult. Generally, it can be extracted by measuring the dependence of the ET rate upon $-\Delta G^\circ$ and using the fact that, from the Marcus theory, the rate is expected to be maximal when $\Delta G^\circ = -\lambda$. Values for $\lambda \sim 0.7$ and 1 eV have been commonly found for intra and interprotein ET, respectively.

Perspectives and Final Remarks

Despite the large efforts devoted to investigate the ET process in metalloproteins, many aspects still remain far from being fully clarified. Recent developments in spectroscopic and scanning probe techniques, together with advanced computational approaches, could help in a further elucidation of the ET process in biomolecules. Laser ultrafast spectroscopy could get insights into the subtle relationships among the structure, dynamics, and functionality by also allowing one to explore the role of water dynamics in the ET process and to evaluate the reorganization energy. The mechanisms involved in intra and intermolecular ET could be deeply investigated by scanning tunneling microscopy and spectroscopy, whose role in the study of biological systems is rapidly growing. Molecular dynamics simulations, also integrated with quantum chemical calculations, can provide valuable information about possible ET pathways, elucidating at the same time, the interplay between the structural and dynamical behavior and the role played by collective motions.

From the practical side, the insights gained from these studies could lead to the introduction of new strategies to design synthetic ET systems with enhanced ET rates and efficiencies. In such a way, by exploiting their nanoscale dimensions, these molecules could be integrated into hybrid systems in the perspective to build nanodevices and nano-biosensors.

Metalloproteins, Structural Determination of

C Luchinat and G Parigi, University of Florence, Florence, Italy

Introduction

About 30% of proteins in all living organisms contain a metal ion. Such metalloproteins may be diamagnetic or paramagnetic systems, depending on the nature of the metal ion and its spin state. The presence of a diamagnetic metal ion in the protein does not affect the NMR parameters appreciably, and the usual techniques for protein solution structure determination can be applied, with the additional problem of locating the metal ion. On the contrary, the presence of a paramagnetic metal ion largely perturbs the NMR parameters, as it affects both the signal line widths and the intensity of the nuclear Overhauser effects (NOEs). In fact, since the magnetic moment of an unpaired electron is 658.2 times larger than that of a proton, the major magnetic interaction of any nucleus not far from the metal ion will be provided by the dipolar coupling with the unpaired electron rather than with other closer nuclei (**Figure 1**). Such interaction sizably increases both their longitudinal and transverse relaxation rates – two parameters strongly affecting the protein NMR spectra.

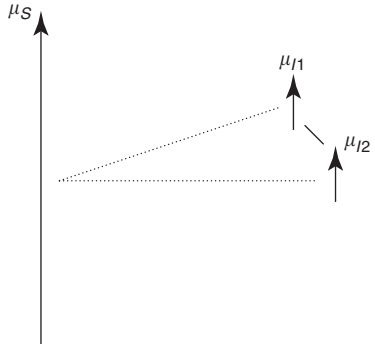

Figure 1 The magnetic interaction of a nuclear magnetic moment with the electron magnetic moment can be larger than that between two close nuclei, due to the larger electron magnetic moment.

If R_{1M} and R_{2M} indicate the paramagnetic contributions to the longitudinal and transverse relaxation rates, respectively, the increase in nuclear signal line width due to the presence of a paramagnetic metal ion will be given by

$$\Delta\nu = R_{2M}/\pi$$

and the change in NOE intensity by

$$\frac{\eta_{I(J)}^{\text{para}}}{\eta_{I(J)}^{\text{dia}}} = \frac{\rho_{I(J)} + \rho_{I(\text{other})}}{\rho_{I(J)} + \rho_{I(\text{other})} + R_{1M}}$$

where $\rho_{I(J)}$ is the contribution to longitudinal relaxation of nucleus I due to the coupling with nucleus J and $\rho_{I(\text{other})}$ includes all other contributions to relaxation of nucleus I, with the exception of the coupling with nucleus J and with the paramagnetic center, R_{1M}.

The increase in line widths and the decrease of NOE intensities make it more difficult to collect data for structure calculations. For $R_{1M} > R_{1\text{dia}}$ and $R_{2M} > R_{2\text{dia}}$, the integrals of NOESY cross-peaks decrease linearly with R_{1M}, and the scalar coupling cross-peaks decrease quadratically with R_{2M}. However, the presence of a paramagnetic metal ion makes available a new class of structural restraints: the paramagnetism-based restraints. The amount of information related to these new restraints is often able to compensate the loss of information due to the effects described above. Paramagnetism-based restraints are derived from contact shifts (CSs), pseudocontact shifts (PCSs), relaxation enhancements, and residual dipolar couplings (RDCs) arising from partial metalloprotein self-orientation, cross-correlation between Curie relaxation and dipole–dipole nuclear relaxation (CCR).

The availability of the paramagnetism-based restraints may also make it convenient to use a paramagnetic metal ion in the place of a native diamagnetic metal or as a probe to be attached to a protein.

Paramagnetism-based restraints have also the advantage of being often quicker to obtain than the classical NOE restraints, especially for proteins of large size. Therefore, the development of protocols for their efficient use is of great perspective importance in order to increase the speed in solving protein structures and to obtain structures of large proteins employing NMR.

The Magnetic Susceptibility in Diamagnetic and Paramagnetic Systems

All the paramagnetism-based effects indicated above originate from the dipolar coupling between protein nuclei and the unpaired electron(s) and from the presence of paramagnetic susceptibility, usually an anisotropic quantity, which is now introduced.

When a molecule is immersed in an external magnetic field $\boldsymbol{H}_0$, an induced magnetic moment is established along $\boldsymbol{H}_0$. A magnetization $\boldsymbol{M}$ thus arises, defined as the induced magnetic moment per unit volume, usually proportional to H_0:

$$M = \frac{\chi_V B_0}{\mu_0}$$

where μ_0 is the permeability of free space and $B_0 = \mu_0(H_0 + M) \approx \mu_0 H_0$. In systems that do not contain paramagnetic ions, χ_V is the diamagnetic susceptibility, usually independent of B_0 and is negative.

In paramagnetic systems, χ_V is dominated by the paramagnetic susceptibility per unit volume, it is independent of B_0 and is positive. An average induced magnetic moment per particle, $\langle \mu \rangle$, is, in fact, established due to the different populations of the electron energy levels, as a consequence of the fact that the magnetic field splits the S manifold of a particle with spin S according to its M_S values (**Figure 2**). The magnetic susceptibility per molecule, χ, is defined as

$$\chi = \frac{V_M \chi_V}{N_A} = \frac{V_M \mu_0 M}{N_A B_0} = \frac{\mu_0 \langle \mu \rangle}{B_0}$$

where V_M is the molar volume and N_A is the Avogadro constant.

The electron magnetic moment is related to the electron spin according to the following equation:

$$\boldsymbol{\mu} = -\mu_B g_e \boldsymbol{S}$$

where g_e is the electron g factor and μ_B is the electron Bohr magneton. The expectation value of $\boldsymbol{\mu}$ along the direction of the applied magnetic field z, is thus given by $-\mu_B g_e S_z$. Analogously, the average induced magnetic moment per particle is

$$\langle \mu \rangle = -\mu_B g_e \langle S_z \rangle$$

where $\langle S_z \rangle$, the expectation value of S_z, in the high-temperature approximation and in the limiting case where there is no contribution from the orbital magnetic moment, is given by

$$\langle S_z \rangle = -\frac{g_e \mu_B B_0}{3kT} S(S+1)$$

where k is the Boltzmann constant and T is the absolute temperature. Therefore, the Curie law is obtained:

$$\chi = \mu_B^2 g_e^2 \frac{\mu_0}{3kT} S(S+1)$$

If the orbital magnetic moment is considered, the magnetic susceptibility becomes anisotropic, and must be represented as a tensor. As a consequence, the average induced magnetic moment depends on the orientation of the $\boldsymbol{\chi}$-tensor with respect to the direction of the applied magnetic field:

$$\langle \boldsymbol{\mu} \rangle = \frac{\boldsymbol{\chi} \cdot \boldsymbol{B}_0}{\mu_0}$$

The energy of a magnetically anisotropic molecule, with average magnetic moment per particle $\langle \boldsymbol{\mu} \rangle$, in a magnetic field is given by

$$E^{\text{aniso}} = -\int_0^{\langle \mu \rangle} \boldsymbol{B}_0 \cdot d\langle \boldsymbol{\mu} \rangle = -\frac{\boldsymbol{B}_0 \cdot \boldsymbol{\chi} \cdot \boldsymbol{B}_0}{2\mu_0}$$

The fact that the energy is orientation dependent has an influence on the probability that the molecule orients along different directions.

The Dipole–Dipole Interaction

The point dipole–point dipole interaction between two particles possessing a magnetic moment is described

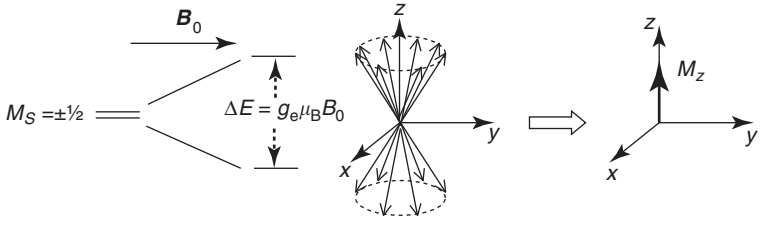

Figure 2 A magnetization arises due to the different population of the electron energy levels corresponding to $M_S = 1/2$ and $M_S = -1/2$.

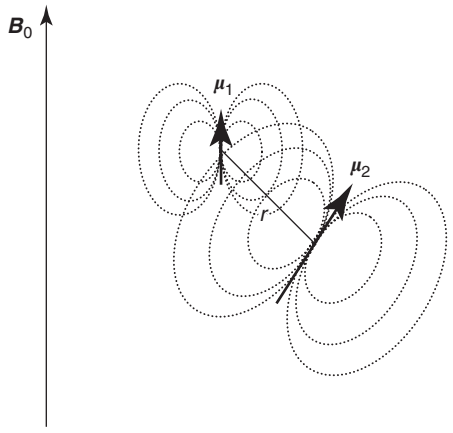

Figure 3 The dipole–dipole interaction between two magnetic moments. The nuclear magnetic moment is along $\boldsymbol{B}_0$, whereas the electron magnetic moment can be along a different direction due to the anisotropy of the magnetic susceptibility tensor.

by the Hamiltonian

$$H = -\frac{\mu_0}{4\pi}\left[\frac{3(\boldsymbol{\mu}_1\cdot\boldsymbol{r})(\boldsymbol{\mu}_2\cdot\boldsymbol{r})}{r^5} - \frac{\boldsymbol{\mu}_1\cdot\boldsymbol{\mu}_2}{r^3}\right]$$

where μ_1 and μ_2 are the interacting magnetic moments and $\boldsymbol{r}$ is the vector connecting the two point dipoles (**Figure 3**). The magnetic moment of the proton is related to its spin $\boldsymbol{I}$ by the relationship $\mu_I = \hbar\gamma_I\boldsymbol{I}$, where γ_I is the proton magnetogyric ratio and $\hbar = h/2\pi$ is the Planck constant. Therefore, if the dominant interaction is between a proton and the average induced electron magnetic moment, the dipolar Hamiltonian can be written as

$$\begin{aligned} H &= -\frac{\hbar\gamma_I}{4\pi}\left[\frac{3(\boldsymbol{I}\cdot\boldsymbol{r})(\boldsymbol{r}\cdot\boldsymbol{\chi}\cdot\boldsymbol{B}_0)}{r^5} - \frac{\boldsymbol{I}\cdot\boldsymbol{\chi}\cdot\boldsymbol{B}_0}{r^3}\right] \\ &= \hbar\gamma_I\boldsymbol{I}\cdot\boldsymbol{\sigma}\cdot\boldsymbol{B}_0 \end{aligned}$$

where $\boldsymbol{\sigma}$ is called dipolar shielding tensor. In case a reference system is chosen with axes coinciding with the main directions of the $\boldsymbol{\chi}$-tensor and origin on the metal ion, the dipolar shielding tensor is

$$\sigma = -\frac{1}{4\pi r^5} \times \begin{pmatrix} (3x^2 - r^2)\chi_{xx} & 3xy\chi_{yy} & 3xz\chi_{zz} \\ 3xy\chi_{xx} & (3y^2 - r^2)\chi_{yy} & 3yz\chi_{zz} \\ 3xz\chi_{xx} & 3yz\chi_{yy} & (3z^2 - r^2)\chi_{zz} \end{pmatrix}$$

where χ_{xx}, χ_{yy}, and χ_{zz} are the principal components of the magnetic susceptibility tensor and x, y, and z are the coordinates of the nucleus in that reference system.

Pseudocontact Shift Restraints

The rotational average of the dipole–dipole interaction between the nucleus magnetic moment and the average induced electron magnetic moment causes a shift of the NMR signals, called PCS. It is calculated by taking the average of the values of the dipolar interaction energy along three principal directions, divided by the Zeeman energy $\hbar\gamma_I B_0$, and thus it is given by

$$\delta^{\text{pcs}} = -\frac{1}{3}\text{Tr}(\sigma)$$

Therefore, in the case where the reference frame coincides with the main directions of the $\boldsymbol{\chi}$-tensor, with the metal ion in the origin,

$$\delta^{\text{pcs}} = \frac{1}{12\pi r^3} \times \frac{(3x^2 - r^2)\chi_{xx} + (3y^2 - r^2)\chi_{yy} + (3z^2 - r^2)\chi_{zz}}{r^2}$$

The latter equation can be written in polar coordinates by using the ϑ and φ angles to specify the position of the nucleus in this reference frame,

$$\delta^{\text{pcs}} = \frac{1}{12\pi r^3} \times \left[\Delta\chi_{\text{ax}}(3\cos^2\vartheta - 1) + \frac{3}{2}\Delta\chi_{\text{rh}}\sin^2\vartheta\cos 2\varphi\right]$$

where $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$ are the axial and rhombic anisotropy parameters of the magnetic susceptibility tensor of the metal,

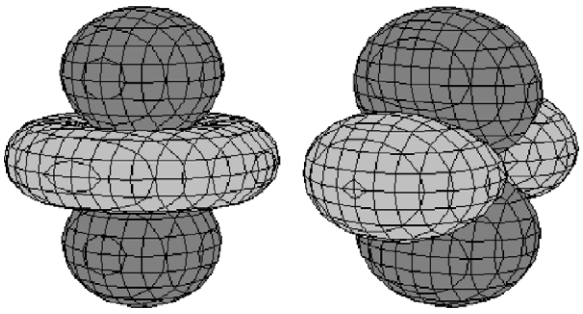
$$\Delta\chi_{\text{ax}} = \chi_{zz} - \frac{\chi_{xx} + \chi_{yy}}{2}, \quad \Delta\chi_{\text{rh}} = \chi_{xx} - \chi_{yy}$$

It should be noted that the PCS depends only on the anisotropy of $\boldsymbol{\chi}$ and not on its magnitude. If the magnetic susceptibility is isotropic, the rotational average of the dipolar energy is zero, and no PCS occurs.

In conclusion, PCS restraints depend on the coordinates of the protein atom, on the values of the magnetic susceptibility anisotropies, and on the three Euler angles defining the principal frame of the magnetic susceptibility tensor. **Figure 4** shows the form of the surface where a nucleus can stay, for a given positive (dark gray) or negative (light gray) value of the PCS and for a given magnetic susceptibility tensor, in the limiting cases of no ($\Delta\chi_{\text{rh}} = 0$) and maximal ($\Delta\chi_{\text{rh}} = 2\Delta\chi_{\text{ax}}/3$) rhombicity.

Relaxation Enhancement Restraints

The recovery to equilibrium of a nuclear spin system is characterized by two time constants, the longitudinal and the transverse relaxation times, indicated by T_1 and T_2, respectively, or by their inverse R_1 and R_2. The longitudinal relaxation time, also called spin–lattice relaxation time, is the time constant for



(a) (b)

Figure 4 Surface constraint for a nucleus with a positive (dark gray) or negative (light gray) PCS value in the case of (a) axial paramagnetic susceptibility tensor ($\Delta\chi_{rh} = 0$) or (b) maximal rhombicity ($\Delta\chi_{rh} = 2\ \Delta\chi_{ax}/3$) of the paramagnetic susceptibility tensor. The metal is located at the origin.

the evolution of the component of the nuclear magnetization along the magnetic field direction toward its equilibrium value. The more numerous and efficient the mechanisms allowing the nuclear spin to jump from one nuclear energy level to another, the shorter the longitudinal relaxation time.

The transverse, or spin–spin, relaxation time is related to the lifetime of the magnetization component in the plane perpendicular to the magnetic field direction, which is zero at equilibrium. The mechanisms causing transverse relaxation comprise those causing longitudinal relaxation, but they are more numerous/efficient, and therefore $R_2 \geqslant R_1$.

The dipolar interaction energy between the electron-spin magnetic moment and the proton magnetic moment can fluctuate in time due to changes in the metal–nucleus distance, for example, detachment of a coordinated molecule bearing the nucleus of interest, rotation of the complex with respect to the external magnetic field, or changes in the M_z or M_{xy} components of the electron-spin magnetic moment (electron relaxation). All these three processes represent mechanisms leading to nuclear relaxation, and thus causing the so-called paramagnetic enhancement of the longitudinal and transverse relaxation rates, R_{1M} and R_{2M}, respectively.

The resulting equation for R_{1M} is proportional to the average of the square of the dipolar interaction energy and to the appropriate spectral density functions:

$$R_{1M} = \frac{2}{15}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\gamma_I^2 g_e^2 \mu_B^2 S(S+1)}{r^6} \times \left[\frac{\tau_c}{1+(\omega_I-\omega_S)^2\tau_c^2} + \frac{3\tau_c}{1+\omega_I^2\tau_c^2} + \frac{6\tau_c}{1+(\omega_I+\omega_S)^2\tau_c^2}\right]$$

where $\omega_I = \gamma_I B_0$ is the proton Larmor frequency, ω_S is the electron Larmor frequency ($\omega_S = 658.2\omega_I$), and τ_c is the correlation time related to the mechanisms responsible for relaxation:

$$(\tau_c^{dip})^{-1} = \tau_s^{-1} + \tau_r^{-1} + \tau_M^{-1}$$

given by the shortest among the electron relaxation time τ_s, the reorientational time τ_r, and the exchange time τ_M. In metalloproteins, τ_c is generally equal to τ_s.

Analogously, the equation for nuclear transverse relaxation rate enhancement is

$$R_{2M} = \frac{1}{15}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\gamma_I^2 g_e^2 \mu_B^2 S(S+1)}{r^6} \times \left[4\tau_c + \frac{\tau_c}{1+(\omega_I-\omega_S)^2\tau_c^2} + \frac{3\tau_c}{1+\omega_I^2\tau_c^2} + \frac{6\tau_c}{1+(\omega_I+\omega_S)^2\tau_c^2} + \frac{6\tau_c}{1+\omega_S^2\tau_c^2}\right]$$

In the case of lanthanides and actinides, the term $g_J J(J+1)$ should replace $g_e S(S+1)$.

The former equations, calculated for systems without zero-field splitting and hyperfine coupling with the metal nucleus, are called Solomon equations. Such equations can be used to provide restraints for solution str7ucture determination as they contain a dependence on the distance between the resonating nucleus and the unpaired electron(s) at the sixth power, thus being very effective for locating the metal ion in the protein frame and for determining nuclear–metal distances for protons close to the paramagnetic center.

The modulation of the dipole–dipole interaction of the nuclear spin with the average induced electron magnetic moment $\langle \mu \rangle$ provides a further relaxation contribution. This relaxation mechanism is usually called magnetic susceptibility relaxation or Curie spin relaxation. Such interaction, of course, cannot be modulated by the electron relaxation, since $\langle S_z \rangle$ is already an average over the electron spin states, and therefore the relevant correlation time is determined by τ_r (in case, τ_M is longer). The contributions to R_{1M} and R_{2M} provided by this mechanism (in the approximation of isotropic magnetic susceptibility) are

$$R_{1M} = \frac{2}{5}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\omega_I^2 g_e^4 \mu_B^4 S^2(S+1)^2}{(3kT)^2 r^6} \frac{3\tau_r}{1+\omega_I^2\tau_r^2}$$

$$R_{2M} = \frac{1}{5}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\omega_I^2 g_e^4 \mu_B^4 S^2(S+1)^2}{(3kT)^2 r^6} \times \left(4\tau_r + \frac{3\tau_r}{1+\omega_I^2\tau_r^2}\right)$$

In the case of lanthanides and actinides, the term $g_J^4 \mu_B^4 (J(J+1))^2$, or more properly the experimental

μ_{eff}^4 value, when available, should replace $g_e^4\mu_B^4(S(S+1))^2$.

The effect of Curie relaxation on R_{2M}, and thus on line widths, is very important in paramagnetic metalloproteins, especially at high magnetic fields, due to the large value of the rotational timer τ_r, compared to the normally shorter electron relaxation time, which appears in the Solomon equation. The effect on R_{1M}, which does not contain nondispersive terms, is instead usually negligible.

Cross-Correlation between Curie and Dipole–Dipole Relaxation Restraints

A novel kind of restraint, yet to be fully exploited, is the cross-correlation arising between the dipole–dipole interaction between two nuclei (for instance, N and H in a protein amide bond) and the dipolar interaction between the magnetic moment of one of the two nuclei and the average induced electron magnetic moment, both the interactions being modulated by the rotational time. Such cross-correlation contributes to nuclear relaxation.

As for the cross-correlation present in diamagnetic systems between the dipole–dipole interaction and the chemical-shielding anisotropy, the cross-correlation between Curie and dipolar relaxation causes a difference in the line width of the two doublet components of, for example, the amide H (or the amide N). This difference in line width for the amide H, in the approximation of isotropic magnetic susceptibility, is given by

$$\Delta\nu_{1/2}^{\text{CCR}} = \frac{2}{15\pi}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{B_0\gamma_H^2\gamma_N\mu_B^2 g_e^2\hbar S(S+1)}{r^3 r_{HN}^3 kT} \times \frac{3\cos^2\theta_{MHN}-1}{2}\left(4\tau_r + \frac{3\tau_r}{1+\omega_I^2\tau_r^2}\right)$$

where the angle θ_{MHN} is that between the proton–nitrogen direction and the proton–metal ion direction and r is the proton–metal ion distance.

CCR restraints thus structurally depend on the inverse of the metal–proton distance at the third power and on the metal–proton–nitrogen angle. Their magnitude increases with the magnetic field and with the metal magnetic susceptibility, rather than with its anisotropy. Coupling between CH or CC pairs can also give rise to cross-correlation with Curie relaxation.

Self-Orientation Residual Dipolar Coupling Restraints

The dipole–dipole interaction between the magnetic moments of two unlike nuclei is given by

$$H = -\frac{\mu_0}{4\pi}\frac{\hbar^2\gamma_A\gamma_B}{r_{AB}^2} I_z^A I_z^B (3\cos^2\gamma - 1)$$

where r_{AB} is the distance between the two nuclei A and B and γ is the angle between the interspin vector $\boldsymbol{r}$ and the external magnetic field, along which both the nuclear magnetic moments are quantized. The isotropic rotational average value of the dipolar coupling is zero. However, in case the different orientations are not all equally populated, different weights must be considered for the different directions, and therefore an RDC arises:

$$\Delta\nu^{\text{rdc}} = \frac{\Delta E}{h} = -\frac{\mu_0\hbar\gamma_A\gamma_B}{4\pi^2 r_{AB}^3}\left\langle\frac{3\cos^2\gamma - 1}{2}\right\rangle$$

This can be written as a function of an orientation tensor-$\boldsymbol{S}$:

$$\Delta\nu^{\text{rdc}} = -\frac{\mu_0\hbar\gamma_A\gamma_B}{8\pi^2 r_{AB}^3}[S_{zz}(3\cos^2\Theta - 1) + (S_{xx} - S_{yy})\sin^2\Theta\cos 2\Phi]$$

where Θ is the angle between the AB vector and the z-axis of the orientation tensor, and Φ is the angle which describes the position of the projection of the AB vector on the xy-plane of the $\boldsymbol{S}$-tensor, relative to the x-axis.

As noted already, the presence of an anisotropic metal magnetic susceptibility induces PCS. It can also contribute to partial orientation of the molecule in high magnetic fields.

The degree of alignment of a molecule relative to a magnetic field can be described by the principal components of the orientation tensor $\boldsymbol{S}$, defined as

$$S_{ii} = \frac{\int \frac{3\cos^2\alpha - 1}{2}\exp\left[-\frac{E^{\text{aniso}}}{kT}(\alpha,\beta)\right]d\cos\alpha\,d\beta}{\int\exp\left[-\frac{E^{\text{aniso}}}{kT}(\alpha,\beta)\right]d\cos\alpha\,d\beta}$$

where α and β are the polar angles describing the direction of $\boldsymbol{B}_0$ in the molecular frame and $E^{\text{aniso}}(\alpha,\beta)$ is the anisotropic energy of the molecule in a field B_0. Therefore, one obtains:

$$S_{ii} = \frac{3}{2}\frac{B_0^2}{15\mu_0 kT}(\chi_{ii} - \bar{\chi})$$

The RDC due to paramagnetism can thus be expressed as a function of $\Delta\chi_{ax}$ and $\Delta\chi_{rh}$,

$$\Delta\nu_{\text{rdc}}^{\text{para}} = -\frac{1}{4\pi}\frac{B_0^2}{15kT}\frac{\gamma_A\gamma_B\hbar}{2\pi r_{AB}^3} \times\left[\Delta\chi_{ax}(3\cos^2\Theta - 1) + \frac{3}{2}\Delta\chi_{rh}\sin^2\Theta\cos 2\Phi\right]$$

where the angles Θ and Φ are defined in the principal frame of the paramagnetic susceptibility tensor. $\Delta\nu_{\text{rdc}}^{\text{para}}$ represents the difference in the measured ^1J

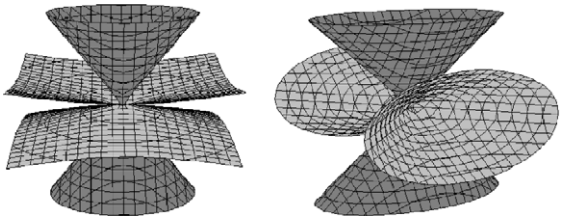


Figure 5 Surface constraint for a nucleus with a positive (dark gray) or negative (light gray) RDC value in the case of (a) axial magnetic susceptibility tensor or (b) maximal rhombicity of the magnetic susceptibility tensor. The coupled nucleus is located on the origin.

values between the paramagnetic system and a diamagnetic analog.

The functional form for PCS and RDC is the same. It is, however, important to note that the polar angles in the equation for RDC define the orientation of the coupled nuclei independently of their position with respect to the metal ion. **Figure 5** shows the surface restraint determined by a given value of the RDC and a given magnetic susceptibility tensor with no and maximal rhombicity.

Contact Shift (and Hyperfine Shift) Restraints

CSs are due to the presence of unpaired electron spin density onto the resonating nucleus, which occurs through direct spin delocalization and/or spin polarization. CSs contain structural information because they are somehow related to chemical bonds, although only in a few cases this information can be translated into structural constraints.

In the case of $Fe_4S_4^{2+}$ clusters (**Figure 6a**), it has been found that the CS of the βCH_2 protons of coordinated cysteines depends on the FeSCH dihedral angle θ as

$$\delta^c = a \sin^2 \theta + b \cos \theta + c$$

where $a \cong 10.3$, $b \cong -2.2$, and $c \cong 3.9$ ppm. The dominant dependence on $\sin^2\theta$ is ascribed to the fact that the spin density is in a *p*-orbital of the S- atom orthogonal to the Fe–S bond (**Figure 6b**). The relative values of the constant c with respect to a give an idea of the importance of the processes of electron delocalization through the σ-bond of Fe–S with respect to the π-bond of Fe–S. In these clusters, the observed hyperfine shifts are essentially contact shifts in origin.

The hyperfine shifts (given by the sum of contact and pseudocontact contributions) of heme methyl protons are given by the following heuristic equation in low-spin Fe(III) heme proteins containing a

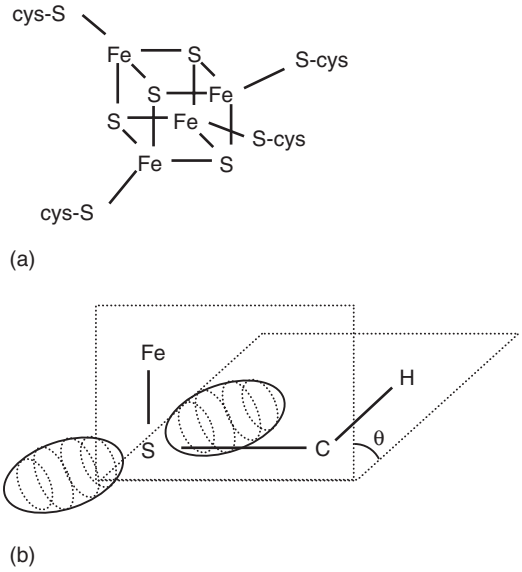

Figure 6 (a) Cybane-type Fe_4S_4 cluster. (b) Dihedral angle θ between the Fe–S–C plane and the S–C–H plane in the case of the spin density being in a *p*- orbital of the S- atom orthogonal to the Fe–S bond.

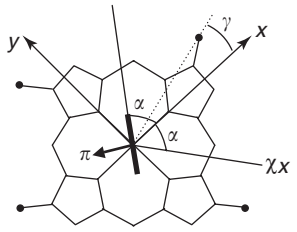

Figure 7 The γ angles for the four methyl groups (indicated with a dot) are defined as the angles between the metal–methyl *i*th vector and the *x*-axis, taken along the metal–pyrrole II direction. The angle α defines the direction of the histidine ring plane.

histidine and a cyanide as axial ligands, at 298 K,

$$\delta_i = a \sin^2(\gamma_i - \alpha) + b \cos^2(\gamma_i + \alpha) + c$$
$$a \cong 18.4, \quad b \cong -0.8, \quad c \cong 6.1$$

where γ_i is the angle between the metal–pyrrole II axis and the metal–*i*th-methyl direction, and α is the angle between the metal–pyrrole II axis and the direction of the histidine ring plane (**Figure 7**). In fact, the unpaired electron occupies one metal 3*d*-orbital that has the correct symmetry to form π-bonds with the axial ligand, and thus the contact contribution will be zero when the methyl protons lie in the nodal plane, and maximal when the methyl protons lie along the direction of the axial π-interaction, and thus $\delta_i^c \propto \sin^2(\gamma_i - \alpha)$. On the other hand, since the *z*-axis of the magnetic susceptibility tensor is always approximately perpendicular to the heme plane, the PCS is proportional to a function of the type $\delta^{PCS} \propto k \cos 2\varphi - l$, with the χ_x-axis rotated clockwise from

the metal–pyrrole direction by an angle which is the same in magnitude, but opposite in direction, to the angle α. Therefore, $\varphi = \gamma_i + \alpha$, and the equation given above is obtained.

Finally, the hyperfine shifts of methyl protons are given by the following heuristic equation in low-spin Fe(III) heme proteins containing two histidines as axial ligands:

$$\delta_i = \cos\beta[a\sin^2(\gamma_i - \alpha) + b\cos^2(\gamma_i + \alpha) + c] + d\sin\beta$$

$$a \cong 38.8, \quad b \cong -10.5, \quad c \cong -1.1, \quad d \cong 9.4$$

where α is the angle between the bisector of the angle β and the metal–pyrrole II axis, and β is the acute angle between the two histidine planes.

Similar considerations can be made for Fe(II) heme proteins with a single histidine in an axial position, when the electron configuration is high-spin and the shifts of the methyl protons are determined by a mixture of σ- and π-delocalization mechanisms.

Collecting the Paramagnetism-Based Restraints

The NMR parameters that can be obtained by performing NMR experiments are the chemical shift, the longitudinal relaxation rate, and the transverse relaxation rate. For a given nucleus, the chemical shift is defined as the resonating frequency of the nucleus with respect to a reference signal (in Hz). The chemical shifts result from the sum of two contributions: the diamagnetic shift, arising from the shielding of the observed nucleus from the external magnetic field due to electrons around, and the paramagnetic shift or hyperfine shift, which consist of the pseudocontact and the contact contributions:

$$\delta^{\text{exp}} = \delta^{\text{dia}} + \delta^{\text{c}} + \delta^{\text{pcs}}$$

As seen earlier, the contact contribution is present only for nuclei close to the paramagnetic center, since it can arise only if electron spin density can be delocalized on the investigated nuclei. Therefore, only the pseudocontact term can affect the hyperfine shift of amino acids that are not directly bonded to the metal center or H-bonded to the donor atoms.

In order to calculate δ^{pcs}, it is necessary to evaluate δ^{dia}. This can be done, to a good approximation, by performing the measurements on the analog diamagnetic protein, obtained by removing the paramagnetic metal ion, by substituting the metal ion with a diamagnetic metal with the same charge, or by reducing the paramagnetic metal to a diamagnetic state.

PCSs have been measured, among others, in many low-spin iron(III) heme containing proteins (**Figure 8** shows those measured in cytochrome b_5) and in lanthanide-substituted calcium-binding proteins (e.g., calmodulin, parvalbumin, and calbindin). As noted previously, their magnitude depends on the magnetic susceptibility anisotropy of the metal. Estimates of the latter are reported in **Table 1** for some metal ions. **Figure 9** shows the observed PCS in the protein calbindin D_{9k} after substitution of Ce(III), Yb(III) or Dy(III) in the C-terminal calcium-binding site. Metal ions characterized by a small magnetic anisotropy (e.g., Ce(III)) permit one to obtain values only for nuclei at short distances, whereas metal ions characterized by a large magnetic anisotropy (e.g., Dy(III)), although they do not provide information for nuclei close to the metal ion, due to the excessive line-broadening caused by Curie relaxation, permit the observation of values for nuclei that are much farther away from the metal.

Once the PCSs have been used to determine the magnetic susceptibility tensor and the structure is known, the contact contribution to the hyperfine shifts for atoms in amino acids close to the metal ion can be obtained. In fact, the pseudocontact contribution for such atoms can be calculated and subtracted from the hyperfine shift.

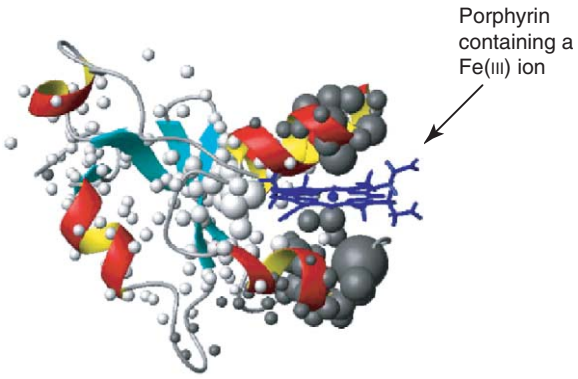

Figure 8 Observed PCS for the heme protein cytochrome b_5. The size of the balls is proportional to the magnitude of the negative (light gray) or positive (dark gray) PCS.

Table 1 Magnetic susceptibility and pseudocontact shifts for some metal ions

	χ_{av} (10^{-32} m^3)	$\Delta\chi_{ax}$ (%)	δ^{pcs} for $r = 10$ Å and $\theta = 0°$ (ppm)

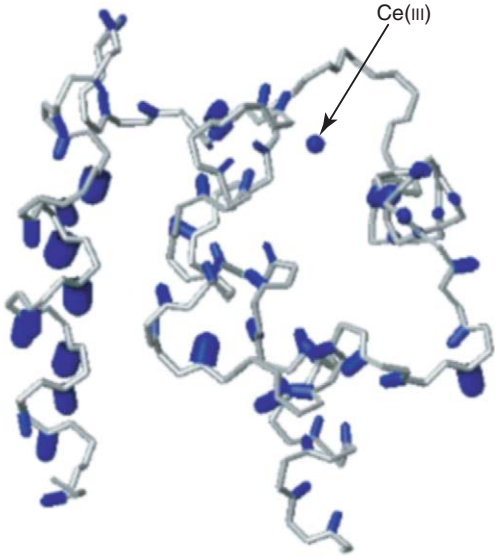

Figure 10 Observed self-orientation RDC for the HN atoms of the protein calbindin D_{9k} after substitution of Ce(III) in the C-terminal metal binding site.

Coupled nuclei experience ^1J splittings of the observed nucleus signals. Such splittings can be measured in HSQC spectra or in J-modulated experiments, and are given by the sum of the diamagnetic ^1J contribution, due to the scalar coupling and diamagnetic RDC, and the paramagnetic contribution. The values for $\Delta\nu_{rdc}^{para}$ can be obtained after subtraction of the ^1J measured at the same field and temperature on the analog diamagnetic protein, obtained by removing the paramagnetic metal ion, by substituting the metal ion with a diamagnetic metal with the same charge, or by reducing the paramagnetic metal to a diamagnetic state. Paramagnetic RDCs have been measured for many metalloproteins. Those related to the protein Ce(III)-calbindin D_{9k} are shown in **Figure 10**.

Relaxation rates are also measured as the sum of the diamagnetic and the paramagnetic contributions. Again, the diamagnetic contribution can be evaluated by performing measurements on the diamagnetic analog of the protein, by removing the paramagnetic metal ion or by substituting it with a diamagnetic one. Another way to estimate the diamagnetic contribution consists in taking an average among all the experimental relaxation rates that are below a given threshold value in the paramagnetic metalloprotein. In fact, R_{1M} is proportional to r^{-6}, and thus it becomes negligible for nuclei far from the paramagnetic center, whereas it is dominant for nuclei close to the paramagnetic center.

Transverse relaxation rates are related to signal line widths. The difference in the line width (in Hz) measured at half-height of, for example, the two components in the proton dimension of the HN doublet in the HSQC spectra of ^{15}N enriched paramagnetic metalloproteins is given by $\Delta\nu_{1/2}^{ccr}$, and it can be used as an additional restraint for protein solution structure determination. **Figure 11a** reports the observed values for amide proton cross correlations between Curie and dipolar relaxation in the Ce(III)-substituted protein calbindin D_{9k}, and **Figure 11b** reports the CCR values observed in metaquomyoglobin.

Solution Structure Determination Programs

Calculations of the solution structure of metalloproteins by employing paramagnetism-based restraints are normally performed using a modified version of the program DYANA, called PARAMAGNETIC DYANA, or the Xplor-NIH package. Both programs use molecular dynamics for energy minimization combined with a simulated annealing algorithm to calculate a family of structures starting from randomly

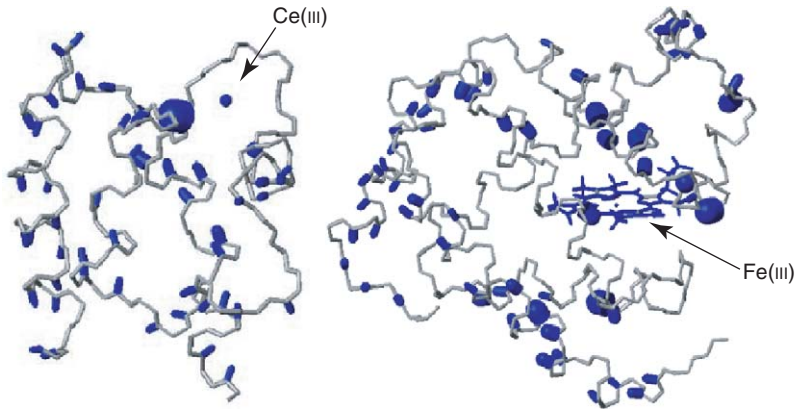

Figure 11 Observed CCR for the HN atoms (a) of the protein calbindin D_{9k} after substitution of Ce(III) in the C-terminal metal binding site, (b) of met-myoglobin, a heme protein containing high-spin Fe(III).

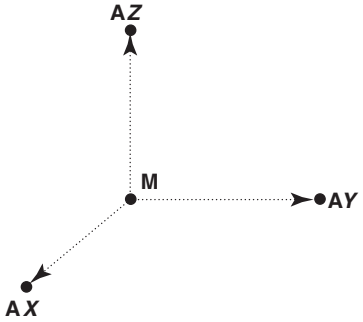

Figure 12 A pseudoresidue is defined containing pseudo-atoms needed to represent in the protein frame the position of the metal ion and the directions of the principal axes of the magnetic susceptibility anisotropy tensor.

generated conformers. Any metal ion and the relative magnetic susceptibility tensor axes are represented using pseudo-atoms as shown in **Figure 12**.

The paramagnetism-based restraints are introduced by calculating a pseudopotential E_l, for each class of new restraints

$$E_l = \sum_i w_i[\max(|X_{i,\mathrm{obs}} - X_{i,\mathrm{calc}}| - \mathrm{tol}_i, 0)]^2$$

to be added to the global target function, which is the quantity to be minimized. The index i runs over all experimental data of the considered class of restraints; tol indicates the tolerance, and w_i the weighting factor for that restraint. $X_{i,\mathrm{obs}}$ represents the experimental data and $X_{i,\mathrm{calc}}$ the calculated values in the present protein configuration according to the equations provided above.

PARAMAGNETIC DYANA and PARArestraints for Xplor-NIH use the PCS and RDC restraints by keeping fixed the values of the magnetic susceptibility anisotropies during the annealing process. These parameters ($\Delta\chi_{\mathrm{ax}}$ and $\Delta\chi_{\mathrm{rh}}$), which can be initially estimated from theoretical predictions, can be obtained by fitting the observed data on the protein structure. Therefore, both their values and the protein structure are actually obtained by a few cycles of structure calculations and fit on the protein structure, until convergence is reached.

Conclusions

It has been shown that paramagnetism-based restraints can provide relevant information for solution structure determination of paramagnetic metalloproteins, both around the metal ion and in the whole protein. CS can, in fact, identify the metal ligands and can provide dihedral angle restraints on the metal ligands. PCSs contain information on the coordinates of the metal ion and on the position of the protein atoms in the frame of the magnetic susceptibility tensor. Nuclear relaxation rates provide metal–nucleus distances. Cross-correlations contain information on distances and angles among the metal ion and coupled nuclei. Self-orientation RDCs provide information on the orientations of internuclear vectors in the magnetic susceptibility frame. All these restraints are vital for obtaining information around the metal ion, where it is usually missing, and can actually be precious to increase the accuracy of the protein structure. Furthermore, it is demonstrated that they provide enough information to be an alternative to classical diamagnetic restraints for protein solution structure determination.

Metals and Alloys, Electronic States of (Including Fermi Surface Calculations)

H Harima, Kobe University, Kobe, Japan

Introduction

Metals are usually or phenomenologically characterized by the physical properties of their excellent electrical and thermal conductivity, ductility, etc. From the point of view of electronic structure, crystals are clearly divided into metals and nonmetals: metals have Fermi surfaces and nonmetals do not. At zero temperature, in the Brillouin zone (which is defined as the Wigner–Seitz cell in the reciprocal space), Fermi surfaces separate two parts, in one of which the electron levels are occupied and in the other they are empty.

When the inversion symmetry is conserved in a paramagnetic crystal, as expected in many crystals, each state for electrons is doubly degenerate (the spin–orbit interaction lifts the degeneracy even in paramagnetic states, if the inversion symmetry is lost.) In this case, crystals with an odd number of electrons in the primitive unit cell must have Fermi surfaces, because the highest occupied electrons cannot fill whole of the Brillouin zone. Metals with this property are known as "uncompensated metals." On the other hand, crystals can be insulators, when the number of electrons in the primitive unit cell is even. Even in this case, they can be "compensated metals," where "compensated" means that the number of electrons equals the number of holes (holes represent the portion in the Brillouin zone unoccupied by electrons).

Most of the physical properties of metals are characterized by the Fermi surfaces, which represent the number of carriers, effective masses, anisotropy, etc. When metals undergo phase transition to superconductivity, magnetic ordering, or another ordered state, at low temperatures, the Fermi surfaces are related to the physical properties of the transition.

In early years, most of the elemental metals were comprehended based on the nearly free electron model. However, for most of the ordered alloys and compounds, numerical simulation is necessary to represent the Fermi surfaces. Otherwise, it is not possible to predict, for most of them, the metallic/nonmetallic nature. In recent years, Fermi surfaces of many crystals have been determined precisely by such simulation with highly developed computer resources and one-particle approximation, which is mostly the local-density approximation (LDA) in the density-functional theory.

Here, electronic structures and the Fermi surfaces are briefly reviewed. All of the figures presented are originally calculated and drawn by using a full-potential linear augmented plane-wave method and the LDA.

Nearly Free Electron Metals

The simplest picture for metals is given by a nearly free electron model. In this model, electrons behave as if they were noninteracting, moving through a weak periodic potential. The wave function of a Bloch state with the irreducible representation $\boldsymbol{k}$ in the translational group can be written as

$$\psi_{\boldsymbol{k}}(\boldsymbol{r}) = \sum_{\boldsymbol{K}} c_{\boldsymbol{k}-\boldsymbol{K}} \mathrm{e}^{\mathrm{i}(\boldsymbol{k}-\boldsymbol{K})\cdot\boldsymbol{r}}$$

where $\boldsymbol{K}$ stands for reciprocal lattice vectors. The coefficient $c_{\boldsymbol{k}-\boldsymbol{K}}$ and the energy level $E_{\boldsymbol{k}}$ are determined with the Fourier components of the crystal potential $U_{\boldsymbol{K}}$ as

$$\left[\frac{\hbar^2}{2m}(\boldsymbol{k}-\boldsymbol{K})^2 - \varepsilon_{\boldsymbol{k}}\right] c_{\boldsymbol{k}-\boldsymbol{K}} + \sum_{\boldsymbol{K}'} U_{\boldsymbol{K}'-\boldsymbol{K}} c_{\boldsymbol{k}-\boldsymbol{K}'} = 0$$

If $U_{\boldsymbol{K}} \sim 0$ for any $\boldsymbol{K}$, $\varepsilon_{\boldsymbol{k}} \sim (\hbar^2/2m)(\boldsymbol{k}-\boldsymbol{K})^2$

These electrons can be realized in some alkali and alkaline-earth metals and aluminum. The energy dispersion for Na in the first Brillouin zone almost satisfies $\varepsilon_{\boldsymbol{k}} = (\hbar^2/2m)(\boldsymbol{k}-\boldsymbol{K})^2$, as shown in **Figure 1**. The density of states $D(E)$ has the energy dependence as $D(E) \sim (m/\hbar^3\pi^2)\sqrt{2mE}$ just like free electrons, except the fine structure from the band splitting due to the effect of the weak crystal potential. (Note that the unit of $D(E)$ in figures is "states/(Ry · Primitive cell).") Electrons in Mg and Al also show such free-electron-like energy dispersions, even in other types of empty lattices, as shown in **Figures 2** and **3**.

In Na, Mg, and Al, the valence electrons actually have nodes (2 for 3*s*, 1 for 3*p*) due to the large attractive potential near the nucleus, so they are never free electrons. This situation can be understood as follows. A Bloch state is generally written as

$$\psi_{n\boldsymbol{k}}(\boldsymbol{r}) = u_{n\boldsymbol{k}}(\boldsymbol{r}) \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}$$

where n stands for a quantum number inside one atom and $u_{n\boldsymbol{k}}(\boldsymbol{r})$ is a function with the periodicity of

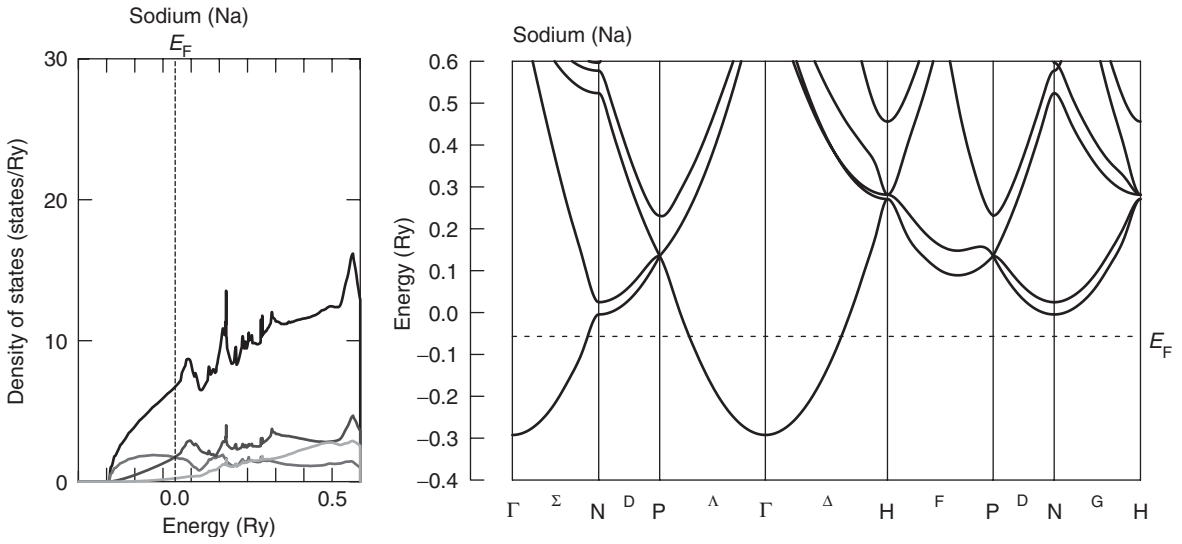

Figure 1 Energy band structure (right) and the density of states (left) of sodium in the body-centered cubic (b.c.c.) structure.

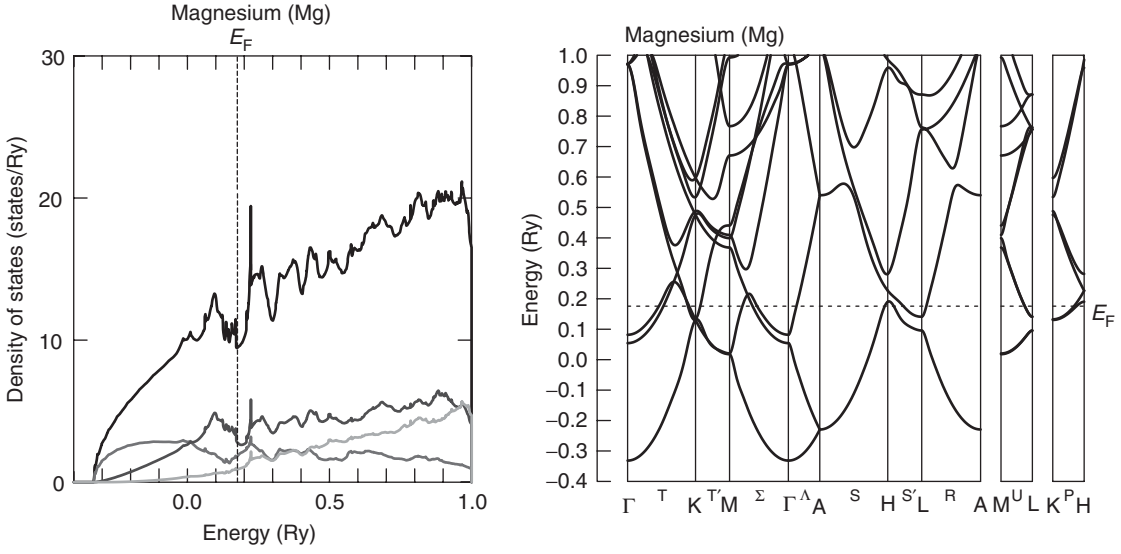

Figure 2 Energy band structure (right) and the density of states (left) of magnesium in the hexagonal structure.

the Bravais lattice:

$$u_{nk}(\boldsymbol{r}+\boldsymbol{R}) = u_{nk}(\boldsymbol{r})$$

The atomic orbitals are sometimes used for $u_{nk}(\boldsymbol{r})$.

The simplest case of $u_{nk}(\boldsymbol{r}) = \text{const.}$ obviously leads to a plane wave. Even when $u_{nk}(\boldsymbol{r})$ oscillates very near the nucleus, it can behave like free electrons, if $u_{nk}(\boldsymbol{r}) \sim \text{const.}$ far from the nuclei, that is, in the interstitial regions. To relate the plane waves with atomic orbitals, one should remember the well-known identity

$$e^{i\boldsymbol{k}\cdot\boldsymbol{r}} = 4\pi \sum_{l=0}^{\infty} \sum_{m=-l}^{l} i^l j_l(kr) Y_l^{m*}(\hat{\boldsymbol{k}}) Y_l^m(\hat{\boldsymbol{r}})$$

where $j_l(kr)$ are spherical Bessel functions of order l, $Y_l^m(\hat{\boldsymbol{r}})$ are spherical harmonics, and l and m are the angular momentum and magnetic quantum numbers. Electrons with the radial wave function $R_l(\varepsilon, r)$, with $r < S$, can be treated as free electrons, when

$$\frac{\mathrm{d}}{\mathrm{d}r} \ln R_l(\varepsilon, r)\bigg|_S \sim \frac{\mathrm{d}}{\mathrm{d}r} \ln j_l\left(\frac{\sqrt{2m\varepsilon}}{\hbar} r\right)\bigg|_S$$

for a large S. This is realized in Na, Mg, and Al, because the positive charges of nuclei are well screened by the Ne core ($(1s)^2(2s)^2(2p)^6$) electrons.

Therefore, the plane-wave bands consist of higher-l components. In the higher-symmetry points in the Brillouin zone, the bands can be distinguished into

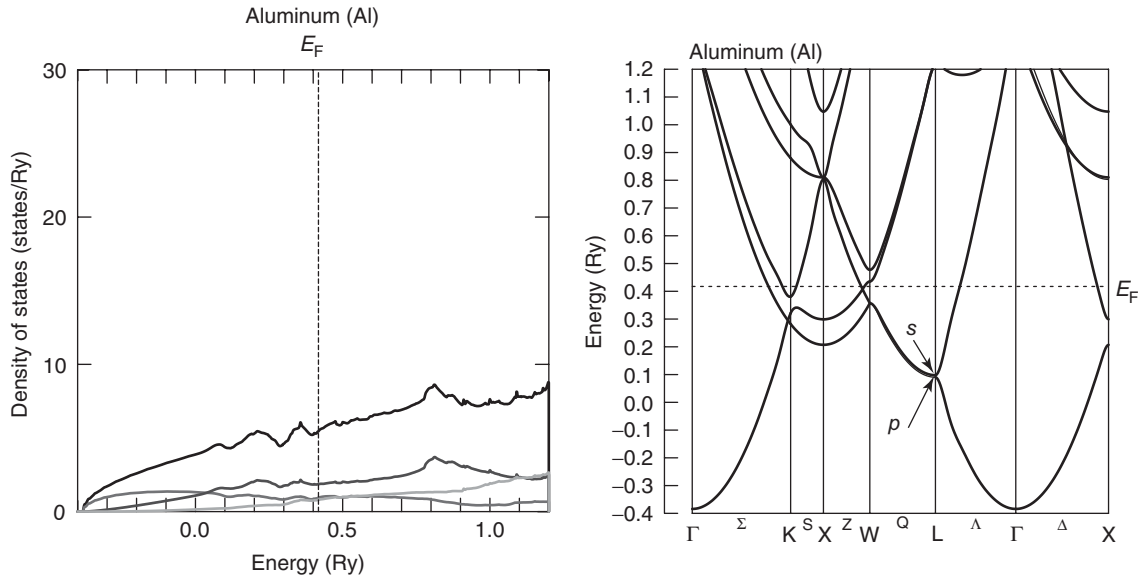

Figure 3 Energy band structure (right) and the density of states (left) of aluminum in the f.c.c. structure.

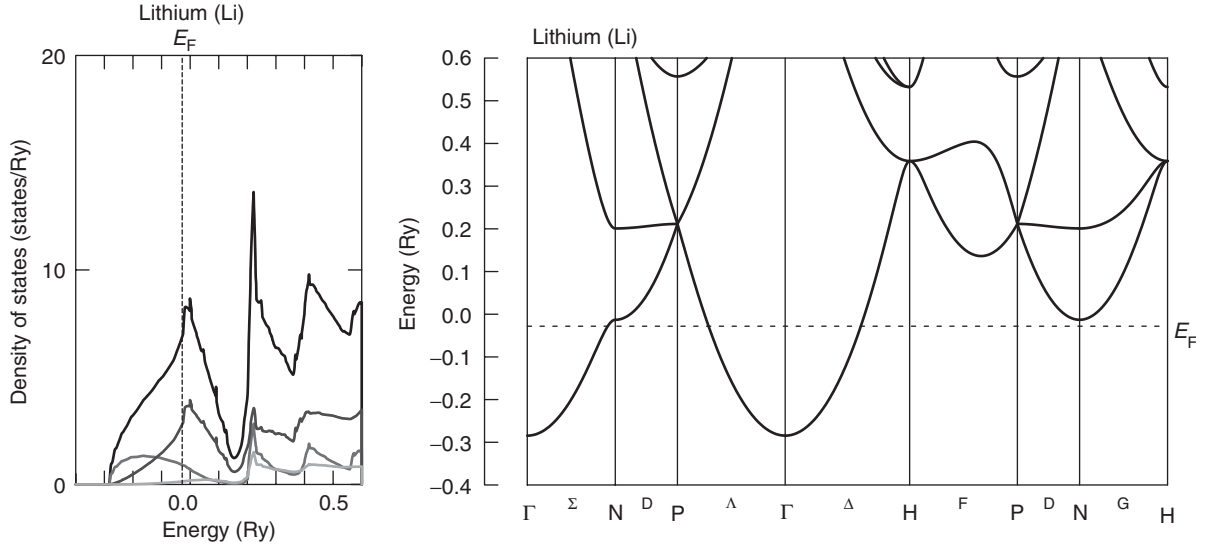

Figure 4 Energy band structure (right) and the density of states (left) of lithium in the b.c.c. structure.

the pure *s* or *p* bands, for example, the bottom contains only the *s* component. At the Brillouin zone boundary, the *s* band and *p* band are nearly degenerated, which is clearly seen at the L point in the case of Al, as in **Figure 3**.

The Fermi surfaces of Al are complicated in shape, but easily comprehended by a systematic procedure to convert a spherical Fermi surface into the first Brillouin zone, as described by Harrison in 1959.

The valence electrons in Li and Be with $(1s)^2$ core electrons do not behave as those in Na and Mg, as shown in **Figures 4** and **5**. The crystal potential affects the energy dispersions, particularly in the Brillouin zone boundary. The electronic structure of Li should be recognized as a mixture between atomic orbitals and free electrons. Actually, the depression in the density of states is clearly seen. Li with a half-filled band shows, however, a similar Fermi surface as in free electrons, while the density of states at the Fermi level in the depression in Be (four electrons in the primitive cell) is much smaller than that expected from a free-electron model.

Noble Metals (Cu, Ag, Au)

In noble metals, there are 11 valence electrons as $(nd)^{10}((n+1)s)^1$, with $n=3$ (Cu), 4 (Ag), and 5

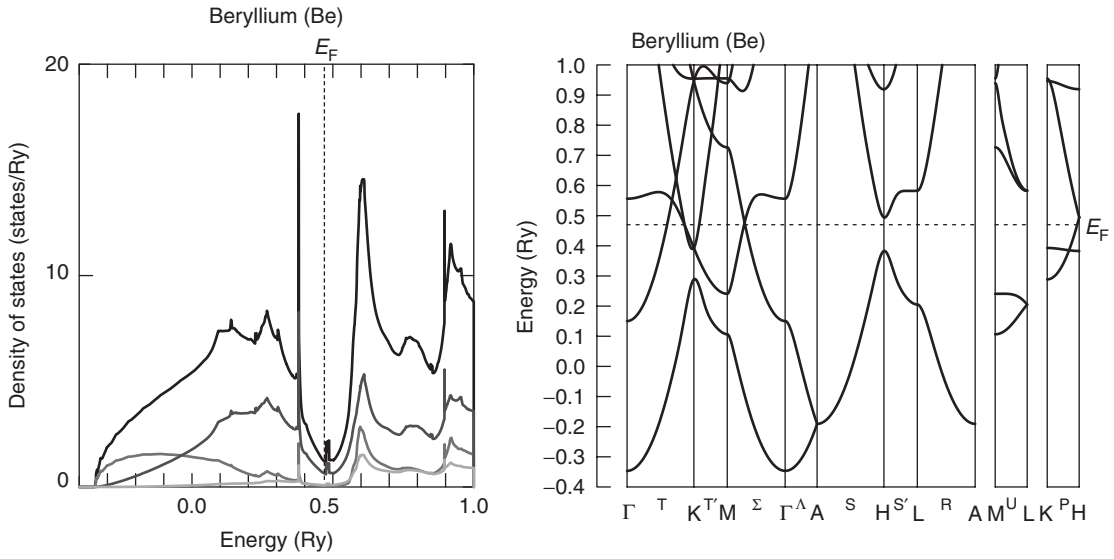

Figure 5 Energy band structure (right) and the density of states (left) of beryllium in the hexagonal structure.

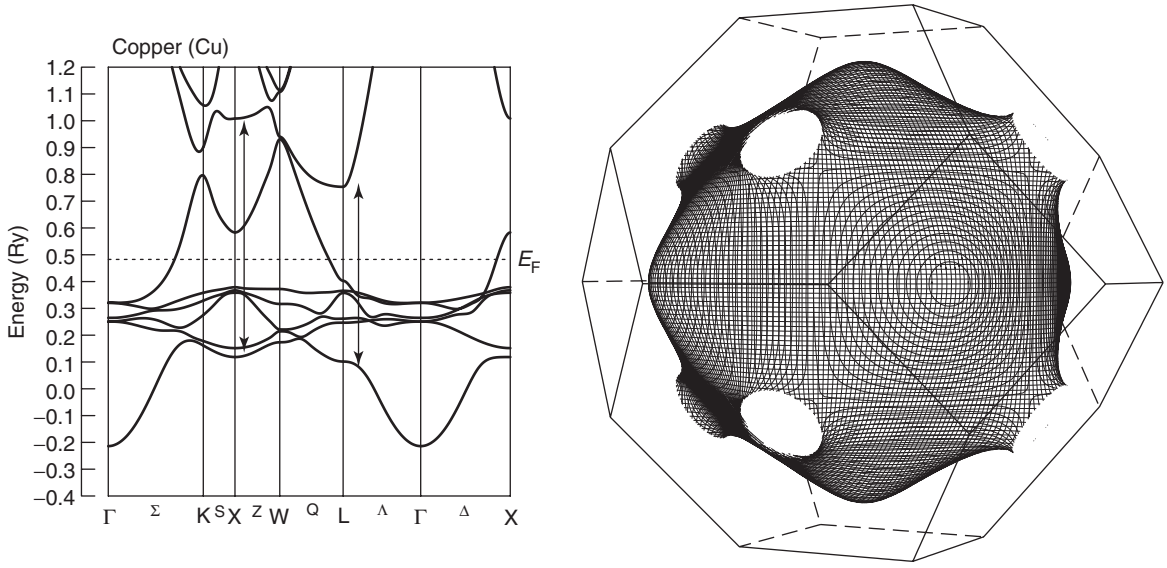

Figure 6 Energy band structure (left) and the Fermi surface (right) of copper. The arrows indicate the hybridization between the bonding and the antibonding states. Compare the band structure of Al in **Figure 3**.

(Au). $(nd)^{10}$ electrons are almost fully occupied, hence the noble metals are often thought to be monovalent metals. In fact, *s* and *p* electrons in noble metals behave as free electrons such as those in Na, while *d* electrons have the characteristics of the atomic orbitals, because the main part of the wave function is located much more inside than that of *s* and *p* electrons. Thus, the five bands with small energy dispersions for *d* electrons appear in the electronic band structure in Cu, as in **Figure 6**, where the *d* bands are located below the Fermi level. Then, the noble metals are monovalent metals. The plane-wave band with *s* character can hybridize with the *d* bands in the whole of the Brillouin zone, resulting in bonding and antibonding bands, while the plane-wave band with *p* character is left undisturbed. In the f.c.c. lattice, the *p*-character band shows the lowest energy at the L point, which is the closest point to the Γ point, on the Brillouin zone boundary.

Consequently, the conduction band is similar to the plane wave, except the low-lying part near the L point. Therefore, the Fermi surface is nearly spherical with the connected part, called the neck, centered at the L point, as shown in **Figure 6**.

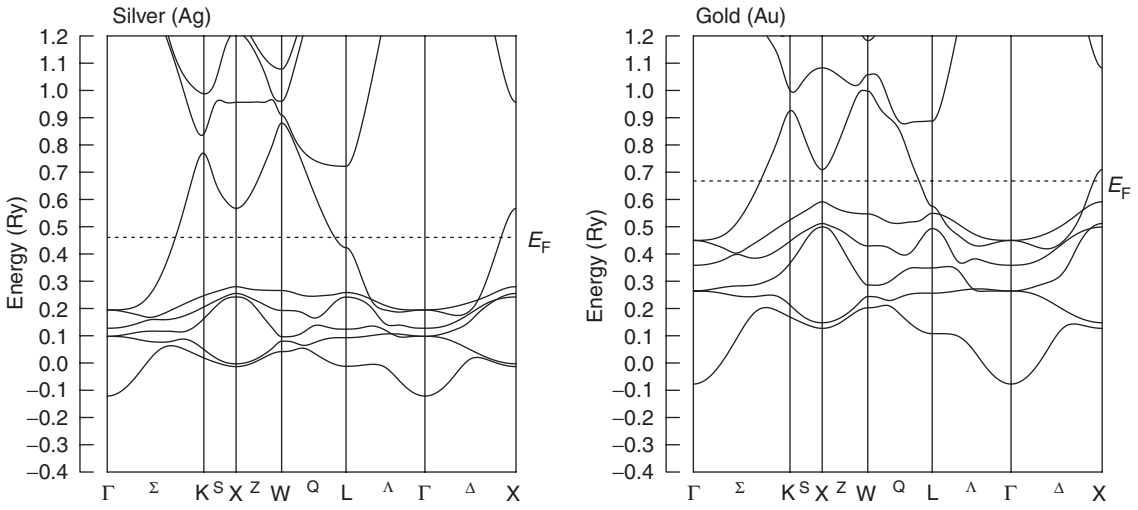

Figure 7 Energy band structure of silver (left) and gold (right).

The electronic structures of silver and gold resemble that of copper, except the location and the width of the *d* bands, as shown in **Figure 7**. The bandwidths become larger from copper to gold, because 5*d* electrons have a larger tail outside the core electrons. Meanwhile, the position of the *d* bands is the deepest in silver, so that there is no absorption from the *d* bands in the energy region of the visible spectrum. As the conduction band is less affected by the deeper *d* bands, the neck is the smallest in silver.

The core electrons screen the nucleus charge for the 4*d* electrons in silver to a lesser degree than for the 3*d* electrons in copper; the energy level of the 4*d* electrons becomes relatively deeper than that of the 3*d* electrons. One can expect much deeper *d* bands in gold; however, the relativistic effect, which is more prominent in heavier atoms, shrinks the core electrons. Then the nucleus becomes more screened in gold. The shrunk core is also noticed in the similar values of atomic radii for silver and gold. (The lattice constants of copper, silver, and gold are 3.615 Å, 4.086 Å, and 4.078 Å, respectively.)

Transition Metals, Alloys, and Compounds

The *d* electrons of the valence band in transition metals can be described within a band theory in which the effect of strong Coulomb interactions is treated as a mean field, because the underlying wide and plane-wave-like *s* and *p* electrons screen such large Coulomb interactions. The band theory explains their electrical and magnetic properties.

In some transition-metal oxides, such as high-temperature superconductors, Coulomb interactions are not negligible, because the oxygen *s* and *p* bands push up *s* and *p* electrons of the transition metal beyond the *d* bands; then the effective Coulomb interactions in *d* electrons become relatively large.

f-Electron Systems

The *f* electrons, which are valence electrons in lanthanide (4*f*) and actinide (5*f*) systems, are located well inside the outer closed shell (Xe or Rn). Even so, the 5*f* electrons are described as *d* electrons in transition metals. Particularly, the 4*f* electrons are less extended beyond the core electrons, and in many cases, are thought to be localized electrons, although the energy levels are comparable with other valence electrons. Such localized electrons, in general, do not affect electronic structures around the Fermi level. A band theory where the 4*f* electrons are treated in the Hartree–Fock approximation, for example, the LDA + *U* method, can predict the energy band structure of such compounds.

Fermi Surface Calculation

The currently available computer resources allow one to calculate energy eigenvalues at each $\boldsymbol{k}$ point very accurately, although some approximation for the exchange correlation potential must be used. When the results are compared with experiments, in many cases, the eigenvalues are interpolated by using plane waves like

$$F(\boldsymbol{k}) = \sum_{m=1}^{M} a_m \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_m}$$

where a_m should be determined under the conditions $F(\boldsymbol{k}_n) = F_n$. Here F_n is an eigenvalue at the point $\boldsymbol{k}_n$

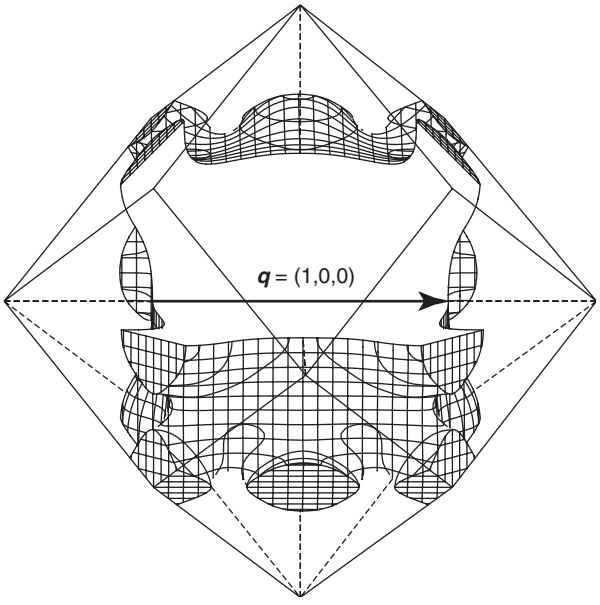

Figure 8 The Fermi surface of $PrRu_4P_{12}$ calculated by using an LDA + *U* method. One quarter is cut for the eye convenience. The volume of the Fermi surface is just a half of the Brillouin zone for the b.c.c. lattice. The arrow indicates the nesting vector.

($n = 1, N$). If $M = N$, a_m can be determined uniquely, but it is not effective. Usually, a_m is determined for $M > N$ under the conditions to minimize $\sum_m \rho_m a_m^2$, where ρ_m is a weight, for example, $1 + C_1|\boldsymbol{R}_m|^2 + C_2|\boldsymbol{R}_m|^4$, to be chosen to prevent higher components in $F(\boldsymbol{k})$. Typically, $M \sim 1.2 \times N$ for $N = 100$–500 gives sufficient accuracy to be compared with Fermi surface measurements.

Nesting Fermi Surface

The shape of the Fermi surface is related to a variety of instabilities of the metal. If the generalized susceptibility

$$\chi_0(\boldsymbol{q}) = \sum_{\boldsymbol{k}} \frac{f(\varepsilon_{\boldsymbol{k}+\boldsymbol{q}}) - f(\varepsilon_{\boldsymbol{k}})}{\varepsilon_{\boldsymbol{k}} - \varepsilon_{\boldsymbol{k}+\boldsymbol{q}}}$$

shows a large value, instability with the $\boldsymbol{q}$ vector is realized, for example, relevant in magnetic ordering, the spin density of wave (SDW), or the charge density of wave (CDW). It happens when some part of the Fermi surface, if displaced by $\boldsymbol{q}$, coincides with another part. This is known as the nesting Fermi surface. The antiferromagnetic chromium may have an SDW state due to such a nesting mechanism.

The nesting mechanism can eliminate a part or whole of the Fermi surface to stabilize an SDW or a CDW state. If the entire Fermi surface is wiped out, it leads to a metal–insulator transition. This is possible for Fermi surfaces that resemble a checkerboard. Even in a cubic system, such a Fermi surface is realized in a skutterudite $PrRu_4P_{12}$, whose Fermi surface is a three-dimensional checkerboard, as shown in **Figure 8**. $PrRu_4P_{12}$ really undergoes a metal–insulator transition at 60 K.

Metals and Alloys, Impurity and Defect States in

J S Faulkner, Florida Atlantic University, Boca Raton, FL, USA

Introduction

The most commonly used methods for treating the impurity and defect states in metals and alloys start with the calculation of the one-electron Green's function $G(E, \boldsymbol{r}, \boldsymbol{r}')$. The density-functional theory (DFT) makes it possible to write a simple equation for this function

$$\left[E + \frac{\hbar^2}{2m}\nabla^2 - V(\boldsymbol{r})\right] G(E, \boldsymbol{r}, \boldsymbol{r}') = \delta(\boldsymbol{r} - \boldsymbol{r}') \quad [1]$$

The local density approximation or the generalized gradient approximation is used to generate the effective one-electron potential $V(\boldsymbol{r})$. In any version of the DFT, $V(\boldsymbol{r})$ is a functional of the density of the electrons in the system, $\rho(\boldsymbol{r})$, which means that the one–electron equation must be solved self–consistently. The charge density is obtained from the Green's function by integration

$$\rho(\boldsymbol{r}) = -\frac{2}{\pi}\int_{-\infty}^{E_F} G(E,\boldsymbol{r},\boldsymbol{r})\ \mathrm{d}E \qquad [2]$$

where the Fermi energy E_F is defined by the requirement that the integral of $\rho(\boldsymbol{r})$ over all space is equal to the total number of electrons, and the 2 is required by the electron spins. The total energy is

$$E_{\text{total}} = \sum_{\text{occ.}} E_i - \frac{1}{2}\int \frac{\rho(\boldsymbol{r})\rho(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}\,\mathrm{d}\boldsymbol{r}\,\mathrm{d}\boldsymbol{r}' + E_{xc}[\rho] - \int \frac{\delta E_{xc}[\rho]}{\delta\rho(\boldsymbol{r})}\,\rho(\boldsymbol{r})\,\mathrm{d}\boldsymbol{r} \qquad [3]$$

The sums are over all occupied states including spin, and the exchange correlation functional $E_{xc}[\rho]$ is determined by the particular method used to calculate the effective one-electron potential.

The one-electron potential for a metal or alloy can be written as a sum of potentials that describe the interaction of the electron with each of the atoms in the solid

$$V(\boldsymbol{r}) = \sum_{i=1}^{N} v_i(\boldsymbol{r}-\boldsymbol{R}_i) \qquad [4]$$

In order to eliminate surface states, it is convenient to imagine that the N atoms in the solid are in a supercell, and that the supercells are periodically reproduced to fill all space. The potential associated with the ith atom with its nucleus at $\boldsymbol{R}_i$, $v_i(\boldsymbol{r}-\boldsymbol{R}_i)$, is zero outside of the region Ω_i. The Ω_i fill the entire supercell and do not overlap. At some point, N is allowed to approach infinity and the supercell to fill all space.

The Green's Function from Multiple Scattering Theory

The multiple scattering equations for wave functions are derived and discussed elsewhere in the encyclopedia. The version of these equations that deals with Green's functions starts from the operator equation

$$G(z) = (z - H_0 - V)^{-1} = G_0(z)\,[I + VG(z)] = G_0(z) + G_0(z)\,T(z)\,G_0(z) \qquad [5]$$

where H_0 is the kinetic energy operator, z is a complex energy, and

$$G_0(z) = (z - H_0)^{-1} \qquad [6]$$

For the case that the potential is a sum of atomic potentials as in eqn [4], the scattering matrix for the system

$$T(z) = V[I + G_0(z)\,T(z)] \qquad [7]$$

can be written

$$T = \sum_{i=1}^{N}\sum_{j=1}^{N}\tau^{ij} \qquad [8]$$

where the scattering path operator τ^{ij} is

$$\tau^{ij} = t^i\delta_{ij} + t^i G_0 \sum_{k\neq i}^{N}\tau^{kj} \qquad [9]$$

and $t^i = (1 - v_i G_0)^{-1} v_i$ is the t-matrix that describes the scattering from $v_i(\boldsymbol{r}-\boldsymbol{R}_i)$ embedded in a vacuum.

A function that is very useful in analyzing experiments is the density-of-states (DOS) $\rho(E)$, which is the number of energy levels between the energies E and $E + \mathrm{d}E$. The DOS associated with just the ith atom can be calculated from

$$\rho_i(E) = -\frac{2}{\pi}\,\mathrm{Im}\lim_{z\downarrow E}\int_{\Omega_i} G(z,\boldsymbol{r},\boldsymbol{r})\ \mathrm{d}\boldsymbol{r} \qquad [10]$$

where $G(z,\boldsymbol{r},\boldsymbol{r}') = \langle \boldsymbol{r}|G|\boldsymbol{r}'\rangle$. Of course, the DOS for the supercell is $\rho(E) = \sum_{i=1}^{N}\rho_i(E)$. The Green's functions and scattering operators that are used henceforth are obtained from the above by letting z approach E from above the real axis.

When the position vectors $\boldsymbol{r}$ and $\boldsymbol{r}'$ are in the region Ω_n, the Green's function in the position representation can be shown to take the form

$$G(E,\boldsymbol{r}_n,\boldsymbol{r}'_n) = \sum_{LL'} Z^n_L(E,\boldsymbol{r}_n)\,\tau^{nn}_{LL'}(E)Z^{n^*}_{L'}(E,\boldsymbol{r}'_n) - \sum_L Z^n_L(E,\boldsymbol{r}_n)\,J^{n^*}_L(E,\boldsymbol{r}'_n) \qquad [11]$$

where

$$\tau^{nn}_{LL'} = t^n_{LL'} + \sum_{L_1,L_2,L_3,L_4} t^n_{LL_1}\sum_{i\neq n,j\neq n} g^{ni}_{L_1L_2}\tau^{ij}_{L_2L_3}g^{jn}_{L_3L_4}t^n_{L_4L'} = t^n_{LL'} + \sum_{L_1,L_2} t^n_{LL_1}\sum_{i\neq n} g^{ni}_{L_1L_2}\tau^{in}_{L_2L'} \qquad [12]$$

and $t^n_{LL'}(E)$ is the scattering matrix for the nth atom. The matrix $\boldsymbol{\tau}$ with elements $\tau^{nn}_{LL'}$ is the inverse of the

matrix $\boldsymbol{M}$ that has elements

$$M^{mn}_{LL'} = m^n_{LL'}\delta_{mn} - g^{mn}_{LL'}(1-\delta_{mn}) \qquad [13]$$

The function $Z^n_L(E,\boldsymbol{r}_n)$ is the solution of the equation

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + v_n(\boldsymbol{r}_n) - E\right] Z^n_L(E,\boldsymbol{r}_n) = 0 \qquad [14]$$

that is regular at the origin and joins smoothly to

$$Z^n_L(E,\boldsymbol{r}_n) \rightarrow \sum_{L'} Y_{L'}(\boldsymbol{r}_n) j_{l'}(\alpha \boldsymbol{r}_n)\; m^n_{L'L}(E) - \mathrm{i}\kappa Y_L(\boldsymbol{r}_n)\; h_l(\alpha \boldsymbol{r}_n) \qquad [15]$$

when $\boldsymbol{r}$ is outside of Ω_n. As usual, $j_l(\alpha r_n)$and $h_l(\alpha r_n)$ are the spherical Bessel and Hankel functions, and $Y_L(\boldsymbol{r}) = Y_{l,m}(\vartheta,\varphi)$ is the spherical harmonic. The matrix $\boldsymbol{m}^n$ with elements $m^n_{LL'}$ is the inverse of the scattering matrix $\boldsymbol{t}^n$ whose elements are

$$t^n_{LL'}(E) = \int\int j_l(\alpha \boldsymbol{r})\; Y^*_L(\boldsymbol{r})\; \langle \boldsymbol{r}|t(E)|\; \boldsymbol{r}'\rangle\; Y_{L'}(\boldsymbol{r}') \times j_l(\alpha \boldsymbol{r}')\; \mathrm{d}\boldsymbol{r}\; \mathrm{d}\boldsymbol{r}' \qquad [16]$$

The function $J^n_L(E,\boldsymbol{r}_n)$ is a real solution of the differential eqn [14] that joins smoothly to $Y_L(\boldsymbol{r}_n)j_l(\kappa \boldsymbol{r}_n)$ when r is outside of Ω_n. The $g^{nn'}_{LL'}$ in eqn [12] can be pictured as propagators that take an electron from site n to m, and are given by

$$g^{nm}_{LL'} = -4\pi i\kappa i^{l-l'} \sum i^{-\lambda} C^{\Lambda}_{LL'} h_\lambda(\kappa R_{nm}) Y^*_\Lambda(\boldsymbol{R}_{nm}) \qquad [17]$$

where $\boldsymbol{R}_{nm} = \boldsymbol{R}_m - \boldsymbol{R}_n$ and the Gaunt factors $C^{\Lambda}_{LL'} = \int Y_\Lambda Y^*_L Y_{L'}\, \mathrm{d}\Omega$ are related to Clebsch–Gordon coefficients. This equation for the Green's function is correct for any kind of solid, but it is difficult to calculate except for pure metals, metals with impurities, and alloys using approximations.

Pure Metals

The expression for the Green's function, eqn [11], is greatly simplified for infinite periodic solids. The case of one atom per unit cell is treated because the extension to more than one atom is straightforward. The atoms are on the sites $\boldsymbol{R}_i$ of a Bravais lattice. Bloch's theorem follows from the invariance of the crystal under translations

$$\psi_{\boldsymbol{k}}(\boldsymbol{r} + \boldsymbol{R}_{ij}) = \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_{ij}}\psi_{\boldsymbol{k}}(\boldsymbol{r}) \qquad [18]$$

There are only N Bloch vectors, $\boldsymbol{k}_i$, because of the periodic boundary conditions. It follows that the matrix $\boldsymbol{g}$ with elements $g^{ij}_{LL'}$ can be put into a block diagonal form by transforming it with the matrix $\boldsymbol{U}$ with elements

$$U^{ij}_{LL'} = \frac{1}{\sqrt{N}}\mathrm{e}^{-\mathrm{i}\boldsymbol{R}_i\cdot\boldsymbol{k}_j}\delta_{LL'} \qquad [19]$$

$$\left[\boldsymbol{U}^\dagger \boldsymbol{g} \boldsymbol{U}\right]^{ij}_{LL'} = g_{LL'}(E,\boldsymbol{k}_i)\delta_{ij} = \sum_{m=1}^{N} \mathrm{e}^{\mathrm{i}\boldsymbol{k}_i\cdot\boldsymbol{R}_{0m}} g^{0m}_{LL'}(E) \qquad [20]$$

Since the matrices $\boldsymbol{m}^i$ are the same for every cell, the transformed matrix $\boldsymbol{U}^\dagger\boldsymbol{M}\boldsymbol{U}$ is easily inverted. When the $\boldsymbol{U}$ matrix is used to transform back and then N is allowed to go to infinity, the scattering path matrix for the periodic crystal is

$$\boldsymbol{\tau}^{nn}_0(E) = \frac{1}{N}\sum_{i=1}^{N} \mathrm{e}^{-\mathrm{i}\boldsymbol{k}_i\cdot\boldsymbol{R}_{nn}}[\boldsymbol{m}(E) - \boldsymbol{g}(E,\boldsymbol{k}_i)]^{-1} = \frac{\Omega}{(2\pi)^3}\int \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_{nn}}[\boldsymbol{m}(E) - \boldsymbol{g}(E,\boldsymbol{k})]^{-1}\, \mathrm{d}\boldsymbol{k} \qquad [21]$$

The angular momentum indices L and L' in this and succeeding equations are suppressed by the use of block matrices.

The functions $\boldsymbol{g}(E,\boldsymbol{k})$ are called structure constants in the Korringa–Kohn–Rostoker (KKR) band theory, and sophisticated methods have been developed for calculating them. The standard approximation in the application of this formula is that the elements of $\boldsymbol{m}(E)$ and $\boldsymbol{g}(E,\boldsymbol{k})$ that correspond to angular momenta such that $l > l_{\max}$ are ignored. Thus, the matrices that must be inverted in eqn [21] have a dimension $(l_{\max}+1)^2$.

Impurities in Metals

When an impurity atom replaces one of the atoms in a periodic metal, the scattering matrix $\boldsymbol{m}^i$ obviously changes on the impurity site. The scattering matrices on the adjoining sites also change because of the effect that the impurity has on its neighboring atoms. Even the Green's functions $\boldsymbol{g}^{ij}$ that connect the atoms are affected by the impurity change, because the size difference between the impurity atom and the host atoms causes displacements from the sites of the original periodic lattice. In metals, it is reasonable to assume that the influence of the impurity is screened beyond a certain number of nearest-neighbor shells to the point that it has no noticeable effect on the rest of the lattice. It follows that the $N \times N$ matrix $\boldsymbol{M}$ for the metal with an impurity can be written as $\boldsymbol{M} = \boldsymbol{M}_0 + \Delta\boldsymbol{M}$, where $\Delta\boldsymbol{M}$ is a matrix with elements

$$\Delta M^{mn}_{LL'} = (m^n_{LL'} - m^n_{0LL'})\;\delta_{mn} - (g^{mn}_{LL'} - g^{mn}_{0LL'})\;(1-\delta_{mn}) \qquad [22]$$

In this equation, $m^n_{0LL'}$ and $g^{mn}_{0LL'}$ are the matrix elements of the original periodic solid. All of the elements of $\Delta \boldsymbol{M}$ are zero except for those associated with the N_I sites of the atoms that are influenced by the impurity. Assuming that there are one or two nearest–neighbor shells, N_I is 13 or 19 for a face-centered-cubic (f.c.c) lattice and it is 9 or 15 for a body-centered cubic (b.c.c) lattice.

Consider the set of sites influenced by the impurity S_I. If $n \subset S_I$, the coefficients $\tau^{mn}_{LL'}$ that appear in the expression for the Green's function in eqn [11] are elements of the matrix

$$\boldsymbol{\tau}^I = \left[\boldsymbol{I} - \boldsymbol{\tau}^I_0 \Delta \boldsymbol{M}^I\right]^{-1} \boldsymbol{\tau}^I_0 \qquad [23]$$

The elements of $\boldsymbol{\tau}^I_0$ are the matrix elements of the scattering path operators for the host lattice $\boldsymbol{\tau}^{mn}_0$, where $m \subset S_I$ and $n \subset S_I$. The matrix $\Delta \boldsymbol{M}^I$ contains only the nonzero elements of $\Delta \boldsymbol{M}$. No angular momentum indices are included beyond $l_{\max}$, so the dimension of the matrices in eqn [26] is $N_I(l_{\max}+1)^2$.

The best way to calculate the DOS and charge density associated with the sites influenced by the impurity is

$$\rho^I_n(E) = -\frac{1}{\pi} \operatorname{Im} \sum_{LL'} \tau^{I,nn}_{LL'}(E) \int_{\Omega_n} F^n_{L'L}(E, \boldsymbol{r}, \boldsymbol{r})\, \mathrm{d}\boldsymbol{r} \qquad [24]$$

and

$$\rho^I_n(\boldsymbol{r}) = -\frac{1}{\pi} \operatorname{Im} \sum_{LL'} \int_{-\infty}^{E_F} \tau^{I,nn}_{LL'}(E) F^n_{L'L}(E, \boldsymbol{r}, \boldsymbol{r})\, \mathrm{d}E \qquad [25]$$

where $F^n_{L'L}(E, \boldsymbol{r}'_n, \boldsymbol{r}_n) = Z^{n^*}_{L'}(E, \boldsymbol{r}'_n)\, Z^n_L(E, \boldsymbol{r}_n)$. In summary, a charge density for the host atoms and a crystal structure are assumed. The DFT is used to calculate the potential for the host atoms, $V_0(\boldsymbol{r})$, and hence the scattering matrix $\boldsymbol{t}_0(E)$. The coefficients $\tau^{nn}_{0,LL'}$ are obtained from eqn [21] and then the Green's function using eqn [11] and the charge density using eqn [2] are calculated. This process is iterated until the charges are self-consistent. At this point one has the coefficients for all the sites of the host lattice, and the elements of the matrix $\boldsymbol{\tau}^I_0$. It is now necessary to guess the charge densities for the impurity sites with $n \subset S_I$, calculate the potentials and scattering matrices, and construct the matrix $\Delta \boldsymbol{M}^I$. The coefficients and Green's functions for these sites are obtained from eqns [23] and [11]. The Fermi energy is not changed, and the new charge densities at the impurity sites are obtained from eqn [25]. The potentials must be iterated to self-consistency. These formulas have been very successful in predicting resistivities, hyperfine energies, and energies of formation, but only if the relaxation of the atoms in the nearest-neighbor shells away from the periodic lattice sites is allowed to occur. The calculations are sensitive to approximations to the shape of the self-consistent potentials, and, where relevant, spin polarization must be included.

An interesting formula for the DOS can be obtained using a theorem from the scattering theory derived by the Russian academician M G Krein. In operator language, Krein's theorem states that

$$\operatorname{Tr}[G(z) - G_0(z)] = \frac{\mathrm{i}}{2\pi} \lim_{\varepsilon \downarrow 0} \int_{-\infty}^{\infty} \frac{\ln \operatorname{Det}(I - \mathrm{i}2\sqrt{E' + \mathrm{i}\varepsilon}\, T(E' + \mathrm{i}\varepsilon))}{(E' - z)^2}\, \mathrm{d}E' \qquad [26]$$

Using the formula for the DOS in eqn [10], this equation can, with some effort, be put into the form

$$\rho(E) - \rho_0(E) = -\frac{2}{\pi} \operatorname{Im} \frac{\mathrm{d} \ln \operatorname{Det} \boldsymbol{M}(E)}{\mathrm{d}E} \qquad [27]$$

where $\rho(E)$ is the DOS for the system of scatterers, $\rho_0(E)$ is the DOS for free electrons, and $\boldsymbol{M}(E)$ is the matrix defined in eqn [13]. This is called Lloyd's formula because Lloyd derived it without the help of Krein's theorem. Krein's theorem can immediately be used for impurities by defining H_0 to be the Hamiltonian for the host lattice rather than just the kinetic energy, and a version of Lloyd's formula that gives the change in the total DOS caused by the impurity can be obtained.

The simplest theory for an impurity is to picture it as a single spherically symmetric scatterer embedded in a free-electron gas. Then Krein's theorem leads to

$$\rho(E) - \rho_0(E) = -\frac{\mathrm{i}}{\pi} \operatorname{Im} \sum_l (2l+1) \times \frac{\mathrm{d} \ln [1 - -2\alpha t_l(E)]}{\mathrm{d}E} \qquad [28]$$

For such a scatterer, the t-matrix defined in eqn [16] becomes $t_{LL'} = t_l \delta_{ll'} \delta_{mm'}$ with

$$t_l = -\frac{1}{\alpha} \mathrm{e}^{\mathrm{i}\eta_l} \sin \eta_l \qquad [29]$$

where the η_l are scattering phase shifts. From this, the Friedel sum is obtained.

$$\rho(E) - \rho_0(E) = \frac{2}{\pi} \sum_l (2l+1) \frac{\mathrm{d}\eta_l}{\mathrm{d}E} \qquad [30]$$

The Friedel formula appears in many text books on condensed matter physics, but the assumptions that

go into its derivation are very limiting. Leaving aside the fact that the electronic spectrum of the host resembles a free electron gas for very few solids, the assumption that the change in the spectrum is confined to one site is internally inconsistent. It is typical that the impurity atom loses or gains charge from the host. The charge is screened to make the system charge neutral, but the screening charge is typically distributed over one or two nearest-neighbor shells.

Coherent Potential Approximation

It should be clear that the impurity equations described in the preceding section can be generalized to deal with several interacting impurities in a metal. It is only necessary to increase the number of sites N_i influenced by the impurity atoms. However, when the concentration of impurities reaches the point at which most of the impurity atoms are within range of each other, the impurity equations are no longer useful. It is then necessary to treat the material as an alloy, and to develop a different class of theories. The problem of finding the solutions of Schrodinger's equation for a potential function that is not periodic is difficult because Bloch's theorem, eqn [18], no longer holds. Progress has been made on substitutional solid-solution alloys that are made up of two or more species of atoms distributed randomly on the sites $\boldsymbol{R}_i$ of a Bravais lattice. In the following, the concentration is on binary alloys, although the generalization to ternary, quaternary, etc. is straightforward.

The ensemble of all alloys that can be constructed out of $N_A = c_A N$ A atoms and $N_B = c_B N$ B atoms contains $M_c = N!/N_A!N_B!$ atomic arrangements. Experimentally, it is observed that all alloys with the concentrations c_A and c_B have the same electronic structure. It follows that, as $N \to \infty$, all of the arrangements have the same electronic structure with probability 1, and it can be found by averaging over the ensemble. The ensemble average of a one-electron wave function has no meaning, but, because of the linear relation between Green's function and the electronic properties, the ensemble average of Green's function is useful.

The ensemble average of the function in eqn [11] can be obtained if the assumption is made that the resulting alloy model is isomorphous. That is, it is assumed that the Green's function takes one of two forms, $G_A(E, \boldsymbol{r}_n, \boldsymbol{r}'_n)$ if there is an A atom on site n and $G_B(E, \boldsymbol{r}_n, \boldsymbol{r}'_n)$ if there is a B atom on that site. With this assumption, the ensemble averaged Green's function is

$$\langle G_n(E, \boldsymbol{r}_n, \boldsymbol{r}'_n) \rangle = c_A G_A(E, \boldsymbol{r}_n, \boldsymbol{r}'_n) + c_B G_B(E, \boldsymbol{r}_n, \boldsymbol{r}'_n) \quad [31]$$

where

$$G_A(E, \boldsymbol{r}_n, \boldsymbol{r}'_n) = \sum_{LL'} Z_L^A(E, \boldsymbol{r}_n) \langle \tau_{LL'}^{nn} \rangle_A Z_{L'}^{A^*}(E, \boldsymbol{r}'_n) - \sum_L Z_L^A(E, \boldsymbol{r}_n) J_L^{A^*}(E, \boldsymbol{r}'_n) \quad [32]$$

and

$$G_B(E, \boldsymbol{r}_n, \boldsymbol{r}'_n) = \sum_{LL'} Z_L^B(E, \boldsymbol{r}_n) \langle \tau_{LL'}^{nn} \rangle_B Z_{L'}^{B^*}(E, \boldsymbol{r}'_n) - \sum_L Z_L^B(E, \boldsymbol{r}_n) J_L^{B^*}(E, \boldsymbol{r}'_n) \quad [33]$$

The charge density for an A atom, $\rho_A(\boldsymbol{r}_n)$, is obtained by inserting $G_A(E,\boldsymbol{r}_n,\boldsymbol{r}_n)$ into eqn [2], and similarly for the B atom. From these charge densities, the potentials $v_A(\boldsymbol{r}_n)$ and $v_B(\boldsymbol{r}_n)$ are calculated. The functions $Z_L^A(E, \boldsymbol{r}_n)$ and $J_L^A(E, \boldsymbol{r}_n)$ are obtained using $v_A(\boldsymbol{r}_n)$ in eqn [13], and the functions $Z_L^B(E, \boldsymbol{r}_n)$ and $J_L^B(E, \boldsymbol{r}_n)$ are obtained using $v_B(\boldsymbol{r}_n)$.

The averages $\langle \tau_{LL'}^{nn} \rangle_A$ and $\langle \tau_{LL'}^{nn} \rangle_B$ are the ensemble averages of the scattering path operator subject to the condition that there is an A or B atom on site n. These averages are simplified considerably by making a mean field approximation. It is assumed that, on an average, the scattering of the electrons from all the sites other than site n is described by replacing the actual potentials on those sites with a potential $v_c(\boldsymbol{r})$, called the coherent potential. The scattering from $v_c(\boldsymbol{r})$ is described by a t-matrix, $\boldsymbol{t}_c(E)$, which has an inverse $\boldsymbol{m}_c(E)$. It follows that, within the coherent potential approximation (CPA), the ensemble averages $\langle \tau_{LL'}^{nn} \rangle_A$ and $\langle \tau_{LL'}^{nn} \rangle_B$ are the elements of the matrices obtained from eqn [23]

$$\langle \boldsymbol{\tau}^{nn} \rangle_A = [\boldsymbol{I} - \boldsymbol{\tau}_c^{nn}(\boldsymbol{m}_A - \boldsymbol{m}_c)]^{-1} \boldsymbol{\tau}_c^{nn} \quad [34]$$

and

$$\langle \boldsymbol{\tau}^{nn} \rangle_B = [\boldsymbol{I} - \boldsymbol{\tau}_c^{nn}(\boldsymbol{m}_B - \boldsymbol{m}_c)]^{-1} \boldsymbol{\tau}_c^{nn} \quad [35]$$

The matrices $\boldsymbol{m}_A$ and $\boldsymbol{m}_B$ are the inverses of the t-matrices calculated from the potentials $v_A(\boldsymbol{r})$ and $v_B(\boldsymbol{r})$. From eqn [24], it can be seen that the matrix $\boldsymbol{\tau}_c^{nn}$ is

$$\boldsymbol{\tau}_c^{nn}(E) = \frac{\Omega}{(2\pi)^3} \int [\boldsymbol{m}_c(E) - \boldsymbol{g}(E, \boldsymbol{k})]^{-1} \, \mathrm{d}\boldsymbol{k} \quad [36]$$

The number of impurity sites N_I is 1, so the matrices in these equations have dimension $(l_{\max} + 1)^2$. As would be expected, none of these equations depend on the choice of a site n.

In the language of the multiple-scattering theory used here, the condition originally put forward by

P Soven that defines the mean field t-matrix $\boldsymbol{t}_c(E)$ is

$$c_A \langle \boldsymbol{\tau}^{nn} \rangle_A + c_B \langle \boldsymbol{\tau}^{nn} \rangle_B = \boldsymbol{\tau}_c^{nn} \qquad [37]$$

In words, this is the condition that, on an average, there is no scattering from A and B atoms embedded in the coherent potential host matrix. Constraints on space do not allow descriptions of all the arguments put forward to justify this CPA condition. Perhaps the most convincing arguments come from the formulation of the problem of calculating the Green's function of an alloy in terms of the infinite order perturbation theory. Diagrams are then used to analyze the contributions to the Green's functions in a manner analogous to the field theory, quantum electrodynamics, or the many-body theory. It has been argued that the CPA contains the maximum number of classes of diagrams that can be included, and still retain a Green's function that is properly analytic. The criterion that is used to specify the diagrams included in the CPA is called the single-site approximation. It has been shown by R Mills and P Ratanavararaksa and also A Mookerjee that it is possible to go beyond the single-site approximation and retain an analytic Green's function, but it is difficult.

The procedure for calculating the electronic states within the CPA is first to guess the starting values for the charge densities $\rho_A(\boldsymbol{r})$ and $\rho_B(\boldsymbol{r})$, and from them calculate $v_A(\boldsymbol{r})$ and $v_B(\boldsymbol{r})$. The t-matrices $\boldsymbol{t}_A(E)$ and $\boldsymbol{t}_B(E)$ are calculated, and a first guess to $\boldsymbol{t}_c(E)$ is just their average $\boldsymbol{t}_c(E) \approx c_A \boldsymbol{t}_A(E) + c_B \boldsymbol{t}_B(E)$. Equations [32]–[35] are then iterated to self-consistency in the charge densities and also in the coherent potential t-matrix $\boldsymbol{t}_c(E)$.

Calculations with this version of the CPA have been carried out on many alloy systems. The predicted electronic DOS agree well with the ones measured in ultraviolet photoemission spectroscopy experiments. The zero-temperature resistivities of alloys have been accurately predicted. Even the propensity of a random alloy to transform into a superlattice structure or into an incommensurately ordered structure has been successfully predicted.

A problem that is endemic to this version of the CPA is that the Coulomb effects are not treated correctly. Integrating the charge densities $\rho_A(\boldsymbol{r})$ and $\rho_B(\boldsymbol{r})$ and subtracting the nuclear charges Z_A and Z_B leads to the net charges on the A and B sites, q_A and q_B. It would seem that there should be a Madelung contribution to the potentials $v_A(\boldsymbol{r})$ and $v_B(\boldsymbol{r})$ as in ordered alloys, but the only Madelung potentials that are commensurate with the assumption of an isomorphous alloy are zero. The isomorphous model of an alloy with the charge q_A on every A atom and q_B on every B atom is not realistic. Using order-N methods that are described in the next section, it is possible to calculate the electronic structure for supercells containing thousands of atoms with no approximation other than the DFT. **Figure 1** shows the charges on 512 copper atoms and 512 zinc atoms distributed randomly on the sites of a supercell with the structure of a b.c.c. lattice. The distribution is broad, and upon reflection, is what would be expected on the basis of physical intuition. It should be compared with the prediction of the isomorphous model that all the Cu atoms would take on exactly 0.09978 electron charges, and Zn atoms would lose the same amount.

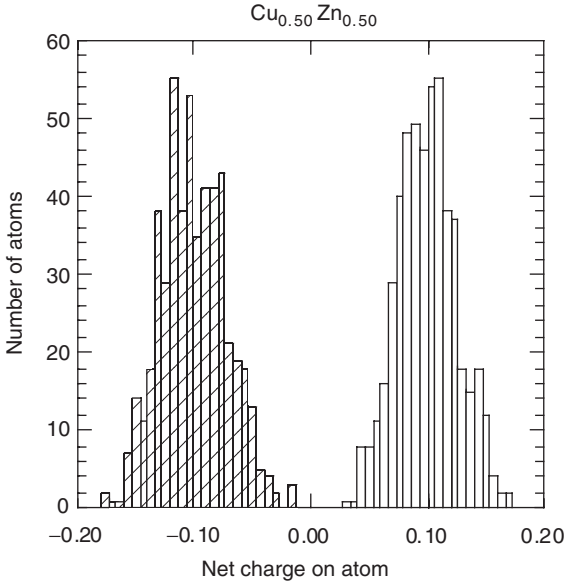

Figure 1 The distribution of charges on the sites of a 50% copper–zinc alloy modeled with a supercell containing 1024 atoms. The charges on the copper sites are shown with the white histograms, and the charges on the zinc sites are cross-hatched.

A version of the CPA can be constructed that leads to a polymorphous model of the alloy in which each atom has a different charge, but it requires a different kind of averaging. Recall that periodically reproduced supercells are considered. In the binary alloy model, N_A A atoms and N_B B atoms are distributed over the $N = N_A + N_B$ sites. The Green's function defined in eqn [11] for the alloy is different for each of the $M_c = N!/N_A!N_B!$ possible atomic arrangements, and can be labeled $G_n^i(E, \boldsymbol{r}_n, \boldsymbol{r}'_n)$ to emphasize that. Then, the ensemble average in eqn [27] can more properly be written as

$$\langle G_n(E, \boldsymbol{r}_n, \boldsymbol{r}'_n) \rangle = \frac{1}{M_c} \sum_{i=1}^{M_c} G_n^i(E, \boldsymbol{r}_n, \boldsymbol{r}'_n) \qquad [38]$$

It is also possible to consider one supercell with the atomic arrangement i, and average over the sites

$$\{G^i(E,\boldsymbol{r},\boldsymbol{r}')\} = \frac{1}{N}\sum_{n=1}^{N} G_n^i(E,\boldsymbol{r},\boldsymbol{r}') \qquad [39]$$

It is seen that, as $N\to\infty$, $\langle G_n(E,\boldsymbol{r}_n,\boldsymbol{r}'_n)\rangle$ is independent of the site index n. It is equally clear that in the same limit, $\{G^i(E,\boldsymbol{r},\boldsymbol{r}')\}$ is independent of the arrangement index i. The equivalence of the ensemble-average in eqn [38] with the site average in eqn [39] is similar to the Ergodic theorem first proposed by Boltzmann, and can be proved by similar arguments. If the condition is imposed that the alloy must be isomorphous, the site average will lead to the same averaged potential as the ensemble average result shown in eqn [27]. However, the site average can lead to a polymorphous model.

Applying the CPA philosophy to the site-averaged Green's function leads to

$$\{G(E,\boldsymbol{r},\boldsymbol{r}')\} = \frac{1}{N}\sum_{n=1}^{N}\{G_n(E,\boldsymbol{r},\boldsymbol{r}')\} \qquad [40]$$

where

$$\{G_n(E,\boldsymbol{r},\boldsymbol{r}')\} = \sum_{LL'} Z_L^n(E,\boldsymbol{r})\{\tau_{LL'}^{nn}(E)\}Z_{L'}^n(E,\boldsymbol{r}') - \sum_L Z_L^n(E,\boldsymbol{r})\, J_L^n(E,\boldsymbol{r}') \qquad [41]$$

and

$$\{\boldsymbol{\tau}^{nn}\} = [\mathbf{I} - \boldsymbol{\tau}_{\mathrm{c}}^{nn}(\mathbf{m}_n - \mathbf{m}_{\mathrm{c}})]^{-1}\boldsymbol{\tau}_{\mathrm{c}}^{nn} \qquad [42]$$

Inserting the Green's function for an index n into eqn [2] produces a charge density, $\rho_n(\boldsymbol{r})$, and hence a one-electron potential, $v_n(\boldsymbol{r})$, for every site. From the potential, one calculates the t-matrix $\boldsymbol{t}_n$ and its inverse $\boldsymbol{m}_n$ which appears in eqn [38]. As in the isomorphous CPA, the scattering path for the coherent potential host lattice $\boldsymbol{\tau}_{\mathrm{c}}^{nn}$ is calculated from eqn [36]. The condition that defines the coherent potential is

$$\frac{1}{N}\sum_{n=1}^{N}\{\tau^{nn}\} = \tau_{\mathrm{c}}^{nn} \qquad [43]$$

instead of eqn [37].

Since the focus is on a specific supercell, the position $\boldsymbol{R}_n$ of each atom is known and the Madelung potential for the nth site is

$$v_n^{\mathrm{M}} = \sum_{m\neq n=1}^{N} M(|\boldsymbol{R}_n - \boldsymbol{R}_m|)q_n \qquad [44]$$

where

$$q_n = \int_{\Omega_n} \rho_n(\boldsymbol{r})\ \mathrm{d}\boldsymbol{r} - Z_n \qquad [45]$$

and $M(|\boldsymbol{R}_n - \boldsymbol{R}_m|)$ is the Madelung matrix. The Madelung matrix is defined so that the sum in eqn [44] gives the contribution to the Coulomb potential from all of the periodically reproduced supercells. A sophisticated method for calculating it was developed by P P Ewald, and it reduces to $1/|\boldsymbol{R}_n - \boldsymbol{R}_m|$ when $N\to\infty$. The potentials $v_n(\boldsymbol{r})$ contain the Madelung shift v_n^{M}.

The polymorphous version of the CPA has been applied to several alloy systems. For alloys that have a large amount of charge transfer, such as copper–gold or copper–palladium, it gives better results than the ones obtained with the isomorphous CPA, but the improvements are quite small for alloys such as silver–palladium that have a small charge transfer. The polymorphous CPA has the disadvantage that it requires the use of a specific supercell. This is a small price to pay for the improvement in the treatment of the Coulomb energy. It is quite easy to apply because the charge densities $\rho_A(\boldsymbol{r})$ and $\rho_B(\boldsymbol{r})$ and the effective t-matrix $\boldsymbol{t}_{\mathrm{c}}$ from the isomorphous CPA are used as the starting values in the self-consistent iterations.

Although the coherent potential $v_{\mathrm{c}}(\boldsymbol{r})$ is introduced in the discussion, it is never calculated or used. The only potentials used in eqn [14] to calculate wave functions are real potentials for real atoms, $v_n(\boldsymbol{r})$. From the analytic properties of $\boldsymbol{t}_{\mathrm{c}}$ it follows that $v_{\mathrm{c}}(\boldsymbol{r})$, if it existed, would be complex and energy dependent.

Order-*N* Methods

A brute force method for calculating the electronic states of a disordered solid is to simply model a portion of the solid in a supercell. The nuclei do not have to be placed on the sites of a Bravais lattice, and any combination of atomic species can be used. This makes it possible to approach a much wider range of problems than the CPA can deal with. Supercells containing a large number of atoms can be treated with the band-theory methods that have been developed to treat solids with N atoms per unit cell. All of these methods require an operation that is the equivalent of inverting or diagonalizing an $N\times N$ matrix, and these operations require an amount of computer time that scales as N^3. Even though computer speeds increase exponentially, this scaling always places a limit on the size of the supercell that can be used. For this reason, considerable effort has been devoted to the development of order-N methods

for electronic structure calculations for which the computer times scale as N rather than N^3.

An order-N method called the locally self-consistent multiple-scattering (LSMS) method was developed by G M Stocks and his collaborators. Each atom in the supercell is considered to be the center of a cluster of a local interaction zone (LIZ) that contains N_{LIZ} atoms. The matrix $\boldsymbol{M}^n$ with elements defined in eqn [13] is truncated so that only the scatterers in the LIZ corresponding to site n are included. This is typically the nth site and its first seven or eight nearest-neighbor shells. Truncating the angular momentum expansions at $l_{\max}$, the order of $\boldsymbol{M}^n$ is $(l_{\max}+1)^2 N_{\mathrm{LIZ}}$ and $N_{\mathrm{LIZ}} < 100$. After the inversion of $\boldsymbol{M}^n$, only the matrix elements $\tau^{nn}_{LL'}$ corresponding to the central atom are used. With these matrix elements, the Green's function $G_n(E, \boldsymbol{r}_n, \boldsymbol{r}'_n)$ is calculated from eqn [11], and hence the charge density $\rho_n(\boldsymbol{r}_n)$ and the net charge on the site q_n are obtained. The Madelung shift on the nth site is calculated using eqn [44], and the next iteration for the potential $v_n(\boldsymbol{r})$ is acquired by adding that to the DFT potential calculated from the charge density. This procedure scales with N, although the prefactor is $(l_{\max}+1)^6 N^3_{\mathrm{LIZ}}$.

The LSMS puts nothing on the sites outside the LIZ. The locally self-consistent Green's function (LSGF) method proposed by I A Abrikosov and his collaborators puts coherent potentials on those sites. The LSGF makes use of the equations for an impurity cluster in a metal, eqns [22]–[25], with the coherent potential scattering matrix $\boldsymbol{m}_{\mathrm{c}}$ replacing the host matrix $\boldsymbol{m}_0$. The matrix $\boldsymbol{\tau}^I$ in eqn [23] contains the average scattering path operators for all the scatterers in the LIZ. Only the matrix for the central site, $\{\boldsymbol{\tau}^{nn}\}$, is used in the equation that defines $\boldsymbol{m}_{\mathrm{c}}$, which is eqn [43]. The charge density $\rho_n(\boldsymbol{r}_n)$ is obtained by inserting the Green's function from eqn [41] into eqn [2]. This charge density and the Madelung shift from eqn [44] is used to calculate the new potential $v_n(\boldsymbol{r})$ in the self-consistent process.

The LSMS has the advantage that the atoms can be placed anywhere in the supercell, while the atoms should be on the sites of a Bravais lattice in the LSGF. The advantage of the LSGF is that the LIZ can be made much smaller. In fact, for $N_{\mathrm{LIZ}} = 1$, which means that it contains only the central atom, the LSGF is identical to the site-averaged CPA described above. That level of approximation is adequate for many calculations on alloys.

The LSMS and LSGF are order-N because the propagation of electrons from one atom to another is treated properly only for atoms within the LIZ. It should be noted that the range of the Coulomb interactions is not assumed to be short. The Ewald sum in eqn [44] includes contributions from all the atoms in the supercell, and indeed from the atoms in the periodically reproduced supercells that fill all space. The calculation of the Madelung shifts takes very little time in comparison with the rest of the calculation, and experience has shown that it is not a good idea to truncate it.

Extensions and Approximations

All of the equations in this article have been written in the nonrelativistic form because they are easier to visualize. They can easily be transformed to the Dirac form using the relativistic density-functional theory (RDFT) of A K Rajagopal, *et al*. The spin-polarized version of these equations has been used very successfully to explain the magnetism of metals and alloys. The calculations can be made easier by employing a shape approximation to the potentials, such as the muffin-tin (MT) or atomic sphere approximation (ASA). Instead of using the full multiple-scattering version of the equations depicted here, many authors choose to approximate them with a variational version called the linear combination of muffin-tin orbitals (LMTO). These approximations are discussed for wave functions elsewhere in this encyclopedia.

The amount of computer time required for calculations with Green's functions can be significantly reduced with the help of sophisticated techniques derived from their properties. Using the analyticity of the Green's functions, it is frequently possible to carry out integrals over the energy, such as eqn [2], by making the energy complex and integrating over a contour rather than along the real axis. It is also possible to use a finite-temperature version of the DFT that improves the convergence of some of the integrals. Finally, the range of the propagators $\boldsymbol{g}^{mn}$ that describe the motion of the electron from one site to another can be made short by shifting the zero of the potential between scatterers.

Of course, many properties of alloys are calculated using statistical methods such as Monte Carlo, molecular dynamics, and the cluster-variational method. The electronic structure appears in these calculations only in the calculation of the interatomic potentials. Different approaches to the calculation of these potentials are the embedded atom method, the generalized perturbation method, and the mixed-space cluster expansion method.

Metals and Metallic Alloys, Optical Properties of

F Forstmann, Freie Universität Berlin, Berlin, Germany

Reflection and Transmission

Metals are characterized by large electrical conductivity and shiny surfaces, that is, intense reflectivity. Because both properties are responses to electromagnetic fields, there is a close connection.

For a transparent discussion, Maxwell's equations which govern optics are presented, with polarization, magnetization, and current shown explicitly:

$$\nabla \times \boldsymbol{B} = \mu_0 \varepsilon_0 \frac{\partial \boldsymbol{E}}{\partial t} + \mu_0 \left(\boldsymbol{j} + \frac{\partial \boldsymbol{P}}{\partial t} + \nabla \times \boldsymbol{M} \right) \quad [1]$$

$$\nabla \cdot \boldsymbol{E} = \frac{1}{\varepsilon_0}(\rho - \nabla \cdot \boldsymbol{P}) \quad [2]$$

$$\nabla \times \boldsymbol{E} = -\frac{\partial B}{\partial t} \quad [3]$$

$$\nabla \cdot \boldsymbol{B} = 0 \quad [4]$$

Here, it is clearly seen that $-\nabla \cdot \boldsymbol{P}$ acts as a source of the electric field like any charge and $\partial \boldsymbol{P}/\partial t$ (and $\nabla \times \boldsymbol{M}$) creates $\boldsymbol{B}$ like any current. This is easily understood from the definition of the polarization $\boldsymbol{P}$ as the amount of charge penetrating a plane normal to $\boldsymbol{P}$ when the polarization is created. It is conventional to distinguish between true charges ρ and apparent charges $-\nabla \cdot \boldsymbol{P}$, true currents $\boldsymbol{j}$ and apparent currents $(\partial \boldsymbol{P}/\partial t + \nabla \times \boldsymbol{M})$. $\boldsymbol{P}$ is then considered due to the shift of bound charges (such as in an oscillator-model). But it is obvious that at very high frequencies with short shifts of all charges, the distinction between free and bound charges will not be possible any more. It is impracticable in metal optics. It is only a theoretical concept. One effectively deals with a total response to the electromagnetic fields and therefore with an effective response function: a complex dielectric function ε, a complex conductivity σ, or a complex polarizability $\chi = \varepsilon - 1$.

Next, linear isotropic responses are assumed:

$$\boldsymbol{j} = \sigma \boldsymbol{E}, \quad \boldsymbol{P} = \chi_{\mathrm{p}} \varepsilon_0 \boldsymbol{E}, \quad \boldsymbol{M} = \chi_{\mathrm{m}} \boldsymbol{H} \quad [5]$$

$$\boldsymbol{D} = \varepsilon_0 \boldsymbol{E} + \boldsymbol{P} = \varepsilon_0 (1 + \chi_{\mathrm{p}}) \boldsymbol{E} = \varepsilon_0 \varepsilon_{\mathrm{p}} \boldsymbol{E} \quad [6]$$

$$\begin{aligned} \boldsymbol{B} &= \mu_0 (\boldsymbol{H} + \boldsymbol{M}) = \mu_0 (1 + \chi_{\mathrm{m}}) \boldsymbol{H} \\ &= \mu_0 \mu \boldsymbol{H}, \quad \varepsilon_0 \cdot \mu_0 = \frac{1}{c^2} \end{aligned} \quad [7]$$

The relation between polarizability and conductivity can be derived by reordering of eqns [1] and [2] to the more conventional form

$$\nabla \times \boldsymbol{H} = \frac{\partial \boldsymbol{D}}{\partial t} + \boldsymbol{j} = \frac{\partial}{\partial t} \boldsymbol{D}_{\mathrm{eff}} \quad [8]$$

$$\nabla \cdot \boldsymbol{D} = \rho \quad [9]$$

$\boldsymbol{D}_{\mathrm{eff}}$ is easily defined for each time Fourier component. A periodicity $\mathrm{e}^{-\mathrm{i}\omega t}$ for all optical fields is introduced (the minus sign is chosen arbitrarily, but it determines many signs from now on) and one gets from [8] and [3]

$$\begin{aligned} \nabla \times \frac{1}{\mu_0 \mu} \boldsymbol{B} &= -\mathrm{i}\omega \left(\varepsilon_0 \varepsilon_{\mathrm{p}} - \frac{\sigma}{\mathrm{i}\omega} \right) \boldsymbol{E} \\ &= -\mathrm{i}\omega \boldsymbol{D}_{\mathrm{eff}} \end{aligned} \quad [10]$$

$$\nabla \times \boldsymbol{E} = +\mathrm{i}\omega \boldsymbol{B} \quad [11]$$

$$\begin{aligned} \nabla \times (\nabla \times \boldsymbol{E}) &= \nabla (\nabla \cdot \boldsymbol{E}) - \Delta \boldsymbol{E} \\ &= \frac{\omega^2}{c^2} \mu \left(\varepsilon_{\mathrm{p}} - \frac{\sigma}{\mathrm{i}\omega \varepsilon_0} \right) \boldsymbol{E} \end{aligned} \quad [12]$$

As explained at the beginning, the polarizability and the conductivity are found to be on the same footing in the wave equation [12] and therefore, the effective

complex dielectric function is defined as

$$\varepsilon = 1 + \chi_p - \frac{\sigma}{i\omega\varepsilon_0}, \quad \boldsymbol{D}_{eff} = \varepsilon_0\varepsilon\boldsymbol{E} \qquad [13]$$

In standard metal optics, it is argued that in conducting metals any charge ρ is quickly dissipated or screened and eqn [2] yields effectively $\nabla \cdot \boldsymbol{E} = 0$. An estimate of the decay time of a charge can be got by putting eqn [9] into the continuity equation

$$\dot{\rho} = -\nabla \cdot \boldsymbol{j} = -\sigma\nabla \cdot \boldsymbol{E} = -\frac{\sigma}{\varepsilon_0\varepsilon_p}\rho \qquad [14]$$

$$\rho = \rho_0 \cdot e^{-t/\tau}, \quad \text{with} \quad \tau = \frac{\varepsilon_p\varepsilon_0}{\sigma} \qquad [15]$$

For silver with $\sigma = (0.016 \times 10^{-4}\ \Omega\ \text{cm})^{-1}$ and, $\varepsilon_p \approx 1$, the decay time $\tau \approx 10^{-19}$ s and, therefore, charges decay faster than most optical fields vary. This estimate with the static conductivity is too optimistic. It is seen later that around $\omega \approx 10^{16}\ s^{-1}$ ($\hbar\omega > 3.5$ eV) charge density waves, plasma waves with $\nabla \cdot \boldsymbol{E} \neq 0$, play a role in optics. But in the regime of visible optics with $\nabla \cdot \boldsymbol{E} = 0$ and eqn [13], the level of standard optics was attained with transverse waves and the complex index of refraction

$$\tilde{n} = \sqrt{\varepsilon\mu} \qquad [16]$$

In most metals, $\mu \approx 1$ is a valid approximation. A treatment of the reflection from the surface of a metal with dielectric function ε_M facing a transparent medium (ε_1) yields the standard Fresnel formulas, which for later use are derived in a handy notation for wave vectors in the xz-plane, surface normal $\|z$ into the metal:

$$\text{in medium 1}: \quad \boldsymbol{E}(\boldsymbol{r},\omega) = \boldsymbol{E}_0 e^{i(k_x x + qz)} + \boldsymbol{R} e^{i(k_x x - qz)} \qquad [17]$$

$$\text{in the metal}: \quad \boldsymbol{E}(\boldsymbol{r},\omega) = \boldsymbol{T} e^{i(k_x x + lz)} \qquad [18]$$

$$q = \sqrt{\frac{\omega^2}{c^2}\varepsilon_1\mu_1 - k_x^2}, \quad l = \sqrt{\frac{\omega^2}{c^2}\varepsilon_M\mu_M - k_x^2} \qquad [19]$$

p- and s-polarization are distinguished and so are $\boldsymbol{E}$ parallel or normal to the plane of incidence, here the xz-plane. Because $\boldsymbol{R}$ and $\boldsymbol{T}$ are orthogonal to their respective wave vectors, only the two z-components have to be determined for p-polarization (the two amplitudes for s-polarization). Therefore, the two standard boundary conditions are used:

$$\text{continuity of } E_{tangential} \text{ or } B_{normal} \qquad [20]$$

$$\text{continuity of } D_{eff,normal} \text{ or } H_{tangential} \qquad [21]$$

Here, an obvious problem is usually brushed under the carpet – what the continuity of the normal component of $\boldsymbol{D}$ from $\nabla \cdot \boldsymbol{D} = 0$ (eqn [19] with $\rho = 0$) or of $\boldsymbol{D}_{eff}$ from $\nabla \cdot \boldsymbol{D}_{eff} = 0$ as eqn [8] or [10] tells us. Because this problem is difficult, one takes refuge in the continuity of H_{tg} which actually makes $D_{eff,normal}$ continuous as a consequence of [8] or [10]. Continuity of H_{tg} requires (from [8]) all fields to be finite, here $\boldsymbol{D}$, and no singular surface currents. But the discontinuity of E_{normal}, which goes with the continuity of $D_{eff,normal} = \varepsilon_0\varepsilon E_{normal}$ and a discontinuous ε, requires singular surface charges, from eqn [2]. Arguing with bound charges $-\nabla \cdot \boldsymbol{P}$ does not help because $\chi_p = 0$, $\boldsymbol{P} = 0$ is often a good description of the metal. Also the normal component of $\boldsymbol{j} = \sigma\boldsymbol{E}$ is discontinuous.

For frequencies in the visible approximation, [21] works. Around the eigenfrequency of the electrons, the plasma frequency ω_p, the charges, and the currents get so large that the problem behind boundary condition [21] must be solved. This is done in the section "Plasma waves in metal optics."

Boundary conditions [20] and [21] yield two linear equations for the reflection and transmission amplitudes. They are related to the reflection and transmission coefficients r and t:

$$p\text{-polarization}: \quad \frac{R_z}{E_{0z}} = \frac{\varepsilon_M q - \varepsilon_1 l}{\varepsilon_M q + \varepsilon_1 l}, \quad \frac{T_z}{E_{0z}} = \frac{2q\varepsilon_1}{\varepsilon_M q + \varepsilon_1 l} \qquad [22]$$

$$r = \left|\frac{R_z}{E_{0z}}\right|^2, \qquad t = \frac{l\varepsilon_M}{q\varepsilon_1}\left|\frac{T_z}{E_{0z}}\right|^2 \qquad [23]$$

$$s\text{-polarization}: \quad \frac{R}{E_0} = \frac{q\mu_M - l\mu_1}{q\mu_M + l\mu_1}, \quad \frac{T}{E_0} = \frac{2q\mu_M}{q\mu_M + l\mu_1} \qquad [24]$$

$$r = \left|\frac{R}{E_0}\right|^2, \qquad t = \frac{l\mu_1}{q\mu_M}\left|\frac{T}{E_0}\right|^2 \qquad [25]$$

In the infrared, the term $\sigma/(\omega\varepsilon_0)$ in eqn [13] is much larger than 1. If $\mu_M \approx \mu_1$ and $\varepsilon_1 = 1$, the reflection coefficient for normal incidence ($k_x \to 0$) can be expanded:

$$r = \left|\frac{\tilde{n}_M - 1}{\tilde{n}_M + 1}\right|^2 \approx 1 - 2\sqrt{2\frac{\omega\varepsilon_0}{\sigma}} \qquad [26]$$

This is called the Hagen–Rubens relation for the decrease of the metallic reflectivity due to the finite conductivity. It is a good approximation (with the

static conductivity) for most metals in the infrared for $\lambda > 10\,\mu m$.

For further discussion of the consequences of eqns [22]–[25], a model for the metallic response is considered, the Drude model, which approximates well the typical properties of metals. It considers only the conducting electrons. It could easily be supplemented by a Debye oscillator model for underlying bound electrons, the polarizability χ_p which could then simply be added as in eqn [13]. The Drude model is the equation of motion of the collection of electrons driven by the electric field and suffering a friction:

$$m\ddot{\boldsymbol{r}} = -e_0\boldsymbol{E} - m\gamma\dot{\boldsymbol{r}}, \quad \boldsymbol{j} = -e_0 n_0 \dot{\boldsymbol{r}} \qquad [27]$$

$$\frac{\partial}{\partial t}\boldsymbol{j} = \frac{n_0 e_0^2}{m}\boldsymbol{E} - \gamma\boldsymbol{j} = \omega_p^2 \varepsilon_0 \boldsymbol{E} - \gamma\boldsymbol{j} \qquad [28]$$

The plasma frequency is introduced here via the mean conduction electron density n_0:

$$\omega_p = \left(\frac{n_0 e_0^2}{m\varepsilon_0}\right)^{1/2} \qquad [29]$$

and the friction constant $\gamma = 1/\tau$ related to the collision time τ. The Drude model (eqn [28]) leads to the static conductivity

$$\sigma_{stat} = \frac{n_0 e^2}{m\gamma} = \frac{n_0 e^2}{m}\tau$$

but more relevantly here to the optical conductivity:

$$\sigma(\omega) = \frac{i\omega_p^2 \varepsilon_0}{\omega + i\gamma} \qquad [30]$$

and from eqn [13] ($\chi_p = 0$) to the typical metal dielectric function:

$$\varepsilon = 1 - \frac{\omega_p^2}{\omega^2 + i\omega\gamma} \qquad [31]$$

From the static conductivity, one can derive an estimate for τ or $\gamma \approx 10^{10}\ s^{-1}$, and find that at least for the visible frequencies, a good approximation is

$$\varepsilon(\omega) \approx 1 - \frac{\omega_p^2}{\omega^2} \qquad [32]$$

ε is negative for small frequencies ω, $\varepsilon = 0$ at $\omega = \omega_p$, and approaches 1 for values smaller than 1 for large ω.

The negative values of ε are responsible for the high reflectivity. In eqn [19] l is purely imaginary and $r = 1$ in [23] and [25] because the numerator and denominator are a conjugate complex. The imaginary l says that the electromagnetic waves do not travel inside the metal, but the fields decay exponentially with the penetration depth

$$d = \frac{1}{|l|} = \left|\left(\frac{\omega^2}{c^2}\,\mu\varepsilon\right)^{1/2}\right|^{-1} = \frac{\lambda_0}{2\pi|\varepsilon^{1/2}|} \qquad [33]$$

much smaller than the vacuum wavelength λ_0. At very low frequencies, ε is determined by γ (eqn [31]), varies little, and d decreases with growing frequency ("skin effect"). There is a turnover ("anomalous skin effect") when $|\varepsilon|$ decreases and approaches zero at ω_p (eqn [32]). At ω_p, l becomes real, the waves are transmitted inside the metal, and the metal becomes transparent.

This threshold of transparency, ω_p, is characterized by the density of conduction electrons in simple metals (eqn [29]). This transparency is not seen because the plasma frequencies lie in the near to far ultraviolet (for tables of plasma frequencies, see "Further reading" section).

Formally, metal optics is normally developed completely parallel to the optics of transparent media. Only the dielectric function is different. It is purely imaginary, $\sim\sigma$, in the infrared (eqn [13]), mainly real and negative in the visible (eqns [31] and [32]), has a zero at ω_p in the near ultraviolet beyond which the metal is transparent with an index of refraction smaller than 1 (eqn [32]). At frequencies below ω_p, electromagnetic fields decay exponentially inside the metal and the optical energy is reflected.

Due to the fact that ε always has some real and some imaginary part, the statements just made are approximate. Around ω_p, for instance, ε (eqn [31]) does not go exactly through zero, and there is a smooth transition from the wave vector $k = (\omega/c)\sqrt{\mu\varepsilon}$ being dominated by the imaginary part to the propagating frequencies with mainly real k, from the anomalous skin effect to transparency.

The approximation [27]–[32], essentially for nearly free electrons, does not work well for d-band transition metals or for the lanthanides. For these metals, a model must at least include a polarizable background leading to an additional χ_p as in eqn [13]. The screening by this background can shift the frequency for $\varepsilon(\omega) \approx 0$ drastically, for example, for silver, from $\hbar\omega_p = 9$ eV according to eqn [29] to the measured $\hbar\omega_p = 3.8$ eV.

In most frequency regions of interest in optics, one cannot determine the index of refraction $\tilde{n} = n(1 + i\kappa) = \sqrt{\mu\varepsilon}$ from the angle of refraction and from light attenuation (absorption). One has to use the information in reflection. The difference in reflectivity of s- and p-polarized light is exploited in ellipsometry. When linearly polarized light with an (equal) s- and

p-component is reflected from a metal surface, there generally appears a difference in phase and amplitude of the reflected components leading to elliptical polarization in the reflected beam. Measurements of the ellipse, the rotation angle of the main axis, and the difference of the two main axes, allow the determination of the real and imaginary part of $\tilde{n}$ or ε, because the reflection amplitudes eqns [22] and [24] contain the relations. The realm of variation of the phase on reflection can be easily estimated from the reflection amplitudes [22] and [24]. The transversality means $R_x = (q/k_x)R_z$ and $E_{0x} = -(q/k_x)E_{0z}$, $R_x/E_{0x} = -R_z/E_{0z}$. Then for normal incidence ($k_x \to 0$), s- and p-reflection amplitudes are the same:

$$\frac{R_x}{E_{0x}} = \frac{\sqrt{\varepsilon_1\mu_M} - \sqrt{\varepsilon_M\mu_1}}{\sqrt{\varepsilon_1\mu_M} + \sqrt{\varepsilon_M\mu_1}} \approx \frac{\tilde{n}_1 - \tilde{n}_M}{\tilde{n}_1 + \tilde{n}_M}$$
$$(\text{for } \mu_1 \approx \mu_M \approx 1 \text{ and } \tilde{n} = \sqrt{\varepsilon}) \qquad [34]$$

If the angle of incidence grows up to glancing incidence ($q \to 0$), the limits are: for p-polarization $R_x/E_{0x} \to 1$, for s-polarization $R/E_0 \to -1$, that is, a phase difference of π. Therefore, one can expect an angle θ, called "the principle angle of incidence," at which the phase difference is $\delta = \pi/2$, that is, circularly polarized light is reflected as linearly polarized. This angle for metals is reminiscent of the Brewster angle for nonmetallic reflectors, which is seen when the numerator in the p-reflection amplitude eqn [22] is zero. Strongly negative ε_M prohibits such a zero. A Brewster angle is also found for metals in the transparent region beyond ω_p, when the imaginary part of ε is small.

The measured effective dielectric functions ε or indices of refraction $\tilde{n}$ of many metals for different frequency regions can be found in several tables (see the "Further reading" section).

Because metal optics is often studied with very thin metal layers, it may be mentioned again that the distinction between nonpropagating and propagating waves is not sharp because l in eqn [19] always has a real and an imaginary part due to the complex ε. Formally, the fields inside the metal and the transmitted field are calculated as in standard optics : general solution on top, general solution inside, general solution below, and the four amplitudes (reflected, down and up inside, transmitted) determined from the four boundary conditions, [20] and [21] at each surface. This yields the exact fields everywhere. There is no use in summing an infinite series of scatterings from the top and bottom of the layer (and approximating this summation by one or two reflections).

The metal optics described so far is essentially a summary of the relevant chapters in the famous book of Born and Wolf, where extensions and details can be found (see the "Further reading" section).

Surface Plasmon Polaritons

In the region where $\varepsilon < 0$, the reflection amplitude eqn [22] has no zero in the numerator, therefore there is no Brewster angle; but the denominator can be zero (eqn [35]). For those values of ω and k_x, there can be reflected and transmitted amplitudes when the incident field vanishes: one finds eigensolutions of the system, which are called surface polaritons or surface plasmon polaritons (SPP) or surface plasmons. Their dispersion relation ω_s ($k_{\text{tangential}}$) or $k_{tg}(\omega_s)$ is found from eqns [22] and [19]:

$$\varepsilon_M(\omega_s)\sqrt{\frac{\omega_s^2}{c^2}\varepsilon_1\mu_1 - k_{tg}^2} + \varepsilon_1\sqrt{\frac{\omega_s^2}{c^2}\varepsilon_M(\omega_s)\mu_M - k_{tg}^2} = 0 \qquad [35]$$

$$k_{tg} = \frac{\omega_s}{c}\sqrt{\frac{\varepsilon_M(\omega_s)\varepsilon_1}{\varepsilon_M(\omega_s) + \varepsilon_1}} \quad (\mu_M = \mu_1 = 1) \qquad [36]$$

The SPP dispersion relations [35] and [36] are best discussed with ε approximated by eqn [32]. For small frequencies ω_s, an expansion with respect to ω_s/ω_p yields

$$k_{tg} = \frac{\omega_s}{c}\sqrt{\varepsilon_1}\left(1 + \frac{1}{2}\varepsilon_1\frac{\omega_s^2}{\omega_p^2}\right) \qquad [37]$$

while $k_{tg} \to \infty$ when the denominator in [36] goes to zero at

$$\omega_s \to \frac{\omega_p}{\sqrt{1+\varepsilon_1}} \text{ or } \omega_s \to \frac{\omega_p}{\sqrt{2}} \quad (\text{for } \varepsilon_1 = 1) \qquad [38]$$

Solutions of eqn [36] for small k_{tg} and $\omega > \omega_p$ are not eigenmodes but indicate the Brewster angle. The dispersion relation for the SPP is shown schematically in **Figure 1**.

One essential point is that $k_{tg} > (\omega_s/c)\sqrt{\varepsilon_1}$ (see eqn [37]), that is, the wavelength of the SPP is shorter than the wavelength of light at the same frequency in the medium 1 above the metal surface, the eigenmode lies "to the right of the light line $k = (\omega/c)\sqrt{\varepsilon_1}$." Therefore, according to eqn [19], the z-components q and l of the wave vector of the surface wave are imaginary; the electromagnetic fields decay exponentially toward both sides of the surface. The excitation energy in the eigenmode is bound to the surface and does not radiate away. On the other hand, this eigenmode cannot directly couple to, or be

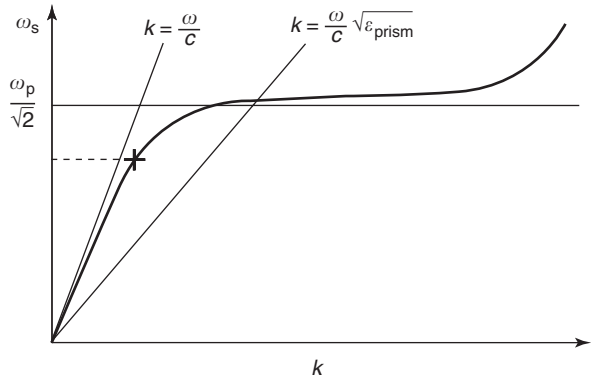

Figure 1 The surface plasmon dispersion. At "+" the wave in a prism can couple to the SPP in an ATR configuration.

excited by the light incident on the surface, because even for grazing incidence, k_{tg} of the light is too small; the periodicity parallel to the surface does not match the one of the SPP. At very large k_{tg}, the eigenfrequency rises above the limit of eqn [38] in **Figure 1**. This is a real plasma effect and is treated in the following section.

These eigenmodes were first derived by Zenneck and Sommerfeld, who explained the transmission of radio waves along the ocean surface. At metal surfaces, they were first seen as energy losses of electrons scattered from metal layers. In optics, it is possible to couple to the SPP if the incident light comes through a prism which shortens λ or increases k. In **Figure 1**, the SPP dispersion is shown for a metal surface towards vacuum or air ($\varepsilon_1 = 1$). Also indicated is the "light line" $(\omega/c)\sqrt{\varepsilon_{prism}} = k$. For angles of incidence φ with

$$k_x = \sin\varphi \frac{\omega}{c}\sqrt{\varepsilon_{prism}} > \frac{\omega}{c} \qquad [39]$$

the light is totally reflected from the prism–air interface because l (eqn [19]) in air becomes imaginary. But when this prism surface is brought in close proximity to the metal surface, at the angle where k_x from [39] fulfills the dispersion relation of the SPP [36], the eigenmode is excited, it develops large fields, soaks up energy, and attenuates the total reflection of the prism. This attenuated total reflection (ATR) method has been widely used to study the SPPs as well as the properties of layers adsorbed on metal surfaces, because adsorbed layers shift the dispersion according to $\varepsilon_1 \neq 1$ in eqn [36]. The large fields near the metal surface, when the SPP is excited, have been used to excite molecules especially brought near the surface. On the other hand, a microscope has been built on the ATR principle in order to see structures in adsorbed layers, which appear in self-organized surface reactions. The SPP can be excited by one prism, then travel along the metal surface and be coupled out by a second prism, and the metal surface between the prisms can be manipulated.

The narrow coupling condition that k_x of the exciting light must fulfill the SPP dispersion eqn [36] is true when the metal surface is translationally invariant. Surfaces with some roughness or any local obstacles can scatter light especially strong near $\omega = \omega_p/\sqrt{1+\varepsilon_1}$, where the density of eigenmodes is very high. If a periodic structure is established on the metal surface, for example, a grid of grooves, the related reciprocal lattice vectors can be added or subtracted to k_{tg} in order to overcome the restrictions for SPP excitation. Then refolding of $\omega_s(k_{tg})$ and gaps due to Bragg diffraction apply as in electron band structures, and there appear possibilities for coupling the SPPs to incident light. Also any irregularities, roughness, adsorbed molecules or metal clusters, which break the translational invariance of the surface, make excitation of surface modes possible. These often lead to extremely large fields around the imperfections. An example is surface-enhanced Raman scattering (SERS) from adsorbed molecules on silver.

Surface waves also play a role when light is transmitted through apertures smaller than the wavelength as in near-field microscopy. Recently, it was shown that light is transmitted through an array of narrow holes in a thick metal layer at a surprisingly large rate. Also, this phenomenon is explained via excitation of SPPs. The same mechanism leads to strong absorption at special frequencies in a system of grooves on a metal surface.

Generally, the excitation of SPPs leads to strong absorption of energy in the metal, to an attenuation of reflection, because the large fields of the eigenmode cause large currents and large losses in the metal. Occasionally, one finds high-energy transport at the excitation condition leading to strong scattering or even high transmission through narrow holes.

When the metal layer is thin enough, the two surfaces excite each other. Then the surface modes on both sides couple symmetrically or antisymmetrically, and the dispersion relations are changed.

Plasma Waves in Metal Optics

In 1953, Bohm and Pines discovered that the electrons in metals can sustain charge density waves with longitudinal electric fields. In an electron gas model of a metal, they found the dispersion relation for plasma waves:

$$\omega^2 = \omega_p^2 + \beta k^2 \qquad [40]$$

The Drude model (eqn [28]) leads to plasma oscillations. Taking the divergence of eqn [28] and using the continuity equation and eqn [9] yields

$$\ddot{\rho} = -\omega_p^2 \rho - \gamma \dot{\rho} \qquad [41]$$

that is, damped oscillations with the plasma frequency ω_p.

In addition to the electric field, the electrons are driven by a gradient in electron pressure, in density, in the local Fermi energy proportional to $(n_0)^{2/3}$. This pressure spreads out the electrons at metal surfaces and metal–metal interfaces leading to surface dipoles and contact potentials. In the Drude model, this additional force can be introduced by a term $-\beta\nabla\rho$:

$$\frac{\partial \boldsymbol{j}}{\partial t} = \omega_p^2 \varepsilon_0 \boldsymbol{E} - \gamma \boldsymbol{j} - \beta \nabla \rho \qquad [42]$$

The coefficient $\beta = (3/5)v_F^2$ in a free electron gas with Fermi velocity v_F^8. The expression for the high-frequency electron gas pressure was derived by Bloch. Equation [42] can be derived from a Boltzmann equation for the electron gas, and it is called the "hydrodynamic approximation" to a quantum mechanical treatment of the free electron gas. This extended Drude model describes plasma waves and makes it easy to include them in metal optics in the correct way.

First, the plasma waves are seen as eigensolutions of the system. Equation [41] is now supplemented to yield

$$\ddot{\rho} = -\omega_p^2 \rho - \gamma \dot{\rho} + \beta \nabla \cdot (\nabla \rho) \qquad [43]$$

which is solved by a wave with the plasmon dispersion [40] when the damping γ is neglected. The mode is a charge density wave (analog to a longitudinal acoustic density wave) with longitudinal electric fields $\boldsymbol{E} \| \boldsymbol{k}$. Transverse waves have necessarily $\rho = 0$ from eqn [9]. Therefore, the response, conductivity $\sigma_\perp$ and $\varepsilon_\perp$, is not affected by the new term in [42], and remains as in eqns [30] and [31]. But the longitudinal response is changed. For a plane wave pertubation $\sim e^{i(\boldsymbol{kr}-\omega t)}$, the continuity equation $(1/i\omega)\nabla \cdot \boldsymbol{j} = \rho$ replaces ρ in eqn [42], and for longitudinal fields and currents,

$$\sigma_\parallel(k,\omega) = \frac{i\omega\omega_p^2\varepsilon_0}{\omega^2 - \beta k^2 + i\omega\gamma} \qquad [44]$$

and with the general relation [13]:

$$\varepsilon_\parallel(k,\omega) = 1 - \frac{\omega_p^2}{\omega^2 - \beta k^2 + i\omega\gamma} \qquad [45]$$

The response functions are now dependent on frequency ω and wave vector $\boldsymbol{k}$. This is the so-called nonlocal response (in time and now also in space), which is familiar in nonlocal metal optics.

What do Maxwell's equations tell one about longitudinal waves? Equation [3] shows that longitudinal plasma waves have no magnetic induction field, $\boldsymbol{B} = 0$. On the other hand, the longitudinal wave is a homogeneous solution of the wave equation [12]:

$$\nabla(\nabla \cdot \boldsymbol{E}) - \Delta \boldsymbol{E} = \frac{\omega^2}{c^2} \mu \varepsilon_\parallel \boldsymbol{E} \qquad [46]$$

For a wave with $\boldsymbol{E} \| \boldsymbol{k}$, the left-hand side is zero and a nontrivial solution requires the general dispersion relation for plasmons

$$\varepsilon_\parallel(k,\omega) = 0 \qquad [47]$$

With eqn [45], neglecting the damping γ, [47] yields [40]. The hydrodynamic approximation (eqns [42], [44], and [45]) should be considered as the long wavelength, small k expansion of any sophisticated treatment of conduction electron response. For the purpose of optics, this approximation has been shown to be sufficient for the analysis of many experiments involving metal surfaces or metal layers at frequencies around the plasma frequency.

The longitudinal plasma waves are homogeneous solutions of Maxwell's equations according to eqn [46], and must therefore be included in the general solutions, which via boundary conditions yield the optical fields. Sauter was the first to point this out in 1964, and he suggested the third boundary condition, which is necessary at a free metal surface to determine the three amplitudes: of the reflected wave $\boldsymbol{R}$ (eqn [17]) and inside the metal of the transmitted transversal wave $\boldsymbol{T}$ (eqn [18]) and of the longitudinal wave $\boldsymbol{L}e^{i(k_x x + \eta z)}$, which completes the general solution [18].

Before the boundary conditions are discussed, the question of energy current is addressed. When it was brought up that the longitudinal waves should be excited on reflection at metal surfaces, it was objected that this additional channel of energy transport would have long been recognized if the suggestion was true. The wrong answer is that the plasma wave does not carry energy, because $\boldsymbol{B} = 0$ and therefore, the Poynting vector $\boldsymbol{S} = 0$. But the excitation of plasma waves becomes appreciable for frequencies of the order ω_p, which is in the UV where hardly any reflection measurements have been done. In addition, the energy current of the plasma wave is small

because of the very small group velocity of plasmons:

$$\frac{\partial\omega}{\partial k}\approx\beta\frac{k}{\omega_{\mathrm{p}}}\sim\frac{v_{\mathrm{F}}^2}{c} \qquad [48]$$

The extension of the material equation [42] leads to an extension of Poynting's theorem: By taking the dot product of eqn [3] with $\boldsymbol{H}$ and subtracting the dot product of $\boldsymbol{E}$ with eqn [3], one obtains

$$-\frac{\partial}{\partial t}\left(\frac{1}{2}\boldsymbol{E}\cdot\boldsymbol{D}+\frac{1}{2}\boldsymbol{H}\cdot\boldsymbol{B}\right)=\nabla\cdot(\boldsymbol{E}\times\boldsymbol{H})+\boldsymbol{E}\cdot\boldsymbol{j} \qquad [49]$$

Multiplying the material equation of motion [42] by $\boldsymbol{j}$, the terms can be rearranged with the help of the continuity equation

$$\omega_{\mathrm{p}}^2\varepsilon_0\boldsymbol{E}\cdot\boldsymbol{j}=\frac{\partial}{\partial t}\left(\frac{1}{2}\boldsymbol{j}^2\right)+\gamma\boldsymbol{j}^2+\nabla\cdot(\beta\rho\boldsymbol{j})+\frac{\partial}{\partial t}\left(\frac{1}{2}\beta\rho^2\right) \qquad [50]$$

which by replacing $\boldsymbol{E}\cdot\boldsymbol{j}$ in eqn [49] yields Poynting's theorem with plasma waves:

$$-\frac{\partial}{\partial t}\left(\frac{1}{2}\boldsymbol{E}\boldsymbol{D}+\frac{1}{2}\boldsymbol{H}\boldsymbol{B}+\frac{1}{2\omega_{\mathrm{p}}^2\varepsilon_0}\boldsymbol{j}^2+\frac{1}{2\omega_{\mathrm{p}}^2\varepsilon_0}\beta\rho^2\right)=\nabla\cdot\left(\boldsymbol{E}\times\boldsymbol{H}+\frac{1}{\omega_{\mathrm{p}}^2\varepsilon_0}\beta\rho\boldsymbol{j}\right)+\frac{\gamma}{\omega_{\mathrm{p}}^2\varepsilon_0}\boldsymbol{j}^2 \qquad [51]$$

On the left-hand side, the kinetic energy density of the electron current and the potential energy density connected with the density perturbation against the electron gas pressure are found. On the right-hand side, one has the energy current density in the plasma wave and the positive definite energy absorption due to the friction coefficient γ.

The problem of "additional boundary conditions" is taken up next. At first, the total response is described by ρ and $\boldsymbol{j}$, that is, formally $\chi_{\mathrm{p}}=0,\ \boldsymbol{P}=0$. It has been mentioned already after eqn [21] that the standard boundary conditions, $D_{\mathrm{eff,n}}$ and H_{tg} continuous, imply a discontinuity in E_{n} caused by singular surface charges, and from eqn [8], the denial of singular surface currents. With $\boldsymbol{j}=\sigma\cdot\boldsymbol{E}$, one also gets a finite normal component of the current up to the surface, which then disappears in a singular sink or source of charge in the surface plane. In nonlocal optics, the charges and currents are treated seriously in the plasma waves, and especially singular charges would lead to infinite pressures in eqn [42]. The model of the surface must be improved. Singular surface charges can only be avoided if the normal component of the current $\boldsymbol{j}$ is continuous (zero at a free surface). With finite charge densities everywhere, the normal component of $\boldsymbol{E}$ is also continuous. These two independent conditions replace the continuity of $D_{\mathrm{eff,n}}$, which is then a consequence. Continuous $\boldsymbol{E}$ and continuous $\boldsymbol{D}_{\mathrm{eff}}$ does not contradict eqn [13], because σ and ε are now tensors with $\varepsilon_\perp\neq\varepsilon_\parallel$.

At an interface with metal only on one side, one has one reflected wave amplitude in the dielectric, and a transverse and a longitudinal wave amplitude in the metal to be determined via three boundary conditions:

(a) continuity of $E_{\mathrm{tangential}}$ [52]

(b) continuity of E_{normal} [53]

(c) $j_{\mathrm{normal}}=\sigma_\perp E_{\perp\mathrm{normal}}+\sigma_\parallel E_{\parallel\mathrm{normal}}=0$ [54]

For the interface between two metals, a fourth amplitude via a fourth boundary condition must be determined because there are plasma waves in both metals. A reasonable requirement is that the interface should not be a singular sink or source of energy. This plausible assumption for our surface model leads to the continuity of the normal component of the energy current; so the boundary conditions at a metal–metal interface are

(a) continuity of $E_{\mathrm{tangential}}$ [55]

(b) continuity of E_{normal} [56]

(c) continuity of $j_{\mathrm{normal}}=\sigma_\perp E_{\perp\mathrm{normal}}+\sigma_\parallel E_{\parallel\mathrm{normal}}$ [57]

(d) continuity of $\frac{\beta}{\omega_{\mathrm{p}}^2\varepsilon_0}\rho=\frac{\beta}{\omega_{\mathrm{p}}^2}\nabla\cdot\boldsymbol{E}=\frac{\beta}{\omega_{\mathrm{p}}^2}\boldsymbol{k}_\parallel\cdot\boldsymbol{E}_\parallel$ [58]

The conductivity $\sigma_\perp$ for transverse fields is also from eqn [42] equal to eqn [30], and $\varepsilon_\perp$ is given by eqn [31]. With (a), (b), and (c), the Poynting vector is continuous; so the requirement [58] suffices to make the total normal energy current continuous. All boundary conditions lead to linear equations for the determination of the reflection and transmission amplitudes, therefore to no complication, in principle, compared to standard optics.

In this treatment of plasma waves in optics, the response functions $\sigma_\parallel$ and $\varepsilon_\parallel$ are dependent on frequency ω as well as on wave vector k or wavelength; hence, this kind of optics is called nonlocal optics. Equation [42] says that the current at r is not only driven by the electric field at $\boldsymbol{r}$ (local relation), but the

charge density in the neighborhood determines the other force $\sim\nabla\rho$. Charge density waves with larger gradients, larger k, oscillate faster according to eqn [40]. The standard local optics is an approximation which neglects charge densities altogether and does not treat the singular surface charges consistently which eqn [21] implies. This standard approximation is simpler and sufficient as long as the charge densities are small. At frequencies of the order of the plasma frequency, the charge densities get large due to resonant eigenmodes and must be treated consistently. The nonlocal optics can lead to results qualitatively different from standard optics and in agreement with the experiment.

A few examples of this nonlocal metal optics are discussed next. One can understand at the beginning that only when there are normal components of $\boldsymbol{E}$, normal currents leading to oscillating charge densities near the surface, a plasma wave is optically excited. Therefore, only for p-polarization with the electric field parallel to the plane of incidence, this nonlocal extension of optics is necessary, and the plasmon gets a nonzero amplitude $\boldsymbol{L}$.

In the case of reflection from a free metal surface, the extension of the treatment in eqns [17]–[23] takes the steps: the outgoing general solution [18] inside the metal is supplemented by the plasma-wave $+\boldsymbol{L}e^{i(k_x x+\eta z)}$ with η from

$$\varepsilon_{\parallel}=0=1-\frac{\omega_p^2}{\omega^2-\beta(k_x^2+\eta^2)+i\omega\gamma} \qquad [59]$$

and with

$$\eta=\sqrt{\frac{1}{\beta}[\omega(\omega+i\gamma)-\omega_p^2]-k_x^2} \qquad [60]$$

and for the longitudinal wave

$$L_x/L_z=k_x/\eta \qquad [61]$$

The three boundary conditions [52]–[54] lead to three linear equations and to the reflection amplitude

$$\frac{R_z}{E_{0z}}=\frac{\varepsilon_\perp q-l+(\varepsilon_\perp-1)k_x^2/\eta}{\varepsilon_\perp q+l-(\varepsilon_\perp-1)k_x^2/\eta} \qquad [62]$$

with $\varepsilon_\perp=\varepsilon_M$ and q, l from eqns [31], [19], and $\varepsilon_1=1,\ \mu_M=\mu_1=1$. The limit $\beta\to 0$ leads back from [42] to local [28], in [60] to $\eta\to\infty$, and from [62] back to [22]. The difference between $r=|R_z/E_{0z}|^2$ from [62] and from [22] is shown in **Figure 2**. The excitation of plasma waves really reduces the reflectivity, but only above the plasma frequency and by a small amount. This case was outlined to demonstrate that this extension of metal optics is straightforward.

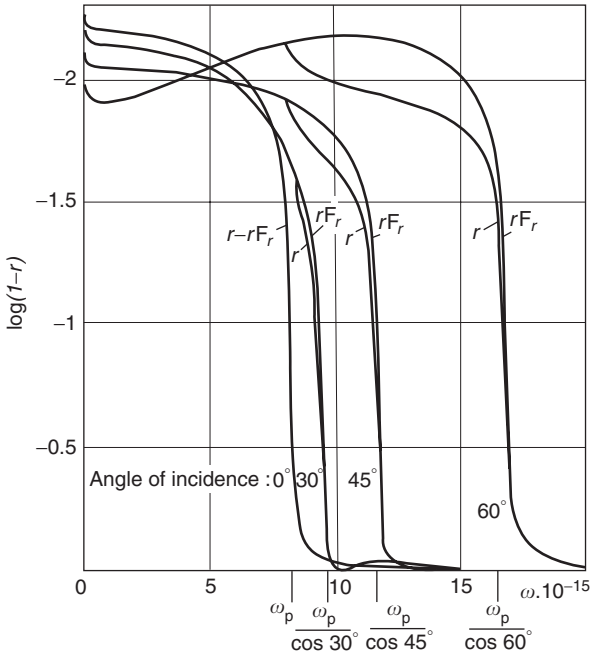

Figure 2 The reflectivity r with plasma waves, r_{Fr} standard Fresnel formula.

As in the previous section, one finds from the zero of the denominator of the reflection amplitude [62], the dispersion relation of the surface plasmon polariton

$$\varepsilon_\perp q+l-(\varepsilon_\perp-1)k^2/\eta=0 \qquad [63]$$

For low frequencies, the last term of the order of $k(v_F\omega/c\omega_p)$ can be neglected and the dispersion agrees with [35]. But for $k\approx(\omega/c)(c/2\sqrt{\beta})^{1/3}$, the frequency of the eigensolution [63] rises above $\omega_p/\sqrt{2}$, which was the limit for [35]. The approximate dispersion in this frequency range is from eqn [63]:

$$\omega_s\approx\frac{\omega_p}{\sqrt{2}}+k\frac{\sqrt{\beta}}{2} \qquad [64]$$

This linear dispersion is often extrapolated toward $k=0$. In optics, this is wrong because then, the light line is crossed and light could couple to the eigenmodes which is not the case. For larger k, the increase of ω_s is stronger than linear which is indicated in **Figure 2**. This dispersion describes the essential facts of the experiments. Only the linear rise [64] is usually suppressed to a plateau due to a skin effect before the final rise, when at large k the electron gas pressure dominates.

The dispersion relation [64] was derived when Ritchie discovered this surface mode in 1957 from an electrostatic approximation to Maxwell's equations

($c \to \infty$) and called it the surface plasmon. When the charge densities in the plasma and Maxwell's equations are treated correctly, it becomes clear that [35] and [64] are approximations to the dispersion [63] of a single kind of surface mode, which is then properly termed the "surface plasmon polariton" (SPP).

The reflection from a simple metal surface is changed so little by the inclusion of plasma waves in optics (**Figure 2**) that this is not the experiment to prove the necessity of nonlocal optics. The first relevant experiment was theoretically predicted by Melnyk and Harrison in 1968 and carried out by Lindau and Nilson in 1970. The transmittance through thin silver layers shows periodic minima when the plasma waves form standing waves in the layer and by the large amplitude, increase the absorption. It turns out that half a wavelength and even three and five halves of a wavelength fit into a layer of 100 Å. One can calculate from eqn [40] that this is the order of the plasma wavelength, while the transverse waves are more than ten times longer, so the experiment can only be explained by the optical excitation of plasma waves in the metal. Another example is shown in **Figure 3**. An electroreflection experiment measures the change in reflectivity $\Delta r/r$ when a strong (static or slowly oscillating) electric field changes the charge density at the metal surface. The optical calculations give qualitatively different results when standard local optics or nonlocal optics is employed. Only nonlocal optics describes the experiment. In the late 1970s and early 1980s, several examples were published with the same outcome (see the "Further reading" section.)

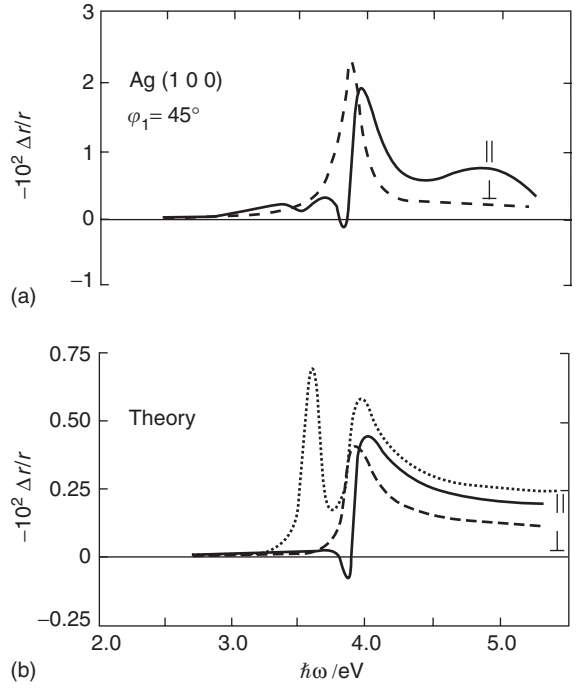

Figure 3 Electroreflection on silver. (a) Experiment for *s*-(⊥) and *p*-polarized (||) light. (b) Theory, (——) nonlocal optics, (....) standard optics.

One can draw the general conclusions: standard optics must be extended to nonlocal optics when the optical frequency ω is around the plasma frequency ($0.5\omega_p < \omega < 2\omega_p$) and when metallic layers, especially very thin ones (1–1000 Å), are involved. The nonlocal optics discussed in this article gives the right answers in these cases.

The treatment of plasma waves in optics in this section is designed for a free electron gas model of a metal, where the total response can be described as conduction electron current density and charge density. The parameters, electron density n_0 and damping γ, could be taken from a fit of a model (eqn [31]) to measure dielectric data. This is a good approximation for most metals except the *d*-band transition metals. But silver is one of the best candidates for demonstrating the effects of nonlocal optics because its plasma frequency is easily accessible just above the visible at $\hbar\omega_p = 3.8$ eV and the plasmons see little damping. The conduction electron density in silver is high and would lead to $\hbar\omega \approx 9$ eV from eqn [29]. $\varepsilon = 0$ is shifted to a lower frequency because of other "bound" electrons.

In such a situation, it has been successful to think of two responding electron systems, free and bound. The free conduction electrons follow eqn [42] while the bound ones are described by a polarizability χ_p. The total measured ε is then separated as in eqn [13]. An assumption of the conduction electron density (and the damping) allows the determination of χ_p from [13]. Then it is consistent to use in [53] and [56] the normal component of $\boldsymbol{D} = (1 + \chi_p)\varepsilon_0 \boldsymbol{E}$. This procedure was used for **Figure 3** and for many other comparisons with experiments on silver.

A final remark shall close this section: the response of a metal to electromagnetic fields is a vast field in solid-state theory where quite a number of theoreticians have invested their ingenuity. Here, a simple extension of standard optics was presented which can easily be applied by experimentalists also and has been successfully used for the analysis of several experiments. Around the plasma frequency, the predictions of nonlocal optics including plasma waves can be qualitatively different from the results of standard optics.

Magnetooptics

The response of metals as well as other materials to electromagnetic waves is determined by the forces

due to the electric field of the wave, because the Lorentz force due to the magnetic field is weaker by a factor $v/c < 1\%$ with electron velocity of the order of the Fermi velocity. Magnetooptics considers the interaction of light with external magnetic fields or strong magnetizations in ferromagnets.

A system with a magnetic field or magnetization acquires a special symmetry with respect to time inversion $(\boldsymbol{E}, \boldsymbol{B}, \boldsymbol{H}, \boldsymbol{M} \rightarrow \boldsymbol{E}, -\boldsymbol{B}, -\boldsymbol{H}, -\boldsymbol{M})$. Onsager's relations require

$$\varepsilon_{ij}(E, B, H) = \varepsilon_{ji}(E, -B, -H) \qquad [65]$$

Therefore, optical effects introduced by (proportional to) $\boldsymbol{B}$ or $\boldsymbol{M}$ manifest themselves as antisymmetric tensor components in an otherwise symmetric dielectric tensor $\hat{\varepsilon}$.

It is briefly shown that an external magnetic field leads to antisymmetric ε-components in an extension of the Drude model (eqns [27] and [28]) and that the consequence in optics is a difference in index of refraction for right and left circularly polarized waves. This leads to the Faraday rotation of the plane of polarization for linearly polarized light in transmission and to the Kerr rotation in reflection.

The Lorentz force $-e_0(\dot{\boldsymbol{r}} \times \boldsymbol{B}_0)$, in an external magnetic field $\boldsymbol{B}_0 = (0, 0, B_0)$ parallel to the z-axis, is added to the equation of motion [27]. To be more general, an elastic restoring force $-\omega_0^2 \boldsymbol{r}$ is also added (for free electrons in metals $\omega_0 \rightarrow 0$):

$$m\ddot{\boldsymbol{r}} = -e_0\boldsymbol{E} - m\gamma\dot{\boldsymbol{r}} - m\omega_0^2\boldsymbol{r} - e_0(\dot{\boldsymbol{r}} \times \boldsymbol{B}_0) \qquad [66]$$

With $\boldsymbol{r} \sim \exp(-\mathrm{i}\omega t)$ and $\boldsymbol{j} = -e_0 n_0 \dot{\boldsymbol{r}}$, one finds from [66] the conductivity tensor and obtains from eqn [13] the dielectric tensor:

$$\hat{\varepsilon} = \hat{1} + \omega_\mathrm{p}^2 \begin{pmatrix} a & \mathrm{i}b & 0 \\ -\mathrm{i}b & a & 0 \\ 0 & 0 & c \end{pmatrix}$$

$$= \varepsilon \begin{pmatrix} 1 & \mathrm{i}Q & 0 \\ -\mathrm{i}Q & 1 & 0 \\ 0 & 0 & \alpha \end{pmatrix} \qquad [67]$$

$$a = \frac{\omega_0^2 - \omega(\omega + \mathrm{i}\gamma)}{(\omega_0^2 - \omega(\omega + \mathrm{i}\gamma))^2 - \omega^2\omega_\mathrm{c}^2}$$

$$b = \frac{\omega\omega_c}{(\omega_0^2 - \omega(\omega + \mathrm{i}\gamma))^2 - \omega^2\omega_\mathrm{c}^2} \qquad [68]$$

$$c = \frac{1}{\omega_0^2 - \omega(\omega + \mathrm{i}\gamma)} \qquad [69]$$

$\omega_c = eB_0/m$ is the cyclotron frequency proportional to B_0. Due to the external magnetic field, one finds an antisymmetric tensor added to an otherwise symmetric $\hat{\varepsilon}$.

The dielectric tensor is now employed on the right-hand side of the wave equation [12]. For a wave traveling in the z-direction parallel to $\boldsymbol{B}_0$

$$\left(\frac{\omega^2}{c^2}\varepsilon - k^2\right)E_x + \mathrm{i}Q\varepsilon\frac{\omega^2}{c^2}E_y = 0$$
$$-\mathrm{i}Q\varepsilon\frac{\omega^2}{c^2}E_x + \left(\frac{\omega^2}{c^2}\varepsilon - k^2\right)E_y = 0 \qquad [70]$$

$$\left(\frac{\omega^2}{c^2}\varepsilon(1 \pm Q) - k^2\right)(E_x \pm \mathrm{i}E_y) = 0 \qquad [71]$$

which yields

$$k_\mathrm{r}^2 = \frac{\omega^2}{c^2}\varepsilon(1 + Q) \quad \text{for } E_x = \mathrm{i}E_y$$
(for right circular polarized light)

$$k_\mathrm{l}^2 = \frac{\omega^2}{c^2}\,\varepsilon(1 - Q) \quad \text{for } E_x = -\mathrm{i}E_y$$
(for left circular polarized light)

$$\text{or} \quad n_\mathrm{r} = \sqrt{\varepsilon}\left(1 + \tfrac{1}{2}Q\right) \quad \text{and}$$
$$n_\mathrm{l} = \sqrt{\varepsilon}\left(1 - \tfrac{1}{2}Q\right) \qquad [72]$$

The increase of the effective ε or polarizability for right circular polarization can be understood for the simple model (eqn [66]) from the direction of the Lorentz force which increases the radius of the circular electron motion. When light travels through a piece of matter of length L, the waves accumulate a phase difference of

$$\delta = (k_\mathrm{l} - k_\mathrm{r})L = \frac{\omega}{c}L(n_\mathrm{l} - n_\mathrm{r}) = -\frac{\omega}{c}LQ \qquad [73]$$

The Faraday rotation of the plane of linear polarization is $\delta/2$. Because Q is proportional to ω due to the Lorentz force, the Faraday rotation is proportional to ω^2.

Generalizations

The dielectric tensor is more generally expressed as

$$\hat{\varepsilon} = \varepsilon \begin{pmatrix} 1 & \mathrm{i}Q_z & -\mathrm{i}Q_y \\ -\mathrm{i}Q_z & 1 & \mathrm{i}Q_x \\ \mathrm{i}Q_y & -\mathrm{i}Q_x & 1 \end{pmatrix} \qquad [74]$$

by the "Voigt vector" $\boldsymbol{Q} = (Q_x, Q_y, Q_z)$.

Then in the refraction indices (eqn [72]), Q is generalized: $Q \rightarrow \boldsymbol{Q}\boldsymbol{k}/|\boldsymbol{k}|$, to the projection of $\boldsymbol{Q}$ on

the direction of propagation $\boldsymbol{k}$. In the model and in transparent materials, Q is mainly real and one finds the Faraday rotation due to the real phase shift (eqn [73]). In ferromagnetic metals, the magnetooptical effects are larger by several orders of magnitude, but here, mainly the absorption, the imaginary part of Q is changed by the magnetization leading to elliptically polarized light in general.

Because ferromagnetism is rooted in the electron spin, a microscopic explanation of the magnetooptical effects in ferromagnets involves the spin–orbit coupling of the electron motion and the unequal number of spins parallel and antiparallel to $\boldsymbol{M}$.

For the investigation of magnetic properties of metallic layers, the magnetooptical Kerr effect (MOKE) in reflection has been developed into an efficient tool. With strong lasers, nonlinear optical response is also exploited (for detailed information see the "Further reading" section).

"Left-Handed Materials," Optics for $\varepsilon<0$ and $\mu<0$

Charge carriers exposed to oscillating electric fields show, in some frequency region, negative polarizability as a forced oscillator has a phase shift of π above resonance. Therefore, in simple metals $\varepsilon<0$ below the plasma frequency (resonance frequency $\omega_0\to 0$) (eqns [31] and [32]). Then the index of refraction $n=\sqrt{\varepsilon}$ is imaginary, electromagnetic waves decay exponentially into the metal, do not propagate at all and the reflectivity goes to 1.

In 1968, V G Veselago pointed out that the wave propagation is really determined by the product $\varepsilon\mu$ (eqns [16] and [19]) and therefore, a system with $\varepsilon<0$ and $\mu<0$ in the same frequency region would be transparent again. One has, in principle, negative magnetic polarizability in diamagnets (due to Lenz's rule) but usually the polarizabilities χ_m are extremely small ($\sim 10^{-6}$), and the susceptibility $\mu=1+\chi_m$ deviates little from 1 and does not go below 0.

Recently materials with $\mu<0$ have been manufactured. Therefore, the surprising optical properties are outlined. The term "left-handed material" (LHM) derives from the fact that Maxwell's equations (e.g., (eqn [3])) for a plane wave $\boldsymbol{k}\times\boldsymbol{E}=\omega\boldsymbol{B}$ and $\boldsymbol{H}=(1/\mu_0\mu)\boldsymbol{B}$ usually make the vectors $\boldsymbol{k},\boldsymbol{E},\boldsymbol{H}$ a right-handed tripod, while with $\mu<0$ the tripod gets left-handed. Consequently, normally the energy current $\boldsymbol{S}=\boldsymbol{E}\times\boldsymbol{H}$ is parallel to the wave vector $\boldsymbol{k}$. In LHMs, the Poynting vector is opposite to $\boldsymbol{k}$.

Refraction at an interface between material I ($\varepsilon_I>0,\ \mu_I>0$) and material II ($\varepsilon_{II}<0,\ \mu_{II}<0$) puts the refracted beam in II on the opposite side of the surface normal than usual. Therefore, diverging rays in I can converge in II which led to speculations about perfect lenses by slabs of LHMs. This uncommon refraction can be understood as follows:

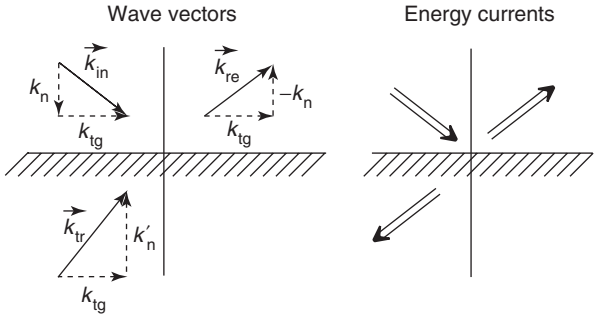

Figure 4 Refraction at a left-handed material.

$\boldsymbol{S}=\boldsymbol{E}\times\boldsymbol{H}$ is antiparallel to $\boldsymbol{k}$ in LHM II. Therefore, the correct homogeneous solution in II which carries the energy from the interface has a wave vector pointing towards the interface. The tangential components of all wave vectors are equal, so the refracted beam (i.e., the energy current) lies in II on the same side of the surface normal as the incoming beam in I (see **Figure 4**).

The subject of optics with LHMs has been revived after 2000 in connection with the investigation of the "optical" properties of conducting networks, three-dimensional wire mesh crystals. If the wavelength of the electromagnetic waves are much larger than the lattice spacing, the conducting network behaves like a metallic conductor with a low density plasma frequency and with a frequency region of negative ε according to eqn [32]. The necessary large diamagnetism is achieved by conducting rings in each cell of the lattice. In such a designed material, $\varepsilon<0$ and $\mu<0$ at frequency $\nu=10.5$ GHz, $\lambda\approx 3$ cm, was demonstrated with $\varepsilon\mu=7.28\pm i0.54$. It was shown that the refraction is indeed as in **Figure 4** (see the "Further reading" section).

Micro- and Macrostructures

G S Rohrer, Carnegie Mellon University, Pittsburgh, PA, USA

Introduction

A crystalline solid is made up of indistinguishable groups of atoms positioned at the sites of a Bravais lattice. If the atomic structure is approximately uniform in both orientation and composition throughout the solid, the material is referred to as a single crystal. When the atomic structure is not uniform, it is known as a polycrystal. In this second and more common instance, the irregularities in the orientation, composition, and configuration of the atomic structure collectively make up what is referred to as the internal structure or microstructure. The term macrostructure is sometimes used to refer to the largest components of the internal structure. Within this article, all components of the internal structure will be referred to as the microstructure.

Polycrystals can be thought of as aggregates of much smaller crystals joined together by a network of internal interfaces, as illustrated schematically in **Figure 1**. Within the aggregate, the individual crystals are referred to as grains. The interface that separates two grains of the same composition, but different lattice orientation, is called a grain boundary and the interface that separates two grains with different compositions is called a phase boundary. The granular nature of polycrystalline matter has been recognized since at least 1775 when Grignon sketched grains observed on the surface of a piece of fractured wrought iron. This first recorded observation points to an important feature of the interfaces within the microstructure: they are frequently points of internal weakness along which failure, by fracture or corrosion, propagates through the interfacial network. During the last century, microstructural studies have flourished amid the realization that many of the macroscopic properties of polycrystalline solids are strongly influenced by the internal structure. While these studies established the solid foundation of knowledge that will be reviewed in this article, it should also be recognized that there are many unresolved questions about microstructural genesis and the microstructure–property link that continue to be actively researched. In general terms, one can say that polycrystalline microstructures result from crystal nucleation, growth, and capillarity-driven morphological changes that lead to a reduction in the interfacial energy. In this article, the basic principles behind these processes will be described and examples of prototypical microstructures will be presented. The article will focus on dense, inorganic, polycrystalline microstructures that occur in man-made materials. Single-phase microstructures are discussed first and multiphased structures are described in the second section.

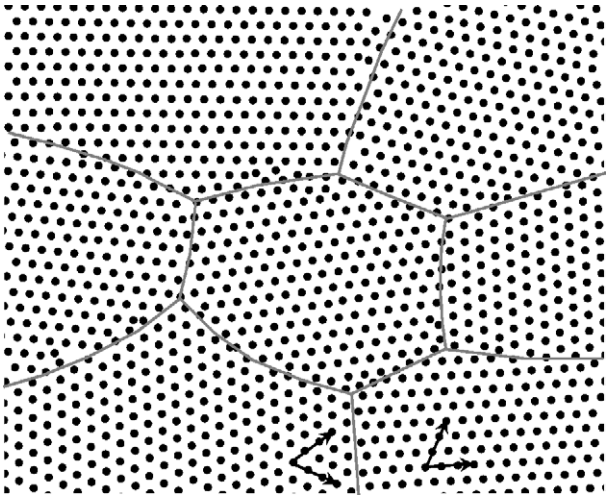

Figure 1 Schematic illustration of a polycrystalline solid, with black dots representing points on the lattice and gray lines denoting boundaries between grains with different orientations.

Single-Phase Microstructures

The term single-phase polycrystal is used to describe an aggregate of crystals that is uniform in its atomic structure and composition. Throughout a single-phase microstructure, it is only the orientation of the Bravais lattice within the individual grains that

differs. The defining elements of the microstructure are the distribution of crystal sizes, the distribution of crystal shapes, the distribution of crystal orientations, and the types of grain boundaries between the crystals. Single-phase microstructures can be formed by sintering a solid powder, by crystallizing a precursing liquid, gaseous, or amorphous phase, or by recrystallizing a deformed precursor. Microstructures resulting from each of these states are described briefly below.

Single-Phase Microstructures by Sintering

The excess free energy per unit area of a grain boundary (γ) can be thought of as the energy to create equal areas of the two free surfaces on either side of the boundary, minus a binding energy associated with the formation of bonds across the interface as the surfaces are joined. Therefore, as long as there is bonding across the interface, it is energetically preferable to replace two free surfaces with a grain boundary of the same area. This is the driving force for the process of sintering, in which individual crystalline particles change shape and bond with one another to form a dense polycrystal. Further heating after complete densification leads to grain growth, an increase in the average grain size. This too is a capillarity-driven process, because as the average grain size increases, the total grain-boundary area (and its associated energy) decreases. If the grain-boundary energy and mobility are not too anisotropic, then an equiaxed microstructure develops. In other words, each grain has approximately the same dimensions in all directions. An equiaxed microstructure is illustrated in **Figure 2**.

The shapes of the grains are determined in part by the relative rates at which the crystal grows in different directions (a kinetic effect), and in part by the requirement that the interfacial forces balance at their points of intersection (an equilibrium effect). The equilibrium equation for the point where three interfaces meet is known as the Herring condition:

$$\sum_{i=1-3} \gamma_i t_i + \frac{\partial \gamma_i}{\partial \beta_i} n_i = 0$$

The terms in this expression are described in **Figure 3**. Under the condition that the energy does not depend on orientation, this reduces to the more familiar Young equation

$$\frac{\gamma_1}{\sin \Psi_1} = \frac{\gamma_2}{\sin \Psi_2} = \frac{\gamma_3}{\sin \Psi_3}$$

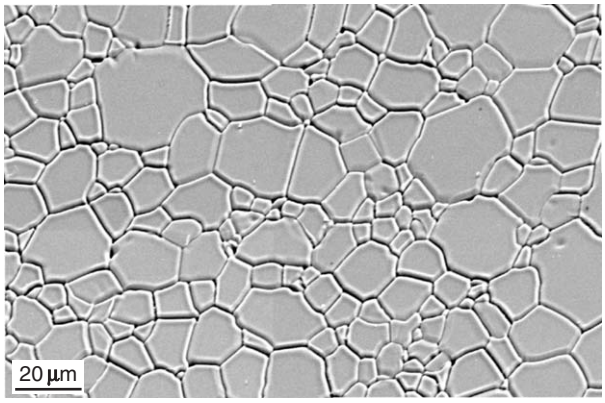

Figure 2 Montage of scanning electron microscope (SEM) images of spinel, $MgAl_2O_4$. The contrast at the grain boundaries results from thermal grooving.

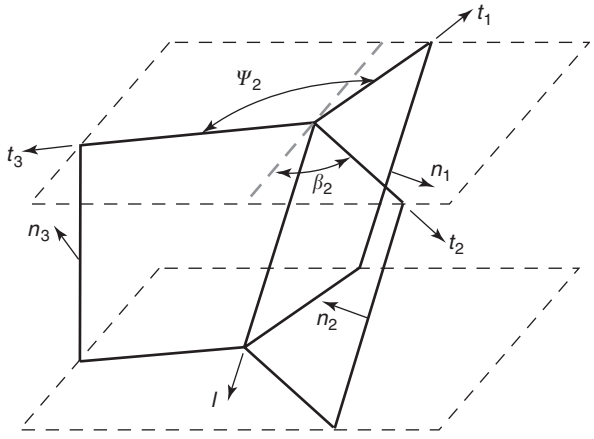

Figure 3 Schematic of the triple line (l) along which three interfaces meet, defining the terms in the Herring equation.

where the Ψ_i are the dihedral angles in **Figure 3**. If the energies of all the interfaces are assumed to be equal, then all of the dihedral angles are 120°. If this is the case, then dihedral angles at quadrajunctions where four triple lines intersect must be 109.5°. To meet these conditions and fill space, some curvature must be introduced in the boundaries and this creates a driving force for motion. Boundaries always move toward their center of curvature to reduce their total area. The situation was considered in two dimensions by von Neumann and Mullins, who showed that if equilibrium dihedral angles are to be maintained in an isotropic structure, then grains with more than six sides will always grow and grains with fewer than six sides will shrink (see **Figure 4**). While the problem is not easily solved in three dimensions, it is currently thought that grains with 13 or fewer faces shrink while those with 14 or more grow. Studies of three-dimensional shapes are consistent with this criterion. In a variety of studies, the average number of faces per grain has been measured to be

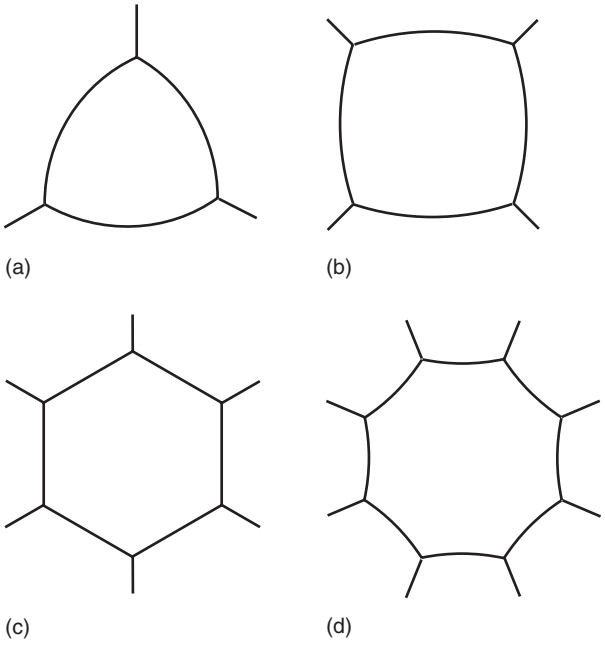

Figure 4 Schematic showing the configurations of boundaries in a two-dimensional system under the assumption that the grain boundary energy is isotropic. In this case, the boundaries must always meet with 120° dihedral angles. This means that if a grain has fewer than six sides, the boundaries are convex and will move inward ((a) and (b)), if it has exactly six sides there is no curvature and the boundaries are stationary (c) and if it has more than six sides (d) the boundaries are concave and move outward.

between 12 and 14. A sketch of a typical grain is shown in **Figure 5**.

Kinetic grain-growth theories generally predict that the average grain size increases with the square root of time (t) so that the average radius, $\langle r \rangle$, is

$$\langle r \rangle = (Kt)^n$$

where K is a positive constant and n, the grain-growth exponent, is ideally equal to 1/2. Furthermore, after the effects of the initial grain size distribution have disappeared, there is a steady-state distribution of grain sizes that is scale invariant. The form of the distribution, originally derived by Hillert, has a maximum grain size that is about 3/2 times the average size:

$$P_{\mathrm{H}}(\rho) = (2e)^3 \frac{3\rho}{(2-\rho)^5} \exp[-6/(2-\rho)]$$

In this equation, $\rho = r/r^*$, where r^* is the critical radius; grains smaller than r^* shrink while grains larger than r^* grow. The distribution is plotted in **Figure 6**. In practice, observed grain-growth exponents are usually less than 1/2, the maximum grain size greatly exceeds 3/2 times the average, and the distribution of

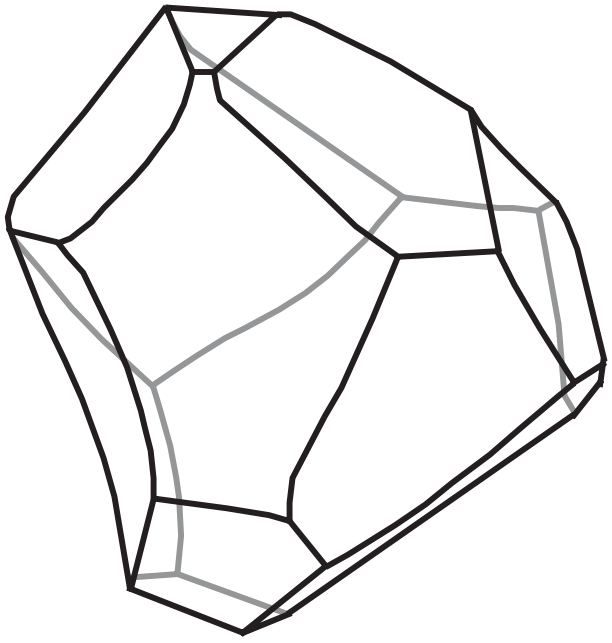

Figure 5 A schematic showing the three-dimensional shape of a grain within a polycrystal. The black lines are edges on the front of the grain and the gray lines are edges on the back of the grain.

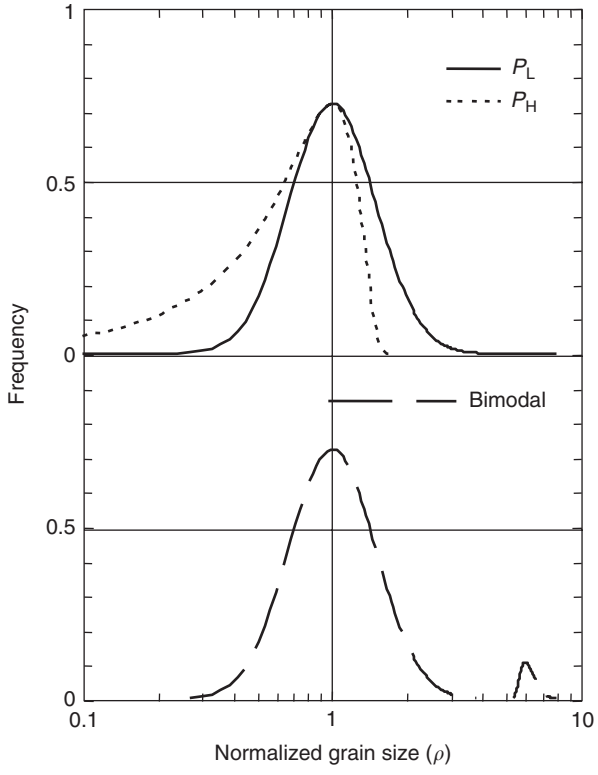

Figure 6 Grain size distributions. The most commonly observed distribution of grain sizes is lognormal (P_{L}) while the theory of capillary-driven grain growth predicts a different distribution (P_{H}). A schematic of a bimodal distribution is shown in the lower part of the figure.

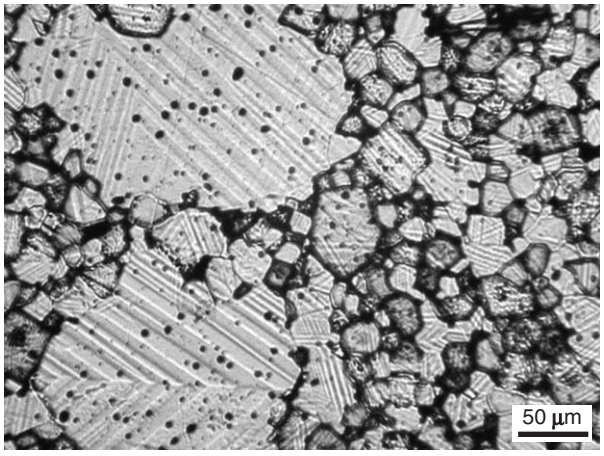

Figure 7 Visible light micrograph showing the microstructure of a polycrystalline $BaTiO_3$ specimen. Parts of two grains on the left are much larger than the cluster of average grains on the right. The regular patterns within each grain are twin plates that formed by a martinsitic transformation during cooling.

grain sizes is most frequently reported to be lognormal, where the number of grains with dimensionless size ρ is

$$P_{\mathrm{L}}(\rho) = \frac{1}{\sqrt{2\pi}\sigma}\frac{1}{\rho r^*}\exp\left[\frac{-(\ln \rho)^2}{2\sigma^2}\right]$$

In this expression, σ is the width of the distribution. Microstructures that exhibit unimodal and roughly lognormal distributions of grain sizes are usually called normal. However, in some cases the distribution of grain sizes is bimodal (see **Figure 6** for comparison to normal distributions) and such distributions are said to be the result of abnormal growth. An example of a microstructure with an abnormal distribution of grain sizes is illustrated in **Figure 7**.

When the anisotropy in the grain-boundary energy and mobility is large, the grains adopt distinct shapes and are frequently bounded by flat interfaces, indicating that the orientation corresponds to a cusp or singularity in the function that describes the orientation dependence of the grain-boundary energy. For example, the microstructure in **Figure 8** shows a section through randomly oriented plate-like grains. Depending on the processing, the shapes may also exhibit preferred orientation or texture, as illustrated in **Figure 9**. In this case, the [0 0 0 1] axes of the rhombohedral lattice of Al_2O_3 are oriented in the vertical direction. The general phenomenon of nonrandom distributions of crystal orientations with respect to the external reference frame, as illustrated in **Figure 9**, is referred to as texture.

Single-Phase Microstructures by Crystallization

When a microstructure forms by crystallization from a liquid, gas, or amorphous matrix, crystal nucleation requires the formation of an interface between the crystalline and noncrystalline phase. Assuming that the interface energy (γ_{s}) is isotropic and that the change in free energy per volume upon crystallization is ΔG_{v}, then the free energy change for the formation of a nucleus with radius r is given by

$$\Delta G(r) = 4\pi r^2\gamma_{\mathrm{s}} - \tfrac{4}{3}\pi r^3\Delta G_{\mathrm{v}}$$

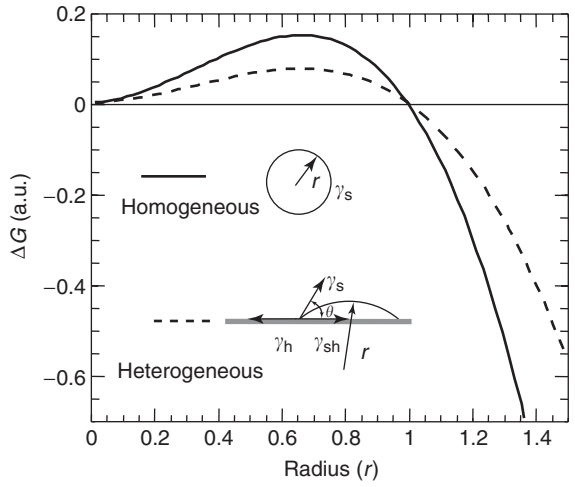

Figure 10 Plot of the free energy change as a function of nucleus radius. The change is initially positive. Additional growth reduces the energy only beyond a critical size. For heterogeneous nucleation, the barrier is lower.

As illustrated in **Figure 10**, the change in the free energy as a function r is initially positive. Only after a critical size is reached will further growth stabilize the crystal. Thus, there is an energy barrier, ΔG^*, that inhibits homogeneous nucleation. If a heterogeneous surface is present (e.g., the mould walls of a casting system or a substrate in a vapor deposition system), and there almost always is, then one not only has to consider the creation of the surface dividing the nucleus from the surrounding liquid or gas, but also has to consider the elimination of the heterogeneous surface and the creation of the interface between the nucleus and the heterogeneous surface. Using the Young equation, the relationship between the various interface energies can be expressed as a contact angle, θ, in the following way:

$$\cos\theta = \frac{(\gamma_h - \gamma_{sh})}{\gamma_s}$$

The terms in the equation above are defined in **Figure 10**, assuming the crystallization of a spherical cap on the heterogeneous surface. With this parameter, the free energy change for heterogeneous nucleation can be written in a form similar to that for homogeneous nucleation:

$$\Delta G(r) = \left[4\pi r^2\gamma_s - \tfrac{4}{3}\pi r^3 \Delta G_v\right] S(\theta)$$

where the shape factor is $S(\theta) = (2+\cos\theta)(1-\cos\theta)^2/4$. Since this term is always less than unity, the free energy change for heterogeneous nucleation is always less than that for homogeneous nucleation. Thus, crystal formation always initiates from a heterogeneity and most frequently from the walls of the container or a deliberately introduced substrate. This leads to so-called columnar microstructures, such as those illustrated in **Figures 11** and **12**. The microstructure in **Figure 11** results from nucleation and growth from the walls of a mould in a casting, and the microstructure in **Figure 12** results from the deposition of a vapor on a substrate. It should be recognized that heterogeneous nucleation can be initiated in a more or less uniform manner by introducing a finely dispersed heterogeneity and this can lead to an equiaxed microstructure. Uniform heterogeneous nucleation can also occur when a material is recrystallized from a deformed matrix.

Grain Boundaries in Single-Phase Microstructures

The complexity of the grain-boundary networks within polycrystals arises from the number of crystallographic degrees of freedom. Three parameters are required to describe the lattice misorientation between two crystals, and two additional parameters are required to describe the orientation of

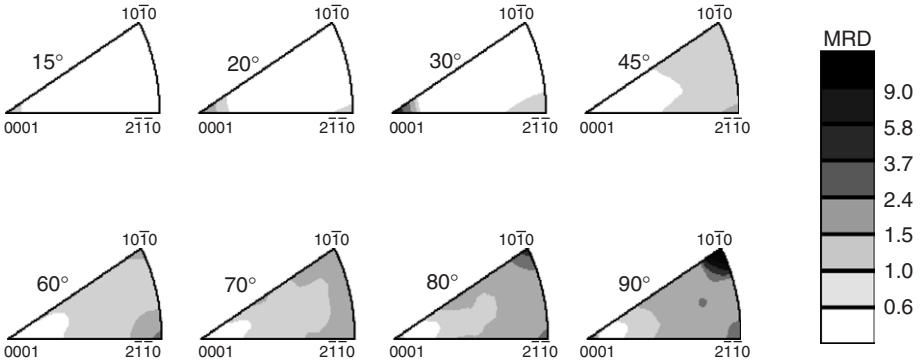

Figure 13 The grain-boundary character distribution in WC, plotted in axis-angle space. The entire range of distinguishable misorientation axes in the hexagonal system is represented in each triangle, and the individual triangles represent different rotations about these axes. The units are in multiples of a random distribution (MRD).

the grain-boundary plane. The number of distinguishable boundary types in this five-dimensional parameter space is large. For example, in a cubic material, if the five parameters are measured with 5° of resolution, then there are 5×10^4 distinguishable types of grain boundaries. In general, the distribution of grain-boundary surface area is not uniform over the five parameters. Textures have been measured both in the space of lattice misorientations and grain-boundary orientations. For example, **Figure 13** shows the distribution of lattice misorientations in WC, showing that boundaries with a 30° misorientation about [0 0 0 1] and a 90° misorientation about [1 0 $\bar{1}$ 0] occur with a higher and random frequency. These data are plotted without regard for the particular boundary plane. In **Figure 14**, the distribution of grain-boundary plane area is shown for the two highly populated misorientations identified in **Figure 13**. These data demonstrate that hexagonal WC has a preference for grain-boundary planes terminated on {0 0 0 1} and {1 0 $\bar{1}$ 0} surfaces.

While the mechanistic origin of the grain-boundary texture is not yet understood, it is known that the frequency with which different grain boundaries occur in a polycrystal is inversely related to the energy. Those boundaries with low energies or some other extraordinary property are thought to be especially influential in determining macroscopic properties. One such boundary is a twin. Twins in different materials have different crystallographic parameters, but the common feature is that they have a well-defined lattice misorientation and habit plane that allows the atoms within the interface to occupy positions that are very similar to those of the bulk. For example, in a cubic close-packed metal, a boundary formed between two crystals whose (1 1 1) planes are parallel, but rotated by 60° around the vector perpendicular to the boundary planes, is a twin. This particular boundary is only a minor disruption in the

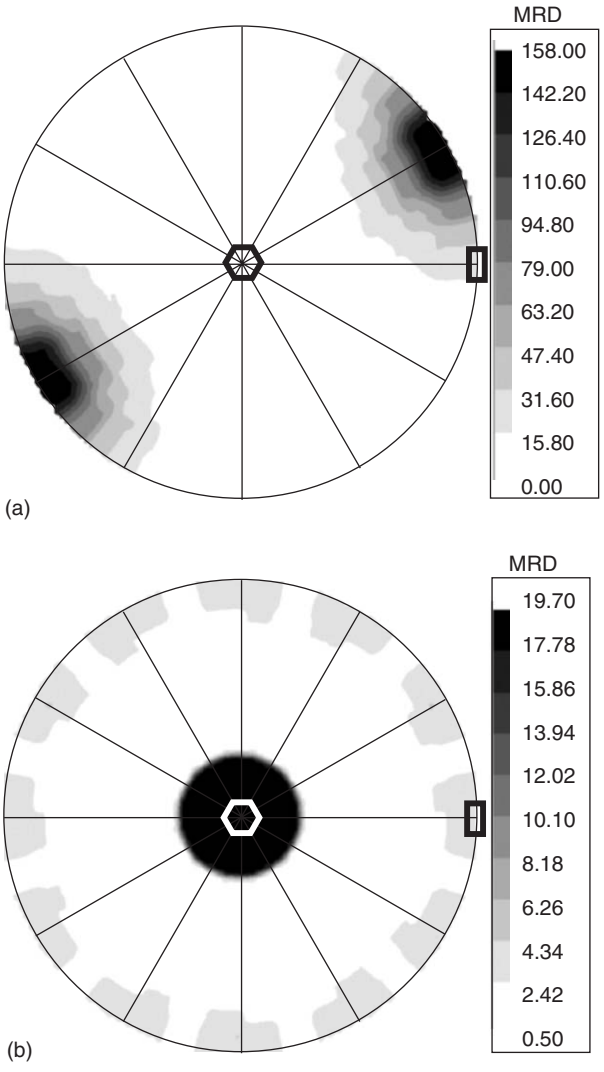

Figure 14 The distribution of grain-boundary planes at two specific misorientations: (a) for 90° rotations about the [1 0 $\bar{1}$ 0] axis and (b) 30° about the [0 0 0 1] axis. The hexagon marks the position of the [0 0 0 1] axis and the rectangle the position of the [1 0 0 0] axis. The positions of the peaks indicate that for both types of grain boundaries, the pure twist configuration is preferred.

long-range structure and is indistinguishable from a stacking fault. All of the atoms in the boundary plane still have 12 nearest neighbors in the same pattern; it is only the configuration of the next near neighbors that differs. This special condition occurs only on this one plane, so it is energetically very costly to rotate this boundary away from the (1 1 1) orientation. While the crystallography varies from system to system, this is a common feature and as a result, twins are very flat, planar boundaries without noticeable curvature. Because a twin has a low energy, the dihedral angle it makes with other more general grain boundaries is usually very close to 180°. These are the geometric characteristics that make twins easy to locate in a microstructure.

In cubic close-packed metals, twins commonly form during recrystallization. An example of a highly twined alpha brass microstructure is illustrated in **Figure 15**. In tetragonal materials, if there is only a small difference between the *a* and *c* lattice parameters, then mosaic twinning is common. A twinned $BaTiO_3$ structure is illustrated in **Figure 16** (this is a higher-resolution image of the twins that were evident in **Figure 7**). This material has a tetragonally distorted perovskite structure with a *c* to *a* ratio of 1.01. The straight boundaries all correspond to 90° rotations about a ⟨1 0 0⟩ axis with the boundary on a {1 1 0} plane.

Boundaries with misorientations that place a high fraction of lattice sites in coincidence are also distinguished from more general boundaries. These boundaries are called coincident site lattice boundaries and are assigned a coincidence number (Σ) based on the inverse of the number of coincident lattice sites. Therefore, a low Σ number signifies high coincidence. For example, illustrations of the Σ5 and Σ13 boundaries are presented in **Figure 17**. In many circumstances, boundaries of high coincidence are also referred to as "special" boundaries, although the term is not always used in a consistent manner. Note that while the coincidence relation depends only on the lattice misorientation, high coincidence is only achieved if the boundary lies on certain planes where the lattice sites overlap. Therefore, of all boundaries with a low Σ misorientation, only those with the interface planes oriented in a specific direction are expected to have special properties. The twin in the cubic close-packed system is a good example. This corresponds to a boundary with a 60° misorientation about the [1 1 1] axis, with the boundary on a (1 1 1) plane. The designation Σ3 refers to the same misorientation, but does not specify the boundary plane.

Boundaries with low Σ misorientations have recently taken on a special significance because it has

been found that certain material properties are improved by increasing the fraction of these low Σ boundaries, particularly those known as $\Sigma 3^n$, including Σ3, Σ9, and Σ27. In cubic close-packed materials with low stacking fault energies, such as Cu, Ni, and Pb, the fractional population of $\Sigma 3^n$ boundaries can be increased by the process referred to as grain-boundary engineering. In this process, the materials undergo repeated cycles of mild deformation followed by recrystallization. After each cycle, the concentration of $\Sigma 3^n$ boundaries increases. The micrograph in **Figure 15**, discussed above, shows an example of a grain-boundary engineered microstructure in which approximately 45% of the boundaries are of the type $\Sigma 3^n$. As the special boundaries increase in concentration, they break up percolating clusters of general boundaries that are more susceptible to failure.

Duplex Microstructures

Duplex microstructures contain two distinct phases, which are materials that can be distinguished on the basis of structure or composition. In principle, a microstructure may contain many different phases, but the discussion here is limited to the case of two phases. The defining elements of the two-phase microstructure are the same as in the single-phase microstructure, only it is also necessary to characterize the configuration of the two phases and the volume fractions. As in the single-phase microstructures, the configuration is determined both by equilibrium phenomena and kinetic phenomena. Because of the added complexity, there is a wider range of possibilities. Selected cases are discussed in the following sections.

Duplex Microstructures Formed by Consolidation

The most direct method to create a duplex microstructure is to physically mix the two phases and then consolidate the mixture by sintering. The degree to which the two phases wet each other strongly influences the configuration. Referring once again to the Young equation, the equilibrium geometry at the points where the phases meet is a function of the interfacial energies. If one labels the phases A and B, and assumes that their interface energies are isotropic, then the dihedral angle between the two AB interfaces (see **Figure 18**) is given by

$$\cos(\Psi) = \gamma_{AA}/2\gamma_{AB}$$

Note that when $2\gamma_{AB} \ll \gamma_{AA}$, the dihedral angle goes to zero and in this case the two phases completely

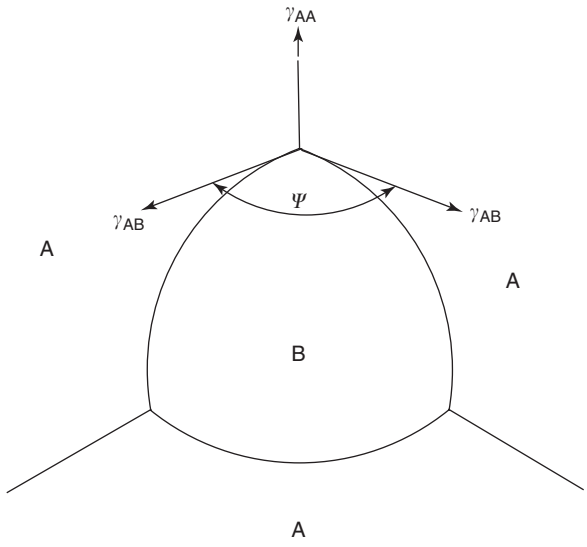

Figure 18 Schematic of the interfacial equilibrium at the point where phase B meets three grains of phase A. The dihedral angle, Ψ, is a measure of the relative interfacial energies.

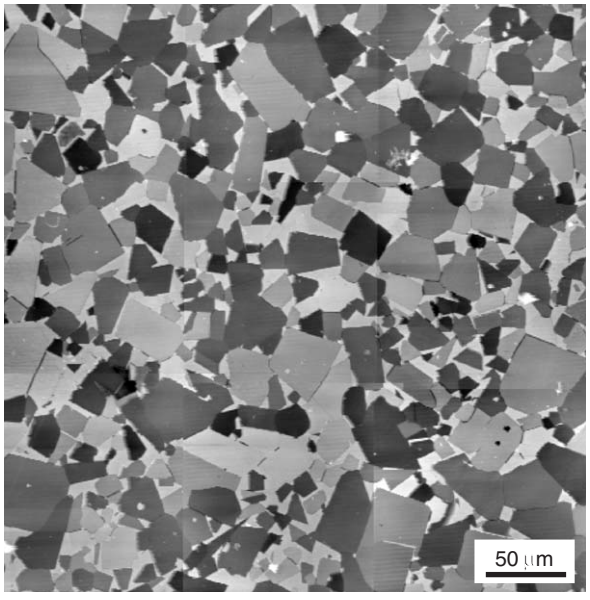

Figure 19 Montage of topographic AFM images of a WC/Co surface. The surface was etched in such a way that the WC crystals were attacked preferentially, and they appear as the darker contrast. The Co matrix has the lightest contrast.

wet each other. As γ_{AB} approached γ_{AA}, the two phases become increasingly nonwetting and the dihedral angle increases toward 120°. Two examples are shown in **Figures 19** and **20**. In **Figure 19**, Co, which is liquid at the processing temperature, completely wets the angular WC crystals. In this case, the WC crystals occupy 90% of the volume and form an interconnected, skeletal network. The aluminum

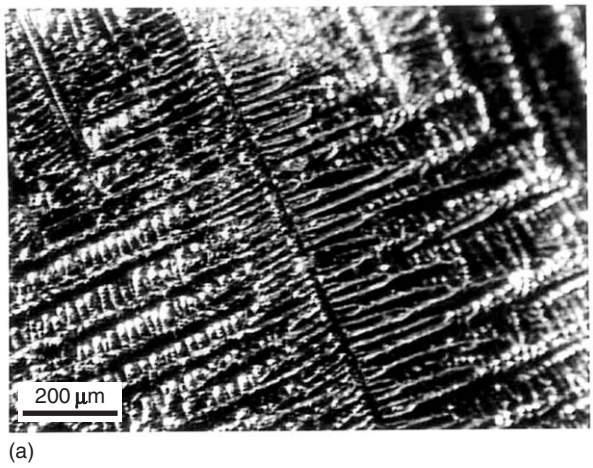
oxide–tanatalum oxide mixture in **Figure 20** provides an example of a nonwetting combination. The dark grains are the Al-rich phase which poorly wets the Ta_2O_5 boundaries.

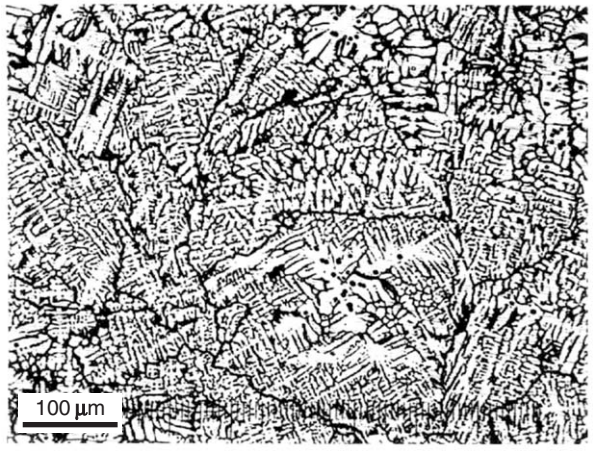
Duplex Microstructures by Solidification

When microstructures form by the solidification of a homogeneous liquid, the phases are not as uniformly dispersed as when formed by a physical mixture followed by consolidation. Interestingly, well-defined patterns can develop under these conditions. When a single-phase liquid is crystallized in a two-phase region where a solid and liquid phase coexist, one of the most common morphological patterns to develop is the dendrite, or branched structure, as illustrated by the microstructures in **Figures 21** and **22**. It should be noted that while dendrites can also form during the solidification of a pure material into a supercooled liquid, this situation is far less common than that of the binary alloy. For the single-phase case, one can imagine that protrusions in the growth front can be stabilized if the liquid is supercooled and the latent heat of crystallization is extracted through the solid. In this case, heat is removed more efficiently from the tip of the protrusion that juts out into the supercooled fluid than it is from the valleys between protrusions.

To describe the mechanism by which dendrites form in a binary alloy, consider the simple binary eutectic phase diagram illustrated in **Figure 23**. For an alloy with composition C at a temperature less than T_L, there is a range of temperatures where the solid and liquid coexist, but with different compositions.



(a)



(b)

Figure 21 (a) A dendrite observed on the surface of an Al-4.5 wt.% Cu casting. (b) A section through the same casting, illustrating the appearance of random sections through the network of Al dendrites. The dark contrast is the Cu-rich phase.

The solid alloy α has composition C_α and always contains less B than the liquid, with composition C_L. In fact, one can say that the solid is always relatively more pure than the liquid from which it crystallizes. This means that as the crystal grows, the liquid at the interface is relatively enriched in B and that the enriched liquid freezes at a lower temperature, specified by the liquidus line in **Figure 23**. Therefore, a protrusion in the interface can be stabilized because it juts into a relatively more pure liquid (see **Figure 24**). In the valleys between protrusions, on the other hand, the liquid rich in B is trapped between opposing growth fronts. Thus, the growth front at the tip of the protrusion is in contact with a liquid that freezes at a higher temperature than the liquid in the valleys between the protrusions. This causes the tip to grow faster than the lateral surfaces and the result is cellular or, more commonly, a dendritic morphology.

(b) (c)

Figure 24 (a) Schematic of interface instability by constitutional supercooling. As solute is rejected from the solidifying crystal, it accumulates in the valleys between the dendritic protrusions (the solute concentration is indicated by the shading). Since the relatively more pure liquid at the ends of the protrusions freezes at a higher temperature, these portions of the solid grow faster. ((b) and (c)) *In situ* laser confocal microscope image of a solidification front in Fe–Co–Ni alloy at 1597°C. (b) The front is planar (c) a few seconds later, an instability develops. (Micrograph courtesy of Chanjoon Paek and Sridhar Seetharaman, Department of Materials Science and Engineering, Carnegie Mellon University.)

When the remaining liquid cools to the temperature T_E, two solid phases (α and β) crystallize directly from the liquid. This most frequently results in a lamellar microstructure, such as those shown in **Figure 25**, where the two phases have alternating bands of dark and light contrast. Because both solids are in equilibrium with the same liquid, but themselves have very different compositions, they must simultaneously reject solute to feed the growth of the other phase. In other words, as a layer of the α phase grows, it must reject solute (B) laterally to supply neighboring lamella of the β phase. As the β phase crystallizes, it rejects A, which sustains the growth of the α phase. This cooperative process, schematically illustrated in **Figure 26**, stabilizes a nearly planar growth front.

In most solidification processes, cooling will take the materials through a region of solid–liquid coexistence, in which a dendritic structure will grow. When the remaining liquid reaches the eutectic temperature, it will solidify in a lamellar microstructure, leading to a mixed microstructure. In general, this situation is not an equilibrium configuration. Annealing at a temperature just below the eutectic will cause the compositional concentration gradients to homogenize and the morphologies of the crystals to spheroidize and become more equiaxed.

(Micrographs courtesy of Nasim Alem and Vinayak P Dravid, Department of Materials Science and Engineering, Northwestern University.)

Duplex Microstructures by Transformation in the Solid Phase

Duplex microstructures can also form by transformation in the solid phase. As an example, consider the rapid cooling of α on the phase diagram in **Figure 23**, from T_s to T_{ss}. At T_{ss}, the supersaturated α phase will decompose to $\alpha + \beta$, and this will happen entirely in the solid state. As with solidification, the characteristics of the microstructure that develop are determined by the nucleation and growth of the phase. The free energy change during the nucleation process is similar to that for heterogeneous nucleation, except that an additional term must be added to account for the volumetric strain energy associated with any expansion or contraction that might accompany the transformation. The disposition and

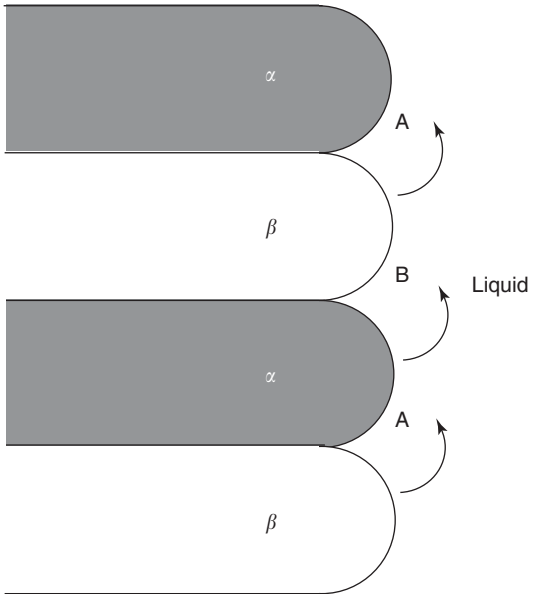

Figure 26 Schematic of the growth of a lamellar microstructure maintaining a nearly planar growth front.

shape of this phase depends on the structural relationship between the parent and daughter phases, features pre-existing in the microstructure that serve as heterogeneous nucleation sites, the degree of supersaturation during the nucleation and growth of the phase, and the mechanism of the transformation. Because of these parameters, there are a wide range of possible microstructures that can form and only a few of the characteristic examples are described in the remainder of this article.

Precipitation from a supersaturated solid solution requires the long-range diffusion of solute to the site of growth. For this reason, the distribution of a precipitated phase will depend on the degree of undercooling or supersaturation. When large, the driving force for the precipitation reaction is amplified and atomic mobility is limited. This leads to a uniform distribution of very small precipitates. For example, the microstructure in **Figure 27** shows cuboidal γ' precipitates in an $Ni_{70}Cr_{20}Al_{10}$ superalloy. In this case, the structure of precipitating phase differs little from that of the parent phase, so there is an orientation relationship between the two. In cases where the kinetics for transport are higher and the supersaturation is not as large, precipitates will nucleate at heterogeneities such as grain boundaries.

The formation of lamellar microstructures from the solidification of a eutectic has already been described. In the case of the eutectoid reaction, where a single solid phase decomposes to two new solid phases, the microstructure that is formed is similar to that formed by the eutectic reaction, but the lamellar phase typically nucleates and grows from the grain

(Micrograph courtesy of Lisha Wang and David E Laughlin, Department of Materials Science and Engineering, Carnegie Mellon University.)

boundaries. Similar microstructures can also be generated by the cellular transformation from a supersaturated solid solution.

There are also solid to solid transformations that do not require long-range diffusion and these processes also lead to distinct microstructures. In the massive transformation, a single phase decomposes to one or more phases that have the same composition, but different crystal structures. Because it is not necessary to alter the composition, the interface can move very rapidly. The massive transformation frequently nucleates at grain boundaries and the rapid interface motion leaves an irregularly shaped precipitate. Ordering transformations can also occur with very little long-range diffusion. In this case, elements A and B originally occupy certain sites in the crystal structure at random. Below a certain temperature, they occupy the same sites, but in an ordered fashion, as illustrated schematically in **Figure 28**. Because the ordering process will begin in many places at once, impingement will create antiphase domain boundaries, where there is a shift in the ordering pattern. A characteristic microstructure with APBs is illustrated in **Figure 29**.

Martensitic transformations are diffusionless processes by which a material changes crystal structure without requiring any of the atoms to change position by more than a lattice spacing. Typically, the parent and daughter structure are related by a shear deformation process. In the resulting microstructure, lens-shaped precipitates grow quickly to the size of the grains of the parent phase, creating the characteristic microstructure, such as the one illustrated in **Figure 7**, where the twins within the grains are formed by a martensitic transformation. It has been shown that the interface between the precipitate and the parent phase can move at velocities approaching the speed of sound.

Introduction

The miniaturization, up to the submicrometer scale, of electronic and optoelectronic components grown on semiconductor substrates generated the computer and communication revolutions at the end of the twentieth century. The miniaturization of electronic components accompanied by the increase in their performances was successful due to a combination of advanced semiconductor technologies such as MBE (molecular beam epitaxy), VLSI (very large scale integration), and due to the employment of new types of semiconductors and heterostructures. However, the main material, which can be found in any computer or communication system, is still silicon.

A second revolution is born, thanks to the microelectromechanical systems (MEMSs), which are three-dimensional (3D) chips that are able to change information with the environment, and which are produced by the simultaneous miniaturization of electronic and mechanical devices. In contrast to electronic or mechanical components, which can be separately designed, fabricated, and eventually assembled in a remote place, the design of MEMSs and their fabrication is an integral process, which cannot be separated in elementary steps. MEMSs have thus the status of a system, the MEMS revolution being characterized by the miniaturization of systems and not of components.

The development of MEMS was dictated by the need for high-speed data processing in global communication systems, which require rapid reconfiguration of various communication routes. Also, the MEMS advance was boosted by the need for integration of sensing and monitoring devices in various applications that range from environment monitoring to medical surgery. Therefore, the MEMS chip is often called "smart" since it can sense the chemical, mechanical, physical, electrical, optical, etc. modifications of the environment and can exploit them in order to perform a specific task. The abilities of the MEMS chip to act and decide are expected to generate astonishing applications in electronics, communications, or biology.

The reduction of mechanical devices at the micrometer or even nanometer scale is implemented using semiconductor materials with excellent mechanical properties, such as Si, and a common semiconductor technology that exploits the already existing technological facilities. Thus, MEMSs are realized with almost the same tools as in the VLSI technology, on semiconductor substrates on which VLSI circuits can also be realized. MEMSs are not always realized using Si, other semiconductors such as GaAs, GaN, SiC, InP being used as well. Many applications also require MEMS made from metals such as gold or silver.

Although quite a large variety of micromechanical or nanomechanical devices exist, the vast majority of MEMS is implemented with only a few mechanical configurations such as cantilevers, microbridges, or membranes. In contrast to common electronic devices, MEMSs contain almost always moving parts (actuators, microrobots, switches, etc.) that are set in motion by electric, magnetic, thermal, or electromagnetic forces exerted between different parts of a MEMS.

Static MEMS (with no moving parts) can also be encountered and fabricated with specific MEMS technologies that are described below. These micro- or nanoscale mechanical devices integrated with various electronic components have succeeded in transforming the sensing, computing, microwave communications, optical communications, and optical processing at the global scale in only a couple of years due to their small sizes, low power consumption, and low costs.

Electronic or mechanical devices with at least one dimension of a few nanometers are the building blocks of nanoelectronics. The nanoelectromechanical systems (NEMSs) are nanosized systems that integrate mechanical and electronic devices in a single assembly. However, NEMSs are not simple scaled-down versions of MEMSs; they involve new concepts and design techniques, which take into account the new physical effects encountered only at the nanoscale (e.g., van der Waals forces). Also, the technological implementation of NEMSs is no longer based on standard silicon processing, but on a set of technologies specific to the nanoscale and generically termed nanotechnologies.

Main Fabrication Techniques of MEMS

Semiconductor micromachining is the main technology for MEMS implementation. Any micromachining technique removes a part of a bulk substrate or of a thin film using various etching methods. Silicon, grown either as a monocrystal or as a polycrystal, is the familiar material for micromachining, performed in this case with standard techniques for silicon processing. As can be seen from **Table 1**, Si has also very good mechanical properties, which are of paramount importance for the moving parts in an MEMS.

Two types of etching are generally used in micromachining: wet or chemical, and dry (or plasma) etching, which generate different etching forms. For example, the etching forms in **Figures 1a** and **1b** can be obtained with isotropic and anisotropic wet etching, respectively, whereas the form in **Figure 1c** is attainable with plasma etching. Anisotropic etching and plasma etching are used for Si, GaAs, or InP. In any micromachining technique, it is essential to achieve controllable, high-precision, and low-roughness shapes. Almost perfect vertical walls can only be obtained using plasma etching methods, but more complex and expensive methods such as laser etching or synchrotron radiation (called LIGA) must be employed to carve in semiconductors almost perfect shapes with low roughness.

Micromachining techniques can be divided into two classes. The first one concerns bulk micromachining, where the back of a wafer is etched to obtain a prescribed mechanical structure on its top. This technique is typical for fabrication of micromechanical membranes, as displayed in **Figure 2**, very large membranes with surfaces of $2 \times 2\,\text{cm}^2$ and thicknesses of 1 μm being achieved using chemical or plasma-etching methods.

The second class, referred to as surface micromachining, allows the fabrication of MEMS or NEMS by successive thin film depositions on a common substrate, followed by the selective etching of one of these thin deposited layers, called the sacrificial layer. The technological realization of a cantilever using surface micromachining is displayed in **Figure 3**.

Table 1 Mechanical properties of some basic materials for MEMS

Material	*Young's modulus* ($\times 10^{11}$ Pa)	*Density* (g cm^{-3})	*Thermal expansion* ($\times 10^{-6} \circ \text{C}^{-1}$)
Silicon	1.5	2.4	2.5
Carbon nanotube	10	1.4	10
Steel	2.1	8	12

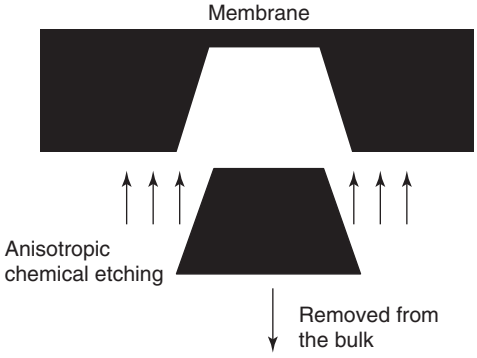

Figure 2 Membrane realization via bulk micromachining.

Basic Micromechanical Devices

The Cantilever

A basic micromechanical component in many MEMSs is the cantilever, represented in **Figure 4**,

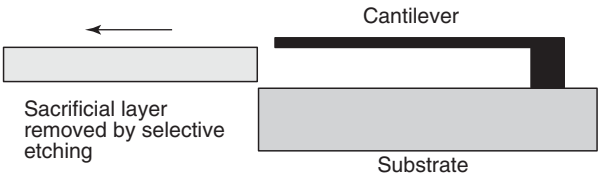

Figure 3 Cantilever realization via surface micromachining.

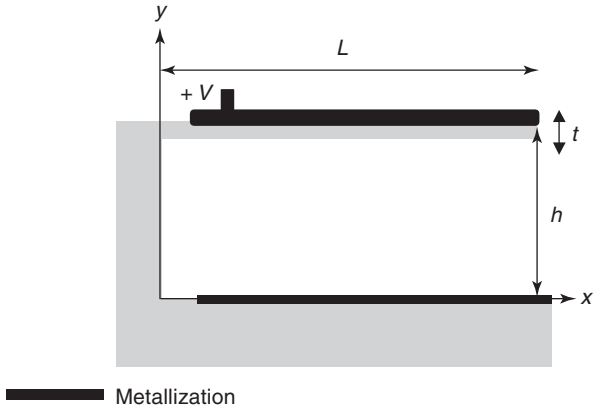

Figure 4 Electrostatic actuation of a cantilever with rectangular cross section.

which is frequently integrated with electronic and/or optoelectronic components for various purposes. Semiconductor cantilevers are mostly fabricated from Si, although very thin GaAs cantilevers were also produced via micromachining technologies. Metallic cantilevers are used mainly as adsorbers of chemical or biological substances, which produce an additional bending that can be detected in sensing applications. Typical micronic cantilevers have lengths of tens of microns and widths and thicknesses of a few microns. Nanosized cantilevers, also called nanocantilevers, have widths and thicknesses of a few nanometers and lengths of a few microns.

An electric, magnetic, or electromagnetic force bends the cantilever, the corresponding actuation being called electrostatic (toward a bottom electrode), magnetic, or optical. Heat can also actuate a cantilever. The most widespread actuation type is electrostatic (see **Figure 4**), in which attractive electrical forces are generated when a DC voltage is applied between the cantilever and the metal deposited on the substrate (the substrate electrode), the cantilever being attracted toward the substrate.

The electrical force $F(y)$ that actuates a cantilever with width W, length L, and thickness t, fabricated from a material with permittivity ε is given by

$$F(y) = -\varepsilon_0 WL \frac{V^2}{2[y + (t/\varepsilon)]^2}$$

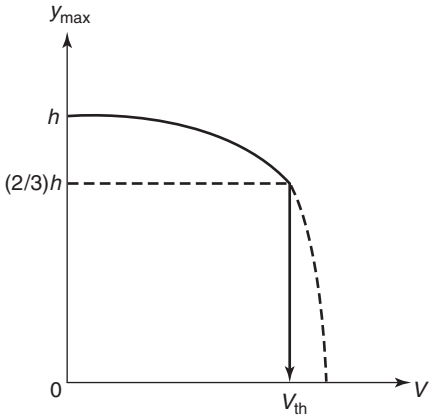

Figure 5 The dependence on voltage of the cantilever deflection.

where ε_0 is the free-space permittivity and V is the voltage applied between the cantilever and the substrate electrode. The bending of the cantilever induced by the applied actuation force can be described by the equation

$$d^2y/dx^2 = M(x)/EI$$

where I is the moment of inertia, equal to $Wt^3/12$ for rectangular cantilevers, E is the Young's modulus, and $M(x)$ is the total moment at position x, completely determined by the electric force. The maximum deflection at $y = L$ is then given by

$$y_{max} = y(L) = h - V^2 \frac{6\varepsilon_0}{Et^3[h + (t/\varepsilon)]^2} \times \left(\frac{L^2x^2}{4} - \frac{Lx^3}{6} + \frac{x^4}{24}\right)$$

The deflection of the cantilever is usually performed with optical systems or electronic detection techniques, which can be either capacitive or based on the tunneling effect. The deflection of the cantilever as a function of the applied voltage is displayed in **Figure 5**.

The dynamical equilibrium of the cantilever is ensured by the balance between the electrostatic and elastic forces, which require that

$$\frac{\varepsilon_0 WLV^2}{2[y + (t/\varepsilon)]^2} - Ky = 0$$

where the spring constant of a cantilever beam is $K = 3EI/L^3 = Et^3W/4L^3$. From **Figure 5** it follows that this equilibrium is maintained up to deflections of about one-third of the cantilever substrate height h, after which the equilibrium between the electrostatic and elastic forces is destroyed and the

cantilever collapses on the substrate electrode. The threshold voltage beyond which the cantilever collapses is given by:

$$V_{th} = \sqrt{8Kh^3/27WL\varepsilon_0}$$

The above formula dramatically changes for nanocantilevers, with nanometric h values, because in this case the equilibrium condition must take into account the van der Waals force that acts only at the nanoscale. The attractive van der Waals force is so strong that it can even pull down the nanocantilever in the absence of a DC voltage. The major influence of the van der Waals force at the nanoscale can be seen from **Figure 6**.

Although the effect of van der Waals forces can be lowered in a double-clamped NEMS, other amazing behaviors associated with the nanoscale occur. In particular, the double-clamped NEMS shows a quantized mechanical movement, the deflection varying in discrete steps every time an electron tunnels through the metallic contacts of the nanobeam (see **Figure 7**).

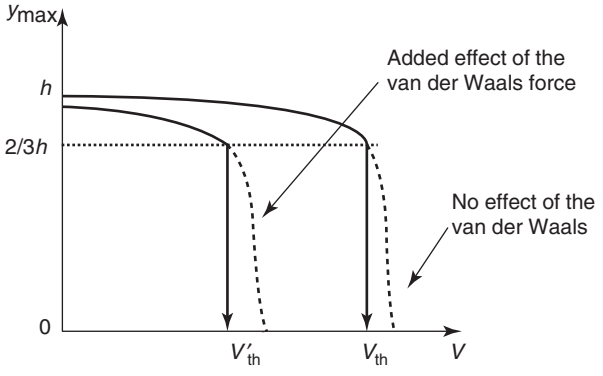

Figure 6 The van der Waals effect on the deflection of nanocantilevers.

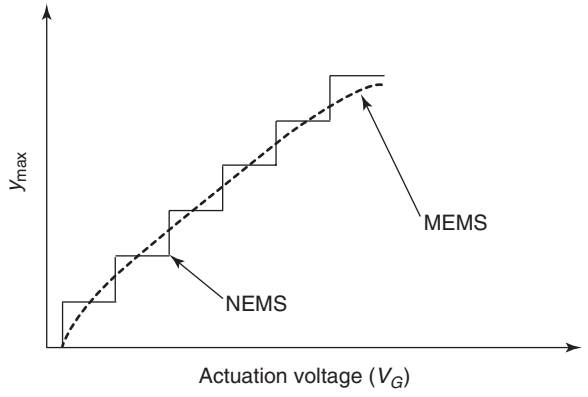

Figure 7 Double-clamped beam deflection at the micro- and nanoscale.

Another specific nanoscale force that acts on NEMS is the Casimir force, which is derived from the quantum field theory. Assuming that the vacuum is not empty but filled with virtual particles that are continuously created and annihilated, vacuum fluctuations manifest in the Casimir force that acts between two arbitrary bodies separated by a distance less than 1 μm. The Casimir force is not a classical force since it depends on geometry and the boundary conditions: it is attractive for two conducting plates separated by free space but becomes repulsive if the plates are replaced by hemispherical shells. For two metallic plates with an area of 1 cm^2 and separated at 500 nm, the Casimir force is $\sim 3\,\mu N$, a value that is easily detectable. Thus, the Casimir force is a mesoscopic force, which can be engineered via the distance between or the shapes of the interacting bodies. This engineering of the Casimir force is used to implement nonlinear mechanical oscillators and switches at the nanoscale, which consist of a metallic plate that moves under the action of an elastic force and a sphere located over the plate.

A complete analysis of the cantilever deflection requires a description of the cantilever motion in both space x and time τ coordinates. The corresponding equation is

$$EI(d^4y/dx^4) + m(d^2y/d\tau^2) = 0$$

where $A = Wt$ is the cross-sectional area of the cantilever and $m = \rho A$ is the cantilever mass per unit length, with ρ, the density of the cantilever material. Assuming a harmonic behavior of the cantilever and imposing appropriate boundary conditions, the natural resonance frequencies ω_n of the cantilever are related to its wavenumbers k_n through $k_n^4 = \omega_n^2 \rho Wt/EI$. The lowest-order wavenumbers are $k_0L = 1.875$, $k_1L = 4.694$, $k_2L = 7.855$, $k_3L = 10.996$, the first resonance frequency of the cantilever being

$$\omega_0 = 2\pi f_0 = 1.015(t/L^2)(E/\rho)^{1/2}$$

The cantilever performances are expressed by the quality factor, defined as

$$Q = 2\pi E_0/\Delta E$$

where E_0 is the stored vibrational energy and ΔE_0 is the total energy lost per cycle of vibration. The cantilever quality factor $1/Q = 1/Q_c + 1/Q_{th} + 1/Q_V + 1/Q_s$ is composed from several components: $Q_c = 2.2(L/t)^3$ originates from clamping losses and is of the order $10^3 - 10^5$, Q_{th} accounts for thermoelastic losses (which are negligible for submicron-thick cantilevers operating at kHz or MHz frequencies).

The losses due to internal friction, $Q_V = E_1/E_2$, are modeled via a complex Young's modulus $E = E_1 + iE_2$, where E_1 is the conventional Young's modulus and E_2 is a dissipation part due to friction, whereas the surface losses $Q_s = WtE_1/2\delta(3W + t)E_2$ can be modeled as a disruption of the atomic lattice having a thickness δ at the cantilever surface or as a surface contamination.

A general loss parameter $\gamma = K/\omega_0 Q$ is introduced to account for the cantilever performances, its value for a rectangular cantilever being

$$\gamma = 0.246Wt^2(E\rho)^{1/2}/LQ$$

This loss parameter is linked with the minimum detectable force F_{min}, a very important parameter in many applications. F_{min} is also related to the thermomechanical noise, which is the mechanical analog of the Johnson noise (white noise). The noise source of the cantilever is the Brownian motion around its equilibrium position resulted from the immersion of the cantilever in a thermal bath with a temperature T. The vibrational noise can be modeled by an equivalent noise force with a constant power spectrum S_F and an equivalent amplitude y. For a rectangular cantilever, the minimum detectable force (or force noise) in a bandwidth B is given by

$$F_{min} = S_F^{1/2}B^{1/2} = (Wt^2/LQ)^{1/2}(E\rho)^{1/4}(k_B TB)^{1/2}$$

or

$$F_{min} = (\gamma k_B TB/0.246)^{1/2}$$

Thus, the minimum detectable force is proportional to the temperature and losses. Nowadays, the minimum detectable force is ~ 1 attonewton (10^{-18} N) at low temperatures, and of a few pN (10^{-12} N) at room temperature.

The Membrane

Another important micromechanical device is the micromachined membrane (see **Figure 2**). The surface of the membrane is usually deformed by mechanical or electrostatic actuation, in the latter case the actuation requiring the deposition of a thin metal film on the back of the membrane. No such metallic film is necessary in applications in which the surface of the membrane is not deformed, that is, when the thin membrane with a thickness of $\sim 1\,\mu m$ is used as a propagating medium with low losses and a refractive index comparable to that of the air.

When the membrane is actuated, the surface deflection $u(x,y)$ is described by a Poisson equation

$$\nabla^2 u(x,y) = -\varepsilon_0 V^2(x,y)/Th$$

where $V(x,y)$ is the bias and T is the membrane tension. A similar Poisson equation in cylindrical coordinates is satisfied by circular membranes. The Poisson equation of rectangular and circular thin membranes has analytical solutions under certain boundary conditions.

MEMS Sensors

MEMS sensors are used in many areas ranging from cars to biology and neurosurgery. In what follows, only a brief review of a part of them is described.

Force sensors are made from a silicon beam, which encompasses a piezoelectric or a resonant strain gauge (see **Figure 8**), the resistance of which modifies in the presence of strain. One can determine the applied force by measuring the resistance.

MEMS pressure sensors are fabricated on a large scale, their applications ranging from car airbags and miniaturized microphones to complicated sensor arrays located in the airplane wings. There are many types of pressure sensors, but basically they consist of rectangular or circular MEMS membranes that vibrate and bend due to an applied pressure. Their bending is detected and transferred in an electrical signal. **Figure 9** displays a pressure sensor.

Acceleration sensors are based on a suspended proof mass linked to a fixed frame by spring elements.

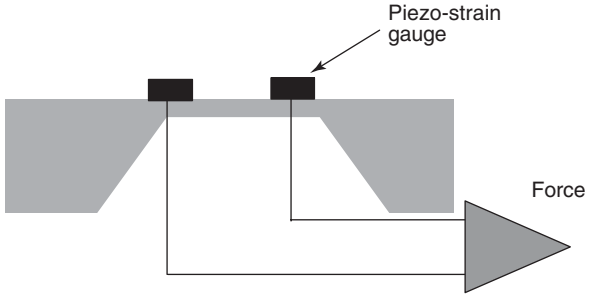

Figure 8 Schematic representation of an MEMS force sensor.

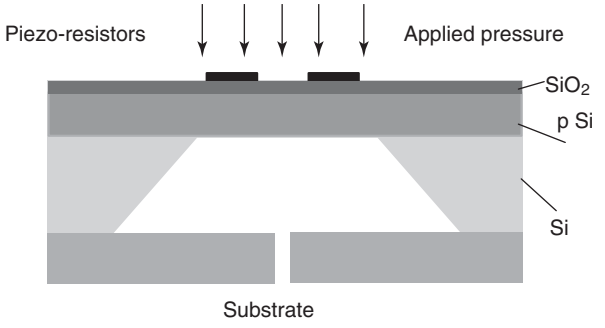

Figure 9 Schematic representation of an MEMS pressure sensor.

Any displacement of the proof mass, which is proportional with the acceleration, is detected by measuring the changes of the capacitance formed between the proof mass and an electrode or by measuring the changes of a piezo-resistor if strain gauges are integrated in the springs. A typical MEMS accelerometer is represented in **Figure 10**.

Thermal flow sensors can be divided into three categories: anemometers, calorimetric sensors, and time-of-flight sensors. In anemometers, one senses the variation of a resistance when heat is flowing over it. Practically, a thin film resistor is deposited on a thin membrane, the lateral diffusion flow of the heat over the membrane (see **Figure 11**) thermalizing the membrane at the temperature of the fluid. The flow rate can be measured with the simple flow sensor displayed in **Figure 12**.

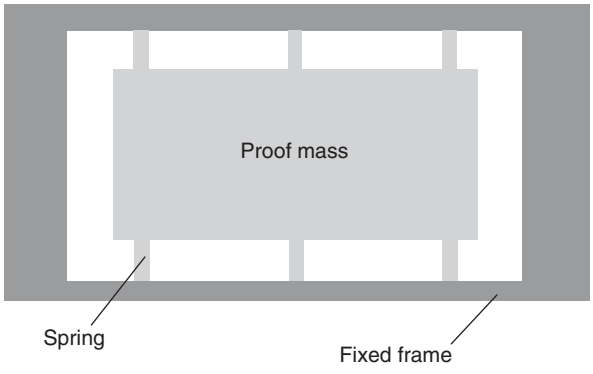

Figure 10 MEMS accelerometer.

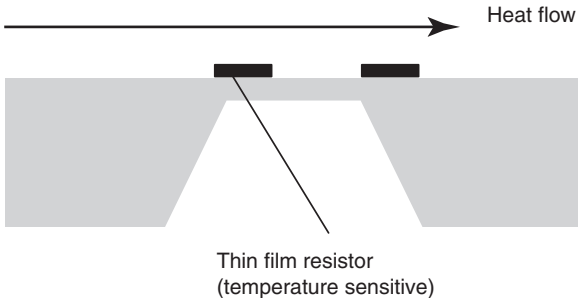

Figure 11 MEMS anemometer.

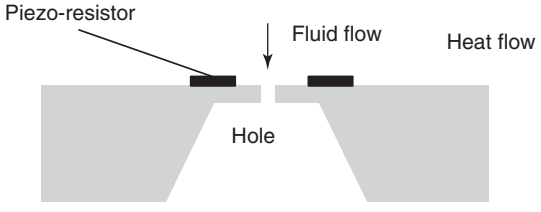

Figure 12 Schematic representation of an MEMS flow sensor.

A special category of sensors based on MEMS, with wide applications in biology and medicine, are the biological MEMS sensors or bioMEMS. For example, in surgery, catheters, pipettes, endoscopes, MEMS robotic surgery devices, including an MEMS submarine capable of traveling in human arteries, are currently fabricated using micromachining techniques; some of them contain several MEMS sensors. Minimally invasive devices able to provide *in vivo* diagnostics and therapy are currently developed using MEMS sensors and devices. Wireless MEMS needles have also been developed and implanted into the nervous system in order to monitor its activity. In the areas of drugs and genetics, MEMS microfluid devices are capable of delivering certain combinations of drugs, MEMS needles are capable of manipulating cells and genetic materials, and even smart labs-on-a-chip are created for point-of-care diagnostics.

RF-MEMS

RF-MEMS encompasses MEMS devices working in the range of microwaves, millimeter waves, and terahertz (THz) frequencies, that is, in the main frequency ranges used nowadays for communications. These frequency ranges are also used for medical imaging, space applications like teledetection, and radioastronomy.

The thriving development of RF-MEMS is caused by the ability of these devices to solve the main drawbacks of high-frequency circuits. These circuits consist of dielectric substrates (such as high resistivity Si or GaAs) over which metallic strips are patterned. The metallic strips and the substrate guide the high-frequency electromagnetic waves, but as soon as the frequency is increased beyond few tens of GHz, the losses in the metal and substrate become so high that the electromagnetic propagation is canceled.

There are two main categories of RF-MEMS devices. The first category encompasses RF-MEMS circuits supported on thin micromachined membranes of Si and GaAs, which allow the electromagnetic fields to propagate in similar conditions as in the air where the losses are minimal. The thickness of the dielectric substrate t has dramatic consequences on the performances of the device. In microwave circuits $t \ll \lambda$, a relation that guarantees the cancellation of substrate modes, which has, as a result, the reduction of the radiation losses and the dielectric losses. On the contrary, at millimeter waves, THz, and FIR frequencies, this inequality is no longer valid and very often the substrate thickness

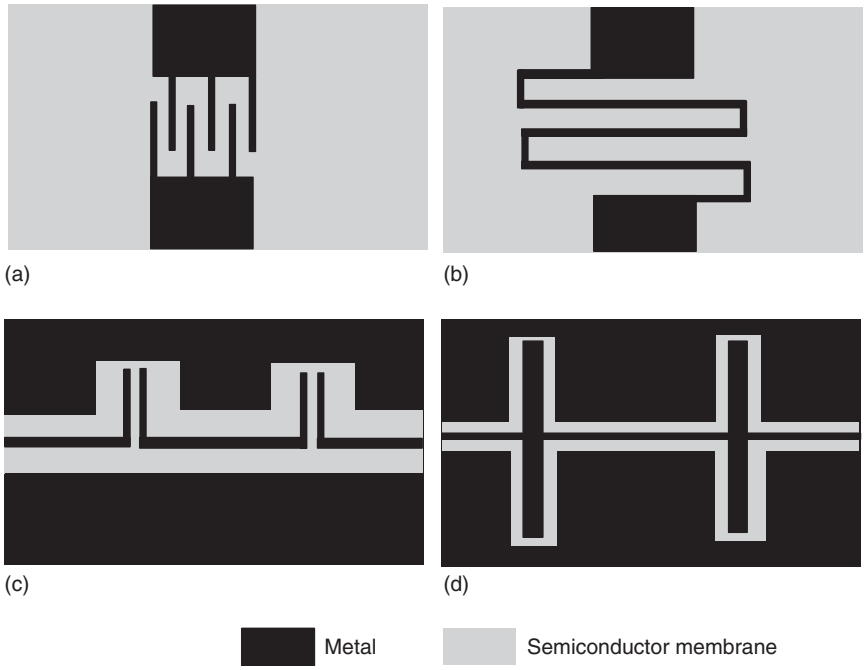

Figure 13 RF-MEMS devices: (a) capacitor, (b) inductor, (c) filter, and (d) double-slot antenna.

well exceeds the wavelength: $t \geqslant \lambda$. As a consequence, the energy generated above a critical angle is trapped in the semiconductor substrate by the substrate modes. Depending on the thickness, a large part of the radiated power (more than 90% in some situations) may become trapped into the substrate. Therefore, small losses at millimeter waves can only be obtained when propagating structures are patterned on very thin substrates. For example, the substrate thickness must be smaller than $0.04\lambda_0$ for a slot antenna and smaller than $0.01\lambda_0$ in the case of dipole antennas, with λ_0 the free-space wavelength. This means that a substrate thickness less than $2\,\mu m$ is needed, about two orders of magnitude thinner than the diameter of a hair. This amazing achievement became possible only in the last years using micromachining techniques, which are specific for MEMS. In **Figure 13**, some RF-MEMS devices realized on thin semiconductor membranes are described.

A second category of RF-MEMS devices are the reconfigurable devices. Filters, antennas, or receivers can change their characteristics in a controllable manner. This can be realized with the help of a series of RF-MEMS switches placed along some metallic paths of the circuit. RF-MEMS switches have many configurations, but in **Figure 14** only the shunt RF-MEMS switch, which is widespread in reconfigurable microwave devices, is described. This switch can also be used to commute between communication channels or communication protocols.

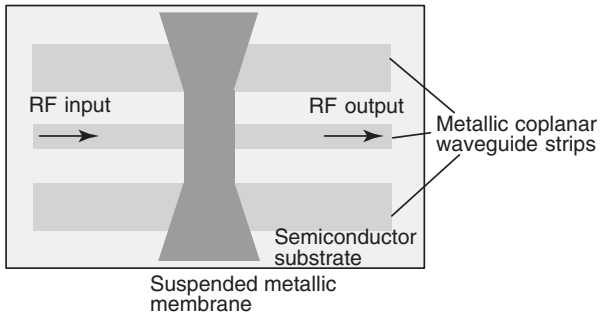

Figure 14 RF-MEMS shunt switch.

Optical MEMS (MOEMS)

Optical MEMSs integrate microoptical with micromechanical devices, the resulting microsystems being called microoptoelectromechanical systems (MOEMSs). MOEMSs are 3D integrated optical circuits that work mainly in free-space where self-calibrated and self-tested optical elements, such as microlenses, mirrors, beam-splitters, and gratings, can be moved in a controlled manner and at the precision required by optics. High-precision mechanical actuation produced by electrical, chemical, or electromagnetic forces are responsible for the controllable movement of the microoptical devices. MOEMSs have shown a huge potential for active and passive devices due to the fact that their main performances change when at least some of their components move. MOEMSs are

thus very versatile, reconfigurable, and moreover, show a high degree of integration never before met in optics and optoelectronics; more than 10^6 microoptical components can be integrated on a single MOEMS chip as in the digital display developed recently by Texas Instruments, which contains 2 million micromirrors, with a resolution of 2000×1000 pixels.

There are three main classes of optical devices based on MOEMS. The first class encompasses free-space optical devices, directly realized with micromachining techniques. The second class comprises optoelectronic devices such as lasers and photodiodes, integrated with micromechanical devices, which enhance their performances. The third class includes very complex circuits where hundreds of thousands of micromechanical devices are integrated with optical/optoelectronic devices in order to perform complex tasks such as optical signal processing, and optical data storage.

A breakthrough in MOEMS was the realization of the first microhinges and the subsequent development of an entire technology based on them, named free-space microoptical bench. In this surface micromachining technology, where selectively etching a sacrificial layer, a silicon plate linked to a hinge pin is able to turn freely around a silicon staple. The silicon plate can be positioned perpendicularly on the substrate or can be positioned at any angle due to a pair of microlatches that can also be realized using microhinges. The mechanical stability of the Si plate increases by adding V-shaped microlatches laterally to the plate. The MOEMS implementation of an integrated micro-Fresnel lens and a polarization beam splitter is displayed in **Figure 15**. In **Figure 16** a micromirror, which is a key element in many MOEMS devices, is displayed.

Optoelectronic devices can be micromechanically tuned. For example, a VCSEL laser tuned by a cantilever is displayed in **Figure 17**. The variable top DBR mirror consists of an *n*-DBR section etched into the shape of a 100 μm long cantilever, a variable air gap, and a fixed *p*-doped DBR mirror consisting of four pairs of alternating layers. Tuning the reversed bias applied on the *p*–*n* junction between the *n*-doped cantilever and the *p*-doped DBR varies the laser wavelength. If the reverse bias is increased, the cantilever is actuated toward the *p*-contact of the top DBR, reducing the air gap with ΔL and thus the laser wavelength. The VCSEL can be modeled as an active Fabry–Perot-like cavity, the change in the laser wavelength being expressed as $\Delta\lambda \cong (2/m)\, n\Delta L$, where m is the longitudinal mode number, and n the index of refraction. A very broad continuous tuning range of $\sim 20\%$ can be achieved in this manner.

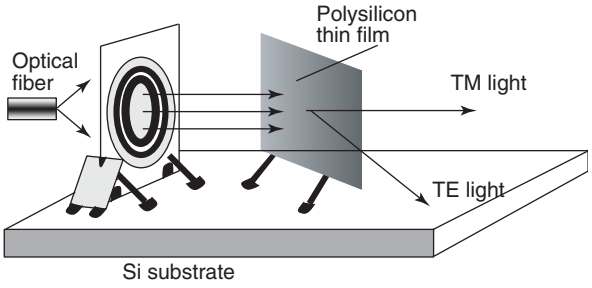

Figure 15 Micro-Fresnel lens integrated with a beam splitter.

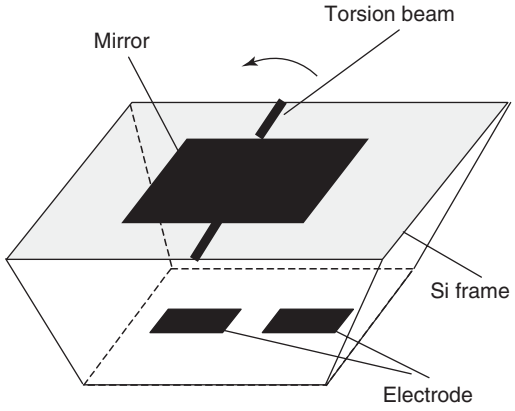

Figure 16 MOEMS micromirror.

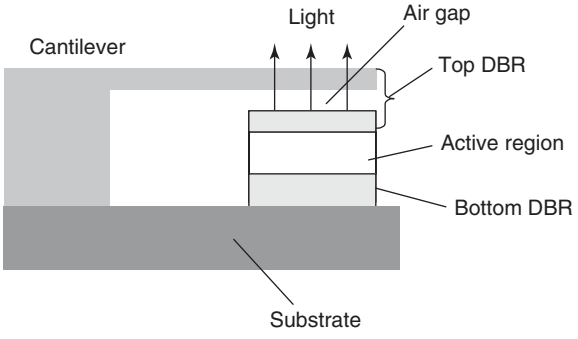

Figure 17 VCSEL tuned by a cantilever.

A more complicated MOEMS, which is an optical computer consisting of an array of cantilevers terminated with a tip, through which electrons are tunneling into a bottom electrode when the cantilever is optically actuated by incoming light, is displayed in **Figure 18**. The incoming 2D (1D) incident light beam should be sufficiently extended (eventually magnified) to cover an extended 2D (1D) array of cantilevers. The number of cantilevers in each dimension determines the step of the respective operation.

The addition $A(x, y) + B(x, y)$ of two incoherent optical beams $A(x, y)$ and $B(x, y)$ simultaneously incident on the array is performed automatically

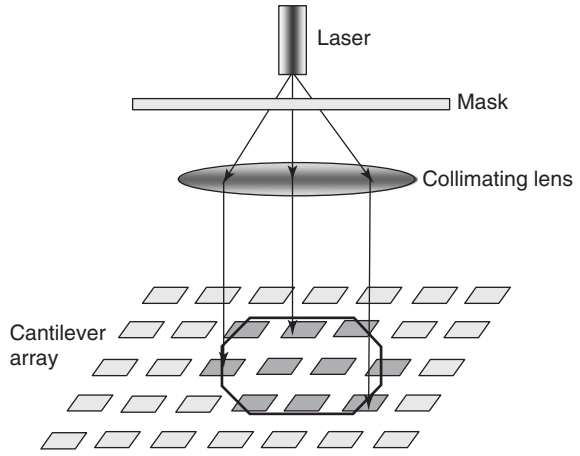

Figure 18 Schematic representation of an MEMS optical computer.

because the total deflection for each cantilever is the sum of deflections for the separate beams (the deflection is linearly proportional to the power). Moreover, since the deflection of the cantilever in the position (x_j, y_k) is proportional to $A(x_j, y_k)$, the integration of a 2D optical signal $A(x, y)$, $\int A(x,y)\mathrm{d}x\ \mathrm{d}y \approx \sum_{j,k} A(x_j, y_k)$, can be computed in one step by adding the tunneling currents of all cantilevers in the array.

Partial integration with respect to x or y is also possible by adding the tunneling currents on columns or rows, partial derivative of a 2D function being performed in a similar manner. To compute $\partial A(x, y)/\partial x$, for example, one must add the tunneling currents of two adjacent cantilevers along the x direction, with opposite signs. The opposite sign can be obtained by opposite biasing, that is, applying a voltage $-V$ instead of V. Analogously, $\partial A(x, y)/\partial y$ as well as $\mathrm{d}A(x, y)$ or even higher-order derivatives can be performed by a suitable connection of the contacts.

The method proposed above to compute integrals and derivatives of a 1D or 2D function based on MEMS devices is a breakthrough in the quest for the implementation of an optical computer since it eliminates many intermediate operations, which must be performed with conventional computing methods. The light power necessary to actuate the cantilevers is readily available from common optical sources, such as laser diodes or arrays of laser diodes.

Nomenclature

$A = Wt$	cross-sectional area of the cantilever
E	Young's modulus
E_0	stored vibrational energy
ΔE_0	energy lost per cycle of vibration
$F(y)$	electrical force
$F_{\min}$	minimum detectable force
h	cantilever substrate height
I	moment of inertia
k_B	Boltzmann constant
k_n	wavenumber
K	spring constant
L	cantilever length
m	cantilever mass
$M(x)$	total moment at position x
Q	quality factor
$u(x, y)$	surface deflection
V	applied voltage
V_{th}	threshold voltage
t	cantilever thickness; also thickness of dielectric substrate
T	temperature; also membrane tension
y	deflection
$y_{\max}$	maximum deflection
W	cantilever width
ε	permittivity
γ	loss parameter
λ	wavelength
ρ	density of cantilever material
ω_n	natural resonance frequencies

Micromechanical Devices and Systems

H Fujita, University of Tokyo, Tokyo, Japan

Introduction

The successful extension of semiconductor technology to fabricate mechanical parts of the sizes from 10–100 μm opened wide ranges of possibilities for micromechanical devices and systems. The fabrication technique is called micromachining. Micromachining processes are based on silicon integrated circuits (IC) technology and used to build three-dimensional (3D) structures and movable parts by the combination of lithography, etching, film deposition, and wafer bonding. The same technology base that enabled miniaturization and large-scale integration of electronics offers three distinctive features defining micromachined devices and systems: miniaturization, multiplicity, and microsystem integration. Miniaturization is clearly essential. Small parts respond fast, constitute miniature machines that work in extremely shallow spaces, add functionality to portable or wearable devices, and realize tools to investigate the nanometric world. Millions of such parts can work cooperatively to do things impossible for a single device alone. Thus, multiplicity is one key to successful micromechanical systems. The coordination of these parts is accomplished by integrating them with electrical circuits. Furthermore, optical, sensing, fluidic, and biological elements are to be integrated in multi-functional microsystems in a cost-effective manner. The research field concerning micromechanical devices is referred to as MEMS (microelectromechanical systems) in USA, Micromachine in Japan, and MST (micro system technology) in Europe.

The root of MEMS research can be found in the research of silicon sensors. A noticeable turning point from sensor research toward MEMS research was the demonstration of micromachined gears and turbines made on a silicon chip in 1987. Since then, development has continued in micromachining processes, material varieties, microactuators, and the application of MEMS.

Micromachining

MEMS generally requires complex microstructures that are thick, 3D, and movable. Therefore, many technologies have been developed on the basis of semiconductor microfabrication processes including lithography, etching, and deposition. Pre-designed patterns are transferred by exposure to resists that have sensitivity to light, X-ray, or electron beam and those that are coated on substrates. Photo lithograph through a glass-chromium mask is most commonly used. Parts of the resist remain on the substrate according to the exposed patterns by development. Using the resist pattern as a masking layer, one can selectively etch the substrate or the film on it. In another process, the resist mold pattern can be replicated by deposition. After resist removal, the next material is deposited on the patterned substrate. The material is, then, patterned by lithography and etching. These sequences are very similar to the IC fabrication.

There are special processes for micromachining to obtain 3D structures and movable parts (**Table 1**). To construct 3D microstructures, researchers have used

Table 1 Micromachining processes

Process (material)	*Feature*	*Application*
Wet anisotropic etching (single-crystal silicon)	Precise structures defined by crystal facets	Pressure sensor membrane, V-groove (channel, fiber alignment), Optical flat mirror surface
Dry anisotropic etching (silicon)	3D structure defined by mask patterns	High aspect ratio microstructure, through hole
Sacrificial layer etching (various thin films)	Integrated circuits compatible fabrication of micromovable structures	Integrated sensor, Arrayed MEMS (e.g., digital micromirror device)
Wafer bonding (Si or glass substrate)	Closed cavity formation, 3D assembly of devices on substrates	Hybrid integration of multifunctional system, Packaging and encapsulation
Electroforming (metal)	Replication of resist patterns by electroplating through the resist mask	Metallic 3D structures, Mater for injection molding
Injection molding and thermal embossing (polymer)	Low cost replication from precise master	3D microstrutures for fiber alignment or microchannels

Table 2 Selectivity of etching

Etching liquid/ gas	*Etched material*	*Resistant material*
HF (+NH_4F)	SiO_2	Si
KOH	Si	SiO_2, Si_3N_4
Hot H_3PO_4	Si_3N_4	SiO_2, Si
XeF_2 (gas)	Si	SiO_2, Si_3N_4
SF_6 (plasma)	Si	Ni, Al
O_2 (plasma)	Polymer	Al

anisotropic wet etching, deep reactive ion etching, and replication of deep lithography patterns. Another 3D fabrication technique is capable of folding micromachined plates out from the substrate by removing either a thin film under it or the substrate itself. The removal process is called sacrificial layer etching. Selective etching of the "sacrificial" material should be performed without damaging microstructures. **Table 2** shows the choice of etching solution or gas, the structural material and the sacrificial material. Even after release etching, microstructures tend to stick to the substrate. Sublimation drying, CO_2 supercritical drying, release etching by plasma or gas, and surface coating are typical methods to prevent sticking. Wafer bonding is also essential to micromachining. 3D stacking of structures, sealing of cavities and channels, hermetic or vacuum encapsulation of sensing/actuation elements and combination of devices made of different materials and processes are accomplished by bonding wafers together. Glass and silicon substrates are bonded by applying 400–500 V at 600–800 K; this is called anodic bonding. Two silicon substrates can be fusion bonded at $\sim$1370 K after careful cleaning of the surfaces to be bonded. Replication of micro molds is the inexpensive way of fabricating many microstructures. Molds can be made by deep lithography or deep etching. Electroplating of metals, chemical vapor deposition (CVD) of polysilicon films, and injection molding of polymers are commonly used for replication. Finally, direct fabrication of microstructures may be possible by beam assisted deposition or solidification by laser beam, electron beam assisted deposition, and focused ion beam (FIB) etching.

Materials for MEMS

Silicon is the most common material in micromachining because (1) the fabrication processes are well established, (2) it has excellent mechanical properties, and (3) integration with electronic circuits and sensors is possible. It also has piezoresistive properties used for strain detection. SiO_2 and SiN films serve as electrical and thermal insulators. They are also excellent masking layers for anisotropic wet etching by TMAH and KOH. Optical waveguides may be made of SiO_2. SiN and other nitride films, e.g., TiN and A1N, are very hard and used for low friction and antiwear coating.

Other materials that may not be common for IC fabrication are also useful in MEMS. Actuator materials produce force and displacement. They include piezoelectric materials (PZT, ZnO, quartz), magnetostrictive material (TbFe), shape memory alloy (TiNi), and some conductive polymers. Compound semiconductors such as GaAs, GaN and InGaAs can be micromachined in a way similar to silicon, and offer optically active and passive components. Metals can be deposited by electroplating, sputtering, and vacuum evaporation. Electroplated copper is widely used for conductors as well as Al thin films. Electroplated nickel is favored for both structural and magnetic elements. Researchers have developed batch fabrication processes for all of those materials achieving the features of MEMS mentioned above.

Microactuators

Microactuators are key devices allowing MEMS to perform physical functions. Many types of microactuators have been successfully operated. Some of them are driven by force associated with physical fields. Force can be generated in the space between stationary and moving parts using electric, magnetic, and flow fields. Some others utilize actuator materials introduced before. Thermal expansion and phase transformations, such as the shape-memory effect and bubble formation, cause shape or volume changes. Micromachining technology allows one to make structures in which a well-controlled field is generated or to deposit and pattern actuator materials. Typical sizes of microactuators are from 10 μm–1 mm. Although the physical principle that describes the motion of macroscopic objects is still applicable to microactuators, the relative importance of various forces changes in small dimensions. It is called a scaling effect. **Table 3** shows the dependence of some physical parameters and forces on the characteristic dimension of an object. The scaling effect and the compatibility with micromachining process are important issues when a microactuator is designed.

One of the most significant scaling effects is that friction dominates over inertia forces in the micro world. Researchers have tried many ways of minimizing friction by suspending movable parts with flexures, applying smooth coatings, using rotational contacts, levitating objects, and using friction drive mechanism.

Table 3 Scaling effect (L: characteristic dimension)

Parameter	*Formula*	*Scaling*	*Comment*
Gravity, f_g	Mg	L^3	g: gravity const., m: mass
Inertial force, f_i	Ma	L^4	a: acceleration
Elasticity, f_e	$eS\Delta L\_/L$	L^2	e: Yang's modulus
Surface tension, F_s	$L\gamma$	L	γ: surface wetting constant
Resonant frequency, ω	$\sqrt{K/m}$	L^{-1}	M: spring constant ($\propto L$)
Moment of inertia, I	$\alpha\, mr^2$	L^5	α: shape constant, r: radius of rotor
Reinors number, R_e	f_i/f_f	L^2	Ratio between inertia and viscosity ($\propto L^2$)
Heat conduction, Q_c	$\lambda\, \delta\, TA/\_d$	L	$\delta\ T$: temperature difference, λ: heat conductivity, A: cross-section area ($\propto L^2$)
Thermal expansion, F_r	$eS\Delta L(T)/L$	L^2	Valid for piezoelectric deformation ($\Delta\ L(E)$)
Magnetic force, F_m	$\mu\, SH^2/2$	L^4	μ: permittivity, H: magnetic field ($\propto L$)
Electrostatic force, F_e	$\varepsilon\, SE^2/2$	L^2	ε: permittivity, E: electric field (constant)

Table 4 Comparison of driving principles

	Electrostatic	*Magnetic*	*Piezoelectric*	*Shape memory alloy*	*Thermal*
Speed	Excellent	Good	Good	Fair	Poor
Force	Poor	Good	Excellent	Excellent	Excellent
Integration with circuits	Excellent	Good	Fair	Good	Excellent
Power consumption	Excellent	Fair	Good	Fair	Poor
Robustness in harsh environments	Poor	Good	Good	Excellent	Excellent

Each actuation principle has its own advantages and disadvantages (**Table 4**). The choice and optimization of an approach should be made according to the requirements of a particular application. Generally speaking, the electrostatic actuator is more suitable for performing tasks that can be completed within a chip (e.g., positioning of devices/heads/probes, sensors with servo feedback for self-test or readout, light deflection and modulation) since it is easily integrated on a chip, easily controlled, and consumes little power. On the contrary, the other types of actuators are more robust, more capable of producing larger forces, and more suitable for performing external tasks (propulsion, manipulation of objects, etc.).

Applications

Figure 1 maps the prospective applications in optics, transportation and aerospace, robotics, chemical analysis systems, biotechnologies, medical engineering, and microscopy using scanning microprobes. Most of these applications have a common feature in that only very lightweight objects such as mirrors, heads, valves, cells, and microprobes are driven, and very little physical interaction with the external environment is necessary.

Sensors

The first successful application of MEMS was pressure sensors for the precise control of an automobile engine combustion for clean exhaust in 1980s. MEMS accelerometers are currently used for air bag ignition sensors. MEMS gyroscopes, or angular rate sensors, are applied to navigation systems, active suspensions, and spin suppression systems. Precisely micromachined membranes serve as pressure sensing element; its deflection by applied pressure is detected by piezoresistive gauges made on the silicon membrane. In the accelerometer, a proof mass suspended by a flexible suspension is micromachined (**Figure 2**). When acceleration is applied to the proof mass, the initial force displaces the mass and the suspension; this motion is detected by either the strain gauge, that is, an integrated piezoresistor, or the change in capacitance between the mass and a fixed electrode. Better linearity and stability can be achieved by feedback measurement in which the inertia force is cancelled by electrostatic force; the magnitude of the force is proportional to the acceleration.

Printers

The ink jet printer head is another example of successful MEMS products. Micro nozzles and channels of 10–20 μm in size are micromachined in an array. A microheater is attached to each channel. The heater generates a bubble in the channel when a current pulse flows through it. An ink droplet is ejected from the nozzle by the pressure pulse caused by the bubble. The amount of the droplet is in the order of a few pL now. A typical head has hundreds

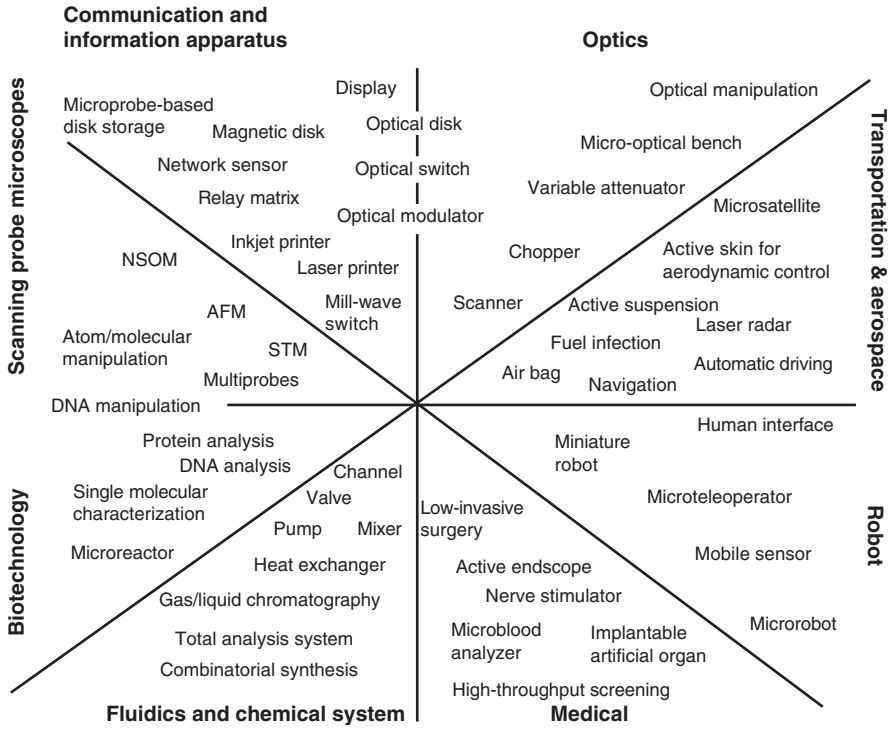

Figure 1 A map of MEMS applications.

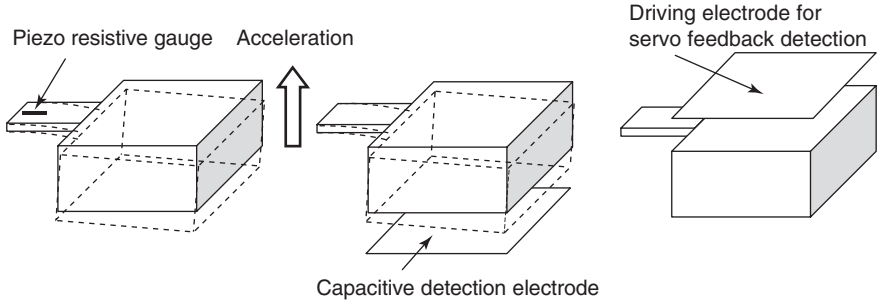

Figure 2 Micromachined accelerometer.

of nozzles and channels which operate as fast as 10 kHz. This device takes the advantage of the scaling effect, that is, the speed of heating and cooling increases with decrease in size. Thus, fine pictures and documents are printed on paper. Some heads use piezoactuators and electrostatic actuators to eject ink droplets.

Optical Devices

MEMS is very suitable to optical applications. Light beams can be controlled easily by moving mirrors, shutters, or gratings. MEMS with small feature sizes, precise motion and arraying capability can realize wide varieties of micro optical MEMS devices and systems based on interference, diffraction and refraction. MEMS technology also enables precisely aligned integration of active and passive optical devices, micromechanical elements and optical fibers. Therefore, optical MEMS devices and systems are used for optical scanners, micro-optical benches, arrayed micromirror displays, optical switches, modulators and attenuators.

The most successful example is a display. An array of movable micromirrors corresponding to pixels reflects light and projects an image on the screen. Each mirror is randomly accessible and tilted either $\pm 10^{\circ}$ by electrostatic force. The pixel becomes bright or dark depending on the angle of the mirror. The mirror moves within 0.1 ms and controls the brightness by pulse-width-modulation of reflected light. The array is micromachined on top of the integrated

circuits which allow the individual control of many mirrors within a short time.

MEMS based optical switches have been intensively studied. Optical switches, by means of mechanical movement, have favorable characteristics such as wave-length independence, polarization independence, large contrast, and small crosstalk. 2D MEMS optical switches change the optical path either straight or to a predetermined angle and connect it to one of the two output paths. The typical configuration of an N port 2D MEMS optical switch is shown in **Figure 3**. Light beams from input optical fibers are collimated by lenses. Micromirrors are inserted at appropriate positions to reflect beams and connect them to the output optical fibers. The alignment between fibers and mirrors is precisely determined by micromachined structures. Arrayed movable mirrors of several hundreds of micrometers in size are driven by microactuators. An on-off motion of the N^2 mirrors is necessary in the switch. The port count, N, is from 2–32. For port counts as large as a few hundreds, 3D MEMS switches are used. The schematic configuration is shown in **Figure 4**. Micromirrors have motion with two degrees of freedom, that is, rotation around two orthogonal axes. Two sets of arrays consisting of N such mirrors are used. Collimated input light beams hit one of the mirrors in the first array that direct the beam to one of the mirrors in the second array. The second mirror reflects the light straight into the output fiber. The analog control of mirror angles allows cross connection of a large number of signals. Those switches have application to optical cross connects, add-drop switches for wavelength divided multiplexing networks, and back-up or inspection apparatuses.

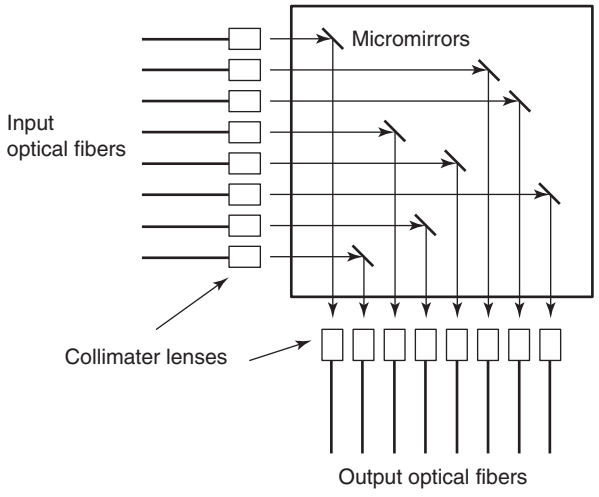

Figure 3 Principle of a 2D MEMS optical switch. Each micromirror is individually driven by a microactuator in the on-off fashion.

Optical scanners based on movable MEMS mirrors have many applications including bar-code readers, laser range finders, scanning laser microscopes, variable optical attenuators, and laser projection display. Some of them are already introduced in the market.

Chemistry and Biomedical Applications

Handling fluid in micromachined channels offers benefits in chemistry and biotechnology because of

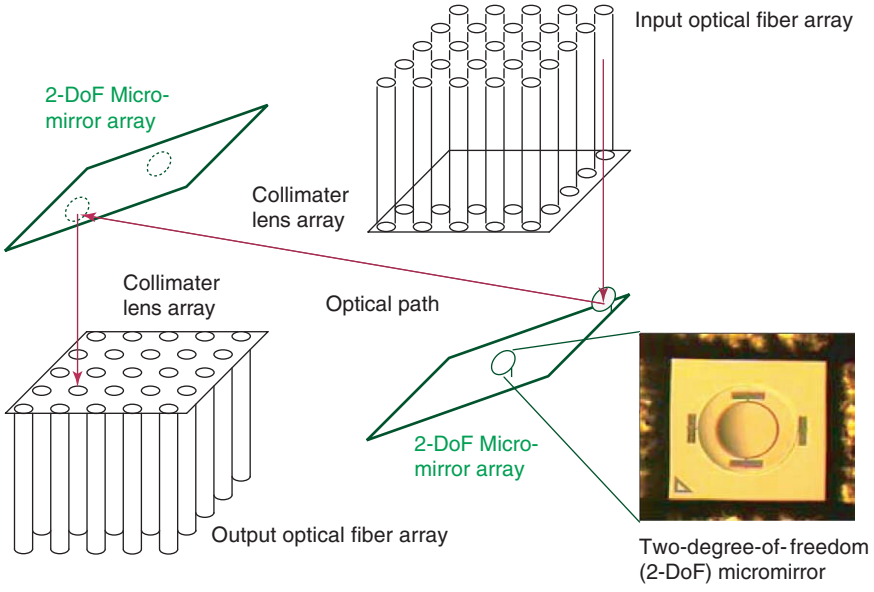

Figure 4 Principle of 3D MEMS optical switch.

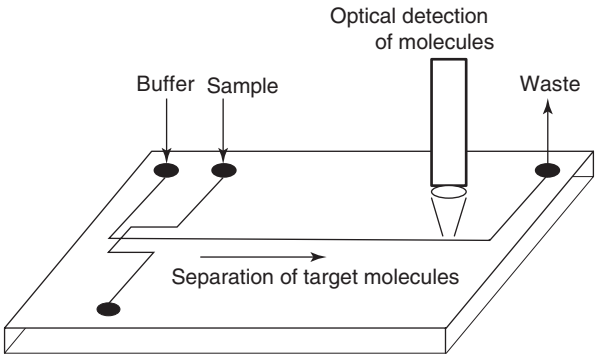

Figure 5 Principle of a chemical analysis chip based on capillary electrophoresis.

the scaling effect. The chemical reaction is completed within a few seconds due to short diffusion time in micro channels and reactors. Fast and precise temperature control is possible. Arrayed channels allow simultaneous chemical processing of a large variety of reactions. Only a small amount of samples or chemicals are required for chemical analysis and medical diagnosis. Even individual handling and observation of a cell or a molecule has been accomplished.

A typical microchemical chip is composed of one layer having grooves of 10–100 μm in dimension and another layer for sealing and connection to external pipes. Fluids flow in the channel to be mixed, heated, reacted, extracted, separated, and analyzed. Glass and PDMS (poly di-methyl siloxane) are two favored materials for the chip. Applications of microchemical chips include DNA analysis and amplification, blood analysis, environmental monitoring, combinatorial chemical synthesis, bioreactors and sensors, and production of fine chemicals.

The most successful product is the DNA electrophoresis in the micro channel. The device has two orthogonal channels (**Figure 5**). The sample solution containing DNA that is labeled by a fluorescent dye is introduced in the shorter channel by electroosmotic effect. A small amount of the sample is injected into the long separation channel by introducing a buffer solution from the end of the other channel. DNA fragments are driven by an electric field in the channel and separated due to the difference in migration speed depending on their length. Separation is completed within seconds and detected by fluorescence.

Future Development of MEMS

The future prospects of MEMS for making contributions to the future society are envisaged in three areas: (1) offering easier access to information for a wider public, (2) making human lifestyles more compatible with the environment, and (3) improving people's social welfare.

Breakthroughs to be accomplished by MEMS would be in five general areas: machine intelligence, downsizing and parallelism, biomimetics, informatics, and environment monitoring/preservation. Downsizing and parallelism will be the direct benefit from miniaturization and multiplicity. Machine intelligence and information networks can be very much improved by introducing MEMS integrated with microelectronics. These breakthroughs are likely to be realized by MEMS technologies within ten years. They may, for example, be used in healthcare for minimally invasive diagnosis and treatment.

Modulators, Optical

G Galzerano and P Laporta, Politecnico di Milano, Milan, Italy

Introduction

Modulated light has been used to transmit information over long distances in a fast and efficient way since the ancient times. The first modulation techniques were essentially manual, and were used to periodically obscure the light source, consisting either of reflected sunlight during the day, or fire beacons at night. Mechanical modulators, based on rotating mirrors and prisms, and different types of choppers, came into use at the beginning of the nineteenth century, producing intensity modulation of the optical source with repetition rate from a few hertz to a few kilohertz. A pulsed optical beam obtained by a rotating cog-wheel was employed for the first laboratory measurement of velocity of light performed by L Fizeau in 1849. The "photophone," invented by A G Bell in 1884, made use of a sunlight beam, the intensity of which was modulated by a mirror vibrating under the sound pressure of the voice, to transmit information. Starting from the 1930s, new modern devices were developed, based on electrooptic, acoustooptic, and magnetooptic effects, able to modulate light beams in the visible and infrared region with high efficiency and large bandwidths. Besides intensity, all relevant physical features of an optical wave, such as polarization, phase, and frequency, have been separately modulated exploiting various characteristics and physical effects, and ultrafast integrated electrooptical devices provide today modulation bandwidths up to several tens of gigahertz. At present, optical modulators are widely used with superior performance in many different fields, including optical communications, signal processing, and optical measurements (distance, velocity, etc.); in particular, they play a key role in all optical telecommunication systems. In this article, a general introduction to the most widely used optical modulators is presented, reviewing the basic principles of the theory and presenting significant results obtained with practical devices. On the basis of the different physical effects exploited, they have been subdivided into electrooptic, acoustooptic, magnetooptic, liquid crystal, and electroabsorption modulators.

Electrooptic Modulator

The term "electrooptics" mainly concerns the local effects induced by an electric field on the optical properties of a material. In particular, the Kerr and Pockels effects are related to the birefringence induced by an applied electric field to transparent materials (electrorefraction). The induced birefringence can be linearly proportional to the electric field (Pockels effect) or to the square of the electric field (Kerr effect). These effects are associated with the distortion of the electronic clouds by the applied electric field. In a quantum approach to the problem, the field modifies the wave functions of the electrons and the energy levels of the system, and consequently the dielectric response.

Electrorefraction provides, therefore, a physical method to directly modify the phase, the direction, and the polarization of a light beam in a controllable way. The Pockels and Kerr effects entered into the era of the optoelectronic technologies early in the 1950s when the use of these effects was proposed and demonstrated for the modulation and the switching of the light.

The optical properties of a material are characterized by the refractive index tensor (also called index ellipsoid), $(1/n^2)_{ij} = 1/\varepsilon_{ij}$, where ε_{ij} represents the ij element of the dielectric constant tensor, whose principal axes and eigenvalues determine the propagation of a light wave in the material. In a transparent material (lossless medium), ε_{ij} are real quantities, and for the symmetry of the tensor $\varepsilon_{ij} = \varepsilon_{ji}$, only six elements of the tensor are independent. The variations in the refractive index tensor induced by an applied electric field $\boldsymbol{E}$ are

$$\left(\frac{1}{n^2(\boldsymbol{E})} - \frac{1}{n^2(\boldsymbol{E}=0)}\right)_{ij} = \Delta\left(\frac{1}{n^2}\right)_{ij} = r_{ijk}E_k + s_{ijkl}E_kE_l + \cdots \cong r_{ijk}E_k + s_{ijkl}E_kE_l$$

where r_{ijk} and s_{ijkl} are the linear (Pockels) and quadratic (Kerr) electrooptic (EO) coefficients, respectively. The applied electric field induces a distortion of the index ellipsoid corresponding to a rotation of the ellipsoid and to a variation of the magnitude of the principal axes with regard to the zero-field condition. Due to the material dispersion and to the finite response time of the EO mechanisms (typically ranging from 10^{-12} to 10^{-14} s), the coefficients depend on the light wavelength and the frequency of the applied electric field. The Pockels effect exists only in materials that do not possess inversion symmetry (noncentrosymmetrical crystals), whereas the Kerr effect is present in all media and it is obviously the dominant term in centrosymmetrical materials (gases and liquids), where the Pockels effect is absent.

The EO coefficients r are in the order of the reciprocal of the internal electric field experienced by the electrons in the material, that is, $r \approx 10^{-11}\,\mathrm{m\,V^{-1}}$. In a similar way, the s coefficients are in the order of the reciprocal of the squared internal electric field, $s \approx 10^{-22}\,\mathrm{m^2\,V^{-2}}$. The number of nonzero and linearly independent EO coefficients is determined by the point symmetry of the material. As an example, **Table 1** reports the Pockels tensors for a few commonly used crystallographic point groups.

From a device operation point of view, the key parameter is the birefringence, Δn_E, associated with the selected direction of propagation in the EO material, induced by the electric field. This corresponds to the difference between the refractive indices, $\Delta n_E = n_1 - n_2$, of the two allowed directions of polarization (eigenmodes), and determines the EO retardation, Γ, between the eigenmodes at the output plane of the material

$$\Gamma = \frac{2\pi \Delta n_E l}{\lambda} = \frac{\omega \Delta n_E l}{c}$$

where λ is the light wavelength in vacuum, l is the length of the material, ω is the angular frequency of the optical beam, and c is the speed of the light in vacuum. In a Pockels material, the retardation can be expressed as $\Gamma = \pi(V/V_\pi)$, where V is the applied voltage and V_π is the voltage corresponding to a retardation equal to π; when a Kerr material is considered the retardation is given by $\Gamma = \pi(V/V_\pi)^2$.

The electric field can be applied parallel to the direction of the light propagation (longitudinal configuration) or perpendicular to it (transverse configuration) (see **Figure 1**). For the longitudinal configuration, used only with Pockels materials, Γ linearly depends on the applied potential, V, and not on the crystal interaction length l (typical values of the V_π voltage are in the range from 1 to 10 kV for visible radiation). In the transverse configuration, Γ depends on both the applied potential (V or V^2 for Pockels or Kerr materials, respectively) and on the crystal length l. In this last case, V_π can be significantly lower than that obtained with the longitudinal configuration (in particular for waveguide structures, **Figure 1c**, where the ratio between the waveguide length and its transverse aperture, d, is much larger than 1), and, in addition, the field electrodes do not interfere with the optical beam. For these reasons, the transverse configuration is widely adopted.

EO phase modulators perform a modulation of the phase of light beams. Longitudinal and transverse configurations can be used. The (linear) polarization of the incoming optical beam has to be along a direction parallel to an externally induced principal axis. In this case, when the light propagates in the modulator, the polarization state is unmodified, but the optical field experiences a refractive index which is a function of the applied electric field. At the modulator output, the phase of the optical wave is incremented by

$$\begin{aligned} \Delta\phi(E) &= \frac{\omega}{c}[n(0) + \Delta n_E(E)]l \\ &= \Delta\phi(0) + \frac{\omega}{c}\Delta n_E(E)l \end{aligned}$$

where $n(0)$ is the unperturbed refraction index (ordinary), and Δn_E can be expressed as $\Delta n_{E,\,\mathrm{Pockels}} = n_0^3 r_{\mathrm{eff}} E/2$ or $\Delta n_{E,\,\mathrm{Kerr}} = n_0^3 s_{\mathrm{eff}} E^2/2$ for Pockels or Kerr modulators, respectively (r_{eff} and s_{eff} are the effective EO coefficients for the Pockels and Kerr

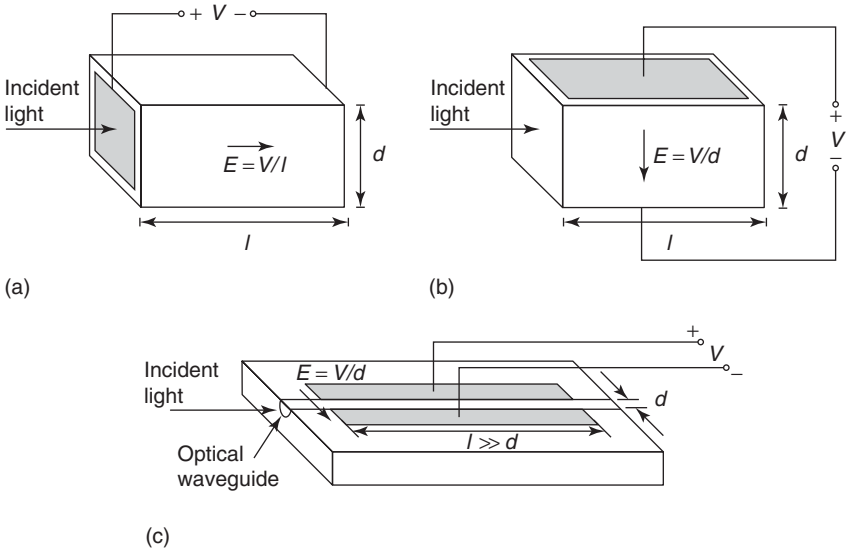

Figure 1 Electrooptic configurations: (a) longitudinal, (b) transversal in bulk crystal, and (c) transversal in an optical waveguide structure. *l* is the interaction length in the EO crystal, *d* is the aperture of the EO modulator, and *E* is the applied electric field.

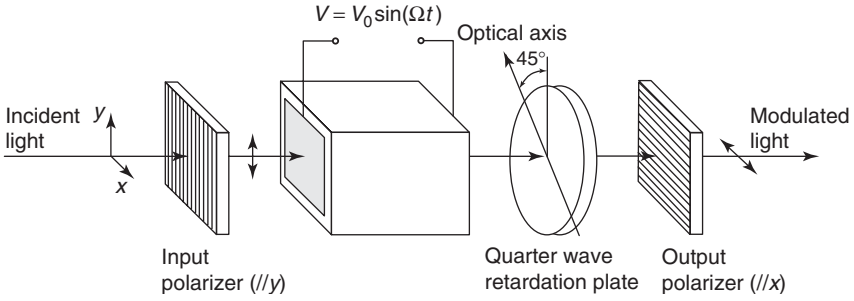

Figure 2 Schematic diagram of a typical longitudinal EO intensity modulator. The EO crystal acts as a variable retardation plate modulated at angular frequency Ω by the applied voltage *V*. The quarter-wave plate is used to obtain effective linear modulation around 50% transmission.

effects, respectively). The phase of the light beam can thus be modulated if the applied electric field is modulated (e.g., $E = E_0 \sin \Omega t$); assuming a Pockels modulator and a sinusoidal modulation of the applied electric field, the instantaneous phase of the light beam at the output of the modulator is

$$\Delta\phi(E) = n_0 \frac{\omega}{c}\left[1 + n_0^2 r_{\text{eff}} \frac{E_0 \sin \Omega t}{2}\right] l$$
$$= \Delta\phi(0) + \beta \sin \Omega t$$

where β is the phase modulation index (in unit of radiant) and Ω is the angular frequency of the modulation electric field.

In the polarization modulators, the EO crystal acts as a variable retardation plate. In this way, by means of a linear polarizer selecting the polarization of the input beam, the polarization state of the output beam is determined by the EO retardation phase Γ, which is modulated by the applied electric field. Transverse and longitudinal configurations can be used to implement an EO polarization modulator. In a general operating condition, the polarization of the transmitted light at the output of the modulator can therefore be changed with continuity between two limiting elliptical states with a frequency equal to that of the modulation signal.

To achieve intensity modulation of a light beam by means of the EO effect, it is necessary to combine a polarization modulator with a polarization analyzer placed at the output of the modulator, consisting of a second linear polarizer with crossed direction with respect to the input polarization (see **Figure 2**). In this configuration, the intensity I_t of the light transmitted by the output polarizer is related to the phase difference between the two eigenmodes of the optical beam propagating in the modulator by the relation

$$I_t = I \sin^2\left(\frac{\Phi}{2}\right) = \frac{I}{2}(1 - \cos \Phi)$$

where I is the intensity of the incident beam, and Φ is the total phase retardation given by the sum of the EO retardation Γ and the intrinsic birefringence of the material, Φ_0, which for a Kerr medium is always zero. For an efficient linear modulation, it is necessary to operate the modulator around Φ values close to $\pi/2$ (see **Figure 3**). This can be achieved either by inserting an additional quarter wave plate (for example, adjacent to the output polarizer), or by using a DC bias which produces a constant phase shift of $\pi/2$. In this case, the intensity of the transmitted light is given by

$$I_t = \frac{I}{2}[1 + \sin(\Gamma)] = \frac{I}{2}\left[1 + \sin\left(\pi \frac{V}{V_\pi}\right)\right]$$

when a Pockels modulator with $\Phi_0 = 0$ is considered. Assuming a sinusoidal modulation $V = V_0 \sin \Omega t$, and $V_0 \ll V_\pi$, the transmitted intensity is

$$I_t = \frac{I}{2}\left(1 + \pi \frac{V_0}{V_\pi} \sin \Omega t\right)$$

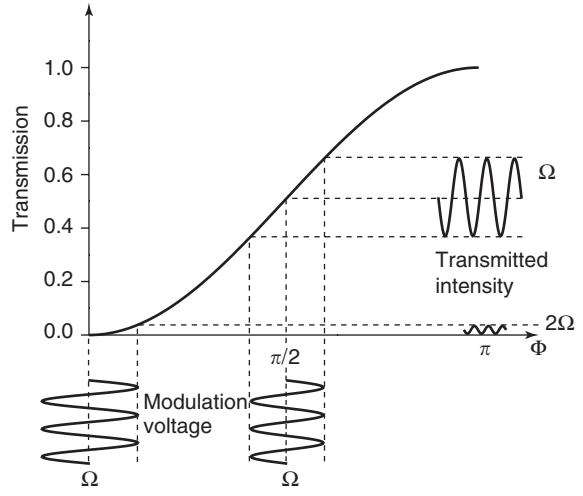

Figure 3 Transmission of the EO intensity modulator as a function of phase retardation Φ. For an operating condition around $\Phi = \pi/2$, the voltage modulation at angular frequency Ω is converted into intensity modulation. When the modulation is applied around $\Phi = 0$, the efficiency strongly decreases while the optical beam is modulated at twice the modulation frequency.

In the above description of the EO modulators, the expressions for the retardation produced by the electric field are valid in the case of low modulation frequencies. Increasing frequency, the transit time of the light through the modulator, $\tau_d = nl/c$, sets a limit, $\Omega_{max} = \pi c/2nl$, to the maximum modulation frequency (typically Ω_{max} is of the order of a few gigahertz). To overcome the transit time limitation, the modulation signal has to be applied in the form of a traveling wave by means of a suitable radiofrequency (RF) waveguide structure. In these devices, the phase velocity of the optical beam is matched to the phase velocity of the RF modulation signal. This form of modulation can be adopted only using transverse geometry (see **Figure 4**). The maximum modulation frequencies of a traveling wave modulator are in the range from 10 to 100 GHz.

EO modulators are widely used in laser and photonics fields thanks to the excellent performance over a wide wavelength spectral range, from the ultraviolet to the far infrared. Pockels modulators are much more diffused than Kerr cells because of the higher efficiency. **Table 2** shows the EO properties of some of the most commonly used Pockels materials. For laser applications, EO modulators are used both inside the laser resonator to obtain different pulsed operation regimes, such as Q-switching, cavity dumping, and mode-locking, and externally to the laser source to directly modulate the intensity, frequency, polarization, and direction of the optical beam at very high modulation frequencies (up to 100 GHz). In particular, active mode-locked lasers based on intracavity EO modulators enable the generation of very short pulses in the picosecond regime at extremely high repetition rates. A very convenient configuration for implementing the EO effect is represented by an optical waveguide structure. In this configuration, typical values of the half-wave voltages are a few volts, and low driving power can be used. The waveguide EO modulators can be realized with a single waveguide or a pair of waveguides (Mach–Zender configuration), and they can operate as phase/intensity modulators or as optical switches. These modulators are commonly fabricated using titanium indiffused $LiNbO_3$ and GaAs waveguides.

Acoustooptic Modulators

Diffraction of light by sound was first predicted by Brillouin in 1922, and experimentally observed some 10 years later by Debye and Sears in liquids, and Raman and Nath in solids. The elastooptical effect is the basic mechanism responsible for the acoustooptic interaction. It describes the change in the refractive index of a medium caused by the mechanical strains related to an acoustic wave traveling through the material. The relationships between the change of refractive index and the strain are in general rather complicated; it can be shown that the change in refractive index is proportional to the square root of the acoustic power. By means of the elastooptical effect, the traveling acoustic wave sets up a periodic spatial modulation of the refractive index, as depicted in **Figure 5**, which, under proper conditions, may diffract the light beam into one or more directions. The interaction of the light beam with the acoustic beam can result in optical beam deflection and modulation of amplitude, frequency, phase, or polarization of the optical wave. A simplified model of the acoustooptic interaction is based on a plane wave analysis. In this model, the incident light is assumed to be a plane wave which is diffracted by a rectangular sound column into a number of plane waves propagating in different directions. The resulting set of coupled wave equations are the Raman–Nath equations. The solution of these equations can be classified in two different regimes, depending on the ratio of the interaction length, L, and a characteristic length, $L_0 = n\Lambda^2/\lambda$, where n is the refractive index of the material and Λ is the wavelength of the acoustic wave. There are two main cases of interest, namely, (1) the Raman–Nath regime, where $L \ll L_0$, and (2) the Bragg regime, corresponding to $L \gg L_0$.

(1) In the Raman–Nath regime, the acoustic diffraction grating is so thin that the diffracted light suffers no further redistribution before leaving the modulator. The light is diffracted as from a simple plane phase grating, with diffraction angles given by $\sin\theta_N = N\lambda/\Lambda$, where $N = 0, \pm 1, \pm 2, \ldots$ are the diffraction orders. A schematic picture of the interaction between the light beam and the sound wave is shown in **Figure 6**. The intensities in the various orders depend on the maximum excursion of the phase delay in the grating, which is related to the amplitude of the acoustic modulating wave. More specifically, the intensity I_N diffracted in the Nth order is given by $I_N = I_i J_N^2[(2\pi/\lambda)L\Delta n]$, where I_i is the intensity of the incident beam, J_N is the Nth order Bessel function, and Δn is the maximum refractive index variation. The largest possible diffraction efficiency in each order is the maximum value of J_N^2; for the first diffraction order this maximum is 33.8%, resulting in a relatively low efficiency of the modulator.

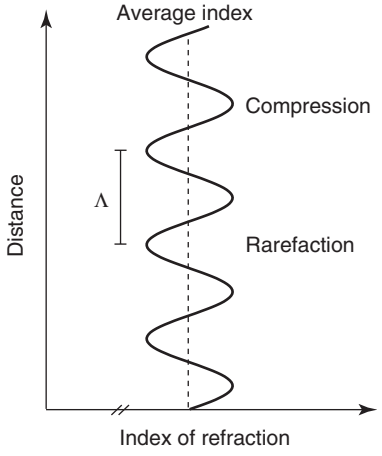

Figure 5 Schematic illustration of acousto-optic modulation. The sound wave produces alternating regions of compression and rarefaction in the medium, resulting in a spatial variation of the refractive index with period Λ equal to the acoustic wavelength.

(2) In the Bragg regime, there is a long interaction path between the sound and the incident light. Under this condition, the periodic modulation of the refractive index induced by the acoustic field behaves as a thick phase grating, and the light undergoes diffraction from a series of parallel acoustic phase fronts acting as partially reflecting mirrors. The condition for constructive interference along a direction can be found by imposing that all the points on a given mirror contribute in phase along this direction and, in addition, the diffraction from any two acoustic phase fronts adds up in phase along the direction of the reflected beam. With reference to **Figure 7**, the two conditions are satisfied when the incident angle is equal to the diffracted angle and is given by

$$\sin \theta_B = \lambda/2n\Lambda$$

where θ_B is the Bragg angle. It can be shown that in this condition the diffraction efficiency $\eta = I_d/I$ (I_d and I are the diffracted and incident intensities) is given by

$$\eta = \sin^2[(\pi/\lambda)/(L\Delta n/\cos \theta_B)]$$

and can theoretically equal 100%. Most acousto-optic devices are therefore designed to operate in the Bragg regime.

The sound wavefronts which generate the diffraction grating are moving through the medium with velocity v_s; as a consequence, the optical diffracted wave undergoes a frequency shift according to the Doppler effect. The frequency shift, $\Delta v = v_d - v$, between the frequency of the diffracted (v_d) and

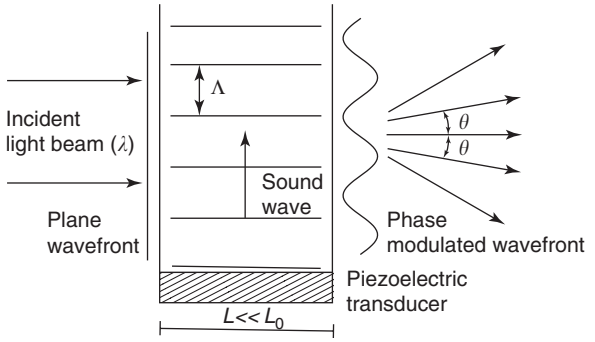

Figure 6 Diffraction of light by an acoustic wave in the Raman-Nath regime and schematic of the modulator. The interaction length $L \ll L_0$ and thus the light is diffracted as from a simple plane phase grating. The first order diffraction angle $\theta \approx \lambda/\Lambda$, where λ and Λ are, respectively, the optical and acoustic wavelength.

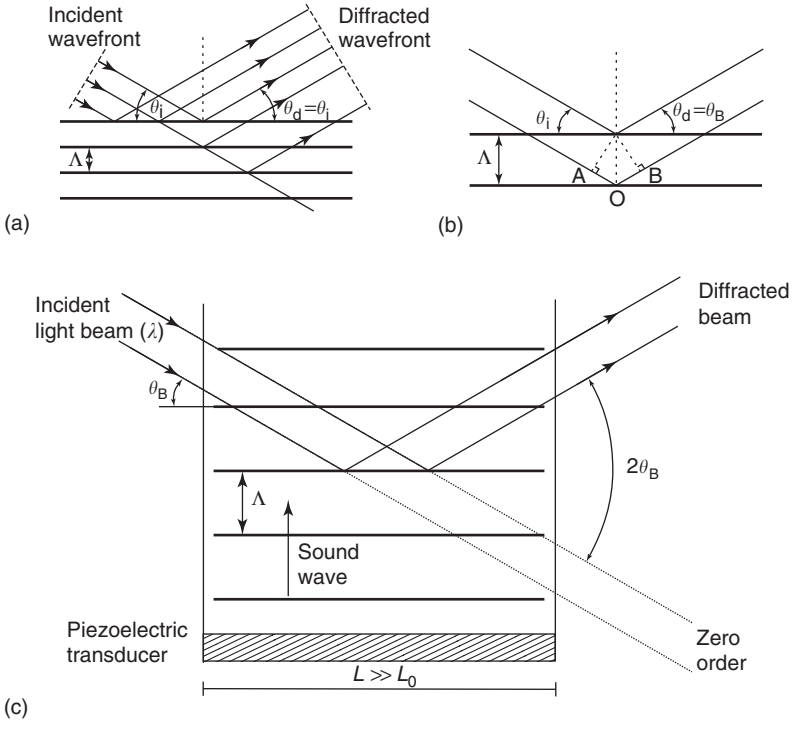

Figure 7 Diffraction of light by an acoustic wave in the Bragg regime. The interaction length $L \gg L_0$ and the light is reflected from successive layers or acoustic phase fronts of the grating. (a) All the points on a given layer contribute in phase at the new diffracted wavefront (diffraction angle θ_d equal to the incident angle θ_i); (b) the optical path difference $\overline{AO} + \overline{OB}$ is equal to one optical wavelength so that the diffraction from any two layers adds up in phase (constructive interference for diffraction angle θ_d equal to Bragg angle θ_B); (c) schematic of the acoustooptic modulator. Λ and λ are, respectively, the acoustic and optical wavelength.

incident (v) beams is given by $\Delta v = \pm 2v\, v_s \sin\theta_B\, n/c$, where the plus sign applies for a sound wave moving toward the optical beam. Substituting the Bragg condition in the above relationship, one obtains $\Delta v = \pm f$, where $f = v_s/\Lambda$ is the acoustic wave frequency. This change in frequency can be used as the basis of a frequency shifter.

Diffraction of light from acoustic waves can also be interpreted in terms of the quantum theory. Accordingly, an optical wave of angular frequency ω and wave vector $\boldsymbol{k}$ is regarded as a stream of photons with momentum $\hbar\boldsymbol{k}$ and energy $\hbar\omega$. An acoustic wave of angular frequency $\omega_s = 2\pi f$ and wave vector $\boldsymbol{k}_s$, likewise, is regarded as a stream of phonons with momentum $\hbar\boldsymbol{k}_s$ and energy $\hbar\omega_s$. Scattering of light by the sound wave can be described as series of collisions, each involving the annihilation of one incident photon and one phonon, and the simultaneous creation of a new diffracted photon with momentum $\hbar\boldsymbol{k}_d$ and energy $\hbar\omega_d$, propagating along the direction of the diffracted beam. The conservation of momentum, when the sound wave moves approaching the incident beam, requires that $\boldsymbol{k}_d = \boldsymbol{k} + \boldsymbol{k}_s$, as illustrated in **Figure 8**. The conservation of energy implies that $\omega_d = \omega + \omega_s$, which is the Doppler formula for upshifted Bragg diffraction. The conservation of momentum is equivalent to the Bragg condition, considering that the sound frequencies of interest are below 10^{10} Hz and the optical frequencies usually above 10^{14} Hz, so that $\omega_s \ll \omega$, $k_d \approx k$, and the magnitude of the sound wave vector is thus $k_s = 2k \sin\theta_B$ (see **Figure 8**).

The diffraction efficiency can be expressed in terms of acoustic intensity. In fact, the refractive index change is related to the strain s_r by $\Delta n = -n^3 p s_r/2$, where p is the photoelastic constant for an isotropic medium, and s_r is related to the acoustic intensity I_{ac} by $s_r = [2I_{ac}/(\rho v_s^3)]^{1/2}$, being ρ the mass density. Combining the above expressions with that of the diffraction efficiency, one obtains under the Bragg condition

$$\eta = \sin^2\left[\frac{\pi L}{\sqrt{2}\lambda\cos\theta_B}\sqrt{MI_{ac}}\right]$$

where $L/\cos\theta_B$ is the oblique distance of penetration of light through the acoustic wave, and $M = n^6 p^2/\rho v_s^3$ is a figure of merit relating the diffraction efficiency (the refractive index change) to the acoustic intensity. M is generally reported as a normalized quantity, referred to the value for fused silica, and turns out to be the acoustooptic figure of merit most frequently used to compare different materials, even if there are several others defined in the literature which may better apply to evaluate specific applications of various acoustooptic devices. For relatively small values, the diffraction efficiency turns out to be linearly proportional to acoustic intensity.

A property which strongly influences device performance is acoustic attenuation, mainly due to losses caused by relaxation of thermal phonon distribution toward equilibrium. In most crystals, it has been observed that the attenuation of the sound wave has a quadratic dependence on the acoustic frequency. In **Table 3**, a list of selected materials used in acoustooptic devices is reported together with their relevant properties.

Acoustooptic interaction can be exploited for temporal, spatial, and spectral modulation of light, using different devices such as intensity modulators, deflectors, tunable filters, and frequency shifters.

Intensity modulation of the optical beam is proportional to the intensity of the acoustic wave, if the sound intensity is sufficiently weak, and a linear analog modulation of light intensity can be obtained. Increasing the acoustic power, the diffraction efficiency η increases but the modulation is no longer linear, and the acoustooptic (AO) modulator serves as an optical switch. An important parameter for AO modulators is the modulation bandwidth, that is, the maximum frequency at which the modulator can efficiently operate. When the amplitude of an acoustic wave of frequency f (carrier) is varied as a function of time by a signal of bandwidth B, the acoustic wave acquires frequency components within a band $f \pm B$. The principle of operation of an AO modulator is schematically illustrated in **Figure 9**. In order to fulfill the Bragg condition and achieve modulation of the optical beam, each of these frequency components will interact with a proper plane wave of the angular spectrum of the incident light beam. The variation of the Bragg angle corresponding to a frequency

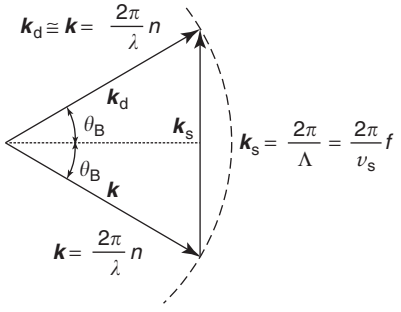

Figure 8 Momentum conservation in the interaction of an optical plane wave with wavevector $\boldsymbol{k}$ (or an incident photon with momentum $\hbar\boldsymbol{k}$) with an acoustic plane wave with wavevector $\boldsymbol{k_s}$ (or a phonon with momentum $\hbar\boldsymbol{k_s}$). The vector relation $\boldsymbol{k_d} = \boldsymbol{k} + \boldsymbol{k_s}$ is equivalent to the Bragg condition $k_s = 2\,k \sin\theta_B$. Λ and λ are, respectively, the acoustic and optical wavelength; n is the refractive index.

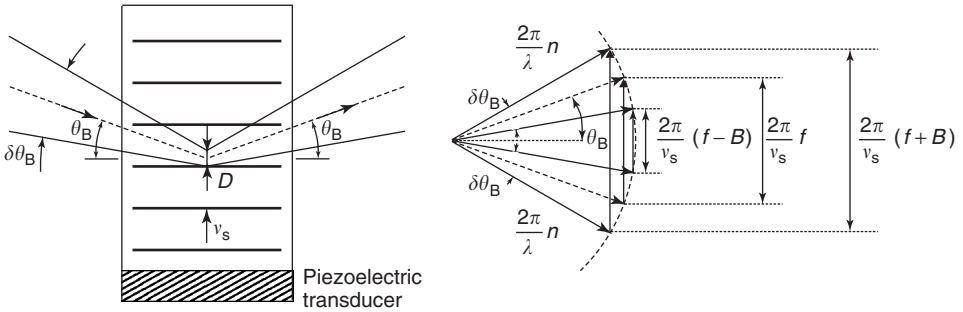

Figure 9 Principle of operation of an AO modulator. The incident optical beam of angular divergence $\delta\theta_B$ is diffracted by a plane acoustic wave with frequency spectrum extending from $f - B$ to $f + B$. Each direction (optical wave vector of a plane wave) within the angular spectrum of the optical beam is matched to a parallel acoustic wave vector with different magnitude. Increasing the modulation bandwidth B requires a corresponding increasing of the angular divergence.

spectrum of $2B$ is $\delta\theta_B = \lambda B/nv_s$ (the angle θ_B being small, $\sin\theta_B \cong \theta_B$). Assuming a plane acoustic wave, $\delta\theta_B$ has to match the divergence angle $\theta_{div} \approx \lambda/nD$, where D is the width of the optical beam inside the modulator. It follows that $B = v_s/D = 1/\tau$, where τ is the transit time of sound across the light beam width. To increase the modulation bandwidth, materials with high sound velocity should be used and the light beam should be focused to a small diameter.

AO modulators are widely used for a variety of applications and present many advantages compared to electrooptic modulators, such as low driving power, simpler electronics, and high extinction ratio; the main drawback is the lower modulation bandwidth. Devices for external laser modulation are available in the visible and in the infrared region, with rise time ranging from few tens to $\sim 2\,\text{ns}$, and efficiency 70–80%. AO devices are also used as laser intracavity modulators (thanks to the high optical quality of materials such as fused silica and $LiNbO_3$) to obtain pulsed operation in various regimes, namely, mode-locking, Q-switching, and cavity dumping. For mode-locking operation, the standing-wave AO modulator introduces a time variable loss with period T_m equal to the inverse of the longitudinal mode spacing, $T_m = 2d_l/c$, where d_l is the laser cavity length.

AO deflectors are based on the property that the direction of the diffracted beam can be varied by changing the driving frequency of the acoustic wave. In fact, starting from the Bragg condition, the deflection angle $\Delta\theta$ between the directions of incident and diffracted beam is found to be proportional to the acoustic frequency change, $\Delta\theta = \lambda\Delta f/nv_s$. To avoid tilting of the sound beam during the angular scan, an acoustic wave with angular divergence $\Delta\theta_s \geqslant \Delta\theta$ is used. A schematic picture of the principle of operation of an AO deflector is shown in **Figure 10**. The interesting parameter here is the number of resolvable spots $N = \Delta\theta/\theta_{div}$, that is, the number of non overlapping angular widths within the angular scan. It is readily obtained that $N = \Delta f(D/v_s) = \Delta f\tau$; the number of resolvable spots is therefore equal to the time–bandwidth product. To increase N, a large transit time τ should be used, but this also limits the random access time which is a measure of the speed of the deflector. There is clearly a trade-off relation between access time and resolution. It is worth noticing that the design requirement of a large τ for high-resolution AO deflector is the opposite of what is needed for large-bandwidth AO modulators.

Relevant applications of AO deflectors include laser scanners and high-resolution/wide-band Bragg cells for optical signal processing. The maximum resolution of AO deflectors is limited to a few thousand; high-performance materials, such as TeO_2 and Hg_2Cl_2, enable 2000–4000 resolvable spots with good efficiency and acceptable access time. Bandwidths of 2 GHz and peak diffraction efficiency in excess of $10\%W^{-1}$ have been demonstrated with $LiNbO_3$ devices.

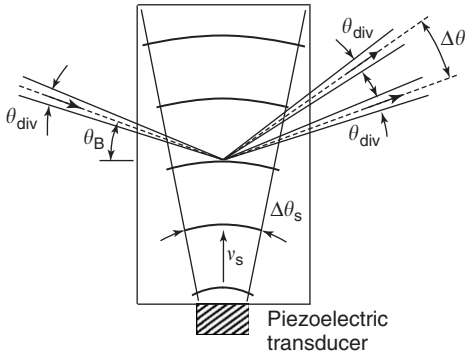

Figure 10 Principle of operation of an AO deflector. The ratio between the deflection angle $\Delta\theta$ and the divergence θ_{div} gives the number of resolvable spots *N*. The sound wave has an angular width $\Delta\theta_s \geqslant \Delta\theta$ to make momentum conservation possible without tilting the sound beam. For a better legibility of the figure, the width *D* of the optical beam inside the modulator is not highlighted.

Acoustooptic tunable filters operate on the principle of acoustooptic diffraction in anisotropic materials. These devices are designed to achieve very narrow bandwidths (from few nanometers to few angstroms) with wide tuning ranges (from few hundreds of nanometers to few microns), obtained by changing the frequency of the applied RF signal. The main advantage is the electronic tunability, but a large driving power is often needed.

AO modulators can also be realized exploiting the interaction between surface acoustic waves (SAWs) and optical modes confined in dielectric waveguides. The confinement of the acoustic power near the surface leads to extremely low modulation power. Integrated AO modulators based on SAW have been fabricated in $LiNbO_3$.

Magnetooptic Modulator

The magnetooptic effect largely used for the modulation of the light is the Faraday effect. It induces a rotation of the polarization plane of an optical beam propagating in a magnetooptic material (such as glass, quartz, zinc sulfide, and water), when a magnetic field is applied parallel to the propagation direction of the optical beam. The angle of rotation is

$$\vartheta = \upsilon \mathscr{B}\, l_m$$

where $\mathscr{B}$ is the magnitude of the magnetic flux, l_m is the length of medium, and υ is the Verdet constant that depends on the specific material and wavelength (see **Table 4** for some representative values). Clockwise or anticlockwise rotation of the polarization plane is related only to the direction of the applied magnetic field (generated by the current circulating in a solenoid) and is independent of that of the light beam. In a way similar to that already illustrated for EO devices, intensity magnetooptic modulators are implemented by inserting a Faraday rotator between two (crossed) polarizers. In this type of device, the modulation frequency is however limited to a few tens of megahertz, due to the inductance of the solenoid.

High-frequency (up to a few gigahertz) magnetooptic modulators, based on a thin film of bismuth-garnet materials (such as MnBi, Bi:YIG, and

Table 4 Typical values of the Verdet constant υ at $\lambda = 589.3$ nm

Material	υ (rad m^{-1} T^{-1})

$Bi_3Lu_3Fe_5O_{12}$), have been recently developed. The main drawback of bismuth garnets is the strong absorption in the near-infrared spectral region (from 800 nm to $\sim$25 μm), which represents a serious limitation to the diffusion of these devices.

Liquid Crystal Modulators

Liquid crystals (LCs), an intermediate phase between a liquid and a crystalline solid, were first observed in 1888 by Reinitzer. These substances, which typically consist of two benzene (or cyclohexane rings, or phenyl rings) linked with a central group, show the mechanical properties of liquids but the optical properties of crystalline solids, in the sense that the arrangement of the molecules exhibits some structural order. LCs having a liquid–crystalline mesophase variable with temperature are indicated as thermotropic; solutions of substances where the mesophase is also dependent on relative concentrations are called lyotropic. Thermotropic LCs have been widely investigated and their applications to light modulation have reached a mature stage. There are three basic types of thermotropic LCs, termed nematic, cholesteric, and smectic; nematic LCs are the most largely utilized at present.

A major characteristic of all LC compounds is the rod-like shape of their molecules. The preferred time-averaged orientation of the molecular long axes is indicated by a director $\boldsymbol{L}$, a unit vector pointing in such a direction. In the nematic state, the molecules are arranged parallel to each other in an arbitrary direction, with a casual distribution of the centers of mass of the molecules (see **Figure 11a**). In the cholesteric state, the molecules have a defined director $\boldsymbol{L}$ on a specific plane as well, but its orientation is not spatially constant. The molecular structure is characterized by equidistant parallel planes, with $\boldsymbol{L}$ rotated by a fixed angle from one plane to the next (see **Figure 11b**); after a spatial period of pitch P (of the order of the optical wavelength), $\boldsymbol{L}$ retraces the original orientation, resulting in a helicoidal ordering. From this point of view, the nematic order can be regarded as a special case of the cholesteric one with $P \to \infty$. In the smectic state, different types of stratified structures exist; for instance, smectic A has the molecules arranged in layers orthogonal to the long axis of the molecules, with casual distribution of the centers of mass in each layer (see **Figure 11c**); smectic B presents, in addition, an ordering of the centers of mass of the molecules inside each layer, similarly to two-dimensional solids (**Figure 11d**); smectic C has the long axis of the molecules tilted with respect to the layers by an angle which is a function of the temperature (see **Figure 11e**).

One important characteristic of LCs is the optical anisotropy characterized by different dielectric constants $\varepsilon_\parallel, \varepsilon_\perp$ depending on whether the polarization of the optical field is parallel to, or perpendicular to, the director $\boldsymbol{L}$. If $\varepsilon_\parallel > \varepsilon_\perp$, the material is denoted as positive, and can be treated as a positive uniaxial crystal with optical axis parallel to $\boldsymbol{L}$. The optical birefringence is rather strong, with typical value $\Delta n_B = n_\parallel - n_\perp$ ranging from 0.1 to 0.3. Another major property is the optical activity, or rotary

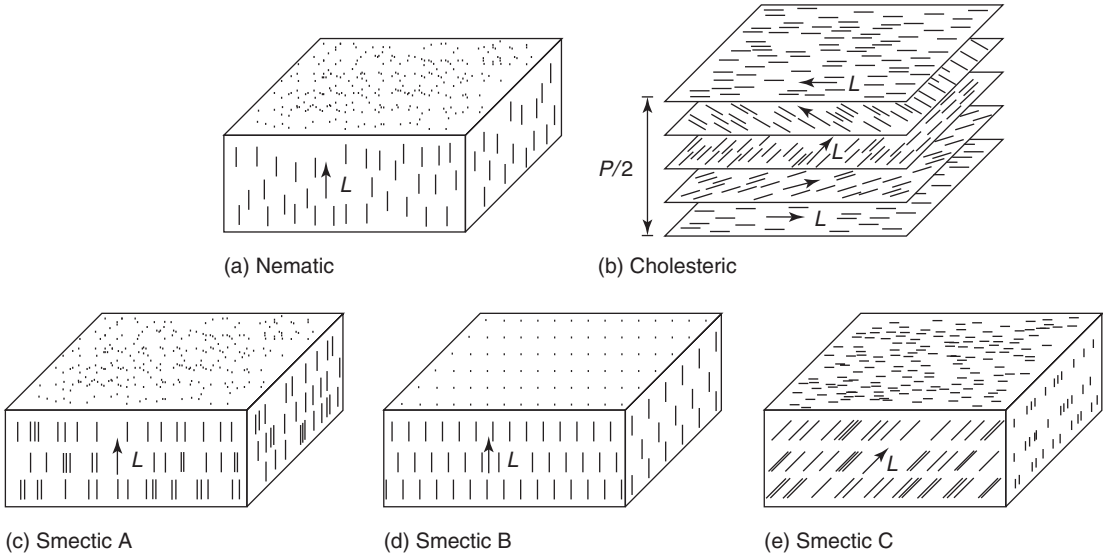

Figure 11 Schematic of the structure of thermotropic liquid crystals: (a) nematic; (b) cholesteric of pitch P; (c) smectic A; (d) smectic B; (e) smectic C.

birefringence, causing the polarization of the impinging optical field (linearly polarized) to rotate its plane of polarization, following the direction of $\boldsymbol{L}$ from the input to the output plane.

Several mechanisms for modulating light using liquid crystals have been developed, including director axis reorientation, nematic–cholesteric phase change, absorption in dichroic dye-LC systems, scattering by LC microdroplets in polymer matrix. The basic principle is related in all cases to the fact that the application of an external electric field to a positive material tends to align the long axis of the molecules parallel to the electric field in order to minimize their energy. Director reorientation is widely used in nematic LCs, where there are two different types of ordering, namely homeotropic and homogeneous, depending on whether the director of the molecules is aligned perpendicular or parallel to the liquid crystal–solid interface. These two forms are produced by a suitable treatment of the solid surface. To obtain homogeneous ordering, microgrooves are produced on the internal surface of the LC cell, usually coated with an optically transparent metallic film such as indium–tin oxide, by rubbing the surface or evaporating thin SiO_2 stripes. A thin layer of an initially homogeneously ordered LC sandwiched between two solid interfaces can be changed into a homeotropic state, when an electric field is applied perpendicularly to the liquid crystal–solid interface. The process is illustrated in **Figure 12** for increasing values of the magnitude of the electric field $\boldsymbol{E}$. If $E > E_{th}$, the molecules begin to align along the field direction; when $E \gg E_{th}$, the majority of the molecules are aligned perpendicularly to the interface.

When a linearly polarized light passes through a homogeneously ordered LC, if the polarization axis forms an angle (usually 45°) with the director, phase retardation occurs due to the birefringence of the material; for a given thickness of the LC layer, the birefringence depends on temperature, wavelength, and applied field. In particular, for $E \gg E_{th}$, birefringence and thus phase retardation sharply decrease as the field is increased, up to a saturation value. Exploiting the large phase changes that can be obtained with small voltage modulations (few volts), intensity light modulators can be fabricated by sandwiching the LC cell between two crossed polarizers. Pure phase modulators and tunable phase retardation plates can be obtained with parallel aligned LC cells as well.

In a twist nematic alignment, the opposite walls of the cell containing the positive LC material are treated to produce a homogeneous arrangement in which the directors at the interfaces are twisted with an angle. Different twist alignments are employed according to the twist angle, usually 45°, 90°, and $>90°$ (supertwist nematic, e.g., 270°). Most common LC displays are based on a 90°-twisted nematic cell. When a linearly polarized beam passes through a 90°-twisted nematic cell, the rotary birefringence causes the polarization plane to follow the twist of the LC directors and to undergo a 90° rotation. If an electric field $E \gg E_{th}$ is applied to the twisted cell, the molecular alignment becomes mainly homeotropic and the light polarization is almost not influenced by the LC layer. A schematic of the changes in a twisted nematic cell under an external electric field is shown in **Figure 13**. A light modulator can be realized by sandwiching a twisted nematic cell between two

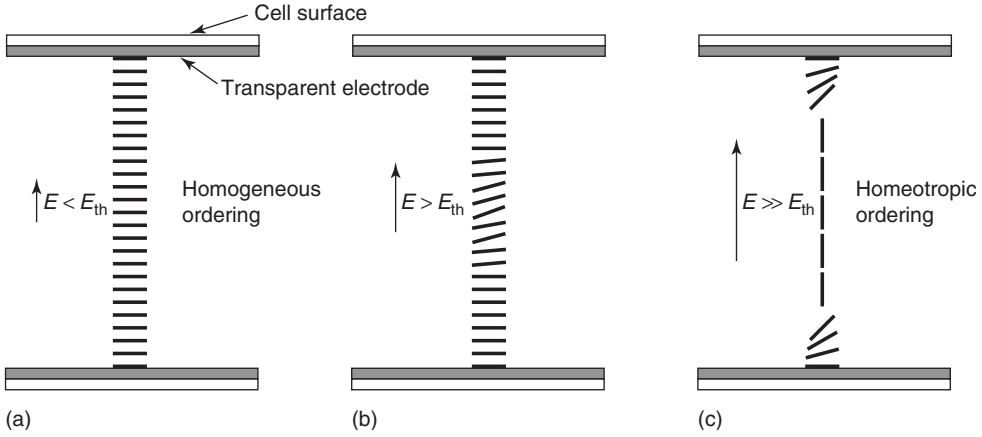

Figure 12 Illustrating director axis reorientation as an increasing electric field $\boldsymbol{E}$ is applied to an initially homogeneously ordered LC in a direction perpendicular to the liquid crystal – cell interface. (a) For $E < E_{th}$ the homogeneous ordering is not affected; (b) for $E > E_{th}$ the molecules begin to align along the field direction; (c) for $E \gg E_{th}$ the molecules are almost completely aligned in the direction of the electric field and the LC cell shows essentially homeotropic ordering.

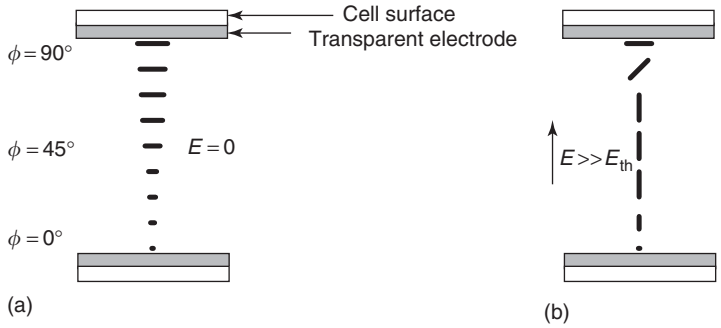

Figure 13 Director axis orientation in a 90° twisted nematic liquid crystal cell. (a) Applied field $E = 0$; (b) $E \gg E_{th}$. φ is the twist angle.

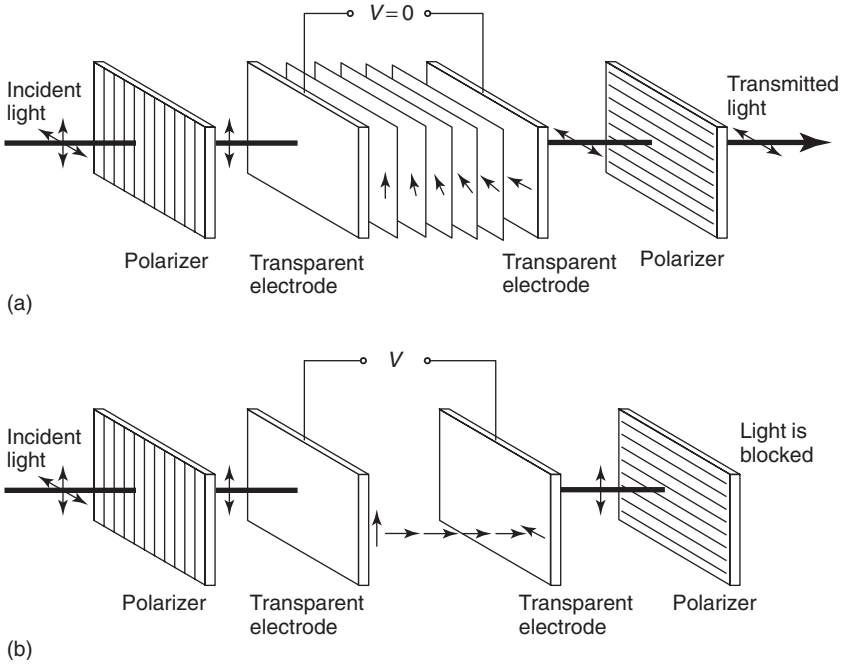

Figure 14 Operation of a twisted nematic LC cell. (a) In the absence of an electric field, the cell acts as a polarization rotator and light is transmitted; (b) in the presence of an electric field, homeotropic order of molecules does not affect the polarization, and light is blocked. V is the voltage applied to the LC cell.

crossed polarizers with axes parallel to the directors of the particular cell interface they are next to (see **Figure 14**). The typical cell thickness is $\sim 10\,\mu m$ or less. In the absence of an external electric field, the polarized beam is transmitted with the polarization plane rotated by 90°, as illustrated in **Figure 14a**; when $E \gg E_{th}$, the cell rotatory power is inhibited and the beam is blocked by the second polarizer, as shown in **Figure 14b**. Operation in the reflection mode is also possible, if a reflecting surface is placed after the second polarizer.

Dicroic dye-LC systems are formed by dissolving a suitable dye in the liquid crystal. The rod-shaped dicroic dye molecules strongly absorb the light polarized parallel to the long axis direction, showing only a weak absorption in the orthogonal direction. The type of bonding between the dye and the liquid crystal molecules tends to align the former parallel to the director and to follow its orientation. The transmission of the solution can be varied by reorienting the liquid crystal director by an external electric field, resulting in intensity modulation of the incident light.

Submicron droplets of LCs dispersed in a polymer matrix can also be used for intensity modulation. It is to be assumed that the ordinary index $n_\perp$ of the LC is equal to the refractive index n_p of the polymer (isotropic), while the extraordinary index $n_\parallel > n_p$. Due to a random orientation of $\boldsymbol{L}$ for each droplet and the consequent refractive index mismatch with the polymer, the LC droplets act as scattering centers for the incoming light, and the transmission through the cell is low. By applying a suitable electric field to the

polymer matrix, the directors of the droplets can be oriented so that the impinging optical field, parallel to the direction of the extraordinary axis (i.e., parallel to $\boldsymbol{L}$), propagates as an ordinary ray through the LC droplets, experiencing a refractive index $n_{\perp} = n_{\mathrm{p}}$; in this case, there is almost no scattering and the light beam is transmitted.

A major limitation of LC optical modulators is the limited time response, which depends on several parameters of the LC such as rotational viscosity, elastic constant, threshold electric field, on-cell geometry, and on the applied electric field (as far as the rise time is concerned). In nematic LCs, the rise and decay times are generally rather slow, of the order of milliseconds. Faster response time can be obtained using cholesteric materials; recently, smectic ferroelectric LC cells have been developed with response time from a few microseconds to a few hundreds of microseconds.

The main application of LC cells regards spatial modulation of light, and is concerned at present with display fabrication, mainly with display elements for digital watches, cellular phones, pocket calculators, flat panels, and light switches. Compared to other types of displays, such as light emitting diodes and plasma displays, the principal advantage of LC displays is their low electrical power consumption, due to the passive nature of the display. They however have a number of disadvantages, besides the relatively slow response time, including optical efficiency, limited by the use of polarizers which absorb at least 50% of the unpolarized incident light, and the angle of view limited by the reduction in the contrast of modulated light when the angle of incidence/reflection is increased. Two common LC display formats are the seven-bar-segment display used to form numbers from 0 to 9, and the 7×5 matrix display used for more complex characters.

Electroabsorption Modulator

Electroabsorption effect is related to the modification of the absorption coefficient, α, of a material induced by an external electric field. This effect permits the direct control of the intensity of a light beam passing through the material. Since the refractive index and the absorption coefficient are related by the Kramers–Kronig dispersion relation, when an electric field induces a change in the refractive index of a material (electrorefraction), the absorption coefficient also changes. The Kramers–Kronig relation,

$$n(\omega) = 1 + \frac{c}{\pi}\,\mathrm{P.V.}\int_0^{\infty} \frac{\alpha(\omega')}{\omega'^2 - \omega^2}\,\mathrm{d}\omega'$$

where P.V. stands for Cauchy principal value of the integral, is completely general and applies to any type of materials. When the photon energies of the incident light is close to the bandgap of the material, the electroabsorption effect is strongly enhanced. High-efficiency electroabsorption modulators are based on semiconductor materials (such as GaAs, InGaAs, and InP) both in bulk and in multiple quantum well structures. In the bulk structure, the applied electric field changes the effective bandgap of the semiconductor (Franz–Keldysh effect), thus increasing the absorption of the semiconductor for frequency lower than the bandgap. Quantum wells are thin (~ 10 nm or less) layers of small bandgap semiconductor material, sandwiched between larger bandgap semiconductors (barriers). A multi-quantum well (MQW) structure consists of alternating small and large bandgap layers of semiconductors. In these structures, the applied electric field shifts the energy levels, producing a similar shift of the absorption edge toward lower frequencies (quantum confined Stark effect).

To realize an intensity modulator based on the electroabsorption, the frequency of the optical beam (i.e., the energy of the incident photons) has to be just below the absorption edge (i.e., the bandgap of the semiconductor). In this way, the light is transmitted through the modulator when the applied electric field is off. When the electric field is increased, the absorption spectrum shifts toward lower frequency (red shift) and the modulator switches from transparent to highly absorbing, reducing the intensity of the transmitted light.

The main advantage of these devices is that they can be directly integrated with the conventional high-speed microelectronic components as well as with semiconductor diode lasers. These integrated optoelectronic structures constitute the key components for the realization of photonic devices needed in wide-band optical communication systems

Molecular Clusters

R A Broglia, University of Milan, Milan, Italy

Introduction

Nanostructured materials are made out of atoms as their more common forms, but the atoms are arranged in nanometer or sub-nanometer size units, which become the building blocks of the new materials. A prototype of these building blocks is the C_{60} fullerene. These tiny grains, atomic aggregates or clusters, in which the surface plays a paramount role, respond to external influences as light, mechanical stress, and electric fields quite differently from bulk matter. Hence, nanostructured materials display an array of novel attributes and properties.

To learn how to produce customer-tailored nanometer materials, one needs to have a thorough knowledge of the physical properties of the associated building blocks, that is, of atomic aggregates. For example, small silver particles dissolved in the stained glasses of medieval cathedrals led to the blues, the distinct ruby being produced by the presence of gold particles.

When trying to understand the color of these particles, it is not enough to refer to the optical response of either the individual atoms or the bulk metal crystals. This is because the way the properties of a solid gradually evolve as atoms are brought together to form increasingly larger units, is far from being trivial. The end points of such evolution is reasonably well understood, but the knowledge of the intermediate situations still remains poor. A sodium atom has a very simple absorption spectrum, as shown schematically in **Figure 1**. It consists of essentially one line in the visible, the well-known yellow light. In quantum physics, this phenomenon is well described as a one-electron transition from a quantal state, known as 3*s*, to an excited state, denoted by 3*p*. A sodium crystal, on the other hand, has a completely different spectrum. The absorption is strong in the infrared, goes through a minimum in the visible, and then rises again in the ultraviolet. The reason for this is that very low energy photons can excite electrons from the continuum of states just below the energy of the last occupied state to states just above the Fermi energy. The strong ultraviolet absorption is caused by interband transitions.

Suppose a small corner of a crystal is chipped off, producing a microcrystal that contains only eight atoms. Again, the absorption spectrum changes completely. A relatively broad absorption maximum displaying different lines (resonances) appears in the visible region. This absorption is due to a collective excitation of outer electrons called a plasmon excitation (collective excitation of valence electrons). It can be viewed as a collective sloshing motion of the electrons from one side of the microcrystal to the other side. Such a motion has a strong dipole moment, behaving as an antenna which gives rise to a strong absorption band in the visible region (see **Figure 2**).

The absorption of light by a sodium atom is well described within the picture of independent particle motion. In this picture, each electron moves in the atom as if it were alone. It is only when an electron tries to leave the atom that it feels that its motion is confined due to the presence of a wall produced by the pullings and pushings of all the other electrons and of the positively charged atomic nuclei. That is, in the independent particle model, the electrons move in the average potential generated by the interaction

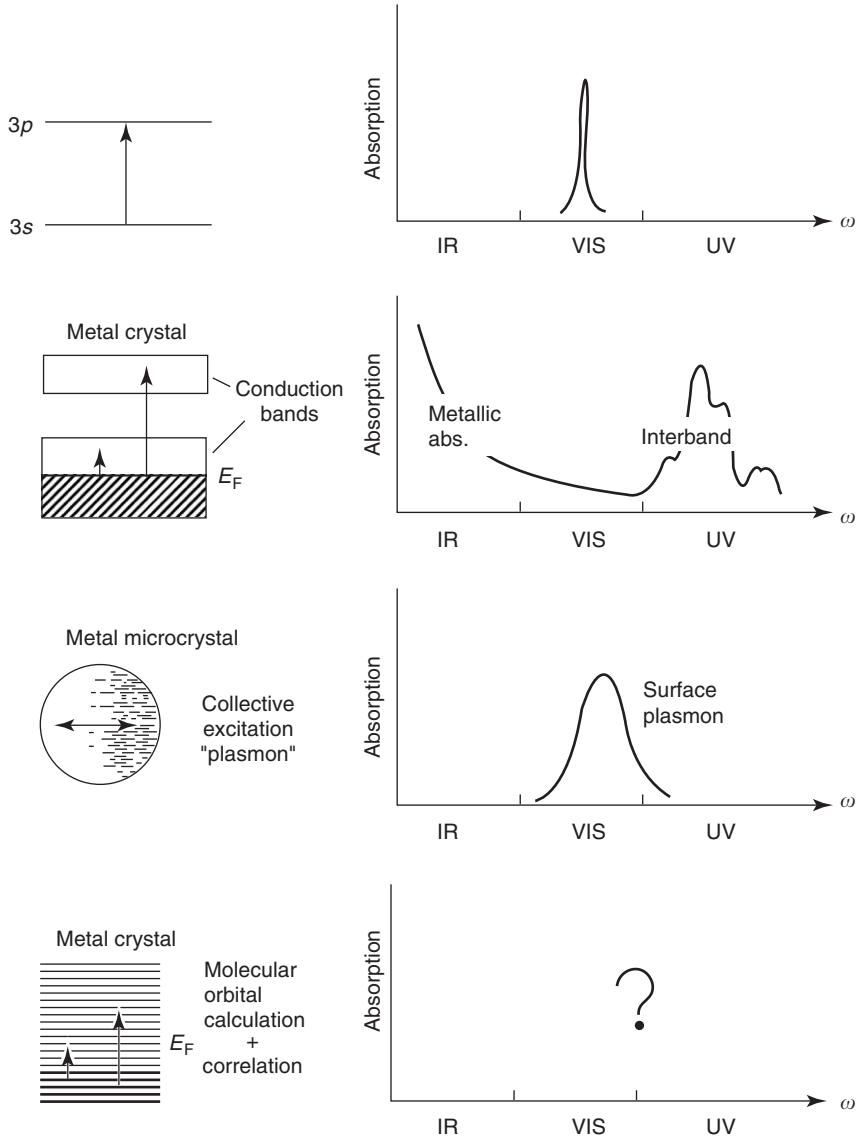

Figure 1 Absorption of light by sodium in different stages of aggregation.

with the other electrons and with the ions. This picture, however, cannot describe even qualitatively the resonance phenomenon (plasmon excitation) that dominates the optical response of an eight-atom cluster. Between one and eight atoms, one must completely change one's way of looking at the optical response of the system.

Because the response to light is quite different in Na_8 than in bulk Na, one would expect that a material made out of small sodium aggregates will display quite a color difference from that of a sodium crystal. It is likely that it will also display a number of other differences, in particular, regarding specific heat, conductivity, elasticity, etc. This is also expected to be true for other metallic aggregates (e.g., Ag- and Au-clusters).

Some of the most promising building blocks of nanophase materials are fullerenes (see **Figure 3**), molecules which have been found to maintain most of their intrinsic characteristics when placed inside an infinite crystalline lattice, whether they form van der Waals or covalent solids. Color, strength, transport properties, and other features of these materials depend on the properties of the isolated molecules, in particular, on the strength with which electrons couple to ionic vibrations (phonons). The mechanisms which are at the basis of this coupling are also important in understanding the properties of carbon nanotubes and linear carbon chains, remarkable examples of molecular quantum wires. This is in keeping with the fact that nanotubes can be obtained by bisecting a fullerene molecule at the equator,

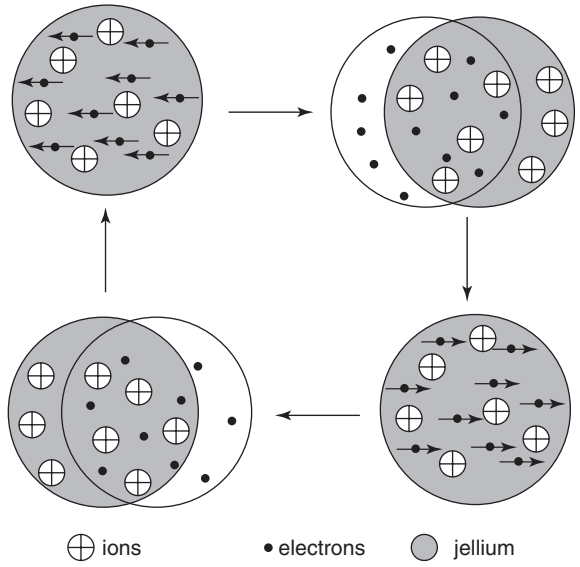

Figure 2 Schematic representation of the collective motion of valence electrons (plasmons) in a metal cluster.

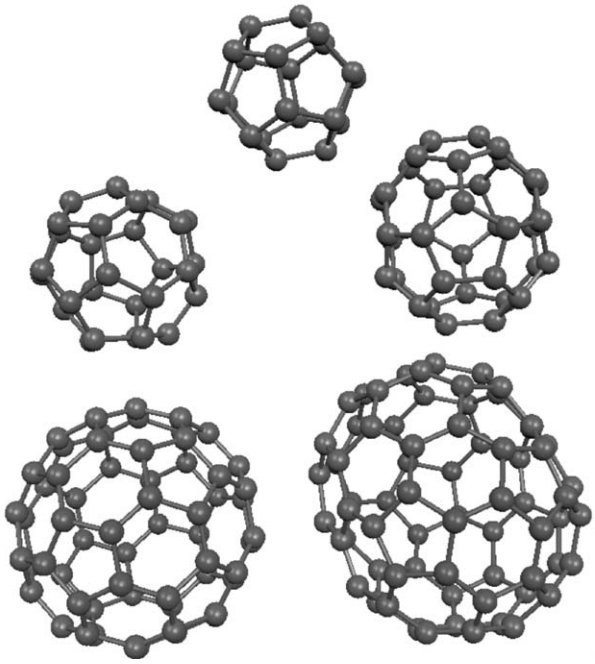

Figure 3 Selected fullerenes: molecular structure for (from top to bottom, and from left to right) C_{20}, C_{28}, C_{36}, C_{60}, and C_{70}.

joining the resulting hemispheres with a cylindrical tube made out of an arbitrary number of belts, each built out of benzoid rings. While single-wall C_{20}-derived nanotubes are the thinnest capped nanotubes which can be thought of, linear chains made out of carbon atoms are the ultimate examples of atomic quantum wires, playing a role in such different phenomena as the presence of diffuse interstellar bands (DIF) in the spectra of distant stars, and, arguably, in the field emission of open-end carbon nanotubes.

Electronic Levels

The basic starting point in the study of atomic aggregates such as metal clusters, fullerenes, nanotubes, and linear carbon chains is the mean field theory, one of the most useful approximations in all of physics and chemistry. In it, the many-particle Schrödinger equation is replaced by a single-particle Schrödinger equation.

For example, the Hartree–Fock equation

$$\left[-\frac{\hbar^2}{2m_e}\nabla^2 + v_H(r)\right]\varphi_j(\boldsymbol{r}) + \int d^3r' U_x(\boldsymbol{r},\boldsymbol{r}')\varphi_j(\boldsymbol{r}') = \varepsilon_j\varphi_j(\boldsymbol{r}) \quad [1]$$

where

$$v_H(\boldsymbol{r}) = \int d^3r' \varrho(\boldsymbol{r}')v(|\boldsymbol{r}-\boldsymbol{r}'|) \quad [2]$$

with

$$\varrho(\boldsymbol{r}) = \sum_{i\in occ} |\varphi_i(\boldsymbol{r})|^2 \quad [3]$$

and

$$U_x(r,\boldsymbol{r}') = -\sum_{i\in occ} \varphi_i^*(\boldsymbol{r}')v(|\boldsymbol{r}-\boldsymbol{r}'|)\varphi_i(\boldsymbol{r}) \quad [4]$$

The functions v_H and U_x are the Hartree and the Fock (exchange) potentials, while $\varphi_i(\boldsymbol{r})$ are the single-particle wave functions. These equations can be solved self-consistently and the total energy of the system calculated. The result is however not sufficiently accurate, in that it lacks the renormalization effects of the single-particle motion arising from correlation effects. Taking these correlation effects adds an ω-dependent correlation potential to $v_H(r)$. Within the local density approximation (LDA), this potential reads

$$v_c = \frac{\partial E_{corr}(n)}{\partial n} = -0.91\ln\left(1+\frac{11.41}{r_s}\right)eV \quad [5]$$

where $E_{corr}(n)$ is the energy of the interacting electron gas, n the density functional of the system, $r_0 = r_s a_B$ the Wigner–Seitz radius while $a_B = \hbar^2/m_e e^2 = 0.529$ Å is Bohr's radius. Within the same approximation,

$$\int d^3r' U_x(\boldsymbol{r},\boldsymbol{r}')\varphi_j(\boldsymbol{r}') \approx v_x(r)\varphi_j(\boldsymbol{r})$$

with

$$v_x(r) = -e^2\frac{1}{\pi}(3\pi^2 n(\boldsymbol{r}))^{1/3} \approx -0.985e^2n^{1/3}$$

The Hamiltonian resulting from the sum of the two terms in the square brackets of eqn [1] plus v_c and v_x, as well as the external field generated by the ions, is known as the Kohn–Sham Hamiltonian. Its solution provides accurate results not only for bulk matter, but also for atomic and molecular aggregates.

What started out as a problem too complicated to solve for all but the smallest systems becomes quite manageable when one deals with one particle at a time. The many-body effects come in via the single-particle potential, which is generated from the particles themselves. The resulting self-consistent mean field theory has been enormously successful in many domains of quantum mechanics. Whenever a many-particle system exhibits single-particle behavior, which happens quite commonly, the mean field theory is likely to be useful.

In the case of metal clusters, fullerenes, nanotubes, linear carbon chains etc., there are a number of observations which testify to the validity of the independent particle picture. In fact, the dependence of quantities such as mass abundance and ionization potential vary strongly with the number of atoms (see **Figures 4** and **5**). In particular, the energy needed to free one electron from the cluster exhibits a distinct shell structure with extreme values at prescribed number of electrons. These discontinuities are strongly connected with the independent particle picture already mentioned. In fact, the orbits in which an electron moves in an average potential display a bunchiness as a function of the number of electrons which can be viewed as layers enveloping the ions, much like the configuration of an onion. These layers or shells each contain a number of orbits and thus a given number of electrons, the so-called magic numbers. Special stability is ascribed to the filling of each of these shells. In particular in the case of C_{60}, the single-particle energy gap between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) is 1.8 ± 0.1 eV, a quantity much larger than room temperature (≈ 25 meV), a fact which testifies to the stability of this system (see **Figure 6**).

Another example of a closed-shell system is provided by Na_8. The lowest energy structures of this system calculated within the LDA are displayed in **Figure 7**. These isomers are characterized by the symmetries associated respectively with the groups $\mathscr{D}_{2d}$ (ground state (GS)), $\mathscr{D}_{4d}$ (89 meV), and $\mathscr{T}_d$ (95 meV) – the figures in parentheses being the total energies calculated in LDA and expressed with respect to the ground-state energy. The Kohn–Sham energy levels for the $\mathscr{D}_{2d}$ system are reported in **Table 1**.

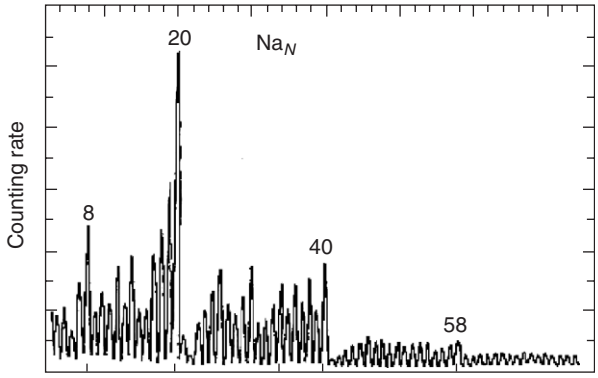

Figure 4 Na clusters abundance.

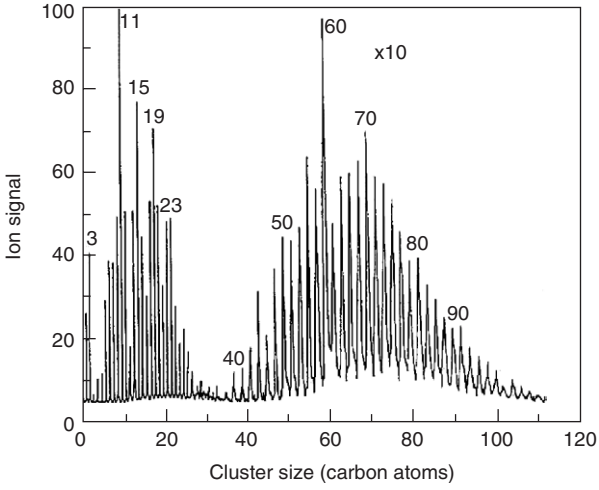

Figure 5 Carbon clusters abundance.

In the Born–Oppenheimer (BO) approximation (also known as adiabatic approximation) used in deriving the LDA equations describing the electronic motion, the equations which determine the electronic state are decoupled from those related to the ionic dynamics. In other words, the atomic motion of the system (molecule, cluster, or solid) is studied under the hypothesis that the electronic system always remains in the electronic ground state associated with the instantaneous geometrical configuration (e.g., **Figure 7**). One can then analyze the solution of the problem of atomic motion in the case of small oscillations near the equilibrium configuration (i.e., when every atom stays always near its equilibrium position, and there is no atomic diffusion). In this case, writing down a second-order expansion of the total potential felt by the ions (harmonic approximation), one can show that it is possible to reduce

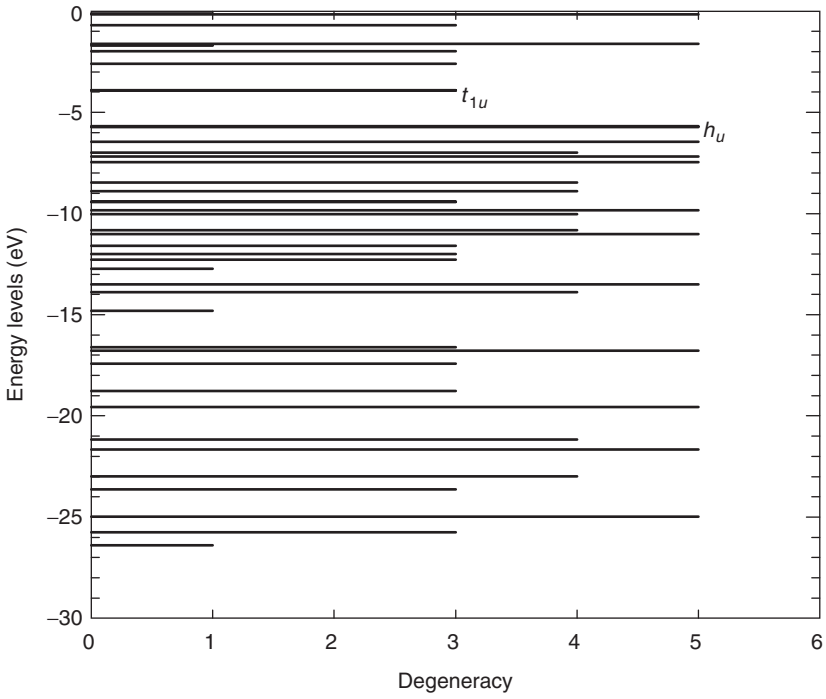

Figure 6 Energy levels of C_{60} calculated in LDA. The HOMO (h_u) and LUMO (t_{1u}) levels are indicated.

the problem to that of a collection of independent harmonic oscillators. The general solution is then a superposition of $3N_{at}$ normal modes of vibration, each of them having its own frequency and its own eigenvector, obtained by diagonalizing the dynamical matrix. The quantum description of this set of independent harmonic oscillators leads to the concept of phonons.

The harmonic approximation is generally a good one for solid-state systems, molecules or atomic aggregates, at sufficiently low temperature. In the case of carbon systems (graphite, diamond, fullerenes), which are characterized by a quite strong covalent bonding, the harmonic approximation is still very good at room temperature.

In the case of atomic and molecular clusters, it is possible to generalize the arguments of the previous section by discussing the general properties of the solution for the ionic motion, valid independently of the actual form of the total potential U acting on the ions: in particular, in order to determine the different

parameters of the model, namely the first and second derivatives of U, and thus the dynamical matrix.

It emerges that this matrix can be obtained from a knowledge of the derivatives, with respect to the independent $3N_{at}$ (Cartesian) atomic displacements, of the force exerted on the atoms. Such derivatives can be computed numerically, evaluating the change of the component β of the force generated on the atom m, when the atom n is displaced by a small amount in the direction α. This can be done by minimizing the DFT functional with respect to the electronic degrees of freedom and hence evaluating the forces on the ions, after having slightly displaced a given atom along a given Cartesian direction. The process must be repeated for the three components x, y, and z of every atom. Since the ionic displacements are small, the requested set of $3N_{at}$ electronic minimizations is largely facilitated if one starts them from the electronic configuration, which corresponds to the equilibrium ionic positions. Many practical applications of the above method can be found in the recent literature. A typical example from the field of carbon clusters is the case of C_{60}. Calculations confirm that good agreement with respect to the experimentally measured vibrational spectra can be obtained by using the Car–Parrinello method in the DFT–LD approximation. Similarly, the cluster C_{28} has been studied at the same level of accuracy. Its normal modes, which couple to the LUMO electronic orbital (i.e., those with A_1, E, and T_2 symmetry), are reported in **Table 2**.

Another interesting case where the *ab initio* methods discussed above can be applied is that of metal aggregates. Among them is the closed-shell Na_8 cluster. In this case, there are 14 distinct nonzero vibrational eigenvalues, four of them being doubly degenerate. Making use of the Car–Parrinello molecular dynamics (CPMD) formalism, one obtains, for the $\mathscr{D}_{2d}$ symmetry configuration, the results displayed in **Table 3**.

Figure 8 reproduces the atomic displacements associated with the highest totally symmetric mode (16.7 meV). The displacement field associated to specific modes is an important physical quantity, to which *ab initio* calculations give direct access. The displacement fields (vibrational eigenvectors) are in fact hardly accessible from the experiment; they are, however, very important objects, since they govern the size of the coupling with the electronic states (electron–phonon coupling).

Plasmons

If a weak external time-dependent perturbation is applied to the electronic system (e.g., a low-intensity electromagnetic field of a sufficiently high-frequency, such that one can neglect the response of the ionic degrees of freedom), the electronic density will start oscillating around the minimum energy configuration. For such weak external fields, one can, to a very good approximation, retain only the linear part of the response. In this approximation, the frequency of the induced oscillations will be determined by the curvature of the energy surface around its minimum. As the density oscillates, the effective potential changes and, in turn, induces a change in the density itself. Therefore, to describe these electron "vibrations," one must require self-consistency between

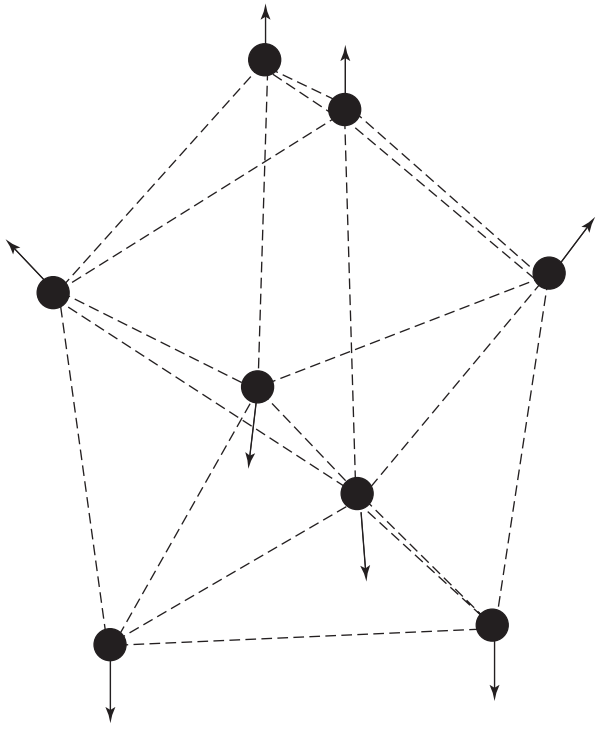

Figure 8 Displacement associated with the A1 phonon in Na_8 at energy 16.7 meV.

the variations of the density and those of the effective potential. In this way, a time-dependent theory can be obtained starting, for example, from Hartree, Hartree–Fock, or LDA energy functional within the linear response approximation. However, the first two approaches are intrinsically based on a mean-field approximation and neglect correlations beyond those arising from the Pauli principle. On the other hand, the time-dependent extension of the LDA (TDLDA) could also be derived, making a local approximation again, from an exact theorem leading to the so-called time-dependent DFT (TDDFT).

Within this scheme, the response of the system to a (weak) time-dependent field

$$V_{\text{pert}}(\boldsymbol{r},t) = V_{\text{pert}}(\boldsymbol{r})\exp(-\mathrm{i}\omega t) + \text{hc} \qquad [6]$$

is expressed in terms of the perturbed density

$$\varrho(\boldsymbol{r},t) = \varrho_0(\boldsymbol{r}) + \delta\varrho(\boldsymbol{r},\omega)\cdot\exp(-\mathrm{i}\omega t) + \text{hc} \qquad [7]$$

where ϱ_0 is the ground-state density, and where

$$\delta\varrho(\boldsymbol{r},\omega) = \int \mathrm{d}^3r'\ \Pi(\boldsymbol{r},\boldsymbol{r}',\omega)V_{\text{pert}}(\boldsymbol{r}) \qquad [8]$$

The quantity $\Pi(\boldsymbol{r},\boldsymbol{r}',\omega)$ is the so-called RPA density–density correlation function.

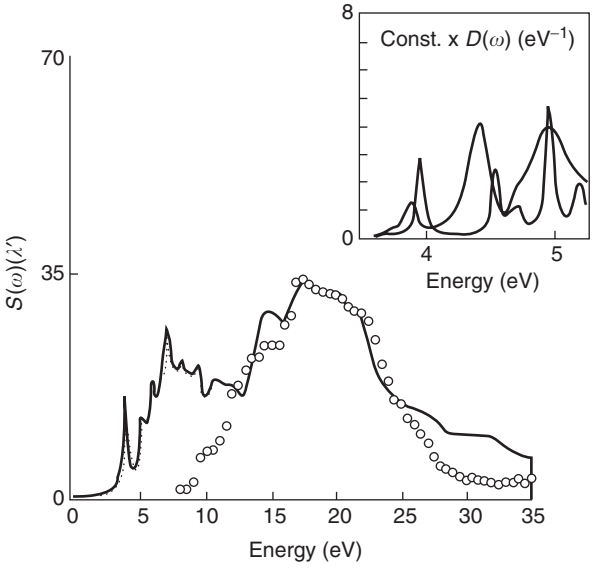

Figure 9 TDLDA response (full line) compared to the experimental points (open circles) (to be noted that the cutoff at $\approx$10 eV is due to the experimental setup). Inset: detailed spectrum at low energies compared to experimental results (broken curve).

From the induced density $\delta\varrho(\boldsymbol{r},\omega)$, one can extract physical quantities of interest such as the dynamical linear polarizability, $\alpha(\omega)$, according to

$$\alpha(\omega) = \int \mathrm{d}^3r\ \delta\varrho(\boldsymbol{r},\omega)V_{\text{pert}}(\boldsymbol{r}) \qquad [9]$$

The excitation of the system by a short-duration perturbation is conveniently described by the strength function $\mathscr{S}(E)$, defined by

$$\mathscr{S}(E) \equiv \sum_n |\langle n|V_{\text{pert}}|0\rangle|^2\delta(E-E_n) \qquad [10]$$

where $E = \hbar\omega$ is the excitation energy, and $|0\rangle$ and $|n\rangle$ denote the ground and excited states of the system, respectively.

The strength function is related to the cross section for photon absorption by the following equation (Golden rule):

$$\sigma(E) = \frac{4\pi^2}{\hbar c}E\mathscr{S}(E) = -\frac{4\pi}{\hbar c}E\ \text{Im}\,\alpha(E) \qquad [11]$$

and the total cross section is given by

$$\int \mathrm{d}E\,\sigma(E) = \frac{2\pi^2e^2\hbar}{m_e c}N \qquad [12]$$

Making use of the single-particle basis displayed in **Figure 6**, the dipole response of C_{60} has been worked out in the TDLDA, and the results are shown in **Figure 9**.

Theory provides an overall account of the experimental findings, also for the width of the plasmon (Mie) resonance located $\sim 17\,\text{eV}$ and amounting to $\sim 12\,\text{eV}$. Consequently, Landau damping, that is the decay of the collective modes into single (unperturbed) particle–hole excitations, can be viewed as the main relaxation mechanism of the above described collective plasmon mode.

The experimental data at low excitation energy correspond to the optical/UV absorption spectra of C_{60} in hexane solution, at room temperature.

The present approach yields a static polarizability of the system of $88.6\,\text{Å}^3$, which can be compared to measurements of $\alpha(0) \approx 80\,\text{Å}^3$ for a single molecule.

Coupling of Electrons to Phonons and to Plasmons

So far, electrons and ions have been considered as independent degrees of freedom. Ions have been taken either as fixed in their ground-state configuration or as moving under the action of a phonon displacement field. The electrons have been treated within the BO approximation. This means that it has been assumed that they are able to follow the evolution of the ionic configuration adiabatically. This approximation (based on the fact that typical frequencies obey $\omega_{\text{electrons}} \gg \omega_{\text{ions}}$) breaks down in a number of cases in which the ionic motion induces correlations between electronic states, in particular, in connection with the mass enhancement factor observed in specific heat measurements as well as in the case of electron–electron pairing correlations at low temperatures.

Furthermore, although the renormalization effects due to the coupling of electrons to plasmons are in principle included in the exact DFT, in practice they are incorporated only to some extent in the correlation potential of the LDA, where important effects of this coupling are left out. Moreover, the exchange of plasmons between electrons, which is the basic mechanism leading to the screening of the Coulomb field, also gives rise to an electron self-energy whose frequency dependence is essential to obtain a proper description of this phenomenon.

In other words, the Hamiltonian to be diagonalized is

$$H = H_{\text{elec}} + H_{\text{phon}} + H_{\text{el,phon}} + H_{\text{plas}} + H_{\text{el,plas}} \qquad [13]$$

where the electron, phonon, and plasmon (H_{elec}, H_{phon}, and H_{plas}, respectively) terms are already diagonal, while $H_{\text{el,phon}}$ and $H_{\text{el,plas}}$ can be diagonalized in the product basis, provided by electron and phonon states, and electron and plasmon states. The corresponding matrix elements g_ν of $H_{\text{el,phon}}$ (see **Figure 10**) lead to the partial electron–phonon coupling constants

$$\lambda_\nu = \alpha \frac{g_\nu^2}{\hbar\omega_\nu} N(0) \qquad [14]$$

where α is a statistical factor depending on the symmetry of the modes ν, $\hbar\omega_\nu$ is the corresponding energy, while $N(0)$ is the density of levels at the Fermi energy in the solid built, making use of the clusters of interest. **Tables 4** and **5** give the corresponding

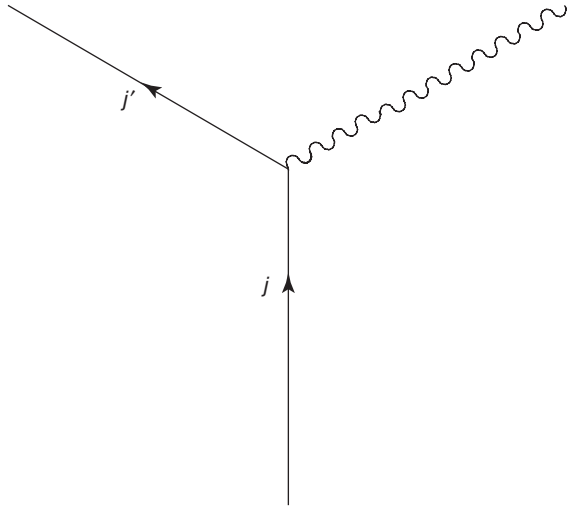

Figure 10 Graphical representation of the electron–phonon or electron–plasmon coupling, where the arrowed line represents the electron while the wavy line stands for either the phonon (ν, μ) or the plasmon (n).

Table 4 Experimental partial electron–phonon coupling constants $\lambda_\nu / N(0)$ in meV which measures the strength with which an electron moving in the t_{1u} LUMO state of C_{60}^- couples to the eight H_g and the two A_g phonons of C_{60} whose wavelengths and energies are shown in columns two and three

	Frequency		$\lambda\nu/N(0)$ (meV)
	λ^{-1} (cm^{-1})	$\hbar\omega_\nu$ (meV)

$A_g(2)$	496	61.5	0
$\sum H_g$			147
$\sum(H_g + A_g)$			158

quantities for C_{60}^- and Na_8. It is seen that the partial coupling constants of Na_8 are, on an average, larger than those associated with C_{60}^-. The main reason for this result lies in the fact that the lowest Na_8 phonons have energies which are almost one order of magnitude smaller than those of C_{60}. Consequently, the square of the zero-point fluctuations $\sqrt{\hbar/2M_\lambda\omega_\lambda}$ entering the expression of $\lambda_v/N(0)$ are also larger by one order of magnitude. On the other hand, the matrix elements of the gradient of the electronic potential are comparable or smaller in Na_8 than in C_{60}^-. In this latter cluster, the delocalization of the $3p$ electrons is larger than that of the C_{60} electrons, which tend to concentrate around the bonds. The more the electrons are delocalized, and therefore far from the ion–ion bonds, the smaller are the electron–phonon matrix elements.

Table 5 Reduced electron–phonon matrix elements g_v and partial coupling constants $\lambda v/N(0)$ associated with the LUMO electron state and selected phonon states of Na_8 calculated making use of the CPMD scheme

	$\hbar\omega$ (meV)	$\lambda v/N(0)$ (meV)	g_v (meV)
A_1 (1)	7.93	36.3	12.0
A_1 (2)	9.48	173.8	28.7
A_1 (3)	15.94	56.9	21.3
A_1 (4)	16.72	12.2	10.1
Total		279.2	72.1

The matrix elements of the electron–plasmon coupling (see **Figure 10**)

$$\langle n, j'|H_{\text{el, plas}}|j\rangle = \int \mathrm{d}^3r\,\mathrm{d}^3r'\varphi^*_{j'}(\boldsymbol{r})\frac{\delta v_{\text{eff}}(\boldsymbol{r})}{\delta\varrho(\boldsymbol{r}')}\delta\varrho_n(\boldsymbol{r}';\omega_n)\varphi_j(\boldsymbol{r}) \quad [15]$$

can be calculated in terms of the functional derivative of the LDA effective potential v_{eff}, and of the matrix between the ground state $|0\rangle$ and the boson (plasmon) state $|n\rangle$, that is, $\langle n|\varrho(\boldsymbol{r}')|0\rangle \equiv \delta\varrho_n(\boldsymbol{r}';\omega_n)$.

In **Figure 11**, the results of a consistent calculation of the photoabsorbtion spectrum of the small metal cluster Na_9^+ in its lowest-energy geometry configuration $\mathscr{D}_{3h}$ calculated, taking into account both the electron–phonon and electron–plasmon couplings, is shown in comparison to the experimental findings. Both the coupling of electrons to plasmons and to phonons were considered and calculated *ab initio*. After diagonalizing the Hamiltonian, the strength function associated with the dipole operator as well as the photoabsorption cross section were calculated.

The main result of the calculation is that the electron–plasmon coupling is essential to shift the TDLDA spectrum downwards. This is shown in **Figure 11** for the case of Na_9^+. The inset of the figure, with the TDLDA peaks displayed by dashed lines and those resulting from the full calculation by solid

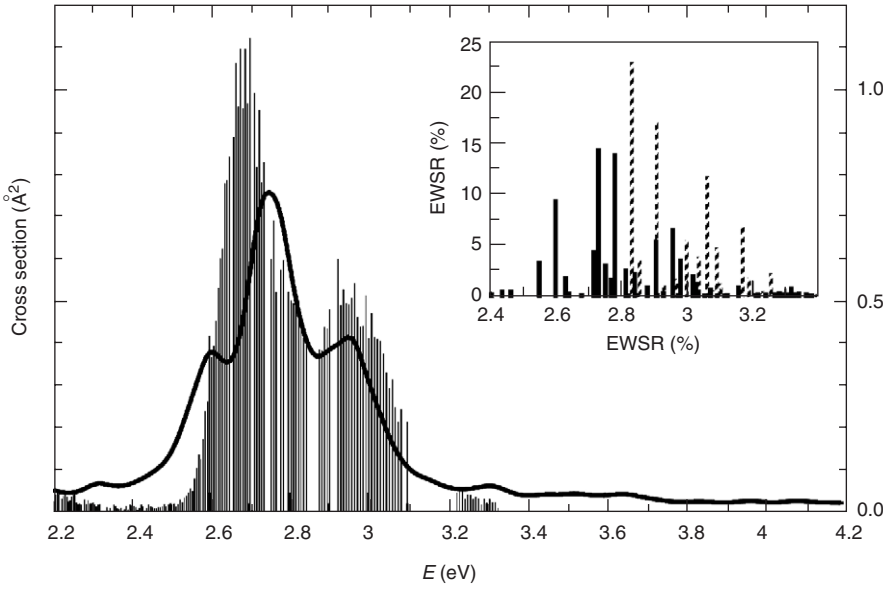

Figure 11 Photoabsorption cross section of Na_9^+ vs. energy E (continuous heavy line) calculated taking into account both the coupling to plasmons and to phonons. The experimental spectrum measured at $T \approx 39$ K is displayed by the thin vertical lines. The inset shows the percentage of the EWSR calculated making use of the TDLDA results (dashed lines), and taking into account the coupling to plasmons (continuous lines).

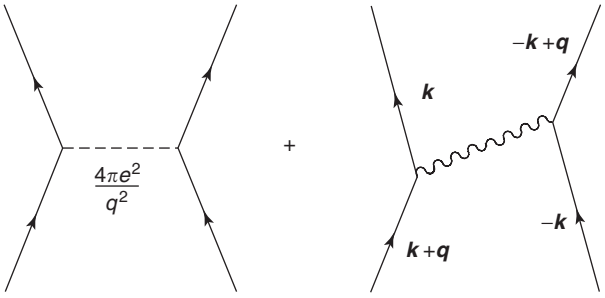

Figure 12 Scattering process of two electrons (arrowed lines) interacting via the bare Coulomb interaction (dotted line) and by exchanging a plasmon (wavy line).

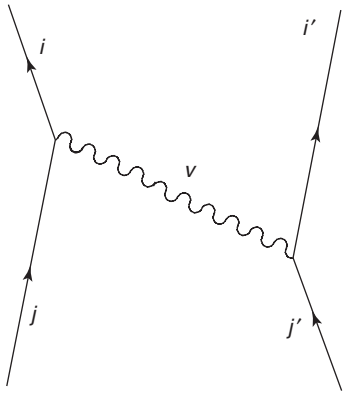

Figure 13 Graphical representation of the effective electron–electron interaction induced by the exchange of a phonon.

lines, demonstrates that the red shift of the main collective peaks is systematic and ~ 0.2 eV. This result indicates that the electron–plasmon coupling can also be of importance in other contexts where calculations of the dynamical screening are in order, for instance, in the case of the screened Coulomb potential μ (see **Figure 12**). A second result of the full calculation is that the electron–phonon coupling acts essentially as an averaging parameter ~ 0.1 eV, leading to a smoothing of the spectrum.

The Effective Electron–Electron Interaction

An electron can interact with the ions through the deformation potential and excite a phonon. This phonon can be absorbed by the same electron (self-energy process) or by a second electron. This second process gives rise to an effective electron–electron interaction (**Figure 13**) whose strength is measured by the dimensionless parameter $\lambda = \sum_v \lambda v$ (see eqn [14]). As mentioned above, the exchange of plasmons also gives rise to an electron–electron interaction (see **Figure 12**), which screens the bare Coulomb potential, an effect which is measured by the dimensionless quantity $\mu = U_e(q,\omega)N(0)$, where $U_e(q,\omega) = 4\pi e^2/q^2\varepsilon(q,\omega)$.

To approximately take into account the ω-dependence of the Coulomb pseudopotential in a way, which is consistent with the ω-dependence kept in the electron–phonon induced interaction, one can change μ to a new effective interaction μ^* obtained as

$$\mu^* = \frac{\mu}{1 + \mu \ln(B/\omega_{ph})} \qquad [16]$$

where B is a typical electron energy (half the bandwidth) and ω_{ph} is a typical phonon energy. If $B/\omega_{ph} \gg 1$, μ^* can be strongly reduced, relative to μ. In the limit $\mu \ln(B/\omega_{ph}) \gg 1$, the above expression simplifies to $\mu^* \approx 1/\ln(B/\omega_{ph})$, which may be ~ 0.1–0.2.

The (summed) effective interaction arising from the exchange of phonons and plasmons between electrons displayed in **Figures 12** and **13** can lead to an attraction between pairs of electrons moving close to the Fermi energy, giving rise to the so-called Cooper pairs, which behave as (quasi)-bosons. The associated binding energy is, in the limit of weak coupling ($\lambda \ll 1$),

$$E = 2\hbar\omega_D e^{-1/(\lambda-\mu^*)} \qquad [17]$$

where μ^* is a typical screened Coulomb potential.

Superconductivity in Fullerides

Fullerenes, for example, C_{60}, have attracted much interest since their discovery in 1985, not least because they are the only finite, and most symmetric, allotropic forms of carbon. This interest has increased drastically because methods were found to produce some of these fullerenes in large quantities, and so it was possible to make solids (fullerites). Intercalating alkali metal atoms in solid C_{60} (a van der Waals solid) leads to metallic behavior displaying a transition temperature $T_c \sim 30$ K.

Although there are still a number of open questions, several experimental findings testify to the fact that superconductivity in doped fullerides is likely to be driven by the coupling of electrons to intramolecular vibrations (phonons) of the fullerene molecules.

Making use of the density of states $N(0) \approx 8.1\ \text{eV}^{-1}$ deduced for fullerite Rb_3C_{60} as well as of the results of **Table 4** ($\lambda/N(0) = 158$ meV), one obtains, for the total electron–phonon coupling,

$$\lambda = 1.3 \qquad [18]$$

In such a situation, the weak coupling expression [17] is not adequate. A better expression is provided by the McMillan solution to Eliashberg equations:

$$T_c = \frac{\hbar\omega_{ln}}{1.2}\exp\left[-\frac{1.04(1+\lambda)}{\lambda-\mu^*(1+0.62\lambda)}\right] \qquad [19]$$

where ω_{ln} is a typical phonon frequency (logarithmic average).

In the case of C_{60},

$$\hbar\omega_{ln} = 102\,\text{meV} = 1184\,\text{K} \qquad [20]$$

The best available estimates of μ^* for alkali-doped fullerites are $0.3 \leqslant \mu^* \leqslant 0.4$. Making use of the results given in [18] and [20], and of the fact that for Rb_3C_{60}, $T_c = 29.5\,\text{K}$, one obtains $\mu^* \approx 0.34$ from [19].

The interest for using fullerenes smaller than C_{60} to produce nanometer superconducting materials can be simply understood by remembering that the critical temperature below which graphite compounds are superconducting is $T_c = 5\,\text{K}$, while the same temperature has reached $\approx 30\,\text{K}$ for C_{60}. Because C_{60} can be viewed as made out of a wrapped carbon lattice plane by introducing defects in the honeycomb lattice so as to create 12 pentagons (C_{60} is made out of these 12 pentagons and of 20 hexagons), curvature effects and electron spill-out seem to be at the basis of the increased electron–phonon coupling and screening of the Coulomb field in going from graphite to C_{60}-based materials. It is thus expected that materials made out of fullerenes (such as C_{36}, C_{28}, and C_{20}) with higher curvature and electron spill-out than those of C_{60} will display higher values of T_c.

Ab initio calculations predict values of λ for these smaller fullerenes as well as for $C_{28}H_4$, considerably larger than for C_{60}. Assuming similar values of $N(0)$ for the corresponding fullerites, one expects critical temperatures which are considerably larger than those for C_{60}-based materials. This is also true for materials based on metal clusters. Further, experimental work is needed to assess the soundness of such expectations.

Molecular Crystallography

M Wilmanns and M S Weiss, EMBL Hamburg, Hamburg, Germany

The description of X-ray crystallography as an experimental technique to determine the three-dimensional structures of molecules at atomic resolution consists of two parts. First, the relationship between the sample studied and its corresponding diffraction pattern must be derived and understood. Second, the way back from the diffraction pattern to the molecular structure must be outlined.

From Objects to Diffraction Patterns

The Scattering Equation

Electromagnetic waves interact with matter. Their electric components force charged particles to oscillate with the same frequency as the incident wave. Oscillating electrons constitute moving charges, which emit electromagnetic radiation of the same frequency into all directions of space. This phenomenon is called "elastic scattering," "Thomson scattering," or "scattering without loss of energy." Atomic nuclei interact with electromagnetic waves in the same way, but since a proton is $\sim$2000 times heavier than an electron, and consequently much less prone to move, for purposes of crystallography as a structure determination technique, scattering by nuclei can be neglected. The mathematical description of the phenomenon of scattering is illustrated in **Figure 1**.

The incoming X-ray wave (from the left) is represented by the vector $\boldsymbol{s}_{in}$ with $|\boldsymbol{s}_{in}| = 1/\lambda$, where λ is the wavelength of the incoming X-ray wave. The wave impinges upon the object and is then scattered by the whole object, in all directions of space. For

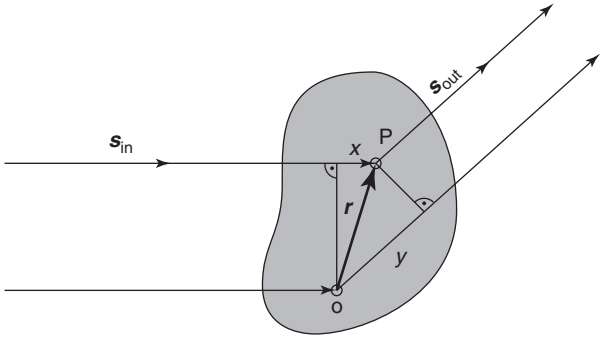

Figure 1 Scattering of electromagnetic waves by an object.

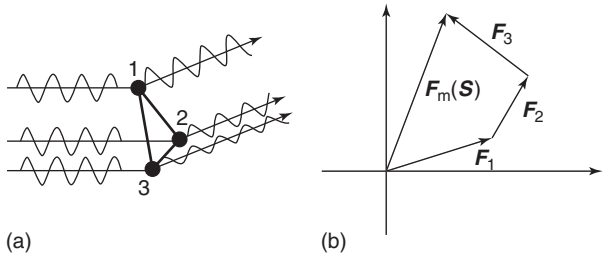

Figure 2 (a) Scattering by a three-atom molecule, with each of the three atoms containing a different number of electrons. (b) Argand diagram with the vector addition of the three individually scattered waves yielding the molecular transform.

simplicity, only the scattering at the points O and P is considered now, and only the scattering in the direction described by $\boldsymbol{s}_{out}$, where $\boldsymbol{s}_{out}$ is a vector representing the scattered wave ($|\boldsymbol{s}_{out}| = 1/\lambda$). The difference vector between $\boldsymbol{s}_{out}$ and $\boldsymbol{s}_{in}$ (i.e., $\boldsymbol{s}_{out} - \boldsymbol{s}_{in}$) is called the scattering vector $\boldsymbol{s}$. The scattering vector describes the change in direction that the X-ray wave undergoes upon scattering. The size of the object, that is, the distance between points O and P in the example given here, leads to a path difference $\Delta x = \boldsymbol{r} \cdot (\boldsymbol{s}_{out} - \boldsymbol{s}_{in})\lambda = \boldsymbol{r} \cdot \boldsymbol{s}\lambda$ between the two scattered waves shown in **Figure 1**. This path difference results in a phase difference $\Delta\alpha = 2\pi\Delta x/\lambda = 2\pi \boldsymbol{r} \cdot \boldsymbol{s}$ between the two scattered waves. The wave scattered at point P has an amplitude proportional to the electron density ρ(P) at point P and a phase of $2\pi \boldsymbol{r} \cdot \boldsymbol{s}$ relative to the wave scattered at point O. In order to compute the total wave f_T scattered by the object depicted in **Figure 1**, an integration over all volume elements (V) of the scattering object has to be performed. This leads to the general scattering equation (eqn [1]). $f_T(\boldsymbol{s})$ describes the scattering by every possible object, which in turn can be described by $\boldsymbol{r}$, $\rho(\boldsymbol{r})$, and V, into the direction defined by the vector $\boldsymbol{s}$:

$$f_T(\boldsymbol{s}) = \int_{Vol} \rho(\boldsymbol{r})\, e^{2\pi i \boldsymbol{r} \cdot \boldsymbol{s}}\, dV \qquad [1]$$

Equation [1] can also be regarded as a "Fourier analysis" of the object to be studied by the X-rays.

Scattering by Atoms and Molecules

The description of the scattering of real atoms starts from the general scattering equation (eqn [1]). The integration over the whole volume V of the atom implies that the function $f(\boldsymbol{s})$ is dependent on the form of the electron cloud of the atom. It is, therefore, also called the "atomic form factor." The atomic form factor is an intrinsic property of an atom or ion, which depends on the exact architecture of the electron cloud of the atom or the ion. Atomic form factors can be calculated using quantum mechanical approximations from the electron distribution of the atoms or ions, but they can also be measured very accurately, for instance, by X-ray scattering. Tables of the atomic form factors for each existing atom or ion are available in the International Tables for Crystallography (see the "Further reading" section).

The scattering by a molecule can now simply be calculated based on the scattering of the atoms belonging to the molecule (**Figure 2a**). The total scattered wave is the sum of the individually scattered waves in any given direction (**Figure 2b**). Using the example of a three-atom molecule, the contributions by the three atoms have to be considered: $\boldsymbol{F}_1 = f_1(\boldsymbol{s})e^{2\pi i \boldsymbol{r}_1 \cdot \boldsymbol{s}}$ for atom 1, $\boldsymbol{F}_2 = f_2(\boldsymbol{s})e^{2\pi i \boldsymbol{r}_2 \cdot \boldsymbol{s}}$ for atom 2, and $\boldsymbol{F}_3 = f_3(\boldsymbol{s})e^{2\pi i \boldsymbol{r}_3 \cdot \boldsymbol{s}}$ for atom 3. The result is shown in eqn [2]. It is also called the "molecular transform:"

$$\boldsymbol{F}_m(\boldsymbol{s}) = \sum_{j=1}^{3} f_j(\boldsymbol{s})\, e^{2\pi i \boldsymbol{r}_j \cdot \boldsymbol{s}} \qquad [2]$$

$f_j(\boldsymbol{s})$ are the atomic form factors and $\boldsymbol{r}_j$ the coordinates of the atoms j.

Scattering by a Crystal

A crystal is defined as an object, which is periodic in three dimensions. In order to build up a crystal from its smallest unit, the unit cell, one just needs to know the contents of the unit cell and the lattice translations $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$. For describing the scattering of one single unit cell of a crystal, $\boldsymbol{F}_{unit\ cell}(\boldsymbol{s})$, the contributions of all N atoms in the unit cell have to be added up (eqn [3]):

$$\boldsymbol{F}_{unit\ cell}(\boldsymbol{s}) = \sum_{j=1}^{N} f_j(\boldsymbol{s})\, e^{2\pi i \boldsymbol{r}_j \cdot \boldsymbol{s}} \qquad [3]$$

In order to consider the scattering by the whole crystal, the contributions of all unit cells of the crystal and all atoms in each unit cell have to be taken

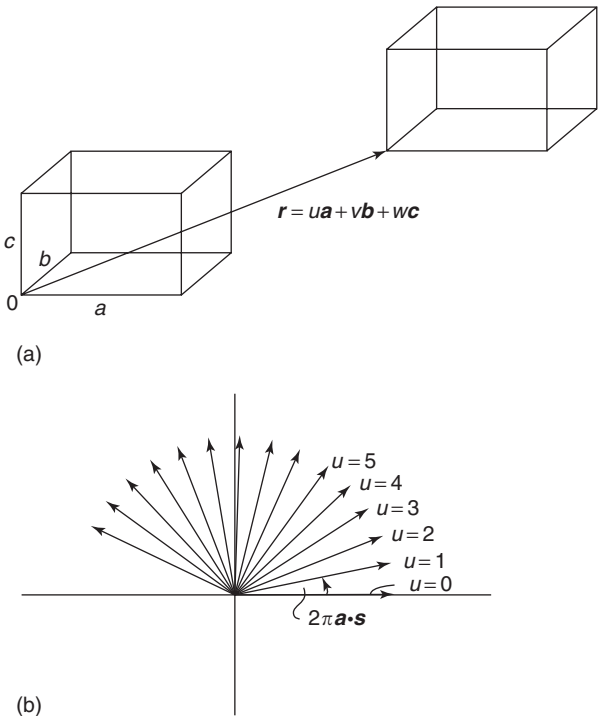

Figure 3 (a) Two unit cells of a crystal and (b) graphical representation of the Laue conditions in one dimension. In the case shown, the scalar product $\boldsymbol{a} \cdot \boldsymbol{s} \neq h$. As a result of this, the waves with different values of u exhibit phase differences different from 2π. Due to the large number of waves to be considered (one for each unit cell of the crystal), the overall sum will be zero.

into account. Let $\boldsymbol{F}_{\text{unit cell}}(\boldsymbol{s})$ be the scattering of the first unit cell, and $\boldsymbol{F}'_{\text{unit cell}}(\boldsymbol{s})$ the scattering of a second unit cell shifted by $\boldsymbol{r} = u\boldsymbol{a} + v\boldsymbol{b} + w\boldsymbol{c}$ relative to the first unit cell (u, v, and w are integer values, and $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ are the lattice translations) (**Figure 3a**). It can be shown that the contribution of just the second unit cell can be expressed as the scattering of the first unit cell and the vector that relates the two unit cells:

$$\boldsymbol{F}'_{\text{unit cell}}(\boldsymbol{s}) = \boldsymbol{F}_{\text{unit cell}}(\boldsymbol{s}) \mathrm{e}^{2\pi i u \boldsymbol{a}\cdot\boldsymbol{s}} \mathrm{e}^{2\pi i v \boldsymbol{b}\cdot\boldsymbol{s}} \mathrm{e}^{2\pi i w \boldsymbol{c}\cdot\boldsymbol{s}} \quad [4]$$

To arrive at the scattering equation for the whole crystal, the sum over all unit cells should be calculated. This can be reduced to summing over all combinations of u, v, and w:

$$\boldsymbol{F}_{\text{crystal}}(\boldsymbol{s}) = \boldsymbol{F}_{\text{unit cell}}(\boldsymbol{s}) \sum_{u=0}^{n_1} \mathrm{e}^{2\pi i u \boldsymbol{a}\cdot\boldsymbol{s}} \sum_{v=0}^{n_2} \mathrm{e}^{2\pi i v \boldsymbol{b}\cdot\boldsymbol{s}} \sum_{w=0}^{n_3} \mathrm{e}^{2\pi i w \boldsymbol{c}\cdot\boldsymbol{s}} \quad [5]$$

where n_1, n_2, and n_3 are the numbers of the unit cells in $\boldsymbol{a}$-, $\boldsymbol{b}$-, and $\boldsymbol{c}$-directions. These numbers are large for typical crystals in the micrometer-size range. This means that the sums $\sum_{u=0}^{n_1} \mathrm{e}^{2\pi i u \boldsymbol{a}\cdot\boldsymbol{s}}$, $\sum_{v=0}^{n_2} \mathrm{e}^{2\pi i v \boldsymbol{b}\cdot\boldsymbol{s}}$, and $\sum_{w=0}^{n_3} \mathrm{e}^{2\pi i w \boldsymbol{c}\cdot\boldsymbol{s}}$ will be zero unless $\boldsymbol{a}\cdot\boldsymbol{s}$, $\boldsymbol{b}\cdot\boldsymbol{s}$, and $\boldsymbol{c}\cdot\boldsymbol{s}$ are integral numbers. These conditions are also known as the "Laue conditions," and they are illustrated in **Figure 3b** as vector additions in an Argand diagram. In the case of the Laue conditions being fulfilled, the product of the three sums is equal to the total number of unit cells in a given crystal.

There are two important consequences of this derivation. First, the scattering of a crystal is proportional to the scattering of just one unit cell and the number of unit cells in the crystal. Consequently, to describe the scattering by the whole crystal, it is sufficient to consider the scattering by just one unit cell. Second, the scattering of a crystal leads to a discrete diffraction pattern. Only in those directions $\boldsymbol{s}$, in which the Laue conditions are obeyed, will scattering be observed. In all other directions the sum of all scattered waves will be zero. This leads to the observation of a diffraction pattern consisting of discrete maxima, the so-called X-ray reflections. Each reflection is identified by a unique combination of the three numbers h, k, and l, the Miller indices:

$$\boldsymbol{F}_{\text{crystal}}(\boldsymbol{s}) = n\boldsymbol{F}_{\text{unit cell}}(\boldsymbol{s}) = n \sum_{j=1}^{N} \boldsymbol{f}_j(\boldsymbol{s}) \mathrm{e}^{2\pi i \boldsymbol{r}_j\cdot\boldsymbol{s}} \quad [6]$$

where n is the number of unit cells. With $\boldsymbol{r}_j = x_j\boldsymbol{a} + y_j\boldsymbol{b} + z_j\boldsymbol{c}$ (x_j, y_j, and z_j are the fractional coordinates of atom j), and with the Laue conditions $\boldsymbol{a}\cdot\boldsymbol{s} = h$, $\boldsymbol{b}\cdot\boldsymbol{s} = k$, and $\boldsymbol{c}\cdot\boldsymbol{s} = l$, eqn [6] can be transformed into eqn [7]:

$$\boldsymbol{F}(\boldsymbol{s}) = \boldsymbol{F}(hkl) = \sum_{j=1}^{N} \boldsymbol{f}_j \mathrm{e}^{2\pi \mathrm{i}(hx_j + ky_j + lz_j)} \quad [7]$$

Equation [7] is also called the "structure factor equation." Together with the "electron density equation" (see below), it constitutes one of the two central equations in X-ray crystallography. It describes the scattering of a crystal defined by the unit cell vectors $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$, and by the atoms inside the unit cells of this crystal as defined by the atomic form factors (f_j) and the fractional coordinates (x_j, y_j, and z_j).

The Diffraction Experiment

A schematic representation of an X-ray experiment is shown in **Figure 4**. The experiment itself involves the production or generation of X-rays, the selection of the X-rays for the experiment, the preparation of the crystal for the experiment, the actual data collection step, and the processing and validation of the resulting data. Of course, if one is interested only in using

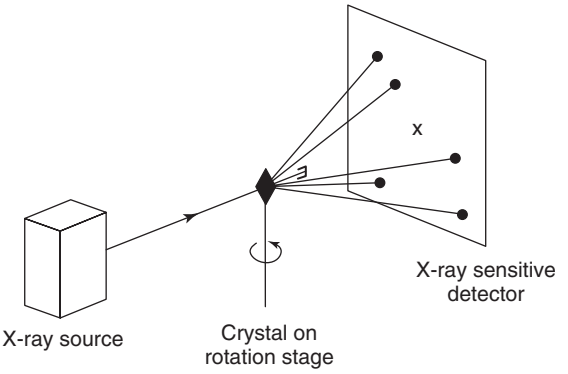

Figure 4 Schematic representation of the diffraction experiment. Depicted are the X-ray source, the object (crystal) mounted on a rotatable device, and the detector for the scattered waves.

X-rays to determine a crystal structure, how X-rays are produced and prepared for the measurement may be of little concern. However, there are some important aspects that can potentially have a great impact on the quality of the obtained diffraction data and consequently on various stages of structure determination and certainly on the information content of the resulting structure. One should always keep in mind that the quality or the information content of a crystal structure is directly determined by the quality or the information content of the diffraction data that are the basis for the determination of the structure. Furthermore, the collection of diffraction data is the last real experimental step to be carried out in the course of a crystal structure analysis. Everything after that is merely an interpretation of the collected diffraction data.

From the Diffraction Pattern to the Structure

The Electron Density Equation

The Fourier transformation of the general scattering equation (eqn [1]) leads to the electron density equation (eqn [8]), the second important equation in crystallography. Instead of integrating over the volume of the scattering object V, the integration proceeds now over diffraction space, which is sometimes also called reciprocal space, because of the reciprocal relationship to the real space with respect to its geometric parameters:

$$\rho(\boldsymbol{r}) = \int_{\mathrm{Vol}^*} f_{\mathrm{T}}(\boldsymbol{s})\, \mathrm{e}^{-2\pi \mathrm{i} \boldsymbol{r}\cdot\boldsymbol{s}}\, \mathrm{d}V^* \qquad [8]$$

Similar to regarding eqn [1] as a "Fourier analysis" of the object, eqn [8] can be regarded as a "Fourier synthesis." The object can be reconstructed from its diffraction pattern by taking into account all scattered waves. A simpler version of the electron density equation (eqn [9]) can be derived considering that the diffraction pattern of a crystal is discrete (see above), and that instead of integrating over the whole volume of diffraction space, one only needs to sum over the observed X-ray reflections:

$$\rho(x,y,z) = \sum_{h,k,l} |\boldsymbol{F}(hkl)|\, \mathrm{e}^{-2\pi\mathrm{i}(hx+ky+lz)+\mathrm{i}\alpha(hkl)} \qquad [9]$$

Two things become clear from eqn [9]. First, in order to calculate the value for the electron density ρ at any given point (x, y, z), all reflections should be taken into account. Second, the summation can only be carried out if both the structure factor amplitude $|\boldsymbol{F}|$ and the phase α are known for each reflection (hkl).

The Phase Problem

In a diffraction experiment, data, which are finally measured, are the intensities I of the reflections (hkl). The intensity $I(hkl)$ can be calculated by multiplying the structure factor $\boldsymbol{F}(hkl)$ with its conjugated complex structure factor $\boldsymbol{F}^*(hkl)$. The net result is that $I(hkl)$ is proportional to the square of the structure factor amplitude $|\boldsymbol{F}(hkl)|$:

$$\begin{aligned} I(hkl) &\propto |\boldsymbol{F}(hkl)|\, |\boldsymbol{F}^*(hkl)| \\ &= |\boldsymbol{F}(hkl)|\, \mathrm{e}^{\mathrm{i}\alpha(hkl)} |\boldsymbol{F}(hkl)|\, \mathrm{e}^{-\mathrm{i}\alpha(hkl)} \\ &= |\boldsymbol{F}(hkl)|^2 \end{aligned}$$

As a consequence, by measuring the intensities, one is only able to back-calculate the amplitudes $|\boldsymbol{F}(hkl)|$ of the waves. The information about the phases $\alpha(hkl)$ is lost. This is known as the so-called "phase problem" in crystallography. The phase problem is the reason why an image of the molecule to be studied cannot be calculated directly from the diffraction data. Approaches to overcome the problem are briefly discussed in the next section.

Phase Determination

Over time, a number of methods have been developed to circumvent the phase problem. Today, the decision as to which method to use seems to be governed by both the size of the molecules to be studied and the diffraction power of the respective crystals. Whereas in small-molecule crystallography (molecules of up to a few hundred atoms, and typically very good diffraction), the so-called "direct methods" are dominant and nowadays also mostly automated, in macromolecular crystallography (more than 1000 nonhydrogen atoms with no apparent upper limit,

but usually limited diffraction) the so-called "replacement methods" are the major methods to be applied. In the following, the different approaches are discussed in brief.

Direct methods The direct methods rely on the principle that the phase information is somehow included in the measured structure factor amplitudes. The underlying rationale is that structure factors are not independent of each other but that they are related through the structure. With the additional constraints that (1) the electron density can never be negative and (2) the structure to be determined consists of discrete atoms, phase sets can be constructed randomly and examined with respect to their validity.

The credibility of a given set of phases can be examined by considering probabilistic relationships between the phases of certain reflections, for example, the "triplet invariants" (eqn [10]). It can be derived that the phases of the three reflections (h_1, k_1, l_1), (h_2, k_2, l_2), and ($-h_1-h_2$, $-k_1-k_2$, $-l_1-l_2$) are related by the following equation:

$$\alpha(h_1,k_1,l_1)+\alpha(h_2,k_2,l_2) + \alpha(-h_1-h_2,-k_1-k_2,-l_1-l_2)\approx 0 \quad [10]$$

This equation is not absolutely but approximately valid, and it is normally formulated as a probability. The stronger the three reflections (h_1, k_1, l_1), (h_2, k_2, l_2), and ($-h_1-h_2$, $-k_1-k_2$, $-l_1-l_2$) are, the higher the probability that the three-phase values sum up to zero or an integral multiple of 2π.

Various measures to evaluate the quality of a given phase set have been introduced over time. The most widely known formula for this purpose is the "tangent formula" (eqn [11]). In this formula, the most probable value of the phase of one reflection $\alpha(h_1, k_1, l_1)$ is given as a function of the values of the phases of all other reflections (h_m, k_m, l_m) and ($-h_1-h_m$, $-k_1-k_m$, $-l_1-l_m$), which share a triplet invariant with (h_1, k_1, l_1). The reliability of the formula depends on the magnitude of the structure factor amplitudes of the reflections considered:

$$\tan[\alpha(h_1,k_1,l_1)] = \frac{\sum_m W_m \sin[-\alpha(h_m,k_m,l_m)-\alpha(-h_1-h_m,-k_1-k_m,-l_1-l_m)]}{\sum_m W_m \cos[-\alpha(h_m,k_m,l_m)-\alpha(-h_1-h_m,-k_1-k_m,-l_1-l_m)]} \quad [11]$$

The two sums in the numerator and the denominator run over all possible triplet invariants m, in which the reflection (h_1, k_1, l_1) is involved, and the numbers W_m describe the weighted product of the normalized structure factor amplitudes of reflections (h_m, k_m, l_m) and ($-h_1-h_m$, $-k_1-k_m$, $-l_1-l_m$).

Relationships such as the triplet invariants and the tangent formula help to reduce the complexity of the phase set. Nevertheless, because of the large number of possible phase sets, direct methods for phase determination are typically only applicable to small structures.

Isomorphous replacement One of the dominant methods in macromolecular crystallography is the method of isomorphous replacement. In this method, diffraction data sets of two isomorphous crystals are compared with each other reflection by reflection. The first crystal may be one of the native macromolecules, the second crystal may be one of the heavy-atom derivatives of the same macromolecule. The latter can be prepared by either co-crystallization or soaking a native macromolecule crystal in a heavy-atom-containing solution. Large solvent channels inside the macromolecule crystals allow the diffusion of the heavy-atom compound through the crystal. If a reactive group on the macromolecule surface is accessible to the heavy-atom compound, it can bind there without changing the structure of the rest of the protein. A detailed comparison of the two diffraction data sets will then, in a first step, yield the differences between the data sets, which are due to the heavy-atom substructure. From these differences, the substructure can be determined. With the substructure at hand, one can then calculate the structure factor amplitude and the phase of just the substructure, and then use this heavy-atom quasiphase as a reference to calculate the phases of the reflections of the macromolecule crystal. An easy way to visualize this is a vector diagram (**Figure 5**). The vector addition of the structure factor of the macromolecule $\boldsymbol{F}_P$ and the structure factor of the heavy atoms $\boldsymbol{F}_H$ will yield the structure factor of the heavy-atom derivative $\boldsymbol{F}_{PH}$. If the magnitudes of both $\boldsymbol{F}_P$ and $\boldsymbol{F}_{PH}$ (these are the structure factor amplitudes which have been measured in the two diffraction experiments) and the magnitude and direction of $\boldsymbol{F}_H$ (this can be calculated once the heavy-atom substructure is known) are now known, all other parameters of the triangle in **Figure 5** can be calculated as well.

However, this vector addition is not unambiguous. The result of this calculation will not be a unique

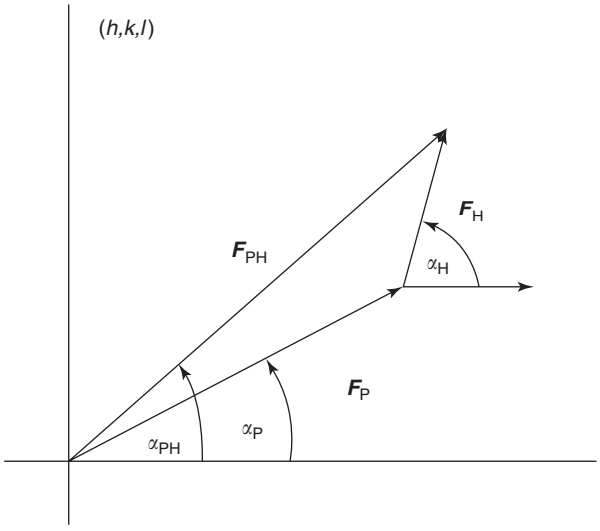

Figure 5 Vector addition of the structure factors for the native macromolecule $\boldsymbol{F}_P$, the heavy-atom substructure $\boldsymbol{F}_H$, and the heavy-atom derivative of the macromolecule $\boldsymbol{F}_{PH}$.

phase $\alpha(hkl)$ for the given reflection, but two possible solutions, which are symmetrical about the vector $\boldsymbol{F}_H$. This situation can be made unambiguous, for instance, by including a second heavy-atom derivative.

Anomalous diffraction If the structure to be determined contains anomalous scatterers (anomalous scattering occurs when the energy of the X-rays used for the diffraction experiment is close to an energy which is absorbed by an atom), a diffraction experiment can be carried out at two (or more) different X-ray energies. The differences between the diffraction patterns can then again be attributed to the anomalously scattering substructure, and in the same way as above, the substructure can be determined, and the substructure phase be used as a reference to determine the phase α_P.

Molecular replacement A conceptually completely different approach can be applied if the structure to be determined is expected to be similar to another structure which is known already. In such a case, the known structure can be placed in the unit cell of the structure to be determined, and the structure factor $\boldsymbol{F}_P$ calculated. The phase α_P of the structure factor amplitude $|\boldsymbol{F}_P|$ will of course not be correct, but it will be approximately correct and can be used as a starting value for further refinement. The initial step in the determination of the molecular replacement structure is the determination of three rotational and three translational parameters, which define, respectively, the correct orientation and the correct translation of the search model (the known structure) in the unit cell of the target structure (the structure to be determined).

Model Building and Refinement

Once initial phases have been determined by one of the methods described above, the electron density can be calculated according to eqn [8]. The electron density is nothing but an image of the structure to be determined. It shows where, in the unit cell, the electrons (i.e., the atoms) are. Since molecular structures are usually described by the position of all of their atoms, the electron density should be interpreted in terms of atomic positions and identities. Finally, the model thus obtained can be subjected to a mathematical optimization procedure called refinement, in order to optimize the fit between the structure factors that can be calculated from the model and the ones that have been observed experimentally. This constant feedback between the model and experimental data is one of the greatest strengths of the crystallographic methods.

Molecular Dynamics Calculations

L Colombo, University of Cagliari, Monserrato, Italy

The Basic Conceptual Framework

Consider a set of N particles with Cartesian coordinates $\{\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N\}$, interacting through a potential $U(\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N)$. Both, atoms and molecules will be referred to as "particles." It is assumed that the interaction potential U does not depend upon particle velocities and it is represented by a well-behaved and differentiable (with respect to interparticle distances) functional.

According to classical mechanics, the total force $\boldsymbol{F}_\alpha$ acting on the αth particle is given by

$$\boldsymbol{F}_\alpha = -\nabla_\alpha U(\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N) \qquad [1]$$

and a mechanical trajectory $\boldsymbol{R}_\alpha = \boldsymbol{R}_\alpha(t)$ can be computed, provided that the instantaneous particle positions are computable at each time t. For condensed matter systems, the trajectories will be typically generated within a periodically repeated simulation cell, containing the full set of N particles. Therefore, the trajectory of any given particle or its periodic image is investigated, in case it migrates through cell boundary. The concept is illustrated in **Figure 1**. Periodic boundary conditions (PBCs) are introduced to minimize the absolute number of particles to deal with and to avoid the undesired free surfaces created by crude truncation at cell boundaries. Furthermore, PBCs allow to simulate ensembles with a constant number of particles, regardless of the diffusivity properties of the simulated system.

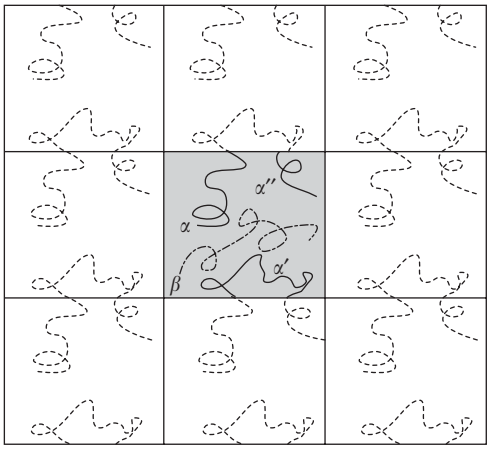

Figure 1 Two-dimensional example of periodic boundary conditions. The full-line trajectory migrates through the simulation cell (shaded area) boundaries; dashed lines represent its periodic images. In this case, the computed properties are collected along the piece-like trajectory $\alpha \rightarrow \alpha' \rightarrow \alpha''$. On the contrary, the dot-dashed trajectory β is fully contained within the simulation cell: no periodic boundary conditions need to be applied.

In order to translate the classical mechanics problem into a form suitable for digital computers, one needs to introduce the discretization of the time evolution. This is obtained by introducing a time-step δt (**Figure 2**), representing the unit of time interval, and by further assuming that the force $\boldsymbol{F}_\alpha$ is constant over δt. The resulting particle motion is linear and uniformly accelerated throughout δt. The optimal value of δt depends on the investigated system. However, in most applications it is of the order 10^{-15} s, so that $\sim$10–100 time-steps are needed to span one typical phonon period. The corresponding equations of motion are formulated according to second-order Newton dynamics

$$\begin{aligned} \boldsymbol{R}_\alpha(t+\delta t) &= \boldsymbol{R}_\alpha(t) + \dot{\boldsymbol{R}}_\alpha(t)\delta t + \tfrac{1}{2}\ddot{\boldsymbol{R}}_\alpha(t)\delta t^2 \\ \dot{\boldsymbol{R}}_\alpha(t+\delta t) &= \dot{\boldsymbol{R}}_\alpha(t) + \ddot{\boldsymbol{R}}_\alpha(t)\delta t \end{aligned} \qquad [2]$$

the particle acceleration being computed from the interaction model

$$\begin{aligned} \ddot{\boldsymbol{R}}_\alpha(t) &= \frac{1}{m_\alpha}\boldsymbol{F}_\alpha(t) \\ &= -\frac{1}{m_\alpha}\nabla_\alpha U\left(\boldsymbol{R}_1(t), \boldsymbol{R}_2(t), \ldots, \boldsymbol{R}_N(t)\right) \end{aligned} \qquad [3]$$

where m_α is the particle mass. This simple formulation allows for setting up a first rudimental iterative scheme to generate by a computer simulation the time evolution of the full system, as reported in **Figure 3**: such a procedure is referred to as molecular dynamics (MD) simulation.

By keeping the cell volume fixed, the MD simulation generates trajectories of a physical system with

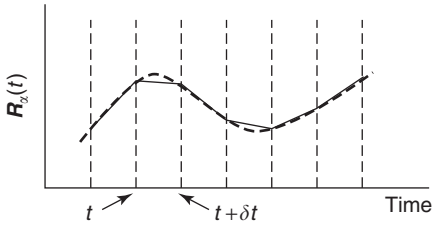

Figure 2 Time discretization of trajectories aging. Bold-dashed line represents the exact trajectory. During the numerical simulation the position $\boldsymbol{R}_\alpha$ is known only at discrete times corresponding to dashed vertical lines. The associated computer-generated trajectory is represented by the full line.

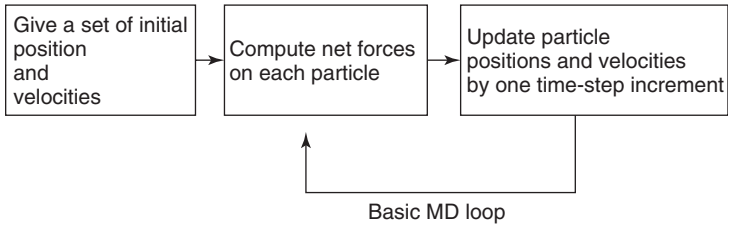

Figure 3 The simplest iterative scheme ruling MD. One iteration corresponds to increasing time by an amount δt.

constant number of particles N, constant volume V, and constant energy E (no external forces are assumed to act on the system). This corresponds to the microcanonical ensemble condition (NVE). The instantaneous kinetic temperature $T(t)$ of the system can also be computed on-the-flight during the MD run:

$$T(t) = \frac{1}{gK_B}\sum_{\alpha=1}^{N} m_\alpha \dot{\boldsymbol{R}}_\alpha^2(t) \qquad [4]$$

where K_B is the Boltzmann constant and g represents the number of degrees of freedom of the system. This relation (based on equipartition) represents the basic link between classical mechanics and thermodynamics. Indeed, one can gauge the instantaneous temperature $T(t)$ to a reference temperature T_{ref} simply by scaling at each time-step all velocities by the factor $\sqrt{T_{ref}/T(t)}$. Although this is a rather crude approach (in the next section more refined and sound algorithms are discussed), it represents a simple and effective way to control the temperature (or, more precisely, the kinetic energy of the system). By keeping T_{ref} constant in time, an approximately constant temperature is generated, that is, canonical (NVT), ensemble. Conversely, by changing the value of T_{ref} during the simulation, the system is allowed to heat or cool. It is important to stress that the present condition of constant kinetic energy is not rigorously equivalent to the condition of constant temperature, as discussed below. Nevertheless, it is widely adopted to simulate canonical systems.

Although conceptually very simple, the above iterative scheme can provide valuable information about a huge set of physical properties relevant to condensed matter physics – provided that a reliable interaction potential U is given. In particular, it is possible: (1) to elaborate structural models of bulk, low-dimensional, and molecular systems; (2) to investigate dynamical processes like film growth, surface diffusion, molecular interactions; (3) to simulate transport phenomena like bulk self-diffusion and defect mobility; (4) to model materials microstructure evolution under ion beam processing, phase transition, melting, and solid-phase epitaxy; and (5) to study the structure and topology of nano-/poly-structured, disordered, and complex materials.

The Generation of Particle Trajectories

The overall reliability of the MD method critically depends on the generation of accurate and stable particle trajectories. Special care must be devoted to selecting the best numerical algorithm for the integration of Newton's equations of motion. A widely adopted scheme is the so-called velocity-Verlet (VV) algorithm, which also represents a prototypical example of numerical integration scheme by finite difference methods. According to the VV algorithm, aging the particle trajectories corresponds to a multiple-step procedure:

1. the particle positions $\boldsymbol{R}_\alpha(t)$ are updated to time $t+\delta t$ as

$$\boldsymbol{R}_\alpha(t+\delta t) = \boldsymbol{R}_\alpha(t) + \dot{\boldsymbol{R}}_\alpha(t)\delta t + \tfrac{1}{2}\ddot{\boldsymbol{R}}_\alpha(t)\delta t^2 \qquad [5]$$

2. the atomic velocities are then computed at the mid step time $t + (1/2)\delta t$ using

$$\dot{\boldsymbol{R}}_\alpha(t+\tfrac{1}{2}\,\delta t) = \dot{\boldsymbol{R}}_\alpha(t) + \tfrac{1}{2}\ddot{\boldsymbol{R}}_\alpha(t)\delta t \qquad [6]$$

3. forces and accelerations are now computed at time $t+\delta t$ as shown in eqn [3]; and
4. particles velocities are finally evolved to time $t+\delta t$ according to

$$\dot{\boldsymbol{R}}_\alpha(t+\delta t) = \dot{\boldsymbol{R}}_\alpha(t+\tfrac{1}{2}\,\delta t) + \tfrac{1}{2}\ddot{\boldsymbol{R}}_\alpha(t+\delta t)\delta t \qquad [7]$$

This finite difference method is correct to the order δt^4.

The VV algorithm is simple and requires a straightforward numerical coding. It also easily allows for temperature control by velocities rescaling. Furthermore, it is not demanding as far as memory is required: just nine basic data (i.e., the Cartesian components of position, velocity, and force vectors) are actually needed for each particle in the system. More importantly, VV algorithm is stable and allows for the use of relatively long time-steps

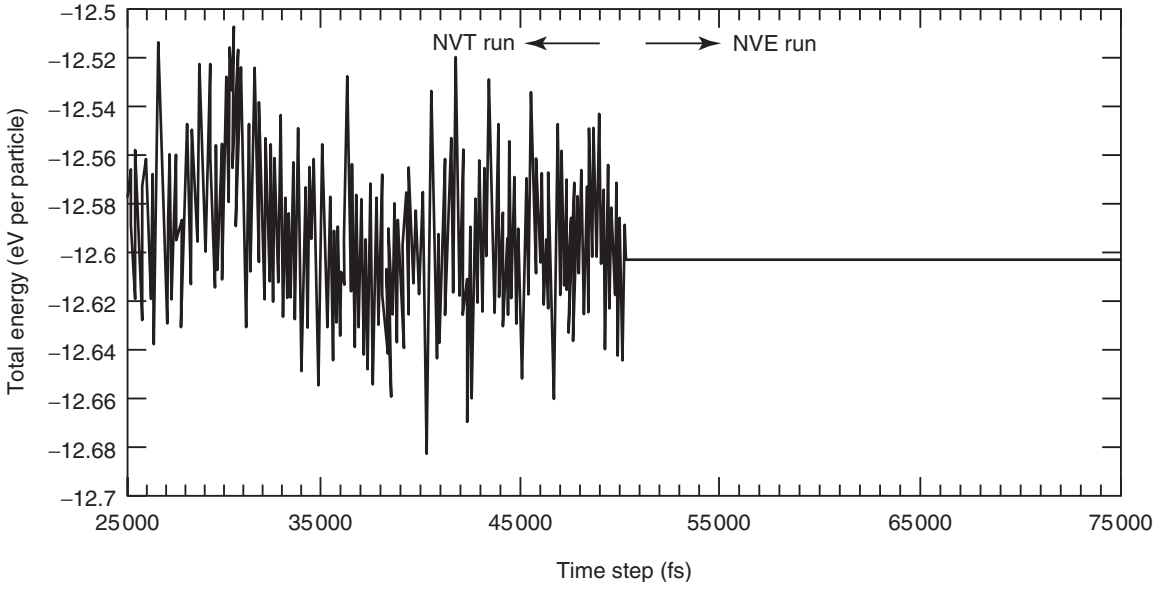

Figure 4 Time evolution of total energy per particle for a model silicon system at $T = 1200$ K. The system has been thermalized during a NVT run until time 50 000 δt. From that time step on the evolution was microcanonical (NVE): total energy is conserved to within 5×10^{-4} eV per particle.

(10^{-15} s $\leqslant \delta t \leqslant 10^{-14}$ s), still giving optimal conservation of the mechanical time-invariant quantities. **Figure 4** shows the time evolution of the total energy E for a solid-state system aged by an NVE MD run.

A common feature of any finite difference method is the calculation of the particle accelerations or, equivalently, forces. This is likely the most computationally intensive step of the MD loop, as explained in the next section. Therefore, the number of force calls at each loop should be minimized. For short-ranged potentials and for large enough systems, many particles do not contribute to the net force acting on a given particle α. It is therefore convenient to exclude those particles that do not interact with α from the expensive calculation of F_α, which, as already explained, depend upon interparticle distances. This can be obtained by means of the Verlet list algorithm, which is illustrated in **Figure 5**. Suppose that the interatomic potential U has a cutoff at d_1. Define a sphere of larger radius d_2 and put all the particles there contained in the neighboring list of particle α. Obviously, d_2 must be much smaller than the simulation cell size, in order to develop a useful algorithm. The actual particles interacting with α are now searched only within the sphere of radius d_2 (instead of within the entire simulation cell). If the difference $|d_2 - d_1|$ is properly chosen, for quite a few time-steps there is no need to refresh the neighboring list (an operation whose CPU workload scales as N^2), thus saving significant computer time. Furthermore, when the Verlet list algorithm is coupled to the linked cell method, it provides a CPU workload linearscaling in the number of particles N.

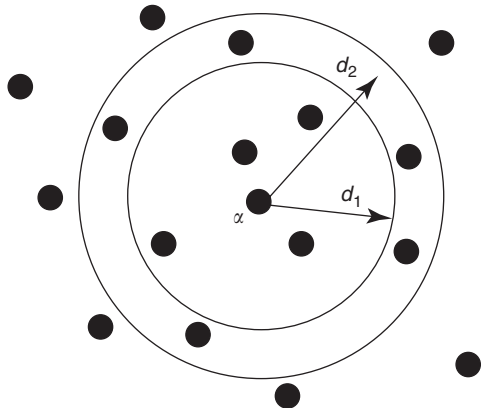

Figure 5 The Verlet neighboring list method.

A rather different approach is required when the potential energy U is long-ranged, as in polar systems where charge–charge (or even dipole–dipole) interactions must be taken into account. In this case one cannot take advantage from potential shortrangeness and it is necessary to compute the Coulomb contribution U_C to potential energy according to

$$U_C = \frac{1}{4\pi\varepsilon_0} \sum_{\alpha=1}^{N} \sum_{\beta} \frac{Z_\alpha Z_\beta}{|\boldsymbol{R}_\alpha - \boldsymbol{R}_\beta|} \quad \text{with } \alpha \neq \beta \qquad [8]$$

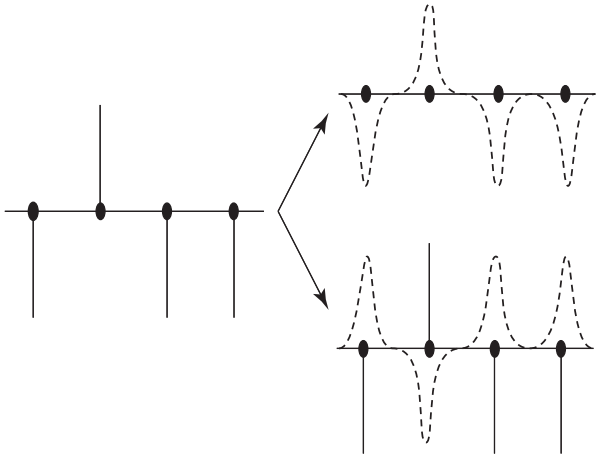

Figure 6 The Ewald sum method: a system of positive and negative point charges (left) is replaced by an equivalent system (right) of point (full line) and diffuse (dashed line) charges with screened (i.e., short-ranged) interactions.

where the index α runs over all the particles in the simulation cell, whereas the index β also labels all the (periodic) image particles. Z_α and Z_β represent the particle point charges (either positive or negative). This expression cannot be computed by a brute-force approach, since it is only conditionally convergent and, of course, cannot be simply truncated. Rather, the system of point charges is replaced with an equivalent system of point and diffuse charges where effective screening takes place. The procedure – known as Ewald sum – is illustrated in **Figure 6**: a diffuse charge of opposite sign is added to any point charge, such that the net charge at each particle position is zero (**Figure 6**, bottom right). Typically, the diffuse charge has a Gaussian-like shape. In this way, the resulting electrostatic potential due to particle α is only due to that fraction of Z_α which is not screened by the added diffuse charge and, therefore, it is short-ranged. A compensating set of diffuse charges is then added to the system to recover neutrality (**Figure 6**, top right). This latter compensating distribution is a periodic and slowly varying function and can be easily computed by a rapidly converging Fourier series.

The Control of the Thermodynamical Ensemble

The previous mechanical formulation of MD can be naturally recast into a statistical mechanics formulation. In fact, the set of instantaneous particle positions $\{\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N\}$ and velocities $\{\dot{\boldsymbol{R}}_1, \dot{\boldsymbol{R}}_2, \ldots, \dot{\boldsymbol{R}}_N\}$ uniquely defines a microstate $\Gamma(t)$ in the $6N$-dimensional phase space of the system. Generating

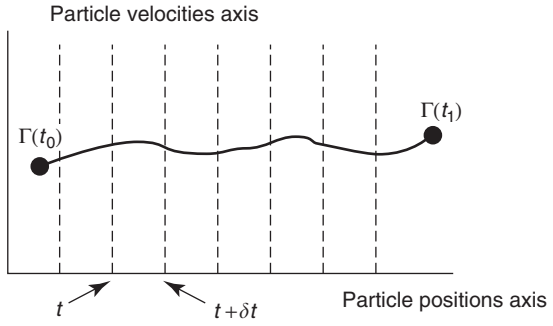

Figure 7 The time evolution of the microstate Γ representing the system under investigation.

trajectories is, therefore, equivalent to generate the time evolution of the microstate $\Gamma(t)$ in the corresponding phase space, as reported schematically in **Figure 7**. This is the basic ingredient for developing a theory based on statistical mechanics.

Consider a given system property (or observable) and define the corresponding microscopic (i.e., computable on the basis of particle positions and/or velocities) operator $\mathcal{O}$. Then, if the microstate $\Gamma(t)$ is known, the instantaneous operator value $\mathcal{O}(\Gamma(t))$ can be evaluated. In other words, one can compute the value assumed by the observable when the system is in that given microstate at time t. According to statistical mechanics, therefore, the macroscopic (i.e., the experimentally measurable) value $\mathcal{O}_{\text{macro}}$ can be defined to be the time average $\langle \mathcal{O}(t) \rangle_{t_{\text{obs}}}$

$$\mathcal{O}_{\text{macro}} = \langle \mathcal{O}(t) \rangle_{t_{\text{obs}}} = \frac{1}{t_{\text{obs}}} \int_0^{t_{\text{obs}}} \mathcal{O}(\Gamma(t))\, \mathrm{d}t \quad [9]$$

where the time integral is performed over the observation time t_{obs}. In practice, the molecular dynamics run is performed over a finite number N_{step} of time steps, so that

$$\mathcal{O}_{\text{macro}} = \langle \mathcal{O}(t) \rangle_{t_{\text{obs}}} = \frac{1}{N_{\text{step}}} \sum_{i=1}^{N_{\text{step}}} \mathcal{O}(\Gamma(t_i)) \quad [10]$$

This major conceptual step allows to refine the previous basic iterative scheme, introducing a system observation procedure as reported in **Figure 8**.

The improvement of the iterative scheme forces us to cope with the choice and the proper implementation of thermodynamical ensembles where time averages are performed. In other words, one needs to operationally select the thermodynamical state of the system so that the trajectory $\Gamma(t)$ is generated only within a subset of the phase space compatible with the imposed conditions of temperature, pressure (or stress), volume, and so on. On the other hand, this formulation widely enlarges the playground for

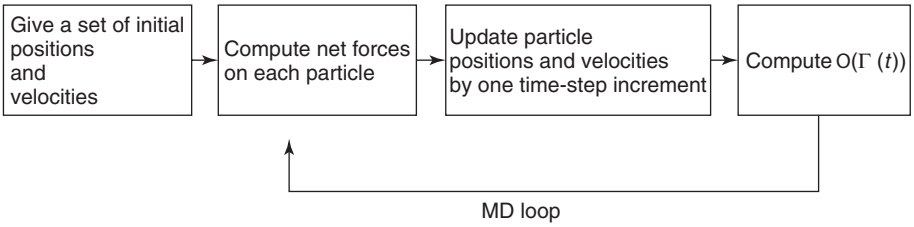

Figure 8 The refined iterative MD loop, including the evaluation of the instantaneous value $\mathcal{O}(\Gamma(t))$ of a given observable. One iteration corresponds to increasing time by an amount δt.

MD investigations of condensed matter systems to include nearly any possible thermodynamical condition.

Constant-Temperature Ensemble

According to statistical mechanics, keeping the system into the canonical ensemble means coupling it to an external thermal reservoir. Several algorithms are available to implement this concept.

In the Anderson method, the thermal bath is mimicked by stochastic collisions (impulsive forces) occasionally occurring at randomly selected particles. The system–bath coupling strength is thus controlled by the collision frequency v which, in turn, is defined by combining physical insight into the system and computational convenience. In order to generate uncorrelated collisionial events, their time distribution (i.e., the distribution of time separations between two consecutive collisions) is Poisson-like. The basic MD loop is simply modified so that, during a time interval equal to the MD time-step, a random particle undergoes a stochastic collision with probability $v\,\delta t$. If this is the case, a new velocity is assigned to that particle as extracted by the equilibrium Maxwell–Boltzmann velocity distribution corresponding to the desired temperature.

A different widely adopted algorithm is offered by the Nosé approach which, at variance with Anderson thermostat, is deterministic. The Nosé method is based on the use of an extended Lagrangian, containing fictitious coordinates and velocities additional to the particle ones. The method is not only important *per se*, but it also represents the prototypical MD approach based on extended Lagrangian formalism, which is very extensively used in modern developments. In order to mimic the coupling to a thermal reservoir, a new fictitious degree of freedom s is added to the system and a classical Lagrangian $\mathscr{L}_{\text{Nosé}}$ is written as

$$\mathscr{L}_{\text{Nosé}} = \frac{1}{2}\sum_{\alpha=1}^{N} m_\alpha s^2 \dot{R}_\alpha^2 + \frac{1}{2} m_s \dot{s}^2 - U(\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N) - g K_B T \ln s \qquad [11]$$

where m_s acts as the effective mass associated with the new coordinate s, and g is the number of degrees of freedom for the extended system. The Nosé Lagrangian allows for energy (i.e., heat) exchange between the physical system and the reservoir (described by s), the thermal inertia being described by the parameter m_s. The new equations of motion are easily derived for system particles

$$\ddot{\boldsymbol{R}}_\alpha = \frac{\boldsymbol{F}_\alpha}{m_\alpha s^2} - 2\dot{\boldsymbol{R}}_\alpha \frac{\dot{s}}{s} \qquad [12]$$

and for the heat reservoir coordinate s

$$m_s \ddot{s} = \sum_{\alpha=1}^{N} m_\alpha s \ddot{R}_\alpha^2 - g\frac{K_B T}{s} \qquad [13]$$

In both cases standard finite difference methods can be used. The new extended system (i.e., the N particles plus the thermal bath) is microcanonical, while it can be proved that ensemble averages performed during a Nosé MD run, reduce to canonical averages. **Figure 9** shows the thermal inertia features of the Nosé approach.

The Nosé method can be generalized into the Nosé–Hoover chains approach: the original thermostat is now coupled to a series of other fictitious thermostats whose role is basically to allow for fluctuations of the variable s. The Nosé–Hoover method has been proved to accurately generate a canonical distribution and to improve the ergodicity of the simulated system.

Constant-Pressure Ensemble

The extended Lagrangian method is useful also to simulate the constant-pressure ensemble, that is, when the system is coupled to an external piston. In this case the new additional variable is the volume V of the simulation cell, which is characterized by an effective mass m_V. Andersen has shown that by introducing the scaled variables

$$\boldsymbol{R}_{s,\alpha} = V^{-1/3}\boldsymbol{R}_\alpha \qquad [14]$$

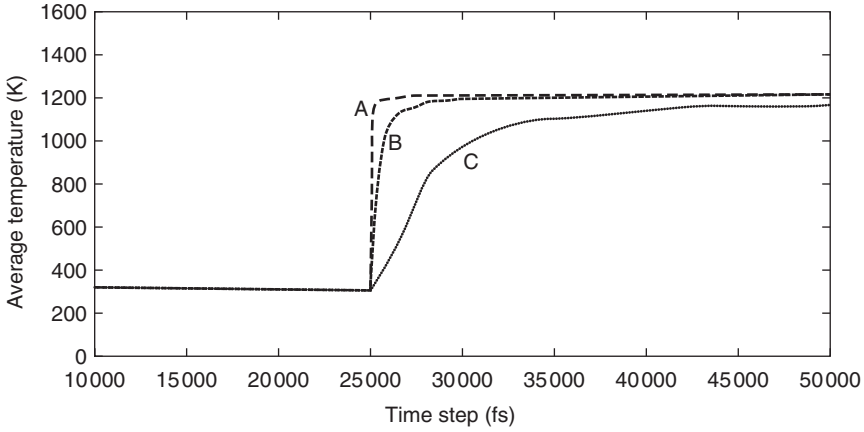

Figure 9 A crystalline silicon system previously thermalized at $T = 300\,\mathrm{K}$ is coupled to a thermostat at $T = 1200\,\mathrm{K}$ via the Nosé Lagrangian at time $25\,000\delta t$. Three different values for the thermostat effective mass m_s have been used, with ratio 1 : 10 : 100, corresponding to the curve A, B, and C, respectively. The thermal inertia effects are governed by the parameter m_s.

and velocities

$$\dot{\boldsymbol{R}}_{s,\alpha} = V^{-1/3}\dot{\boldsymbol{R}}_{\alpha} \qquad [15]$$

the new extended Lagrangian $\mathscr{L}_{\mathrm{Andersen}}$ reads as

$$\mathscr{L}_{\mathrm{Andersen}} = \frac{1}{2}V^{2/3}\sum_{\alpha=1}^{N} m_{\alpha}\dot{R}_{s,\alpha}^{2} + \frac{1}{2}m_V\dot{V}^2 - U(\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N) - P_{\mathrm{piston}}V \qquad [16]$$

where P_{piston} is the (hydrostatic) pressure applied by the piston to the system. The new equations of motions for scaled particle coordinates are

$$\ddot{\boldsymbol{R}}_{s,\alpha} = \frac{1}{m_{\alpha}V^{1/3}}\boldsymbol{F}_{\alpha} - \frac{2}{3}\dot{\boldsymbol{R}}_{s,\alpha}\frac{\dot{V}}{V} \qquad [17]$$

whereas the new variable V evolves according to

$$\ddot{V} = \frac{P_{\mathrm{int}} - P_{\mathrm{piston}}}{m_V} \qquad [18]$$

where P_{int} is the system internal pressure (e.g., computed by virial theorem). Once again, standard finite difference methods are applied to solve the above equations and the resulting dynamics of the extended system is microcanonical. Ensemble averages performed on unsealed trajectories are proved to be isobaric (with isotropic changes in the simulation cell volume).

The Andersen method can be generalized according to Rahman and Parrinello so as to allow for both volume and shape changes of the simulation cell. Basically, the additional variable V is now replaced by the nine components of the metric tensor $\boldsymbol{H} = (\boldsymbol{h}_1, \boldsymbol{h}_2, \boldsymbol{h}_3)$, whose columns $\boldsymbol{h}_{1,2,3}$ are vector quantities representing the simulation cell edges. The Rahman–Parrinello Lagrangian (or its extensions) allows for investigating nonisotropic deformations under hydrostatic pressure, as well as the effect of any kind of applied stress.

The Interaction Scheme

The physics produced by an MD simulation crucially depends upon the adopted interatomic potential $U(\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N)$. A good interaction model should be accurate (i.e., it should provide accurate estimation of total energy and related quantities, for example, its derivatives), reliable (i.e., it should be firmly rooted into a fundamental description of interparticle interactions and it should provide deep physicochemical insight into the investigated system), and transferable (i.e., it should be able to manage the same system in arbitrary conditions of temperature, pressure/stress, state of aggregation, order/disorder, external load).

The simplest possible approach to elaborate a theory for U consists in formally expanding the total potential into a series of two-body $U^{(2)}$, three-body $U^{(3)}, \ldots,$ n-body $U^{(n)}$ terms as

$$U(\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N) = \sum_{\alpha>\beta} U^{(2)}(\boldsymbol{R}_{\alpha}, \boldsymbol{R}_{\beta}) + \sum_{\alpha>\beta>\gamma} U^{(3)}(\boldsymbol{R}_{\alpha}, \boldsymbol{R}_{\beta}, \boldsymbol{R}_{\gamma}) + \cdots \qquad [19]$$

The series is then arrested at a given order, as guessed by the chemical nature of the underlying interparticle bond. For instance, just a two-body term is needed to model simple metals (although at a very crude level), while both a two-body and a three-body term are

indeed required to simulate materials with directional and/or covalent bonding. Full set of interatomic potentials are now available for nearly any class of materials. Most of them are short-ranged (i.e., the sums in the above formal expansion are limited just to the nearest-neighbor particles), but long-ranged potentials (i.e., containing Coulomb interactions) are available as well for ionic and/or polar materials.

The actual expression for the $U^{(2)}$, $U^{(3)}$, …, $U^{(n)}$ functionals is either guessed by physicochemical intuition on the investigated system, or simply determined for numerical convenience. In any case, the functionals depend upon empirical parameters that need to be fitted once for all onto a suitable database of system properties. The resulting simulation is therefore classified as a model-potential MD (MPMD). The empirical character of U dramatically improves the overall numerical efficiency of the simulation, since the resulting CPU workload typically scales (for short-ranged potentials) as $m \times N$, where m is the (average) number of neighbors for each of the N system particles. Present-day massively parallel computers allow for simulations up to $N \sim 10^8$, although a more typical number is below 10^5–10^6. Unfortunately, the same empiricity also limits (sometimes even severely) the transferability of the potential itself. In other words, model potentials are computationally inexpensive, but often not accurate enough for predictive materials modeling.

In order to overcome this limitation, one can develop a theory at the more fundamental quantum level. Within the Born–Oppenheimer approximation and adopting the one-electron picture, the total potential energy of a system of ion cores (nuclei and core electrons) and (valence) electrons can be expressed as

$$U(\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N) = U_{\mathrm{ee}} + U_{\mathrm{ei}} + U_{\mathrm{ii}} \qquad [20]$$

where i and e labels indicate ions and electrons, respectively. In order to compute such an expression, electron energies ε_n and wave functions Ψ_n should be known. Once they are known, for example, by solving numerically the one-electron Schrödinger equation, the total potential energy U can be written as

$$\begin{aligned} U &= U_{\mathrm{ie}} + U_{\mathrm{ii}} + U_{\mathrm{ee}} \\ &= 2\sum_{n}^{\mathrm{occ}} \varepsilon_n + U_{\mathrm{ii}} - U_{\mathrm{ee}} \end{aligned} \qquad [21]$$

where the sum is perfomed over the energies of the occupied states and the $-U_{\mathrm{ee}}$ contribution corrects the double counting of the electron–electron interactions in the first term. The factor of 2 takes into account the spin degeneracy. By applying the Hellmann–Feynman theorem (with or without Pulay's correction, depending on the choice of basis orbitals) it is straightforward to obtain interparticle forces which, therefore, contain a full quantum mechanical picture of particle interactions. The two most computationally intensive steps of this first-principles MD (FPMD) scheme are: (1) Schrödinger equation solution and (2) self-consistent evaluation of U_{ee}. The resulting CPU workload typically scales as N^3 and a large prefactor is also found, thus preventing in practice first-principles simulations with much more than $\sim 10^2$ particles.

Although the above formalism has been developed from first principles, it is convenient – in order to save computer time – to introduce some important approximation, namely the tight-binding (TB) picture. In this framework, the electron wave function Ψ_n values are expanded as linear combinations of atomic orbitals $\{\phi_{l\alpha}\}$:

$$\Psi_n = \sum_{l\alpha} c^n_{l\alpha} \phi_{l\alpha} \qquad [22]$$

where l is the quantum number index. For simplicity, the basis set is assumed to be orthogonal. The matrix elements $\langle \phi_{l'\beta} | h | \phi_{l\alpha} \rangle$ of the one-electron Hamiltonian are then treated – according to Slater–Koster theory – as disposable constants to be fitted, instead of computed, self-consistently. The fitting step is typically carried out assuming: (1) a minimal basis set, (2) short-range hoppings, and (3) two-center approximation. Furthermore, the difference $U_{\mathrm{ii}} - U_{\mathrm{ee}}$ is replaced by a totally empirical effective potential U_{eff} which is calibrated similarly to model potentials. It results a semi-empirical MD (SEMD) scheme with improved accuracy and transferability with respect to MPMD. However, the computational workload is dramaticaly reduced with respect to an FPMD approach since no self-consistency is required. However, it is still significantly heavy since the diagonalization of the TB matrix is needed at each step of the MD loop. This operation has a complexity scaling as N^3. SEMD simulations are typically performed on systems containing as many as several hundred particles.

The SEMD approach represents an interaction scheme bridging model-potential to first-principles simulations. Although it could be of great help in many cases, it nevertheless leaves unsatisfied the most demanding requirements of accuracy and transferability. There is, in other words, a real need of parameter-free MD simulations in modern condensed matter and materials physics. The best-available answer to such a need is represented by the Car–Parrinello MD (CPMD) scheme. Within the CPMD method the properties of the system are computed – according to the basic formulation of MD – as time

averages, while particle interactions are derived from the underlying electronic structure, provided by density-functional theory (DFT). The key idea consists in replacing the real quantum (ions + electrons) system with a fictitious classical one. The fictitious system is in fact described by the Car–Parrinello Lagrangian $\mathscr{L}_{\mathrm{CP}}$:

$$\begin{aligned}\mathscr{L}_{\mathrm{CP}} = \mu \sum_{j}^{\mathrm{occ}} \int |\dot{\psi}_j(\boldsymbol{r})|^2 \, \mathrm{d}\boldsymbol{r} + \frac{1}{2}\sum_{\alpha=1}^{N} m_\alpha \dot{\boldsymbol{R}}_\alpha^2 \\ - E[\{\psi_j\}, \{\boldsymbol{R}\}] \\ + \sum_{jk} \Lambda_{jk} \left(\int \psi_j(\boldsymbol{r})^* \psi_k(\boldsymbol{r}) \, \mathrm{d}r - \delta_{jk} \right) \end{aligned} \quad [23]$$

where $\boldsymbol{r}$ denotes electron coordinates and $E[\{\psi_j\}, \{\boldsymbol{R}\}]$ is the DFT potential energy functional of the coupled electron–ion system. The parameter μ plays the role of an effective mass for the electronic degrees of freedom. The Lagrangian multipliers Λ_{jk} are simple holonomic constrains imposing the orthogonality of the electron wave functions $\{\psi_j(\boldsymbol{r})\}$. As usual for extended systems, a new set of equations of motion can be derived for both the ionic degrees of freedom,

$$m_\alpha \ddot{\boldsymbol{R}}_\alpha = -\nabla_\alpha E[\{\psi_j\}, \{\boldsymbol{R}\}] \quad [24]$$

and the electronic degrees of freedom

$$\mu \ddot{\psi}_j = -\frac{\delta E[\{\psi_j\}, \{\boldsymbol{R}\}]}{\delta \psi_j^*} + \sum_{jk} \Lambda_{jk} \psi_k \quad [25]$$

In principle, the ionic trajectories generated by $\mathscr{L}_{\mathrm{CP}}$ do not coincide with the real ones, unless the functional $E[\{\psi_j\}, \{\boldsymbol{R}\}]$ is at the minimum. However, it has been proved that by a proper choice of the fictitious electronic mass μ, the electrons follow adiabatically the ionic motion, since their generated timescale is much shorter than the ionic one. When this condition is fulfilled, any sizeable deviation of the nuclear trajectories from the minimum electron energy surface corresponding to the actual ionic configuration (Born–Oppenheimer surface) is typically observed only after times much longer than a typical MD time step. Consistently, meaningful time averages can be performed. The key point of the CPMD method is that a self-consistent minimization of the total energy functional $E[\{\psi_j\}, \{\boldsymbol{R}\}]$ is not required at each step of the simulation. Rather, the equations of motion for the electronic degrees of freedom act so as to keep electrons constantly close to (ideally at) the Born–Oppenheimer surface. As usual, the MD method (e.g., control of temperature, pressure, stress) can be applied to CPMD, thus making it the most fundamental and superior simulation scheme now available for condensed matter systems.

Introduction

The idea of simulating the microscopic behavior of matter by directly solving Newton's equations on the computer for a collection of atoms was first proposed by E Fermi in the 1940s. The technique is generally referred to as "molecular dynamics (MD)." The exponential increase of computer power and the continuous refinement of simulation techniques have turned molecular dynamic simulations from a toy model of statistical physics into an extremely valuable and predictive tool nowadays. The application of molecular dynamics is widespread in many fields of condensed matter physics, materials science, chemistry, and molecular biology.

Evolving Newton's equations

$$\ddot{\boldsymbol{R}}_I = -\frac{1}{M_I}\frac{\partial V}{\partial \boldsymbol{R}_I}(\boldsymbol{R}_1, \ldots, \boldsymbol{R}_N) \quad I = 1, N \qquad [1]$$

for a collection of N atoms with positions $\{\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N\}$ and masses $\{M_1, M_2, \ldots, M_N\}$ implies that the potential $V(\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_N)$ of interaction among them must be given. Determining the interatomic potential is one of the more challenging problems in molecular dynamic simulations, as discussed in detail in Colombo's contribution. In this article, the focus is on how to determine the interatomic potential V from "first principles," based on the laws of quantum mechanics, and without any empirical input. By doing so, the computational complexity of a molecular dynamic simulation increases dramatically, implying, for example, that a much smaller number of atoms can be simulated and for much shorter times than conventional molecular dynamic simulations. First-principle (or *ab initio*) molecular dynamics combines the advantages of conventional molecular dynamics in terms of statistical sampling with the accuracy of quantum mechanical methods in describing electronic structure and chemical bonding in condensed matter.

First-Principles MD

Here, the concentration is on the problem of determining a reliable interatomic potential, to be used in the MD eqn [1]. The approach that is followed starts from the "first-principles," namely from the fundamental quantum mechanical laws that govern the behavior of a collection of electrons and nuclei. Although these laws are well known – the Schrödinger equation for the coupled electrons–nuclei system – solving them on the computer without any further approximation would require an exceptional effort, many orders of magnitude more than what is available at present in terms of computer memory and speed. The first approximation to be introduced is the so-called "adiabatic," Born–Oppenheimer approximation. This approximation stems from the consideration that electrons react much faster than nuclei to external perturbations, due to their smaller mass. As a consequence, electrons can be considered to be always in their ground state, for every instantaneous nuclear configuration $\{\boldsymbol{R}_1, \ldots, \boldsymbol{R}_N\}$. Therefore, the interaction potential V can be expressed as

$$V(\boldsymbol{R}_1, \ldots, \boldsymbol{R}_N) = \langle \psi_\circ | H_e(\boldsymbol{R}_1, \ldots, \boldsymbol{R}_N) | \psi_\circ \rangle \qquad [2]$$

where $\psi_\circ$ is the electronic ground-state wave function calculated for the nuclear configuration $\{\boldsymbol{R}_1, \ldots, \boldsymbol{R}_N\}$, according to the Hamiltonian

$$H_e = -\sum_{i=1,N_e} \frac{\hbar^2}{2m_e}\nabla_i^2 + \sum_{i=1,N_e}^{j=1,i-1} \frac{e^2}{|\boldsymbol{r}_i - \boldsymbol{r}_j|} - \sum_{i=1,N_e}^{I=1,N} \frac{Z_I e^2}{|\boldsymbol{r}_i - \boldsymbol{R}_I|} + \sum_{I=1,N}^{J=1,I-1} \frac{Z_I Z_J e^2}{|\boldsymbol{R}_I - \boldsymbol{R}_J|} \qquad [3]$$

where N_e is the number of electrons and Z_I the atomic number of atom I. Note that the Hamiltonian [3] acts on the electrons, and depends on $\{\boldsymbol{R}_1, \ldots, \boldsymbol{R}_N\}$ only parametrically. This implies that the ground-state wave function ψ_0 will also depend parametrically on $\{\boldsymbol{R}_1, \ldots, \boldsymbol{R}_N\}$, that is, a different wave function is obtained for every nuclear configuration. Although the Born–Oppenheimer approximation allows one to simplify the problem considerably, finding ψ_0 for the Hamiltonian [3] remains a very difficult numerical task, at least for systems with more than a few electrons, because of the many-body nature of the electron–electron Coulomb interaction (second term in the right-hand side of [3]). Among the approximations that allow one to overcome the problem, those based on the density-functional theory (DFT) are probably among the most widespread and accurate, particularly when dealing with relatively large systems (hundreds of electrons or more). DFT is an exact theory that allows one to recast the problem of finding the many-electron ground state of [3] into the problem of finding the ground state of a system of independent electrons in a potential that explicitly depends on the electron density. Although the theory is formally exact, approximations have to be made in order to derive the functional form of the potential. The most common of these approximations is the so-called local-density approximation (LDA), whereby the potential is approximated locally with the functional form of the uniform electron gas, which is known almost exactly from numerical calculations. The LDA can be systematically improved by adding contributions from the local gradient of the density (gradient corrections, or GGA).

A final approximation that is commonly made in first-principles calculations is to assume that core states are actually frozen in their atomic shape and energy. Orthogonalization of the valence states to the core states is ensured by the replacement of the electron–nuclei Coulomb potential, the third term in the right-hand side of [3], with a so-called "pseudopotential," whose scattering properties are constrained to be identical to those of the full atomic potential. When the basis set over which the wave functions are expanded consists of plane waves, a very popular choice in first-principles codes, smoother

pseudopotentials may be less demanding in terms of basis set size.

The above approximations have finally brought the problem into the category of those that can be nowadays solved numerically on a powerful computer. To summarize, a rough flow chart of how the MD time step is accomplished in a first-principles MD code consists of: (1) choosing an initial set of nuclear positions $\{\boldsymbol{R}_1, \ldots, \boldsymbol{R}_N\}$, (2) solving the electron Hamiltonian [3], that is, determining the ground-state wave function for that particular nuclear configuration, (3) calculating the forces on the nuclei as the derivative of the potential [2] [N.B. this can be accomplished either numerically, by finite differences, or by exploiting the so-called Hellman–Feynman theorem, whereby the derivative of the potential can be expressed as the expectation value of the derivative of the Hamiltonian in [2], on the ground-state wave function], (4) evolving Newton's equations for all nuclei with a finite time step δt, that is, determining the new set of nuclear positions corresponding to time $t + \delta t$, and finally going back to (2) with the new set of positions. This procedure is iterated for a large number of time steps, depending on the system and on the property under study. In order to integrate Newton's equations properly, the time step δt of integration must be much smaller than the fastest period of oscillation of the nuclei. Since typical periods (vibrations, phonons, etc.) are in the range 10^{-14}–10^{-12} s, typical δt are in the range of a fraction of 10^{-16}–10^{-15} s, which means that one picosecond of simulation requires $\sim 10^4$ time steps. One of the computationally heavier steps of a first-principles MD simulation is the determination of the ground-state wave function. Considering that this step has to be repeated 10^4 times, most of the methodological effort has been focused on the search for efficient ways to update the wave function from one time step to the next one. Most of the differences between existing codes for first-principles MD [CASTEP (Cambridge), VASP (Vienna), CPMD (Stuttgart/Zürich), PARATEC (Berkeley), and FPMD (Trieste), just to name a few] can be ascribed to different techniques in the way wave functions are evolved.

The Car–Parrinello Method

A rather original and very efficient way to evolve the wave functions was proposed in 1985 by Car and Parrinello. Instead of solving the Hamiltonian [3] at each time step very accurately, they relaxed the constraint that the wave function be exactly in the ground state. The exact solution was replaced by a fictitious dynamics of the wave function about the exact ground state. In the Car–Parrinello method, the solution of the Hamiltonian [3], which is equivalent to minimizing the right-hand side of [2] with respect to the wave function, is replaced by the dynamical evolution of the following "extended" Lagrangian

$$\mathscr{L} = \frac{1}{2}\sum_i \mu \langle \dot{\psi}_i | \dot{\psi}_i \rangle + \frac{1}{2}\sum_I M_I \dot{\boldsymbol{R}}_I^2 - E[\{\psi_i\}, \{\boldsymbol{R}_I\}] + \sum_{ij} \Lambda_{ij}(\langle \psi_i | \psi_j \rangle - \delta_{ij}) \quad [4]$$

where E is the DFT functional, expressed here in terms of the wave functions and, parametrically, of the positions of the nuclei, μ is a fictitious mass that can be used to control the timescale of the electronic dynamics, and Λ_{ij} are Lagrange multipliers that ensure the orthogonality of the wave functions. The second term on the right-hand side of [4] is the kinetic energy of the ions T, while the first term is the fictitious kinetic energy of the electrons T_e. The equations of motion that can be obtained from the above Lagrangian are:

$$\mu \ddot{\psi}_i = -\frac{\delta E}{\delta \psi_i} + \sum_j \Lambda_{ij}\psi_j \quad [5]$$

$$\ddot{\boldsymbol{R}}_I = -\frac{1}{M_I}\frac{\partial E}{\partial \boldsymbol{R}_I} \quad [6]$$

Equation [5] defines the dynamics of the wave functions, which oscillates (by virtue of the second-order time derivative) around the equilibrium condition

$$\frac{\delta E}{\delta \psi_i} = \sum_j \Lambda_{ij}\psi_j \quad [7]$$

Notice that eqn [7] is the mathematical rephrasing of the DFT prescription of minimizing the DFT functional E with respect to variations of the (orthogonal) set of orbitals. Thus, by definition, $E[\{\psi_{\circ i}(\{\boldsymbol{R}_I\})\}, \{\boldsymbol{R}_I\}] = V(\{\boldsymbol{R}_I\})$. Equation [6], instead, coincides with Newton's eqn [1] as obtained from the first-principles potential [2], with the only difference that the wave functions in [6] are not at the exact ground state.

If the atoms are not allowed to move, the period of oscillation of the wave functions around the ground-state scales with $\mu^{1/2}$, which means that for a sufficiently small value of μ, the oscillations can be made much faster than the typical timescales of the dynamics of the nuclei. In this limit, the effect of the fast oscillations averages out on the timescale of the dynamics of the nuclei, and the resulting net force on the nuclei is very similar to the force that would be calculated with the electrons in their ground state.

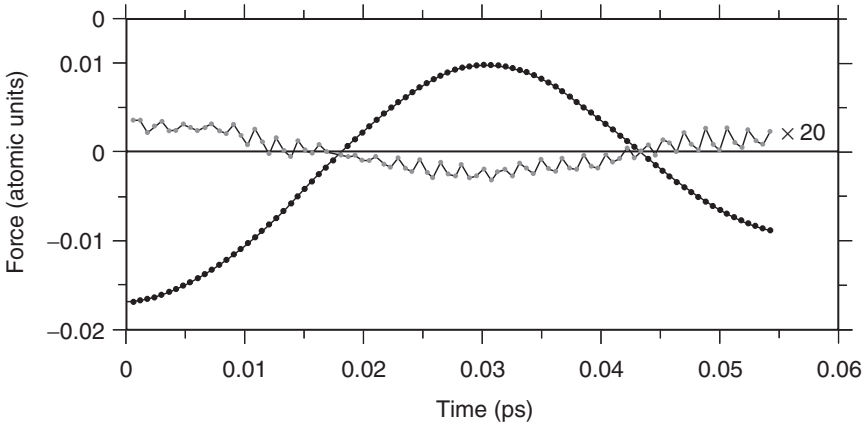

Figure 1 Time dependence of a Cartesian component of the force on a selected atom in a simulation of crystalline silicon with a cell containing 64 atoms at room temperature. The smooth curve corresponds to the force calculated along the Car–Parrinello MD trajectory (1 atomic unit corresponds to $\sim 14.4\,\mathrm{eV\,\AA^{-1}}$). Also shown is the difference (multiplied by 20) between the Car–Parrinello and Born–Oppenheimer force along the Car–Parrinello trajectory.

This is only strictly true if the atomic positions are kept fixed during the electronic dynamics. The consequences of the Car–Parrinello approximation when the atoms are allowed to evolve according to the classical equations of motion [6] are illustrated in **Figure 1**, where the force acting on a silicon atom in a Car–Parrinello simulation of crystalline silicon at room temperature is compared with the force calculated by putting the electrons in their instantaneous ground state at each step of the MD trajectory. The difference (amplified by a factor $\times 20$ in the figure) can be clearly seen to contain a fast component (much faster than the nuclear oscillation) and a slow component with frequency comparable with the nuclear motion. While the fast component is harmless as its contribution to the nuclear dynamics averages away on the timescale of the nuclear oscillations, the slow component interferes with the nuclear dynamics giving rise to a systematic bias of the nuclear trajectories, and must therefore be strictly controlled to ensure that the trajectory generated with the Car–Parrinello equations of motion retains the accuracy of a trajectory generated in the Born–Oppenheimer limit, that is, with the electrons in their instantaneous ground state. In the case of silicon, the difference is anyway very small, but in other systems, such as ionic liquids, the difference can be significant. It is important to remark that the difference can be systematically reduced by decreasing μ, which implies, however, that a shorter time step needs to be used to integrate the electronic equations of motion.

Spectral Properties from *ab initio* Molecular Dynamics

MD calculations are very useful in extracting equilibrium thermodynamics, static and dynamical information from a system. One of the most important and useful quantities that can be evaluated from an MD simulation is the time correlation function C_{AB} that correlates two time-dependent quantities A and B,

$$C_{AB}(t) = \langle A(t_0)B(t_0+t)\rangle \qquad [8]$$

where the average $\langle \ldots \rangle$ is over the initial time t_0.This function is important because it provides detailed information on the dynamics of a system. Furthermore, the Fourier transform of a time correlation function is often related to relevant experimental observables. For example, the Fourier transform of the nuclear velocity–time autocorrelation function is related, in solids, to the phonon density of states $D(\omega)$:

$$D(\omega) \propto \int_0^\infty \mathrm{e}^{\mathrm{i}\omega t} \sum_I \langle \boldsymbol{V}_I(t_0)\cdot \boldsymbol{V}_I(t_0+t)\rangle \,\mathrm{d}t \qquad [9]$$

where $\boldsymbol{V}_I$ is the velocity of atom I. The time correlation formalism was recently extended for the calculation of the infrared absorption coefficient $\alpha(\omega)$. The absolute absorption coefficient of an isotropic system can be obtained from

$$\alpha(\omega) = \frac{4\pi\omega}{3nc}\,\mathrm{Im}\sum_\gamma \chi_{\gamma\gamma} \qquad [10]$$

where n is the refractive index and c the speed of light. The imaginary part of the electronic susceptibility $\chi_{\gamma\gamma}$ is given by

$$\mathrm{Im}\,\chi_{\gamma\gamma} = \frac{V}{2\hbar}(1-\mathrm{e}^{-\hbar\omega/k_\mathrm{B}T})\int_0^\infty \mathrm{e}^{\mathrm{i}\omega t} \times \langle P_\gamma(t_0)P_\gamma(t_0+t)\rangle \,\mathrm{d}t \qquad [11]$$

where $P_\gamma(t_0)$ is the polarization vector along the γ direction. The total polarization can be evaluated from an *ab initio* (e.g., Car–Parrinello) MD simulation using the discrete Berry phase at the single-point limit.

An Example: The Water Molecule

Here, the application of Car–Parrinello MD is illustrated using a simple example – the calculation of the infrared spectrum of a H_2O molecule. To focus attention on both the strengths and weaknesses of the Car–Parrinello approach, a $T = 300$ K MD simulation in a 10 Å periodically replicated cubic box, is performed in three ways: (1) using a large, $\mu = 400\, m_e$ (m_e the electronic mass) and an MD time step $\delta t = 0.1$ fs for a duration $\Delta t = 2$ ps; (2) using smaller, $\mu = 200\, m_e, \delta t = 0.05$ fs, and $\Delta t = 1$ ps; (3) with Born–Oppenheimer forces $\delta t = 0.25$ fs and $\Delta t = 1$ ps. Note that the calculation is designed to serve only as an illustration of basic principles, but does not provide a numerically accurate representation of the vibrational properties of a gas-phase water molecule. The relevant energies for 2000 steps of simulation (1) are shown in **Figure 2**. The DFT energy E is dominated by oscillations with a period of ~ 1 fs and amplitude of 0.004 atomic units (1 atomic unit of energy corresponds to ~ 27.21 eV), resulting from the stretching motion of the O–H bonds. The sum of the nuclear kinetic (T) and DFT (E) energies, which corresponds to the total energy of a classical MD simulation and should be conserved for exact Newtonian dynamics, also oscillates with a similar frequency as the nuclear motion, but with a smaller amplitude. This is due to the fact that the Hamiltonian contains an extra term corresponding to the fictitious kinetic energy of the electrons (T_e), which when summed into $T + E + T_e$, gives a perfectly conserved quantity. As can be inferred from the above discussion, the magnitude of the oscillations in $T + E$, is a consequence of the choice of $\mu = 400\, m_e$, which induces a drag on the nuclei, hence perturbing the nuclear dynamics. The effect may be reduced by decreasing $\mu = 200\, m_e$ but this requires a simultaneous decrease in $\delta t = 0.05$ fs to retain the same degree of energy conservation. Finally, the Born–Oppenheimer forces can be used to eliminate the effect entirely, with the benefit that a larger $\delta t = 0.25$ fs may be employed. However, each MD step now requires ~ 10 self-consistent cycles to converge the wave function coefficients to 10^{-6}, which is required to obtain sufficiently converged forces for stable Newtonian dynamics. Thus, run (1) is the computationally least demanding in terms of CPU time, but also the least accurate, whereas for run (3) the converse is true.

The vibrational spectrum of water, above $2000\,\mathrm{cm}^{-1}$, is dominated by two fundamental vibrational frequencies ν_1 antisymmetric O–H stretching, and ν_2 symmetric O–H stretching, both of which may be adequately sampled on the 1–2 ps timescale.

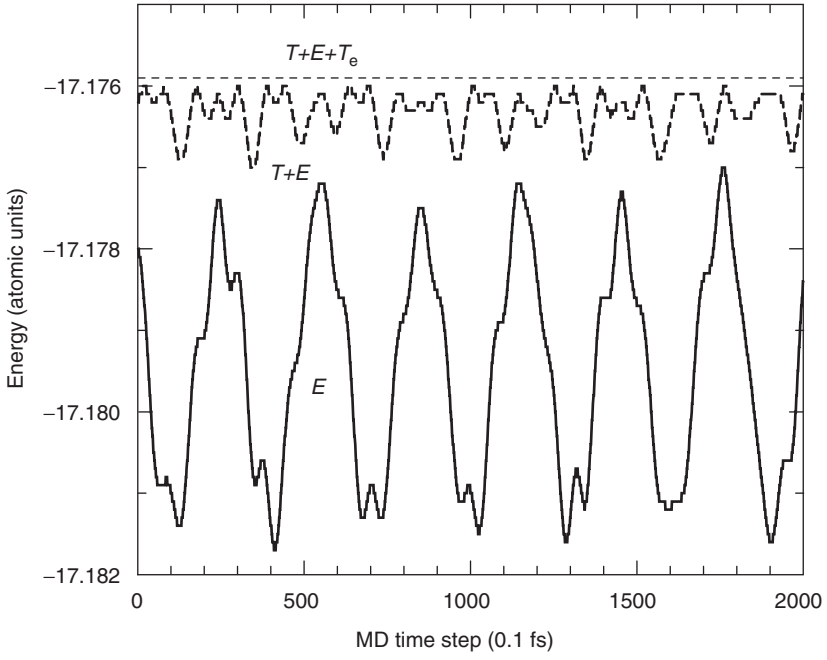

Figure 2 Time dependence of the DFT (E), nuclear kinetic (T), and total ($T + E + T_e$) energies in a Car–Parrinello MD simulation of a water molecule.

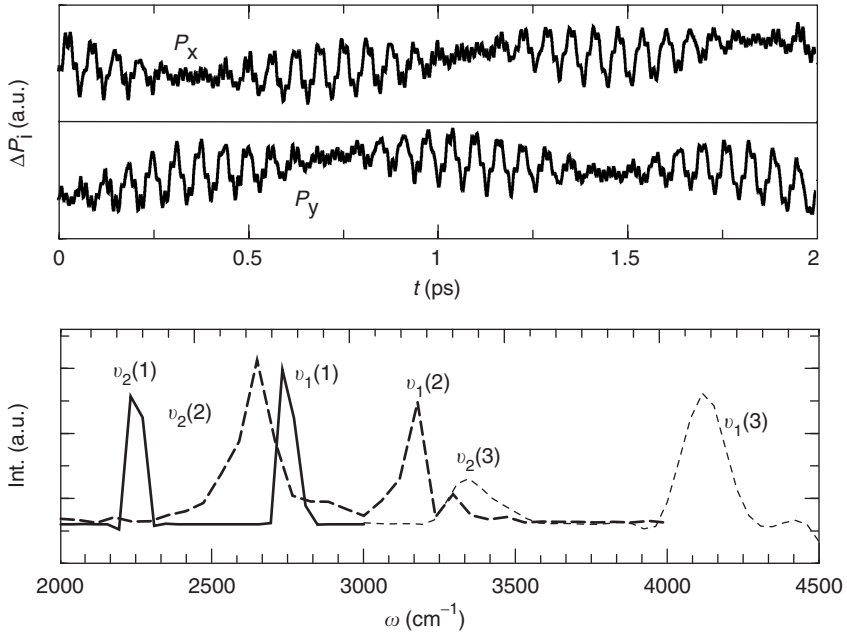

Figure 3 (Upper panel) Time dependence of the Cartesian components of the polarization vector of a water molecule lying on the *x*–*y* plane. (Lower panel) IR absorption spectrum in the region of the O–H stretching and bending modes calculated with Car–Parrinello MD with two different values of the electronic fictitious mass, as well as with Born–Oppenheimer MD.

To obtain the IR adsorption spectrum, the polarization vector is calculated at each MD time step. The water molecule is constrained to lie within the *x*,*y*-plane providing only two components of the polarization vector (P_x and P_y) which are plotted in **Figure 3** for run (1). The two components show oscillations on the femtosecond timescale due to O–H stretching, superimposed onto lower frequencies arising from the bending mode and a weak coupling to the periodic images. Upon applying eqns [10] and [11], the IR adsorption spectrum (see **Figure 3**) is obtained, which, for trajectories of a picosecond in duration, will reliably yield the peak positions but not the relative intensities or the peak shape. All three MD trajectories provide qualitatively the same spectrum, where υ_2 is red-shifted from υ_1 by $\approx 20\%$ of their average. However, the Born–Oppenheimer dynamics provides values, which are in excellent accord with the calculated harmonic frequencies of $\upsilon_1 = 3350\ \text{cm}^{-1}$ and $\upsilon_2 = 4150\ \text{cm}^{-1}$, whereas the average O–H frequency of the Car–Parrinello trajectories are red-shifted by a factor which is proportional to $\sqrt{\mu}$. Note that this rigid shift of the Car–Parrinello peaks allows one to formulate a simple correction by which the nuclear masses may be lessened to account for the electronic drag.

Conclusions

Car–Parrinello *ab initio* MD provides a computationally efficient scheme, whereby Newton's equations of motion may be integrated subject to a potential energy function derived from first-principles electronic structure theory for systems of up to several hundreds of atoms. This procedure can provide a stable nuclear dynamics, and thus allows for an effective sampling of configuration space to obtain reliable statistical distribution functions. For many systems, the Car–Parrinello approach is computationally more efficient than a procedure by which the forces required in MD simulations are obtained from exact ground-state wave functions. However, the method requires that one chooses the fictitious electronic mass μ with great care and for accurate calculation of nuclear dynamical variables, the forces must be corrected due to the drag on the nuclei by the electronic degrees of freedom.

Molecular Monolayers and Thin Films

M K Sanyal, Saha Institute of Nuclear Physics, Bidhannagar, Kolkata, India

Introduction

The last few decades has witnessed a dramatic improvement in the growth processes of thin films that involve sequential deposition of molecular monolayers on a substrate. Here, thin films and monolayers of organic molecules are discussed as the other films have been discussed elsewhere in this encyclopedia. Organic films are being studied widely as the properties of these materials can be tuned by modifying specific functional groups of the molecules and the tailor-made films thus formed are useful for various technological and biological applications. Moreover, organic films provide easy-to-form model systems to enhance the understanding regarding nanostructured materials. The size of nanostructured materials – or nanomaterials – in at least one of the three directions becomes comparable with the molecular size; as a result, the effect of molecular confinement and reduced dimensionality can alter various physical and chemical properties of these materials. For example, one can form two-dimensional (2D) nanomaterials simply by making ultrathin films, where molecules are confined between the top surface and film-substrate interface. As the sizes of organic molecules are big, even relatively thick organic films start exhibiting theoretically predicted properties of 2D systems.

Perhaps the first controlled experiments on molecular monolayers confined in air–water interface were performed by Pockels in 1891 and then, this technique of monolayer formation of amphiphilic molecules on water surface was perfected by Langmuir around 1917. One part (hydrophilic) of these molecules is soluble in water while the other part (hydrophobic) is insoluble. On water, amphiphilic molecules, which are commonly called surfactants, take a preferential orientation with the hydrophilic part (also called the head) immersed in water while the hydrophobic part (also called the tail) stays away from water. The amphiphilicity of a molecule depends on the balance between the hydrophilicity of the head group and the hydrophobicity of the tail, the latter depending on the chain length. Blodgett succeeded in transferring, monolayer by monolayer, these amphiphilic molecules from the water surface to solid (hydrophilic or hydrophobic) substrates to form multilayer organic films. The multilayer films deposited by this technique are known as Langmuir Blodgett (LB) films and the monolayers at the air–water (or any gas–liquid) interface used for this deposition has been termed as Langmuir monolayers.

Self-assembled monolayer (SAM) formation is another technique to grow thin organic films either from a solution or from a gas phase. In this technique, one also uses differential affinity of a particular portion of an organic molecule with a substrate. The term "self-assembly" signifies a spontaneous and natural process observed all around us in the formation of molecular assemblies ranging from crystals to mammals. Various materials are being fabricated using this process of self-assembly, which involves designing molecules and supramolecular entities so that shape-complementarities causes them to aggregate into desired structures. Formation of thin organic films through the process of self-assembly has a number of advantages like atomic-level modification of structure and production of structures that are relatively defect-free, self-healing, and rapid. SAM structures are generally prepared from solutions although molecules in vapor or gas phase can also be used for this purpose. The organic molecular beam deposition technique is generally used for SAM formation from the gas phase. In this technique, an organic material is evaporated in an ultrahigh vacuum chamber to get it deposited on the substrate directly as done for inorganic materials in a conventional molecular beam epitaxy (MBE) chamber.

Mentioned here briefly are two more types of organic thin films, namely, thin polymer films and liquid-crystal films. These systems are not discussed here as it has been covered elsewhere in this encyclopedia. Thin polymer films are generally deposited on

a solid substrate using spin-coating technique. In this technique, a polymer solution in a volatile solvent is spread on a substrate and then it is rotated at high speed so that the solvent leaves the surface, keeping the polymer on it. One can control the thickness of the film by altering the spinning speed and concentration of the polymer in the solution used for this purpose. Molecular layering and associated interesting mechanical and thermal properties of polymers have been observed in ultrathin films. A unique property of smectic liquid crystals is their ability to form films that are freely suspended or freestanding over an aperture in a frame. Apart from various technological applications, the availability of liquid crystalline films of variable thickness helps one to study the crossover from three- to two-dimensional behavior. 2D crystals melt through hexatic phase – a phase having long-range orientational order and short-range translational order – and both crystal-to-hexatic and hexatic-to-liquid phase transitions are theoretically predicted to be continuous in nature. Ultrathin smectic membranes (freely suspended liquid-crystal films) have been used extensively to study this melting process. It is interesting to note that one gets back conventional 3D melting with fixed melting point in thick liquid crystal films.

Experimental Techniques

Recent advances in microscopy and scattering techniques have revived the interest in organic thin films as one can now monitor the structure and orientation of molecules responsible for generating particular microscopic and macroscopic properties. Sensitivity of various spectroscopy techniques has also improved and one can now even take spectroscopic data from monolayers of organic films. Recent advances in computer simulation techniques, molecular modeling, and the phenomenological theory of phase transitions have also provided substantial amount of knowledge regarding organic monolayers and thin films.

The grazing incidence X-ray and neutron scattering techniques have provided most of the structural and morphological information regarding the organic monolayers and thin films. Three different measurements, namely specular reflectivity, diffuse scattering, and grazing incidence diffraction (GID), are generally used. In these studies, the surface of the sample is located in the x–y plane and a well-collimated incident beam of radiation is kept in the x–z plane. The scattering measurements are performed as a function of the incident angle α (starting from few milliradians) with the x–y plane, and exit angles β and ϕ with the x–y and x–z planes, respectively. The components of the wave vector transfer, q (q_x, q_y, q_z), corresponding to the incident wavelength λ are $q_x = (2\pi/\lambda)$ ($\cos\beta\cos\phi - \cos\alpha$), $q_y = (2\pi/\lambda)$ ($\cos\beta\sin\phi$), $q_z = (2\pi/\lambda)$ ($\sin\alpha + \sin\beta$). In reflectivity measurements, $\alpha = \beta = \theta$, so that $q_x = 0$ and $q_z = (4\pi/\lambda)(\sin\theta)$, the scattering vector q is perpendicular to the surface (specular direction), and one obtains information about the mean electron density profile (EDP) as a function of the depth (z). The diffuse scattering measurements are performed as a function of q_x and q_y to obtain information regarding the morphology of surfaces and interfaces through a height–height correlation in an interface and between interfaces.

One can now measure X-ray diffuse scattering data over 10 orders of magnitude in intensities at a synchrotron source, but neutron scattering studies are basically limited to reflectivity measurements due to lack of intensities. In the neutron scattering studies, the measured intensity depends on the scattering length of the nucleus, which varies considerably from one element to another and even for different isotopes of the same element. In particular, the deuterium nucleus has a large positive scattering length whereas the hydrogen nucleus has a low negative value. This property has been exploited quite extensively in the structural investigation of organic monolayers and thin films. Here, one uses this contrast variation technique to highlight part of a molecule or selected molecules or monolayers in a film by replacing hydrogen with deuterium and then investigate the film structure with neutron scattering.

In GID, one obtains in reciprocal space, rods of intensities – known as the crystal truncation rods (CTR) – corresponding to a surface structure instead of spots obtained for 3D structures. GID studies are performed by keeping the incident angle α fixed just below the critical angle, α_c, and by measuring intensity as a function of β and ϕ. This technique has been used primarily to study the structures of the different phases of the Langmuir monolayer. As α is less than α_c, X-rays are confined within a depth of a few tens of nanometers below the interfacial plane, whereas they travel in the plane (x and y directions) with a wavelength close to the free-space wavelength. This is the condition for GID that is exploited to study the structure of the interfacial region at atomic resolution, and any periodicity in the positions of the molecules gives rise to peaks of the scattered intensity. The measured intensity distribution depends primarily on two factors, namely the structure factor reflecting a 2D translational order of the molecular centers in the plane of the monolayer and the form factor of the individual molecules.

Various scanning probe microscopy (SPM) techniques have become important tools in the study of

organic films in recent years. All the SPM techniques involve scanning of a very fine probe tip over the surface of the sample in a raster pattern, measuring the interaction, and collating the information into an image of the surface. Scanning tunneling microscopy (STM) has very high lateral resolution but is limited to monolayers on conducting substrates or to conducting films. Atomic force microscopy (AFM) does not have this limitation, and can provide direct information on the surface morphology of the sample. All of the SPM techniques yield structural and morphological information about only the top surface of a film. The nature of interactions between the probe and surface can be of varied nature ranging from tunneling current, van der Waals force, to other forces such as electrostatic, frictional, capillary, or magnetic.

Optical methods such as polarized fluorescence microscopy (PFM) and Brewster-angle microscopy (BAM) are generally used more than SPM techniques to study Langmuir monolayers. These techniques have identified various phase transitions in Langmuir monolayers as a function of temperature and surface pressure. Fourier transform infrared (FTIR) spectroscopy has become a very important tool for investigating the structure of LB films and Langmuir monolayers as it is now possible to obtain satisfactory signal-to-noise ratio. To examine LB films, two types of infrared measurement are often used, namely attenuated total reflection (ATR) and grazing incidence reflection (GIR). In the ATR technique, the LB film is deposited onto both sides of an IR-transmitting crystal, for example, germanium or silicon. The radiation enters the crystal at one end so that it is incident on the sides at an angle less than the critical angle. It thus undergoes multiple reflections inside the crystal before emerging at the far end. On each reflection, the evanescent field of the IR beam penetrates the LB film and absorption may take place. GIR is performed on a highly reflective metal substrate, and *p*-polarized IR light is normally used in these measurements. This method is particularly sensitive to the orientation of the molecular groups on the substrate. In addition to FTIR measurements, several other spectroscopic measurements, such as Raman spectroscopy, are also being carried out but these techniques are not being used frequently as it demands special sample preparation. Similarly, electron microscopy and diffraction techniques are also used infrequently to characterize organic films.

Monolayers and Thin Films

Formation of Langmuir Monolayers

The Langmuir monolayer of any organic molecule is generally formed by spreading a measured quantity of this material on water by using a spreading solvent. It is desirable that the solvent be capable of dispersing the molecules of the film-forming material at the air–water interface and then evaporate completely so that the film is not contaminated. It is essential to understand the structure of Langmuir monolayers to control the growth process of LB films. Moreover, the Langmuir monolayer is an ideal model system on a smooth liquid surface for investigating ordering in two-dimensions. Monolayers of lipids or amphiphilic molecules have been studied in detail to generate a complete phase diagram as a function of two thermodynamic variables, temperature and surface pressure. The surface pressure of these monolayer films is measured by calculating the difference in surface tensions between a clean or pure liquid surface and that covered by the film. The surface tension is determined by measuring accurately the downward force on a suspending plate, known as the Wilhelmy plate – made of sandblasted platinum or any other material that is wetted by the liquid. Surface tension has also been measured using diffuse scattering technique as a function of the length scale, and interesting effects of the molecular interaction on this thermodynamic variable have been observed.

Figure 1 indicates a basic experimental setup and generally obtained surface pressure versus area isotherms of fatty acids. The area of the monolayer and hence, the average area per molecule is varied by moving barriers across the water surface in a trough at various temperatures, and the resultant surface pressure is measured to generate these isotherms – the main source of thermodynamic data. An abrupt

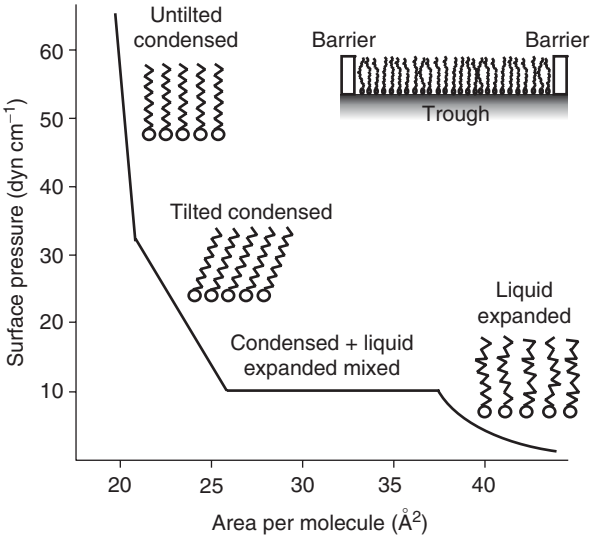

Figure 1 A typical molecular area vs. surface tension isotherm is shown with a sketch of a trough. Sketch of molecular arrangements in different phases are also indicated.

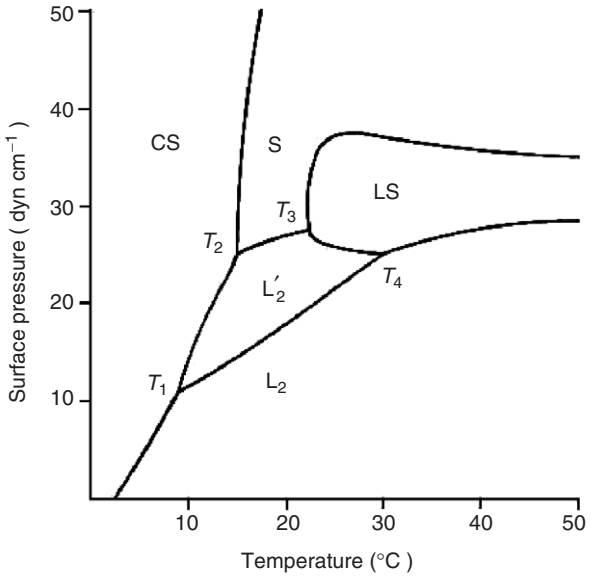

Figure 2 A typical phase diagram of monolayer of a fatty acid is shown as a function of temperature and pressure. Various phases are also marked as discussed in the text.

fracture of the monolayer occurs and 3D structures appear if the monolayer is compressed beyond a "collapse" pressure. One obtains different phases such as 2D gas (G), liquid-expanded (LE or L_1), and condensed phases with decreasing molecular area. Molecular configurations, structures of the various phases, and associated phase transitions have been identified by optical microscopy and GID techniques. The observed features have been explained in terms of the Landau theory. It should be mentioned here that these phases may not be in a thermodynamic equilibrium state, as implied by the term, but these are stable in an experimental timescale. **Figure 2** shows the phase diagram of a well-studied behenic acid as an example where T_1, T_2, T_3, and T_4 indicate phase-transition temperatures. L_2 and L_2' phases are both known as liquid-condensed (LC) and both have a centered rectangular lattice but the tails are tilted toward the nearest neighbor (NN) in the L_2 phase and in the L_2' phase, this tilt is toward the next nearest neighbor (NNN). At higher-pressure, one reaches solid (S), super-liquid (LS), or closed-packed solid (CS) phases depending upon the temperature and in all these phases, the tails become normal to the water surface without any tilt. One obtains a centered rectangular lattice in S and CS phases, but the LS phase retains a hexagonal lattice. It was observed that the temperature of a phase transition increases with the length of the hydrocarbon chain of the molecules. A significant alteration of the phase diagram of acid monolayers due to interactions between head groups has been observed as different metal ions in the subphase are added and the pH of the subphase is altered. Several other phases have been identified in Langmuir monolayers, for example, the Ov phase is a hexagonal lattice with an NNN tilt. However, the situation may become more complicated for molecules having multiple chains. For example, the biologically important class of amphiphiles and phospholipids should give rise to additional order due to the linkage between chains, but X-ray scattering techniques have not been able to detect these new phases – perhaps more sensitive measurement techniques are required.

Deposition of LB Films

To deposit an LB film, the precursor monolayer is prepared in a condensed phase and is maintained at a fixed temperature (refer **Figures 1** and **2**). During deposition, the surface pressure is held constant by moving the barriers to compensate the material transferred onto the substrate. It is well known that monolayers of salts of fatty acids are much easily transferred onto a solid support than the acids. Hence, most LB films are prepared from salts of the fatty acids. There are two different ways in which LB films of salts of long chain fatty acids, the prototypical amphiphilic molecules, may be deposited. The most common method is to spread the monolayer of the corresponding acid on a controlled subphase of the suitable inorganic salt kept at a definite pH (usually alkaline) in water. In the other method, the salt is actually prepared and spread on water at normal pH ($\sim$5.6). Although chemically, these two methods are expected to give identical results, the isotherms are found to be different for these methods. The substrates used for deposition of these films have to be treated specially for good transfer (they are made hydrophilic in most depositions). Normally, the transfer is quantified by a parameter called "transfer ratio" that is defined as the ratio of the area swept by the moving barriers of the trough during transfer to the area of film deposition on the substrate. Ideally, this should be close to unity. For hydrophilic substrates, the first stroke of deposition should be from below the water to air for efficient transfer of molecules from the Langmuir monolayer. If the substrate is made hydrophobic, then the first stroke should start from above the water. The substrate is deposited with a monomolecular layer during each subsequent up/down stroke through the Langmuir monolayer. However, it has been found by X-ray and neutron scattering techniques that substantial reordering of molecules takes place after the molecules are transferred on the substrate (**Figure 3**).

The scattering studies and AFM measurements have revealed that LB films have remarkably well-ordered vertical structure independent of the condition of deposition but in-plane morphology can change drastically depending upon substrate morphology and deposition condition. It was also observed that in-plane morphology remains unaltered at elevated temperatures. The X-ray reflectivity curve of a typical LB film and the extracted EDP by model fitting are shown in **Figure 4**. The interference (Kiessig) fringes observed in the reflectivity curve are due to the total film thickness. If Δq_z is the separation between two consecutive Kiessig fringes (refer **Figure 4**), the total film thickness (D) can be estimated as $D = 2\pi/\Delta q_z$. The separation of Bragg peaks in **Figure 4** gives a quick measure of the bilayer thickness. The extracted density profiles from a detail fitting of the reflectivity data (refer, for example, inset of **Figure 4**) provide us information about the molecular configuration. For example, from these studies on monolayer and trilayer films, one could conclude that molecules of divalent salts near a hydrophilic substrate remain in asymmetric configuration with a metal ion near the substrate, but in upper layers molecules take a natural symmetric configuration. The in-plane structure of LB films having single and multiple layers has been studied extensively. These structures have a strong similarity to structures of the condensed phases of Langmuir monolayers.

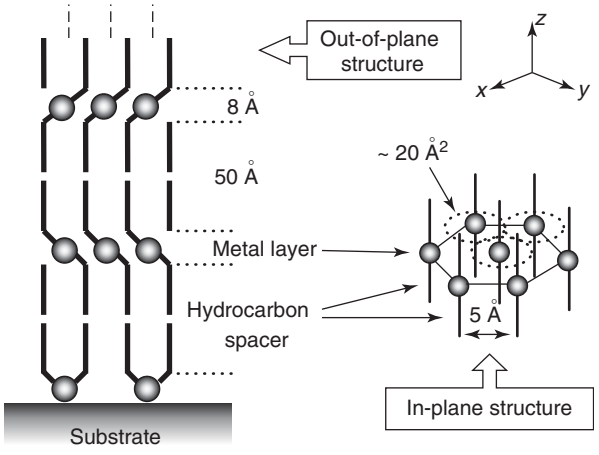

Figure 3 Model of out-of-plane and in-plane re-ordered structure of a typical Langmuir–Blodgett film of a divalent fatty acid salt is shown. The metal–metal distances in various directions are also indicated. The molecular configuration of the first monolayer near substrate is different from the upper layers as discussed in text.

Diffuse X-ray scattering studies have shown that the interfacial correlation of LB films can vary from self-affine fractal, observed in diverse physical systems, to long-range logarithmic, characteristic of capillary waves on liquid surfaces. Systematic studies of these interfacial morphologies can provide a clear basis for the theoretical and simulation studies undertaken to link the evolution of interfacial morphology with the possible growth mechanism of the LB films.

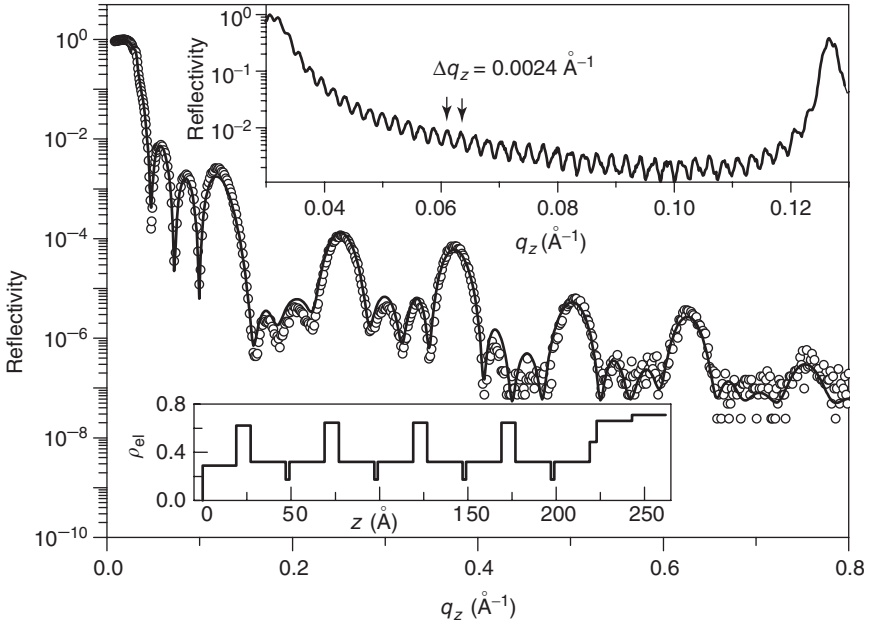

Figure 4 X-ray reflectivity profile of nine monolayer gadolinium stearate LB film (open circles) with calculated profile (solid line) for the electron density profile (shown in lower inset) corresponding to the model shown in **Figure 3**. The data of 101 monolayer film (upper inset) exhibit small separation of Kiessig fringes (marked by arrows) confirming the presence of 50 equally spaced bilayers in the LB film.

Growth of Self-Assembled Monolayers

Preparation of SAMs from a solution is a simple process – one has to only keep the substrate for a certain amount of time in a solution having the desired molecules. However, one should be very careful in cleaning the substrate surface and in keeping the solution free from contaminants. The defining feature of SAM formation is to identify the pair of the chemisorbing head-group of the molecule and the substrate. Although several systems have been found to form SAM, probably the most popular system is that of thiols on an Au(111) substrate. Organo-silicon monolayers on hydroxylated surfaces are another class of a well-studied system though these monolayers do not exhibit the same degree of long-range order observed for thiols on gold. The (111) surface of gold is the lowest energy surface and thus easy to form by evaporating gold on less-expensive substrates, such as glass, to make it more suitable for applications rather than using gold single crystals. Moreover, the relative inertness of the gold surface makes it comparatively easy to clean and SAMs of various thiol molecules form a well-defined order in a full-coverage phase. The full-coverage phase, by definition, corresponds to the highest possible packing of the molecules on a substrate surface. Early diffraction studies of the structure of alkanethiols on Au(111) indicated the existence of the full-coverage phase forming a $(\sqrt{3} \times \sqrt{3})$ structure, which was confirmed by STM. The tilt structure of the SAM was obtained directly from the analysis of the X-ray diffraction data and it was found that hydrocarbon chains are tilted by 32° from the surface normal. An IR spectroscopy study of this surface confirmed this finding. SAM can also form in a "lying down" condition on Au(111) and a lattice is obtained even in this configuration. In the "lying down" condition, molecules occupy large substrate space forming a low-coverage phase with a structure like $(23 \times \sqrt{3})$.

SAM of thiols and other molecules have also been prepared on Au(0 0 1) and other surfaces, and the obtained structure was found to be much more complicated. Even an Ag(1 1 1) surface, which is quite similar to the Au(1 1 1) surface, forms a much more complicated SAM structure of thiols including incommensurate structures. It is obvious that formation of a self-assembled lattice is a delicate process involving chain–chain interaction and headgroup–substrate interaction. Various models have been developed to understand this delicate growth process and the structural variation of SAM as a function of temperature. Another active research area in this field is to develop a heterostructure in SAM and the simplest approach is to use the end-group of SAM to adsorb other molecules. The adsorbed molecules may vary from "simple adsorbates" such as water to "complex adsorbates" such as protein or other bio-related molecules.

Specular reflectivity, diffuse scattering, and GID techniques are being used to characterize the SAM structures and the adsorbed molecules on these structures. Neutron scattering techniques have added advantage in characterizing the adsorbed layers as one can have better scattering density contrast here. Low-energy atom diffraction (LEAD) and low-energy electron diffraction (LEED) are other techniques being used for the structural characterization of SAM grown through both the solution and vapor routes. In addition to these diffraction techniques, SPM and various spectroscopy techniques are used for these films.

Applications of Organic Monolayers and Thin Films

Perhaps the first application of organic thin films was demonstrated by Franklin in calming water waves. In early 1930, coatings of amphiphilic monolayers were used to control the wetting properties of metal condenser plates in steam engines. Control of wetting, lubrication, and adhesion properties of various materials continue to be important application areas of organic films. Organic thin films are also being used to anchor capped metallic nanoclusters in the form of thin films to fabricate devices for nanotechnology. The application areas for these heterostructures range from nonlinear optics to soft-magnets. The idea of anchoring these adlayers has also been exploited to make chemically attached polymer films, which are very different from the spin-coated polymer films. Organic films are also used to link inorganic materials to biological materials for various biotechnological applications. A "dip-pen" writing technique has been developed that involves transfer of thiol molecules from an AFM tip to a gold substrate to form a patterned SAM. This technique is potentially useful for creating nanoscale devices.

Apart from all these technological applications, organic thin films are providing ideal model systems to investigate low-dimensional physics. LB films are suitable for studying 2D magnetic ordering with a fatty acid salt of a magnetic ion like gadolinium. Langmuir monolayers, on the other hand, have been used to study the interplay between hexatic ordering, chirality, and tilt in generating order in two-dimensions.

Mössbauer Spectroscopy

P Schaaf, Universität Göttingen, Göttingen, Germany

Introduction

The discovery of the recoilless nuclear resonance emission and absorption in solids is approaching its fiftieth anniversary. Although the resonance absorption of gamma rays by nuclei is analogous to the well-known optical phenomenon of resonance fluorescence and the underlying physics of the phonon theory of the lattice (Debye) and its quantum mechanical theory (Dirac, Lamb) had been well known and nuclear resonance absorption had already been predicted in 1929, it was only in 1957 that Rudolf L Mößbauer discovered this phenomenon during his doctoral studies. So it took a long time to combine nuclear physics with solid-state physics and to transfer absorption and emission resonances from the electron shell to the nucleus. This recoilless nuclear resonance absorption was named after R L Mößbauer, who was awarded the Nobel prize in 1961, and has been known as the Mössbauer effect since then. This effect is an easy way to eliminate the recoil energy loss that occurs during the emission and absorption of photons. Consequently, γ-lines of the highest possible sharpness could be obtained and applied. Soon after the discovery of the Mössbauer effect, it became obvious that this effect can be used to study various properties of materials on a microscopic scale via hyperfine interactions with an unprecedented resolution. This was the beginning of a new analytical tool – Mössbauer spectroscopy, which has now developed into a standard analytical technique in many laboratories.

The purpose of this article is to first give a short introduction to the basic physical processes and the hyperfine interactions, to sketch the typical experimental setup, and then to show how this can be applied as a unique analytical tool to many problems in solid-state physics. For more details and further reading, the reader is referred to the "Further reading" section, where the physical principles and applications of the Mössbauer effect and Mössbauer spectroscopy are described in great detail in a series of books. Nevertheless, regarding the most recent developments and applications of the method (e.g., the synchrotron-based methods), the current original literature should be referred to, because a recent review is still missing.

The Nucleus and Nuclear Radiation

When either an atom or a nucleus undergoes a transition from an excited state (E_e) to a lower or the ground state (E_g), a quantum of electromagnetic radiation (a photon) is emitted. This photon, in turn, can induce the opposite transition in an atom or nucleus of the same kind. This principle of resonant emission and absorption is sketched in **Figure 1**.

If a nucleus in an excited state with a mean lifetime of τ_N (e.g., $\tau_N = 141$ ns for ^{57}Fe) emits γ-radiation, the energy distribution $I(E)$ follows the Breit–Wigner law (Lorentzian):

$$I(E) = I_0 \times \frac{(\Gamma/2)^2}{(E - E_0)^2 + (\Gamma/2)^2} \qquad [1]$$

where E_0 is the transition energy ($E_0 = E_e - E_g$) and $\Gamma = \hbar/\tau_N$ is the resonance width (FWHM) ($E_0 = 14.401$ keV, $\Gamma = 4.7 \times 10^{-9}$ eV for ^{57}Fe). The momentum of the γ quantum is $\boldsymbol{p} = \hbar\boldsymbol{k}$.

Momentum conservation for the emission process causes the energy available for the emission process to be shared by the emitted quantum and the recoiling atom or nucleus. A free atom of mass M emitting a γ-quantum will experience a recoil with the energy $E_r = p_\gamma^2/2M$, which is generally much larger than the natural line width Γ ($E_r = 2 \times 10^{-3}$ eV is much higher than $\Gamma = 4.7 \times 10^{-9}$ eV for ^{57}Fe). As the same is true for the absorption process also, the absorption energy is increased by the recoil energy of the absorbing nucleus. Thus, the energy shifts by the recoiling nuclei are big enough to preclude resonance absorption of the emitted photon by other nuclei. This is sketched in **Figure 2** for the free atom. The shifts lead to only a very small overlap of the emission and absorption Lorentzians and thus a very low probability of resonance, illustrated in **Figure 2** by the shaded area.

If the nucleus is bound in a solid and the springs in **Figure 2** are strong enough, that is, the atoms are bound rigidly, the recoil goes to the whole lattice, and the recoiled mass M is drastically increased ($M \rightarrow 10^{16}M$). Thus, the recoil energy E_r becomes negligibly small. Since the lattice does not consist of rigid springs, in other words, the phonon system (the spring) is a quantized system, there is a certain probability that lattice vibrations (phonons) will be excited and the recoil of the atom is transferred to phonons. On the other hand, there is also a high probability that no phonons will be excited and the whole solid takes the recoil. Thus, in a solid for a certain fraction of nuclei, the emission, and in an equivalent manner the absorption, occurs without recoil energy loss. The chance that the emission takes place without inducing any phonons is called, in analogy to X-ray diffraction, the Debye–Waller factor, $f_D = \exp(-k^2 \langle x^2 \rangle)$, where $\boldsymbol{k}$ is the wave vector of the photon and $\langle x^2 \rangle$ the mean square displacement of the nuclei (atom). This factor – sometimes more accurately called Lamb–Mössbauer factor – depends on the temperature T, the energy of the γ-quantum $k = E_0/\hbar c$, and the Debye temperature Θ_D (representing the stiffness of the lattice springs) of the solid:

$$f_D(T) = \exp\left(-\frac{3\hbar^2 k^2}{4Mk_B\Theta_D}\left[1 + 4\left(\frac{T}{\Theta_D}\right)^2 \times \int_0^{\Theta_D/T} \frac{y}{\exp(y) - 1}\,dy\right]\right) \qquad [2]$$

The fraction of recoilless emission or absorption is $f_D = 0.76$ for ^{57}Fe in α-Fe with $\Theta_D = 470$ K at room temperature and thus allows fast measurement of the nuclear resonance, the Mössbauer effect. For the sake of completeness, it should be mentioned that the

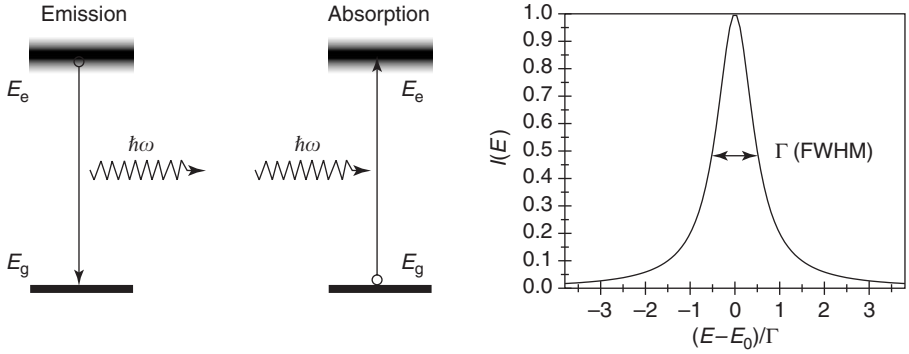

Figure 1 Schematic view of resonant emission and absorption. States with a finite lifetime are spread in energy according to the Heisenberg uncertainty principle, as indicated for the excited levels. This gives rise to a Lorentzian shape in the energy distribution of the corresponding emission (absorption) line.

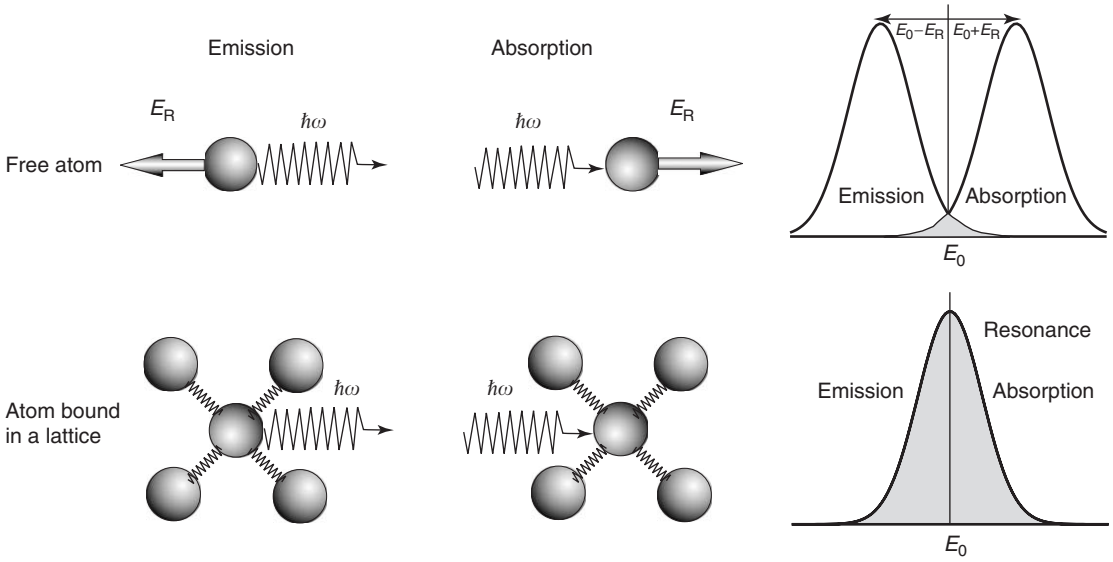

Figure 2 Principles of emission and absorption with and without recoil. In the upper part, a free atom involves recoil for emission and absorption. If the atom and thus the nucleus is bound in a lattice, the recoil is transferred to the whole lattice if the springs are tight enough. The shaded area represents the probability for resonance absorption.

Debye–Waller factors can be different in different crystallographic directions, causing the Goldanski–Karyagin effect, which leads to an anisotropy in the observed line intensities.

Another decisive factor for the feasibility and speed of the measurements is the cross section of the absorption. It determines the probability of a photon with matching energy to be absorbed by the corresponding nucleus. This cross section σ is given, together with the maximum cross section σ_0, as a Lorentzian by

$$\sigma = \sigma_0 \times \frac{(\Gamma/2)^2}{(E-E_0)^2 + (\Gamma/2)^2} \qquad [3]$$

The maximum cross section can be determined from the nuclear spin number I in the excited and ground state, the photon wavelength λ, and the internal conversion coefficient α via

$$\sigma_0 = \frac{\lambda^2}{2\pi} \frac{2I_e + 1}{2I_g + 1} \frac{1}{1+\alpha} \qquad [4]$$

The internal conversion coefficient α represents the ratio of the number of γ quanta interacting upon emission with the electron shell and thus leads to the emission of conversion electrons and conversion X-rays to the number of γ quanta with undisturbed emission, that is, the resulting probability of the γ emission is $1/(1+\alpha)$.

In order to obtain the γ quanta, one has to populate the excited state; in other words, one needs a source for the Mössbauer radiation. This is normally achieved easily via parent isotopes, which then decay to the corresponding nucleus in the excited state. Such a source is illustrated in **Figure 3**, where the decay scheme of the ^{57}Co source for ^{57}Fe Mössbauer spectroscopy is shown. The ^{57}Co isotope decays via electron capture to the excited state of ^{57}Fe. The half-life of ^{57}Co is $\sim$272 days so that with such a source, one can easily measure for a couple of years. The parent isotopes are normally produced by nuclear reactions (neutrons, deuterons, protons) in reactors or in accelerators and are commercially available. In addition, the radioactive isotopes are embedded into an appropriate matrix – normally chosen to be a cubic nonmagnetic material – in order to achieve a high Debye–Waller factor and a single line source.

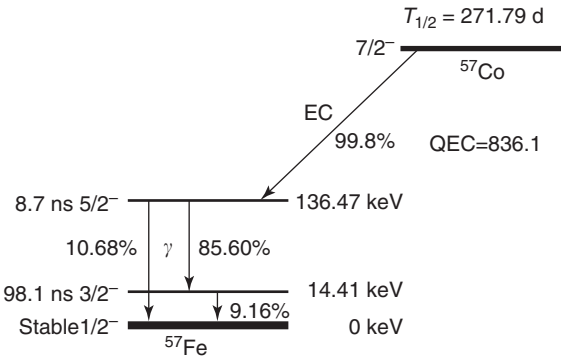

Figure 3 Schematic view of the ^{57}Co source for ^{57}Fe Mössbauer spectroscopy. The energy levels, spins, probabilities, and lifetimes are indicated.

Embedding in magnetic material can give multiline and polarized sources for certain applications. ^{57}Co is mostly embedded into the f.c.c. Rh metal as the source for Fe Mössbauer spectroscopy.

From the Effect to Spectroscopy

In the case of recoilless emission and absorption, one observes extremely sharp γ lines, the so-called Mössbauer lines. The width of these lines is often much smaller than the line shifts caused by interactions between the emitting or absorbing nuclei and their environment in the solid. For this reason, the Mössbauer effect is very suitable for resolving and measuring hyperfine interactions via a Doppler modulation of the γ energy by moving the source and the absorber relative to each other with velocity v:

$$E(v) = E_0 \times \left(1 + \frac{v}{c}\right) \qquad [5]$$

Usually, the source is moved and the velocities required for ^{57}Fe lie in the range of $10\,\mathrm{mm\,s^{-1}}$, which can easily be produced and controlled in the lab. Another Doppler effect is caused by the thermal vibrations in the lattice. The atoms and nuclei in the source and absorber have a finite temperature, have thermal energy, and are thus vibrating. As seen before, the movement causes a shift in energy, but the thermal velocities are isotropic and thus the positive and negative velocities cancel each other leading to only a small broadening of the spectral lines. Nevertheless, there are also relativistic effects, which are causing a net shift of the energies with the temperatures, which is called "second-order Doppler shift" (SOD):

$$\delta_{\mathrm{SOD}} = \frac{\bar{v}^2}{2c^2} E_0 \qquad [6]$$

The standard geometry of Mössbauer spectroscopy is the transmission geometry (transmission Mössbauer spectroscopy (TMS)), which is shown schematically in **Figure 4**.

The sample is irradiated from the source and the absorption is measured with a detector behind the sample. The source is moved by a drive system (constant acceleration, sinusoidal or constant velocity) and the emitted and Doppler-modulated photons move through an aperture toward a detector. Only those quanta are counted that have the involved transition energy E_0. Gas-filled proportional counters or solid-state detectors are most widely used for that purpose. For the measurement, the sample is placed between the source and detector, and it absorbs photons at certain energies represented by a certain source velocity. Of course, this absorption is again followed by emission, but it is not directed to the detector any more, but emitted more or less homogeneously into the full 4π solid angle (and additionally diminished by the internal conversion process). This way, one obtains a velocity-correlated intensity spectrum $I(v)$, which then contains all the

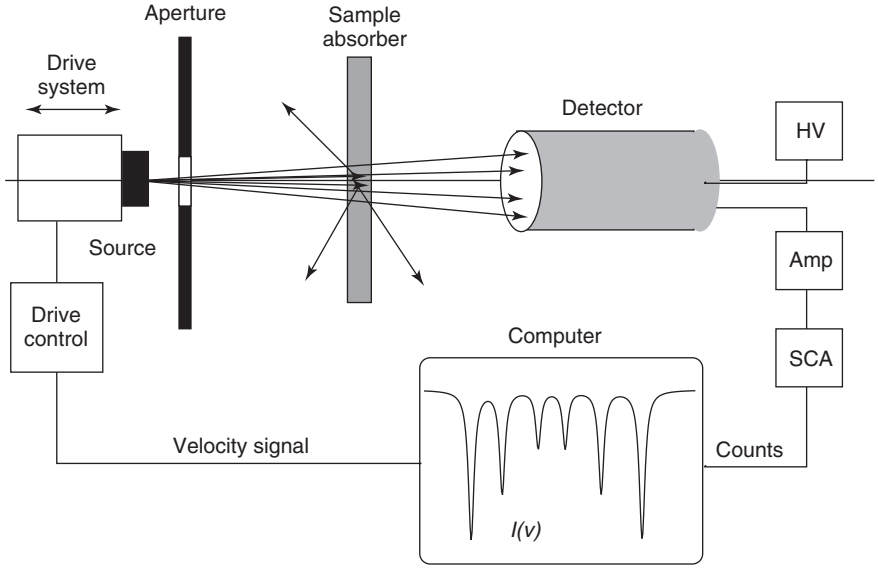

Figure 4 Schematic view of the setup for measuring a Mössbauer spectrum in transmission geometry. The source is moved in a controlled way and the photons are detected in a detector (HV – high voltage), whose signals are amplified (Amp). The single-channel analyzer (SCA) selects only those signals corresponding to the desired Mössbauer transition. These counts are stored in the computer for the respective drive velocities.

Table 1 Properties of the most frequently used Mössbauer isotopes

Isotope	a (%)	E_0 (keV)	τ_N (ns)	I_e	I_g	σ_0 (10^{-20} cm^2)	2Γ (mm s^{-1})	E_r (10^{-3} eV)
^{57}Fe	2.19	14.41300	98.1	3/2	1/2	256.6	0.1940	1.957
^{57}Fe	2.19	136.4743	8.7	5/2	1/2	4.300	0.2304	175.4
^{119}Sn	8.58	23.871	17.75	3/2	1/2	140.3	0.6456	2.571
^{151}Eu	47.82	21.64	9.7	7/2	5/2	11.42	1.303	1.665
^{125}Te	6.99	35.46	1.48	3/2	1/2	26.56	5.212	5.401
^{121}Sb	57.25	37.15	3.5	7/2	5/2	19.70	2.104	6.124
^{129}I		27.77	16.8	5/2	7/2	40.32	0.5863	3.210
^{197}Au	100	77.35	1.90	1/2	3/2	3.857	1.861	16.31
^{161}Dy	18.88	25.65	28.1	5/2	5/2	95.34	0.3795	2.194
^{161}Dy	18.88	43.84	920	7/2	5/2	28.29	0.006782	6.410
^{161}Dy	18.88	74.57	3.35	3/2	5/2	6.755	1.095	18.55

a – natural isotopic abundance, E_0 – transition energy, τ_N – half-life, I_e and I_g – nuclear spin quantum number of excited and ground states, σ_0 – maximum resonance cross section, Γ – natural line width (FWHM), E_r – recoil energy of a free atom.

information from the Mössbauer effect. These Mössbauer spectra are stored in a multichannel scaler. Sometimes, the source or the absorber (sample) is put into a cryostat, an oven, a magnetic field, etc., in order to measure temperature-dependent effects or the effects of certain physical situations. If the sample is too thick, then there is no count rate left behind it, and multiple absorption and emission processes can influence the spectra. If the sample is too thin, there are not enough nuclei for the absorption process, and not enough statistics for analysis is available (there is always nonresonant background). To be concise, one has to solve the full Hamiltonian (transmission integral) to find the absorption spectrum ($I(E) \sim I(v)$). Nevertheless, one can derive an analytical solution for the transmission integral (i.e., the folding of the emission, absorption, and re-emission over the sample), if the absorber can be treated as a thin absorber. The adimensional effective thickness of the absorber (sample) t_A is given by

$$t_A = \sigma_0 f_A N_A d_A a_A \qquad [7]$$

with the maximum cross section σ_0, the recoilless fraction (Debye–Waller factor) f_A, the atomic density N_A, the absorber thickness d_A, and the abundance of the Mössbauer isotope a_A. For ^{57}Fe at room temperature, the following values are obtained: $\sigma_0 = 256.6 \times 10^{-20}$ cm^2, $f_A \approx 0.75$, $N_A = 8.476 \times 10^{22}$ atoms cm^{-3}, and $a_A = 2.19\%$. The effective thickness should have values of $t_A \approx 1$, allowing fast measurements with the thin absorber approximation still valid. Then, there is the simple folding of the emission and the absorption spectra (with their respective energy eigenvalues E_i or v_i), resulting in a Lorentzian line again:

$$I(v) = I_0 - I_{abs} \frac{\Gamma^2}{(E - E_0)^2 + \Gamma^2} \qquad [8]$$

In this thin absorber approximation, this results in the double line width (more general by the sum of source and absorber line width: $\Gamma = \Gamma_S + \Gamma_A$). If the absorber becomes thicker, the lines become somewhat broader due to multiple re-emission and absorption effects, and for thick samples, one has to solve the full transmission integral.

A calibration of the Mössbauer spectrometer is carried out by measuring standard materials with well-known properties. For Fe, calibration is usually performed using a 10–25 μm α-Fe foil at room temperature (α-Fe: $B_{hf} = 33$ T or 10.6245 mm s^{-1}). All isomer shifts are normally related to the center of the α-Fe spectrum at room temperature. The spectra are fitted according to a least-squares routine by superimposing Lorentzian lines in simple cases or by more sophisticated theories for complicated samples.

If a sample consists of several sites or phases, the relative area of the corresponding set of Lorentzians gives the atomic fraction of the Mössbauer spy isotope in the site or phase. In order to calculate the real fraction, this area has to be corrected by the Debye–Waller factor. The latter is hardly known, so it has to be determined experimentally. As a simplification, it is often assumed that all subspectra and all phases have the same Debye–Waller factors f_D and neglecting (most of the times) smaller errors caused by that. Thus, the phase fraction can be identified with the relative fractions (areas) of the phases in the Mössbauer spectrum.

The isotopes most frequently used for Mössbauer spectroscopy are (listed according to their importance): ^{57}Fe, ^{119}Sn, ^{151}Eu, ^{121}Sb, ^{125}Te, ^{197}Au, ^{129}I, ^{155}Gd, ^{161}Dy, and some others. Their properties are summarized in **Table 1**.

Internal Conversion

The effect of internal conversion plays an important role in Mössbauer spectroscopy. It is most important

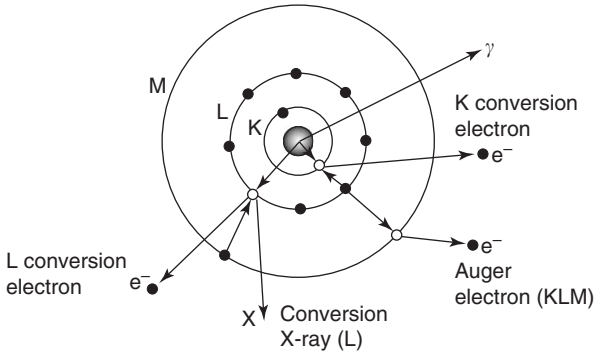

Figure 5 The internal conversion process during emission of γ-radiation. Instead of the photons conversion electrons can also be emitted leading to a cascade of Auger electrons and conversion X-rays.

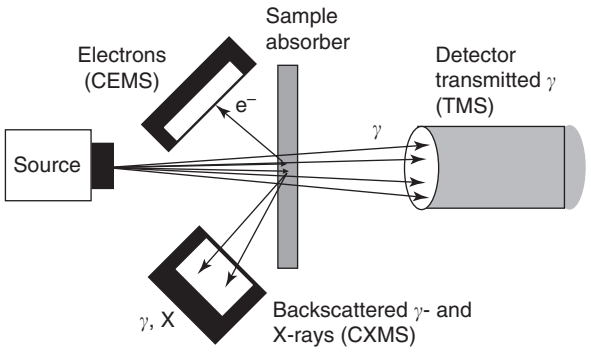

Figure 6 Mössbauer measurements in backscattering geometry leading to CEMS and CXMS. In combination with TMS, this results in STRMS.

for lower mass numbers and becomes negligible for very heavy atoms. For a certain fraction of nuclei, the emitted photon does not leave the atom, but spends its energy for kicking off an electron from the shell – a conversion electron. As a result of internal conversion, conversion electrons, and subsequently a cascade of Auger electrons and conversion X-rays are emitted. They too can be used for the measurements, since they contain the same information as the originally absorbed (emitted) photon. This internal conversion is shown in **Figure 5**.

If the electrons originating from the internal conversion process are detected for the Mössbauer measurement, this is called (conversion electron Mössbauer spectroscopy (CEMS)). Because the electrons cannot penetrate detector windows, the samples have to be mounted inside an appropriate detection system. Depending on the material and the electron energies, the electrons can only escape from the sample surface within 10–500 nm. Therefore, CEMS is especially suited for the investigation of surfaces and thin films (up to a depth of some 100 nm for Fe-Mössbauer spectroscopy) and is even able to measure the properties of a monolayer.

Also the conversion X-rays or re-emitted γ-radiation can be used to measure the Mössbauer effect in the samples under investigation. This method is named (conversion X-ray Mössbauer spectroscopy (CXMS)). The X-rays can penetrate $\sim$10–30 μm of most metals and thus the information depth of CXMS is in this order. For such backscattering measurements as visualized in **Figure 6** in reasonable times, special detectors with large solid angles have been developed.

Based on the different information depths of the different modifications of Mössbauer spectroscopy, it is especially interesting to measure these different radiations simultaneously. Simultaneous measurements achieve a discrete depth profile of the measured samples. The arrangement for the simultaneous measurement of all three modifications was named (simultaneous triple-radiation Mössbauer spectroscopy (STRMS)). It should be noted again that the sampling range in the case of iron-based materials for the CEMS measurements is $\sim$150 nm, while for CXMS, it is 10–20 μm and TMS scans the whole sample.

Hyperfine Interactions

Hyperfine interactions are based on effects caused by the interplay between the atomic nucleus and its electronic environment. As early as in 1924, Wolfgang Pauli interpreted the hyperfine structure of atomic spectral lines by the magnetic coupling between the nucleus and its electronic shell, and also predicted properties of the Zeeman and Paschen–Back splittings in the presence of a nuclear magnetic moment. So the hyperfine interactions were merely an extension of the fine structure and observed in the atomic spectra with increasing resolution of the experiments in atomic physics.

The high-energy resolution of the Mössbauer effect (as well as that of other nuclear methods such as nuclear magnetic resonance or perturbed angular correlation) allows the direct observation of the hyperfine interactions, that is, the change of the energy levels due to electric or magnetic fields acting at the Mössbauer nucleus. These interactions are mainly the electric monopole interaction, the electric quadrupole interaction, and the magnetic dipole interaction.

Isomer Shift

The electric monopole interaction is the interaction of the nuclear charge *Ze* with the electron density at the nucleus with finite size. It leads to a difference in

the energy states in the source (S) and absorber (A), when comparing to a point nucleus (infinite small):

$$E_S = E_0 + \tfrac{2}{5}\pi Ze^2|\Psi_S(0)|^2[R_e^2 - R_g^2] \qquad [9]$$

$$E_A = E_0 + \tfrac{2}{5}\pi Ze^2|\Psi_A(0)|^2[R_e^2 - R_g^2] \qquad [10]$$

where R is the radius of the nucleus in the appropriate state (g – ground state, e – excited state) and Ψ the electron wave function. $e|\Psi(0)|^2$ then gives the electron density at the nucleus. These shifts of the levels (equivalent to the isotope effect in atomic physics) lead to the isomer shift δ as sketched in **Figure 7**:

$$\begin{aligned}\delta &= E_A - E_S \\ &= \tfrac{2}{5}\pi Ze^2[|\Psi_A(0)|^2 - |\Psi_S(0)|^2][R_e^2 - R_g^2] \end{aligned} \qquad [11]$$

Thus, the lines for materials with different electron densities at the nucleus are shifted by δ with respect to the undisturbed center. Thus, charge densities in the materials can be calculated from this isomer shift.

Quadrupole Splitting

An electric quadrupole moment of the nucleus eQ, that is, a nonspherical shape of the nucleus, interacts with an electric field gradient (EFG) acting at the nucleus, which leads to a splitting of the energy levels, as displayed in **Figure 7**. Diagonalizing the EFG tensor $V_{ij} = \partial^2 V/\partial r_i \partial r_j$ (V = electrical potential) with $|V_{zz}| \geqslant |V_{yy}| \geqslant |V_{xx}|$ and $V_{xx} + V_{yy} + V_{zz} = 0$, the asymmetry parameter η is given by

$$\eta = \frac{V_{xx} - V_{yy}}{V_{zz}} \qquad [12]$$

and the energy eigenvalue for a state with spin I and magnetic quantum number m_I is

$$E_q(m_I) = \frac{eQV_{zz}}{4I(2I-1)}[3m_I^2 - I(I+1)]\sqrt{1 + \frac{1}{3}\eta^2} \qquad [13]$$

For ^{57}Fe with $I_g = 1/2$ and $I_e = 3/2$, only the excited state splits and the quadrupole splitting ΔE_q is

$$\begin{aligned}\Delta E_q &= E_q\left(m_I = \tfrac{3}{2}\right) - E_q\left(m_I = \tfrac{1}{2}\right) \\ &= \tfrac{1}{2}\, eQV_{zz}\sqrt{1 + \tfrac{1}{3}\eta^2}\end{aligned} \qquad [14]$$

This leads to a doublet in the Mössbauer spectrum, where the splitting, that is, the distance between the two lines, determines the magnitude of the quadrupole interaction and thus the field gradient. Consequently, charge distributions of atomic arrangements or defect structures can be deducted. Lattices with cubic symmetry and without any defects always result in single lines, because, due to the symmetry, no EFG can be present.

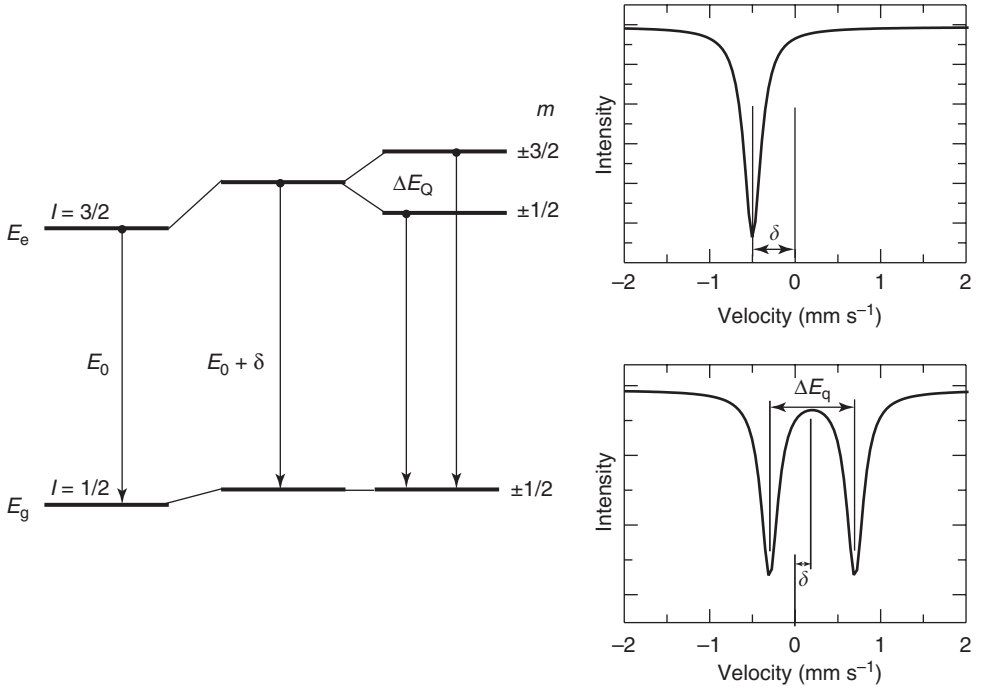

Figure 7 Electric monopole and quadrupole interactions cause a shift and a splitting of the nuclear levels, and accordingly shift and split the lines in the Mössbauer spectrum.

Magnetic Splitting

The magnetic moment μ of the nucleus interacts with a magnetic field B acting at the nucleus (nuclear Zeeman effect). This interaction gives rise to the splitting of the otherwise degenerated states. The state with spin I splits into $2I + 1$ magnetic substates with the eigenvalues:

$$E_m = -\frac{\mu B m_I}{I} = -g_N \mu_N B m_I \qquad [15]$$

where the magnetic quantum number m_I can have the values $m_I = I,\ I-1, \ldots, -(I-1),\ -I$. The magnetic moment μ is given by the Bohr magneton μ_N and the Landé factor g_N by

$$\mu = g_N \mu_N I \qquad [16]$$

Based on the selection rule for absorption (emission) of dipole radiation $\Delta m = 0, \pm 1$, only six transitions are allowed, and they represent the significant Zeeman sextet structure in the Mössbauer spectra of magnetic materials, as demonstrated in **Figure 8**.

Mixed Hyperfine Interaction

If the magnetic dipole interaction and electric quadrupole interaction act together, the eigenvalues cannot be determined as easily as for each interaction alone. Normally, perturbation methods are applied. As the magnetic interaction is usually much stronger, first the eigenvalues are determined for this magnetic interaction and the electric interaction is treated as a perturbation. For the energy states in a first-order perturbation calculation, one finds

$$E_m = -g_N \mu_N B m_I + (-1)^{|m_I|+1/2} \times \tfrac{1}{4} \times eQV_{zz} \times \tfrac{1}{2}(3\cos^2\theta - 1 + \eta \sin^2\theta \cos 2\phi) \qquad [17]$$

where θ and ϕ are the angles between the direction of the magnetic field B and the principal axis of the EFG tensor V_{zz}. For ^{57}Fe,

$$E_q = \tfrac{1}{8} eQV_{zz}(3\cos^2\theta - 1 + \eta \sin^2\theta \cos 2\phi) \qquad [18]$$

Now the line positions for the general case can be given by eqn [19]:

$$\begin{aligned} L_1 &= \delta - g_1 \mu_N B + E_q \\ L_2 &= \delta - g_2 \mu_N B - E_q \\ L_3 &= \delta - g_3 \mu_N B - E_q \\ L_4 &= \delta + g_3 \mu_N B - E_q \\ L_5 &= \delta + g_2 \mu_N B - E_q \\ L_6 &= \delta + g_1 \mu_N B + E_q \end{aligned} \qquad [19]$$

The g-factors g_i result from the Landé factors of the ground-state g_g and the excited state g_e:

$$\begin{aligned} g_1 &= \tfrac{1}{2} \times (3|g_e| + g_g) \\ g_2 &= \tfrac{1}{2} \times (|g_e| + g_g) \\ g_3 &= \tfrac{1}{2} \times (|g_e| - g_g) \end{aligned} \qquad [20]$$

The resulting shift of the energy levels and the shift of the inner four lines in the spectrum with respect to the outer lines 1 and 6 is sketched in **Figure 9**.

Angular Dependence of Absorption and Emission

The relative line intensities I_i for a sextet depend on the angle $\theta = \angle(\boldsymbol{k}, \boldsymbol{I})$ between the propagation direction $\boldsymbol{k}$ of the γ-radiation and the direction of the spin (magnetization) $\boldsymbol{I}$, as shown in **Figure 10**.

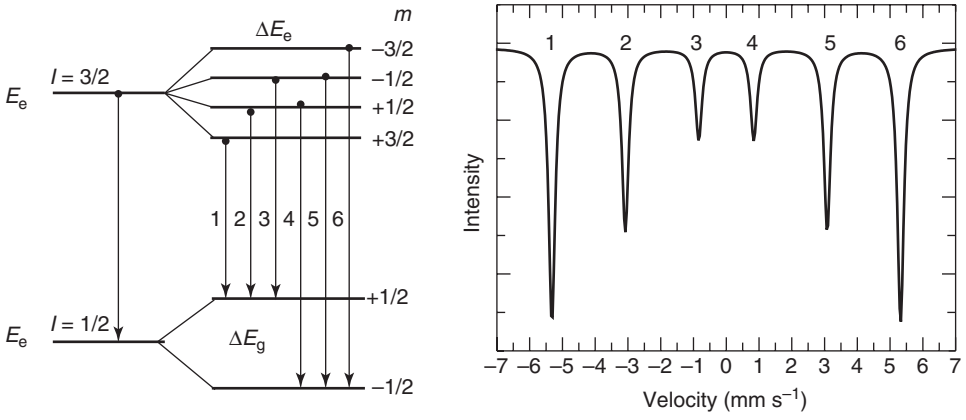

Figure 8 Magnetic dipole interaction causes a splitting of the nuclear levels, and accordingly leads to the typical Zeeman sextet in the Mössbauer spectrum.

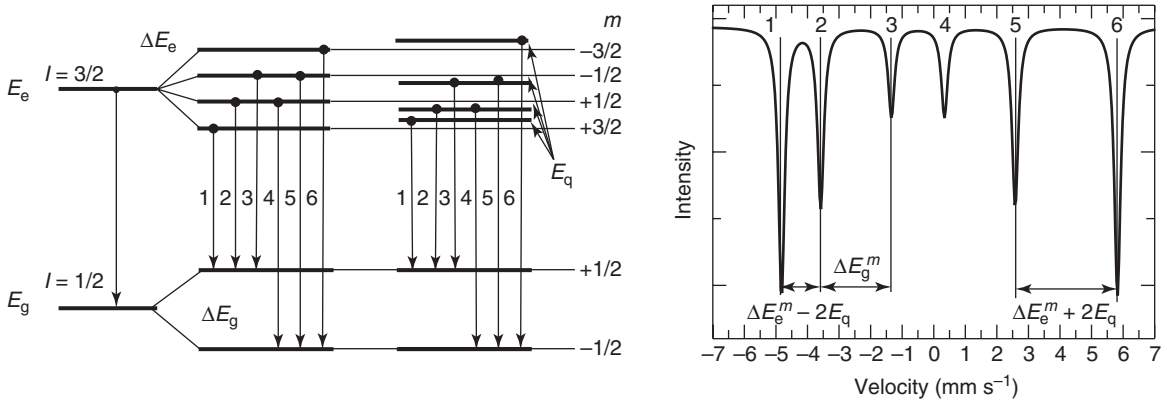

Figure 9 Mixed hyperfine interaction: magnetic dipole interaction causes a Zeeman splitting of the nuclear levels and an additional smaller electric quadrupole interaction shifts the split lines, which is also visible in the Mössbauer spectrum.

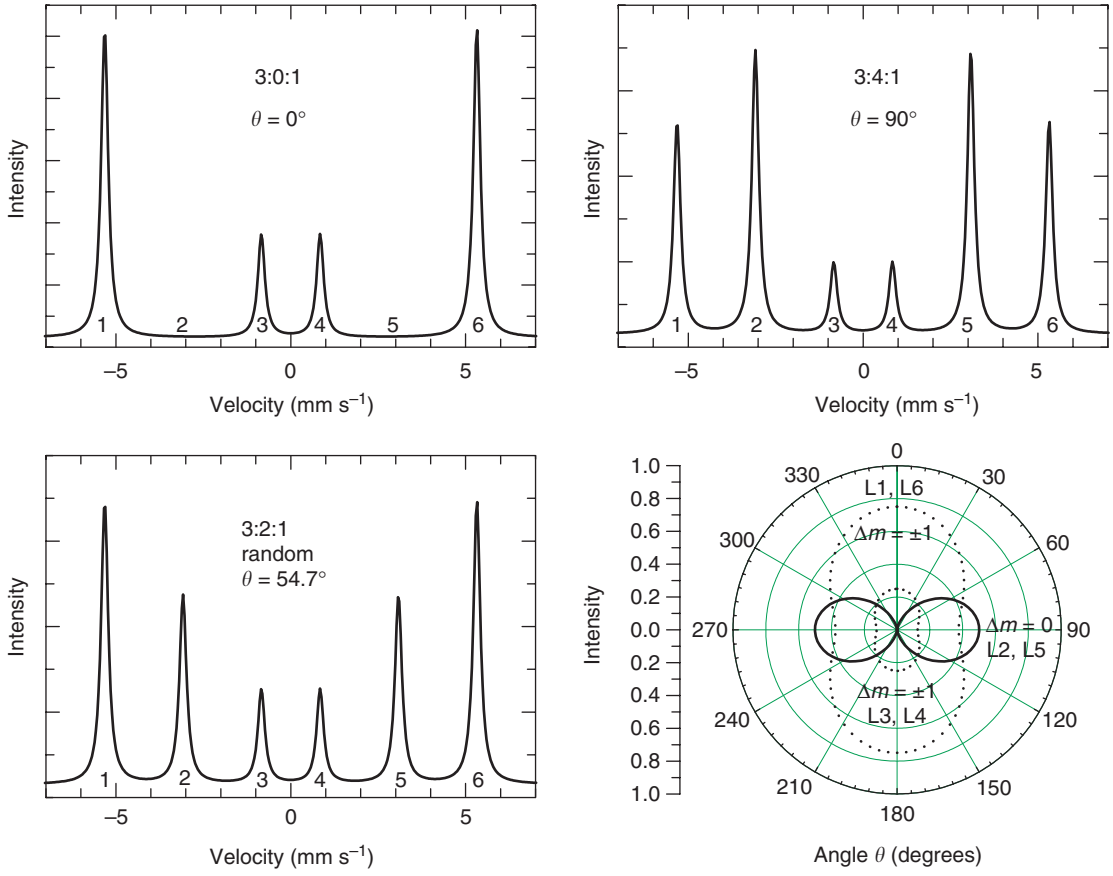

Figure 10 Angular characteristics of the dipole radiation: the angle θ is formed by the k vector of the γ radiation and the spin direction of the nucleus (i.e., the magnetization direction). The shown emission Mössbauer spectra illustrate some important cases.

For $\theta = 90°$, the intensity ratio is $I_1 : I_2 : I_3 = 3 : 4 : 1$, whereas for $\theta = 0°$, the lines 2 and 5 disappear and the ratio is $I_1 : I_2 : I_3 = 3 : 0 : 1$. If the directions of magnetization are randomly (isotropic) distributed ($\bar{\theta} = 54.7°$), the ratios are $I_1 : I_2 : I_3 = 3 : 2 : 1$.

This can be used to determine the magnetization orientation in the sample. Mössbauer polarimetry and magnetic orientation Mössbauer spectroscopy (MOMS) have evolved as specialized methods for this purpose.

Applications

One of the first applications of the Mössbauer effect was the proof of the gravitational red shift. Due to its extremely high-energy resolution, Mössbauer spectroscopy was able to verify the tiny energy shift of $\delta_{grav} = (gd/c^2)E_0$, which a γ-quantum experiences when it falls only by $d = 20$ m in the Earth's gravity g.

Phase Analysis

One of the standard applications of Mössbauer spectroscopy is the accurate phase analysis. One of the first examples was the determination of the amount of retained austenite in heat-treated steels. Here, Mössbauer spectroscopy is superior to any other method (e.g., XRD) with respect to its detection limit ($<1\%$) and accuracy ($<1\%$). In addition, by using Mössbauer spectroscopy the question of the interstitial arrangements of carbon and nitrogen in the retained austenite could be solved and it also allows an accurate calculation of the carbon or nitrogen content.

Another famous application of Mössbauer spectroscopy is the determination of Fe^{2+}/Fe^{3+} ratios in biomatter, minerals, and other oxides for medical, archeological, or industrial applications. Currently, the first Mössbauer spectrometer is doing this even on the surface of Mars.

The excellent resolution of the hyperfine interactions also allows the determination of the magnetic properties of materials, which is especially useful in alloys, and magnetic and amorphous materials. Due to the short lifetime of the nuclear states, all dynamic effects occurring in this time regime influence the Mössbauer spectra in shape and line width. This fact has been used to study diffusion and hopping mechanisms, relaxation, superparamagnetism, nanocrystalline materials, effects by RF-fields, and other time-dependent effects. More recent developments also deal with Mössbauer diffraction or the production of X-ray lasers.

Site Determination

The ability of Mössbauer spectroscopy for determining and quantifying different sites in a phase is demonstrated by a simple example, the iron nitride γ'-Fe_4N.

This material has an antiperovskite structure Pm3m, which is presented in **Figure 11**. The iron forms an f.c.c. structure and the nitrogen is located in the center of the unit cubes in an ordered manner. There are two crystallographic iron sites, Fe-I at the corners of the cube and Fe-II at the face centers, both sites having 12 iron nearest neighbors at the same distance. The Fe-I site has no nitrogen nearest neighbor (0 nn N), whereas the Fe-II sites have exactly two nitrogen nearest neighbors (2 nn N).

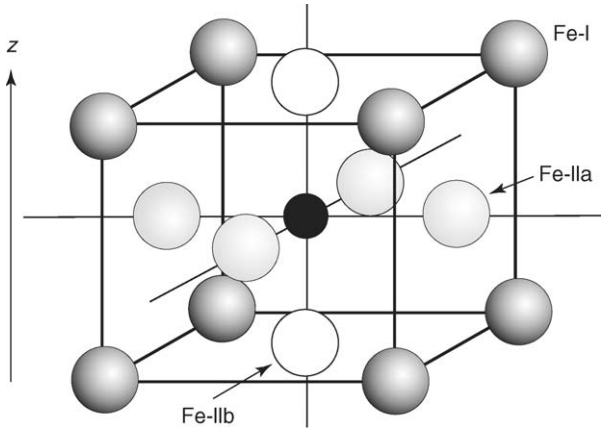

Figure 11 Crystallographic structure of the cubic γ'-Fe_4N with site assignment explained in the text.

In contrast to these two crystallographic sites, the Mössbauer spectrum of this material, as shown in **Figure 12**, has to be fitted with three subspectra corresponding to three different arrangements for the iron. The hyperfine fields are 34 T for the Fe-I sites and 21.6 T for the Fe-II sites. The difference in the two different Fe-II sites has to be explained by the magnetism of the material, which is invisible for X-ray diffraction.

The hyperfine parameters and the subspectral abundances are summarized in **Table 2**.

The f.c.c. material is ferromagnetic with a Curie temperature of $T_C = 767$ K, that is, well above the measurement temperature, which in this case is the room temperature. The magnetic easy axis is the (1 0 0) direction, which is indicated by the z-axis in **Figure 11**. There is no electric field gradient for the Fe-I site, but one for the Fe-II site having nitrogen neighbors. Thus, one has to distinguish two cases for the Fe-II site: for site Fe-IIa, the main component V_{zz} is collinear with the hyperfine field B_{hf}, that is, $\theta = 0°$. For the site Fe-IIb, EFG and z-axis are perpendicular, that is, $\theta = 90°$. For both cases, the asymmetry parameter is $\eta = 0$ and V_{zz} is identical. From eqn [18], it follows that the magnitude of E_q for the Fe-IIb site is twice as large as that for the Fe-IIa site but of opposite sign. This exactly matches the experimental findings in **Table 2**.

The subspectra areas should behave like Fe-I : Fe-IIa : Fe-IIb = 1 : 2 : 1, because 25% of the iron atoms are located at the corners, and Fe-IIa : Fe-IIb = 50% : 25% because four Fe-atoms at the face centers have $\theta = 0$ and only two have $\theta = 90°$. This theory is nicely reflected in the experimental results. This example demonstrates the ability and power of Mössbauer spectroscopy in site determination.

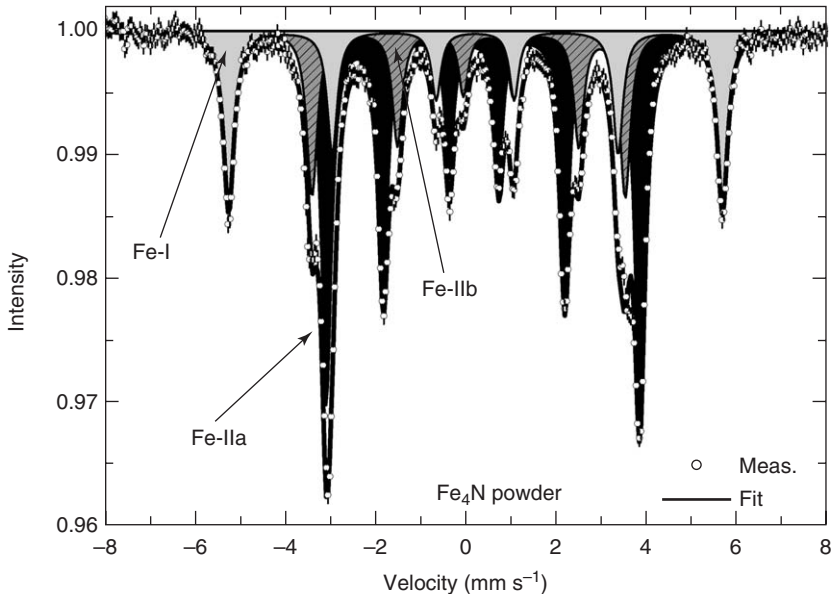

Figure 12 Mössbauer spectrum at room temperature in transmission geometry of Fe_4N powder. The spectrum is fitted by superimposing three Lorentzian sextets, corresponding to three different atomic Fe sites in the material as explained in the text.

Table 2 Hyperfine parameters as measured for Fe_4N powder at room temperature

Site	*IS* δ (mm s^{-1})	*QS* E_q (mm s^{-1})	*BHF* B_{hf} (T)	*LW* Γ (mm s^{-1})	*RA f* (%)
Fe-I	0.19(2)	0.00(1)	34.0(2)	0.28(1)	25.0(13)
Fe-IIa	0.27(2)	0.10(1)	21.6(2)	0.28(1)	51.9(09)
Fe-IIb	0.26(2)	− 0.22(1)	21.6(2)	0.28(1)	23.1(21)

IS – isomer shift, QS – quadrupole splitting, BHF – hyperfine field, LW – line width, RA – relative area.

Magnetic Orientation Mössbauer Spectroscopy

For Mössbauer polarimetry, magnetic fields and multiline Mössbauer sources (e.g., ^{57}Co in Fe gives six lines from the source and when measuring Fe with six absorption lines, this results in a spectrum of 36 lines) are used to polarize the quanta from the source and thus obtain information about the magnetic domain orientations in magnetic samples. On the other hand, with a proper modification of the traditional Mössbauer technique, with a method called magnetic orientation Mössbauer spectroscopy (MOMS), one is also able to determine the spin distribution in a sample. An important advantage of this MOMS technique in comparison to, for example, the magneto-optical Kerr effect technique (MOKE) is the absence of any external magnetic field during the measurements, which may change actual magnetization and spin distribution. Thus, it is also a magnetically nondestructive method.

In standard geometry, the photon beam is incident along the normal direction of the sample. For the MOMS experiments, the specimen normal is tilted by various angles α away from the incident γ-beam and then the spectra are measured subsequently after different sample rotations around their normal. This way, the spin distribution can be obtained by fitting the intensity ratio $I_2(\varphi)/I_3(\varphi)$ of the second and the third sextet lines as a function of the various tilt and rotation angles, yielding a "picture" of the spin distribution in the sample.

Synchrotron-Based Methods

The improvement of recent synchrotron facilities and the development of new channel-cut monochromators with superior resolution allowed the transformation from the classical Mössbauer spectroscopy in the energy domain into the time domain of nuclear resonance scattering (NRS). Many methods and applications have evolved here. Unfortunately, here this comprehensive subject cannot be treated.

Summary

In summary, it should have become obvious that Mössbauer spectroscopy is a very powerful method, which has proven its suitability for many problems in

solid-state and materials physics, chemistry, geology, archeology, environmental and space physics, and even relativistics. Mössbauer spectroscopy is based on nuclear physics, solid-state physics, and hyperfine interactions. It gives a microscopic image of the Mössbauer spy isotope and its immediate surroundings, which makes the method very powerful to study properties, short-range order and dynamic effects in many interesting materials. It is still under development and not used as widely as it should be. This may be due to the fact that "suppliers" (Mössbauer spectroscopists) and "customers" (scientists with questions) do not know enough of each other. Especially, the new developments of its synchrotron-based branch seem to lead to another push in its applications. Mössbauer spectroscopy should be seen as a powerful analytical tool, which can significantly contribute to answer many open questions for many materials. So ask your questions to a Mössbauer spectroscopist.

Nomenclature

a, a_A	isotopic abundance
a_A	atomic density ($1\,cm^{-3}$)
c, c_0	speed of light ($m\,s^{-1}$)
d_A	absorber thickness (m)
E_0	transition energy (eV)
E_n, E_g, E_e	energy levels of states, excited, ground state (eV)
f_D, f_A	Debye–Waller factor
h, $\hbar$	Planck constant (J s, eV s)
I	spin, nuclear spin I
I, I_0, $I(v)$, $I(E)$	intensity (counts)
M	mass, atomic mass
p	momentum ($\boldsymbol{p} = \hbar\boldsymbol{k}$)
t_A	effective thickness ($t_A = \sigma_0 f_A N_A d_A a_A$)
Z	atomic number
α	conversion coefficient
δ	isomer shift, shift (eV, $mm\,s^{-1}$)
γ	photon, radiation
Γ	line width (FWHM) (eV, $mm\,s^{-1}$)
λ	wavelength ($v \cdot \lambda = c$)
ν, ω	frequency ($\omega = 2\pi\nu$)
σ, σ_0	cross section, maximum cross section (barn)
τ_n	lifetime (s)
v	velocity ($m\,s^{-1}$)

Multicircle Diffractometry Methods

D A Walko, Argonne National Laboratory, Argonne, IL, USA

Introduction

When a monochromatic, collimated beam of radiation (X-rays or neutrons) is incident upon a stationary single crystal, the diffraction condition will probably be satisfied for few if any reflections, depending on a number of parameters such as the size of the unit cell, crystal mosaicity, and the energy spread of the radiation. It is even less likely that any particular reflection will be observed, and useful information, such as a reflection's integrated intensity, is not immediately available. Over the years, several methods of collecting scattering data have developed. The earliest X-ray experiments were performed with polychromatic radiation and a two-dimensional (2D) detector (photographic film); known as the Laue method, this technique has remained useful for quick sample alignment and has found new use in timing experiments in which an entire diffraction pattern is collected in a very short exposure. The powder-diffraction method consists of literally grinding the sample to a powder, effecting an ensemble average over all sample orientations; a powder-diffraction pattern is then collected with 1D scan of the detector. The rotation method consists of rotating a single-crystal sample through a given angle while measuring the pattern on a 2D detector with the use of modern image plates or charge-coupled device (CCD) detectors; this is the standard technique for macromolecular protein crystallography. While the above methods are practical for collecting integrated intensities of sharp, well-defined Bragg points, they may compromise on measurement of diffuse features. As an alternative, multicircle diffractometry uses computerized control of a high-precision goniometer (i.e., angle-positioning instrument) in order to hold both sample and detector at precise orientations, becoming a powerful tool to provide quantitative scattering data at well-defined positions in reciprocal space. Monochromatic radiation is used and, typically, observed by a point detector (a detector with a small, well-defined aperture).

Multicircle diffractometry is regularly applied to studies of systems in which orientational information cannot be sacrificed, such as measurement of pole figures for texture analysis or residual stress analysis; grazing-incidence or grazing-exit diffraction for studies of surfaces, thin films, and superlattices; and observation of diffuse scattering due to short-range order, defects such as twins or voids, or thermal diffuse scattering. Two examples of scattering data that require multicircle collection methods are shown in **Figure 1**. The reciprocal-space map in **Figure 1a** is from an Ni film grown on MgO(0 0 1); the peaks in the diffraction pattern are used to identify the various epitaxial orientations of the Ni crystal relative to the substrate, as well as the film's strain and mosaic spread. **Figure 1b** shows integrated intensities from two truncation rods of an epitaxial $SrTiO_3$ film on Si(0 0 1); the rods are continuous, diffuse features which can be analyzed to determine the atomic structure of the film and interface. The foremost drawback of multicircle diffractometer methods, compared to the other methods mentioned above, is that data are collected relatively slowly, often one point at a time rather than over a wide range of reciprocal space at once. The fairly involved calculations of the technique, described in some detail below, are no longer the issue that they once were, given the power and economy of modern computers; various diffractometer-control software packages are available.

In this article, several geometries of multicircle diffractometers, beginning with the standard four-circle Eulerian diffractometer, are reviewed. An overview of the transformation between reciprocal space and angle space is given, and various options in operating a diffractometer are described. Other diffractometer geometries will then be presented, including alternate four-circle geometries, then progressing to five- and six-circle geometries. Throughout the article, an attempt is made to point out potential sources of confusion, such as those caused by conflicting systems of nomenclature; correspondingly, the names of angles used here may differ from those in the literature or those implemented on various instruments. In that vein, it is to be noted that this article uses the term "multicircle diffractometers" to refer to instruments whose circles rotate the sample or detector; additional circles, which are used for polarization analysis or wavelength-dispersive analysis of the radiation, are not counted.

Four-Circle Eulerian Geometry

The basic four-circle diffractometer geometry is shown in **Figure 2**. The sample sits at the center of rotation on the ϕ circle, which rotates on the χ circle. The χ and ϕ circles together constitute a Eulerian

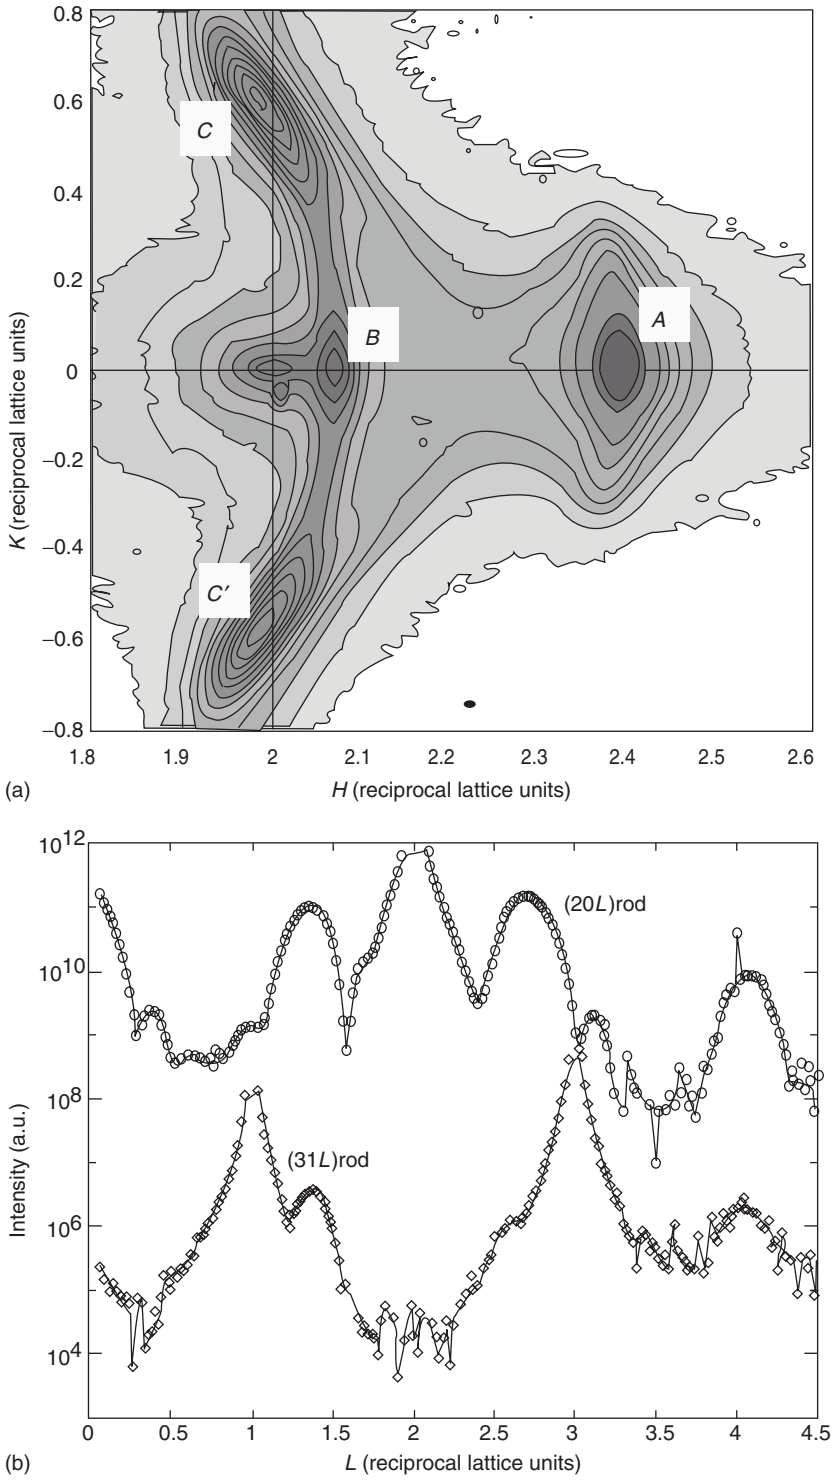

Figure 1 Two examples of thin-film diffraction data collected on a six-circle diffractometer. In both cases, the reciprocal lattice of the substrate material is used as a reference. (a) Reciprocal-space map of a 12 nm film of Ni grown at MgO(0 0 1). The map was made at $L = 0.05$ reciprocal lattice units, with the incident beam set at a grazing angle of 0.2°; the contours are spaced logarithmically. The sharp peak near the main MgO(0 0 2) peak at $H = 2$, $K = 0$ shows that the substrate is somewhat twinned. The peak marked *A* corresponds to an Ni(2 0 0) peak with relaxed cube-on-cube epitaxy. The peaks marked *B*, *C*, and *C′* are Ni(1 1 1) peaks due to regions with the epitaxial relationship (1 1 0)Ni ∥ (0 0 1)MgO. (b) Truncation-rod data of five unit cells of $SrTiO_3$ grown on Si(0 0 1), collected with a fixed 0.3° angle of incidence. Circles indicate integrated intensities along the (20*L*) rod, and diamonds represent the (31*L*) rod (vertically offset for clarity). Data points very close to the bulk Bragg points (2 0 2), (3 1 1), and (3 1 3) were not measured, since they have very high intensities and no surface sensitivity.

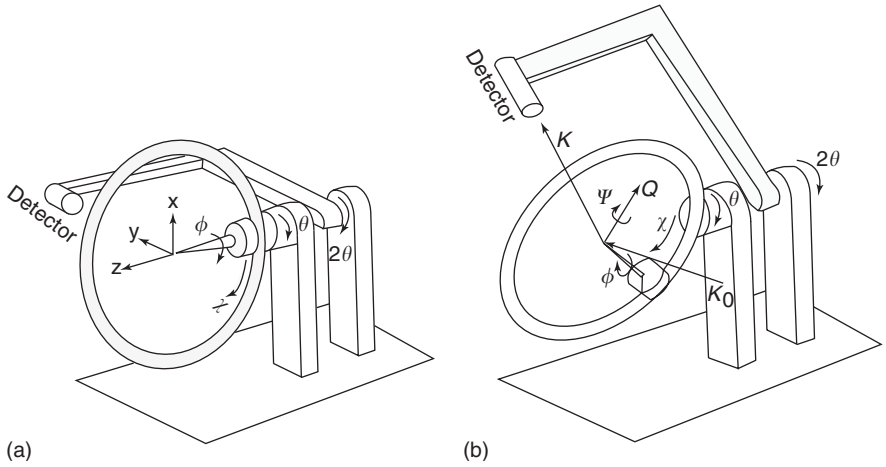

Figure 2 Diagram of a four-circle Eulerian diffractometer with (a) all angles at 0° and (b) all angles with positive displacements. The coordinate system is shown in (a), while incident wave vector $\boldsymbol{K}_0$, diffracted wave vector $\boldsymbol{K}$, scattering vector $\boldsymbol{Q}$, and azimuthal angle ψ are shown in (b).

cradle, for which this geometry is named. The Eulerian cradle then rotates on the θ circle. The detector rotates on the 2θ circle. The θ-axis is collinear with the 2θ axis; since both axes are perpendicular to the incident beam, this diffractometer is classified as normal-beam geometry. The scattering plane is defined as the plane that contains the diffracted wave vector $\boldsymbol{K}$ and the incident wave vector $\boldsymbol{K}_0$, as well as their difference, the scattering vector $\boldsymbol{Q}$, as shown in **Figure 2b**. The scattering plane is often horizontal for a laboratory-based X-ray diffractometer, so that the effects of gravity are minimized; at synchrotron sources the scattering plane is usually vertical, to take advantage of the (typically) *s*-polarization of the radiation and the higher degree of collimation in the vertical plane.

The correct operation of a diffractometer hinges on its being properly configured. **Figure 2a** shows the Eulerian four-circle diffractometer with all angles at their zero positions, in which case the direct beam travels along the axis of the χ circle, defining the zero position of θ; the detector intercepts the direct beam, defining the zero of 2θ; and the θ and ϕ axes are collinear, defining the zero of χ. The zero of ϕ is arbitrary. The sense of rotation, as shown in **Figure 2b**, is left-handed for all axes except χ.

The origin of the rather inelegant naming system is historical. In Bragg's original derivation of X-ray diffraction, the incident and exit X-ray beams both made an angle of θ with the diffracting planes, for a total scattering angle of 2θ. For normal-incidence diffractometers, the scattering angle is set by a single rotation typically labeled 2θ. The sample angle θ is not necessarily equal to one-half of 2θ, except in the special case of some three-circle diffractometers where the axes are mechanically coupled with a 1:2 gear ratio. Thus, although Bragg's law is often written as $\lambda = 2d \sin\theta$, it is better written as

$$\lambda = 2d \sin(2\theta/2) \qquad [1]$$

where λ is the wavelength and d is the lattice-plane spacing. The angle between θ and 2θ is ω, which is defined as

$$\omega = \theta - (2\theta)/2 \qquad [2]$$

The case of $\omega = 0$ is called the symmetric mode of diffraction. Unfortunately, there is no standard notation even for the most common type of diffractometer, and the θ circle is sometimes labeled ω.

Common angle scans performed on a four-circle Eulerian diffractometer include θ and $\theta/2\theta$ scans. A scan of the θ-axis probes the sample at a given magnitude of the scattering vector $|\boldsymbol{Q}|$ (defined below in eqn [9]). As an example, a θ scan might be used to probe a sample's mosaic spread; one possible source of instrumental broadening for this scan would be the beam divergence. In the $\theta/2\theta$ scan, the 2θ circle rotates at twice the rate of the θ circle. The trajectory of the $\theta/2\theta$ scan is radially outward from the origin of reciprocal space (i.e., $\boldsymbol{Q}$ increases in magnitude, with constant direction). This two-angle scan might be used to measure variations in a sample's lattice-parameter or strain; a source of instrumental broadening could be the radiation's band pass (i.e., the spread in wavelength). A $\theta/2\theta$ scan is preferable to a single-axis 2θ scan because the reciprocal-space trajectory of a $\theta/2\theta$ scan is simpler to interpret. However, the power of modern multicircle diffractometry is to move to arbitrary positions and scan in arbitrary directions of the reciprocal

space; the following sections of this article show how this is accomplished.

Angle Calculations

The Diffraction Equation

The fundamental problem in multicircle diffractometry is to map a sample's reciprocal-space coordinates to the diffractometer's angles: to measure the scattered intensity at a certain point in reciprocal space, what values should the angles have? The solution to this question was worked out by Busing and Levy for the case of a four-circle diffractometer, with extensions by many authors to other geometries. Here, the principles for the ideal four-circle case are outlined; detailed calculations for a variety of geometries can be found in the literature.

The question of mapping from reciprocal space to angle space could be restated as how to set the scattering vector $\boldsymbol{Q}$ equal to a desired reciprocal-lattice point $\boldsymbol{h}$, that is,

$$\boldsymbol{h} = \boldsymbol{Q} \qquad [3]$$

The two sides of eqn [3] must be written in the same reference frame and in the same coordinates; here one may choose to transform eqn [3] to Å^{-1} units in the laboratory frame. Beginning with the left-hand side of eqn [3], the transformation of reciprocal-lattice vector $\boldsymbol{h}$ from reciprocal-lattice coordinates ($\boldsymbol{h}$, with no subscript) to lab coordinates ($\boldsymbol{h}_\text{l}$) is achieved in a number of steps by successive application of a number of matrices. First, $\boldsymbol{h}$ in reciprocal-lattice units is transformed into Cartesian coordinates ($\boldsymbol{h}_\text{c}$, in Å^{-1} units) via the matrix $\boldsymbol{B}$:

$$\boldsymbol{h}_\text{c} = \boldsymbol{B}\boldsymbol{h} \qquad [4]$$

where $\boldsymbol{B}$ is constructed from the lattice parameters. The matrix $\boldsymbol{B}$ is most easily expressed as a combination of real-space lattice parameters a_i, α_i, and reciprocal-space lattice parameters b_i, β_i ($i = 1$–3):

$$\boldsymbol{B} = \begin{pmatrix} b_1 & b_2\cos\beta_3 & b_3\cos\beta_2 \\ 0 & b_2\sin\beta_3 & -b_3\cos\beta_2\cos\alpha_1 \\ 0 & 0 & 2\pi/a_3 \end{pmatrix} \qquad [5]$$

where $a_i \cdot b_j = 2\pi\delta_{ij}$. Generally, $\boldsymbol{B}$ is not orthonormal, but the other matrices in this section are all orthonormal rotation matrices. The next step is to transform $\boldsymbol{h}_\text{c}$ into the coordinate system of the diffractometer's ϕ axis:

$$\boldsymbol{h}_\phi = \boldsymbol{U}\boldsymbol{h}_\text{c} \qquad [6]$$

where $\boldsymbol{U}$ describes the orientation of the crystal relative to the diffractometer, and as such, is known as the orientation matrix. The determination of $\boldsymbol{U}$ is a critical step in multicircle diffractometery and is described in the next section. $\boldsymbol{h}_\phi$ is then transformed into laboratory coordinates by the successive application of the diffractometer-axes rotation matrices $\boldsymbol{R}$:

$$\boldsymbol{h}_\text{l} = \boldsymbol{R}(\theta)\boldsymbol{R}(\chi)\boldsymbol{R}(\phi)\boldsymbol{h}_\phi \qquad [7]$$

where

$$\boldsymbol{R}(\theta) = \begin{pmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix}$$
$$\boldsymbol{R}(\chi) = \begin{pmatrix} \cos\chi & 0 & \sin\chi \\ 0 & 1 & 0 \\ -\sin\chi & 0 & \cos\chi \end{pmatrix} \qquad [8]$$
$$\boldsymbol{R}(\phi) = \begin{pmatrix} \cos\phi & \sin\phi & 0 \\ -\sin\phi & \cos\phi & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Turning to the right side of eqn [3], the scattering vector or momentum transfer, $\boldsymbol{Q}$, is defined as

$$\boldsymbol{Q} = \boldsymbol{K} - \boldsymbol{K}_0 \qquad [9]$$

where $\boldsymbol{K}$ and $\boldsymbol{K}_0$ are the diffracted and incident wave vectors, respectively. Their magnitudes are equal and defined as

$$|\boldsymbol{K}| = |\boldsymbol{K}_0| = K = 2\pi/\lambda \qquad [10]$$

The magnitude of $\boldsymbol{Q}$ is then

$$|\boldsymbol{Q}| = \frac{2\pi}{d} = \frac{4\pi\sin(2\theta/2)}{\lambda} \qquad [11]$$

It should be noted that numerous conventions exist for the definitions of eqns [9] and [10]. For example, the symbols $\boldsymbol{s}$ and $\boldsymbol{s}_0$ or $\boldsymbol{k}'$ and $\boldsymbol{k}$ may be used for the diffracted and incident wave vectors respectively. These wave vectors are often defined without the factor of 2π in eqn [10]; correspondingly, the factors of 2π are removed from eqns [5] and [11]. Other common symbols for the scattering vector include $\boldsymbol{G}$, $\boldsymbol{H}$, and $\boldsymbol{K}$.

In laboratory units, the incident wave vector is along the y-axis:

$$\boldsymbol{K}_0 = \begin{pmatrix} 0 \\ K \\ 0 \end{pmatrix} \qquad [12]$$

The diffracted wave vector is along the y-axis of the detector frame, which can be transformed into the lab frame with a rotation matrix for the 2θ axis:

$$\boldsymbol{K} = \boldsymbol{R}(2\theta)\begin{pmatrix} 0 \\ K \\ 0 \end{pmatrix},$$

$$\boldsymbol{R}(2\theta) = \begin{pmatrix} \cos 2\theta & \sin 2\theta & 0 \\ -\sin 2\theta & \cos 2\theta & 0 \\ 0 & 0 & 1 \end{pmatrix} \qquad [13]$$

The scattering vector $\boldsymbol{Q}$, then, equals $[\boldsymbol{R}(2\theta) - \boldsymbol{I}]\,\boldsymbol{K}_0$, where $\boldsymbol{I}$ is the identity matrix. Substitution into eqn [3] results in the basic diffractometer equation for a four-circle diffractometer:

$$\boldsymbol{R}(\theta)\boldsymbol{R}(\chi)\boldsymbol{R}(\phi)\boldsymbol{UBh} = [\boldsymbol{R}(2\theta) - \boldsymbol{I}]\begin{pmatrix} 0 \\ K \\ 0 \end{pmatrix} \qquad [14]$$

Several possible generalizations of the above procedure are fairly straightforward to derive. For another diffractometer geometry, one simply incorporates the appropriate rotation matrices $\boldsymbol{R}$ into eqn [14]. One can also measure the directions of a diffractometer's rotation axes with, for example, an autocollimator, creating empirical $\boldsymbol{R}$ matrices rather than the idealized ones of eqns [8] and [13]. One also need not assume that the incident beam is perfectly collinear with the y-axis but can generalize the beam's direction (eqn [12]). This can be very useful in situations where the incident beam is not level (e.g., deflected upwards by a grazing-incidence mirror), but the entire diffractometer cannot be tilted. Several authors have worked out the equations for completely general diffractometer geometries.

Determining the Orientation Matrix

With the diffraction equation (eqn [14]) otherwise solved, the orientation matrix $\boldsymbol{U}$ must be determined; $\boldsymbol{B}$ must also be found if the sample's lattice parameters are not precisely known. Busing and Levy demonstrated several methods of determining $\boldsymbol{U}$ that result in a 1D set of solutions in diffractometer-angle space. To uniquely determine $\boldsymbol{U}$, a constraint must be added; selection of constraints are discussed in the following section.

If the sample's lattice parameters are known, then two noncollinear orientation reflections, $\boldsymbol{h}_1$ and $\boldsymbol{h}_2$, must be found to determine $\boldsymbol{U}$. Then, in principle, solving the following equations for $\boldsymbol{h}_1$ and $\boldsymbol{h}_2$ will determine $\boldsymbol{U}$:

$$\boldsymbol{h}_{i\phi} = \boldsymbol{UBh}_i \qquad [15]$$

where $i = 1, 2$ and the $\boldsymbol{h}_{i\phi}$ vectors are calculated from the observed angular positions of $\boldsymbol{h}_i$. But in practice, experimental uncertainties prevent one $\boldsymbol{U}$ matrix from exactly satisfying eqn [15] for both $\boldsymbol{h}_{1\phi}$ and $\boldsymbol{h}_{2\phi}$. Errors can arise from effects such as mosaic spread, refraction, beam divergence, or mechanical imperfections in the diffractometer. Therefore, the following procedure is commonly used to determine $\boldsymbol{U}$: $\boldsymbol{h}_{1\phi}$, called the primary reflection, exactly satisfies eqn [15], but $\boldsymbol{h}_{2\phi}$, as the secondary reflection, only determines the rotation of the coordinate system about $\boldsymbol{h}_{1\phi}$. Exchanging $\boldsymbol{h}_1$ and $\boldsymbol{h}_2$ generally results in slightly different solutions for $\boldsymbol{U}$. Generally, to minimize the effect of angular misalignment and achieve a more accurate solution of $\boldsymbol{U}$, the orientation reflections should be at fairly high angles (high $|\boldsymbol{Q}|$) and fairly far apart in angle (as a suggestion, the angle between $\boldsymbol{h}_1$ and $\boldsymbol{h}_2$ should be at least 40°). On the other hand, when a good alignment is not easily maintained, one could select orientation reflections that are close to each other and then probe only the nearby region of reciprocal space. Then, when another region is to be probed, a new set of orientation reflections can be chosen in the new region.

When the sample's lattice parameters are not known, the matrix $\boldsymbol{UB}$ must be determined; sometimes the $\boldsymbol{UB}$ matrix, rather than just $\boldsymbol{U}$, is known as the orientation matrix. In the unknown lattice-parameter case, three non-coplanar reflections ($\boldsymbol{h}_1$, $\boldsymbol{h}_2$, $\boldsymbol{h}_3$) with known (or assumed) Miller indices should be found that, with the selection of one constraint as discussed below, allows for a unique solution of $\boldsymbol{UB}$ in eqn [15]. With four or more reflections, a least-squares fitting method can be applied to eqn [15] to refine the lattice parameters. The resulting lattice parameters will not exactly reflect the symmetry of the crystal lattice but should be fairly close. For example, with a cubic crystal, the unit cell lengths should be nearly equal, and the angles should be within a few tenths of 90°. With a sufficiently large set of orientation reflections $\boldsymbol{h}_i$, still other parameters may also be refined, such as a displacement of the crystal from the diffractometer's center of rotation.

Operating Modes

As mentioned above, the calculation of diffractometer angles for a given reciprocal-lattice point is under-determined, since reciprocal space is three-dimensional while a four-circle diffractometer has, obviously, four degrees of freedom. An additional constraint is needed that is usually achieved by freezing one angle at a certain value. In the case of a four-circle normal-incidence diffractometer, the detector angle 2θ is determined by the magnitude of the

scattering vector $\boldsymbol{Q}$; a constraint cannot be placed on 2θ without restricting the range of accessible reciprocal space to a single magnitude of $|\boldsymbol{Q}|$. Therefore, constraints in the four-circle Eulerian geometry should be applied only to a diffractometer's sample angle or to an appropriately defined azimuthal angle.

The simplest and perhaps most common four-circle mode is to constrain ω (see eqn [2]) at a fixed value. The constraint of $\omega = 0$ is called the symmetric or bisecting mode, since the incident and diffracted beams make the same angle to the plane of the χ circle; generally, this mode permits the greatest access to reciprocal space. Another mode based on sample angles is to constrain χ or ϕ to a fixed value; such a mode might be useful when a sample environmental cell (e.g., oven, cryostat, or vacuum chamber) has a small window that must be kept oriented to the incident beam, but is otherwise fairly limiting.

Another possible operating mode is to choose a zone, a plane of reciprocal space passing through the origin, as the scattering plane. A zone can be defined by two non-collinear Bragg points; appropriate values of χ and ϕ are then selected to place the two Bragg points in the scattering plane. This mode contains two constraints, that is, it freezes two sample angles. Thus, access to reciprocal space is reduced to a single plane, but data collection is simplified since the zone can be studied with movements of only 2θ and θ.

Instead of constraining a particular sample angle to a given value, one can also constrain the azimuthal rotation of the sample about the scattering vector. As shown in **Figure 2b**, ψ is the azimuthal rotation about $\boldsymbol{Q}$. In defining ψ, a reference vector $\boldsymbol{N}$ must be chosen. $\boldsymbol{N}$ can point in any direction except parallel to $\boldsymbol{Q}$, but is often a special direction for the sample, for example, the surface normal, a magnetic field direction, or the direction of polarization in a polar material. The definition of $\psi = 0^\circ$ is when $\boldsymbol{N}$ lies in the scattering plane; $\psi = 90^\circ$ when $\boldsymbol{N}$ lies in the plane defined by $\boldsymbol{Q}$ and the diffractometer's $\theta/2\theta$ axes. The constrained-ψ mode is particularly useful in surface diffraction when $\boldsymbol{N}$ is chosen to be the surface normal. Mochrie has shown how to calculate ψ for a given incident angle or exit angle, which provide particularly convenient modes for grazing-incidence or grazing-exit studies. The constraint of $\psi = 90^\circ$ sets the incident angle equal to the exit angle.

Equivalent Angle Settings

In addition to selection of an operating mode, other choices of angle must be made in the operation of a diffractometer. Although any angle can theoretically be rotated by 360° without changing anything, the axes of most diffractometers have limited ranges of motion and cannot rotate indefinitely. The diffractometer-control software must determine, for example, whether a rotation from -170 to $+170^\circ$ will be done with a motion of -20 or $+340^\circ$. Furthermore, symmetry operations make some sets of angle combinations equivalent. For example, for a given χ and ϕ, the pair of angles $(2\theta, \omega)$ are equivalent to $(-2\theta, \omega - 180)$, but both settings may not be equally practical or accessible on a given diffractometer. In general, seven sets of angles can substitute for the set of $(2\theta, \theta, \chi, \phi)$, although not all of these sets are compatible with all operating modes. A diffractometer-control program must, implicitly or explicitly, select one of these sets. A convenient choice is to select angles that fall within the allowed range as set by software limits.

Alternative Four-Circle Geometries

Kappa Geometry

Several types of four-circle diffractometer geometries exist in addition to the Eulerian geometry described above. Perhaps the most common is the "kappa" geometry, originally developed by Enraf–Nonius. As shown in **Figure 3**, the χ circle of the Eulerian geometry is replaced by a κ-axis, which is built on an arm at an angle of α_0 to the θ_κ axis; typically, α_0 is nominally 50°. The κ-axis rotates another arm with another angle of α_0, upon which sits the ϕ_κ-axis. The "κ" subscripts on the θ_κ and ϕ_κ circles distinguish

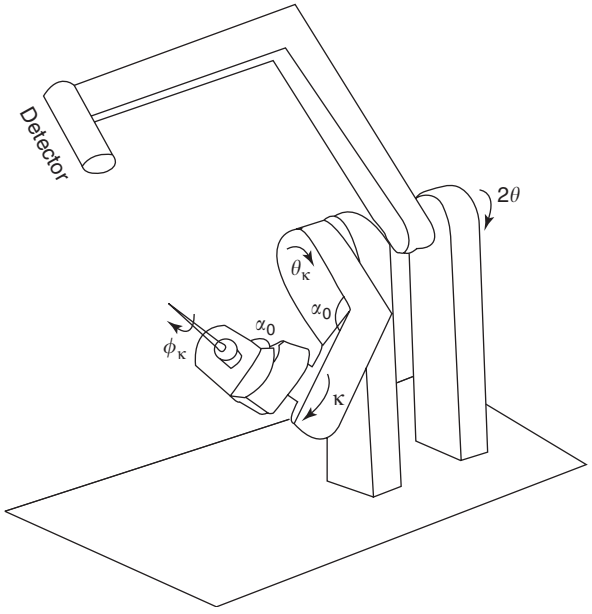

Figure 3 Diagram of a four-circle kappa diffractometer. The angles are chosen to hold a sample at the same place as the Eulerian diffractometer shown in **Figure 2b**, via the relations given eqn [16].

those circles of the kappa diffractometer from similar θ and ϕ circles of a standard Eulerian diffractometer, although not all systems of nomenclature make this explicit distinction. One could incorporate the rotation matrix of κ in deriving solutions to the diffraction equation (eqn [14]). However, it is often simpler to directly relate the kappa angles (θ_κ, κ, ϕ_κ) to the Eulerian angles (θ, χ, ϕ):

$$\begin{aligned}\theta &= \theta_\kappa - \cos(\kappa/2)/\cos(\chi/2)\\ \chi &= 2\arcsin[\sin(\kappa/2)\sin\alpha_0]\\ \phi &= \phi_\kappa - \cos(\kappa/2)/\cos(\chi/2)\end{aligned} \qquad [16]$$

The relations in eqn [16] are straightforward to be included in the diffractometer-control software after an appropriate solution to eqn [14] is computed in Eulerian geometry, with the advantage of allowing users to operate a kappa diffractometer just as the more familiar Eulerian diffractometer is. In doing so, (θ, χ, ϕ) are called "pseudoangles," whereas the physically present (θ_κ, κ, ϕ_κ) are called "real" angles.

The foremost advantage of a kappa-geometry diffractometer is the elimination of the χ circle. The primary weakness of Eulerian geometry is the limited mechanical perfection of the χ circle; any deviation from a perfect circle will, for example, increase the sphere of confusion. This issue is often exacerbated for diffractometers with an open or split χ circle. On the other hand, a closed χ circle blocks the incident or diffracted beam for some values of θ; beam blockage is less of an issue with kappa geometry. A related advantage is the relative compactness of the κ arm compared to the χ circle, making kappa geometry popular for confined spaces or crowded experimental stations. One hypothetical drawback of the kappa geometry is its limited angular range. As seen in eqn [16], a kappa diffractometer whose κ-axis has a full range of $\pm 180^\circ$ emulates a Eulerian diffractometer with a maximum theoretical range of $\chi = \pm 2\alpha_0$ (i.e., typically $\pm 100^\circ$). This issue can be dealt with by selection of a suitable angular setting, as discussed above, and should not generally pose a problem. A practical caution is that the asymmetric shape of the kappa arm, as it folds and unfolds, makes it particularly vulnerable to collisions with nearby objects (e.g., the input flight path or the detector arm); care should be taken to properly set hardware and software limit switches such that collisions cannot occur in any potential angular configuration.

Four-Circle General-Inclination Geometries

Another class of diffractometers, known as general-inclination geometries, is distinct from the normal-incidence geometries in that it provides more than one degree of freedom to the detector. Such geometries can significantly increase the range of accessible reciprocal space in situations where the angular range is limited by a sample cell. In contrast to the normal-incidence geometry, the scattering plane (containing $\boldsymbol{K}$, $\boldsymbol{K}_0$, and $\boldsymbol{Q}$) of the general-inclination geometry is no longer fixed; there is no simple one-to-one correspondence between the general-inclination and normal-incidence geometries such as that which exists between the Eulerian and kappa geometries. Since the position of the detector in a general-inclination geometry is a compound motion of several angles, the total scattering angle 2θ must be calculated, and cannot be simply read from one dial on the instrument. In this article, the convention that 2θ is the total scattering angle is followed. As such, only the normal-incidence geometry has a single circle that can be properly labeled 2θ, although many systems of nomenclature use 2θ as the label for one of the detector circles.

Several variations of four-circle inclined-geometry diffractometers have been developed, two of which are illustrated in **Figure 4**. For the "Z-axis" diffractometer (**Figure 4a**), the sample sits on the η-axis and the detector on the δ and γ-axes; all three axes then rotate about the α-axis. It may be noted that many Z-axis diffractometers call the sample axis θ (or ω); here, this axis is labeled as η to emphasize that it is not equivalent to the Eulerian θ-axis, since the η-axis is not orthogonal to the X-ray beam when $\alpha \neq 0$. The Z-axis geometry is particularly useful in holding heavy sample equipment such as vacuum chambers, as it minimizes motions that must be coupled through the sample chamber. The total scattering angle 2θ is given by

$$2\theta_{Z\text{-axis}} = \arccos(\cos\gamma\cos\delta\cos\alpha + \sin\alpha\sin\gamma) \qquad [17]$$

Another example of inclined geometry is the "S2D2" diffractometer. As shown in **Figure 4b**, the S2D2 geometry is composed of two pairs of orthogonal axes: the sample rotates on η and μ, while the detector rotates on δ and ν. Indeed, the name "S2D2" is meant to indicate that this geometry has two degrees of freedom for the sample ("S2") and two degrees of freedom for the detector ("D2"). In this nomenclature, the normal-incidence four-circle Eulerian and kappa diffractometers both have "S3D1" geometry. The Z-axis geometry does not exactly fit into this naming system, since one degree of freedom is shared between the sample and detector, but the designation $(\text{S1D2})^*1$ has been used, implying that a Z-axis diffractometer is an S1D2 (three-circle) diffractometer mounted upon a fourth circle. A practical advantage of the S2D2 geometry is

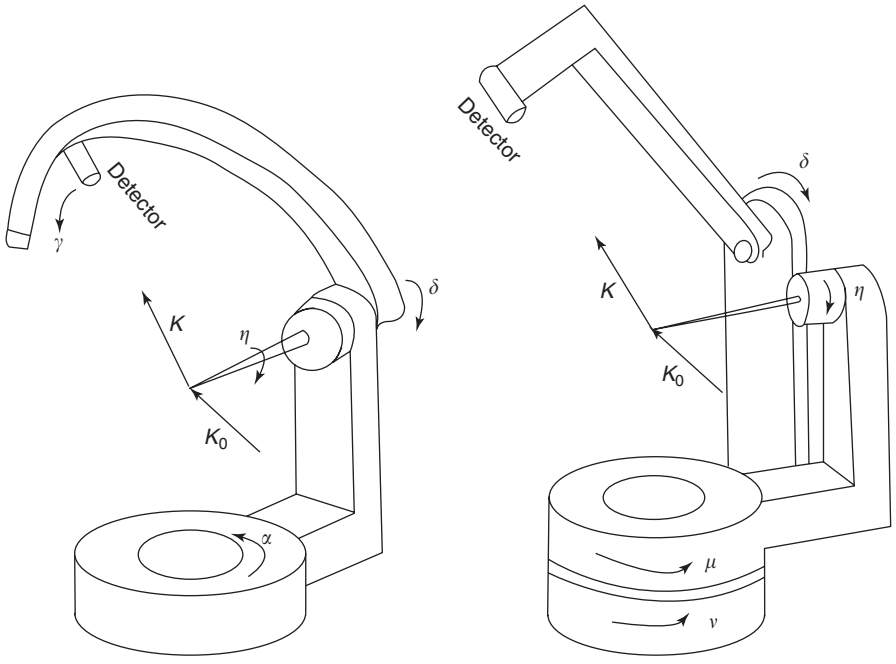

Figure 4 Two examples of general-inclination four-circle diffractometers: (a) *Z*-axis geometry; (b) S2D2 geometry.

the mechanical decoupling of the sample and detector motions, limiting the propagation of mechanical errors. The scattering angle of the S2D2 diffractometer is given by eqn [17] with γ set to zero:

$$2\theta_{S2D2} = \arccos(\cos \nu \cos \delta) \qquad [18]$$

The orientation matrix $\boldsymbol{U}$ of a four-circle inclined geometry can be calculated in the same way as for the four-circle normal-incidence geometry case, and a mode with one constraint must be selected. The diffraction equations are similar to the normal-incidence case, but the appropriate rotation matrices for the sample and detector axes must be incorporated on both sides of eqn [14].

The *Z*-axis and S2D2 geometries are particularly useful for surface scattering when the surface normal is aligned parallel to the η-axis, since the angle of incidence is given simply by the diffractometer angle α or μ, respectively. However, sufficiently precise sample alignment is often not easy, especially in a vacuum environment, which leads naturally to the desire for additional degrees of freedom for the sample. Such diffractometer geometries are described in the next section.

Five-Circle and Six-Circle Diffractometers

Representing the next level of complexity and flexibility, five- and six-circle diffractometer geometries all fall into the class of inclined geometries. In general, such diffractometers have been developed to provide better access to larger ranges of reciprocal space or to provide greater flexibility in sample positioning, given the constraints of a particular experiment.

Several varieties of five- and six-circle diffractometers have been constructed. The basic five-circle diffractometer could be characterized as a four-circle normal-incidence diffractometer (either Eulerian or kappa) with the θ-axis horizontal, mounted on a fifth rotation stage whose axis is vertical. The sample and detector motions are coupled by the fifth circle, so this five-circle geometry could be labeled $(S3D1)^*1$. This five-circle diffractometer can be converted into a six-circle instrument by the addition of another vertical axis, upon which sit the sample circles (θ, χ, and ϕ); the entire diffractometer rotates on the bottommost axis. Alternatively, one could add the χ and ϕ circles of a Eulerian cradle (or the κ and ϕ_κ circles of a kappa arm) to an S2D2 diffractometer (**Figure 4b**); this geometry decouples the sample and detector motions and would thus be labeled S4D2. Another six-circle geometry is formed by adding a Eulerian cradle to a *Z*-axis diffractometer (**Figure 4a**); the sample and detector motions of this geometry are coupled through the α-axis.

While the additional degrees of freedom in five- and six-circle diffractometers provide much greater flexibility in operation, the degree of complexity in

operation increases correspondingly. On a practical level, five- and six-circle diffractometers are generally quite large, with more (and heavier) counterweights than four-circle diffractometers. The large size and extra degrees of freedom increase the possibility of collisions and the damage that a collision can cause; hardware and software limits must be carefully set to avoid a collision in any potential angular configuration. More fundamentally, the choice of a mode becomes more complicated. Each additional degree of freedom (rotation axis) requires an additional constraint in the transformation between angle space and reciprocal space. Specifically, to uniquely determine the angle settings for a reciprocal lattice point, a five-circle or six-circle diffractometer requires, respectively, two or three constraints. The number of possible operating modes becomes correspondingly larger, and the geometry calculations supported by the diffractometer-control software also grow in complexity.

Although the modes of a five- or six-circle diffractometer require selection of several constraints, the constraints cannot be chosen arbitrarily. For example, one could not constrain two detector circles, since that would limit reciprocal-space access to a single magnitude of $|\boldsymbol{Q}|$. In the case of surface diffraction, one could not choose both the incident angle and the exit angle since that would overconstrain the azimuthal angle; one could choose to make the incident and exit angles equal but could not select a specific value for both. In the particular case of S4D2 geometry, a system was developed by You to organize mode selection by categorizing the angles which could be subject to constraints. The three categories of angles are detector, azimuthal, and sample. A detector constraint would fix one of the angles upon which the detector rotates, or would fix the angle of $\boldsymbol{Q}$ or reference vector $\boldsymbol{N}$ with respect to the horizontal plane; for example, $\boldsymbol{Q}$ or $\boldsymbol{N}$ could be fixed to lie in the horizontal or vertical plane. Azimuthal constraints include fixing the incident or exit angle, or otherwise fixing the azimuthal angle ψ. Possible sample constraints include fixing a sample angle at a certain value or constraining it relative to another angle. The key to this method is that no more than one constraint may be placed on either detector angles or azimuthal angles; the remaining constraint(s) must be applied to sample angles. Both sets of data in **Figure 1**, for example, were collected on an S4D2 diffractometer with one detector constraint (fixed angle of $\boldsymbol{N}$), one azimuthal constraint (fixed angle of incidence), and one sample constraint (η was fixed to be half of δ). One could also select one detector or azimuthal constraint and two sample constraints, or one could select three sample constraints.

The development of five- and six-circle diffractometers was driven by the need for flexibility in diffractometer operation, especially for access to the widest possible range of reciprocal space, given the experimental constraints. While some future advances in this technique may lie in the area of new diffractometer geometries, more critical needs lie in the area of improved data-collection efficiency. For example, many experiments may benefit from detectors with the sometimes-conflicting qualities of better resolution, larger dynamic ranges, or parallel data collection by use of 1D or 2D detectors. The overhead expense of motor motion can be reduced by the so-called trajectory or on-the-fly scanning: rather than collect data point by point, the diffractometer axes rotate continuously and the incoming data are binned into multichannel counters. In general, just as modern computers have made multicircle diffractometry viable as a regular research tool, increased automation will improve the efficiency in all steps of a diffraction experiment.

Acknowledgments

Data in **Figure 1** were collected at the Advanced Photon Source beamline 7ID, in collaboration with R Clarke and C Cionca (**Figure 1a**), and M J Bedzyk and D M Goodner (**Figure 1b**). Nomenclature

a_i, α_i $(i = 1–3)$	real-space lattice parameters (Å,°)
b_i, β_i $(i = 1–3)$	reciprocal-space lattice parameters (Å,°)
$\boldsymbol{B}$	matrix which produces a Cartesian coordinate system for reciprocal space ($Å^{-1}$)
d	lattice-plane spacing (Å)
$\boldsymbol{h}$	reciprocal lattice vector (reciprocal lattice units)
$\boldsymbol{h}_c$	reciprocal lattice vector in Cartesian coordinates ($Å^{-1}$)
$\boldsymbol{h}_l$	reciprocal lattice vector in lab frame ($Å^{-1}$)
$\boldsymbol{h}_\phi$	reciprocal lattice vector in frame of ϕ axis ($Å^{-1}$)
$\boldsymbol{K}$	diffracted wave vector ($Å^{-1}$)
$\boldsymbol{K}_0$	incident wave vector ($Å^{-1}$)
$\boldsymbol{N}$	reference vector ($Å^{-1}$)
$\boldsymbol{Q}$	scattering vector ($Å^{-1}$)
$\boldsymbol{R}(\zeta)$	rotation matrix describing the effect of diffractometer axis ζ (unitless)
$\boldsymbol{U}$	orientation matrix (unitless)
α_0	kappa diffractometer angle (°)
γ, δ, η, α	Z-axis diffractometer angles (°)
δ, ν, η, μ	S2D2 diffractometer angles (°)
2θ	total scattering angle (°)
2θ, θ, χ, ϕ	four-circle Eulerian diffractometer angles (°)
2θ, θ_κ, κ, ϕ_κ	kappa diffractometer angles (°)
λ	wavelength (Å)
ψ	azimuthal angle (°)

Muon Spin Rotation

A Amato, Paul Scherrer Institut, Villigen, PSI, Switzerland
D Andreica, Babes-Bolyai University, Cluj-Napoca, Romania

Introduction

μSR spectroscopy uses implanted muons to probe properties of matter at the microscopic level. According to one of the earliest definitions of μSR – appeared on the cover of the first issue of the μSR Newsletter in 1974 – : "*μSR stands for Muon Spin Relaxation, Rotation, Resonance, Research or what have you*". The intention of the mnemonic acronym was to draw attention to the analogy with NMR and ESR, the range of whose applications were already well known at that time. More generally speaking, the abbreviation covers any study of the interactions of the magnetic moment of the muon with its surrounding when implanted into any kind of matter.

μSR is a relatively new nuclear method. Roughly speaking, it can be classified in between NMR and diffraction techniques. The NMR technique which is the closest parallel to μSR is "pulsed NMR," in which one observes time-dependent transverse nuclear polarization or a so-called "free induction decay" of the nuclear polarization. However, a key difference is the fact that in μSR, one uses a specifically implanted spin (the muon's) and does not rely on internal nuclear spins. In addition, and due to the specificity of the muon, the μSR technique does not require any radio-frequency technique to align the probing spin. On the other hand, a clear distinction between the μSR technique and those involving neutrons or X-rays is that scattering is not involved. Neutron diffraction techniques, for example, use the change in energy and/or momentum of a scattered neutron to deduce the sample properties. In contrast, the implanted muons are not diffracted but remain in a sample until they decay. Only a careful analysis of the decay product (i.e., a positron) provides information about the interaction between the implanted muon and its environment in the sample.

Similar to many of the other nuclear methods, μSR relies on discoveries and developments made in the field of particle physics. Following the discovery of the muon by Neddermeyer and Anderson in 1936, pioneer experiments on its properties were performed with cosmic rays. Indeed, with one muon hitting each square centimeter of the earth's surface every minute, the muons constitute the foremost constituent of cosmic rays arriving at ground level. However, μSR experiments require muon fluxes of the order of 10^4–10^5 muons per second and square centimeter. Such fluxes can only be obtained in high-energy accelerators which have been developed during the last 50 years.

Muon Production, Properties, and Implantation

Muon Production

The collision of an accelerated proton beam (typical energy 600 MeV) with the nuclei of a production target produces positive pions (π^+) via the possible reactions

$$\begin{aligned} p + p &\rightarrow p + n + \pi^+ \\ p + n &\rightarrow n + n + \pi^+ \end{aligned} \quad [1]$$

From the subsequent decay of the pions ($\tau_{\pi^+} = 26.03$ ns), positive muons (μ^+) are formed via the two-body decay

$$\pi^+ \rightarrow \mu^+ + \nu_\mu \quad [2]$$

Since the neutrino has a helicity $h = -1$, both the neutrino and the μ^+ have their spin antiparallel to their momentum in the pion rest frame. According to the value of the pion momentum at the decay time, two types of μ^+-beams are available for μSR measurements.

The first type of muon beam is formed by the π^+ escaping the production target at high energies. They are collected over a certain solid angle by quadrupole magnets, and directed on to a decay section consisting of a long superconducting solenoid with a field of several tesla. If the pion momentum is not too high, a large fraction of the pions will have decayed before they reach the end of the solenoid. In the laboratory frame, the polarization of a high-energy muon beam is limited to $\sim$80%, and its energy is $\sim$40–50 MeV. Although such a high-energy beam requires the use of suitable moderators and samples with sufficient thickness, it guarantees a homogeneous implantation of the muons in the sample volume. Such beams are also used to study specimens inside recipients, for example, samples inside pressure cells.

The second type of muon beam is often called the "surface" or "Arizona" beam (recalling the pioneer works of Pfifer *et al.* from the University of Arizona). Here muons are used that arise from π^+ decaying at rest still inside, but near the surface, of the production target. Such muons, which are 100% polarized, ideally monochromatic, and have a very low momentum of 29.8 MeV c^{-1}, which corresponds to a kinetic energy of 4.1 MeV, have a range width in matter $\sim$180 mg cm^{-2}. Hence, the paramount advantage of this type of beam is the possibility of using relatively thin samples.

Finally, muon beams of even lower energy ("ultra-slow muons" with energy down to the eV–keV range) can be obtained by further reducing the energy of an Arizona beam using moderators, as a thin layer of a van der Waals gas frozen on a substrate. The tunable energy range of such muon beams corresponds to implantation depths in solids of less than a nanometer up to several hundred nanometers. Therefore, the study of magnetic properties as a function of the distance from the surface of the sample is possible.

In addition to the above-mentioned classification based on energy, muon beams are also divided according to the time structure of the particle accelerator, that is, continuous or pulsed.

For continuous muon beams, no dominating time structure is present. By selecting an appropriate muon incoming rate, muons are implanted into the sample one by one. The main advantage is that the time resolution is solely determined by the detector construction and the read-out electronics. There are two main limitations for this type of beam: (1) a non-negligible random background signal and (2) a rather limited muon incoming rate. Only the background problem can be overcome by using electrostatic deflectors to ensure that no muons enter the sample until the decay of the precedent muon has been observed.

For pulsed muon beams, protons hitting the production target are bunched into pulses which are also reflected on the secondary muon beam. The advantages of a pulsed muon beam are that, in principle, one can use the entire incoming muon intensity and there is almost no background due to accidental coincidences between the incoming muons and decay positrons. The absence of background allows the extension of the time window for measurements up to about $10 \times \tau_\mu$. The reverse of the medal is that the width of the muon pulse limits the time resolution.

μSR-Relevant Muon Properties

The main properties of the muon relevant to μSR are listed below:

- Charge: $+e$
  Since condensed matter physics or chemistry studies are carried out almost exclusively with positive muons, the following description will be limited to these muons (studies involving negative muons are primarily of interest to nuclear physicists).
- Magnetic moment: $3.183345118(89)\mu_p = 8.89059698(23)\mu_N$
- Gyromagnetic ratio: $\gamma_\mu = 2\pi \times 13.553882$ $(\pm 0.2$ ppm)kHz/gauss
  This large magnetic moment makes the muon an accurate magnetometer which can be implanted directly into a sample.
- Spin: 1/2
  The muon is free of quadrupolar interaction. Compared to NMR experiments, this simplifies

the analysis of the μSR spectra, with a reduced set of adjustable parameters.

- Mass: $m_\mu = 206.7682838(54) \times m_e = 0.112\ 609\ 526\ 9(29) \times m_p$.
  The muon can be considered as a light isotope of the proton.
- The decay of the muon into an electron and two neutrinos occurs via the weak interaction process after an average lifetime of $\tau_\mu = 2.19703(4)\ \mu$s:

$$\mu^+ \rightarrow e^+ + \nu_e + \bar{\nu}_\mu \qquad [3]$$

The parity violation in the weak interaction leads to an anisotropic distribution of the positron emission with respect to the spin direction of the μ^+ at the decay time. The positron emission probability is given by

$$W(\theta)\mathrm{d}\theta \propto (1 + \mathscr{A} \cos\theta)\mathrm{d}\theta \qquad [4]$$

where θ is the angle between the positron trajectory and the μ^+-spin, and $\mathscr{A}$ is an asymmetry parameter which depends on the polarization of the muon beam and positron energy. This anisotropic emission constitutes, in fact, the basics for the μSR technique.

The asymmetry of W is given by $\mathscr{A} = aP_\mu(0)$, where $P_\mu(0) = |\boldsymbol{P}_\mu(0)|$ is the beam polarization (~ 1), and a is an intrinsic asymmetry parameter determined by the weak decay mechanism. Theoretically, an average of $\langle a \rangle = 1/3$ is obtained if all emitted positrons are detected with the same efficiency irrespective of their energy. Practically, values of $\mathscr{A} \simeq 0.25$ are routinely obtained (**Figure 1**).

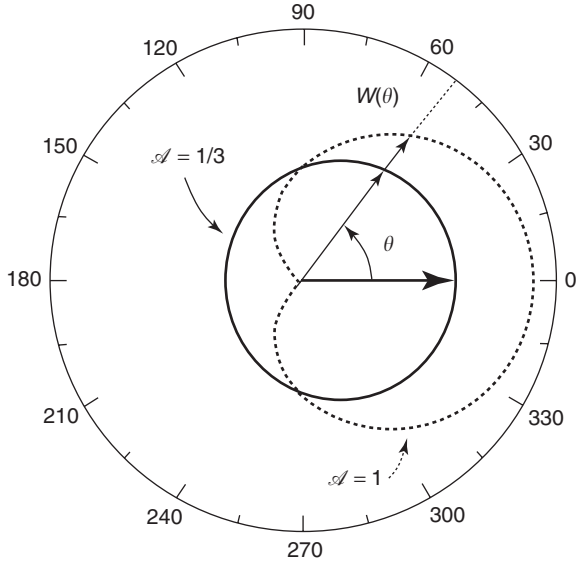

Figure 1 Polar diagram of the angular distribution $W(\theta)$ of positrons from muon decay: for the maximum positron energy (dotted line) and integrated over all positron energies.

Muon Implantation

The muons are implanted into the sample of interest where they lose energy very quickly. Fortunately, this deceleration process occurs in such a way that it does not jeopardize a μSR measurement. On one side it is very fast (~ 100 ps), which is much shorter than a typical μSR time window (up to 20 μs), and on the other side, all the processes involved during the deceleration are Coulombic (ionization of atoms, electron scattering, electron capture) in origin and do not interact with the muon spin, so that the muon is thermalized without any significant loss of polarization.

The muons invariably adopt interstitial sites of the crystallographic lattice. In metallic samples, the muon's positive charge is collectively screened by a cloud of conduction electrons. Thus, in metals, the muon is in a so-called diamagnetic state and behaves like a free muon. In insulators or semiconductors, a collective screening cannot take place and the muon will usually pick up one electron and form a so-called muonium ($\mathrm{Mu} = \mu^+ e^-$), which has size (Bohr radius), reduced mass, and ionization potential similar to the hydrogen atom.

The Technique

The Fundamentals

A schematic diagram of a μSR experiment is shown in **Figure 2**. Incoming muons trigger a clock that defines a time t_0. The trigger is defined either by the signal produced by the muon crossing a thin plastic detector located in front of the sample (continuous beam), or by the well-defined arrival time of a muon pulse (pulsed beams). If the implanted μ^+ are subject to magnetic interactions, their polarization becomes time dependent, $\boldsymbol{P}_\mu(t)$. Since the decay of the muon is asymmetric, the polarization of the muon ensemble can be deduced by measuring the positron distribution as a function of time in different detectors located around the sample. In the time-differential μSR technique, repeated measurements ($\sim 10^7$) are made of the time interval between the μ^+ implantation into the sample and the detection of the emitted positron in a particular direction, say, in the direction of the initial polarization $\boldsymbol{P}_\mu(0)$; the extension of the following discussion for other arbitrary directions of detection is straightforward.

The time histogram of the collected time intervals has the form

$$N_{e^+}(t) = B + N_0 \exp\left(-\frac{t}{\tau_\mu}\right) \times \left[1 + \mathscr{A}\,\frac{P_\mu(t)}{P_\mu(0)}\right] \qquad [5]$$

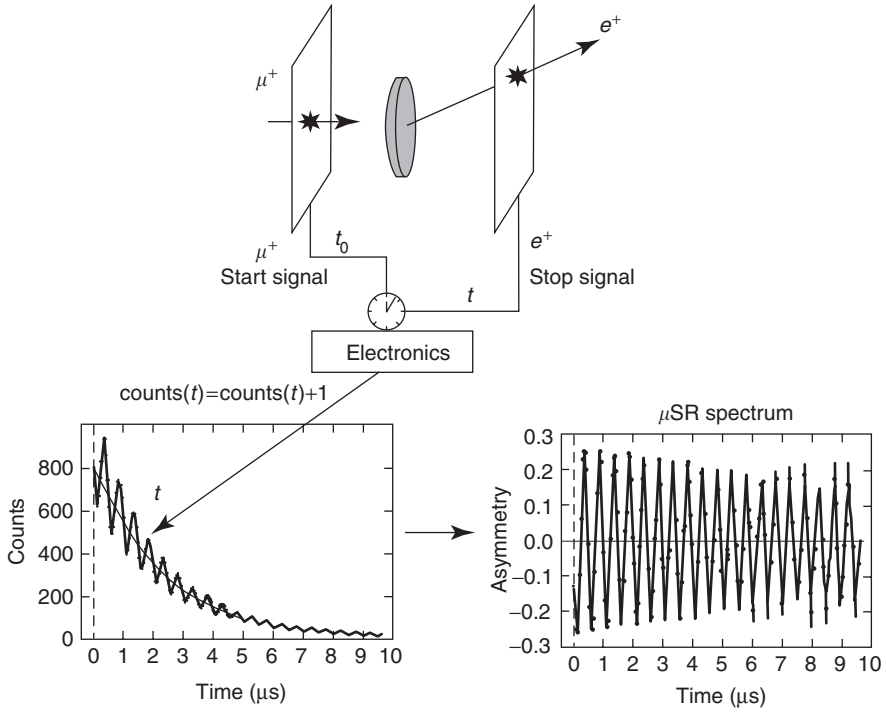

Figure 2 Schematic illustration of a μSR experiment. The arrival time t_0 of the muon is either given by a special detector (continuous beam, see figure) or by the arrival of a muon pulse (pulsed beams, not shown). The time between the muon arrival and the subsequent decay recorded by a positron emission at time t is used to build a rate vs. time histogram. By removing the exponential decay due to the muon lifetime and a possible background, one obtains the μSR signal reflecting the time dependence of the muon polarization.

where B is a time-independent background, N_0 is a normalization constant, and the exponential accounts for the decay of the μ^+. $P_\mu(t)$ is defined as the projection of $\boldsymbol{P}_\mu(t)$ along the direction of the initial polarization, that is, $P_\mu(t) = \boldsymbol{P}_\mu(t)$. $\boldsymbol{P}_\mu(0)/P_\mu(0) = G(t)P_\mu(0)$, where $G(t)$ reflects the normalized μ^+-spin auto-correlation function

$$G(t) = \frac{\langle \boldsymbol{S}(t) \cdot \boldsymbol{S}(0) \rangle}{S(0)^2} \qquad [6]$$

which depends on the average value, distribution, and time evolution of the internal fields, and therefore contains all the physics of the magnetic interactions of the μ^+ inside the sample. Equation [5] can therefore be written as

$$N_{e^+}(t) = B + N_0 \exp\left(-\frac{t}{\tau_\mu}\right)[1 + \mathscr{A}G(t)] \qquad [7]$$

where $\mathscr{A}G(t)$ is often called the μSR signal and the envelope of $G(t)$ is known as the μ^+-depolarization function. Since N_0 and B do not contain physical information about the sample investigated, usually only the μSR signal $\mathscr{A}G(t)$ is reported for a μSR measurement.

Precession and Relaxation

A first example is taken to understand the ability of the muon to study internal magnetic fields. The presence of a local internal field $\boldsymbol{B}_\mu$ (e.g., created by a magnetic state) at the muon stopping site is to be assumed. If the magnetic field is at an angle θ to the initial muon polarization, the muon will precess around a cone about the magnetic field (see **Figure 3**). The time evolution of the μ^+-polarization is therefore given by

$$G(t) = \cos^2\theta + \sin^2\theta \cos(\gamma_\mu B_\mu t) \qquad [8]$$

where $B_\mu = |\boldsymbol{B}_\mu|$ and the angular frequency $\gamma_\mu B_\mu$ is known as Larmor precession.

By assuming that the internal field is always perpendicular to the muon polarization (e.g., if an external field is applied), the first term on the right-hand side of eqn [8] disappears and a simple oscillation of the muon precession is observed (see **Figure 2**). On the other hand, if the internal field direction is entirely random (e.g., for spontaneous fields in a magnetic polycrystalline sample), then a simple averaging would yield

$$G(t) = \tfrac{1}{3} + \tfrac{2}{3}\cos(\gamma_\mu B_\mu t) \qquad [9]$$

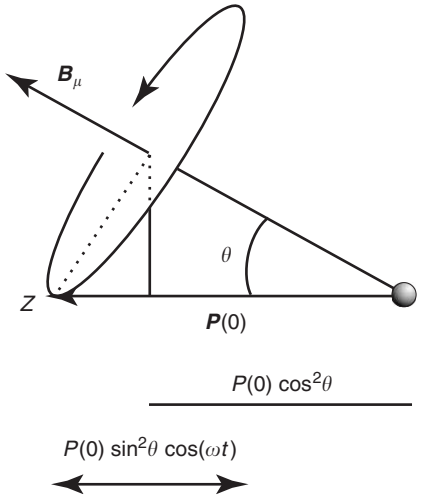

Figure 3 Muon-spin precession around an internal field B_μ at an angle θ. The wiggling and nonwiggling components of the polarization are schematically represented.

Considering the gyromagnetic ratio of the muon and a typical measurement time-window of 10–20 μs, tiny internal fields as low as 0.1 G can be detected by the μSR technique.

So far, a well-defined value of the internal field was assumed. But nature is of course more complicated and usually a distribution has to be considered. Such a distribution can arise from disorder, dynamics, or additional sources of internal field (as nuclear moments). In the case of static local magnetic fields, and assuming a magnetic field distribution function $f(\boldsymbol{B}_\mu)$, $G(t)$ is given by

$$G(t) = \int f(\boldsymbol{B}_\mu)[\cos^2\theta + \sin^2\theta\,\cos(\gamma_\mu B_\mu t)]\mathrm{d}\boldsymbol{B}_\mu \qquad [10]$$

In other words, the value of the Larmor precession observed in the μSR signal provides the value of the internal field, whereas the envelope of the signal provides information on the type and strength of the field distribution itself.

Hence, even field distributions centered around zero can be detected through a depolarization of the μSR signal. As an example, if the strength of the local magnetic field is taken from a Gaussian distribution with zero average, then one observes a signal

$$G(t) = \frac{1}{2} + \frac{2}{3}(1 - \Delta^2 t^2)\exp\left(-\frac{1}{2}\Delta^2 t^2\right) \qquad [11]$$

where Δ^2/γ_μ^2 represents the second moment of the field distribution along one Cartesian axis perpendicular to the initial μ^+-polarization, that is,

$$\Delta^2/\gamma_\mu^2 = \langle B_x^2 \rangle = \langle B_y^2 \rangle = \langle B_z^2 \rangle \qquad [12]$$

This relaxation function is often observed experimentally and reflects the field due to the neighboring nuclear dipoles, which are randomly oriented and considered static within the μSR time window.

Transverse-Field (TF) Technique

For this technique, an external field $\boldsymbol{H}_{\mathrm{ext}}$ is applied perpendicular to the initial muon polarization $\boldsymbol{P}_\mu(0)$. $\boldsymbol{P}_\mu(t)$ precesses around the total field $\boldsymbol{B}_\mu$ at the muon site, the value of which can be extracted from the oscillatory component of $G(t)$, recalling that the μ^+ frequency $\nu_\mu = \omega_\mu/2\pi = \gamma_\mu B_\mu/2\pi$ (see eqn [8]).

For a system which is not magnetically ordered, the total field at the muon site is given by

$$\boldsymbol{B}_\mu = \boldsymbol{H}_{\mathrm{ext}} + \boldsymbol{B}_{\mathrm{hf}} + (\boldsymbol{B}_{\mathrm{DF}} + \boldsymbol{B}_{\mathrm{LF}}) \qquad [13]$$

The last two terms are the demagnetization and Lorentz fields which can be easily calculated from the bulk magnetization and demagnetization tensor. $\boldsymbol{B}_{\mathrm{hf}}$ are the internal fields induced by $\boldsymbol{H}_{\mathrm{ext}}$.

The μ^+-frequency shift

$$K_\mu^* = \frac{|\boldsymbol{B}_\mu| - |\boldsymbol{H}_{\mathrm{ext}}|}{|\boldsymbol{H}_{\mathrm{ext}}|} = \frac{\omega_\mu}{\omega_{\mathrm{ext}}} - 1 \qquad [14]$$

(where $\omega_{\mathrm{ext}} = \gamma_\mu|\boldsymbol{H}_{\mathrm{ext}}| \equiv \gamma_\mu H_{\mathrm{ext}}$) can be corrected for the contributions of $\boldsymbol{B}_{\mathrm{DF}}$ and $\boldsymbol{B}_{\mathrm{LF}}$ to furnish the μ^+-Knight shift K_μ which, as in NMR, contains the relevant information about the hyperfine fields, and therefore about the local susceptibility. In addition, the knowledge of the μ^+-Knight shift provides valuable indication concerning the type of interstitial site occupied by the muon in the crystallographic lattice.

In addition, the TF technique allows one to gain more insight into the inhomogeneous field distribution at the muon site caused by static fields and into the presence of $1/T_2$ processes responsible for homogeneous line broadening.

Zero-Field (ZF) and Longitudinal-Field (LF) Techniques

With the ZF technique, one monitors the time evolution of the muon ensemble under the action of internal magnetic fields. This technique is widely utilized to measure the spontaneous μ^+-Larmor frequencies in magnetically ordered phases, providing information about the values of the static moment and the type of magnetic structures (see, e.g., eqn [9]). The observation of spontaneous μ^+-frequencies is, however, limited to systems where the presence of

static electronic moments produces well-defined local fields at the μ^+-stopping site. Hence, the μ^+-spin autocorrelation function $G(t)$ depends sensitively on details of the magnetic structure and of course on the μ^+-stopping site.

In a ZF experiment, a depolarization can occur due to the presence either of a static distribution of internal fields arising from static nuclear or electronic dipole fields (see eqn [11]), or of a time dependence of the internal fields at the muon site. This time dependence may arise from a fluctuation of the magnetic moments or from muon diffusion. For fast fluctuation (diffusion) the depolarization function will no more assume a Gaussian character at early times, but will be given by

$$G(t) = \exp(-\lambda t), \quad \lambda = 2\Delta^2\tau \qquad [15]$$

where τ represents the characteristic fluctuation (diffusion) time.

In an LF configuration (i.e., $\boldsymbol{H}_{\text{ext}}||\boldsymbol{P}_\mu(0)$), by choosing $\boldsymbol{H}_{\text{ext}}$ to be stronger than the internal fields, the muon's states "up" and "down" are eigenstates of the Zeeman Hamiltonian and any inhomogeneous (static) distribution of the internal fields will not affect the time evolution of the μ^+-polarization, which will remain constant. This behavior reflects the decoupling of the μ^+-spin from the static internal fields. Hence, to pinpoint the origin of the depolarization, decoupling experiments in a longitudinal field are routinely performed.

μSR and Condensed Matter

The aim of this section is to present some aspects of the application of μSR in a condensed matter. The interested reader is referred to more complete review articles.

Magnetism

There are several advantages in using the μSR technique to study magnetic systems.

- As said, due to the large muon magnetic moment, the technique is sensitive to extremely small internal fields, and therefore can probe local magnetic fields which can be nuclear or electronic in nature.
- The local probe character of the muon makes μSR very sensitive to spatially inhomogeneous magnetic properties. Hence, the occurrence of different phases in the sample will be reflected by different components in the μSR signal, that is,

$$\mathcal{A}G(t) = \sum_i \mathcal{A}_i G_i(t) \qquad [16]$$

  A careful analysis of the amplitude $\mathcal{A}_i$ of these components furnishes a direct measure of the fraction of the sample involved in a particular phase (with the condition $\sum_i \mathcal{A}_i = \mathcal{A}$). Similarly, μSR is a powerful tool when the magnetic order is of short range and/or random nature where neutron experiments will fail. In addition, the μSR technique can be utilized to check the coexistence of different types of ground states at the microscopic level.
- In magnetic phases, the possibility given by μSR to extract independently the value of the ordered static moment and the sample volume involved in the magnetic phase allows one to overcome a shortcoming of other techniques (such as the neutron scattering technique), for which these two parameters are strongly coupled, therefore hampering their absolute determination.

Organic magnets constitute a typical example of the application of the μSR technique to study magnetic phenomena. It is well known that neutron scattering can provide extensive information on magnets, in particular, on the magnetic structure and on the excitations. But in compounds with small magnetic moments such as the organic magnets, the μSR technique is a sensitive and useful probe: it easily yields the value of the critical temperature and information on the thermal behavior of the order parameter. Hence, the first direct observation of spontaneous magnetic order in the system para-nitrophenyl nitronyl nitroxide (*p*-NPNN) was made using the μSR technique, and has been subsequently confirmed by neutron diffraction.

Figure 4 exhibits the zero-field muon spin rotation frequency in the organic ferromagnet *p*-NPNN, which orders only at very low temperatures ($T_C = 0.67$ K. The temperature dependence of the frequency of oscillations is a direct measure of the temperature dependence of the internal magnetization, that is, of the ferromagnetic order parameter.

Superconductors

An important research area of recent μSR studies is the characterization of the superconducting state.

Meissner state For a superconducting sample in the Meissner state, diamagnetic shielding currents flowing close to the sample surface screen a static magnetic field from the interior of the body. Near the sample surface, the magnetic field falls off exponentially with distance over a characteristic length scale λ, called the "magnetic penetration depth." Inversely, the superconducting order parameter increases and is

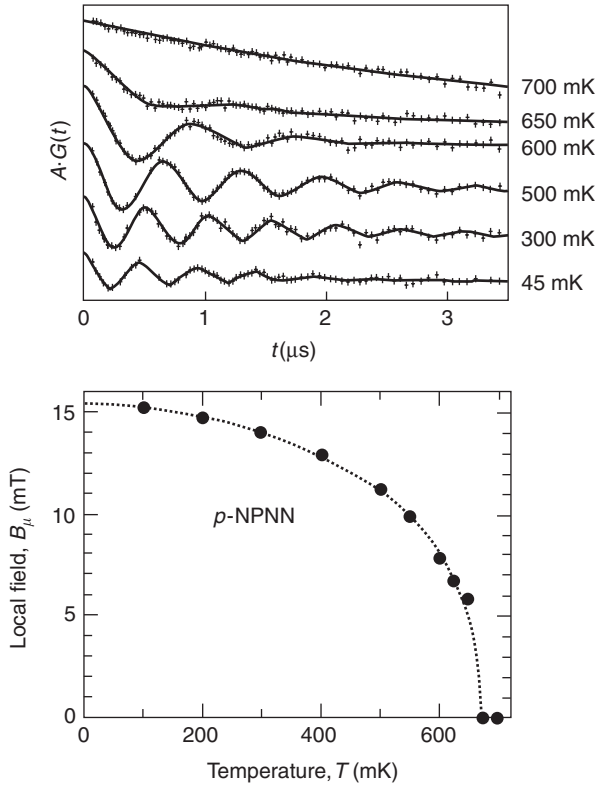

Figure 4 Zero-field muon-spin rotation frequency in the organic ferromagnet *p*-NPNN (Reproduced with permission from Blundell SJ (1999) Spin-polarized muons in condensed matter physics. *Contemporary Physics* 40: 175.) and temperature dependence of the local field at the muon site deduced from the observed frequency.

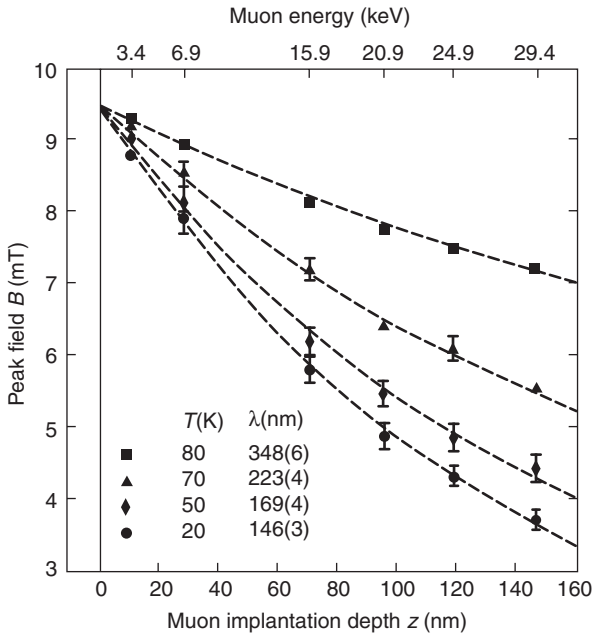

Figure 5 Values of field vs. depth measured in a high-T_c sample ($YBa_2Cu_3O_{7-\delta}$) for various values of temperature. The muon implantation depth is changed by tuning the kinetic energy of the muons. (Reproduced with permission from Jackson TJ, Riseman TM, Forgan EM, Glückler H, Prokscha T, *et al.* (2000) Depth resolved profile of the magnetic field beneath the surface of a superconductor with a few nm resolution. *Physical Review Letters* 84: 4958.)

characterized by the coherence length ξ which controls the length scale over which the superconducting order parameter can vary near the surface without undue energy cost. In the limit where the penetration depth is much larger than the coherence length ξ, and where the mean free path for scattering of the normal electrons $l \gg \xi$, a magnetic field applied parallel to the surface of a semi-infinite superconducting slab in the Meissner state decays with depth z according to the exponential decay law

$$B(z) = B \exp(-z/\lambda) \qquad [17]$$

Although generally accepted, such a law was only very recently confirmed on a high-T_c system ($YBa_2Cu_3O_{7-\delta}$) by using low-energy muons. In this experiment, muons were implanted at several different depths in the superconducting film, by adjusting their kinetic energy (**Figure 5**). Therefore, the internal field $B(z)$ could be measured directly as a function of depth, and the validity of eqn [17] could be verified experimentally for the first time. In contrast, with bulk experiments, such as magnetization, or even μSR using usual muons, the funtional form of eqn [17] is assumed when appropriate, and the magnetic penetration depth is extracted. This direct determination illustrates the power of low-energy muons for near surface studies in superconductivity and magnetism.

Vortex state It is well known that for a type-II superconductor in the mixed (or vortex) phase, an applied magnetic field $H_{c1} < H < H_{c2}$ enters the superconductor in the form of quantized flux lines or vortices arranged into a lattice, usually hexagonal. Each vortex contains one quantum of flux $\Phi_0 = h/2e$, and the distance d between vortices is, except at very high magnetic fields, much larger than the unit-cell dimensions (given for a hexagonal vortex-lattice by the relation $d^2 = 2\Phi_0/\sqrt{3}B$). Outside the core region of a vortex, the magnetic field falls off exponentially with distance over a characteristic penetration depth λ (see above). Since the implanted muons sit at certain crystallographic sites and since the vortex lattice is incommensurate with the crystal lattice, the muon ensemble will randomly sample the field distribution of the vortex lattice (see **Figure 6**). This field distribution will create a dephasing of the muon polarization, reflected by a relaxation of the μSR signal. Assuming a Gaussian

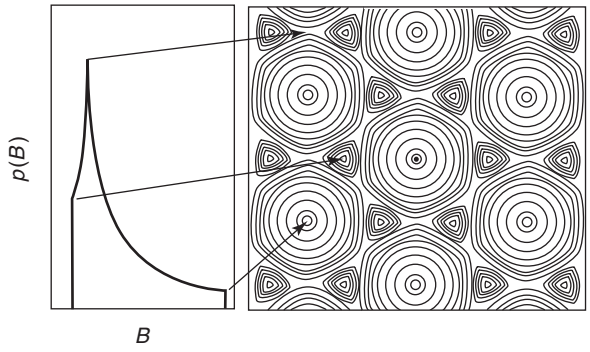

Figure 6 Schematic field distribution in a type-II superconductor in the mixed (vortex) state. The right-hand side of the figure represents a contour plot of the field *B*. (Reproduced with permission from Blundell SJ (1999) Spin-polarized muons in condensed matter physics. *Contemporary Physics* 40: 175.)

relaxation of the signal, the relaxation rate of the observed precession signal is related to the penetration depth λ by

$$\sigma = \gamma_\mu \langle B^2(\boldsymbol{r}) - \langle B(\boldsymbol{r}) \rangle^2 \rangle^{1/2} = \frac{0.0609 \gamma_\mu \Phi_0}{\lambda^2} \quad [18]$$

where $B(\boldsymbol{r})$ is the field at position **r**, and the averages are taken over all positions. Therefore, the relaxation rate σ of the μSR precession signal is a measure of the magnetic penetration depth. Its temperature dependence yields valuable information concerning the symmetry of the superconducting gap and therefore about the pairing mechanism. In addition to the determination of the magnetic penetration depth, a detailed analysis of the data provides information about the coherence length ξ.

Semiconductors

As said, implanted into semiconductors and insulators, the muon often picks up an electron and forms muonium. Muonium can exist in three charge states: Mu^0, Mu^+, and Mu^- which correspond to the three distinct charge states of isolated hydrogen: H^0, H^+, and H^-. This opens new directions of investigation as the behavior of muonium provides important information on the charge state, lattice site, and dynamics of its hydrogen analog. For example, implanted in silicon, neutral muonium has been observed at the tetrahedral site (T) and at a bond-centered (BC) site between two silicon atoms (**Figure 7**). While the muonium at the T site was found to be mobile, and rapidly diffusing between such sites, the BC muonium is stationary. The electronic state in the

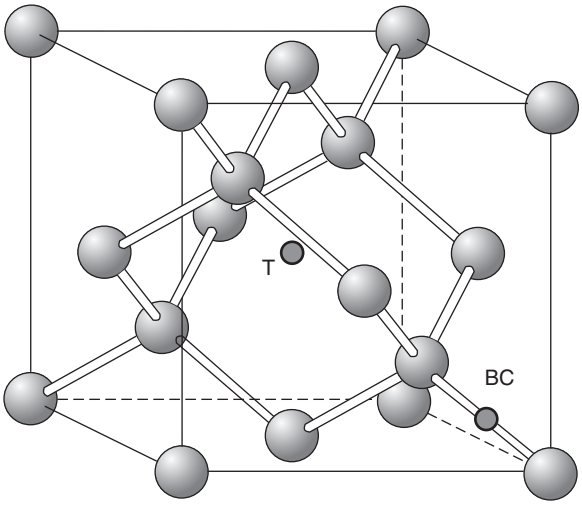

Figure 7 The crystal structure of silicon, showing the possible muonium (and therefore hydrogen) sites (T = tetrahedral site, BC = bond-center site).

T site is isotropic, whilst it is highly anisotropic for the BC site, with axial symmetry along the Si–Si bond. Such site characterization appears rather important since hydrogen is present, as an impurity, in all semiconductors but its low concentration makes it difficult to be investigated using direct spectroscopical methods. In addition, hydrogen is able to passivate dangling bounds known to be present at grain boundaries in the promising new multicrystalline Si photovoltaic cells.

In certain II–VI compounds, on the other hand, it appears that hydrogen may instead act as a shallow donor – in other words, it could be used as a dopant in its own right. This has important implications for the electronic properties of new wide-gap materials, now under development for optoelectronic applications. The most recent and compelling evidence for these shallow donor states comes from studies not of hydrogen itself but of its pseudo-isotope, muonium. Such results are particularly significant in that they confirm recent theoretical predictions.

Introduction

At the atomic scale, electronic states are typically characterized by discrete energy levels that are often separated by electron volts; the spatial distribution of these states is highly localized. In contrast, electronic states in crystalline matter are typically characterized by energy bands: the energy states form a quasicontinuous spectrum with delocalized spatial distributions. At the nanoscale, the distribution of energy states resides between these limits. This evolution of energy levels from an atom to large clusters to "quantum dots" is illustrated in **Figure 1**. A large cluster in this scheme may possess hundreds or thousands of atoms. When its surface is electronically passivated, such large clusters are called quantum dots. While the energy spacing between electronic levels in a quantum dot is not quasicontinuous, it is usually too small to be measured. For example, the spacing may be much smaller than the thermal energy associated with a vibrational mode.

Understanding the evolution of the electronic structure of matter at the nanoscale is a challenging task. Matter at this length scale is not especially amenable to techniques based on atomic or macroscopic descriptions, as the spatial and energetic distribution of electron states are quite disparate. Methods for calculating the electronic properties of these systems usually start from either the atomic or molecular limit or from the solid-state limit. Atomic or molecular methods are often not equipped to handle the large number of atoms or electrons in nanoscale materials whereas solid-state methods often require translational symmetry, which is not present for confined systems. Moreover, the electronic interactions and spatial extent of wave functions at the nanoscale can be remarkably different than either the atomic or macroscopic limit.

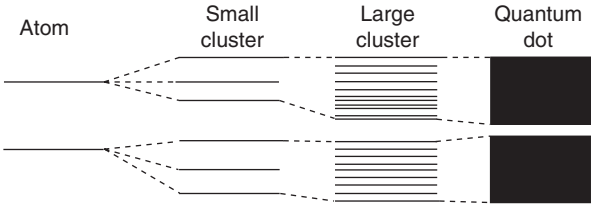

Figure 1 Schematic energy levels for an atom, a cluster, and a quantum dot.

An electron confined within a one-dimensional box of size a is considerd. The lowest energy level of this system is given in elementary textbooks as

$$E = \frac{\pi^2 \hbar^2}{2ma^2} \qquad [1]$$

where $\hbar$ is the Planck constant divided by 2π, and m is the mass of the particle, for example, the mass of an electron. If the size of the box is reduced, then E increases.

This phenomenon, that is, the energy level spacing increasing with reduced dimensionality, is called quantum confinement. Quantum confinement can be readily understood from the Heisenberg uncertainty principle. The uncertainty principle states that the uncertainty in momentum and position must be such that the product exceeds $\hbar/2$:

$$\Delta p \cdot \Delta x \geqslant \frac{\hbar}{2} \qquad [2]$$

where Δp is the uncertainty in the momentum and Δx is the uncertainty in the position of the electron. Consider the energy of a free electron with momentum p:

$$E = \frac{p^2}{2m} \qquad [3]$$

Since the uncertainty in the momentum cannot exceed the momentum itself, one can write $p > \Delta p$. As such, one has the following inequality:

$$E > \frac{\hbar^2}{8ma^2} \qquad [4]$$

If one tries to localize the position of an electron by reducing the box size, its energy must increase and diverge as the confining region vanishes.

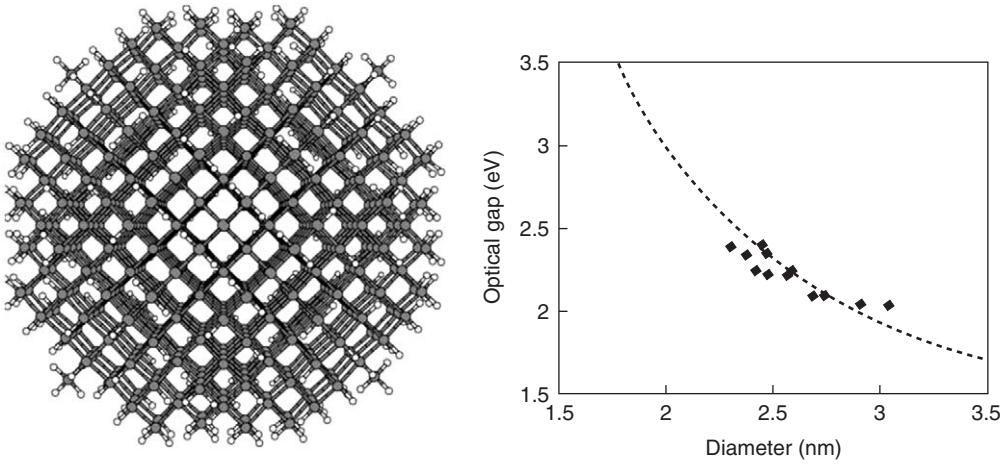

Figure 2 Ball and stick model for a quantum dot of hydrogenated silicon (left). The gray balls represent the silicon atoms, the white balls represent the hydrogens. Also shown is the corresponding optical absorption. Note the increase in gap size from the known bulk gap of silicon, which is 1.1 eV.

Although this very simple picture of quantum confinement is given for one dimension, it is also true for an electron confined in three dimensions. For example, if a particle is confined within a sphere whose radius is R, one might expect an energy level to vary with the radius according to

$$E(R) = E_\infty + \frac{\alpha}{R^2} \qquad [5]$$

where α is a constant and E_∞ is the energy as $R \to \infty$. Suppose one considers an optical gap, E_{gap}, as the difference between the high filled and lowest empty states for a system confined in a sphere of size R. In the simplest description of the gap, one might expect E_{gap} to scale as

$$E_{\text{gap}}(R) = E_{\text{gap}} + \frac{\beta}{R^2} \qquad [6]$$

where β is a constant.

Quantum confinement has been observed experimentally for nanostructures such as quantum dots of Si and CdSe. In **Figure 2**, a quantum dot of hydrogenated silicon is illustrated. The interior of the dot consists of silicon atoms in the bulk diamond structure; the surface of the dot is hydrogenated. Hydrogen removes any dangling bonds on the surface. As such, all the atoms in the system should be fully coordinated and should not contribute to the electronic properties of the quantum dot. Typically, a quantum dot is a few nanometers to tens of nanometers in size. The smallest dots contain hundreds of atoms whereas large dots may contain hundreds of thousands of atoms.

Also illustrated in **Figure 2** is the corresponding optical gap as a function of the dot size. The quantum dot gap with this size range is approximately twice the gap of crystalline silicon; silicon exhibits weak optical absorption near 1.1 eV. The absorption is weak owing to the nature of the gap in silicon. It is an indirect gap because the optical excitation couples an electron with a hole of different crystalline momentum or wave vector. Conservation of crystal momentum would require the electron and hole to have the same momentum. As such, this process can only occur by the participation of the quantized vibrational modes of the lattice or phonons, which provide the required momentum to satisfy the conservation rules. Unlike a two-body process (electron and hole), a three-body process (electron, hole, and phonon) results in a very weak interaction between light and matter.

In finite systems, crystal momentum is not well defined, owing to the lack of translation symmetry. As the system approaches nanoscale sizes, the nature of an indirect gap or direct gap becomes moot. Consequently, the optical absorption becomes stronger in quantum dots and the size of the gap increases owing to quantum confinement. An approximate fit of eqn [6] is consistent with the experimental data shown in **Figure 2**. This example shows the striking effect of size on the electronic structure of nanostructures, that is, silicon at this length scale is transformed from an optical inactive material to an optically active one.

Theory for the Electronic Structure at the Nanoscale

Quantum mechanical laws that describe the behavior of matter at the nanoscale were discovered in the first

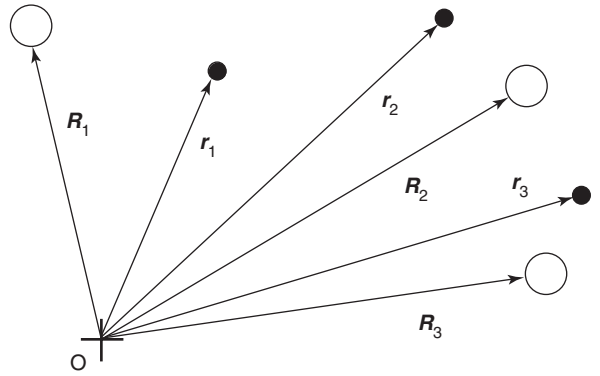

Figure 3 Simplified picture of electrons and nuclei in matter.

part of the twentieth century. Using these laws, it is possible to predict the electronic structure of matter from the atomic- to nano- to the macroscale, at least in principle. While it is relatively easy to write down the equations for interacting atoms, that is, interacting nuclei and electrons, obtaining a solution to the problem that is sufficiently accurate to make predictions is a formidable task.

Consider N nuclei of charge Z_n at positions $\{\boldsymbol{R}_n\}$ for $n = 1, \ldots, N$ and M electrons at positions $\{\boldsymbol{r}_i\}$ for $i = 1, \ldots, M$. This is shown schematically in **Figure 3**. The quantum mechanical equation for this system in its simplest form can be written as

$$\begin{aligned}\mathscr{H}(\boldsymbol{R}_1, \boldsymbol{R}_2, \boldsymbol{R}_3, \ldots; \boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3 \ldots) &= \sum_{n=1}^{N} \frac{-\hbar^2 \nabla_n^2}{2\mathscr{M}_n} + \frac{1}{2} \sum_{n,m=1, n\neq m}^{N} \frac{Z_n Z_m e^2}{|\boldsymbol{R}_n - \boldsymbol{R}_m|} \\ &\quad - \sum_{i=1}^{M} \frac{\hbar^2 \nabla_i^2}{2m} - \sum_{n=1}^{N} \sum_{i=1}^{M} \frac{Z_n e^2}{|\boldsymbol{R}_n - \boldsymbol{r}_j|} \\ &\quad + \frac{1}{2} \sum_{i,j=1, i\neq j}^{M} \frac{e^2}{|\boldsymbol{r}_i - \boldsymbol{r}_j|} \end{aligned} \quad [7]$$

$\mathscr{M}_n$ is the mass of the nucleus. This expression omits some terms such as those involving relativistic interactions, but captures the essential features for nanoscale matter.

Using the Hamiltonian in eqn [7], the quantum mechanical equation known as the Schrödinger equation for the electronic structure of the system can be written as:

$$\begin{aligned}&\mathscr{H}(\boldsymbol{R}_1, \boldsymbol{R}_2, \boldsymbol{R}_3, \ldots; \boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3 \ldots) \\ &\quad \times \Psi(\boldsymbol{R}_1, \boldsymbol{R}_2, \boldsymbol{R}_3, \ldots; \boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3 \ldots) \\ &\quad = E\Psi(\boldsymbol{R}_1, \boldsymbol{R}_2, \boldsymbol{R}_3, \ldots; \boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3 \ldots)\end{aligned} \quad [8]$$

where E is the total electronic energy of the system and Ψ is the many-body wave function.

Soon after the discovery of the Schrödinger equation, it was recognized that this equation provided the means of solving for the electronic and nuclear degrees of freedom. Using the variational principle which states that an approximate wave function will always have a less favorable energy than the true ground-state energy, one had an equation and a method to test the solution. One can estimate the energy from

$$E = \frac{\int \Psi^* \mathscr{H} \Psi \mathrm{d}^3 R_1 \mathrm{d}^3 R_2 \mathrm{d}^3 R_3 \ldots \mathrm{d}^3 r_1 \mathrm{d}^3 r_2 \mathrm{d}^3 r_3 \ldots}{\int \Psi^* \Psi \mathrm{d}^3 R_1 \mathrm{d}^3 R_2 \mathrm{d}^3 R_3 \ldots \mathrm{d}^3 r_1 \mathrm{d}^3 r_2 \mathrm{d}^3 r_3 \ldots} \quad [9]$$

However, a solution of eqn [8] for anything more complex than a few particles becomes problematic even with the most powerful computers. Obtaining an approximate solution for systems with many atoms is difficult, but considerable progress has been made since the advent of reliable computers.

Approximations to the Electronic Structure Problem

A number of highly successful approximations have been made to solve for both the ground-state and excited-state energies of matter. These approximations are constructed to remove as many unimportant degrees of freedom from the system as possible.

For example, one common approximation is to separate the nuclear and electronic degrees of freedom. Since the nuclei are considerably more massive than the electrons, the electrons will respond instantaneously to any changes in the nuclear coordinates. This approximation is called the Born–Oppenheimer or adiabatic approximation. It allows one to treat the nuclear coordinates as classical parameters. For most condensed matter systems, this assumption is highly accurate.

Another highly useful approximation is the pseudopotential approximation. The pseudopotential model of a solid has led the way in providing a workable model for computing the electronic properties of materials. Using pseudopotentials, it is possible to predict accurately the properties of complex nanosystems such as quantum dots with hundreds, if not thousands of atoms. The pseudopotential model treats matter as a "sea of valence electrons" moving in a background of ion cores (**Figure 4**). The ion cores are composed of nuclei and inert inner electrons. Within this model, many of the complexities of an all-electron calculation are avoided. Since only the valence electrons are considered, a group IV solid such as C with six electrons is no more difficult than Pb with 82 electrons as both elements have four valence electrons.

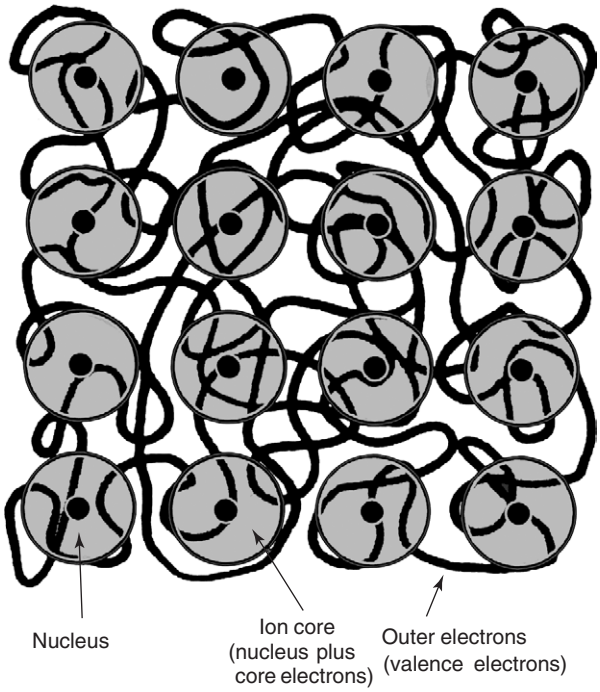

Figure 4 Schematic of the pseudopotential model of condensed matter.

Pseudopotential calculations center on replicating the wave function in the spatial region from the core, that is, within the chemically active bonding region. The smoothly varying pseudo-wave-function is taken to be identical to the all-electron wave function in the bonding regions.

A third approximation is based on the density-functional theory. Methods for understanding the electronic structure of matter based on a knowledge of the charge density have existed since the late 1920s. For example, the Thomas–Fermi description of atoms was based on a knowledge of the electronic density. This theory was one of the first attempts at a quantitative theory for the electronic structure of atoms.

Most contemporary treatments of the density-functional theory begin by considering a free electron gas of uniform charge density. The justification for this starting point comes from the observation that simple metals, such as aluminum and sodium have properties that appear to resemble those of a free electron gas. In the mid 1960s, Hohenberg, Kohn, and Sham published a classic set of papers on the density-functional theory. Their work justified the replacement of the many-body wave function by one-electron orbitals based on the electronic charge density.

A key aspect of their work is the local density approximation. Within this approximation, one can express the exchange energy as

$$E_x[\rho(\boldsymbol{r})] = \int \rho(\boldsymbol{r})\mathscr{E}_x[\rho(\boldsymbol{r})]\mathrm{d}^3r \qquad [10]$$

where $\mathscr{E}_x[\rho]$ is the exchange energy per particle of uniform gas at a density of ρ. Within this framework, the true exchange potential is replaced by a potential determined from the functional derivative of $E_x[\rho]$:

$$V_x[\rho] = \frac{\delta E_x[\rho]}{\delta\rho} \qquad [11]$$

One serious issue is the determination of the exchange energy per particle, $\mathscr{E}_x$, or the corresponding exchange potential, V_x. The exact expression for either of these quantities is unknown, save for special cases. If one assumes the exchange energy to be given by the Hartree–Fock expression for the exchange energy of the free electron gas, then one can write

$$E_x[\rho] = -\frac{3e^2}{4\pi}(3\pi^2)^{1/3}\int[\rho(\boldsymbol{r})]^{4/3}\mathrm{d}^3r \qquad [12]$$

and taking the functional derivative, one obtains

$$V_x[\rho] = -\frac{e^2}{\pi}(3\pi^2\rho(\boldsymbol{r}))^{1/3} \qquad [13]$$

In contemporary theories, numerical studies have been performed on uniform electron gases resulting in local density expressions of the form: $V_{xc}[\rho(\boldsymbol{r})] = V_x[\rho(\boldsymbol{r})] + V_c[\rho(\boldsymbol{r})]$, where V_c represents contributions to the total energy beyond the Hartree–Fock limit. It is also possible to describe the role of spin explicitly by considering the charge density for up and down spins: $\rho = \rho_\uparrow + \rho_\downarrow$. This approximation is called the local spin density approximation.

The Kohn–Sham Equation

The work of Kohn and Sham resulted in a workable framework for the electronic structure problem. Specifically, the Kohn–Sham equation for the electronic structure of matter is given by

$$\left(\frac{-\hbar^2\nabla^2}{2m} + V_p^{\mathrm{ion}}(\boldsymbol{r}) + V_H(\boldsymbol{r}) + V_{xc}[\rho(\boldsymbol{r})]\right) \times \phi_i(\boldsymbol{r}) = E_i\phi_i(\boldsymbol{r}) \qquad [14]$$

V_p^{ion} is the ion core pseudopotential, V_H is the Hartree or Coulomb potential, and V_{xc} is the exchange–correlation potential. The Hartree potential

is obtained from

$$\nabla^2 V_{\mathrm{H}}(\boldsymbol{r}) = -4\pi e\rho(\boldsymbol{r}) \quad [15]$$

where the charge density is given by

$$\rho(\boldsymbol{r}) = -e \sum_{i,\mathrm{occup}} |\phi_i(\boldsymbol{r})|^2 \quad [16]$$

The summation is over occupied states. When pseudopotentials are employed, these states correspond to the valence states of the system.

The Kohn–Sham equation is solved self-consistently. An approximate charge is assumed to estimate the exchange–correlation potential and to determine the Hartree potential from eqn [15]. These estimated potentials are inserted in the Kohn–Sham equation. Once the Kohn–Sham equation is solved, a new output charge density is determined from eqn [16]. The output charge density is used to estimate new exchange–correlation and Hartree potentials. The process is repeated until the input and output charge densities or potentials are identical to within some prescribed tolerance.

Given a solution of the Kohn–Sham equation, the total energy, E_{T}, can be computed from

$$E_{\mathrm{T}} = \sum_i^M E_i - 1/2 \int \rho(\boldsymbol{r}) V_{\mathrm{H}}(\boldsymbol{r}) \mathrm{d}^3 r + \int \rho(\boldsymbol{r})(E_{\mathrm{xc}}[\rho(\boldsymbol{r})] - V_{\mathrm{xc}}[\rho(\boldsymbol{r})])\mathrm{d}^3 r \quad [17]$$

where E_{xc} is a generalization of eqn [10], that is, the correlation energy density is included. The electronic energy as determined from E_{T} must be added to the ion–ion interactions to obtain the structural energies. This is a straightforward calculation for confined systems.

Owing to its ease of implementation and overall accuracy, the local density approximation is a popular choice for describing the electronic structure of matter. It is relatively easy to implement and surprisingly accurate. Recent developments have included the so-called generalized gradient corrections to the local density approximation. The generalized gradient approximation often yields accurate cohesive energies.

Computational Approaches for Nanostructures

Several methods exist for determining the electronic structure of nanostructures. These methods are often based on choosing a basis set for the electronic wave functions and directly solving the Kohn–Sham equation. For example, the wave functions can be expanded as

$$\Psi_n(\boldsymbol{r}) = \sum_{jk} a_{j,k}(n)\Phi_j(\boldsymbol{r} - \boldsymbol{R}_k) \quad [18]$$

where the sum is over (j, k). These indices label the atomic positions, given by $\boldsymbol{R}_k$, and a local orbital, Φ_j, associated with an (s, p, d, …) state. The local orbitals, Φ_j, can be taken to be atomic orbitals, Gaussians, exponentials, and so on. With the form of eqn [18] as the basis, the eigenvalue problem takes the form of the matrix equation:

$$\mathbb{H}^{\mathrm{KS}}\boldsymbol{\Psi}_n = E_n \mathbb{S}\boldsymbol{\Psi}_n \quad [19]$$

where the Hamiltonian matrix elements, $H_{\mathrm{lm}}^{\mathrm{KS}}$, are given by

$$H_{\mathrm{lm}}^{\mathrm{KS}} = \sum_{jkj'k'} a_{j,k}^*(l) a_{j',k'}(m) \int \Phi_j^*(\boldsymbol{r} - \boldsymbol{R}_k) \times H^{\mathrm{KS}} \Phi_{j'}(\boldsymbol{r} - \boldsymbol{R}_{k'})\mathrm{d}^3 r \quad [20]$$

and the overlap matrix elements, S_{lm}, is given by

$$S_{\mathrm{lm}} = \sum_{jkj'k'} a_{j,k}^*(l) a_{j',k'}(m) \int \Phi_j^*(\boldsymbol{r} - \boldsymbol{R}_k) \times \Phi_{j'}(\boldsymbol{r} - \boldsymbol{R}_{k'})\mathrm{d}^3 r \quad [21]$$

The Kohn–Sham Hamiltonian is given as in eqn [14]:

$$H^{\mathrm{KS}} = \frac{-\hbar^2\nabla^2}{2m} + V_{\mathrm{p}}^{\mathrm{ion}}(\boldsymbol{r}) + V_{\mathrm{H}}(\boldsymbol{r}) + V_{\mathrm{xc}}[\rho(\boldsymbol{r})] \quad [22]$$

The matrix elements can be computed directly if H^{KS} is specified. Otherwise, the matrix elements can be fit to experiment. Once the matrix elements are specified, the eigenvalue and eigenfunctions can be found using standard matrix operation packages.

Methods using local orbitals can be very efficient for nanostructures. If the local orbital expansion is restricted to a small number of orbitals, the size of the matrix in eqn [19] can be quite tractable.

Another option is to use a plane wave basis instead of a localized basis, such as a set of Gaussian orbitals. In the case of a plane wave basis, pseudopotentials play a crucial role. The pseudopotential can be expanded using a rapidly converging set of plane waves. Likewise, no cusps are present in the wave functions allowing a much smaller set of plane waves than would be sufficient to converge the all-electron wave function. The plane wave basis can be

written as

$$\Psi_{n,k'}(\boldsymbol{r}) = \sum_{G} a_G(n) \exp(\mathrm{i}(\boldsymbol{k} + \boldsymbol{G}) \cdot \boldsymbol{r}) \qquad [23]$$

$\boldsymbol{k}$ is a wave vector as for a Bloch state in a crystal and $\boldsymbol{G}$ is a reciprocal lattice vector. The reciprocal lattice vectors are defined by the size and shape of the crystalline unit cell. They are defined such that

$$\exp(\mathrm{i}\boldsymbol{G} \cdot \mathscr{R}) = 1 \qquad [24]$$

where $\mathscr{R}$ is a lattice vector.

A plane wave basis is a well-known and utilized instrument for calculating the electronic structure of crystalline matter. Methods based on a plane wave basis can be implemented for localized systems such as a quantum dot by retaining an artificial periodic system, for example, by placing the system of interest in a large unit cell, or supercell. Provided the cell size is sufficiently large, the solution of the problem results in the electronic structure of the isolated quantum dot. This method is very easy to implement and has been employed for systems of several thousand atoms. A significant complication concerns charged systems. In this case, the supercell is not neutral and the net charge on the system diverges. Compensating background charges are sometimes used to overcome this problem.

It is also possible to solve the Kohn–Sham equations without the use of an explicit basis. One approach is to solve the eigenvalue problem in real space where a grid serves the role of a basis. The real space method is highly advantageous over the plane wave method in a number of respects. Real space methods do not require supercells, and as a consequence, can be employed to examine charged systems without adding compensating backgrounds.

Real space methods for nanostructures are often based on a three-dimensional cubic grid. The Kohn–Sham equation can be discretized via a higher-order finite differencing procedure over the grid to yield

$$\begin{aligned} -\frac{\hbar^2}{2m}\Bigg[& \sum_{n_1=-M}^{M} C_{n_1}\psi_n(x_i + n_1 h, y_j, z_k) \\ & + \sum_{n_2=-M}^{M} C_{n_2}\psi_n(x_i, y_j + n_2 h, z_k) \\ & + \sum_{n_3=-M}^{M} C_{n_3}\psi_n(x_i, y_j z_k + n_3 h)\Bigg] \\ & + [V_{\mathrm{ion}}(x_i, y_j, z_k) + V_{\mathrm{H}}(x_i, y_j, z_k) \\ & + V_{\mathrm{xc}}(x_i, y_j, z_k)]\psi_n(x_i, y_j, z_k) \\ & = E_n\psi_n(x_i, y_j, z_k) \end{aligned} \qquad [25]$$

where h is the grid spacing, $C(n_1, n_2, n_3)$ are coefficients for the finite difference, the summation is over M neighboring grid points, for example, if $M = 1$, then standard finite differencing is used.

Real space methods can be utilized without a uniformly spaced cubic grid, but such implementations are more complicated, especially when used to compute interatomic forces. A uniformly spaced grid within a three dimensional is frequently used for nanostructures. Simple boundary conditions are employed, such as outside a spherical domain, the wave functions are constrained to zero. Special data structures are used to discard these points and keep only those having a nonzero value for the wave function. Iterative diagonalization methods, which can be made very efficient for sparse grids, are easy to implement for real space problems.

Calculated Electronic Levels in Nanostructures

Solutions of the Kohn–Sham equation can be used to describe the electronic structure of a variety of nanostructures such as nanowires, nanotubes, or quantum dots. In the case of nanowires or nanotubes, the structure is localized in two dimensions and often periodic in the third. In this case, Bloch wave functions can be used for the periodic structure. For quantum dots, supercells or localized domains can be utilized along with plane waves or grid methods.

In **Figure 5**, the evolution of energy levels are illustrated for GaAs quantum dots. The stoichiometry

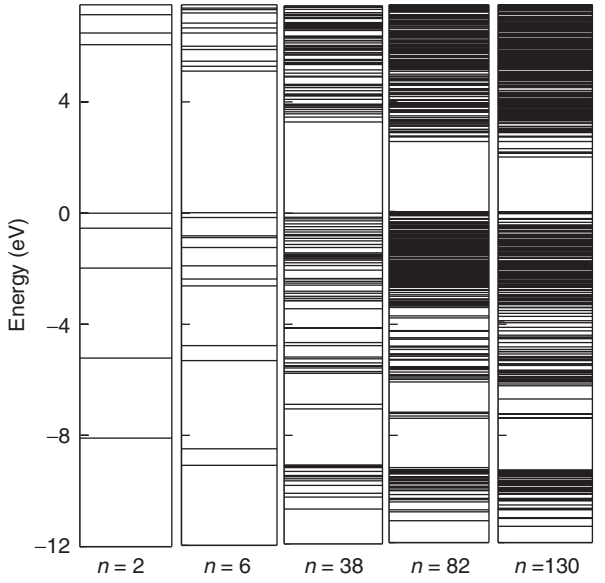

Figure 5 Energy levels of $(GaAs)_n H_m^*$ quantum dots. The number of GaAs units is indicated in the figure. The highest occupied level is taken as the zero energy reference.

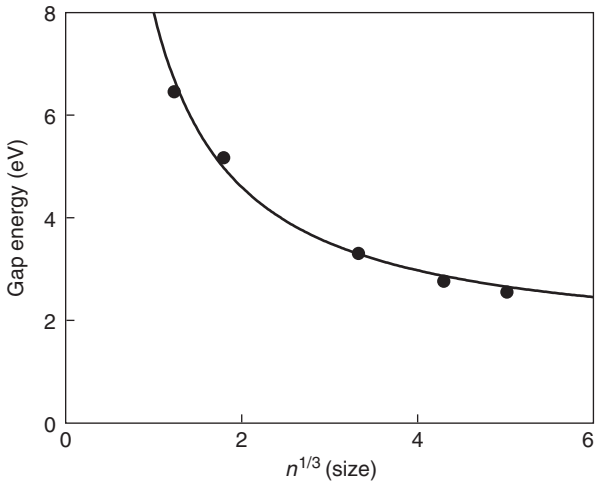

Figure 6 The energy gap in quantum dots of $(GaAs)_nH^*_m$ vs. the size of the dot. The size of the dot is estimated by the cube root of the number of GaAs units in the dot. The curve is after eqn [6] with a scaling of R^{-1}, see text.

of the dots are $(GaAs)_nH^*_m$. The H^*_m notation refers to fictitious hydrogen-like atoms used to passivate any dangling or partially occupied bonds. In this example, the structure of the dots is taken to be that of a fragment of the GaAs crystal. For small dots such as $(GaAs)_2H^*_6$, the energy levels are well separated and the gap between filled and empty states is of the order of $\sim$6 eV. Technically, this gap cannot be compared to the observed gap as these energy levels do not correspond to those created by an electron–hole pair. The Kohn–Sham eigenvalues have meaning only in solving for the total energy as in eqn [17]. However, more realistic approaches to excited state properties have validated the use of Kohn–Sham eigenvalues as a qualitative or, in some cases, a semiquantitative method of determining the optical gap.

As a function of cluster size, the size of the gap between empty and filled states decreases as the size of the cluster increases. This is illustrated in **Figure 6** where the gap size is plotted versus the cube root of the number of GaAs units present. The cube root should scale with the diameter of the quantum dot, provided a large number of atoms are present. The general trend of the gap with the size of the dot is consistent with eqn [6] with one notable exception. The scaling is not consistent with R^{-2} behavior, which would only be expected for a particle contained by an infinite well. Owing to the finite size of the quantum well in real systems, the scaling obtained from accurate calculations yields gaps that scale closer to R^{-1} as indicated in **Figure 6**.

A notable feature of the energy level spacings is the distribution of these states as a function of the dot size. For large systems, the distribution of the

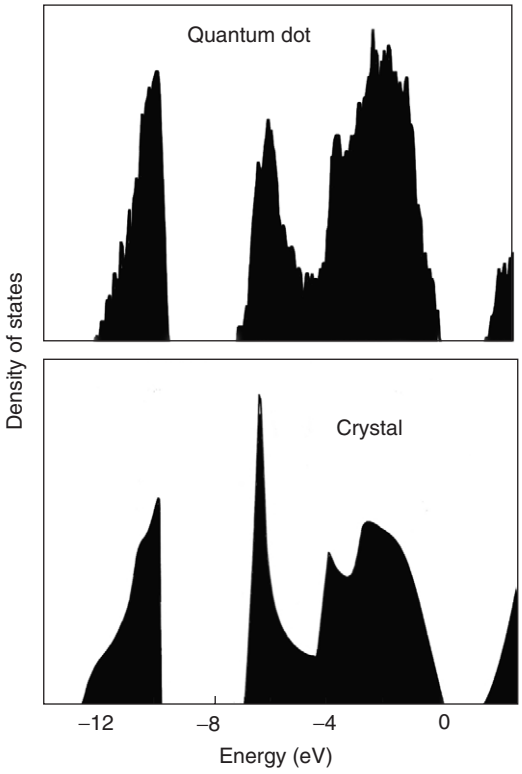

Figure 7 Densities of states for crystal gallium arsenide (bottom) and the eigenvalue distribution for $(GaAs)_{342}H^*_{192}$ quantum dot (top). Extrinsic contributions have been removed from the plot.

eigenvalues should approach the crystalline state. In **Figure 7**, the crystalline density of states is compared, that is, the number of states per unit energy, to the number of eigenvalues per unit of time for a large dot. The structure in the density of states can be attributed to the topology of energy bands. When the energy band is flat, that is, the derivative of the energy with respect to the wave function vanishes, the density of states possesses an identifiable structure. As a function of size, one would expect large clusters to possess similar structural features. The number of atoms in a dot required to reproduce bulk features of the density of states can be assessed through the direct calculation of the eigenvalue spectrum. In **Figure 7**, a comparison between the crystal and dot density of states for the dot, $(GaAs)_{342}H^*_{192}$ is illustrated. The distribution of eigenvalue states matches the bulk density of states very well with one notable exception. Some states are associated with the fictitious hydrogens; these states have been removed from **Figure 7**. More complex nanostructures can be examined using similar approaches.

Nanostructures, Optical Properties of

K Cho, Osaka University, Osaka, Japan

Introduction

The reason for the optical properties of nanostructures to attract special attention is the explicit dependence of optical response on the size, shape, and internal structure of a matter, which leads to an additional possibility of controlling materials for various applicational purposes. In view of the importance of the coherence of matter excitations in the description of the optical processes in nanostructures, which has been neglected in the traditional theory for bulk systems, it is worth having a separate item for this subject.

The optical properties of matter are a consequence of the interaction between matter and light (oscillating electromagnetic (EM) field), which depends sensitively on the space–time structure of the EM field and the induced polarization of the matter. The factors that determine this dependence are the frequency or pulse structure, polarization, and propagation direction of light, and the amplitudes of the induced polarization of matter with various resonance frequencies corresponding to the quantum mechanical level structure of the matter.

The light–matter interaction is fully described by the equations of motion for the dynamical variables of light and matter. For variables, a usual choice is the electric field $E(r, t)$ and polarization $P(r, t)$, but there is another choice, that is, vector potential of light $A(r, t)$ and current density of matter $J(r, t)$. The

latter is slightly more general, because the current density may include the magnetic one (proportional to the rotation of magnetization). If this contribution is neglected, $J(r, t)$ and $P(r, t)$ are simply related as $\boldsymbol{J} = \partial \boldsymbol{P}/\partial t$, which applies to most cases of optical response of matter.

The scheme of equations of motion for A and J (or E and P) is common to quantum electrodynamics (QED) with a quantized EM field and the semiclassical treatments in terms of a classical EM field. The difference is whether the vector potential is treated as an operator or not. This difference does not always lead to a difference in the calculated physical quantities. In QED, the photons of each mode are described as a statistical ensemble, while in the semiclassical picture, the EM field of each mode is represented by a complex amplitude corresponding to an average value of the photon ensemble. The QED description is absolutely necessary when the physical quantity is related with some details of the photon ensemble, or when the optical processes involve the contribution of a noncommutative relation of the photon creation and annihilation operators. Typical examples are the squeezed light or various multitime correlation functions. However, there are many other quantities which can be correctly calculated semiclassically, that is, those depending just on the average photon number and phase (of each mode) arising from the optical processes without involving noncommutative terms of the photon operators. Examples are the light intensities arising from the linear and nonlinear processes without involving the same photon modes in the elementary steps of light–matter interaction.

Another important aspect in optical processes is the microscopic spatial structure in $E(r, t)$ and $P(r, t)$. This has been neglected in macroscopic response theories, and also in QED treating atoms and molecules. In such a treatment, the r-dependence of the EM field is assumed to be always much weaker than that of induced polarization, so that the latter is represented by its zeroth moment, that is, the electric dipole moment of the transition,

$$\int \mathrm{d}\boldsymbol{r} \, \langle \mu | \hat{\boldsymbol{P}}(\boldsymbol{r}) | v \rangle \qquad [1]$$

where μ, v are the quantum numbers of matter eigenstates. In other words, all the optical transitions are approximated as point-like electric dipoles with various eigenfrequencies and amplitudes in the long-wavelength approximation (LWA) for an EM field.

Nanostructures have attracted attention because of the size-quantized energy levels of matter. The microscopic spatial structure of induced polarization is exactly the counterpart of the energy quantization, so that it is quite consistent to consider these aspects simultaneously in the description of optical response in nanostructures. Every quantum state has its own resonant frequency and the characteristic spatial structure in its induced polarization, which depend sensitively on the size and shape of matter. Though this applies in principle to atomic and macroscopic systems also, it is only in nanostructures that one can easily observe the size θ and shape dependence of optical responses.

Optical properties of matter are usually described in terms of linear and nonlinear polarizabilities (electric susceptibility, or more simply, susceptibility). In macroscopic systems, they are considered to be intensive quantities, that is, independent of the size and/or shape of matter, which can be derived by the so-called Lorentz oscillator model based on classical mechanics (forced oscillation of harmonic oscillator with damping) under LWA. However, a quantum mechanical calculation of polarizabilities without the use of LWA gives an expression in terms of the energy eigenvalues $\{E_v\}$ and the matrix elements of the dipole density operator, a result different from that of the Lorentz model. For example, the linear susceptibility at absolute zero Kelvin is given, in units of ε_0, as

$$\chi^{(1)}_{\xi\eta}(\boldsymbol{r}, \boldsymbol{r}', \omega) = \sum_v \left\{ \frac{\langle 0 | \hat{P}_\xi(\boldsymbol{r}) | v \rangle \, \langle v | \hat{P}_\eta(\boldsymbol{r}') | 0 \rangle}{E_v - E_0 - \hbar\omega - \mathrm{i}0^+} + \frac{\langle 0 | \hat{P}_\eta(\boldsymbol{r}') | v \rangle \, \langle v | \hat{P}_\xi(\boldsymbol{r}) | 0 \rangle}{E_v - E_0 + \hbar\omega + \mathrm{i}0^+} \right\} \qquad [2]$$

where $v = 0$ stands for the ground state. The positive infinitesimal (0^+) represents the adiabatic switching of light–matter interaction. When the nonradiative damping of the matter excitations needs to be considered, the $\{0^+\}$s are replaced with the self-energies of the excitations caused by nonradiative scattering, and are often approximated by a phenomenological parameter.

This polarizability, as well as higher-order ones, is not an intensive quantity, but a position-dependent integral kernel with various resonances appearing as poles of frequency-dependent functions. It depends on the size and shape of matter through the resonant frequencies $(E_v - E_0)/\hbar$ and the coupling matrix elements of transitions, which is most conspicuously seen in the range of nanometers. One of the fundamental problems is the evolution of polarizabilities from size-dependent to size-independent regimes, which is due to the size dependence of (1) the contribution of single quantum states, and (2) the intervals of neighboring quantum states. In the case

of nonlinear polarizabilities, the size dependence is deeply related with the so-called cancellation problem.

The dependence of the resonance frequencies, that is, absorption and/or emission peaks, on the system size and shape is due to the boundary condition for the wave function of each excited state extending coherently over the whole structure. This is understood from an analogy of a particle of mass M confined in a one-dimensional well of size d. The boundary condition restricts the form of its wave function to $\sin(kx)$ and the energy eigenvalue $E = \hbar^2 k^2/2M$, with the size-quantized wave number $k = \text{integer} \times \pi/d$.

This allows one to design the optical properties of matter for various aims. Together with the technical development of nanosize fabrication, it has encouraged the studies of applicational aspects of nanostructures. At the same time, this has opened a new phase of fundamental character of matter, in particular of nanostructured materials, where the coherence of matter states plays an essential role. Due to the coherence of the excited state of matter maintained over the whole nanostructure, a full quantum mechanical treatment of polarizabilities is required. In other words, the microscopic character of the EM field and induced polarization need to be thoroughly considered, which inevitably leads to the nonlocal polarizability.

The nonlocal nature of optical response in the microscopic theory means that the cause (EM field) and the result (polarization) may occur at microscopically different spatial points, as far as the points are within the extension of the relevant wave functions. The nonlocality of response is a common feature to all excitations of a wave-like character, such as sound, light, and the quantum mechanical excitations described by wave functions.

It may seem to be a complication that polarizabilities become position-dependent integral kernels, in comparison with their constant values in the macroscopic approach. It is simply not the case, however, because the fact that they are, in general, separable kernels allows one to rewrite the (Maxwell) integral equations as simultaneous polynomial equations, which is certainly easier to handle. In this sense, nonlocal response is a key method to provide a good overview and technical ease, based on the first-principles formulation of light–matter interaction.

Scheme of Microscopic Response

For a given initial condition of light and matter, the optical response is obtained in the following way. The polarization induced by an EM field and the EM field produced by polarization are expressed, and then solved simultaneously. For nanostructures, it is necessary to do this in terms of the microscopic polarizabilities and without the use of the LWA. In view of the importance of resonant processes in nanostructures, which reflect the size and shape dependence sensitively, it is essential to solve the equations self-consistently (simultaneously).

The two sets of equations to be solved, in the case of, for instance, a linear response, are

$$P_\xi(\boldsymbol{r},\omega) = \varepsilon_0 \sum_\eta \int \mathrm{d}\boldsymbol{r}'\ \chi^{(1)}_{\xi\eta}(\boldsymbol{r},\boldsymbol{r}';\omega) E_\eta(\boldsymbol{r}';\omega) \quad [3]$$

and

$$E_\xi(\boldsymbol{r},\omega) = E^{(0)}_\xi(\boldsymbol{r},\omega) + \sum_\eta \int \mathrm{d}\boldsymbol{r}'\ G_{\xi\eta}(\boldsymbol{r},\boldsymbol{r}';\omega) P_\eta(\boldsymbol{r}';\omega) \quad [4]$$

The latter equation is the solution of the Maxwell equations for a given source polarization $\boldsymbol{P}(\boldsymbol{r},\omega)$ in terms of the radiation Green function $\boldsymbol{G}(\boldsymbol{r},\boldsymbol{r}';\omega)$ of a vacuum EM field

$$\boldsymbol{G}(\boldsymbol{r},\boldsymbol{r}';\omega) = \frac{4\pi}{V} \sum_{k\sigma} \hat{\boldsymbol{e}}_\sigma(\boldsymbol{k}) \frac{\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{r}-\boldsymbol{r}')}}{k^2 - (q+\mathrm{i}\delta)^2} \hat{\boldsymbol{e}}_\sigma(\boldsymbol{k}) \quad [5]$$

where $q = \omega/c$ and $\hat{\boldsymbol{e}}_\sigma(\boldsymbol{k})$ $(\sigma = 1, 2)$ are two mutually orthogonal unit vectors perpendicular to k, and $\mathrm{V}\ (\to \infty)$ is the quantization volume. This Green function describes the propagation of light in vacuum. The initial condition of light (e.g., incident light) is represented by $E^{(0)}_\xi(\boldsymbol{r},\omega)$, and that of matter (usually, the ground state) is included in the susceptibilities. For a nonlinear response, the terms of nonlinear polarizations are to be added to the right-hand side of eqn [3]. The equations are a closed set for a given frequency ω in the case of a linear response, but they are not so in nonlinear cases.

The set of integral equations, [3] and [4], can be put into a set of simultaneous linear equations for the variables $X_{\mu 0}(\omega) = g_\mu(\omega) F_{\mu 0}(\omega)$, and $X_{0\mu}(\omega) = h_\mu(\omega)\ F_{0\mu}(\omega)$, where

$$g_\mu(\omega) = \frac{1}{E_\mu - E_0 - \hbar\omega - \mathrm{i}0^+} \qquad h_\mu(\omega) = \frac{1}{E_\mu - E_0 + \hbar\omega + \mathrm{i}0^+} \quad [6]$$

$$F_{\mu\nu}(\omega) = \int \mathrm{d}\boldsymbol{r}\ \boldsymbol{E}(\boldsymbol{r},\omega) \cdot \langle \mu | \hat{\boldsymbol{P}}(\boldsymbol{r}) | \nu \rangle \quad [7]$$

The solution of such equations gives the polarization P as

$$\boldsymbol{P}(\boldsymbol{r},\omega)=\sum_{v}[X_{0v}\langle v|\hat{\boldsymbol{P}}(\boldsymbol{r})|0\rangle+X_{v0}\langle 0|\hat{\boldsymbol{P}}(\boldsymbol{r})|v\rangle] \quad [8]$$

The simplest version of the linear equations to determine $\{X\}$ is the one in the rotating wave approximation (RWA) and is given as

$$F^{(0)}_{\mu 0}(\omega)=\sum_{v}[(E_v-E_0-\hbar\omega-\mathrm{i}0^{+})\delta_{\mu v} + \mathscr{A}_{\mu 0,0v}(\omega)]X_{v0}(\omega) \quad [9]$$

where

$$F^{(0)}_{\mu 0}(\omega)=\int \mathrm{d}\boldsymbol{r}\,\boldsymbol{E}^{(0)}(\boldsymbol{r},\omega)\cdot\langle\mu|\hat{\boldsymbol{P}}(\boldsymbol{r})|0\rangle \quad [10]$$

is a known factor for a given incident light, and the radiative correction $\mathscr{A}$ is defined as

$$\mathscr{A}_{\mu 0,0v}(\omega)=-\int \mathrm{d}\boldsymbol{r}\int \mathrm{d}\boldsymbol{r}'\langle\mu|\hat{\boldsymbol{P}}(\boldsymbol{r})|0\rangle \cdot\boldsymbol{G}(\boldsymbol{r},\boldsymbol{r}',\omega)\cdot\langle 0|\hat{\boldsymbol{P}}(\boldsymbol{r})|v\rangle \quad [11]$$

This is a complex quantity representing the interaction energy between two induced dipole densities $\langle 0|\hat{\boldsymbol{P}}(\boldsymbol{r})|\mu\rangle$ and $\langle 0|\hat{\boldsymbol{P}}(\boldsymbol{r})|v\rangle$ through the EM field of frequency ω. The real and imaginary parts of a diagonal term ($\mu=v$) represent the shift and width, respectively, of the matter transition energy $E_\mu-E_0$. The off-diagonal elements $A_{\mu 0,0v}$ represent the radiative interaction among different matter excitations, giving additional contribution to the radiative shift and width.

The solution of eqn [9] determines the polarization through eqn [8] (without the terms X_{0v} because of the RWA), which further determines the induced field through eqn [4]. In this way, the optical response is determined uniquely from the set of simultaneous linear equations. In the case of nonlinear response, eqn [3] contains nonlinear terms of the factors $F_{\mu v}(\omega)$ for various $\mu,\ v,$ and ω, and in this case the equations to be solved are a set of simultaneous polynomial equations of the order N, where N is the order of nonlinearity in consideration.

In this way of solution, there is obviously no requirement of the boundary conditions for an EM field at the surface/interface of matter. This is because the boundary conditions (of the matter system) are already taken into account in the expression of polarizability. An additional boundary condition (ABC) is not required when the matter excitations contain the effect of spatial dispersion. In fact, such a method is developed from an ABC-free formalism to solve confined exciton problems without using the ABC.

It should be stressed that the condition $\det|\boldsymbol{S}|=0$, where $\boldsymbol{S}=(E_v-E_0-\hbar\omega)\boldsymbol{1}+\mathscr{A}$, for the existence of nontrivial solution of eqns [9] in the absence of an external field (i.e., $F^{(0)}=0$), is exactly the resonance condition for X in the presence of the external field. The modes satisfying this condition are the eigenmodes of the coupled light–matter system. They are self-sustaining modes in the sense that they consist of finite amplitudes of E and P in the absence of external excitation. Thus, one understands that the resonance in the optical spectra appears at the frequency of a self-sustaining mode, that is, matter excitation energy corrected by a radiative shift and broadening. When there is translational symmetry in the matter system, the matrix S is diagonal with respect to the corresponding wave number, so that $\det|S|=0$ holds for each wave number separately, giving the dispersion relation $\omega=\omega(k)$. This is a most general dispersion equation for interacting light–matter systems.

The factor X_{v0} contains an energy denominator which diverges at a matter excitation energy E_v-E_0, while the factor X_{v0} itself is enhanced, not at E_v-E_0, but at the energy corrected by a radiative shift. One of the peculiar points of nanostructures is that the intervals of matter excitation energies and the radiative corrections, which are both sensitive to the size and shape of matter, are comparable in magnitude. Thus, the proper treatment of a radiative shift is essential in obtaining correct results of optical responses. An example of the size dependence of (complex) eigenmode energies with the radiative shift $\mathrm{Re}[\mathscr{A}]$ and width $\mathrm{Im}[\mathscr{A}]$ is shown in **Figure 1** for an exciton weakly confined in a dielectric sphere. The large resonant variation at a certain size for each mode is due to the radiative correction $\mathscr{A}$, which shows the central importance of this quantity in the calculation of the response spectrum.

In a macroscopic response theory, a resonance is ascribed to that of susceptibility, that is, the resonance with a matter excitation energy. However, in the microscopic treatment, the resonance is ascribed to the resonant enhancement of the internal electric field. Thus, the self-consistent treatment of response is seen to lead to a rather different picture of resonance.

Cavity Effect

Nonlocal Scheme in Terms of Cavity Green Function

Induced polarization consists of various frequency components corresponding to the transitions among

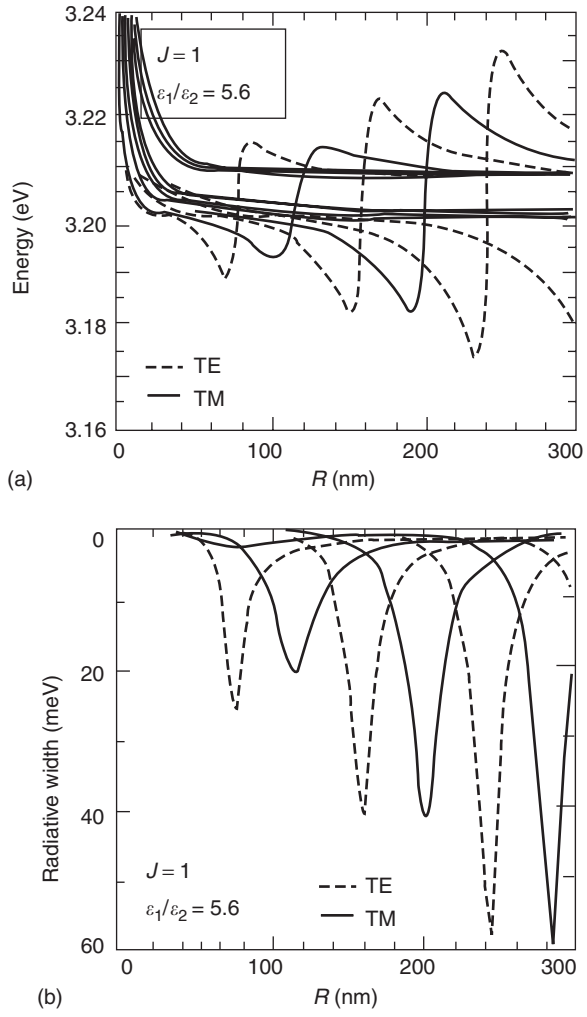

Figure 1 (a) Real and (b) imaginary parts of the eigenmode energies of an exciton in a sphere with background dielectric constant of $\varepsilon_b = 5.6$. The material parameters correspond to those of the Z_3 exciton in CuCl. Each curve is specified by total angular momentum J, its projection, TE or TM mode character, and radial quantum number for the exciton state. (from Cho K (2003) Optical Response of Nanostructures: Microscopic Nonlocal Theory. Berlin: Springer. Reproduced with permission of Dr. Hiroshi Ajiki.)

quantized levels of matter. For a given frequency of incident light, some of them are resonant and others are nonresonant. Since the number of transitions is infinite in general, it is not feasible to consider all the transitions in the above set of eqns [9]. To neglect all the nonresonant components is permissible only for optically thin systems, such as gases of atoms and molecules. For solids (and liquids, too), however, one needs to consider the effect of nonresonant (but infinitely many) components in dealing with the motions of resonant components. For appropriate configurations, these components produce "cavity modes" of an EM field, which have a completely different frequency spectrum and spatial structure from those of the vacuum modes. The interaction of cavity modes and resonant matter transitions offers very interesting problems of cavity QED, remarkable enhancement effects, and various typical situations showing the mechanism of light–matter interaction in a simplified manner.

A well-known recipe dealing with this kind of situation is to regard all the nonresonant components as an effective background medium of a given shape and size with electric susceptibility χ_b (background polarizability). Then, the Maxwell equation to determine the electric field $\boldsymbol{E}(\boldsymbol{r}, \omega)$ is written as

$$\nabla \times \nabla \times \boldsymbol{E} - q^2 \varepsilon_0 [1 + \chi_b \Theta(\boldsymbol{r})] \boldsymbol{E} = q^2 \boldsymbol{P}_{res} \quad [12]$$

where P_{res} is the resonant part of the polarization. Defining the EM Green function $\boldsymbol{G}_b(\boldsymbol{r}, \boldsymbol{r}'; \omega)$ of the background medium as

$$\nabla \times \nabla \times \boldsymbol{G}_b - q^2 \varepsilon_0 [1 + \chi_b \Theta(\boldsymbol{r})] \boldsymbol{G}_b = q^2 \delta(\boldsymbol{r} - \boldsymbol{r}') \quad [13]$$

where $\Theta(\boldsymbol{r}) = 1$ or 0 for r inside or outside the background medium, respectively, one can derive the solution of eqn [12] as

$$\boldsymbol{E}(\boldsymbol{r}, \omega) = \boldsymbol{E}_b(\boldsymbol{r}, \omega) + \int d\boldsymbol{r}' \, \boldsymbol{G}_b(\boldsymbol{r}, \boldsymbol{r}'; \omega) \cdot \boldsymbol{P}_{res}(\boldsymbol{r}'; \omega) \quad [14]$$

where E_b is the field due to the background polarization alone. This field is equivalent to that of [4], expressed differently in terms of the Green function G_b.

In a nanostructure, the resonant polarization of interest will consist of a few frequency components, and is written in the form of eqn [8] with $v = 1, 2, \ldots, s$. The equations to determine the Xs are eqns [9] for $v = 1, 2, \ldots, s$, but the parameters in the equations should be changed as follows. (1) The excitation energies $\{E_v - E_0\}$ contain the interaction energy of induced polarizations, which are affected by the presence of background dielectrics. This "screening" effect can be divided into bulk-type and surface- or interface-type contributions. The former is the screened Coulomb interaction by the factor $1/\varepsilon_b$, where $\varepsilon_b = 1 + \chi_b$, and the latter is the image potential effect for the interaction among the components of induced charge density. (2) The evaluation of radiative interaction $\mathscr{A}$ should be made in terms of G_b instead of G. In terms of the modified excitation energies $\{E'_v - E_0\}$ and radiative correction $\mathscr{A}^{(b)}$, eqns [9] are solved for $v = 1, 2, \ldots, s$ to obtain the (modified) expansion coefficients X, which uniquely determine the response field and induced polarization.

A typical effect of cavity on the optical response of matter is the modification of the mode structure of an EM field and the characteristic spatial pattern of each mode. Through this change in the EM field, the coupling with matter excitations can be strongly affected, and their resonant frequencies and widths are modified rather strongly. In optical response, there appear the resonant contributions of both cavity modes and matter excitations in general, where one can distinguish two regimes, namely, the case where the cavity mode has a much smaller Q-value than that of the matter excitation, and the case where their Q-values are comparable. In the former case, only the effect on the matter excitation is appreciable as an increase in its width, while, in the latter, there occur new coupled modes through the mixing of the cavity mode and matter excitation.

The two regimes mentioned above can be described by the single scheme of the microscopic response in a cavity. The condition for the existence of a nontrivial solution of the modified equations for $\{X_{v0}\}$ in the absence of an external field leads to the eigenmodes of the matter in a cavity. The fact that this solution covers two different regimes can be seen from the structure of the eigenmode equation. The Green function G_b has poles at the energies of the cavity modes, so that the radiative correction $\mathscr{A}$ has the same poles with the strength determined by the coupling with the matter excitations. Thus, the eigenvalue equation

$$\det |(E'_v - E_0 - \hbar\omega)\mathbf{1} + \mathscr{A}^{(b)}| = 0 \qquad [15]$$

provides complex roots for the coupled cavity modes and matter excitations. Depending on the coupling strength in $\mathscr{A}^{(b)}$ and the imaginary parts of the cavity modes contained in G_b, two regimes appear as mentioned in the previous paragraph.

EM Green Function of Cavity Polariton

A typical example of matter in a cavity is a quantum well (QW) in a distributed bragg reflector (DBR). In this case, the coupled modes are called cavity polaritons, and the nonlinear response of cavity polaritons is a very popular subject of study, such as in pump–probe spectroscopy, four-wave mixing, parametric amplification, and so on. In these optical processes, probe beams are sent from outside the cavity, and the result of the nonlinear process inside the cavity is observed as an external light coming out of the cavity. A standard treatment of these processes is the so-called quasi-mode coupling scheme, where the cavity mode is assumed to be completely confined in the cavity, that is, to have an infinitely large Q-value. The well-defined cavity mode allows a simple and rigorous treatment of the light–matter coupling at various nonlinear levels, and the resulting signal light is calculated by assuming the coupling of the $Q = \infty$ cavity mode and the photon modes outside the cavity. The coupling strength is assumed to be such that it reproduces the radiative width of the cavity polaritons. This is used rather often, but it is a kind of make-shift approach. This cannot be justified in a rigorous sense, because the problem of the boundary condition at the cavity surfaces cannot be translated into that of interaction between spatially separated modes of the EM field.

An alternative way to handle such a problem rigorously is to use the Green function of the cavity polariton, which is defined by renormalizing the exciton linear polarization as well as the background polarization comprising the cavity mode, into the definition of the EM field causing the nonlinear optical interaction. The equation to define this Green function G_{cp} has a similar form as eqn [13]. The only difference is that it additionally contains, on the left-hand side, a term representing the linear polarization due to the exciton:

$$\nabla \times \nabla \times \boldsymbol{E} - q^2\varepsilon_0[1 + \chi_b\Theta(\boldsymbol{r})]\boldsymbol{E} + \varepsilon_0 \int d\boldsymbol{r}'\, \chi_x^{(1)}(\boldsymbol{r}, \boldsymbol{r}'; \omega)\boldsymbol{E}(\boldsymbol{r}') = q^2\boldsymbol{P}_{NL} \qquad [16]$$

Keeping the nonlocal character of $\chi_x^{(1)}$, one can solve this integro-differential equation, and obtain the analytical form of G_{cp} in terms of G_b alone. Since G_b is obtained in a simple form for a QW in a DBR cavity, G_{cp} can be used as a practical tool. Considering that G_{cp} describes the propagation of the EM field both inside and outside the cavity according to the detailed construction of the cavity, one understands the merit of this Green function to calculate the signal field outside the cavity caused by the nonlinear interaction in the cavity.

The EM field produced by the nonlinear polarization is given as

$$\boldsymbol{E}(\boldsymbol{r}, \omega) = \boldsymbol{E}_{cp}(\boldsymbol{r}, \omega) + \int d\boldsymbol{r}\, \boldsymbol{G}_{cp}(\boldsymbol{r}, \boldsymbol{r}', \omega) \cdot \boldsymbol{P}_{NL}(\boldsymbol{r}', \omega) \qquad [17]$$

The main issue in this formalism is to give the explicit form of P_{NL} according to the problem in question. The nonlinear polarization contains several components of the EM field, so that one needs self-consistency conditions based on the above solution. It is noteworthy that the Green function for the cavity polariton is obtained in a closed form through the use of a nonlocal form of exciton linear polarizability. The use of local approximation for this polarizability

leads to a Bethe–Salpeter type equation, which is rather complicated to solve. Thus, a nonlocal description makes the solution much easier than the local one. This is another example of recommending the use of the nonlocal way of description.

Nomenclature

$A(\boldsymbol{r}, \omega)$	vector potential at position r with frequency ω
$\mathscr{A}_{\mu 0,0\nu}(\omega)$	radiative interaction energy between the matter excitations $(0\rightarrow\mu)$ and $(0\rightarrow\nu)$ via the EM field of frequency ω
$\mathscr{A}^{(\mathrm{b})}$	radiative interaction energy between the components of induced polarization via the EM field of background dielectric
$\boldsymbol{E}(\boldsymbol{r}, \omega)$	electric field at position r with frequency ω
$\boldsymbol{E}^{(0)}$	solution of homogeneous differential equation, usually an incident field inducing polarization
$\boldsymbol{E}_{\mathrm{b}}$	electric field induced by the scattering of an incident field from background dielectric alone
$\boldsymbol{E}_{\nu}$	energy of the νth eigenstate of matter, $\nu = 0$ for the ground state
$\boldsymbol{E}'_{\nu}$	energy eigenvalue including the screening effect of the background dielectrics
$F_{\mu\nu}$	expansion coefficient of induced polarization
$\boldsymbol{G}$	Green function describing the propagation of an EM field
$\boldsymbol{G}_{\mathrm{b}}$	Green function describing the propagation of an EM field in the presence of a background dielectric
$\boldsymbol{G}_{\mathrm{cp}}$	Green function describing the propagation of an EM field of a cavity polariton
$\boldsymbol{J}(\boldsymbol{r}, \omega)$	current density at position r with frequency ω
$\boldsymbol{P}(\boldsymbol{r}, \omega)$	polarization at position r with frequency ω
$\hat{\boldsymbol{P}}(\boldsymbol{r})$	electric dipole density operator
$\boldsymbol{P}_{\mathrm{res}}$	resonant part of induced polarization
$\boldsymbol{P}_{\mathrm{NL}}$	nonlinear part of induced polarization
q	wave number of light in vacuum $(=\omega/c)$
Q-value	quality factor of a resonance, that is, resonant frequency divided by resonance width
$\boldsymbol{S}$	coefficient matrix of the linear equation to determine X
$X_{\mu\nu}$	another expansion coefficient of induced polarization
$\chi^{(1)}$	linear polarizability
χ_{b}	polarizability of a background dielectric
ε_0	dielectric constant of vacuum
ε_{b}	background dielectric constant
Θ	Heaviside function to describe the size and shape of a background dielectric
ξ, η	Cartesian coordinates

Neuroscience

E Boncinelli, Scientific Institute San Raffaele, Milan, Italy

Introduction

Neuroscience aims at studying, directly or indirectly, the structure and activity of the animal nervous system, including the brain. This system is responsible for receiving stimuli from the external world and producing internal states and ultimately movement in response to them, according to the scheme, perception → information processing → action. As is the case for any other biological system or apparatus, the nervous system is composed of cells, the basic elements of living beings. Many cell types are present in the nervous system but those functionally specific for it are termed "neurons." Neurons are highly specialized cells, primarily characterized by an abnormally high surface-to-volume ratio, even three orders of magnitude higher than that of other types of cells,

making them extremely well suited for exchanging information with their environment, cellular or otherwise. Neurons continually communicate with one another and are interconnected in circuits and supercircuits. The study of the nervous system requires knowledge about the nature and functions of neurons, about the way they exchange information and how this is analyzed, mostly in centralized structures, and ultimately utilized. All this is very strongly influenced by the history of its development and subsequent modifications.

General Overview of the Nervous System

From the nucleus-containing cell body, sometimes termed "soma," of a typical neuron emerge two types of protrusions: many thin and relatively short dendrites and, on the opposite side, a single thick and sometimes very long axon. Although all of them share some general features, it is appropriate to point out that neurons occur in an incredible number of different types. Neurons are strictly polarized – neural information can, in fact, flow through each one of them only in one direction, from dendrites to the cell body and from this to the axon – and tightly interconnected cells. Upstream of every neuron there is a neuron or, exceptionally, a sensory receptor, in contact with the environment, both external and internal to the body. Downstream from every neuron there is a neuron, or sometimes a muscle cell, deputed to generate movement, or internal anatomical structures able to release specific molecules in their own environment.

Every neuron on its own and the nervous system on the whole primarily work at the integrative level. On a small scale, neurons may be regarded as combined into neural circuits, some of which are clearly identifiable, whereas others may be traced only on a physiological basis. Most circuits are interconnected. On a broader scale, the entire nervous system may be regarded as composed of pathways and centers. Pathways are essentially one-dimensional sequential successions of neurons, whereas centers are three-dimensional assemblies of interconnected cell bodies. Pathways include nerves which are bundles of axons running from one location to another, often wrapped up in a myelin sheath. Pathways and centers are in turn combined into systems that serve specific functions, for example, the visual system or the auditory system. A more general distinction in the nervous system is that between the sensory and the motor systems.

From the anatomo-physiological point of view, the nervous system has been traditionally subdivided into central and peripheral components. The central nervous system comprises the brain (including the brain proper, or cerebrum, the cerebellum, and the connecting the brainstem) and the spinal cord. The peripheral nervous system includes sensory neurons, connecting the sensory receptors to the brain and spinal cord, as well as motor neurons, connecting the brain and spinal cord to muscles and glandular structures. The motor components of the peripheral nervous system are, in turn, assigned to a somatic division, which innervates skeletal muscles, and an autonomic division, innervating smooth muscles, cardiac muscles, and glands. Neurons or pathways carrying information toward the spinal cord and from this to the brain are termed "afferent," whereas those carrying information away from the brain to the spinal cord and from this to the periphery of the body are termed "efferent." A number of neurons, mostly but nonexclusively present in centers, reciprocally connect neurons and help in processing the nervous signal; they are generally termed "interneurons." Most of the processing work carried out in the brain is through interneurons.

Electrical Signals of Nerve Cells

Neural information is generated and propagated throughout the nervous system as electrical signals and neurons have evolved elaborate mechanisms for generating them, based on the flow of ions across their plasma membranes. Generated near the soma, electrical signals run along neuronal axons, which may be very long. Although capable of passively conducting electricity, axons are not good electrical conductors. In order to compensate for this deficiency, neurons have evolved a sort of a booster system allowing them to conduct electrical signals over great distances. The electrical signals produced by this booster system are called "action potentials," also referred to as "spikes" or "impulses." The production of an action potential is, of course, an energy-consuming process, but energy is also required for a neuron at rest in order to be ready to produce and conduct it. While resting, a living neuron continually generates a negative potential, termed the "resting membrane potential." The action potential abolishes the negative resting potential and makes the transmembrane potential transiently positive. Generation of both the resting potential and the action potential is best understood in terms of the nerve cell's selective permeability to different ions and the normal distribution of these ions across the cell membrane.

A difference in electrical potential is generated whenever ions flow across cell membranes. Such ion fluxes occur when the membranes are permeable

to one or more ion species, and when there is an electrochemical gradient that favors ion flow. The negative resting potential results from a net efflux of K^+ across neuronal membranes that are predominantly permeable to K^+. An action potential occurs when a transient rise in Na^+ permeability allows a net flow of Na^+ across a membrane that is now predominantly permeable to Na^+. The brief rise in Na^+ membrane permeability is followed by a secondary, transient rise in membrane K^+ permeability that repolarizes the neuronal membrane and produces a brief undershoot of the action potential. As a result of this series of molecular events, the membrane is transiently depolarized in an all-or-none fashion. When these active permeability changes subside, the membrane potential returns to its resting level because of the high resting membrane permeability to K^+. All this requires both selective membrane permeability and specific ion concentration gradients across the plasma membrane. The membrane proteins that ensure these two essential conditions are called "ion channels" and "pumps," respectively. These mechanisms appear to account for virtually all of the observed properties of all-or-none action potentials. By virtue of local current flow, action potentials can also be propagated along the length of neuronal axons, explaining how electrical signals are conveyed throughout the nervous system.

For a given axon, form, duration, and amplitude of the action potential are fixed. As a consequence, the intensity of a stimulus is encoded in the frequency of action potentials rather than in their amplitude. The velocity of signal propagation also differs from axon to axon, as the rate of the action potential propagation depends on the diameter and on the degree of electrical insulation. In this light, by acting as an electrical insulator, a myelin sheath surrounding an axon greatly speeds up its action potential conduction. Myelinated axons can conduct at velocities up to $150\,m\,s^{-1}$.

Synaptic Transmission

Communication among neurons is mediated by synapses, specific functional contact microstructures. Synapses transfer from one neuron to another (or, occasionally, to a muscle cell) the information carried by action potentials. Although there are many synaptic subtypes, they can be subdivided into two classes: electrical and chemical synapses. Electrical synapses, a minority, permit direct, passive flow of electrical current from one neuron to another. Most synapses are actually chemical and enable communication via the secretion of neurotransmitters. Chemical agents released by the presynaptic neuron produce secondary current flow in postsynaptic neurons by activating specific receptor molecules. Neurotransmitters are released from presynaptic terminals in quantal packets after the arrival of an action potential. The secretion of neurotransmitters is triggered by voltage-dependent Ca^{2+} channels, which elevate Ca^{2+} within the presynaptic terminal. The rise in Ca^{2+} concentration causes synaptic vesicles – presynaptic organelles that store neurotransmitters – to fuse with the plasma membrane and release their contents into the space, termed "synaptic cleft," between the pre- and postsynaptic cells.

The functional cycle of all neurotransmitter molecules is similar. They are synthesized and packaged into vesicles in the presynaptic cell; they are then released from the presynaptic cell and bound to receptors on one or more postsynaptic cells; once released into the synaptic cleft, they are rapidly removed or degraded. Many synapses release more than one type of neurotransmitter, and multiple transmitters are sometimes packaged in the same synaptic vesicle. The total number of neurotransmitters is not known, but is believed to be well over 100. Despite this diversity, these agents can be classified into two general categories: small-molecule neurotransmitters and neuropeptides. In general, small-molecule neurotransmitters mediate rapid reactions, whereas neuropeptides tend to modulate slower, ongoing neural functions. For this reason, neuropeptides, mostly present in the brain, are sometimes also termed neuromodulators. Glutamate is the major excitatory neurotransmitter in the brain, whereas GABA and glycine are the major inhibitory neurotransmitters.

Neurotransmitters evoke postsynaptic electrical responses by binding to members of a diverse group of proteins called neurotransmitter receptors, which, in turn, give rise to electrical signals by opening or closing ion channels in the postsynaptic membrane. The postsynaptic currents produced by the synchronous opening and closing of the ion channels change the membrane potential of the postsynaptic cell. Changes in potential that increase the probability of firing an action potential are excitatory, whereas those that decrease this probability are inhibitory. Whether the postsynaptic actions of a particular neurotransmitter are excitatory or inhibitory is determined by the class of ion channel affected by the transmitter. Because postsynaptic neurons are usually innervated by many different inputs, the integrated effect of all excitatory and inhibitory postsynaptic potentials produced in a postsynaptic cell at any moment determines whether or not the cell fires an action potential.

Neurotransmitter Receptors and Their Action

There are two major classes of receptors: those in which the receptor molecule is also an ion channel, and those in which the receptor and ion channel are separate molecules. The former are called "ionotropic receptors" or ligand-gated ion channels. They give rise to fast postsynaptic responses that typically last only a few milliseconds. The latter are called "metabotropic receptors," and they produce slower postsynaptic effects that may endure much longer. Metabotropic receptors affect postsynaptic ion channels indirectly by activating transducer molecules called G-proteins. These proteins may alter the properties of ion channels directly, or may activate intracellular second-messenger pathways that then modulate the channels.

Synapses may be distinguished according to the kind of processes that take part in them. Thus, a contact from an axon onto a cell body is termed an "axosomatic" synapse, whereas that onto a dendrite is termed "axodendritic" synapse. Similarly, a contact between two axons is termed "axoaxonic" and one between two dendrites a "dendrodendritic" synapse. Within the brain, a synapse seldom occurs in isolation; on the contrary, it is usually one of a number of very small varicosities present mostly on dendrites and termed "spines." In addition, it has to be pointed out that the synapse is not a simple mechanism for unidirectional transmission between neural cells. The complexity revealed by modern research has widened this view to include several new concepts. First, the presynaptic terminal may have receptors for its own released products; thus, the presynaptic terminal may be postsynaptic as well to its own transmitter. This can be seen as an expression of a general principle of regulation by feedback of the output. Second, the postsynaptic terminal may send retrograde signals to the presynaptic terminal. These may be rapid signals, as in the case of gaseous molecules such as NO, which mediate activity-dependent effects, or they may be slowly acting growth factors, which play roles in determining the types of neurotransmitters produced. By these actions, the synapse can be viewed as having at least a bidirectional nature. Third, the synapse is not a simple link between two neurons, but rather a complex organelle in its own right. Furthermore, it is unique among cell organelles in being constructed by more than one cell; it is, in fact, a multicellular organelle. This view allows one to appreciate the synapse as a building block of nervous circuits. It also helps one to understand how synaptogenesis, that is the establishment of new synaptic contacts (see below), is a main concern of neuronal development and evolution during life, and to what extent the synapse is adapted for information-processing functions in different nervous pathways.

Neural Signal Generation

Ultimately, the neural information is generated in sensory receptors that, through sensory components of the peripheral nervous system, provide information to the central nervous system about the internal and external environment. Here, there are specific receptor cells tuned to be sensitive to different forms of energy in the environment. These forms of energy serve as stimuli for the receptor cell that responds by generating a receptor potential, or generator potential, which ultimately leads to encoding of the response in an impulse discharge, sent to the higher centers in the brain. The receptor potential is graded smoothly and continuously in amplitude in relation to the intensity of the stimulus. This translates, in turn, within the cell, into a specific impulse frequency of the transmitted neural signals. Sensory reception thus involves the transformation from a continuously varying domain of sensory stimuli into a neural domain of all-or-nothing impulses.

In all of these processes the integrative properties of neurons prove essential, which are at the heart of the neural action and represent the essence of neural processes. Most neurons have an extensive somadendritic surface and a complex branching geometry, which provide multiple sites for local processing of synaptic and active properties. In this view, the neuron is not one node but many; it is itself an extensive computational system, equivalent in computer terms to an integrated multifunction chip. This rich complexity is, in turn, incorporated into a number of neural circuits.

Circuitry

At the first level, there is the arrangement of synapses at a local site on a cell body, dendrite, or axon terminal. These may involve simple convergence of several inputs onto that site, or simple divergence to several output sites. In addition, it may involve serial relays of information, or reciprocal interactions. In all these cases, there is a set of synaptic connections that acts as an integrative unit. These local patterns of connections have been termed microcircuits. It is very common for a particular type of microcircuit to be repeated throughout a given region or on a given cell type, thus acting as a module for a specific kind of information processing or memory storage. The microcircuits on a computer chip represent the same operating principle.

At a higher level of organization is the circuit that connects different neurons over longer distances

within a given region. This transmission may take place through a dendritic branch or dendritic trunk or it may take place through the axon of an interneuron, or the axon collateral of an output neuron. The key point about all of these pathways is that they remain within a given region. The term introduced for all these is "local circuits." The most restricted local circuits include microcircuits; the most extensive involve interlaminar and intraregional axonal connections. The function of these different types varies widely. Some provide for re-excitatory spread of activity from neuron to neuron; others provide for antagonistic interaction between neighboring integrative units within a region.

The next highest level of organization involves connections of one region with another; one may refer to this as a "projection circuit." Generally, a region receives an input from more than one other region and projects output to more than one other region. Thus, the same principles of convergence, divergence, and integration of different kinds of information operate at this level too. There are also feedback lines from one region to another. Note that feedback loops are present at all levels. The more local feedback loops can be regarded as nested within the more extensive projection feedback loops.

At a still higher level are sequences of connections through several regions. These are said to constitute a system. The function is normally to transmit information from the periphery into the central nervous system (as in a sensory system), or from the central nervous system to the periphery (as in a motor system). However, in any pathway there are often connections running in the opposite direction to provide for descending, ascending, or centrifugal control. Finally, at the highest level are sets of connections between a number of regions, which together mediate a behavior that involves, to some extent, the whole organism. These are called distributed systems. They are characteristic of higher functions of motor and sensory systems, and of many central systems.

Development and Plasticity

Nervous circuits and subtle connections are neither inborn nor established once and for all at any stage of life. On the contrary, the processes through which this working circuitry is laid down during individual development and continually modified throughout life are an integral part, if not the most characteristic part, of the study of the nervous system. Its function in fact, depends critically on its anatomy and microanatomy, and it is fundamental for its full functionality that the connectivity may be subtly adjusted throughout life. As a consequence, a major field of investigation in neuroscience is the description of the construction and modification of neural circuits. This is, by the way, a qualifying difference from human-designed artificial computing machines. Furthermore, any alteration in one of these processes is likely to cause major developmental defects or contribute to some complex genetic disorders of the nervous system. The initial development of the nervous system entails the birth of neurons, the formation of specific axonal pathways, the elaboration of vast numbers of synapses, and the emergence of increasingly complex behaviors. After birth, experiences during postnatal life shape behavioral repertoires and cognitive abilities in highly specific ways, typically within restricted temporal windows. Even in maturity, synaptic connections continue to be modified as new memories are laid down and older ones reshuffled or discarded.

Fortunately, a great deal has been learnt in the past decades about the events and principles of biological development of the animal body and, in particular, of the nervous system, and new data emerge every day. The underlying cellular and molecular mechanisms have been explored and a number of principles and developmental pathways of general validity have been discovered. Many of these appear to be evolutionarily conserved. For example, in taxa as different as vertebrates and insects, a key role in the regulation of these developmental events is played by the so-called regulatory genes, genes acting through the control of the expression of other genes placed hierarchically downstream from them and sometimes termed target genes. Regulatory genes generally code for transcription factors, that is, nuclear proteins able to recognize specific DNA sequences and modulate the level of expression of the corresponding genes.

The nervous system arises as a longitudinal tube in the dorsal midline of the embryo with a definite rostro-caudal as well as dorso-ventral polarity. Subsequently, the neural tube has to be properly segmented into the head-to-tail sequence of body regions and the appropriate cellular and functional areas have to emerge and differentiate. Uncovering the forces, and ultimately the genetic instructions behind these events has been one of the major triumphs of today's genetics and molecular biology. Within the neural tube, and to some extent away from it, neuronal development, that is neurogenesis, involves a series of steps. The first step is the proliferation of precursor cells through a sequence of cell divisions up to the birth of the neuron. After this final division, the cell is destined to become a neuron of a given type or limited range of types. Soon after, the cell begins to migrate from its site of origin to its final location and to differentiate toward its final form,

with extension of axon and dendrites and with growth in size. During this time, the expression of functional membrane properties and the formation of synapses begin. All of these mechanisms characteristically have well-defined time periods that overlap considerably. Maturation of the cell into its final form and function is a process that in many animals, especially humans, may last over considerable periods of time. In addition to production of cells and cell processes, pruning of the synaptic connections and cell death are important factors in early maturation as well as in old age. Many of these events take place in an activity-dependent fashion.

A general rule in the vertebrate nervous system is that neurons do not remain at their site of origin, but rather, migrate to their final position. This is a necessary consequence of the fact that the nervous system starts as a relatively thin tube within the embryo (the neural tube), and the final product is a much larger structure (the nervous system). In addition, the initial relations between the sites of origin of neurons may be very different from their final relations. Neurons of the peripheral nervous system, in particular, arise largely from the neural crest, so called because it is a clump of cells which first appears on the dorsal surface of the neural tube. During migration, neurons begin to elaborate the axons and dendrites that will eventually form neural pathways and networks. Axons, in particular, have to make long journeys to form their synaptic connections. At the progressing ends of the fibers, there are enlargements endowed with ameboid movements termed "growth cones." These movements enable them to push aside obstacles in their way until they reach their own destination. The study of the progression of growth cones has offered invaluable information about molecules and mechanisms favoring neuronal growth and those providing positional clues to direct the progression and pathfinding process. The essence of nervous organization is the establishment of synaptic circuits. Normal behavior requires precision in assembling these circuits, and many of the disorders of behavior that occur in humans and other animals are due to abnormalities in the development of the circuit connections. Many developmental factors contribute to keep this developmental program as near as possible to the programmed scheme.

In addition to all this, there are firm reasons to believe that at least part of learning and memory rely on the formation and reshuffling of synaptic connections in the brain, especially at the level of microwiring and establishment of dendritic spines within the cerebral cortex. In the human brain, there are not less than 10^{11} neural cells, each one possessing an average of 10^4 synaptic contacts. This makes a grand total of approximately 10^{15} synapses. Common wisdom at present maintains that the essence of our cerebral cortex unambiguously resides in the configuration of these 10^{15} synapses. The ability of neural circuits and synaptic connections to undergo major or minor changes throughout life is usually termed plasticity or neuronal plasticity.

Neutron Sources

A Furrer, ETH Zürich, Villigen, Switzerland

Introduction

Neutron scattering is an important scientific and technological resource that provides essential information about the fundamental properties of condensed matter. The quality and precision of neutron scattering experiments are determined by the available neutron flux. The history of neutron sources has seen a tremendous increase of the neutron flux of fission reactors from $10^7\,\mathrm{n\,cm^{-2}\,s^{-1}}$ in 1942 to $10^{15}\,\mathrm{n\,cm^{-2}\,s^{-1}}$ in 1972; since then no further progress has been reported. Only very recently, some projects utilizing accelerator-based spallation sources

have been initiated and are expected to be realized within a few years in order to surpass the limit achieved in 1972.

This article starts with a summary of the unique character of neutron scattering experiments in the investigation of the static and dynamic properties of condensed matter. Then a survey of the historical evolution of neutron sources is presented. The basic principles of the most commonly used neutron sources based on nuclear fission and spallation reactions are discussed in greater detail. All neutron sources release neutrons in the MeV energy range; however, thermal neutrons in the MeV energy range are needed to perform scattering experiments in condensed matter research; thus, a section is devoted to the moderation of neutrons as well as to the devices that transport the thermal neutrons to the instrument positions. Finally, some prospects for future neutron sources are discussed.

Neutron Scattering: A Unique Experimental Tool for Condensed Matter Research

Modern materials research, together with the traditional scientific interest in understanding condensed matter at the atomic scale, requires a complete knowledge of the arrangement and the dynamics of the atoms and molecules, and of their magnetic properties as well. This information can be obtained by investigating the interactions of the material in question with various types of radiation, such as light, X-rays or synchrotron radiation, electrons, ions, and neutrons. Among all these tools, neutrons have outstanding properties, as simply stated in the 1994 physics Nobel prize award to Cliff Shull and Bertram Brockhouse: "Neutrons reveal where atoms are and what atoms do." The most relevant, unique character of thermal neutrons, which can hardly be matched by any other experimental technique, can be summarized as follows:

- The neutron interacts with the atomic nucleus, and not with the electrons as X-rays do. This has important consequences: the response of neutrons from light atoms (e.g., hydrogen, oxygen) is much higher than for X-rays; neutrons can easily distinguish atoms of comparable atomic number; and finally, neutrons easily distinguish isotopes which allows one, for example, by deuteration of specific parts of macromolecules (or biological substances) to focus on specific aspects of their atomic arrangement.
- For the same wavelength as hard X-rays, the neutron energy is much lower and comparable to the energy of elementary excitations in matter. Therefore, neutrons do not only allow the determination of the "static average" chemical structure, but also the investigation of the dynamic properties of atomic arrangements which are directly related to the physical properties of materials.
- By virtue of its neutrality, the neutron is rather weakly interacting with matter, which means that the properties of the investigated materials remain unchanged under neutron irradiation; furthermore, there is almost no radiation damage to living biological objects under study. Also, the rather weak interaction with matter results in a large penetration depth and therefore the bulk properties of matter can be studied. This is also important for the investigation of materials under extreme conditions such as very low and very high temperatures, high pressures, high magnetic, and electric fields, or several of these together; in such cases, the studied sample is always surrounded by numerous shields which make the use of X-rays difficult.
- The neutron carries a magnetic moment which makes it an excellent probe for the determination of the static and dynamical magnetic properties of matter (magnetic ordering phenomena, magnetic excitations, spin fluctuations).

The quality and precision of neutron scattering experiments are primarily determined by the counting rate and, therefore, by the flux of the available neutrons, normally quoted in units of neutrons per square centimeter per second ($n\,cm^{-2}\,s^{-1}$). Although about half of the world is made up of neutrons, they are tightly bound deep inside the atomic nucleus and quite difficult to set free. Facilities that accomplish this task in a manner useful for scientific and technological applications are called neutron sources.

Historical Evolution of Neutron Sources

For all neutron sources, nuclear reactions are dealt with. Some nuclear reactions with a practical potential are listed in **Table 1**. Neutrons were observed for the first time in 1932 by Chadwick who used the interaction of α-particles from decay of natural polonium with beryllium, and subsequently neutron sources based on natural α-radiation were the basis of the earliest neutron physics research. Nuclear fission reactions were the next generation of sources; however, they were initially built for research in the nuclear industry, and the consequent possibility of

Table 1 Neutron yields and deposited heat for some neutron-producing reactions

Reaction	*Energy/event*	*Yield* (n/event)	*Deposited heat* (MeV/n)
T(d,n)	0.2 MeV	8×10^{-5} n/d	2500
W(e,n)	35 MeV	1.7×10^{-2} n/e	2000
^{9}Be(d,n) 15 MeV		1.2×10^{-2} n/d	1200
^{235}U(n,f) fission		~1 n/fission	200
(T,d) fusion		~1 n/fusion	3
Pb spallation	1 GeV	~20 n/p	23
^{238}U spallation	1 GeV	~40 n/p	50

studying neutron scattering was simply an unforeseen spin off. The development started in 1942 with a thermal neutron flux of $10^{7}\,\mathrm{n\,cm^{-2}\,s^{-1}}$ (CP-1, USA) and had its climax in 1972 with the reactor at the Institute Laue-Langevin (ILL) in Grenoble, a dedicated neutron scattering facility with thermal neutron fluxes just exceeding $10^{15}\,\mathrm{n\,cm^{-2}\,s^{-1}}$.

Meanwhile, pulsed sources, starting with Alvarez's use of a radiofrequency (RF)-pulsed cyclotron, and in particular, electron accelerators that produce neutrons through Bremsstrahlung photoneutron reactions have been increasingly applied for slow-neutron research. In addition, repetitively pulsed reactors have been developed. However, all these facilities could not really compete, for instance, with the overall performance of the ILL reactor, except perhaps the pulsed reactor IBR at Dubna (Russia) which produces instantaneous thermal fluxes up to $10^{16}\,\mathrm{n\,cm^{-2}\,s^{-1}}$ in pulses several hundred microseconds long. Today the most intense pulsed neutron sources are based on proton accelerators and the production of neutrons by spallation. Currently, the worldwide leading facility is the spallation neutron source ISIS at Didcot (UK), which provides instantaneous thermal neutron fluxes over $10^{16}\,\mathrm{n\,cm^{-2}\,s^{-1}}$ with short pulse lengths $\sim 50\,\mu\mathrm{s}$. Next-generation pulsed neutron sources with fluxes $> 10^{17}\,\mathrm{n\,cm^{-2}\,s^{-1}}$ are currently under construction in USA and Japan.

Practical Requirements for Neutron Sources

The primary goal of a neutron source must be to release as many neutrons as possible in as small a volume as possible to achieve a high luminosity. Another important property of neutron sources is the heat deposition going along with the neutron release, since cooling problems are a limiting factor in practically all neutron source designs. In this respect, fusion is by far the most optimal process for neutron production as can be seen from **Table 1**, followed by spallation and fission. Fusion may be the technique of neutron production in the far future, but today the two most commonly employed reactions are thermal nuclear fission in ^{235}U and spallation by protons in the energy ~ 1 GeV, thus the discussion is restricted to the latter two reactions.

Fission and Spallation Neutron Sources

Fission Sources

Fission of the uranium isotope 235 by slow neutron capture has been the most frequently employed reaction in neutron sources till date. The reaction can be made self-sustaining because it is exothermal and releases more neutrons per fission process than are needed to initiate the process. If a slow neutron is captured by a fissionable nucleus, the resulting deformation can cause the nucleus to break into two fragments as visualized in **Figure 1**. Very often, a neutron is released directly during this process, but mostly the neutrons "evaporate" from the fragments. This is a very important feature, because a small fraction of these evaporation neutrons are released with a time delay of the order of seconds (up to minutes) and thus enable a critical arrangement to be run in a controlled fashion. The spectral distribution of the fission neutrons are well described by a Maxwellian

$$n(E) = \frac{2}{\pi^{1/2} \cdot E_{\mathrm{T}}^{3/2}} \sqrt{E} \cdot \exp\left\{-\frac{E}{E_{\mathrm{T}}}\right\} \qquad [1]$$

with a characteristic energy $E_{\mathrm{T}} = 1.29$ MeV. Fission reactors produce a continuous flux of neutrons (except IBR at Dubna which is designed as a pulsed reactor).

Spallation Sources

The term "spallation" is applied to a sequence of events that take place, if target nuclei are bombarded with particles (e.g., protons) of a de Broglie wavelength $\lambda = \sqrt{h^2/2mE}$, which is shorter than the linear dimension of the nucleus. In this case, collisions can take place with individual nuclides

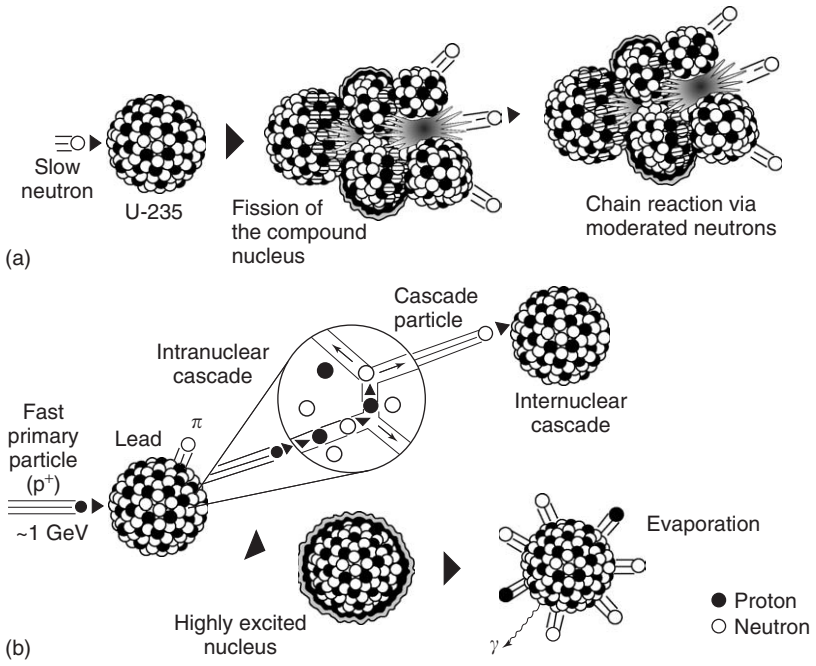

Figure 1 Schematic representation of (a) fission and (b) spallation.

inside the nucleus and large amounts of energy are transferred to the nuclides which, in turn, can hit other nuclides in the same nucleus. The net effect of this intranuclear cascade is twofold (see **Figure 1**): first, energy is more or less evenly distributed over the nucleus leaving it in a highly excited state; second, energetic particles may leave the nucleus and carry the cascade on to the other nuclei (internuclear cascade) or escape from the target. The excited nucleus left behind will start evaporating neutrons (and to a lesser extent protons). The low-energy part of the spectrum of these evaporation neutrons is quite similar to the one resulting from fission (eqn [1]), but as a consequence of the neutron escape during the intranuclear cascade, the spectrum extends to energies up to that of the incident particles (i.e., up to 1 GeV). The release of spallation neutrons takes place within less than 10^{-15} s after the nucleus was hit, so that the time distribution of spallation neutrons is exclusively determined by the time distribution of the driving particle pulse.

Modern spallation sources are generally based on a linear accelerator (linac). The process starts at the front end of the linac with the creation of negatively charged hydrogen ions by powerful ion sources. As they are electrically charged, these hydrogen ions can be accelerated in RF structures with strong fields along the linac to kinetic energies in the GeV range (which is $\sim$90% of the speed of light). When this highly energetic particle stream exits the linac, the hydrogen ions are stripped off their electrons by letting them pass through a thin carbon sieve, so that the hydrogen ions have become protons. The protons are then fed into a compressor ring which collects the protons from a large number of successive bunches fired out of the linac into a single very high-intensity proton pulse. For this purpose, an assembly of magnets bends each accelerated proton bunch into a circular orbit of such a diameter ($\sim$50–100 m) that the next bunch of protons arrives exactly when the previous has gone around once. In this way, all these bunches pile up. After $\sim$1000 revolutions, sufficient intensity is accumulated and the full proton pulse with a pulse length of $\sim$1 μs is extracted and propelled toward the target, which is normally a liquid metal (mercury or a lead–bismuth eutectic mixture) encased in special materials to take up a beam power of a few megawatts. This whole process – from the creation of the hydrogen ions to the arrival of the highly energetic protons at the target – should occur with a pulse repetition rate in the range of 10–100 Hz in order to achieve an optimal neutron economy in scattering experiments.

Neutron Energies and Neutron Properties

The energies of neutrons produced by neutron sources span many orders of magnitude. **Table 2** gives a summary of terms commonly used to characterize
